The advent of large language models (LLMs) has revolutionized Natural Language Generation (NLG), offering unmatched text generation capabilities. However, this progress introduces significant challenges, notably hallucinations—semantically incorrect yet fluent outputs. This phenomenon undermines content reliability, as traditional detection systems focus more on fluency than accuracy, posing a risk of misinformation spread.

Our study addresses these issues by proposing a unified strategy for detecting hallucinations in neural model-generated text, focusing on the SHROOM task in SemEval 2024. We employ diverse methodologies to identify output divergence from the source content. We utilized Sentence Transformers to measure cosine similarity between source-hypothesis and source-target embeddings, experimented with omitting source content in the cosine similarity computations, and Leveragied LLMs' In-Context Learning with detailed task prompts as our methodologies. The varying performance of our different approaches across the subtasks underscores the complexity of Natural Language Understanding tasks, highlighting the importance of addressing the nuances of semantic correctness in the era of advanced language models.

1 Introduction

The SHROOM task (Mickus et al., 2024) aims to address the challenge of detecting grammatically sound outputs containing incorrect semantic information in NLG systems. This task is crucial due to the prevalent issue of neural models producing fluent but inaccurate outputs, referred to as "hallucinations" (Maynez et al., 2020). Given the critical importance of correctness in NLG applications, SHROOM aims to foster interest in automating the detection of these hallucinations. Participants were tasked with the binary identification of such hallucinations across different NLG tasks, including Definition Modeling (DM), Machine Translation (MT), and Paraphrase Generation (PG).

Our system leveraged three distinct approaches to tackle the SHROOM task: A baseline cosine similarity, MultiNLI classification (Williams et al., 2018), and Large Language Models (LLMs), specifically Mixtral-8x7B-Instruct (Jiang et al., 2024). Each approach was tailored to identify hallucinations in NLG outputs by comparing them with the source input and detecting inconsistencies in semantic information. Through various combinations of these approaches, we aimed to accurately identify grammatically sound but incorrect outputs generated by neural models.

2 Background and Related Work

Previous research efforts have attempted to detect and control (Filippova, 2020) hallucinations. Dziri et al. (2022) worked on the origins of hallucinations, concluding that $> 60\%$ of the standard benchmarks consist hallucinated responses. Xiao and Wang (2021) proposed a simple extension to beam search to reduce hallucination. Obaid ul Islam et al. (2023) proposed a natural language inference (NLI) based method to preprocess the training data to reduce hallucinations.

The most similar to our work, Guerreiro et al. (2023) studied hallucinations in Neural Machine Translation. They analyzed multiple methods to detect hallucinations and developed `DeHallucinator` which overwrites the translation detected as a hallucination with a better one.

3 Dataset

In this section, we provide a detailed overview of the SHROOM dataset, highlighting its composition, structure, and associated challenges.

* Equal Contribution.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1584–1588

3.1 Composition

The SHROOM dataset consists of two main tracks: model-aware and model-agnostic, encompassing three subtasks: paraphrase generation, machine translation, and definition modeling. The test dataset comprises 3000 objects, with 1500 belonging to each of the model-aware and model-agnostic tracks. Additionally, the development data consists of 500 objects for each track, while the trial data comprises 80 objects. The unlabeled training data comprises 5000 objects for both the model-aware and model-agnostic tracks.

3.2 JSON Object Structure

Each dataset object contains the following components:

Task Description: Indicates the subtask to which the object belongs. Source (src): Input passed to be processed by the NLP model. Target (tgt): Intended correct processed "gold" text. Hypothesis (hyp): Actual output produced by the NLP model. Reference (ref): Specifies whether the reference includes the source, target, both, or neither. Labels: Each object is labeled by five human annotators as hallucination or not hallucination. Probability of Hallucination (p(hallucination)): Represents the probability of the hypothesis being a hallucination, ranging from 0.0 to 1.0. This probability is determined based on the consensus of the annotators. Label: Indicates the majority vote among the annotators, labeling the object as hallucination or not hallucination.

3.3 Issues with the Dataset

Several challenges were encountered while working with the SHROOM dataset:

Unlabeled Training Data: The unlabeled nature of the training data posed challenges, limiting the applicability of certain approaches and requiring alternative strategies for model training. **Format Discrepancy in Definition Modeling Task:** The test data for the definition modeling task deviated from the format of the development data, missing the <define> tag and presenting the definition as a question at the end. This inconsistency caused issues in several approaches and led to hallucinations in the Large Language Model (LLM) approach. **Imbalance in Language Representation:** The machine translation subtask lacked a balanced representation of multiple languages, potentially skewing the evaluation results and posing challenges for system development.

4 System Overview

In this section, we provide an overview of the three approaches employed in our system to address the SHROOM task.

4.1 Baseline Approach - Cosine Similarity

Our baseline approach utilizes cosine similarity to compare embeddings derived from source-hypothesis and source-target pairs. We employ Sentence Transformers (Reimers and Gurevych, 2019) to compute the cosine similarity, facilitating the comparison between the generated hypothesis and the target output. This approach serves as the foundation upon which subsequent refinements are built.

4.2 Approach 2 - MNLI Classification

In this approach, we leveraged the MultiNLI (MNLI) dataset for classification and similarity comparison between hypothesis and target outputs. We utilized the bart-large-mnli model, which is pre-trained on MNLI, to predict the entailment relationship between the hypothesis and target, subsequently examining similarity, and predict hallucination.

4.3 Approach 3 - Large Language Models

Leveraging LLMs, we prompt-engineered instructions for each subtask, utilizing the In-Context Learning power of these models, specifically Mixtral-8x7B-Instruct model, to detect hallucinations. We use the model for inference and experiment with temperature adjustments to optimize performance. This approach capitalizes on the contextual understanding and generative capabilities of LLMs to accurately identify hallucinations in NLG outputs.

5 Experimental Setup

In this section, we outline the experimental setup used for evaluating our system's performance on the SHROOM task.

5.1 Data Splits

We utilized the provided development set extensively for experimentation, as the training set was unlabeled. This allowed us to iteratively refine our approaches before selecting the final submissions for the test set evaluation.

Task	Hypothesis	Reference	Source	Target	Model	Labels	Label	P(H)
DM	(linguistics) The study of the relationships between words and their meanings.	Target	The <define> metaontology </define> debate has now migrated from discussions of composition.	The ontology of ontology.	-	H/N/N/N	N	0.4
PG	When did you see him?	Either	When did you last see him?	When was the last time you saw him?	tuner007/ pegasus_paraphrase	N/N/N	N	0.0
MT	It uses a giant rocket over 100 feet high to launch a satellite or telescope into space.	-	Ngini mamakai roket raksasa malabihi 100 kaki tingginya gasan maandak satelit atawa teleskop ka luar angkasa.	It takes a giant rocket over a 100 feet high to put a satellite or telescope in space.	-	N/N/N/H/N	N	0.4

Table 1: Examples from the dataset. The dataset includes three subtasks: Definition Modeling (DM), Paraphrase Generation (PG), and Machine Translation (MT). The dataset is labeled by crowdworkers as Hallucination (H) and Not Hallucination (N). P(Hallucination) indicates the probability of the hallucination based on the labels.

5.2 Preprocessing and Model Selection

Minimal preprocessing was applied to the data. Furthermore, we did not create separate distinctions for the model-aware and model-agnostic subtasks. Our decision was driven by the belief that a unified, model-agnostic solution would be the most optimal approach for addressing the task. For cosine similarity, we employed Sentence Transformers. MNLI classification utilized the Facebook bart-large-mnli model. In the case of LLMs, we initially employed Mixtral-8x7B-Instruct model and conducted an additional run post-evaluation with some changes to model settings like output token size and temperature, processing queries in batches.

5.3 Evaluation Measures

The evaluation measures used in the task primarily revolved around accuracy percentages. We assessed the accuracy of our models in correctly identifying grammatically sound outputs containing incorrect or unsupported semantic information, inconsistent with the source input. This metric served as the primary indicator of our system's performance on the SHROOM task.

This Experimental Setup section provides essential details about our methodology and the specifics of our experimental setup, enabling reproducibility and facilitating a clear understanding of our system's performance on the SHROOM task.

6 Results

In this section, we present the quantitative analysis of our system's performance on the SHROOM task. We evaluated the performance of our system approaches on the test data for each of the three subtasks: Paraphrase Generation (PG), Machine Translation (MT), and Definition Modeling (DM). Our system comprises three distinct approaches: cosine similarity, MNLI classification, and Large Language Models (LLMs), specifically Mixtral. **We note that Mixtral is the only system submitted to the task, and other results are post-evaluation experiments.**

6.1 Model-Agnostic Setting

Table 2 provides the accuracy of model-agnostic setting. We observe that our cosine similarity approach achieved the highest accuracy, with 70.3% overall accuracy. Specifically, it performed well in PG (77.9%) and MT (75.8%) subtasks. However, the Mixtral approach yielded lower accuracy at 50.5%, with varying performance across subtasks: DM (48.4%), PG (50.1%), and MT (52.9%). After changing the settings (temperature) the accuracy improved to 60.2% (Mixtral*).

6.2 Model-Aware Setting

Table 3 provides the accuracy of model-aware setting. In the model-aware setting, the MNLI classification approach achieved the highest accuracy at

	Cosine	MNLI	Mixtral	Mixtral*
Accuracy	62.1	65.13	49.8	56.1
DM	60.4		48.3	53.5
PG	57.6		48.2	56.1
MT	66.7		52.3	58.7

Table 2: Results on model-agnostic setting. We report accuracy for all the instances and accuracy on each subtask.

	Cosine	Mixtral	Mixtral*
Accuracy	70.3	50.5	60.2
DM	59.8	48.4	56.8
PG	77.9	50.1	61.9
MT	75.8	52.9	62.2

Table 3: Results on model-aware setting. We report accuracy for all the instances and accuracy on each subtask.

65.13%, followed by the cosine similarity approach at 62.1%. The MNLI approach showed consistent performance across subtasks, while the cosine similarity approach performed particularly well in MT (66.7%). The Mixtral approach had the lowest accuracy at 49.8%, with varying performance across subtasks: DM (53.5%), PG (56.1%), and MT (58.7%). After changing the settings— (temperature) the accuracy improved to 56.1% (Mixtral*).

7 Conclusion

In conclusion, our system for addressing the SHROOM task employed three distinct approaches: baseline cosine similarity, MNLI classification, and Mixtral. Each approach was carefully designed to tackle the challenge of identifying hallucinations in natural language generation outputs.

Our experimental results demonstrated varying degrees of success across the different subtasks. While cosine similarity and MNLI classification showed promising performance, leveraging LLMs proved to be particularly effective in accurately identifying hallucinations.

Looking forward, our system's performance suggests several avenues for future work. Firstly, further exploration and refinement of each approach tailored to the specific subtleties of each subtask could potentially yield improved performance. Additionally, investigating ensemble methods or hybrid approaches that combine the strengths of different techniques may enhance overall system robustness.

Despite the challenges encountered, our system's competitive performance in the SHROOM task underscores the importance of automated, multi-expert, mechanisms for detecting and mitigating hallucinations in NLG systems. As the field continues to evolve, addressing these challenges will be crucial for advancing the reliability and accuracy of NLG applications.

In summary, our system represents a significant step towards addressing the complexities of hallucination detection in NLG outputs, and we are optimistic about the potential for future advancements in this area.

Abstract

This paper describes the architecture of our system developed for Task 3 of SemEval-2024: Multimodal Emotion-Cause Analysis in Conversations. Our project targets the challenges of subtask 2, dedicated to Multimodal Emotion-Cause Pair Extraction with Emotion Category (MECPE-Cat), and constructs a dual-component system tailored to the unique challenges of this task. We divide the task into two subtasks: emotion recognition in conversation (ERC) and emotion-cause pair extraction (ECPE). To address these subtasks, we capitalize on the abilities of Large Language Models (LLMs), which have consistently demonstrated state-of-the-art performance across various natural language processing tasks and domains. Most importantly, we design an approach of emotion-cause-aware instruction-tuning for LLMs, to enhance the perception of the emotions with their corresponding causal rationales. Our method enables us to adeptly navigate the complexities of MECPE-Cat, achieving a weighted average 34.71% F1 score of the task, and securing the $\mathbf{2}^{nd}$ rank on the leaderboard.[1] The code and metadata to reproduce our experiments are all made publicly available.[2]

1 Introduction

Emotion cause analysis is a critical component of human communication and decision-making, offering substantial applications across diverse fields. It enables a deeper and more detailed understanding of sentiments. The introduction of emotion-cause analysis in textual conversations by Poria et al. (2021); Xia and Ding (2019) has paved the way for advancements in understanding emotional dynamics within dialogues. However, textual analysis alone does not fully capture the complexity of human emotional expression, as emotions and their causes are often conveyed through a blend of modalities (Hazarika et al., 2018; Wu et al., 2023a; Fei et al., 2023b). Subtask 2 of SemEval-2024 Task 3, referred to as MECPE-Cat, seeks to expand this analysis into the multimodal domain, focusing on English-language conversations. The task draws inspiration from the seminal work of Wang et al. (2023), which sets out to jointly extract emotions and their corresponding causes from conversations across multiple modalities, including text, audio, and video, and it also encompasses the identification of the corresponding emotion category for each emotion-cause pair.

In our system, we leverage LLMs such as GPT-3 (Brown et al., 2020), Flan-T5 (Chung et al., 2022), and GLM (Du et al., 2021) known for their exceptional performance in various natural language processing tasks. We employ parameter-efficient fine-tuning, specifically LoRA (Hu et al., 2021), to efficiently fine-tune LLMs, enhancing their performance with minimal computational overhead. Additionally, we harness emotion-cause-aware prompt-based learning and instruction-tuning to enhance model performance such that the LLMs can more accurately perceive the emotions with their corresponding causal rationales. Prompt-based learning guides LLMs to generate contextually relevant outputs, while instruction-fine-tuning models for our specific tasks by improving their response to explicit instructions.

In this paper, we investigate the optimal LLM for the MECPE-Cat task, selecting ChatGLM based on its superior zero-shot performance. We further refine ChatGLM through instruction-tuning, using carefully crafted prompts to enhance its task-specific accuracy. Our fine-tuned model achieves the second-highest score on the official test set for subtask 2, with a weighted average of 34.71% F1,

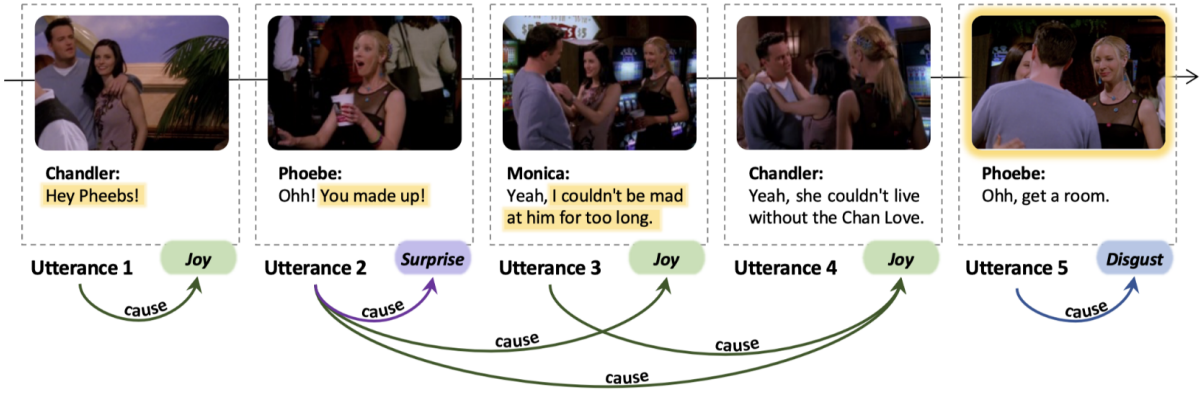

Figure 1: An example of an official task and annotated dataset. Each arc points from the cause utterance to the emotional triggers. The cause spans have been highlighted in yellow. Background: Chandler and his girlfriend Monica walked into the casino (they had a quarrel earlier but made up soon), and then started a conversation with Phoebe.

underscoring the effectiveness of our approach. We also discuss the current limitations of our model and methodology, alongside directions for future research and improvement. We will release our codes and resources mentioned in this paper to facilitate relevant research.

2 Background

2.1 Task and Dataset Description

The SemEval-2024 Task 3 (Wang et al., 2024) is based on the multimodal conversational emotion-cause dataset, Emotion-Cause-in-Friends (ECF; Wang et al., 2023), by choosing a multimodal dataset MELD (Poria et al., 2018) as the data source and further annotating the corresponding causes for the given emotion annotations. The ECF dataset contains 9,794 emotion-cause pairs, covering three modalities. The subtask 2 is to extract all emotion-cause pairs in a given conversation under three modalities, where each pair contains an emotion utterance along with its emotion category and a cause utterance, e.g., (U3_Joy, U2), which means that the speaker's joy emotion in utterance 3 is triggered by the cause from utterance 2. Figure 1 displays a real example of this task and annotated dataset. In this conversation, it is expected to extract a set of six utterance-level emotion-cause pairs in total, e.g., Chandler's Joy emotion in Utterance 4 (U4 for short) is triggered by the objective cause that he and Monica had made up and Monica's subjective opinion in U3, forming the pairs (U4_joy, U2) and (U4_joy, U3); The cause for Phoebe's Disgust in U5 is the objective event that Monica and Chandler were kissing in front of her (mainly reflected in the visual modality of U5), forming the pair (U5_disgust, U5).

2.2 Related Work

The exploration of ECPE within textual and conversational contexts has been approached through various methodologies, each tailored to specific task settings (Chen et al., 2022). Cheng et al. (2023) reframe the ECPE task as a process akin to engaging in a two-stage machine reading comprehension (MRC) challenge. Zheng et al. (2023) expand the ECPE task to Emotion-Cause Quadruple Extraction in Dialogs (ECQED), focusing on detecting pairs of emotion-cause utterances and their types. They present a model utilizing a heterogeneous graph and a parallel grid tagging scheme for this purpose. In addressing the specific challenge of the MECPE-Cat task, Wang et al. (2023) set a benchmark for this task by introducing two preliminary baseline systems. They utilize a heuristic approach to leverage inherent patterns in the localization of causes and emotions, alongside a deep learning strategy, MECPE-2steps, which adapts a prominent ECPE methodology for news articles to include multimodal data.

Drawing from the varied methodologies of previous work, it becomes clear that effectively solving the MECPE-Cat task demands a deep understanding of dialogue content, precise identification of conversational emotions, extraction of emotion-cause pairs, and the integration of multimodal information. Motivated by the strong performance of LLMs on various metrics, we opt to utilize these models to address this intricate challenge. Through exhaustive model evaluations and extensive prompt

testing, we have showcased the practicality, superiority, and adaptability of our chosen approach.

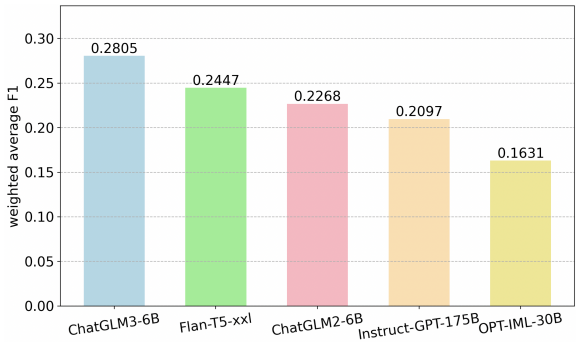

Figure 2: Zero-shot test set performance of various instruction-tuned LLMs.

3 Methodology

In this section, we first conduct preliminary experiments to determine which LLM to select as a backbone reasoner. We then elaborate on how we design the system and emotion-cause-aware instructions for tuning our chosen LLM.

3.1 Pilot Study for LLM Selection

Currently, there exists a variety of LLMs, such as OPT-IML (Iyer et al., 2022), GPT-3, Flan-T5, and GLM. However, it is essential to select a model that not only performs optimally but is also the most suitable for our specific task. To this end, we carry out a pilot study to determine the most appropriate model selection. For our zero-shot testing experiment, we rigorously evaluate several models, including OPT-IML[3], Instruct-GPT[4] (Ouyang et al., 2022), Flan-T5[5], alongside the ChatGLM models, to identify the most effective tool for this specific task. We customize instructions for each model's specific tuning style, recognizing that a single set of instructions does not suit all models effectively. We also embed expected output labels within these instructions to secure precise responses from each model. Figure 2 depicts the zero-shot performance of these models. The ChatGLM[6] LLM is ultimately selected based on its superior performance in these tests. This selection is informed not merely by the innovative features or the advanced training methodologies of ChatGLM but by empirical evidence of its exceptional zero-shot performance among the models considered.

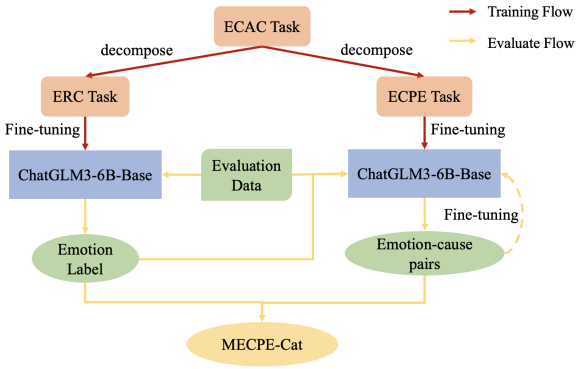

Figure 3: Proposed method workflow for the MECPE-Cat task.

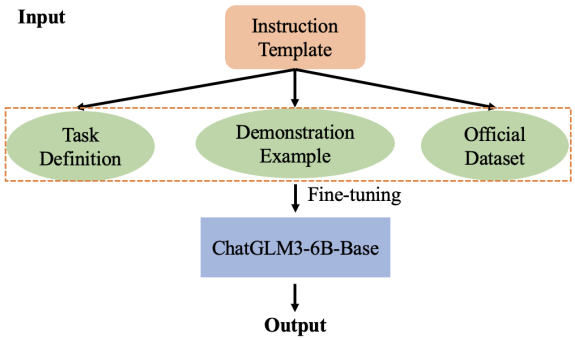

Figure 4: The construction of the instruction template and the flow of model input and output.

3.2 Multimodal Feature Encoding

Given that the inputs for our task incorporate multimodal signals, including visual information to assist in more accurate emotion recognition, it is imperative to fully leverage the non-textual modal information. However, our LLM backbone does not natively support the direct inclusion of non-textual modal signals. To address this, we consider employing ImageBind (Girdhar et al., 2023) for encoding the multimodal portion of input information, owing to its robust multimodal alignment capabilities and visual perception proficiency. Subsequently, we concatenate the multimodal representations with other textual embeddings before feeding them into the LLM.

3.3 Constructing Emotion-Cause-aware Instructions for LLM Tuning

Figure 3 first illustrates the workflow of our proposed framework. Initially, we fine-tune the model on the ERC task. Following this, we incorporate

the predicted emotion labels into each utterance, setting the stage for the ECPE task execution. Subsequently, we employ the model, now fine-tuned with data labeled with emotion tags, to perform inference on the MECPE-Cat task, yielding an initial set of emotion-cause pairs. These preliminary results are then reintegrated into the original training dataset for a second round of fine-tuning, culminating in the refinement of our model to produce the final set of emotion-cause pairs.

Task Definition:
"You're an expert in sentiment analysis and emotion cause identification. Below is a conversation containing multiple utterances from different speakers, along with the corresponding emotion label for each utterance. Your task is to identify the indices of the candidate utterances that elicited the emotion in the target utterance."

Input conversation:
1_joy. Chandler: Hey Pheebs!
2_surprise. Phoebe: Ohh! You made up!
3_joy. Monica: Yeah, I couldn't be mad at him for too long.
4_joy. Chandler: Yeah, she couldn't live without the Chan Love.
5_disgust. Phoebe: Ohh, get a room.

Candidate utterances:
1_joy. Chandler: Hey Pheebs!
2_surprise. Phoebe: Ohh! You made up!
3_joy. Monica: Yeah, I couldn't be mad at him for too long.

Target utterance:
4_joy. Chandler: Yeah, she couldn't live without the Chan Love.

Question:
The emotion-cause indices of the target utterance are:
[LLM output]

To enhance the perception of identifying emotion-cause pairs and mitigate the task's inherent complexity and potential confusion, we design the template for producing emotion-cause-aware instructions to guide the model. Figure 4 illustrates the construction of the instruction template, which encompasses the task definition, a demonstration example, and the dataset for which the model is expected to predict outcomes. This structured approach not only simplifies the task's complexity for the model but also aligns the model's processing capabilities with the requirements of accurately identifying emotion-cause pairs in conversations. In the above box we showcase a real example.

4 Experiments

This section will quantify the effectiveness of our systems via experiments and also show more analyses to gain more observations.

4.1 Implementation

The hyperparameter of our system used to achieve the highest weighted average F1 score on the subtask 2 is listed in 1. The ChatGLM model was fine-tuned using a learning rate of 1e-4 with LoRA-specific configurations including a rank of 8, alpha value of 32, and a dropout rate of 0.1. The training was conducted with a maximum instruction length of 2048 tokens and an output length limited to 128 tokens, using a batch size of 1. We used a single gradient accumulation step across 2 training epochs. These parameters were meticulously selected to optimize our model's performance.

Hyperparameter	Value
Learning rate	1e-4
LoRA rank	8
LoRA alpha	32
LoRA dropout	0.1
Max instruction length	2048
Max output length	128
Batch size	1
Gradient accumulation steps	1
Epochs	2

Table 1: Hyperparameter used for the best performing model.

4.2 Evaluating Template Designing

In constructing the instruction dataset for tuning LLMs, we systematically transform each dialogue in the dataset into training samples by embedding them into a fixed template as described above. The data source for this transformation is the officially provided ECF dataset, which comprises 13,619 utterances. Consequently, we constructed a total of 13,619 templates based on this dataset, each

Condition	F1 Score
Only Task Definition	0.2981
Task + Example	0.3124
Task + Example + Candidate	**0.3207**

Table 2: Performance using different templates for constructing instruction tuning.

tailored to facilitate the model's learning and application of emotion-cause-aware instructions.

We here perform an ablation study on the contributions of each part of the instructions we designed for the task. We derive three variants:

- **Only Task Definition:** Compared to the zero-shot paradigm, this condition offers a more detailed and precise description of the task.
- **Task + Example:** We provide a demonstrative example to clearly show the expected outcome in a real-world dialogue, offering the model a practical reference for task execution
- **Task + Example + Candidate utterances:** This design simplifies the task by introducing 'candidate utterances,' enabling the model to analyze emotion-cause pairs sentence by sentence, rather than across entire dialogues, and pinpoint the specific causes of emotions from the preceding content.

Table 2 demonstrates the comparative performance of these diverse templates. We see that different components of the instruction templates show clear influences, such as task definition, example demonstration, and candidate utterances. Thus, we apply all these components into our instruction templates.

4.3 Instruction-tuning LLM

For our experiments, we adopt a meticulous fine-tuning process for the ChatGLM. We set a learning rate of 1e-4, aiming for a balance between rapid convergence and maintaining the model's ability to adapt without overfitting. We leverage the LoRA technique with a rank of 8 and alpha of 32 to introduce task-adaptive parameters without bloating the model size, alongside a dropout rate of 0.1 to prevent overfitting. The model processed inputs with a max sequence length of 2048 tokens, accommodating the depth of context required for our task, while the outputs are capped at 128 tokens to focus on generating concise and relevant responses. Both batch size and gradient accumulation steps are set to 1, tailored to our computational resources while ensuring effective backpropagation. This configuration, selected after careful evaluation of various setups, is instrumental in fine-tuning the ChatGLM model to achieve the best performance on our task.

Our experiments capitalize on the robust computational capabilities provided by NVIDIA A800-SXM GPUs, each boasting 80 GB of VRAM, to ensure sufficient resources are available to train large language models. This fine-tuning process is facilitated using a customized script derived from the Hugging Face Transformers framework, chosen for its extensive support of transformer models and seamless integration with our setup, thereby enabling us to leverage advanced hardware capabilities while utilizing a leading-edge software environment for our model's optimization.

4.4 Task Decomposition

We decompose the MECPE-Cat task into ERC and ECPE phases to strategically alleviate its complexity. This division offered a two-fold advantage: firstly, it distills the task into clearer, more focused components, facilitating a more straightforward understanding and execution of the model. Secondly, by leveraging emotion labels obtained from the ERC phase during the ECPE phase, we enhance the model's capability to pinpoint emotion-cause pairs with greater accuracy. Tabel 3 showcases incremental improvements in weighted average F1 scores across three distinct setups. This progression underscores the dual benefits of our approach: simplifying the task's complexity for the model and enriching the ECPE phase with contextual emotion labels, thereby optimizing the extraction of emotion-cause pairs.

Methods	F1 Score
Single Stage	0.3207
Two Independent Stages	0.3288
ECPE with Emotion Labels	**0.3396**

Table 3: Comparison of weighted average F1 Scores under different methods.

4.5 Data Augmentation

We find that augmenting the training dataset with trial data significantly enhanced model accuracy, achieving a high weighted average F1 score of 0.3416, as shown in Table 4. Furthermore, we employ a trick by incorporating the model's inference results on the ECPE task back into the training dataset for an additional round of fine-tuning. This iterative fine-tuning strategy yielded a further improvement in our test data performance. These

enhancements demonstrate the efficacy of not only expanding the training dataset but also utilizing the model's own outputs to refine its accuracy.

Data	Epoch 1	Epoch 2	Epoch 3
Train	0.3390	0.3396	0.3393
Train + Trial	0.3404	0.3410	0.3406
Iterative Train	0.3408	**0.3416**	0.3411

Table 4: Comparison of weighted average F1 Scores across different training data and epochs.

4.6 Multimodal Integration

To assess the impact of multimodal information on our model's performance, we adopt a methodological approach that harnessed GPT-4V Achiam et al. (2023) for extracting insights from modalities beyond text. Specifically, we enrich the instruction template with "video description of target utterance" derived from GPT-4V, presenting it as supplementary information to guide the model. This strategic integration of multimodal data leads to an improvement in the model's F1 score, as shown in Table 5, which validates the utility of multimodal information in providing richer contextual understanding.

Information	F1 Score
Text	0.3416
Text + Video	**0.3471**

Table 5: Comparison of weighted average F1 Scores between pure text and multimodal information.

5 Conclusion

In this work, we explore the LLMs for solving the Multimodal Emotion-Cause Pair Extraction with Emotion Category (MECPE-Cat) task. Through a pilot study, we first select an LLM, ChatGLM, that assists in achieving optimal task performance. The backbone ChatGLM receives textual dialogue, and also perceives the multimodal information via the ImageBind vision encoder. Lastly, we devise an emotion-cause-aware instruction-tuning mechanism for updating LLMs, which enhances the perception of the emotions with their corresponding causal rationales. Our system achieves a weighted average F1 score of 34.71%, securing second place on the MECPE-Cat leaderboard.

University of Tübingen
aron.winkler@student.uni-tuebingen.de

Abstract

Recent developments in the field of NLP have brought large language models (LLMs) to the forefront of both public and research attention. As the use of language generation technologies becomes more widespread, the problem arises of determining whether a given text is machine generated or not. Task 8 at SemEval 2024 consists of a shared task with this exact objective. Our approach aims at developing models and strategies that strike a good balance between performance and model size. We show that it is possible to compete with large transformer-based solutions with smaller systems. Our code can be found on GitHub. [1]

1 Introduction

Recent developments in the field of NLP have brought large language models (LLMs) to the forefront of both public and research attention. With the introduction of GPT-3 (Brown et al., 2020), made accessible to the public through ChatGPT, the gates were open to the generation of high-quality text through AI. This leads to a sort of arms race both in integrating AI into customer-facing products, as well as in developing the models themselves, leading, among others, to Facebook's Llama (Touvron et al., 2023) and the open source model Mistral (Jiang et al., 2023).

Many fields have seen a dramatic increase in the use of LLMs, including arts, education, software development, and many more. Initial public reaction to the popularisation of LLM-powered chat interfaces already highlighted its potential problems for plagiarism detection in scientific, educational and other contexts (Dehouche, 2021). In a landmark development, the 5-month-long strike of the Writer's Guild of America[2] resulted in an agreement which included safeguards for writers against the use of artificial intelligence.[3]

The widespread use of language generation technologies is only expected to grow. However, this development is accompanied by a surging need to automate the process of flagging machine-generated text.

Crothers et al., 2023 offers a comprehensive survey of machine-generated text detection strategies. Statistical methods, with global text vector representations, were among the early strategies adopted to tackle the issue. These feature vectors include, for example, TF-IDF, frequency features investigating word or n-gram distributions, readability-related features such as the Gunning-Fog index, or linguistic features such as POS-tag distributions and coreference resolution relationships within a text. The subsequently introduced neural approaches show better performance, even when paired with the aforementioned text representation strategies. Most prominently, transformer fine-tuning has established itself as more or less of a standard, with RoBERTa (Liu et al., 2019) in particular being the most strongly represented model. Zero-shot approaches, optionally coupled with fine-tuning, have also seen experimentation, but have been observed to generalise poorly across domains.

Task 8 at SemEval-2024 (Wang et al., 2024) is a shared task built around the idea of detecting machine-generated texts across a variety of domains and setups. It is structured across three subtasks (subtask A, subtask B, subtask C), our team decided to only tackle subtasks A and C. Subtask A is a binary classification task, with the objective of determining whether a text is human- or machine-generated. The subtask has a monolingual (English) and a multilingual track - our team only

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1597–1601

submitted for the monolingual track. Subtask C is a boundary detection task: here, texts have a human segment followed by a machine-generated segment. The objective of the subtask is to correctly predict the boundary index.

Our approach for both tasks was to try to obtain competitive solutions with low resource cost. For this reason we deployed two different model classes: LSTM-based models (Hochreiter and Schmidhuber, 1997) and Multilayer Perceptrons (MLP) (Popescu et al., 2009) and relied on various strategies of representing the input texts, either at the token or at the text level. We experimented with character-level approaches, systems relying on pretrained Word2vec (Mikolov et al., 2013) embeddings, and linguistically motivated features at the text level through spaCy (Honnibal et al., 2020) and the TextDescriptives (Hansen et al., 2023) package.

2 Methods and experimental setup

2.1 Subtask A

For subtask A, our intuition was that surface-level and stylistic features would be more effective than semantics in discriminating between human and machine-generated text. To build on this idea, we developed three approaches.

The first approach involved training a character-level LSTM. We expect the stylistic features of the texts to be good indicators of the generator, and working at the character level is known to capture this information well. For example, character n-gram models have been used successfully in the field of authorship attribution, which relies heavily on style (Stamatatos et al., 2013).

First, input texts are tokenized at the character-level, all tokens are mapped to their lowercase variants, and lastly numerals and punctuation are mapped to a <NUM> and a <PUNCT> special token respectively. White-space elements (space, tab, newline) are also mapped to a special token <WS>. At this point, the tokenized and transformed inputs are fed through an LSTM, and the representation of the last token is used for prediction.

The second approach is constructed along the lines of the first in terms of technical setup, but deals with words rather than characters. Large transformer-based solutions benefit from vast amounts of pre-training, but at a heavy computational cost – using pretrained embeddings as model inputs appeared to be a good compromise between heavy models and training from scratch, as was the case with the character-level LSTM. We used the pretrained Word2vec embeddings from the Wikipedia2Vec (Yamada et al., 2020) project to map texts to vectors, but maintained the other steps, such as mapping numerals, punctuation and white-space to special tokens.

The third approach is not recurrent in its nature – instead, we used the TextDescriptives pipeline (Hansen et al., 2023) through Spacy (Honnibal et al., 2020) to obtain 66 lingustically motivated features to globally represent the text. Such linguistic features have a long tradition in NLP, for example in the field of readability analysis (for example Vajjala and Meurers, 2012), and have been observed to be valid and cheap-to-compute representations in a variety of settings. Since they are most well known for capturing the style of a text, rather than semantics, they appear to be very well suited for the present task. Additionally, we computed the mean perplexity of the document using GPT-2 (Radford et al., 2019) and added it to the feature vectors. This follows the idea that the perplexity of a document assigned by a LLM should be higher for human written texts than for machine generated texts (Chaka, 2023). Our third approach computes this global feature vector for the input text, then generates a prediction through a simple MLP. The model consists of 3 linear layers with Tanh activation functions in between and was trained for 2000 epochs with a learning rate of 0.0003.

Lastly, we formulated a joint model which takes as input the final representations (the last hidden states) of each of the three previous approaches, thus generating a single prediction.

Model	Type	L*	H**
Character-level	LSTM	2	512
Word2vec	LSTM	2	512
Language features	MLP	3	256
Joint model	FFN	-	512

Table 1: Summary of models for subtask A. * Number of layers. ** Hidden size.

2.2 Subtask C

For subtask C, which required predicting the boundary position in texts between a human and a machine-generated segment, we adopted the same guiding principles in developing our solutions as

we had done in subtask A. The overarching objective was to arrive at competitive models while remaining within a certain size constraint.

An additional challenge for this subtask, aside from an increase in difficulty in the objective itself, was the relative scarcity of training data. While in subtask A the training set had over one hundred thousand records, the training material in subtask C consisted of just below four thousand texts. As such, any strategy that did not involve pretraining would be severely disadvantaged in this setting.

Our first approach for this subtask was also a character-level solution, with the same general setup as in subtask A. For generating a prediction, however, the representations at every token are evaluated, and a classification is performed. In this sense, the model is predicting whether any given character is in the human or the machine-generated segment of the text. The first token predicted to be machine-generated is taken to be the boundary position. Importantly, the LSTM we implemented for this subtask is bidirectional, meaning at every token the model has awareness of both the left and right contexts.

To offset the relative lack of training items, together with the absence of any model pre-training in this case, we trained this model on both subtask A and subtask C data for 5 epochs, then trained further on only task C data for 3 further epochs. This improved performance significantly on the development set.

We also implemented a Word2vec solution along the lines of what was described for subtask A. We opted for a bidirectional LSTM, and enhanced the training data as described earlier, though the effects of this were less prominent owing to the use of pretrained embeddings.

We also built a joint model over the aforementioned character- and Word2vec models. This consisted in a FFN whose inputs were the concatenated representations at the word level. For the character-level model, this meant averaging the representation at every character for any given word.

Model	Type	L*	H**
Character-level	LSTM	2	512
Word2vec	LSTM	2	512
Joint model	FFN	-	256

Table 2: Summary of models for subtask C. * Number of layers. ** Hidden size.

3 Results

3.1 Subtask A

Model	Dev	Test	Ranking
Baseline	0.72	0.88	20
Character-level	0.85	0.55	127
Word2vec*	0.82	0.72	85
Language features*	0.63	0.88	21
Joint model*	0.83	0.69	96

Table 3: Results for SemEval-2024 Task 8, subtask A. Dev and Test columns report the accuracy on the respective data partitions. The ranking column refers to the model ranking in the shared task competition. The scores and ranking of the unofficial submissions were not provided by the organisers and computed by us. There was a total of 137 submissions.
* unofficial submissions

Table 3 shows the results for each model on subtask A. On the development set, almost all models outperform the transformer baseline provided by the organisers. The best performing model was the character-level model, with an accuracy of 0.85 – this was our final submission for the shared task.

While the two recurrent models and the joint model do not differ very much from one another, the FFN built on linguistically motivated global feature vectors sets itself apart in that it is the worst performing model on the development set.

The character-level model only achieves an accuracy of 0.55 on the test set, while the Word2vec and joint models achieve 0.72 and 0.69 respectively – all falling short of the baseline. Surprisingly, the language feature model is head and shoulders above the rest when it comes to the test set, with an accuracy of 0.88 that matches the baseline. Our assumption is that this is due to a conceptual difference between development and test set. A possible reason could be that the domain for human-written texts in the test set were student essays only. The development set on the other hand consisted of human-written texts from multiple domains. The linguistic features prevalent in the student essays seem to be more distinctive for classifying the documents compared to the texts from multiple domains.

3.2 Subtask C

Table 4 outlines our results for subtask C. In this subtask, we were unable to match the transformer baseline.

Model	Dev	Test	Ranking
Baseline	3.53	21.54	14
Character-level*	8.35	45.83	28
Word2vec*	7.02	38.35	27
Joint model	6.36	34.88	25

Table 4: Results for SemEval-2024 Task 8, subtask C. Dev and Test columns report mean absolute error (MAE) on the respective data partitions. The ranking column refers to the model ranking in the shared task competition. The scores and ranking of the unofficial submissions were not provided by the organisers and computed by us. There was a total of 33 submissions.
* unofficial submissions

Our official submission, the joint model, achieved a mean standard error of 6.36 on the development set, falling short of around 3 points from the baseline provided by the organisers. The difference is even more dramatic when it comes to the test set, where the gap widens to around 13 points. This is also far off from the best performing solutions in the shared task, which achieved a MAE of 15.7.

The character and Word2vec models failed to outperformed both the baseline and the joint model for the development set, and this remains the case in the test set. This reinforces the idea that extracting as much information as possible from the texts is key to performance in this subtask.

Overall, the models developed for subtask C have proven to be somewhat unrefined. The test set seems to be particularly punishing towards solutions that do not generalize well, but the results, while highlighting the shortcomings of our models, also point toward the potential that these approaches can have, with more attention dedicated to them.

4 Conclusion and Discussion

Our objective for Task 8 at Semeval-2024 was to compete with large-scale solutions with models that could run on commonplace systems like mid-range laptops. For this purpose, we discarded LLM-based solutions that are prevalent in the related work in the field, opting instead for LSTMs and MLPs whose size can more easily be controlled.

While our team did manage to keep model size under control (none of the proposed solutions require more than 1 GB of memory), the systems we proposed performed less than ideally in the task itself. On both subtasks we participated in, our best models failed to match the transformer baseline in the test set, despite positive results in the development set.

Despite the final results, we believe our approach to be valid. Our development processes likely ended up producing models that were overly tuned to the development set. With more time, it would be possible to produce more refined and generalizable solutions. Trying different training strategies, like contrastive learning, or different architectures, such as mixture-of-experts systems, might be a good direction to follow in future work.

To most problems that arise in the field of NLP, researchers and companies increasingly respond with huge models that require dedicated servers to run. But for many users, keeping their data safely on their own machines is a priority, thus discarding many of the contemporary LLM-based services. System designers should aim to strike a compromise between size and performance, and prioritise users being able to own their workflows when possible. Like our attempt did for this shared task, we believe researches should consider these objectives when proposing new solutions.

Abstract

It is known that human thought can be distinguished into lateral and vertical thinking. The development of language models has thus far been focused on evaluating and advancing vertical thinking, while lateral thinking has been somewhat neglected. To foster progress in this area, SemEval has created and distributed a brainteaser dataset based on lateral thinking consist of sentence puzzles and word puzzle QA. In this paper, we test and discuss the performance of the currently known best model, Gemini, on this dataset.

1 Introduction

Human thought is known to be distinguished into lateral and vertical thinking. (Jiang et al., 2023) cites (Waks, 1997) in mentioning, based on modern neuroscience, that vertical thinking is associated with the left hemisphere of the brain, while lateral thinking is associated with the right hemisphere. Moreover, this paper notes that during the development of language models, there has been a focus on problem-solving abilities in vertical thinking, neglecting the capabilities based on lateral thinking. This paper anticipates that lateral thinking puzzles may not be easily solved with just additional adaptations and extensions of the LLM (Large Language Model) approach, yet this paper is prepared to counter that expectation. It evaluates the performance of Google's ambitious model, Gemini(Team et al., 2023), which is said to surpass GPT-4, by measuring performance solely through changes in demonstration, as it was not possible to fine-tune Gemini.

Gemini is anticipated to show increased performance due to the scaling law mentioned in (Kaplan et al., 2020), as it utilizes significantly more parameters than GPT-4. Being a multimodal model trained with additional learning resources such as visual and auditory inputs, it is speculated that these characteristics might give rise to unique emergent abilities. (Wei et al., 2022) These two aspects are expected to contribute to performance improvements in lateral thinking.

Our approach is straightforward. First, we formalize Gemini's responses by adding demonstrations, following the same few-shot provision method as used by SemEval, and second, we provide only the relevant task few-shot examples for the two brainteaser tasks: sentence puzzles and word puzzles. Through the second method, we investigate whether providing clear few-shot examples for tasks alone can aid in performance improvement.

2 Background

2.1 Vertical thinking

As illustrated in Figure 1 of the (Jiang et al., 2023), vertical thinking is generally considered a logical form of thought. The first example of vertical thinking in Figure 1 of the paper, regarding the question "How do you flood a room?", involved associating the meaning of the word "flood" with the span "Cover with water". This association led to the selection of a similar meaning, "Fill it with water", as the answer. The second example of vertical thinking was in response to the question "I have five fingers, but I am not alive. What am I?". Here, the span "five fingers" led to the association of a similar span "Five separate parts", and "Not alive" led to the association of "item like a hand", which, despite "not alive" having a broader meaning, was contextually restricted by the span "five fingers". The only option that simultaneously had the properties of "Five separate parts" and "item like a hand" was "Glove". This problem, even though it is a riddle as mentioned in brainteasers, could be solved through vertical thinking. Such an ability to associate a specific word span with another span of similar meaning could be implemented in transformer

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1602–1606

models, as mentioned in (Dai et al., 2021), where the feed-forward network contains knowledge, and the context patterns created in the attention layer act as a key, enabling the association of a particular part of the input with another similar span.

2.2 Lateral thinking

Let's look at the first example of lateral thinking from Figure 1 of the overview paper. It is common sense to associate "Man shaves everyday" with "His beard gets clean everyday". However, the condition "yet keeps his beard long" blocks this inference path. Therefore, the model must use a different reasoning path, and to solve the problem, it must break away from the common sense that the man shaves himself and instead think of the possibility that he shaves someone else. This example forces the most commonsensical reasoning path to be blocked and requires navigating an alternative reasoning path.

The second example asks, "What type of cheese is made backwards?" This question is not commonsensical in itself. However, if "made" is not considered as a verb but as a sequence of letters, the problem is solved. Reversing "made" spells "edam," which is a type of cheese.

2.3 Brain-Teaser Benchmark

Brain teaser tasks (Jiang et al., 2024) are designed to explore whether language models are capable of lateral thinking, diverging from traditional methods. These tasks involve reading a question and providing an answer in a QA format, structured as a multiple-choice question with options (A), (B), (C), (D) to ensure clear output.

Sentence puzzles involve semantic exercises that break conventional thinking, while word puzzles use arrangements of alphabets in words to provide answers that play on words, challenging common sense.

There are two variations of both sentence and word puzzles. One is semantic reconstruction, where the question is paraphrased to measure if the problem can still be solved effectively while the answer and options remain unchanged. The other is context reconstruction, where the thought process to solve the problem remains the same, but the question and options are changed.

Two methods are used to measure performance: instance-based accuracy, which measures the accuracy of original, semantic, and context reconstructions separately, and group-based accuracy, which increases accuracy if the original and semantic reconstructions are answered correctly together or if correct answers are provided for original, semantic, and context reconstructions all at once.

Approximately 1,000 training examples were provided by Semeval, but this study measures the intrinsic ability of Gemini without using the training dataset.

3 System overview

In this study, we used Gemini, an ambitious model released by Google, known to surpass ChatGPT. We utilized the Gemini-Pro API and followed the ChatGPT evaluation method provided by SemEval.

3.1 Add Demonstration

Gemini tends to include explanations in its responses, resulting in varying output styles for each question. For example, it can be feel like this:

The answer is (A), because [explanation.....]

[explanation.....] so, the answer is (A)

(B) is [explanation.....]
(C) is [explanation.....]
(D) is [explanation.....]
so, the answer is (A)

To use the brain teaser score calculator, the answers must be clear in the form of (A), (B), (C), or (D). The output style described above is not suitable for input into the answer calculator, especially in the last example where all options (A), (B), (C), and (D) are included in the output. Implementing an algorithm to post-process this and select a clear single answer, like (A), from such outputs is complex. Therefore, to avoid these difficulties, we structured the demonstration to include the following feel.

[demonstration...]
question
option (A)
option (B)
option (C)
option (D)

3.2 Use only relevant few-shot examples

To determine if providing only sentence puzzle examples for sentence puzzles or only word puzzle

examples for word puzzles helps resolve confusion between examples and aids in problem-solving, we conducted 1-shot, 2-shot, and 4-shot evaluations using the same set of examples.

In this case, we did not add a demonstration because the few-shot examples clearly provide the style of output. When using only relevant few-shot examples, we follow this format:

For sentence puzzles:

N examples
[sentence puzzle question
option (A)
option (B)
option (C)
option (D)
Answer: (A) or (B) or (C) or (D)]

problem
[sentence puzzle question
option (A)
option (B)
option (C)
option (D)
Answer:]

For word puzzles:

N examples
[word puzzle question
option (A)
option (B)
option (C)
option (D)
Answer: (A) or (B) or (C) or (D)]

problem
[word puzzle question
option (A)
option (B)
option (C)
option (D)
Answer:]

4 Experimental setup

Although SemEval provided aproxymately 1,000 training examples, this study did not use the training data as it did not involve fine-tuning. Instead, we directly used the brain teaser test data to measure the intrinsic capabilities of Gemini-Pro. Gemini-Pro occasionally does not output an answer. In such cases, we considered (D) as the answer. If it does not output a response in the structured form of (A), (B), (C), (D), we also treated it as (D). For all other cases, we followed the ChatGPT methodology as outlined by SemEval.

5 Results

5.1 With Demonstration

As shown in table 1, for zero-shot, sentence puzzle performance was generally superior to chatGPT, except it showed exceptionally lower performance in context reconstruction. In few-shot, when two examples were provided, it only showed superiority in original, and tied with four-shot in ori&sem&con, while four-shot generally showed superior performance elsewhere, and performance actually decreased in eight-shot.

For word puzzles, zero-shot performance was superior to chatGPT in original, semantic, and context, but uniquely showed lower performance in Ori&sem and ori&sem&con. In few-shot, original showed overwhelming performance in two-shot, semantic was superior in eight-shot, and context had the best performance in four-shot. Overall, the best performance was seen in eight-shot.

5.2 Without Demonstration and Use only relevant few-shot examples

When only sentence puzzle examples were provided for sentence puzzles, the performance in two-shot and four-shot was comparable to the original method. In two-shot, original performance dropped by 10 points, semantic increased by 8 points, context increased by 3 points, ori&sem dropped by 3 points, and ori&sem&con dropped by 5 points, with overall scores remaining the same. In four-shot, original remained unchanged, semantic dropped by 3 points, context dropped by 10 points, Ori&sem increased by 8 points, and ori&sem&con remained the same, with overall dropping by 5 points.

For word puzzles in two-shot, original dropped by 10 points, semantic increased by 6 points, context increased by 4 points, but uniquely, performance remained the same in ori&sem and ori&sem&con, with overall performance unchanged. In four-shot, original performance increased by 10 points, semantic by 19 points, context dropped by 3 points, ori&sem increased by 16 points, and ori&sem&con by 16 points, with an

Four-shot	0.75	0.75	0.84	0.59	0.56	0.76

Table 1: Result of evaluation on Gemini-Pro

overall increase of 7 points.

Sentence puzzles showed a tendency for scores to drop, regardless of how the examples were organized, making it unclear whether the scores dropped randomly. Word puzzles showed a tendency for significant performance increases, but with only 96 test examples for word puzzles and no clear direction in the fluctuations of scores, it is uncertain whether the performance increase was due to providing only word puzzle examples or if the performance randomly improved.

6 Conclusion

As observed in Figure 2 of (Jiang et al., 2023), increasing the number of examples in sentence puzzles did not consistently improve performance, and while an overall upward trend in performance for word puzzles was noted, it did not improve regularly. Similarly, in the experiments of this paper, performance fluctuations with the number of examples were erratic, but it is clear that performance is generally higher compared to chatGPT. The leaderboard for brainteasers often shows many cases scoring over 90, which is likely due to the use of fine-tuning methods on the brainteaser training set. Without training specialized for brainteasers, the effect of using the method of demonstration appears to be minimal or almost nonexistent in a pure model state, and it has been found that larger models exhibit more pronounced performance improvements. Particularly, Gemini, despite being a multimodal model trained with both visual and auditory inputs, significantly underperforms compared to human capabilities. Contrary to the original paper's expectation, it was observed that merely increasing the model size could spontaneously develop problem-solving abilities for lateral thinking tasks, suggesting that even the capability for lateral thinking falls within the range of emergent abilities. According to (Jawahar et al., 2019), as the training of transformer models progresses, layers specialized for tasks are formed, with it being speculated that lateral associations are made in highly differentiated semantic layers in layers closer to the end. Perhaps the improvement in performance in LLMs, as mentioned in the context of brainteasers, might simply be due to memorizing content from the corpus.(Carlini et al., 2022) It remains to be seen whether probing layers specialized for semantic tasks in the future could unveil the mechanism behind lateral thinking.

Abstract

The SemEval task on Argument Reasoning in Civil Procedure is challenging in that it requires understanding legal concepts and inferring complex arguments. Currently, most Large Language Models (LLM) excelling in the legal realm are principally purposed for classification tasks, hence their reasoning rationale is subject to contention. The approach we advocate involves using a powerful teacher-LLM (ChatGPT) to extend the training dataset with explanations and generate synthetic data. The resulting data are then leveraged to fine-tune a small student-LLM. Contrary to previous work, our explanations are not directly derived from the teacher's internal knowledge. Instead they are grounded in authentic human analyses, therefore delivering a superior reasoning signal. Additionally, a new 'mutation' method generates artificial data instances inspired from existing ones. We are publicly releasing the explanations as an extension to the original dataset, along with the synthetic dataset and the prompts that were used to generate both. Our system ranked 15th in the SemEval competition. It outperforms its own teacher and can produce explanations aligned with the original human analyses, as verified by legal experts.

1 Introduction

Semeval-2024 Task 5 (Held and Habernal, 2024) concerns Legal Reasoning within the realm of US Civil Procedure, based on the *Legal Argument Reasoning Task in Civil Procedure* dataset (Bongard et al., 2022). It requires understanding legal concepts and advanced reasoning capabilities, such as the ability to grasp analogy-based arguments and identify contradictions. It is cast as a binary classification problem where, given a question and a candidate answer, the system has to respond whether the candidate answer is correct or not. The questions and answers originate from a textbook widely used by US law schools.

Introduction
... Klaxon: a federal diversity court should use the choice-of-law rules of the state in which it sits. ...
Question
A Rhode Island citizen goes skiing in Vermont. He falls and gets injured. He brings a diversity action against the operator in federal court in Rhode Island. ... The judge would probably apply
Answer (label: *correct*)
Vermont law, because the accident happened there.
Expert Analysis
Rhode Island's choice-of-law rule calls for application of the law of the place of injury. ...
Model Explanation
The federal district judge would probably apply Vermont law, as per Klaxon holding that the judge should use the local state's choice-of-law rules.

Table 1: Example of a training instance and a system-generated explanation aligned with the expert's analysis.

Our system leverages two data augmentation strategies to enrich the provided training set. The first strategy involves extending each data point with Chain-of-Thought (Wei et al., 2023) style explanations originating from the author's original analysis and refined by GPT-3.5. The second strategy generates additional synthetic examples inspired by the original training examples. The synthetic examples are also accompanied by explanations. We call this method *data mutation*. The data generated from GPT-3.5 for both methods and the prompts used are publicly available.[1]

We fine-tune a Llama-2 (Touvron et al., 2023b) model using both synthetic and original data, incor-

[1]github.com/nlpaueb/multiple-choice-mutation

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1607–1622

porating explanations, to develop a model capable of generating responses and explaining the reasoning supporting them. Our findings indicate that both data augmentation methods significantly improve the model's performance. We conducted ablation studies to analyze the effects of each method. In addition, legal experts evaluate our model's explanations manually to offer us valuable insights about the quality of the produced explanations and the root causes of its errors.

2 Background

2.1 Task Setup

The dataset used in SemEval-2024 Task 5 is derived from a textbook on US civil procedure (Glannon, 2018). Each data instance consists of three parts: introduction, question, and answer (with the label of the answer), as shown in Table 1. The training and development instances also have an additional section, containing an analysis of the textbook's author (see 'expert analysis' in Table 1). The goal is to predict the label (correct or incorrect) of the given answer. The latter has the form of a completion of an incomplete text (the 'question' part of the instance). Each chapter of the book addresses a specific topic, which is introduced in the 'introduction' of each instance.

2.2 Related Work

In the last few years, several models were proposed for legal tasks. LegalBERT (Chalkidis et al., 2020), a BERT-based model (Devlin et al., 2019) that has been further pre-trained on legal data, achieved state-of-the-art results in three downstream tasks. However, LegalBERT is unable to generate explanations for its decisions. In subsequent work to address this limitation, a new hierarchical extension of LegalBERT was proposed (Chalkidis et al., 2021) that can select paragraphs of the input texts that justify its decisions, but it has to be trained with annotated data. Lawyer LLaMA (Huang et al., 2023) enhanced the Chinese LLaMA (Cui et al., 2023), a descendant of LLaMA-1 (Touvron et al., 2023a), with legal knowledge. This was achieved by supervised fine-tuning on synthetic or manually created legal Chinese datasets.

Chain-of-Thought (CoT) (Wei et al., 2023) was introduced as "a series of intermediate natural language reasoning steps that lead to the final output". Few-shot CoT prompting (Wei et al., 2023) is a method that enhances the reasoning skills of LLMs by providing a few CoT demonstrations as exemplars in the prompt before asking the LLM for the final answer. Furthermore, it has been shown that CoT prompting can be improved by using a technique called self-consistency decoding (Wang et al., 2023), where sampling is used during decoding to obtain multiple answers, and then the most consistent one is chosen (e.g., via majority voting).

Instruction tuning (Ouyang et al., 2022) fine-tunes an LLM on a wide range of input requests and the desirable responses, in order to train the LLM to follow instructions. WizardLM (Xu et al., 2023) implements instruction tuning on synthetic instruction data of progressively increasing complexity. The synthetic instruction data are commonly generated by a powerful teacher-LLM. Reinforced Self-Training (ReST) (Gulcehre et al., 2023) iteratively enhances synthetic data by automatically filtering out lower-quality samples and then utilizing the remaining synthetic data to improve the model that produces the synthetic data. Orca (Mukherjee et al., 2023) introduces explanation tuning, which incorporates fine-tuning on CoT data generated by GPT-4 to teach advanced reasoning skills to a smaller LLM.

3 System overview

3.1 Method

Our approach is based on a small open-source LLM (LLama-2-7B), which is fine-tuned to generate CoT-like explanations supporting its predictions. A much larger teacher LLM (GPT-3.5) is utilized to acquire appropriate reasoning data (CoT explanations) with two data augmentation techniques. The first technique modifies the experts' analyses (Section 3.3) to turn them into CoT explanations appropriate for fine-tuning. The second technique 'mutates' an original training instance to generate a synthetic one that incorporates alternative fictitious elements, but requires the application of similar legal reasoning to arrive at the correct answer (Section 3.4). Experiments show that both techniques boost the performance of the baseline model, which is the same LLM fine-tuned without explanations.

3.2 Prompt structure

To create appropriate reasoning data, GPT-3.5 has to perform challenging tasks and the key to achieve this is handcrafting clear and concise prompts. We follow prompt-engineering best practices (Bsharat et al., 2024) to create prompts for both data aug-

mentation techniques. Each prompt has three parts: system instructions, an example of a query and an appropriate response, and a new query that GPT-3.5 has to respond to as in the example. The system instructions are designed to a) delineate the model's role, typically attributed as a legal expert in US Civil Procedure, b) outline the task to be executed, and c) specify the desired output format. Complete examples are provided in Appendix A.1.

3.3 Human-guided explanations (HGE)

CoT explanations that will be leveraged for fine-tuning must adhere to a uniform and formal style. Furthermore, we desire our model's explanations to be succinct so that reasoning fallacies can be easily detected by legal experts. Although the expert analysis (Table 1) provided by the dataset is similar to a CoT explanation, it is tailored for students and therefore more detailed and informal. We refine the expert's analysis with the assistance of GPT-3.5 (Table 2 shows the prompt used) to align it with our desired properties.

HGE
Input: Training instance **Prompt:** Explain why the answer is correct/incorrect according to the analysis. **ChatGPT's response:** Explanation: ...

Table 2: The Human-Guided Explanations (HGE) prompt asks the LLM to provide a CoT explanation that aligns with the analysis of the legal expert and follows a specific format.

3.4 Multiple choice mutation (MCM)

Our goal with this technique is to generate artificial data that demand similar reasoning skills and legal knowledge to the original ones. You can see an example in Table 3 for the training instance in Table 1. We use GPT-3.5 as the teacher-LLM. We implement this in two different prompting stages.

In the first prompting stage (see Table 4), we provide an instance from the training data (introduction, question and answer) and ask GPT-3.5 to generate a multiple choice question with four options. Initially, the responses were often not satisfactory (you can find more details in Appendix A.2). To improve them we introduced two prompt engineering artifacts, which we call 'concept' and 'question background', that clarify the type of questions we want to generate. These artifacts are demonstrated in the example provided with the prompt. The 'concept' aims in identifying the legal outcome of the case and the 'question background' aims in generating a different fictional scenario that is not related to the original one. The final prompt asks for a multiple choice question, with a different 'background' than the original question, that illustrates the same 'concept'. We then concatenate

MCM example
Concept: Choice of Law in Civil Procedure **Question Background:** Alex, a Florida resident, buys a rare art piece from Carter, a California resident. The contract stipulates that any disputes arising from the agreement will be resolved in Arizona. A disagreement arises over the authenticity of the artwork. Alex sues Carter in federal court in Florida. ... **Multiple Choice Question:** Which state's contract law would most likely be applied in Alex's case against Carter? **Options**: A) California (label: *incorrect*) Explanation: Carter's residence is not a determining factor as the contract specifies the choice of law. B) Arizona (label: *correct*) Explanation: The contract explicitly states that any disputes will be resolved in Arizona. C) Florida (label: *incorrect*) Explanation: ... D) New York (label: *incorrect*) Explanation: ...

Table 3: Example of the MCM algorithm applied on the training instance shown in Table 1. Each option becomes a distinct mutated instance.

MCM Stage A
Input: Training instance **Prompt:** Generate a multiple choice question that illustrates the same concept with a different question background. **ChatGPT's response:** Concept Mutated Question (Question Background + Multiple Choice Question) Options: a, b, c, d Correct option: *X*

Table 4: In stage A of MCM, we generate a synthetic example question and four options, one of which is correct.

MCM Stage B
Input: Mutated question and options **Prompt:** Choose the correct option and provide an explanation for each option. **ChatGPT's response:** Correct option: *Y* Explanation for a: ... Explanation for b: ... Explanation for c: ... Explanation for d: ... **Filtering:** If X=Y, an instance for each option is created.

Table 5: In Stage B of MCM, the teacher-LLM predicts the correct option again and generates explanations for each option.

the 'question background' and the 'multiple choice question' that are both generated by the model to get the 'mutated question' that we will use as synthetic data. We discard the 'concept'. In the same prompt we also ask for the correct answer out of the candidate options.

For the second prompting stage (see Table 5) we provide as input the output of the first prompting stage without the correct answer (concept, mutated question, candidate answers). We ask again GPT-3.5 to choose the correct choice and we also ask for an explanation that justifies each choice as correct or incorrect. To avoid introducing noisy synthetic training instances, if the option chosen in the first stage is not same as the option chosen in the second stage, meaning that GPT-3.5 answered inconsistently this question, the example is discarded. We call this process the consistency filter, as it is inspired from the self-consistency approach of (Wang et al., 2023). Around 30% of the generated examples were discarded.

4 Experimental setup

4.1 Data

The initial data splits provided for the competition included a train split of 666 samples, a development (dev) split of 84 samples, and a test split of 98 samples. Out of the 84 samples of the development set, only 17 were labeled as correct. We found that these were not enough for our qualitative analysis (Section 5.6) and for this reason, we expanded the dev set by including 101 samples from the training set, resulting in 185 samples and a reduced training split of 565 samples. (We cannot conduct qualitative evaluation on the test set, as we do not possess the expert's analysis for those instances.) The F1 score is the official evaluation measure due to the dataset's imbalance, with accuracy serving as the secondary metric.

4.2 ChatGPT Prompting setup

All of our data augmentation was conducted with the model `gpt3.5-turbo-1106`. The total cost for data augmentation remained under $20. We also use GPT models with few-shot prompting as baselines. For the experiments listed in Table 6, the scores on the development set were averaged over three different random seeds for GPT-3.5 and one seed for GPT-4. In all experiments, the default OpenAI parameter values were kept.

4.3 Llama-2-7B Tuning setup

As the student model, we employed the 8-bit quantized version of the `Llama-2-7b` foundational model. We trained with QLoRA (Dettmers et al., 2023) for one epoch, with a batch size of 4, and a learning rate of 1e-4. We utilized the Hugging Face Transformers library and the Llama recipes from Facebook Research.[2] We used a single NVIDIA GPU A6000 with 48GB of GPU RAM.

5 Results

5.1 Main Results

Our best method ranked 15th among 20 competitors. However, unlike other models, it can generate concise explanations to justify its answers. Our main baseline is a Llama-2 model (Llama-2-base) fine-tuned on the (reduced) training set without data augmentation. Extending the dataset with human-guided explanations (Llama-2-HGE, Section 3.3) greatly improves performance (Table 6) while providing insightful explanations as a byproduct. Employing additional synthetic data generated by the multiple choice mutation method (Llama-2-MCM, Section 3.4) along with the human-guided explanations further enhances performance. Additionally, Llama-2-MCM outperforms GPT-3.5 prompted with CoT examples (GPT-3.5-CoT), a strong baseline that can also provide explanations. This is a notable achievement for several reasons. First of all, GPT-3.5 produced the data that were used for fine-tuning Llama-2-MCM. Furthermore, it is a much more capable few-shot reasoner than Llama-2-7B (Zheng et al., 2023) and it is a significantly larger model in terms of parameters (probably more than ten times larger, but the exact number is unknown).

5.2 BERT models

We report BERT scores (Table 6) from the work that introduced the dataset (Bongard et al., 2022). BERT-base without legal-specific pretraining achieves mediocre performance, while LegalBERT with legal pretraining is exceptional, as it would rank 8th in the competition and has similar results to a (prompted) GPT-4, a much larger (but not fine-tuned) model. However, as argued by Bongard et al. (2022), LegalBERT's responses are of limited utility, as they do not provide explanations of the reasoning behind them.

[2] github.com/facebookresearch/llama-recipes

Model	F1 (dev)	Acc (dev)	F1 (test)	Acc (test)
BERT-base (F)	-	-	56.80	**80.22**
LegalBERT (F)	-	-	65.73	76.92
GPT-3.5-base (P)	31.92	32.97	27.60	30.61
GPT-3.5-CoT (P)	55.29	59.10	43.81	45.92
GPT-4-CoT (P)	**70.43**	**75.00**	**65.88**	72.45
Llama-2-base (F)	36.13	36.24	31.25	35.33
Llama-2-HGE (F)	50.88	65.08	50.00	59.18
Llama-2-MCM (F)	55.87	66.70	51.43	61.22

Table 6: Results for BERT-based models, prompted GPT models, and Llama fine-tuned models. (F) stands for fine-tuning and (P) stands for few-shot prompting.

5.3 OpenAI GPT models

We evaluate GPT-3.5 and GPT-4, which are powerful general-purpose models, prompted with appropriate system instructions and one-shot examples. GPT-3.5-base, without CoT, acting only as a classifier model (no explanations) that predicts the correct label, performs poorly in both dev and test set (Table 6). Leveraging CoT (GPT-3.5-CoT) shows better performance, but still underperforms BERT-base and our Llama-2-MCM in the test set. GPT-4-CoT outperforms GPT-3.5-CoT (by a large margin) and has similar performance with LegalBERT (would rank 8th as well); in addition it can also produce explanations. Interestingly, the performance of GPT-3.5-CoT and GPT-4-CoT drops substantially in the test set if compared to the dev set. The decrease is larger in the case of GPT-3.5-CoT, probably because it is a less powerful model. Note that the test set is harder according to Bongard et al. (2022).

The downsides of OpenAI models are that they are costly and cannot be fine-tuned in the specific domain as easily as open-source models.

5.4 Llama models

Our main baseline, Llama-2-base, is fine-tuned on the training set without data augmentation. It produces the predicted label only, without an explanation. In a similar fashion to its GPT-counterpart (GPT-3.5-base), it performs poorly, which highlights the importance of using CoT data either in a prompting or a fine-tuning setting. Llama-2-HGE (Section 3.3), fine-tuned on the original data extended with explanations created by GPT-3.5 according to the expert's analysis, outperforms GPT-3.5-CoT on the test set. Llama-2-MCM (Section 3.4), fine-tuned on HGE data along with artificial data generated by our 'mutation' method, prevails over both Llama-HGE and GPT-3.5-CoT in every metric. It falls short of BERT-base's performance. The boost in performance that further pretraining provides to LegalBERT might suggest that such an approach (domain adaptation) would benefit our model substantially as well.

5.5 Ablation Study

In the first rows of Table 7, we report an experiment without the expert's analysis (no anls) to assess the effects of human guidance (Section 3.3). Instead, we rely on CoT explanations from GPT-3.5's inherent knowledge, following Mukherjee et al. (2023). The addition of the expert's analysis slightly improves performance, but for a more comprehensive assessment of the analysis's impact, manual evaluation of the explanations is necessary. However, we defer this aspect to future research. We also evaluate the impact of MCM's filtering process (Section 3.4). MCM's performance drops significantly (4 percentage points) without consistency filtering (no fltr, see Table 7), highlighting its value in discarding poor synthetic examples.

The plot in Fig.1 shows the effect of using more synthetic data from MCM. In the x-axis, we can see how many additional synthetic MCM instances are used for fine-tuning; the denominator is the number of synthetic data generated and the nominator (184, 344, 561, 709) are those kept after filtering. After all of the 565 original instances are utilized once, we add a second generation of synthetic data (red$^{\triangle}$ points) with a different random seed. The second generation decreases performance, which may be attributed to the addition of two synthetic instances (that describe the same legal outcome) per original instance, potentially causing overfitting.

Model	F1 (dev)	Acc (dev)
No anls	49.99	60.76
HGE	50.88	65.08
No fltr	51.14	69.41
MCM	55.87	66.70

Table 7: The effects of the expert's analysis (anls) and the consistency filter (fltr).

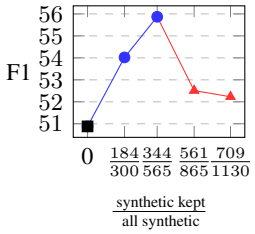

Figure 1: Llama-2-MCM scores in dev set. More mutated examples from the same GPT-3.5 query (red$^{\triangle}$) do not improve F1 score.

5.6 Qualitative Analysis

We investigate how often the model fails to generate an accurate explanation, but nevertheless succeeds to predict the correct answer-label. For this we asked two legal experts (a professor in Law and a J.D. candidate) to annotate whether the explanations of 16 correct predictions of our Llama-2-MCM model align with the expert's analysis or not (Figure 2). 8 of them were 'aligned' and the other 8 were 'not aligned'. This is an indication that performance can be deceiving, because a model might perform well without accurate reasoning. In Table 8 you can see an example that is 'not aligned' due to a deficiency in legal knowledge.

The same experts were also asked to assess 16 false predictions of Llama-2-MCM in terms of 'clarity', i.e., clear vs. unclear (see Fig.3) and comment on their observations. The objective of the second experiment was to investigate the nature of the model's errors. 12 out of 16 incorrect predictions were accompanied by clear explanations that enabled the experts to provide insightful feedback. These explanations fall into two categories: reasoning deficiencies (4) and legal knowledge deficiencies (8). Notably, the model demonstrated confusion regarding the distinction between federal and state courts in two instances, which is a critical aspect of legal knowledge. Table 9 presents an example in which the model appeared to comprehend the relevant legal knowledge, but ultimately failed due to constraints in its reasoning abilities.

6 Conclusion

This paper described the Archimedes-AUEB submission to SemEval-2024 Task 5. The submitted method is based on a LLM fine-tuned on CoT data in order to offer justifications for the predictions it generates. The training explanations are generated by GPT-3.5 in conjunction with expert analyses. Concurrently, we implement an innovative prompting procedure, dubbed Multiple Choice Mutation, designed to produce artificial instances. Both approaches contribute to a significant increase in performance. Our solution ranks 15th out of 20 contestants. Unlike other competitors, it generates explanations for its predictions. It also surpasses a strong GPT-3.5 baseline that can also produce explanations. We also assessed the output of our system qualitatively, with assistance from legal experts. In many cases the system generated high-quality explanations. The errors made by the model can be attributed to either its reasoning limitations or its deficiencies in legal knowledge. We recommend including similar qualitative evaluations in future work, as they reveal pivotal insights about the model that performance metrics alone cannot capture.

Figure 2: Correct predictions annotated for correct alignment with expert analysis.

Figure 3: Incorrect predictions annotated for clarity.

Correct prediction but inaccurate explanation
Question: A computer programmer living in Texas did some work for a corporation which is located in the Northern District of Illinois, but they refused to pay him. **Correct answer:** The court would have the authority to transfer to the Northern District of Illinois, but probably would not. **Expert analysis:** It is unlikely that the convenience of witnesses and the interests of justice require transfer of this case to Illinois. **Model output:** It would not be an appropriate venue, as the case should have been filed in the Texas district.

Table 8: Example where the model predicted the correct label, but failed to produce an accurate explanation due to a deficiency in legal knowledge.

Incorrect prediction but plausible explanation
Question: A sues his former corporation, claiming that he was fired based on his age. B, one of his former supervisors, is about to move to South Korea. A's counsel should **Correct answer:** prepare for the deposition, and cross-examine B as if he were doing so at trial. **Model output:** Incorrect, because a plaintiff who is planning to call B as a witness should not cross-examine her during the deposition to preserve her trial opportunities. **Legal expert feedback:** The AI failed to recognize that the witness planned to leave the country and there will not be any opportunity to examine him at trial.

Table 9: Example where the model understood legal concepts, but failed due to reasoning limitations.

Acknowledgements

We are most grateful to the legal experts, Philippe Jougleux, Associate Professor, School of Law, European University Cyprus, and Helen Bougas, J.D. Candidate, Southern Methodist University.

A Appendix

A.1 Complete prompt examples

The following are examples with the complete prompts used for data augmentation with GPT-3.5 (see Table 10 for HGE, Table 11 for MCM-A and Table 12 for MCM-B). For each example we provide system instructions, an example of the task and the ideal response. During generation with GPT-3.5, we would also provide the actual training instance formatted as in the task example (Introduction, Question, Answer). To find the best prompts that worked well consistently we performed some initial experiments and inspected the quality of individual examples. We present examples of this process for Stage A of MCM in Appendix A.2.

Human-guided explanations
System instructions You are an expert lawyer in the domain of U.S. civil procedure. You are given an introduction to a legal case, a question, an answer and an analysis that justifies the correctness of that answer. These are taken from a legal textbook, however they are not formal and they refer to multiple choice letters (A, B, C, D). Read the given analysis carefully and explain why the answer is correct in a short, formal, clear way, without mentioning anything about letters A, B, C, D. **Task example** Introduction: Section 1391(d), which defines the residence of a corporation that has contacts in one district within a state but not others, is confusing. [...] Question: Arthur wishes to bring a diversity action in federal court against Cleveland Manufacturing Company. Cleveland has its factory and principal place of business in the Northern District of Illinois, but no other contacts with Illinois. The claim is based on alleged negligence in making a toaster at the Illinois factory, which caused a fire in Arthur's home in the Middle District of Georgia. Answer: The Southern District of Illinois is not a proper venue under §1391 because no events giving rise to the claim took place there and Cleveland does not reside there under the venue statute. Analysis: So, C is the right answer. The Southern District of Illinois is not a proper venue. **Ideal response** Explanation: The Southern District of Illinois cannot serve as a proper venue for Arthur's lawsuit against Cleveland Manufacturing Company under Section 1391(d) because Cleveland lacks sufficient contacts in this district to be considered as 'residing' there within the venue statute.

Table 10: Prompt instructions and one-shot example for generating human-guided explanations. The query for the training instance is not shown, but it follows the same structure as the 'Task example'.

Multiple choice mutation - Stage A

System instructions
You are an expert lawyer in the domain of U.S. civil procedure. You are given an introduction that describes a legal case, a question about that case and an answer to that question. First, you must identify what legal concept the question is talking about. Note that the given question contains some background on the details of the case. Provide a different background for your question and then ask a multiple choice question in the style of the original question, to illustrate that concept to law students.
Training instance
Introduction:
...
Question:
Chu, a Californian, went skiing at Aspen, in Colorado, which has only one federal judicial district. After he discovered that he was somewhat out of shape, he bought an exercise machine from Jackson, a friend from Kansas with a two-week time share in Aspen, who had brought the machine with him to Aspen after buying it in Texas. The machine was made by Sweda- Trak, a Texas company that sells its products only in Texas, and with its only place of business in the Western District of Texas. Chu brought the machine back to Los Angeles, California, where he was injured using it. Chu brings a diversity action against Jackson and Sweda-Trak in federal court, alleging that Jackson was negligent in maintaining the machine, and Sweda-Trak in designing it. Venue in Chu's action would be
Answer:
proper in the Southern District of California under §1391(b)(2), because a substantial part of the events giving rise to the claim took place there.
Ideal response (Mutated instance)
Concept:
Venue in Civil Procedure
Background:
Sophia, a New York resident, wants to sue Eric, a Texas resident, claiming that he infringed on her copyright by using her work in his recent publication. Sophia has never been to Texas, but she knows that Eric frequently visits New York for business meetings. According to U.S. law, venue refers to the most appropriate location for a trial. It can be the district where the defendant resides or where the events related to the claim occurred.
Question:
In which district would venue be proper if Sophia brings a copyright infringement lawsuit against Eric in federal court?
Choices:
A) The Southern District of New York, where Sophia resides
B) The Western District of Texas, where Eric resides
C) The Eastern District of New York, where Eric frequently visits for business meetings
D) The Northern District of Texas, where Sophia's work was originally created
Correct Answer:
A) The Southern District of New York, where Sophia resides

Table 11: Prompt instructions and one-shot example for generating a mutated question and candidate answers (choices/options) from an original training instance with MCM - Stage A.

Multiple choice mutation - Stage B

System instructions
You are an expert lawyer in the domain of U.S. civil procedure. You are given an introduction that describes legal concepts, one of these concepts, background of a legal case and a multiple choice question about that case. First, answer which answer is the correct one and then for each choice explain in one sentence why it is correct or wrong.
Task example
Introduction:
...
Concept:
Venue in Civil Procedure
Background:
Mark, a resident of Florida, wants to file a personal injury lawsuit against GreenCo, a multinational corporation headquartered in Delaware, for injuries sustained due to a defective product. The product was purchased online and delivered to Mark's home in Florida. Mark believes the defective product was manufactured and designed at GreenCo's facility in Kansas.
Question:
In which district would venue be proper if Mark brings a personal injury lawsuit against GreenCo in federal court?
Choices:
A) The District of Delaware, where GreenCo is headquartered
B) The Middle District of Florida, where Mark resides
C) The District of Kansas, where the defective product was manufactured and designed
D) The Southern District of Florida, where the product was delivered to Mark's home
Ideal response
The correct answer is:
B) The Middle District of Florida, where Mark resides
Choices:
A) The District of Delaware, where GreenCo is headquartered
Incorrect, because while GreenCo's headquarters are in Delaware, there doesn't seem to be any significant actions related to the claim that occurred there.
B) The Middle District of Florida, where Mark resides
Correct, because the product was delivered to Mark's home in Florida, causing the injury. Therefore, a significant portion of the events related to the claim occurred there.
C) The District of Kansas, where the defective product was manufactured and designed
Incorrect, although the product was manufactured and designed in Kansas, the significant harm occurred in Florida, making this district less relevant for this case.
D) The Southern District of Florida, where the product was delivered to Mark's home
Incorrect, because Mark does not reside in the Southern District of Florida and no specific information was given that suggest the Southern District as the proper venue.

Table 12: Prompt instructions and one-shot example for filtering inconsistent responses and generating explanations for each candidate answer from a mutated question and its candidate answers with MCM - Stage B.

A.2 Prompt engineering artifacts for MCM

As explained in Section 3.4, the initial prompt we came up with was not generating consistent responses from GPT-3.5 and for this reason we added the artifacts of 'concept' and 'question background'. We experimented with many different prompts and inspected their outputs to optimize these artifacts. Here we present an example of a training instance in Table 13 (it is the same example as in Table 1) and show the different mutated instances that would be produced with and without artifacts in Table 15 and Table 14 respectively. It is clear even from just one example that the response is much closer to the original training instance when we use artifacts. It is notable that we did not encounter the same problems with GPT-4.

Original training instance
Introduction: [...] the Supreme Court addressed this issue in Klaxon Co. v. Stentor Mfg. Co., 313 U.S. 487 (1941). Klaxon held that a federal diversity court should use the choice-of-law rules of the state in which it sits. ... Question: Your law or mine? Whitney, a Rhode Island citizen, goes skiing at a ski area in Vermont. When he purchases his lift ticket, he quickly signs a release of liability, waiving his right to sue, should he be injured due to negligence of the operator. While coming down an expert trail, he comes suddenly upon a bare spot full of rocks. He falls and is injured. He brings a diversity action against the operator in federal court in Rhode Island, basing personal jurisdiction on the fact that it had sent him an offer there for a weekend ski package that induced him to go to Vermont to ski. Assume that Rhode Island tort law refuses to enforce advance waivers of liability for negligence, unless they were individually negotiated. Assume further that Vermont tort law holds such waivers enforceable. Assume further that Rhode Island's choice-of-law rule for tort cases is to apply the law of the place of the injury, while Vermont's choice-of-law rule involves an assessment of the interests of the parties and states involved. It is less predictable under this balancing approach to choice of law whether the court would apply Rhode Island or Vermont law. The Rhode Island federal district judge would probably apply Answer: Vermont law to Whitney's case, because the accident happened in Vermont.

Table 13: Original training instance example.

Mutated question without artifacts
Vanilla prompt
You are an expert lawyer in the domain of U.S. civil procedure. You are given an introduction that describes a legal case, a question about that case and an answer to that question. Ask a multiple choice question in the style of the original question.
Response
Question: In a scenario where Emma, a Florida resident, sues Jack, a Georgia resident, for breach of contract in a federal court located in Georgia, which state's law would the federal court likely apply to the case under the principle established in Klaxon Co. v. Stentor Mfg. Co.? Choices: A) Florida law, where Emma resides B) Georgia law, where Jack resides C) Texas law, where the contract was signed D) New York law, where the federal court is located Correct Answer: B) Georgia law, where Jack resides

Table 14: The mutated question is missing some key elements when artifacts are not used, because GPT-3.5 has limited ability to understand complex prompts.

Mutated question with artifacts
Prompt with artifacts
You are an expert lawyer in the domain of U.S. civil procedure. You are given an introduction that describes a legal case, a question about that case and an answer to that question. **First, you must identify what legal concept the question is talking about. Note that the given question contains some background on the details of the case. Provide a different background for your question** and then ask a multiple choice question in the style of the original question, **to illustrate that concept to law students.**
Response
Concept: Choice of Law in Diversity Cases Background: Megan, a Florida resident, enters into a contract with Alex, a Georgia resident, for the purchase of a rare antique clock. The contract was negotiated over the phone and through emails, with the clock to be delivered to Megan in Florida. However, when the clock arrives, Megan discovers that it is damaged beyond repair. She decides to sue Alex in federal court in Georgia for breach of contract. The issue arises as to which state's law should govern the contract - Florida where Megan resides, or Georgia where Alex resides. Question: In a diversity action where Megan brings a breach of contract lawsuit against Alex, which state's law would a Georgia federal court likely apply, based on traditional choice-of-law doctrine? Choices: A) Florida law, where Megan resides B) Georgia law, where Alex resides C) The law of the state where the contract was formed, based on the traditional choice-of-law rule D) The law of the state with the most significant contacts to the contract, based on the traditional choice-of-law rule Correct Answer: C) The law of the state where the contract was formed, based on the traditional choice-of-law rule

Table 15: The mutated question is closer to our desired format when we use artifacts.

A.3 System response samples

In this section we present samples of complete instance-response pairs from our system (from the extended development set) annotated by legal experts. We present two samples of alignment between expert analysis and model explanation (Tables 16 and 17) and one sample that the explanation was not aligned (Table 18). We also present one sample where the prediction was wrong and the explanation was inacurrate because of legal deficiencies (Table 19), another one that failed because of limitations in reasoning cabilities (Table 20) and a sample that failed but the explanation was unclear to the legal experts (Table 21).

Aligned explanation - 1

Introduction:
The message of the Erie case is clear: "federal court: apply state law in a diversity case." [...] Every state has "choice-of-law" rules to deal with this problem, which arises frequently in state cases as well as federal diversity cases. [...] Three years after Erie, the Supreme Court addressed this issue in Klaxon Co. v. Stentor Mfg. Co., 313 U.S. 487 (1941). Klaxon held that a federal diversity court should use the choice-of-law rules of the state in which it sits. Thus, a New York federal court should apply whatever state substantive law the New York state court would apply to the case. If a New York court, under its choice-of-law rules, would apply New York tort law to Tompkins's accident (even though it took place in Pennsylvania), the New York federal court should do so as well. On the other hand, if a New York court would, under its choice-of-law rule for torts, apply Pennsylvania law to Tompkins's case, the New York federal court should similarly look to Pennsylvania law.
...
Question:
Your law or mine? Whitney, a Rhode Island citizen, goes skiing at a ski area in Vermont. When he purchases his lift ticket, he quickly signs a release of liability, waiving his right to sue, should he be injured due to negligence of the operator. While coming down an expert trail, he comes suddenly upon a bare spot full of rocks. He falls and is injured. He brings a diversity action against the operator in federal court in Rhode Island, basing personal jurisdiction on the fact that it had sent him an offer there for a weekend ski package that induced him to go to Vermont to ski. Assume that Rhode Island tort law refuses to enforce advance waivers of liability for negligence, unless they were individually negotiated. Assume further that Vermont tort law holds such waivers enforceable. Assume further that Rhode Island's choice-of-law rule for tort cases is to apply the law of the place of the injury, while Vermont's choice-of-law rule involves an assessment of the interests of the parties and states involved. It is less predictable under this balancing approach to choice of law whether the court would apply Rhode Island or Vermont law. The Rhode Island federal district judge would probably apply
Answer: Vermont law to Whitney's case, because the accident happened in Vermont.
Expert analysis:
Label: *Correct*
Although Rhode Island wouldn't enforce this waiver in a domestic case, its choice-of-law rule calls for application of the law of the place of injury, and that means Vermont law rather than its own.
Model explanation:
Label: *Correct*
The Rhode Island federal district judge would probably apply Vermont law to Whitney's case, as per Klaxon holding that the judge should use the local state's choice-of-law rules, resulting in Vermont law being likely applied.

Table 16: An example of alignment between expert analysis and model explanation (this is the complete prompt and response for the instance that was shown in Table 1).

Aligned explanation - 2

Introduction:
Rule 8 contains simple, sensible provisions governing the defendant's responses to the allegations in the complaint. First, Rule 8(b) requires the defendant to admit or deny each of the allegations in the complaint.
[...]
Under Rule 8(b)(2), a "denial must fairly respond to the substance of the allegation." If the defendant means to deny only a part of an allegation, she must specify what is true and deny only the parts that are not. Failing to deny an allegation constitutes an admission of it. Fed. R. Civ. P. 8(b)(6). The idea is that, if the parties plead conscientiously by the Rules, the parties and the court can compare the allegations in the complaint and the responses in the answer, and determine which issues are contested and which are agreed upon (and therefore need not be litigated).
Question:
Patterson sues Applied Electronics, Inc., for injuries suffered in an accident with Adair, one of AE's delivery drivers. Patterson alleges in Paragraph 4 of his complaint that Adair was an employee of AE at the time of the accident, that Adair was acting in the scope of employment at the time of the accident (which Patterson must prove in order to recover from the employer), that Adair was talking on his cell phone at the time of the accident, and that Adair's negligent driving caused the accident. AE answers Paragraph 4 as follows: "The defendant admits that Adair was its employee at the time of the accident, denies that Adair was negligent, but is without sufficient information to form a belief as to the truth of the allegation that Adair was talking on his cell phone at the time of the accident." Under Federal Rule 8,
Answer:
AE has admitted that Adair was its employee, but not that he acted in the scope of employment. The allegation that Adair was talking on his cell phone is treated as denied.
Expert analysis:
Label: *Incorrect*
This question simply requires you to compare Patterson's allegations with the defendant's responses, and apply the provisions of Rule 8 as to the effect of a denial, failure to deny, or allegation that the pleader is "without sufficient facts to form a belief." Naturally, AE has admitted that Adair was its employee, by admitting it! (Sometimes even the pleading rules are commonsensical.) The allegation that Adair was talking on his cell phone is treated as denied: Under the Rule 8(b)(5), the "without sufficient information" response is treated as a denial. Adair hasn't responded at all to the allegation that Adair acted in the scope of employment at the time of the accident. Frequently, defendants would like to ignore allegations in the complaint, if they aren't sure of their truth, or it would be awkward to admit them. But this head-in-the-sand strategy doesn't work under the Rules: Rule 8(b)(6) provides that allegations that are not denied are deemed admitted. So, effectively, AE has admitted that Adair was its employee and that he acted in the scope of employment, but denied negligence and that Adair was chatting on the cell phone.
Model explanation:
Label: *Incorrect*
The answer is incorrect because the language used by AE is not consistent with the treatment described in Rule 8(b)(6), which requires the defendant to deny only a part of the accusation if not admitting the whole.

Table 17: Another example of alignment between expert analysis and model explanation. Note that the model's explanation is much more concise.

Failed alignment of explanation

Introduction:
Sometimes a case is filed in a court that has subject matter jurisdiction over the case, personal jurisdiction over the defendant, and is a proper venue under the venue statutes, yet the court concludes, as a matter of common sense, that it should be litigated somewhere else.
[...]
In response to the Gulf Oil decision, Congress enacted 28 U.S.C. §1404(a), the federal transfer-of-venue statute. Under this section, a judge may transfer a case filed in her court that should be litigated elsewhere to the more appropriate federal district, instead of dismissing it for forum non conveniens. (a) For the convenience of parties and witnesses, in the interest of justice, a district court may transfer any civil action to any other district or division where it might have been brought or to any district or division to which all parties have consented. This statute makes good administrative sense. Because the federal district courts are all units of the same system, Congress has the authority to provide for transfer of cases among them to promote efficiency.
...
Question:
The federal shuffle. Connors, a computer programmer living in the Northern District of Texas, did some contract work for Ace Corporation, which is incorporated in Delaware with its principal place of business in the Northern District of Illinois. Ace has an office in the Northern District of Texas, but no other offices in Texas. It has large operations in three other states. Connors negotiated the contract by phone and e-mail from his home, dealing with Ace employees in the Texas office and the Illinois office. He did the programming work, which was to be used for Ace's Texas operation, at his home. Ace Corporation claimed that Connors had only done half the work, and refused to pay. Connors, believing that he had completed all the work called for under the contract, brought a diversity action against Ace for the contract price ($200,000) in federal court in the Northern District of Texas.
Answer:
The court would have the authority to transfer to the Northern District of Illinois, but probably would not.
Expert analysis:
Although the court would have authority under 28 U.S.C. §1404(a) to transfer this case to the Northern District of Illinois, why would it? Most of the events giving rise to the claim took place in the Northern District of Texas. Connors did the work there, dealt with Ace employees there, and suffered the damages there. The programming was to be used in Ace's Texas office. The defendant, a corporation with a local office, would not be greatly inconvenienced or put to great expense to litigate this case in Texas. Some witnesses and evidence may be in Illinois, but it seems very doubtful that more would be there than in Texas. It seems highly unlikely that the convenience of witnesses and the interests of justice require transfer of this case to Illinois.
Model explanation:
The federal court in Texas would have the authority to transfer the case to the Northern District of Illinois under §1404(a), but the court would probably not do so because it would not be an appropriate venue, as the case should have been filed in the Texas district.

Table 18: A sample that the model explanation failed to align with the expert's analysis (this is the complete prompt and response for the instance that was shown in Table 8).

Incorrect response due to legal deficiency

Introduction:
In Hanna, the Court addressed the power of Congress to promulgate rules that govern procedure in the federal courts. See 380 U.S. at 464. Analytically, it had to do so, because the power to write the Federal Rules of Civil Procedure is granted by Congress to the Court, in the Rules Enabling Act. Surely, Congress could not delegate to the Court any broader rule-making power than it possesses itself. In Hanna, the Court describes Congress's rule-making authority as follows: the constitutional provision for a federal court system (augmented by the Necessary and Proper Clause) carries with it congressional power to make rules governing the practice and pleading in those courts, which in turn includes a power to regulate matters which, though falling within the uncertain area between substance and procedure, are rationally capable of classification as either. 380 U.S. at 472. That's a mighty broad test for Congressional power over federal court procedure: If the provision can rationally be viewed as regulating procedure, Congress may enact it, even if it will affect the outcome of litigation. Consider, however, how the Court would rule if Congress enacted a statute that impinges on state law rights that can reasonably be classified as "substantive."
Question:
Limits on limitations. Congress, in an effort to avoid complex and time-consuming litigation on the proper time for filing diversity cases in the federal courts, enacts the Federal Diversity Limitations Act (FDLA), establishing a two-year limitations period for diversity cases in the federal courts, regardless of the applicable state limitations period for the claim. Sanchez brings a diversity action against Bernstein in federal court for fraud arising out of a real estate transaction. The relevant state limitations period for fraud claims is four years. Sanchez's suit is brought two years and five months after the alleged fraud was committed. The federal court should
Answer:
dismiss the claim, because the FDLA applies and bars it.
Expert analysis:
While this limitations period would not apply if it were a matter of federal judicial practice (see York), and probably could not be validly adopted as a Federal Rule (see 28 U.S.C. §2072(b)), there's a strong argument, under Hanna's description of congressional power over procedure, that this statute could be enacted by Congress. After all, under Hanna, Congress has very broad authority to regulate procedure in the federal courts. You could imagine that Congress might seek to protect those courts from expending limited judicial resources on state claims by imposing a limitations period on diversity cases. It is very likely within its power to do so, and should be. Of course, it hasn't, and probably won't pass such a limitations statute, since such a statute would interfere significantly with the administration of state causes of action. The members of Congress do, after all, represent the states.
Model explanation:
Label: *Incorrect*
The answer is incorrect because federal courts should not dismiss a case on the basis of federal statutes of limitations if state law permits the claim to be raised, unless there are grounds not based on the applicable federal limitations period to question admissibility of the claim.
Legal expert feedback:
The system has difficulty distinguishing the differences between state and federal court.

Table 19: An example where the model demonstrated confusion in distinguishing the state with the federal court.

Incorrect response due to limited reasoning capabilities

Introduction:
A deposition is the examination of a witness under oath. Depositions are the most effective means of previewing the detailed testimony of witnesses.
[...]
Depositions serve several purposes. They "get the witness on the record." That is, the witness tells her story under oath. If she contradicts that story at trial, she can be impeached with her deposition testimony.
[...]
However, in some cases a party may depose a witness in order to obtain the party's testimony for use at trial. If, for example, a witness is moving out of the country, the party who wants to use that witness's testimony at trial may take her deposition as a substitute for her live testimony at the trial. The deposition will be admissible at trial if the witness is not available to testify in person. Fed. R. Civ. P. 32(a)(4). Note that in this scenario, unlike the typical deposition, the party noticing the deposition will be the party who plans to use that witness's testimony, not the opposing party.
Question:
Your witness.
Czonka is fired from his job at fifty-nine, after twenty-one years with NorthStar Corporation. He sues in federal court under the Federal Age Discrimination in Employment Act (ADEA), claiming that he was fired based on his age. Two months after filing suit, Czonka's counsel learns that Roh, one of his supervisors at NorthStar, has just retired, and is about to move to South Korea. Although discovery has just begun, NorthStar has noticed Roh's deposition.
Czonka's counsel should
Answer:
prepare as fully as possible for the deposition, and cross-examine Roh as if she were doing so at trial.
Expert analysis:
Label: *Correct*
If Roh does not appear at trial, cross-examining at the deposition will be the only opportunity Czonka's counsel has to cross- examine Roh under oath. She had better do it as well as she can.
Model explanation:
Label: *Incorrect*
The answer is incorrect because a well-prepared plaintiff who is planning to call Roh as a witness should not cross-examine her during the deposition to preserve her trial opportunities, but should focus on clarifying points and getting her story on the record.
Legal expert feedback:
AI based the reasoning on trial opportunity whereas the protagonist planned to leave the country and there will not be any opportunity to examine him at trial.

Table 20: An example where the model failed, even though it understood legal knowledge, due to limited reasoning capabilities (this is the complete prompt and response for the instance that was shown in Table 9).

Incorrect response with unclear explanation

Introduction:
The discussion so far has focused on motions by the defendant. But the plaintiff may seek summary judgment as well, under the same standard: that there is no genuine issue of material fact and she is entitled to judgment as a matter of law. However, the effect of summary judgment for the plaintiff is often different from the grant of the motion for a defendant.
Question:
Insulation from liability. Maxwell sues Chao for breach of a contract to insulate Chao's house. He alleges that they had a contract, and that he did the work, but Chao refused to pay the agreed price for the work. Maxwell seeks recovery in the alternative on a quantum meruit theory. Chao denies that Maxwell can sue for breach of contract, because the writing Maxwell relies on as the contract—a scribbled note indicating the price for the job—fails to satisfy the requirements for a valid contract under the relevant statute of frauds. Chao also claims that the insulation used was substandard and improperly installed. Maxwell moves for summary judgment on the question of whether the parties had a contract. In support of his motion, he submits the scribbled note itself, an affidavit attesting that it was signed by Chao in his presence, and a brief arguing that the note is sufficient to constitute a binding contract under the statute of frauds. Chao submits no opposing materials, but submits a brief arguing that the note does not constitute a contract, because the terms are insufficiently described in it. **Answer:**
If the judge concludes that the note meets the requirements of a valid contract, she should enter partial summary judgment for Maxwell on the issue of the validity of the written contract.
Expert analysis:
Label: *Correct*
If the judge concludes that the note suffices as a writing, she should grant partial summary judgment for Maxwell on the issue of the sufficiency of the note as a contract. But she would not enter judgment for Maxwell on the claim as a whole, because his motion only establishes one element of the claim, existence of the contract. Maxwell still has to establish other elements of the contract claim (such as adequate performance) or the quantum meruit claim, in order to recover from Chao.
Model explanation:
Label: *Incorrect*
The answer is incorrect because while a judge may enter partial summary judgment on the issue of the written contract's validity, the plaintiff's alternative claim is the subject of different issues, and partial summary judgment will only cover those issues where there is no genuine issue of material fact.

Table 21: An example of an incorrect explanation that the experts found unclear.

A.4 Experts' evaluation

For the manual evaluation process by legal experts we created Google Forms automatically with the Google Apps Script software.[3] Each form contains eight examples in total, four of which are correct labels and the other four incorrect. The experts were given general instructions (Table 22) in order to fill in the forms as consistently as possible. They were also given specific instructions for each task (Table 23). Each example in the form contained an input instance(introduction, question, answer and label of answer, expert analysis) and the prediction of Llama-2-MCM along with the generated explanation for that particular instance.

General Instructions for experts
Outlined Steps Carefully review the Question, Answer, and corresponding Labels. Read the Human Explanation briefly to gain a preliminary understanding. Read the AI explanation and evaluation question carefully. If you know the evaluation question, provide a direct response. Otherwise, revisit the skipped sections for further clarification. In cases of uncertainty after revisiting the essential sections, you can proceed to the subsequent question. The objective is to provide definitive answers wherever possible while optimizing time efficiency. Note that sometimes the explanations (either human or AI), refer to letters, such as "A is correct". Please ignore these, as the letters used to refer to multiple choice questions, but they have been shuffled. Disclaimer: All legal scenarios presented are fictitious and derived from 'The Glannon Guide To Civil Procedure: Learning Civil Procedure Through Multiple-Choice Questions and Analysis, 4th edition.'

Table 22: General instructions provided to legal experts before they fill in the Google Form.

Correct Predictions
In this scenario, the AI has correctly predicted an outcome, and we aim to assess whether it did so for the right reasons or merely by chance. To accomplish this, carefully read both the Question and the Answer, followed by the Human explanation. Next, review the AI explanation and determine if it seems plausible and consistent with the human explanation. Consider whether the AI truly comprehended the reasoning behind the answer. Please refrain from comparing it to the Human explanation, as our intention is not to ascertain whether the AI outperforms the human (which it does not, of course). If you're unsure about what the AI actually understood, you may leave your answer blank, but we encourage you to respond to as many samples as possible.
Incorrect Predictions
In this scenario, the AI has provided an incorrect prediction, resulting in an erroneous explanation. However, our objective is to assess the frequency with which the AI engages in what is known as "hallucination", where it imagines an explanation without genuine reasoning, versus instances where it genuinely attempts to reason but arrives at an incorrect conclusion. In the former case, akin to a student failing to put effort into their homework, we aim to identify instances where the AI requires correction. If you find the purpose of the AI explanation unclear, please indicate as such.

Table 23: Instructions for the alignment task (Correct) and the task about the clarity of incorrect predictions (Incorrect) provided to legal experts before they fill in the Google Form.

Abstract

This document contains the details of the authors' submission to the proceedings of SemEval 2024's Task 8: Multigenerator, Multidomain, and Multilingual Black-Box Machine-Generated Text Detection Subtask A (monolingual) and B. Detection of machine-generated text is becoming an increasingly important task, with the advent of large language models (LLMs). In this paper, we lay out how using weighted averages of RoBERTa layers lets us capture information about text that is relevant to machine-generated text detection.

1 Introduction

Language modeling is a foundational task in NLP, and encompasses learning of all the features that make up language. Different levels of linguistic information are stored in language models' (LM) hidden states. This may include syntax, morphological features, phrasing, and so on. (Rogers et al., 2021) Our aim is to leverage this encoded information to help us discern machine-generated text.

The advent of large language models (LLMs) has transformed the digital landscape, and this has also led to the proliferation of machine-generated text in spaces spanning from legal proceedings, to articles, to school submissions. With this, there has been a consequential rise in the need to be able to distinguish between machine- and human-generated text across domains. Just as important is the need to be able to identify the generators for text that has been flagged as being generated by machines.

In this paper, we describe our methodology and attempts to create a system that can perform the task effectively.

2 System Overview

We have used RoBERTa-base for all experiments in the scope of this paper. The baseline set by the task organizers is reported to have been from a finetuned RoBERTa model. RoBERTa has the same architecture as BERT, but uses a byte-level BPE as a tokenizer and uses a different pretraining scheme and has become a SOTA model since its release (Liu et al., 2019).

2.1 Weighted Layer Averaging

The standard fine-tuning setup uses the [CLS] Representation of the last layer of RoBERTa. It has been shown that different layers of BERT-like models capture different levels of linguistic information, the lower layers capture lexical information and word order,the middle layers capture syntactic information, and the higher layers capture semantic and task specific information (Rogers et al., 2020). We believe that using just the last layer representation may discard some of the syntactic and lexical information, which could be crucial for the task of detecting machine generated text. We use the weighted sum of all the token representations, where each layer is assigned a corresponding weight, trained along with the downstream task, similar to ElMo (Peters et al., 2018). Let $x_0, x_1, ...x_n$ be the input sequence. Roberta generates the following hidden states.

$$\texttt{RoBERTa}([x_0, x_1, \ldots, x_n]) = H$$

Where H is a matrix consisting of hidden state vectors $\mathbf{h}_i^j$ corresponding to the j^{th} layer, and the i^{th} token. $i = 0$ represents the embedding layer

[†]These authors contributed equally to this work.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1623–1626

output.

$$H = \begin{bmatrix} \mathbf{h}_0^0 & \mathbf{h}_1^0 & \dots & \mathbf{h}_n^0 \\ \mathbf{h}_0^1 & \mathbf{h}_1^1 & \dots & \mathbf{h}_n^1 \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{h}_0^{12} & \mathbf{h}_1^{12} & \dots & \mathbf{h}_n^{12} \end{bmatrix}$$

The standard fine-tuning setup uses $\mathbf{h}_0^{12}$ which corresponds to the [CLS] token and passes it through another Feed Forward Network to get the output class probabilities. We propose averaging all of the layer hidden states. The input **y** to the Feed Forward Network that produces the class probabilities is computed as follows.

$$\mathbf{y} = \frac{1}{12} \cdot \sum_{j=0}^{12} \frac{\lambda_j \sum_{i=0}^{n} \mathbf{h}_i^j}{n}$$

λ_j is the layer weight assigned to the layer j. $[\lambda_0, \lambda_1, ...\lambda_{12}]$ are trained along with the classification task.

2.2 Parameter Efficient Tuning with AdaLoRa

A full continual finetune of RoBERTa (and LLMs, in general) with all the weights being updated is known to potentially lead to catastrophic forgetting (Ramasesh et al., 2022), which may cause the model to become unable to generalize, with the pretraining being, for all intents and purposes, in vain.

It has also been shown that common pre-trained models have a very low intrinsic dimension; in other words, there exists a low dimension reparameterization that is as effective for fine-tuning as the full parameter space (Aghajanyan et al., 2020). This implies that full continual finetuning – being potentially harmful as well as unnecessary – can be replaced with a better, more parameter efficient method, which grants us more freedom with regards to model and data sizes.

Low-rank Adapters (LoRA) (Hu et al., 2021) were designed with this in mind. LoRA freezes the pretrained model weights and injects trainable rank decomposition matrices into each layer of the Transformer architecture, greatly reducing the number of trainable parameters for downstream tasks. They also offer an improvement over unfreezing just the last few layers by attaching to every layer in the model, which allows them to modify information flow at every step, starting from the source.

For our task, we made use of Adaptive LoRA (AdaLoRA) (Zhang et al., 2023), which adjusts the matrices based on parameters learned during training, i.e. the ranks of the adapters themselves are learned. Our hope is that by doing this, we prevent unnecessarily large adapters where there is not much to do, and conversely provide the flexibility to have larger matrices to handle greater amounts of information change.

3 Data

Data for the task was provided by the organizers(Wang et al., 2024a). It is an extension of the M4 Dataset (Wang et al., 2024b). The name stands for multi-generator, multi-domain, and multi-lingual corpus for machine-generated text detection. As the name suggests, the dataset has been created with text from different generators spanning multiple domains. The data for subtask A and B follow the same format, consisting of source (such as Wikipedia), model (such as Dolly), label (such as Human), and the text to be classified. The data for subtask C contains text with a combination of human- and machine-generated text, and a label indicating the word index at which the split occurs.

For our experiments, we resplit the training and dev datasets and split them uniformly across generators and domains in an 80-20 split‘. Our split of the dev set is bigger than the official dev set, to get a better estimate of our model’s performance.

4 Experimental Setup

We use RoBERTa’s tokenizer and trained our models for Subtask A (monolingual) (Binary Classification) and Subtask B (Multi-Class Classification) on the resplit train data and use the resplit evaluation data for early stopping. Our Hyperparameter Configuration has been specified in Appendix A.

5 Results

Our model while doing really well on our evaluation set, falls short on the test set scoring around 13 percentage points lower than the baseline for subtask A and around 1 percentage point lower than the baseline for subtask B. This could be attributed to the model not being as good in generalising to unseen domains and generators. We hypothesize more hyperparameter tuning, better aggregation of

Model	Accuracy
Ours	0.7535
Baseline	0.8846

Table 1: Results for Subtask A as computed by the organizers

Model	Accuracy
Ours	0.7387
Baseline	0.7460

Table 2: Results for Subtask B as computed by the organizers

the token representations than averaging by utilizing models like LSTMs (Hochreiter and Schmidhuber, 1997), may help the model better generalise to unseen domains and generators by being able to capture more complex features and patterns. The submission scores as computed by the task organizers have been reported in Tables 1 and 2. Scores on our Validation, the official validation and the official test set as computed by us have been reported in Tables 3 and 4.

6 Conclusion

We have demonstrated that linguistic information encoded in the various layers of large language models such as RoBERTa can be used to effectively demonstrate if a text is machine-generated or not, across different domains and generators.

Abstract

Large Language Models (LLMs) have showcased impressive abilities in generating fluent responses to diverse user queries. However, concerns regarding the potential misuse of such texts in journalism, educational, and academic contexts have surfaced. SemEval 2024 introduces the task of Multigenerator, Multidomain, and Multilingual Black-Box Machine-Generated Text Detection, aiming to develop automated systems for identifying machine-generated text and detecting potential misuse. In this paper, we i) propose a RoBERTa-BiLSTM based classifier designed to classify text into two categories: AI-generated or human ii) conduct a comparative study of our model with baseline approaches to evaluate its effectiveness. This paper contributes to the advancement of automatic text detection systems in addressing the challenges posed by machine-generated text misuse. Our architecture ranked 46th on the official leaderboard with an accuracy of 80.83 among 125.

1 Introduction

The task of classifying text as either AI-generated or human-generated holds significant importance in the field of natural language processing (NLP). It addresses the growing need to distinguish between content created by artificial intelligence models and that generated by human authors, a distinction crucial for various applications such as content moderation, misinformation detection, and safeguarding against AI-generated malicious content. This task is outlined in the task overview paper by (Wang et al., 2024), emphasizing its relevance and scope in the NLP community.

Our system employs a hybrid approach combining deep learning techniques with feature engineering to tackle the classification task effectively. Specifically, we leverage a BiLSTM (Bidirectional Long Short-Term Memory) (Schuster and Paliwal, 1997) neural network in conjunction with RoBERTa (Liu et al., 2019), a pre-trained language representation model, to capture both sequential and contextual information from the input sentences. This hybrid architecture enables our system to effectively capture nuanced linguistic patterns and semantic cues for accurate classification.

Participating in this task provided valuable insights into the capabilities and limitations of our system. Quantitatively, our system achieved competitive results, ranking 46 relative to other teams in terms of accuracy and F1 score. Qualitatively, we observed that our system struggled with distinguishing between sentences generated by AI models trained on specific domains or datasets with highly similar linguistic patterns.

We have released the code for our system on GitHub[1], facilitating transparency and reproducibility in our approach.

2 Related Works

In the field of detecting machine-generated text, numerous methodologies and models have been examined. A distinguished methodology is the application of the RoBERTa Classifier, which enhances the RoBERTa language model through fine-tuning for the specific purpose of identifying machine-generated text. The proficiency of pre-trained classifiers like RoBERTa in this domain has been affirmed through various studies, including those conducted by (Solaiman et al., 2019) and additional research by (Zellers et al., 2019; Ippolito et al., 2019; Bakhtin et al., 2020; Jang et al., 2020; Uchendu et al., 2021). Concurrently, the XLM-R Classifier exploits the multilingual training of the XLM-RoBERTa model to effectively recognize machine-generated text in various languages, as demonstrated by (Conneau et al., 2019).

*Equal contribution.

Alternatively, the exploration of logistic regression models that incorporate GLTR (Giant Language model Test Room) features has been undertaken. These models strive to discern subtleties in text generation methodologies by analyzing token probabilities and distribution entropy, as investigated by (Gehrmann et al., 2019). Furthermore, detection efforts have utilized stylometric and NELA (News Landscape) features, which account for a broad spectrum of linguistic and structural characteristics, including syntactic, stylistic, affective, and moral dimensions, as reported by (Li et al., 2014) and (Mitchell et al., 2023). Additionally, proprietary frameworks like GPTZero, devised by Princeton University, focus on indicators such as perplexity and burstiness to analyze texts for machine-generated content identification. Although the specific technical details are sparingly disclosed, the reported effectiveness of GPTZero in identifying outputs from various AI language models highlights its significance in the ongoing development of machine-generated text detection strategies (Ouyang et al., 2022; Brown et al., 2020; Radford et al., 2019; Touvron et al., 2023).

3 Background

3.1 Dataset

For the machine-generated text, the researchers used various multilingual language models like ChatGPT(OpenAI, 2024), textdavinci-003(OpenAI, 2022), LLaMa(Touvron et al., 2023), FlanT5(Chung et al., 2022), Cohere(Cohere, 2024), Dolly-v2(databricks, 2022), and BLOOMz(Muennighoff et al., 2023). These models were given different tasks like writing Wikipedia articles, summarizing abstracts from arXiv, providing peer reviews, answering questions from Reddit and Baike/Web QA, and creating news briefs. As evident from Table 1, the training set lacks any sentences generated by the Bloomz model, which stands as the sole model represented in the validation set. This deliberate choice ensures a robust assessment of our model's generalization capabilities across all machine-generated outputs, regardless of the specific model generating them. By exposing our model to diverse machine-generated sentences during training, including those from unseen models like Bloomz in the validation set, we aim to evaluate its ability to effectively generalize to novel inputs and make reliable predictions across the spectrum of machine-generated text.

3.2 Task

We focused on Subtask-A of the SemEval Task 8 which involves developing a classifier to differentiate between monolingual sentences generated by artificial intelligence (AI) systems and those generated by humans. This classification task is essential for distinguishing the origin of text and understanding whether it was produced by AI models or by human authors.

3.2.1 Objective

The primary objective is to build a robust classifier capable of accurately distinguishing between AI-generated and human-generated sentences. The classifier should generalize well across various AI models and domains, ensuring consistent perfor-

Model	Accuracy	F1	Precision	Recall	Params*
Full RoBERTa fine tune	80.68	80.54	81.55	80.68	124M

Table 2: The performance of the models tried on the dev set of the dataset.
*The params only accounts for trainable unfreezed parameters.

mance regardless of the specific model or domain from which the text originates.

The goal was to design a model that not only performs this task with high accuracy but also adapts to various AI models and domains. It's crucial for the classifier to accurately identify the origin of sentences, regardless of the technology used to generate them or their subject matter, ensuring broad applicability and effectiveness

4 System Overview

Based on our observation (See 7), we discovered that language modeling task encodes the various features required for detection of AI written text. So we used pretrained RoBERTa in most of our architectures so exploit this power of language models.

4.1 Full RoBERTa Finetune

The Full RoBERTa(Liu et al., 2019) Finetune model, chosen as our baseline, boasted an extensive architecture and possessed the highest parameter count among the models under evaluation. Serving as a comprehensive starting point, this model allowed us to assess the effectiveness of subsequent enhancements in comparison.

4.2 LoRA with RoBERTa (Frozen)

Incorporating Low Rank Adapters (Hu et al., 2021), we applied fine-tuning techniques to the RoBERTa model while strategically freezing all layers. This approach enabled us to adapt the model to our specific task domain, leveraging pre-trained representations effectively.

4.3 LoRA with LongFormer

The limitation of RoBERTa's context length (max 512 tokens) posed challenges for handling lengthy sentences in our dataset. To address this, we investigated LongFormer (Beltagy et al., 2020), a model designed to efficiently manage longer contexts. Despite employing LoRA for fine-tuning, the model's performance on the validation set fell short of expectations, indicating potential difficulties in generalization.

4.4 RoBERTa (2 Layers unfreezed) + BiLSTM

Expanding upon RoBERTa's capabilities, we introduced a hybrid architecture by unfreezing two layers and integrating a BiLSTM network (Schuster and Paliwal, 1997). RoBERTa served as the primary encoder for sentence representations, with the subsequent BiLSTM layer trained to classify based on the last hidden state.

4.5 RoBERTa (Frozen) + GRU

In our endeavor to augment RoBERTa's capabilities, we devised a hybrid architecture by integrating a Gated Recurrent Unit (GRU) (Chung et al., 2014) network with the frozen RoBERTa model. Within this framework, RoBERTa served as the encoder for generating sentence representations, while a subsequent GRU layer was incorporated for sequential processing and classification tasks. This amalgamation aimed to leverage the strengths of both RoBERTa's contextual understanding and GRU's recurrent dynamics, contributing to enhanced performance on our target task.

4.6 RoBERTa (Frozen) + BiLSTM

In our pursuit of enhancing RoBERTa's capabilities, we devised a hybrid architecture by coupling a Bidirectional Long Short-Term Memory (BiLSTM) network with the RoBERTa model (Liu et al., 2019). In this setup, RoBERTa functioned as the encoder for sentence representations, while a subsequent BiLSTM layer was employed for classification, utilizing the last hidden state for decision-making. For a detailed visual representation of the model's architecture, please refer to the accompanying Figure

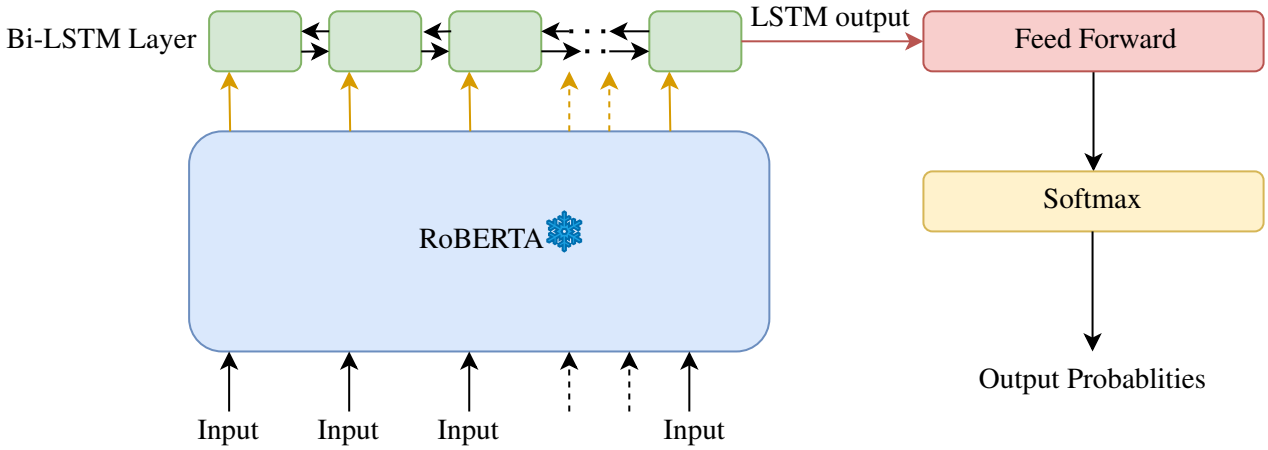

Figure 1: Our proposed architecture of BiLSTM with freezed RoBERTa

1.

We explored various methodologies (refer to Table 2 for detailed performance metrics) before selecting the optimal approach as our final model. Subsequently, we assessed the performance of the chosen model, RoBERTA (Freezed) + BiLSTM, on the test dataset.

5 Experiments

5.1 Preprocessing

All textual data underwent standard preprocessing steps, including tokenization, lowercasing, and punctuation marks. Additionally, specific domain-related preprocessing, such as handling special characters or domain-specific terms, was performed as necessary.

5.2 Hyperparameter Tuning

Hyperparameters were tuned using a combination of grid search and random search techniques. We explored various hyperparameter combinations to identify the optimal configuration for each model variant.

The configuration for LSTM and GRU used in Table 2 is `hidden_size=256`, `layers=2`, `dropout=0.2`, with `LoRA rank being 20` has been found as the best configuration for the models. For RoBERTa+LSTM model's feedforward had a single weight matrix of dimension 512*2.

6 Results

We tested our models on various models on the test set. The results can be viewed in (Table: 3).

Ranking: Our BiLSTM+RoBERTa model achieved a ranking of 46 out of 125 participants in the competition, demonstrating its competitive performance (as shown in Table 3). These results highlight the effectiveness of various models, including BiLSTM+RoBERTa and GRU+RoBERTa, in addressing the task objectives. We submitted BiLSTM+RoBERTa based on its strong performance on the validation set. However, after testing all models listed in Table 3, we found that GRU+RoBERTa achieved a significantly better result, with an accuracy increase of approximately 4%.

7 Conclusion

In conclusion, our BiLSTM+RoBERTa model effectively tackled the task, achieving competitive results, thanks to its deep learning and pre-trained language model. While a similar model with unfrozen RoBERTa boasted higher precision, its complexity came at the cost of increased parameters.

Impressively, our model ranked 46th out of 125 competition entries (Table 3), showcasing its potential alongside approaches like GRU+RoBERTa. Interestingly, post-competition analysis revealed GRU+RoBERTa's superior accuracy (by about 4%). This highlights the value of exploring diverse architectures and hyperparameter tuning for peak performance.

Moving forward, there are several avenues for future work to explore. Firstly, further experimentation with different model architectures, including alternative combinations of encoders and classifiers, could potentially yield improvements in performance. Additionally, fine-tuning hyperparameters and exploring advanced techniques for model optimization may enhance the robustness and generalization capabilities of our system. Furthermore,

Model	Accuracy	F1	Precision	Recall	Params*
Full RoBERTa fine tune^{+}	**88.47**	**88.44**	**93.36**	84.02	124M
LoRA with RoBERTa (Freezed)	80.91	80.18	83.88	80.14	0.7M
LoRA with LongFormer	63.39	57.51	72.45	61.67	6M
BiLSTM with RoBERTa (Un-Freezed)	80.80	80.19	83.08	80.12	18M
GRU with RoBERTa (Freezed)	84.71	84.33	86.53	84.13	3M
BiLSTM with RoBERTa (Freezed)	80.83	80.83	74.65	**96.16**	4M

Table 3: The performance of the models tried on the test set of the dataset.
* The params only accounts for trainable unfreezed parameters.
+ Baseline mentioned in task overview paper

incorporating additional contextual information or domain-specific knowledge could potentially augment the model's understanding and performance on specific tasks. Overall, our findings contribute to the ongoing research efforts in natural language processing and provide valuable insights for future developments in this domain.

Appendix A

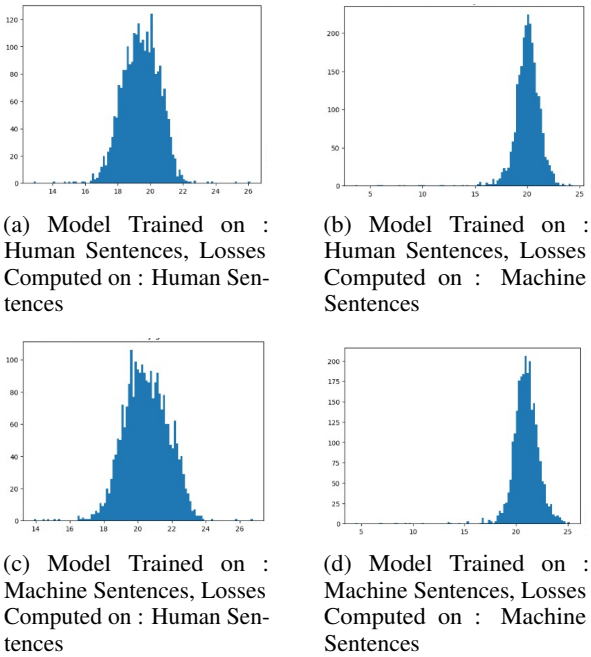
A. Setup

In this study, we implemented a methodology aimed at distinguishing human-generated sentences from machine-generated ones within a training dataset. To achieve this, we initially segregated the dataset into two distinct subsets: one containing human-generated sentences and the other comprising machine-generated ones. Subsequently, we trained separate models utilizing these segregated datasets. Specifically, we employed two distinct models for this task : i) Bidirectional Long Short-Term Memory (**BiLSTM**) model, ii) **RoBERTa** model.

Following the training phase, we proceeded to evaluate the performance of both models on a validation dataset. During this evaluation, we measured the loss incurred by each model when tasked with discerning between human-generated and machine-generated sentences. This evaluation process was crucial for assessing the efficacy and generalization capabilities of the trained models in accurately distinguishing between the two types of sentences.

B. Results

The results are in form of graphs in Figure 2



(a) Model Trained on : Human Sentences, Losses Computed on : Human Sentences

(b) Model Trained on : Human Sentences, Losses Computed on : Machine Sentences

(c) Model Trained on : Machine Sentences, Losses Computed on : Human Sentences

(d) Model Trained on : Machine Sentences, Losses Computed on : Machine Sentences

Figure 2: Overall Results on Models trained on Human and Machine Generated Sentences and Losses Calculated on Human and Machine Generated Sentences

We noted a consistent pattern across both sets of models – those trained on human-generated sentences and those trained on machine-generated sentences. Specifically, we observed that the losses incurred by human-generated sentences on the validation set exhibited a wider distribution with higher variance, while the losses associated with machine-generated sentences displayed a narrower distribution with lesser variance.

This observation leads to a compelling inference regarding the predictive nature of the model losses for each type of data. The wider distribution and higher variance in losses for human-generated sentences suggest a greater level of unpredictability associated with these sentences. In contrast, the narrower distribution and lesser variance in losses for machine-generated sentences indicate a higher level of predictiveness in the model's performance on these sentences.

This finding sheds light on the inherent characteristics of human-generated versus machine-generated sentences, particularly regarding their predictability when processed by the trained models. Such insights are crucial for understanding the intricacies of model behavior and the challenges posed by different types of data in natural language processing tasks.

HW-TSC 2024 Submission for the SemEval-2024 Task 1: Semantic Textual Relatedness (STR)

Mengyao Piao, Chang Su, Yuang Li, Xiaosong Qiao, Xiaofeng Zhao, Yinglu Li, Min Zhang, Hao Yang, Dandan Tu
Huawei Translation Services Center, China
{piaomengyao1, suchang8, liyuang3, qiaoxiaosong, zhaoxiaofeng14, liyinglu, zhangmin186, yanghao30, tudandan}@huawei.com

Abstract

The degree of semantic relatedness of two units of language has long been considered fundamental to understanding meaning. In this paper, we present the system of Huawei Translation Services Center (HW-TSC) for Task 1 of SemEval 2024, which aims to automatically measure the semantic relatedness of sentence pairs in African and Asian languages. The task dataset for this task covers about 14 different languages, These languages originate from five distinct language families and are predominantly spoken in Africa and Asia. For this shared task, we describe our proposed solutions, including ideas and the implementation steps of the task, as well as the outcomes of each experiment on the development dataset. To enhance the performance, we leverage these experimental outcomes and construct an ensemble one. Our results demonstrate that our system achieves impressive performance on test datasets in unsupervised track B and ranked first place for the Punjabi language pair [1].

1 Introduction

The semantic relatedness of two units of language is the degree to which they are close in terms of their meaning (Abdalla et al., 2021). The linguistic units can be words, phrases, sentences, etc. Though our intuition of semantic relatedness is dependent on many factors such as the context of assessment, age, and socioeconomic status (Harispe et al., 2015), it is argued that a consensus can usually be reached for many pairs (Harispe et al., 2015). In the SemEval 2024 shared task 1 (Ousidhoum et al., 2024b), there are three sub-tracks — Track A: Supervised, Track B: Unsupervised, and Track C: Cross-lingual and each track involves several language pairs. Our team — Huawei Translation Services Center (HW-TSC) — participated in the Track B: Unsupervised one which covers most African and Asian language pairs and has to be developed without the use of any labeled data for semantic relatedness. In this paper, we describe HW-TSC's system for unsupervised semantic relatedness tasks, which leverages multiple pre-trained multilingual language models to capture the semantic relatedness of different language pairs. The main features of our system are as follows:

- **N-gram Chars Method**: We employ the tokenizers of two base models for this method. The first one is XLM-RoBERTa (Conneau et al., 2019), a large unsupervised cross-lingual model that extends Facebook's RoBERTa model with more languages and data. The second one is MultilingualBERT (Devlin et al., 2018), a transformers model that is pre-trained on a large multilingual corpus using self-supervised objectives. To measure the similarity between two sentences, we use their n-gram dictionaries as features and compute a similarity score based on them.

- **BERTScore Method**: This method adopts a metric, named BERTScore (Zhang* et al., 2020). It is a metric to assess the quality of the generated text. BERTScore is mainly based on the idea of computing a score from the cosine similarity of the token-level representations obtained from the BERT model for the generated and reference texts.

- **Pretrained Large Language Model Method**: We use XGLM (Lin et al., 2021), a large-scale auto-regressive language model, as the backbone of this method. XGLM is a pre-trained language model that can handle multiple languages and domains. By leveraging the powerful large language model, we can efficiently

[1] https://docs.google.com/spreadsheets/d/1KGN26MYVlfEOqooq-bzD6EBNnpl-YT5XrY9COKESS-g/edit?usp=sharing

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1634–1638

obtain the token logits and perform calculations with them.

- **Translate to English and N-gram Chars Method**: This method needs us to process data with a translation system first, which converts the data from various languages into English. After the translation, we follow the same procedure as the N-gram Chars Method, which uses the n-gram character dictionaries of the generated and the reference texts to compute a similarity score.

- **Dataset**: We utilize the original development and test dataset from SemRel2024 (Ousidhoum et al., 2024a), a novel collection of semantic relatedness datasets annotated by native speakers for 14 languages: Afrikaans, Algerian Arabic, Amharic, English, Hausa, Hindi, Indonesian, Kinyarwanda, Marathi, Moroccan Arabic, Modern Standard Arabic, Punjabi, Spanish, and Telugu.

In this paper, we analyze the characteristics of the shared task and describe our solutions, which include the ideas and implementation processes. We use Sentence-BERT (Reimers et al., 2019) as our baseline for the experiment. We conduct various experiments with the base model, large language models, etc. Our model achieves the best performance for the Punjabi language pairs in the unsupervised track B. The results are encouraging for semantic relatedness, although there is still scope for improvement.

2 Related Work

Our track is unsupervised, meaning that the systems submitted by participants do not rely on any labeled data for measuring semantic relatedness or similarity between text units longer than two words in any language. Consequently, any pre-trained language models that are further fine-tuned with text similarity data, using methods such as instruct-tuning, classification, or a similarity objective, are disqualified from our track. For our baseline score, we used Sentence-BERT (Reimers et al., 2019) (SBERT), a variant of the pre-trained BERT network that employs siamese and triplet architectures to generate sentence embeddings that are semantically meaningful and comparable by cosine similarity. SBERT has been fine-tuned on natural language inference (NLI) data, resulting in sentence embeddings that surpass other state-of-the-art methods. Hence, we selected SBERT as our baseline model and obtained our baseline score.

We introduce BERTScore (Zhang* et al., 2020) secondary, which is an automatic evaluation metric for text generation. Analogously to common metrics, BERTScore computes a similarity score for each token in the candidate sentence with each token in the reference sentence. What is more, different from other matches, it computes token similarity using contextual embeddings. BERTScore correlates better with human judgments and provides stronger model selection performance than existing metrics.

3 Method

3.1 N-gram Chars Method

The n-gram method (Kondrak and Grzegorz, 2005) is a statistical method used in natural language processing (NLP) to analyze the co-occurrence of words in a given text. It involves breaking down the text into sequences of words, where each sequence contains a fixed number of words, referred to as n-grams. The most common types of n-grams are bi-grams (2-grams), tri-grams (3-grams), and quadri-grams (4-grams), but n-grams can have any length. The primary purpose of using n-gram models is to capture the statistical dependencies between words in a language. By analyzing these dependencies, n-gram models can be used for various NLP tasks, such as language modeling, text generation, machine translation, and information retrieval. In this task, we first realized this way, for tokenizing, we tried pre-trained model XLM-Roberta (XLMR) and Multilingual-BERT (MBERT) because it is a multilingual task. At last, we calculate the similarity score with two sentences' n-gram dictionary shown as algorithm1.

3.2 BERTScore Method

BERTScore is a metric for evaluating the quality of text generation, particularly for tasks like machine translation, summarization, and text completion. BERTScore leverages the pre-trained BERT model (Bidirectional Encoder Representations from Transformers) to measure the semantic and syntactic alignment between the generated text and its reference or target text. The core idea behind BERTScore is to compute a score based on the cosine similarity of token-level representations from the BERT model for the generated text and

Algorithm 1 N-gram Chars Score Method

Require: Word sequences of the two sentences Sq_a, Sq_b; there length $Len_a \leftarrow len(Sq_a)$, $Len_b \leftarrow len(Sq_b)$; N-gram window width N

Ensure: $0 < N < min(Len_a, Len_b)$

$Dict_{\{a,b\}} \leftarrow \{\}$
for $i \leftarrow 0$ **to** $Len_{\{a,b\}} - N$ **do**
  $W_{\{a,b\}i} \leftarrow Sq_{\{a,b\}}[i : i + N]$
  if $W_{\{a,b\}i}$ **not in** $Dict_{\{a,b\}}$ **then**
    $Dict_{\{a,b\}}\}[W_{\{a,b\}i}] = 1$
  else
    $state \leftarrow Dict_{\{a,b\}}[W_{\{a,b\}i}] + 1$
    $Dict_{\{a,b\}}[W_{\{a,b\}i}] \leftarrow state$
  end if
end for
$same \leftarrow 0$
for all key **from** $Dict_a$ **do**
  if key **is in** $Dict_b$ **then**
    $count \leftarrow min(Dict_a[key], Dict_b[key])$
    $same \leftarrow same + count$
  end if
end for
$score \leftarrow \frac{2 \times same}{Len_a + Len_b - 2N + 2}$
return $score$

the reference text. Additionally, BERTScore does not require training or tuning and is based on a publicly available pre-trained model. This makes it a useful and practical tool for evaluating the quality of generated text in various natural language processing tasks. Therefore, we calculate the score with the leverage of BERTScore.

3.3 Pretrained Large Language Model Method

Different from the method above, we take advantage of the pre-trained large language model to obtain the logits of the token and compute the score. XGLM is an open-source general language model pre-training framework[2]. The model architecture is general and can be easily extended, supporting various model scales and task-specific architectures. XGLM uses a Transformer-based architecture, after pre-training XGLM learns language structure and grammatical rules, and can generate high-quality natural language text. All in all, XGLM is a flexible and powerful general language model pre-training framework, that supports only Chinese and English. Therefore, we first use the model on the English task to get the logits of the token. Then try to calculate the sum, mean, and half of the logits in proper order.

[2] https://huggingface.co/docs/transformers/main/en/model_doc/xglm

3.4 Translate to English and N-gram Chars Method

Though XLMR and MBERT can support multiple languages, if we look closely at the training data we can see that most of it is in English. Our track mainly faced 14 different African and Asian languages, in order to satisfy our track more, we took advantage of our team to process the data with a translation system to make the data from African and Asian languages into English. And then get the logits of the token as well as the last one.

4 Experiments Results

In the beginning, we applied the following three methods to the English development dataset: N-gram Chars Method with XLMR and MBERT, BERTScore Method, and Pre-trained Large Language Model Method with XGLM to calculate the sum, mean, and half of the logits. See Table 1 Different methods on English development dataset. We can see Ngram-XLMR, Ngram-MBERT, and BERTScore got really impressive performance than every method on XGLM, though XGLM is a large language model and can generate high-quality natural language text almost all the methods with XGLM are below 0.5 in the score.

Method-Model	Score
Ngram-XLMR	0.651
Ngram-MBERT	0.604
BERTScore	0.650
sum-XGLM	0.091
mean-XGLM	0.314
half-XGLM	0.211

Table 1: Different method on English development dataset

Afterwards, we use these methods on the Afrikaans development dataset. What's more, we add Translate to English and N-gram Chars Based method. See Table 2 Different methods on Afrikaans development dataset. we can conclude that Ngram-XLMR and BERTScore still perform better than other methods. What is more, the Translate to English and N-gram Chars Based method did not bring us too many surprises. The table shows that the methods that translate to English are

Method-Model	Score
Ngram-XLMR	0.475
Ngram-MBERT	-0.170
BERTScore	0.102
eng-Ngram-XLMR	-0.171
eng-Ngram-MBERT	0.014
eng-BERTScore	0.102

Table 2: Different method on Afrikaans development dataset

almost all below the methods that did not.

Ngram-XLMR ratio	Score
0	0.650
0.1	0.689
0.2	0.690
0.3	0.689
0.4	0.685
0.5	0.680
0.6	0.676
0.7	0.674
0.8	0.673
0.9	0.672
1	0.651

Table 3: Different ensemble ratio with Ngram-XLMR and BERTScore on English development dataset

Ngram-XLMR ratio	Score
0	0.175
0.1	0.126
0.2	0.106
0.3	0.093
0.4	0.088
0.5	0.084
0.6	0.082
0.7	0.080
0.8	0.080
0.9	0.080
1	0.099

Table 4: Different ensemble ratio with Ngram-XLMR and BERTScore on Punjabi development dataset

From the experiments above, we can see N-gram Chars Based with XLMR and MBERT, BERTScore Based can always get better performance in English and Afrikaans. Will they get a better performance in the other 12 languages? See Table 5 this shows three methods and a Baseline on all language development datasets. To compare with the result from the three methods and baseline, we can see Ngram-XLMR and BERTScore always get better scores in all languages.

At last, we make other experiments to ensemble the results of Ngram-XLMR and BERTScore methods to find out if this way can bring us better performance. We make Ngram-XLMR with ratio A, and BERTScore method with ratio (1-A). See Table 3 Different ensemble ratio with Ngram-XLMR and BERTScore on English development dataset. See Table 4 Different ensemble ratio with Ngram-XLMR and BERTScore on Punjabi development dataset. We can see that the ensemble way may or may not improve the performance.

5 Conclusion

This paper describes HW-TSC's unsupervised system for Semantic Textual Relatednes shared task held in SemEval 2024 Task 1 and also presents the design, the data, and the results. The participants of the shared task were provided with a collection of unsupervised datasets in multiple languages. The shared task is challenging, partly due to the unsupervised development data, and can not use models that have fine-tuned with text similarity data whether through instruct-tuning (e.g., BLOOMZ (Muennighoff et al., 2022)), classification, or a similarity objective (like SBERT). Our system uses three base models with the dataset and carries out comprehensive experiments with different pre-trained models and methods. Finally, our system achieved the 1st best performance in the Punjabi language. For some of the problems reflected in this task, there is still a lot of research space. In the future, we will investigate the transfer method to transfer the knowledge of one language to multiple languages to improve efficiency and we plan to leverage other multiple languages model's skills.

KnowComp at SemEval-2024 Task 9: Conceptualization-Augmented Prompting with Large Language Models for Lateral Reasoning

Weiqi Wang, Baixuan Xu, Haochen Shi, Jiaxin Bai, Qi Hu, Yangqiu Song
Department of Computer Science and Engineering, HKUST, Hong Kong SAR, China
{wwangbw, bxuan, hshiah, jbai, qhuaf, yqsong}@cse.ust.hk

Abstract

Lateral thinking is essential in breaking away from conventional thought patterns and finding innovative solutions to problems. Despite this, language models often struggle with reasoning tasks that require lateral thinking. In this paper, we present our system for SemEval-2024 Task 9's BrainTeaser challenge, which requires language models to answer brain teaser questions that typically involve lateral reasoning scenarios. Our framework is based on large language models and incorporates a zero-shot prompting method that integrates conceptualizations of automatically detected instances in the question. We also transform the task of question answering into a declarative format to enhance the discriminatory ability of large language models. Our zero-shot evaluation results with ChatGPT indicate that our approach outperforms baselines, including zero-shot and few-shot prompting and chain-of-thought reasoning. Additionally, our system ranks ninth on the official leaderboard, demonstrating its strong performance.

1 Introduction

Recently, the Natural Language Processing (NLP) community has witnessed remarkable advancements driven by large language models, such as GPT-3.5 (OpenAI, 2022) and GPT4 (OpenAI, 2023), that demonstrated impressive capabilities in tasks like text generation (Chung et al., 2023; Maynez et al., 2023; Maiorino et al., 2023), translation (Mu et al., 2023; Bawden and Yvon, 2023; Zhang et al., 2023), reasoning (Huang and Chang, 2023; Chan et al., 2024; Gaur and Saunshi, 2023; Ho et al., 2023; Shi et al., 2023), complex reasoning (Bai et al., 2023; Fang et al., 2024), analogical understanding (Cheng et al., 2023; Ye et al., 2024)and sentiment analysis (Carneros-Prado et al., 2023; Deng et al., 2023). However, these models predominantly rely on conventional sequential thinking, often struggling to exhibit the creativity and innovative problem-solving abilities that humans possess. This limitation has spurred researchers to explore the realm of lateral thinking within the NLP domain (Veale and Li, 2013).

Lateral thinking, a concept popularized by De Bono (1970), refers to the ability to break free from established thought patterns and approach problems from unconventional angles. It encourages the exploration of unorthodox ideas, perspectives, and solutions, leading to breakthroughs and the discovery of new opportunities that may have otherwise remained hidden (Lawrence et al., 2016). Harnessing the power of lateral thinking can significantly enhance the capabilities of language models, enabling them to tackle complex, non-linear challenges by thinking "outside the box." However, engaging in this type of reasoning presents a significant challenge, as it demands the ability to contradict common knowledge—a skill highly valued by cutting-edge language models like ChatGPT (OpenAI, 2022) and GPT4 (OpenAI, 2023). Challenging traditional modes of commonsense reasoning poses a serious obstacle for these language models, as it requires them to set aside their inherent strengths and approach the problem from a different perspective.

In light of this direction, Jiang et al. (2023) have recently introduced BrainTeaser, a human-curated benchmark that evaluates the lateral thinking ability of language models. This benchmark encompasses sentence and word puzzles in a question-answering format that challenge common sense, demanding language models to demonstrate innovative thinking in order to provide accurate and insightful responses. The findings of this study expose a significant disparity in the lateral thinking capacities of even large-scale language models, including those augmented with commonsense knowledge (Wang et al., 2023a), when compared to human performance. This gap in accuracy exceeds 40%, emphasizing the necessity for novel

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1639–1645

approaches to enhance the reasoning capabilities of language models.

We propose a new approach to enhance the lateral thinking capability of language models by applying conceptualization (He et al., 2022). Conceptualization is the process of abstracting instances into high-level concepts, which introduces abstract knowledge associated with the concept for the instance (Tenenbaum et al., 2011). Our method involves instructing ChatGPT to perform conceptualization over the premises in the question via a step-by-step process that identifies instances, conceptualizes them into concepts, generates relevant abstract knowledge, and merges them back into the prompt. To make the judgment less biased among choices, we transform the questions into declarative formats. We test our framework with ChatGPT (OpenAI, 2022) in a zero-shot manner, where no training data is used. Our experiment results show that our framework achieves an overall accuracy of 78.3% for sentence puzzles and 85.4% for word puzzles, ranking ninth and eighth in the official leaderboard, respectively.

2 Related Works

2.1 Lateral Reasoning

Lateral reasoning, also known as "thinking outside the box," has garnered significant attention in cognitive psychology and educational research (Evans and Alderson, 2000). Over the past decades, researchers have explored various aspects of lateral reasoning, aiming to understand its underlying processes and develop effective strategies to enhance individuals' lateral thinking abilities (Millar and Taylor, 1995). It is known to be challenging as such type of reasoning usually defies commonsense knowledge, which is knowledge about facts in the world that is typically shared among individuals (Mueller, 2014; Fang et al., 2021b,a). In the domain of NLP, Jiang et al. (2023) are the first to construct evaluation benchmarks that evaluate such cognitive ability. They formulate the task as a question-answering task and design a data collection protocol to crawl sentence puzzles and word puzzles from the web with quality filtering. Experiment results on various language models show the difficulty of their collected dataset.

2.2 Conceptualization

Conceptualization aims to abstract a set of entities or events into a general concept, thereby forming abstract commonsense knowledge within its original context (Murphy, 2004). Existing works primarily focused on entity-level conceptualization (Durme et al., 2009; Song et al., 2011, 2015; Liu et al., 2022), with He et al. (2022) pioneering the construction of an event conceptualization benchmark by extracting concepts for social events from WordNet (Miller, 1995) synsets and Probase (Wu et al., 2012). Wang et al. (2023b,a) further proposed a semi-supervised framework for conceptualizing CSKBs and demonstrated that abstract knowledge can enhance commonsense inference modeling and question answering. Wang et al. (2024) proposed distilling such type of knowledge from large language models to improve commonsense reasoning. Wang et al. (2023c) and Yu et al. (2023) also leveraged similar method to acquire abstract knowledge as high-level knowledge representation. In this paper, we share similar aspirations from previous works and leverage the power of conceptualization to assist large language models in performing lateral reasoning.

	Sentence Puzzle	Word Puzzle
#Data	120	96

Table 1: Number of data in the testing set of the BrainTeaser (Jiang et al., 2023) benchmark.

3 Task Definition and Dataset

We follow the identical task definition as proposed by Jiang et al. (2023), where each data entry can be viewed as a Question-Answering (QA) task. In each QA pair, the question describes a specific context or puzzle, and the answer serves as the lateral explanation or solution to the puzzle. The goal is to find an explanation that supports and does not contradict a given set of premises (P), which includes explicitly stated clauses and implicitly derived clauses through default commonsense inferences or associations. The set of premises (P) plays a crucial role in the puzzle. It encompasses the atomic premise set, which includes explicitly stated clauses (p_1, p_2, p_3) provided by the context, as well as implicit clauses (p_4, p_5) obtained through default commonsense inferences or associations. These implicit premises can sometimes lead to incorrect assumptions or constraints that hinder finding the correct solution (Bar-Hillel et al., 2018). The puzzle is presented in a multiple-choice format,

where the answer choices represent potential explanations or solutions. This format is chosen to make the task more amenable to automated evaluation and facilitate human comprehension.

We use the dataset presented by Jiang et al. (2023, 2024) as our evaluation benchmark and follow the the original released split of data. Since we approach this task by following a zero-shot manner, no training and validation data is used. As shown in Table 1, there are 120 sentence puzzles and 96 word puzzles in the testing set. On average, the questions in this dataset consist of 34.88 tokens, while the corresponding answers have an average length of 9.11 tokens.

4 Method

In this section, we introduce our proposed method. Our method can be divided into three steps: (1) automatically identify instances in the premises in the question and conceptualize them; (2) transform the QA pair into declarative statements; and (3) Prompt ChatGPT in a zero-shot manner to obtain its prediction.

4.1 Conceptualization Augmentation

Our approach to conceptualization follows the method proposed by Wang et al. (2024). First, we provide ChatGPT with a question from the BrainTeaser QA pairs and instruct it to identify relevant keywords and instances in the question. Specifically, we ask it to focus on instances that are pertinent to the question at hand. Next, we utilize the prompt from Wang et al. (2024) to guide ChatGPT in generating conceptualizations for the identified instances. We also instruct ChatGPT to generate abstract knowledge that is relevant to the context of the question. Both the generated conceptualizations and abstract knowledge are integrated into the prompts to assist in the reasoning process. For example, consider the question "A man shaves everyday, yet keeps his beard long" in a sentence puzzle. ChatGPT identifies *shave* and *beard* as the two key instances. The instance "shave" is then conceptualized to "shaving," which further implies that *shaving causes a man's beard go short.*

4.2 Declarative Transformation

We then convert each puzzle into a declarative format and modifying the task to involve selecting the most plausible statement from the options, rather than the traditional question-and-answer format. To achieve this, we present ChatGPT with the question and one of the potential answers, and instruct it to generate a declarative statement that conveys the same meaning as the given question and answer with minimal alterations. For instance, consider the question "In a small village, two farmers are working in their fields - a diligent farmer and a lazy farmer. The hardworking farmer is the son of the lazy farmer, but the lazy farmer is not the father of the hardworking farmer. Can you explain this unusual relationship?" and one of the options, "The lazy farmer is his mother." In response, ChatGPT produces the statement "In a small village, there are two farmers working in their fields - a diligent farmer and a lazy farmer. The hardworking farmer is the son of the lazy farmer, but the lazy farmer is not the father of the hardworking farmer. This peculiar relationship can be clarified by asserting that the lazy farmer is, in fact, the mother of the hardworking farmer."

4.3 Zero-shot Prompting

Finally, we prompt ChatGPT again to ask it to select the most plausible one from the given three statements. For each statement, we also append the derived conceptualizations and associated abstract knowledge into the statement such that they can also be considered during the selection process. We also ask ChatGPT to focus on whether the abstract knowledge has any conflict to the statement presented, which aims at identifying conflicts between commonsense knowledge and the presented statement.

5 Experiments

In this section, we present details of experiments we conducted on the BrainTeaser benchmark.

5.1 Setup

We access ChatGPT through Microsoft Azure APIs[1]. The code of the accessed version for ChatGPT is `gpt-35-turbo-20230515`. The maximum generation length is set to 100 tokens and the temperature is set to 1.0. All other hyperparameters remain unchanged as default. We experiment with three random seeds and report the best performances achieved according to the leaderboard's ranking. For the evaluation metric, we keep using accuracy as the metric and also evaluate the puzzles in instance-based and group-based fashions.

Table 2: Main zero-shot results over two BrainTeaser subtasks across all models in all metrics: Ori = Original, Sem = Semantic, Con = Context, Concept = Conceptualization. The best performance among all models is in bold, and the second-best performance is underlined. Most of the results are reported by Jiang et al. (2023).

5.2 Baselines

For baselines, we largely follow Jiang et al. (2023) and use the officially reported results as baselines. These include instruction-based language models such as ChatGPT (OpenAI, 2022), T0 (Sanh et al., 2022), and FlanT5 (Chung et al., 2022), which were evaluated in a zero setting using specific instruction templates. In addition, commonsense models were also evaluated, including RoBERTa-L (CSKG; Ma et al., 2021) and CAR (Wang et al., 2023a), which were enhanced with commonsense knowledge and achieved impressive zero-shot performance on multiple tasks. The models were evaluated using a scoring method defined in previous studies and the choice with the highest score is selected. Meanwhile, we also report the performances of ChatGPT in a few-shot setting with up to eight shots.

5.3 Results and Analysis

Table 2 presents the results of our study. Our method significantly improves the performance of ChatGPT, outperforming all baselines. In fact, it surpasses all large language models in a zero-shot scenario and even outperforms ChatGPT itself with eight-shot prompting. For sentence puzzles, we observe an overall improvement of 13.87%, while for word puzzles, there is a 28.90% improvement. However, our method still falls short of human performance, indicating room for further improvement. Interestingly, we notice a larger improvement in word puzzles compared to sentence puzzles. This gain may be attributed more to our declarative trans-

formation than to conceptualization, which theoretically offers little help in solving word puzzles.

6 Conclusion

In conclusion, this paper describes the solution by the KnowComp group to task 9 of SemEval-2024. Our method tackles the task of lateral thinking by leveraging the framework of conceptualization, which is a traditional reasoning method performed by humans, to assist large language models in answering brain teaser questions in a zero-shot manner. Experiment results show the superiority of our method, outperforming all previous zero-shot baselines with the same large language model as the backbone.

Abstract

Large Language Models (LLMs) have demonstrated impressive performance on many Natural Language Processing (NLP) tasks. However, their ability to solve more creative, lateral thinking puzzles remains relatively unexplored. In this work, we develop methods to enhance the lateral thinking and puzzle-solving capabilities of LLMs. We curate a dataset of word-type and sentence-type brain teasers requiring creative problem-solving abilities beyond commonsense reasoning. We first evaluate the zero-shot performance of models like GPT-3.5 and GPT-4 on this dataset. To improve their puzzle-solving skills, we employ prompting techniques like providing reasoning clues and chaining multiple examples to demonstrate the desired thinking process. We also fine-tune the state-of-the-art Mixtral 7x8b LLM on our dataset. Our methods enable the models to achieve strong results, securing 2nd and 3rd places in the brain teaser task. Our work highlights the potential of LLMs in acquiring complex reasoning abilities with the appropriate training. The efficacy of our approaches opens up new research avenues into advancing lateral thinking and creative problem-solving with AI systems.

1 Introduction

In recent years, the advent of advanced language models has revolutionized the field of NLP, steering research towards challenges that necessitate intricate and implicit reasoning processes akin to human commonsense reasoning. Such tasks often require vertical thinking, an analytical and methodical approach to problem-solving. This paradigm has enjoyed substantial popularity and success within the NLP community. However, lateral thinking puzzles, which demand creative reasoning and the ability to perceive indirect or non-obvious solutions, have not been equally explored. Lateral thinking involves breaking away from conventional patterns to reveal novel insights, a feat that models based on rigid commonsense associations often struggle with.

Task	Type	Train size	Eval size	Test size
Subtask 1	Word Puzzle	396	120	96
Subtask 2	Sentence Puzzle	507	120	120

Table 1: Task dataset description

Recognizing this disparity, we introduce LLMs in "BRAINTEASER," a meticulously curated multiple-choice Question Answering (QA) task in order to evaluate LLMs' capabilities for lateral thinking. The dataset(Jiang et al., 2023b, 2024b) contains two subtasks: word and sentence brain teasers. Word puzzles are word-type brain teasers where the answer deviates from the typical meaning of the word and instead focuses on the letter composition. Sentence puzzles are sentence-type brain teasers centered around nonsensical or illogical snippets of text. The key characteristics of the dataset are described in Table 1.

In our approach, we employ the formidable GPT-4 language model to address BRAINTEASER's questions under both zero-shot and few-shot conditions, thereby assessing its inherent reasoning capabilities without and with limited context. Additionally, we leverage prompt engineering strategies and incorporate a Chain of Thought (CoT) prompting technique to enhance GPT-4's comprehension of the task requirements. This innovative methodology not only facilitates clearer demonstration of the problem-solving process but also aligns the model's reasoning with human-like thought patterns.

Examples of the word and sentence puzzle samples are provided in Tables 2 and 3, respectively. Semantic Reconstruction (SR) rephrases the original question without altering the correct answer or distractor. Context reconstruction (CR) maintains

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1646–1651

ID	Question	Choice List

Table 2: Dataset samples for subtask 1: word puzzles. Each choice list has four choices. The ground truth is bold.

ID	Question	Choice List
SP-48	*Why is it so cold on Christmas?*	**Because it's in December.** Because people are waiting for the New Year. Because people are celebrating. None of above.
SP-48_SR	*Why is Christmas Day so chilly?*	**Because it's in December.** Because people are waiting for the New Year. Because people are celebrating. None of above.
SP-48_CR	*Why is Independence Day so hot?*	Because people are enjoying the firework. Because people are celebrating. **Because it's in July.** None of above.

Table 3: Dataset samples for subtask 2: sentence puzzles. Each choice list has four choices. The ground truth is bold.

the reasoning path but changes both the question and answer to reflect a new situational context.

The results of our experiments are both promising and insightful. Our model achieved commendable rankings, securing 2nd and 3rd places in the task, which underscores the potential of LLMs in mastering complex, creative problem-solving tasks that extend beyond the scope of traditional commonsense reasoning. These outcomes not only validate the efficacy of our methods but also pave the way for further explorations into the untapped potential of lateral thinking in AI-driven language understanding.

2 Related work

2.1 LLM

Language is a uniquely human ability that allows us to communicate, express ourselves, and record information. In AI research, language models refer to models that can predict the next word or token in a sequence given the previous words or context. Early language models are based on statistical techniques that calculate the probability of each possible next word. These statistical language models are later superseded by neural network-based models, which can more accurately estimate the probability of the next token using deep-learning methods. The development of neural language models marks a major advance in NLP capabilities. By utilizing neural networks to model the complexities of language, today's state-of-the-art language models can generate surprisingly human-like text and show impressive language understanding abilities.

Subsequently, pretrained language models (PLM) like BERT(Devlin et al., 2018), BART(Lewis et al., 2019), and GPT2(Radford et al., 2019) are proposed. These models represent milestones in the development of language models, as they are based on the classical transformer architecture(Vaswani et al., 2023) and significantly increase the text generation capabilities of models. Initially, most of these models have relatively small sizes.

Research has shown that even by solely increasing model size while keeping model architecture similar, abilities on difficult tasks can substantially improve(Brown et al., 2020). This phenomenon of emerging abilities with scale is referred to as

emergent behavior(Wei et al., 2022). This has led to the development of LLMs which have profoundly impacted research and society. For example, the release of LLM has created much interest due to its strong text generation abilities like abstract writing and logical reasoning. This has catalyzed further research into LLMs, with models like LLaMA(Touvron et al., 2023a), LLaMA 2(Touvron et al., 2023b), Mistral 7B(Jiang et al., 2023a), GPT 4(OpenAI et al., 2023), and Mixtral 8x7B(Jiang et al., 2024a) demonstrating impressive performance on various tasks.

2.2 Prompt Engineering

Template-based prompts are among the early attempts at single-stage prompting (Paranjape et al., 2021).

However, the Chain of Thought (CoT) technique leads to more significant improvements in model capabilities (Wei et al., 2023) and attracts substantial interest. By providing a few reasoning demonstrations or "exemplars" in the prompt, CoT yields impressive performance gains. CoT also reveals LLMs' innate zero-shot reasoning abilities — simply prompting the model with "Let's think step-by-step!" enables complex inferential reasoning.

Additionally, prompt quality factors like reasoning complexity in exemplars, number of reasoning steps, and diversity of exemplars impact performance of LLM.

Since single-stage prompting may enable end-to-end reasoning, (Press et al., 2023) also explores constructing multi-stage prompts with follow-up questions and answers to provide detailed reasoning. (Jung et al., 2022) propose prompts based on trees of explanations generated abductively and recursively, e.g. X is true, because Y; Y is true, because...

(Zhou et al., 2023) find that decomposing complex questions into a series of simpler subquestions was beneficial for constructing effective prompts.

3 Method

3.1 GPT-4: From Zero-Shot to Few-Shot

Since GPT-3.5 and GPT-4 demonstrate strong performance on tasks like QA and text generation, we utilize these models to directly answer the training questions by providing the question and choice list.

For the zero-shot stage, we first explain what a word or sentence puzzle is in the prompt, presenting the question and options simultaneously. Then we use GPT-3.5 to predict answers one by one.

During this stage, we observe precision of only 17% for word puzzles on the training set. Errors frequently occur because many questions defy common knowledge, leading models to be overconfident in the "None of the above" choice. Therefore, we modify the prompt by appending "please don't choose 'None of the above', because in most cases, it is not the correct answer", increasing the precision to 66%.

We also notice some questions are too difficult for the model, such as "How many days are there in a month?". We think that providing the model with reasoning clues or demonstration may be beneficial. For this challenging sample, we guide the model to not only simply count days, but also approach the question from a new perspective — identifying which words on a calendar contain "day", like Monday and Tuesday, rather than numerals like January 1st.

A similar puzzle is "How many seconds are there in one year?". GPT-4 cannot find a correct answer if it counts the actual number of seconds in a year. We should tell it this is not to count the actual number of seconds and it should try to answer the question in another way, that is, to count the number of dates that contain second (2nd) in a year. For the hard sample "What is in front of a woman and at the end of a cow?", as an explanation, we tell GPT-4 this is a word game, and it should interpret the questions in two parts and find which letter is at the start/beginning of one word and at the end of the other word. For the question "What is at the end of a cow and in front of a woman?", we remind the model that the word woman starts with the letter "w", and the word cow ends with the letter "w". The correct answer is the letter "W". "What is at the beginning of eternity and the end of time?" For this question, the word "eternity" starts with the letter "e", and the word "time" ends with the letter "e". The correct answer is the letter "E". In this way, GPT-4 can think in the way we expect and correctly answer similar categories of brain teaser puzzles.

To address incorrectly answered examples, we identify and categorize over 20 challenging training instances to include in an extended prompt, as shown in 2. This prompt is designed to guide the model towards lateral thinking. Each illustrative example comprises the original question, choice

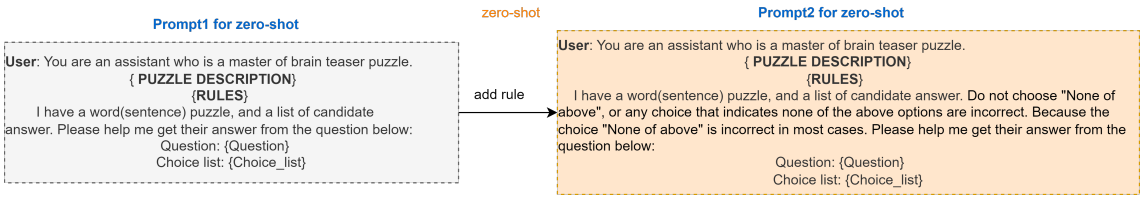

Figure 1: The left figure illustrates Prompt 1, which only provides the definition of a word or sentence puzzle before concatenating the question and choice list from the dataset. As the model tended to select 'None of the above', Prompt 2 adds a rule to avoid this answer. Both prompts are used in a zero-shot setting without examples.

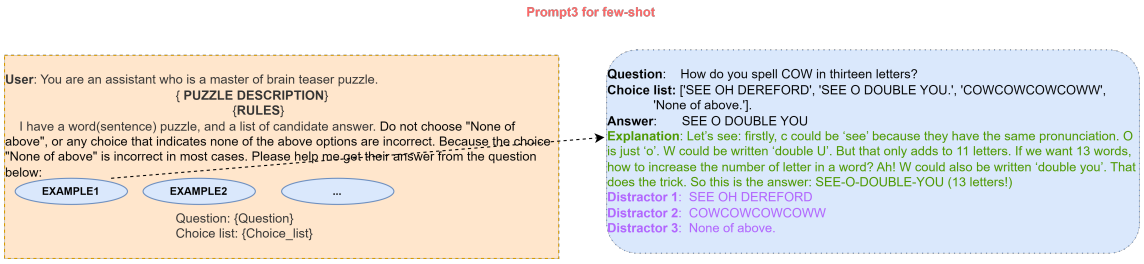

Figure 2: For the third strategy, we concatenate explanation of each example as well as distractors in the choice list. This is a few-shot strategy.

list, correct answer, and an explanatory reasoning clue extracted from the training data. Additionally, we find that supplementing each example with the three distractor options further improves GPT performance. Therefore, the full set of multiple-choice options is appended to each illustrated case. As depicted, these elements are combined to demonstrate the desired thought process.

3.2 Mixstral Fine-tuning

We also experiment with fine-tuning the Mixtral 7x8b model to predict solutions for these brain teaser puzzles. Mixtral 7x8b is a leading open-source LLM, comprised of a Mixture-of-Experts (MOE) architecture with approximately 45 billion parameters. It is regarded as state-of-the-art, outperforming models such as LLaMA 270B and GPT-3.5 on many benchmarks. Mixtral 7x8b offers both a base model and an instruct model, with the latter fine-tuned for enhanced performance on conversational tasks. Therefore, we select Mixtral-7x8b-instruct-v0.1 for fine-tuning on our dataset of around 1000 puzzle examples.

4 Experiment and Result

4.1 Experiment

Experiments are conducted on a test set to evaluate the three prompt designs introduced previously. Initially, GPT-3.5 was used to test Prompts 1 and 2 for subtask 1 (word puzzles). As the evaluation deadline approached, we switched to GPT-4 for greater efficiency. We evaluated Prompt 3 five times, and an ensemble voting strategy was adopted. Besides, we proceeded with only Prompt 3 (GPT4, with ensemble) for subtask 2's test set, omitting Prompts 1 and 2.

4.2 Result and Analysis

Experiment results on the training set are shown in Table 5, and our final results are shown in Table 6. As shown in Table 5, there is a substantial performance increase from Prompt 2 (GPT-3.5, zero-shot) to Prompt 3 (GPT-4, few-shot, with ensemble). This demonstrates the efficacy of our strategy utilizing Prompt 3 with GPT-4 in a few-shot learning setting. Besides, for the same question, GPT-4 would sometimes generate inconsistent answers or refuse to answer. To mitigate this, we ensemble the answers from 5 evaluations of each prompt by a voting strategy. This ensemble approach improves performance compared to single evaluations. Ultimately, we achieve an accuracy of 0.980 on the training subset.

	ft_mixtral_instruct
WP training set	0.21
SP training set	0.26

Table 4: Result of ft_mixtral_instruct

WP Training set (random 100 data samples)	Prompt 1 zero-shot	Prompt 2 zero-shot	Prompt 3 few-shot, with Ensemble
GPT-3.5	0.170	0.660	-
GPT-4	-	-	0.980

Table 5: Result on subtask 1: word puzzle. We use three kinds of prompt strategies on the training dataset for this subtask. We try GPT-3.5 to verify Prompt 1 and Prompt 2, and then use GPT-4 for Prompt 3. The latter strategy shows a much better performance.

SP Test Set	S_ori	S_sem	S_con	S_ori_sem	S_ori_sem_con	S_overall
	1.000	0.975	0.925	0.975	0.900	0.967
WP Test Set	W_ori	W_sem	W_con	W_ori_sem	W_ori_sem_con	W_overall
	0.969	0.938	1.000	0.938	0.938	0.969

Table 6: Final result on subtask 1 and subtask 2. We use three kinds of prompt strategies on the training dataset for the subtask. We try GPT-3.5 to verify Prompt 1 and Prompt 2, and then use GPT-4 for Prompt 3. The latter strategy shows a much better performance.

5 Conclusion

In conclusion, we demonstrate our prompt design method to enhance creative problem-solving in LLMs, enabling strong performance on brain teaser puzzles. Through prompting strategies and model fine-tuning, our methods attain 2nd and 3rd place rankings on this lateral thinking task. These results validate our techniques and highlight the potential for developing multifaceted reasoning skills in AI. Our work provides promising pathways toward more human-like language understanding and flexible thinking in natural language models. In summary, we take steps toward training AI systems capable of creative problem-solving.

Abstract

This paper presents our approach and findings for SemEval-2024 Task 5, focusing on legal argument reasoning. We explored the effectiveness of fine-tuning pre-trained BERT models and the innovative application of large language models (LLMs) through prompt engineering in the context of legal texts. Our methodology involved a combination of techniques to address the challenges posed by legal language processing, including handling long texts and optimizing natural language understanding (NLU) capabilities for the legal domain. Our contributions were validated by achieving a third-place ranking on the SemEval 2024 Task 5 Leaderboard. The results underscore the potential of LLMs and prompt engineering in enhancing legal reasoning tasks, offering insights into the evolving landscape of NLU technologies within the legal field.

1 Introduction

Legal texts, including laws, interpretations, arguments, and agreements, are commonly conveyed through writing, resulting in great amount of legal documents. Analyzing these documents, a core aspect of legal work, becomes more intricate as these collections expand. Natural language understanding (NLU) technologies offer potential assistance to legal professionals in this regard. However, their effectiveness hinges on the ability of current state-of-the-art models to adapt to diverse tasks within the legal field.

The legal argument reasoning task (Bongard et al., 2022) of SemEval-2024 represents a significant challenge in the domain of natural language processing (NLP) and an informal addition to the currently existing model evaluation benchmarks such as LexGLUE (Chalkidis et al., 2022b).

Our approach involves fine-tuning pre-trained BERT models and exploring the innovative use of large language models (LLMs) through prompt engineering to address this task.

As a result of our work, we are ranked 3-rd in the SemEval 2024 Task 5[1] Leaderboard out of 20 participating teams. The implementations of the different approaches is available on Github[2] and the fine-tuned models could be accessed in Huggingface[3].

2 Background

Task 5 of SemEval 2024 is novel NLP problem focused on legal argument reasoning within the context of U.S. civil procedure. It contributes a dataset comprised of instances each containing a general introduction to a case, a specific legal question, a proposed solution argument, and a detailed analysis explaining the applicability of the argument. This dataset aims to benchmark the performance of legal language models, posing a significant challenge due to the complexity and nuanced understanding required for legal reasoning. Instances are organized to support a binary classification task: determining the correctness of a given answer to a legal question, aimed at facilitating research on legal argument reasoning.

In the domain of text classification, conventional methodologies often employ "short encoders" such as BERT (Devlin et al., 2018), RoBERTa (Liu et al., 2019), and XLNet (Yang et al., 2019), which have demonstrated commendable efficacy in diverse contexts, ranging from news topic classification to sentiment analysis in movie reviews. Nevertheless, these encoders are constrained by their 512-token processing limit, rendering them less effective for analyzing extensive documents like court judgments. To circumvent this limitation, more advanced approaches, including the Hierarchical Attention Network (HAN) (Yang et al., 2016), a synergy of BERT and CNN, and the combination

[3] https://huggingface.co/frisibeli

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1652–1658

of XLNet with BiGRU (Chenxi et al., 2022), have been developed, enhancing the semantic understanding of longer texts. Despite these technological strides, the pursuit of an optimal algorithm that can adeptly navigate the complexities of extended documents persists.

The application of automated systems in the legal domain encounters distinct challenges, arising from the specialized language employed and the necessity for intricate multi-step reasoning over extensive texts. Furthermore, the potential of leveraging recent advancements in prompting techniques for legal domain-specific tasks remains largely unexplored. Typically, effective prompting in general NLP tasks has been noted with concise inputs, often limited to a single sentence or a small collection of sentences, accompanied by a restricted array of target labels. This underscores the ongoing quest to adapt and refine NLP techniques to meet the unique demands and intricacies of legal reasoning.

3 System Overview

After analyzing the dataset, we identified that the final system should be capable of handling relatively lengthy contexts and to perform well on reasoning and fact-checking tasks. In this section we separately introduce the different approaches we have experimented with on solving the Legal Argument Reasoning task by dividing them into methods for handling long texts and such for optimizing the NLU capabilities for the legal domain.

3.1 Handling Long Texts

Observing the distributions (Fig. 2) of the token lengths for the dataset entries we could say that a system capable of processing contexts of 2000 tokens would be sufficient to cover the majority of the cases.

3.1.1 Sliding Window (SW)

We leveraged the sliding window techniques as described in (Bongard et al., 2022), as a baseline to overcome the maximum token limit problem. We experimented with **Sliding Window Simple** and **Sliding Window Complex**

3.1.2 Transformer-based models for long text

Transformer-based models encounter difficulty processing lengthy sequences due to their self-attention operation, which exhibits quadratic scaling with sequence length. In response to this constraint, we experimented with the Longformer (Beltagy et al., 2020) model, featuring an attention mechanism that scales linearly with sequence length and increases the maximum input length to 4096 sub-word tokens, which may also improve the performance in understanding legal documents. Additionally, we experimented with Legal-RoBERTa and Legal-Longformer - pre-trained models on legal corpus introduced in (Chalkidis et al., 2023).

3.1.3 Summarizing

A different approach we tried for preprocessing lengthy texts was utilizing summarization models. By condensing extensive content into concise summaries, we not only mitigate the challenges posed by the length limitations of Transformer-based architectures but also streamline subsequent processing stages by reducing the presence of extraneous or tangential content, such as author's thoughts and remarks (Fig. 3).

As part of our solution, we examined several summarization models - BART (Lewis et al., 2019), LexRank (Erkan and Radev, 2004) and ChatGPT4[4].

3.2 Optimising NLU Capabilities for the Legal Domain

Research has demonstrated the efficacy of language model pre-training in enhancing numerous natural language understanding tasks like natural language inference (Devlin et al., 2019). In addition to learning linguistic knowledge, these models are retaining relational knowledge (Petroni et al., 2019) present in the training data which could be beneficial in solving downstream tasks in domains such as the legal one and more precisely - US Civil Procedure where the legal system is based on precedents. In this section we are going to reflect on the methods used by us to improve the performance of the system by enhancing its reasoning capabilities.

3.2.1 Pre-trained Transformer Models on Legal Corpus

As a starting point in addressing the problem, we decided to use Legal-BERT (Chalkidis et al., 2020), being the most successful baseline experiment described in the work of the organizers of the task (Bongard et al., 2022). We fine-tuned it on the task and additionally - on a custom legal dataset 3.2.2. Our contribution continued with the exploration

[4] https://platform.openai.com/docs/models/gpt-4-and-gpt-4-turbo

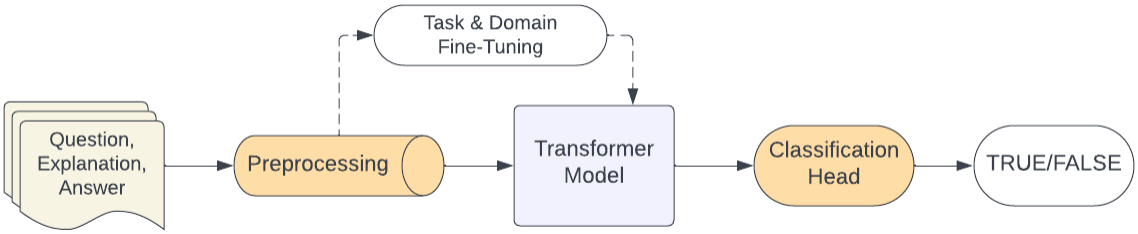

Figure 1: Transformer-based classifier system architecture

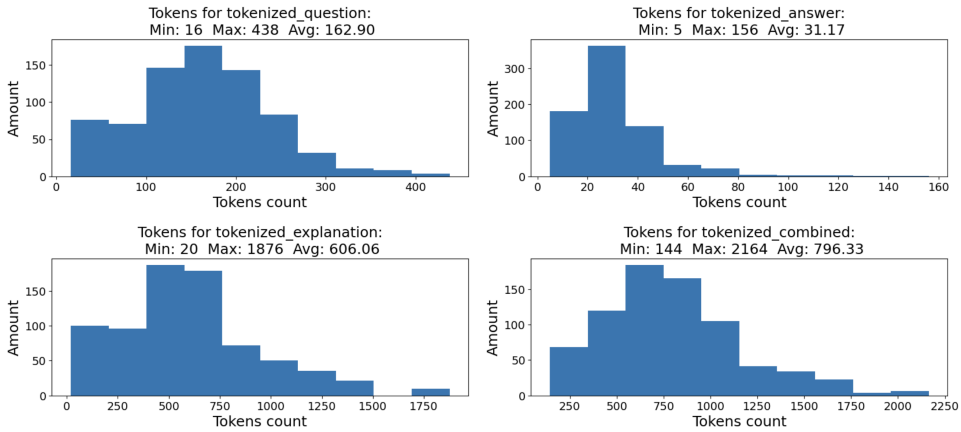

Figure 2: Token count distribution of the dataset per entry parts - Question, Explanation, Answer and Concatenated

of alternative legal transformer models: CaseHold-BERT (Zheng et al., 2021), variants of Legal-BERT (small, large), Legal-RoBERTa (Chalkidis et al., 2023) and InLegalBERT (Paul et al., 2023).

3.2.2 Fine-tuned BERT on Custom Dataset

We additionally fine-tuned the best performing models from 3.2.1 on a custom-tailored dataset of an American civil procedure data (4.3), similar to the entries from the task. The goal with this approach was to strengthen the model's relational knowledge and contextual representations of the language used in the legal domain (Petroni et al., 2019).

3.3 LLM + Legal Prompt Engineering

So far we observed the task as a supervised classification problem, where the models are trained with labeled data to classify inputs into a binary output. Another approach is to use the relatively new method of prompt engineering in combination with some of the currently best-performing generative models (Fig. 4). With prompting, there's generally no need for additional training as the model receives a prompt, which could be a question, examples of input-output pairs (few-shot learning), or task descriptions. This approach allows the model to leverage its pre-trained knowledge to produce outputs for specific tasks in a zero-shot manner, meaning it can generate correct responses without having seen examples of the specific task during its training phase. For this setup, we experimented with several types of LLMs: Mistral-7b-Instruct (Jiang et al., 2023), Llama2-70b (et al., 2023), GPT-3.5-Turbo and GPT-4 [5]; as for most of those models we performed prompt fine-tuning and Legal prompt engineering (Trautmann et al., 2022).

4 Experimental Setup

4.1 Data

For the transformer-based classifier systems (Fig. 1) we performed experiments on the SemEval 2024 Task (Bongard et al., 2022) dataset. We stratified the train partition (750 entries) into train* (88%) and train-dev (12%), ensuring that the distribution of label values was maintained. The dev partition (84 entries) and the test partition were solely utilized for validation to prevent overfitting and bias in the model.

[5] https://platform.openai.com/docs/models

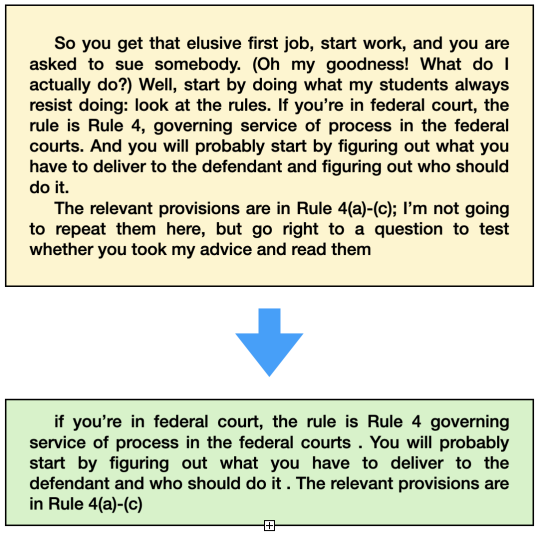

Figure 3: Preprocessing an Explanation from the dataset using T5 for summarization

On other hand, for the generative-based classifier systems (Fig. 4) we used only the dev and test partitions leveraging the generalization capabilities of the large models and inferring in a zero-shot manner.

4.2 Fine-Tuning & Hyperparameters

All experiments related to transformer-based classifier systems (Fig. 1) were conducted using a single A100 40GB GPU, with the following hyperparameters: 5 training epochs and a learning rate of $2e-5$. Additionally weight-decay and early-stopping (patience = 3) were applied.

For the generative-based systems different environments were used:

- Local setup (Apple M2) + OpenAI access for GPT-4, GPT-3.5-turbo
- Local setup (Apple M2) including Ollama[6] for running Mistral-7b and Llama2

We experimented with low temperature hyperparameter values, ranging $0-0.2$, in order to achieve more deterministic results.

4.3 Custom Legal Dataset

For MLM fine-tuning the transformer classifier, a new custom-tailored U.S. Civil Procedure dataset (Ref. 3.2.2) was used. It was collected first by automatically extracting the keywords from each unique explanation+question entry, then manually creating search queries and finally - using the open search API of the Caselaw Access Project[7] downloading relevant cases. The final corpora consists of 1985 different legal texts (cases), sourced by storing each 20 most relevant results for 100 queries.

4.4 Legal Prompt Engineering (LPE)

In (Trautmann et al., 2022), the authors define "Legal prompt engineering (LPE)" as the process of creating, evaluating, and recommending prompts for legal NLP tasks. In the current work as an alternative approach to the transformer-based classifier systems we investigate the performance of LPE on the SemEval 2024 Legal task. We used more than 15 prompts (A.1), as for their creation, we followed some of the 26 principles described in (Bsharat et al., 2024). Modification of a prompt version was done after evaluating how certain changes affect the performance.

The general frame of the prompt was in the form of a task or question, for which the model has to answer only with "TRUE" or "FALSE". An interesting observation is that GPT-3/4 and Llama2 almost always follow that restriction and return one of the two desired outputs with very few times returning something slightly different (e.g. different casing or appending punctuation - "false.", "True"). Contrarily, Mistral-7b-instruct always returns the answer with an additional explanation, which led to a more complex post-processing step for that model.

We used LangChain[8] for prompt template processing, model-agnostic interface unification and easy response post-processing.

5 Results

Table 1 shows the results of the different experiments. The evaluation of different models for the SemEval-2024 Task 5 on Legal Argument Reasoning presents interesting observation on how different models and system types, described in the current work perform on the dev and test dataset partitions. Our baseline approaches, Majority and Random, set the initial benchmarks with Macro-F1 scores significantly lower than those achieved by advanced models, underscoring the complexity of the task. The application of transformer models, including those equipped with a Sliding Window

Table 1: Model Performance on Development and Test Sets

technique and summarization capabilities, such as BART, showed improvement over the baselines, indicating the value of contextual understanding and content summarization in legal reasoning tasks.

Notably, the integration of Large Language Models (LLMs) with Legal Prompt Engineering (LPE) techniques, particularly with GPT-3.5-turbo and GPT-4, led to a significant leap in performance metrics. These models outperformed traditional transformer models, highlighting the effectiveness of LPE in enhancing the model's ability to interpret and reason over legal texts.

The comparative analysis of model performances on both development and test datasets revealed consistent patterns. Models utilizing LLMs with LPE not only achieved the highest Macro-F1 scores but also demonstrated robustness across different data sets, underscoring their potential for real-world applications in legal reasoning and argumentation.

6 Conclusion

Our participation in SemEval-2024's legal argument reasoning task has yielded valuable insights into the capabilities of transformer-based models and LLMs in processing and reasoning over legal texts. While our methods have shown promise, particularly in leveraging LLMs and prompt engineering, the complexity of legal reasoning poses ongoing challenges.

Further investigation can be done in a solution based on a hierarchical transformer variant such as HIER-BERT (Chalkidis et al., 2022b), (Chalkidis et al., 2019) (Chalkidis et al., 2022a). Our initial experiments with that model architecture did not lead to very high results (0.47 f1-macro on the dev partition) and because of the setup complexity, we decided to leave it for future research opportunities.

Abstract

Although Large Language Model (LLM) excels on generating headline on ROUGE evaluation, it still fails to reason number and generate news article headline with an accurate number. Attending SemEval-2024 Task 7 subtask 3, our team Challenges aims on using contrastive loss to increase the understanding of the number from their different expression, and knows to identify between different number and its respective expression. This system description paper uses T5 and BART as the baseline models, comparing its result with and without the constrative loss. The result shows that BART with contrastive loss have surpassed all the models, and its performance on the number accuracy has the highest performance among all.

1 Introduction

This paper is a description of the methods we have applied for our implementation on this year's SemEval Task 7, NumEval: Numeral-Aware Language Understanding and Generation. SemEval is an annual workshop which is consisted of various natural language processing shared tasks. Teams that join the tasks is required to design systems that could enhance the understanding or improve results on various kinds of semantic evaluation challenge. The task we decide to join was task 7, NumEval: Numeral-Aware Language Understanding and Generation (Huang et al., 2023). Specifically, we focus on the second subtask from the third task in NumEval, which centers on generating proper news headline based on the provided news articles. Different from article summary, a headline must condense the essence from the full length article. Although the encoder-decoder language models nowadays has excelled on generation of the text based on the ROUGE metric, it still fails on providing precise numeral generation in headlines owing to the fact that the representation of the number may differ in various kinds of forms. Therefore, the goal of this task is to enhance the accuracy of the model in the generation of the number from the headline of a news article.

While the numeral expression in the article consists of text and numbers, our system aims to use the technique of contrastive learning. With this technique, it is possible to help the model enclose the similarity between the number and its text expression, and enlarge the difference between different numbers (and its respective expression).

The evaluation of the performance is divided into two parts, one is to evaluate the accuracy of the predicted number, the other is to evaluate the accuracy of the word prediction, which uses ROUGE, BERTScore, and MoverScore to evaluate the results.

Two datasets are included in the task. One is the dry-run dataset that is provided on the official site. It contains a total of 100 instances; the other is the official training set that is provided after the registration of the task, which includes a total of 21157 instances. All of them have the same data structure. Each instance contains both the news article that includes the date of release, and its respective headline. Each team is expected to generate a precise news title from its respective news article.

Numbers are one of the most important element among medical, business, and legal article, and it could be dangerous if the large language model has misunderstood the content of the article. The finding of this paper could further discover a better way for large language model to detect and reason the numbers from the respective article, and thus generate the accurate headline with correct number.

Our system description is divided into three main section. First, we present the main approach that we used as the final submission result in detail, including the preparation of the dataset, its augmentation, and the structure of the model in contrastive learning that we designed in order to solve the task.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1659–1662

Hence, we talk about the adjustment of the model, including parameter optimization on the model. Finally, we present our experimental result. In the end, we discuss about the possible future work, and conclude with a brief summary of our system.

2 Related work

Large Language Model (LLM) like ChatGPT has been long commented with its brittleness on the ability of numerical reasoning. When the questions presented in the varying textual form (comprising words and numbers), LLM would result in inconsistent performance (Ahn et al., 2024). In (Huang et al., 2023)'s work, it shows that although large language model excelled based on ROUGE metrics, it still fails to generate precise numeral in headline.

Researchers have applied contrastive learning in natural language processing. To generate headline with different author style, (Liu et al., 2022) has applied contrastive learning to integrate the stylistic feature of the author into the model. This research hence inspires us to use contrastive learning on integrating the numeral features in different text form to the model, in order to let model identify the correct number from the news article.

3 Methodology

In this section, we propose the methodology of our system. It mainly consists of three parts. First, we will talk about the augmentation of the data. Secondly, the model training and fine-tuning, and finally, parameter optimization.

3.1 Data pre-processing and augmentation

A total of two vectors are used in our experiment. The first vector enhance the model understanding of different expression on number. One is to change all the text expression of number into numeral expression, and vice versa. While it encloses the similarity between the different expression of the same number, we call it positive distorted sample. With this change, model can better learn the different expression from the same number. We manually annotated the dataset to change the number into different kind of form. For example, if the number is *1000*, then it would be transferred into *1K*. The purpose of this is to increase the range of the understanding of the number in all forms.

The other vector, on the other hand, serves as the role that teaches the model to identify different numbers. It helps to enlarge the difference between the different numeric expressions, we call it negative distorted sample. Therefore, we also apply ChatGPT with the prompt[1] to change the number from every news article.

Positively Distorted
30K Walmart Part-Timers to Lose Health Insurance.
Thirty thousand Walmart part-timers to Lose Health Insurance
Negatively Distorted
Dax Shepard: Wedding to Kristen Bell Cost $142.
Dax Shepard: Wedding to Kristen Bell Cost eight hundred

Table 1: Examples of positively and negatively distorted headlines

3.2 Encoder

Transformer Seq2Seq Model (Vaswani et al., 2017) revolutionized the field of sequence-to-sequence learning. The implementation of the self-attention mechanism allowed weighting of the importance of different input tokens during the generation of each output token. The creation of multi-head attention enhanced the ability of the model to capture the diverse relationship between tokens. Based on transformer model advantages, the pre-trained BART-base model (Lewis et al., 2020) was selected as an encoder for headline representation creation. For the comparison, the T5 (Raffel et al., 2020) model was also utilized.

3.3 Models

In this section, we aim to delineate the types of models we trained and the portion of data utilized for training. The first model, referred to as **BART(sub)**, represents the outcomes of a model submitted for evaluation. In this model, the hyperparameters of the pre-trained BART model with Contrastive Learning (CL) were fine-tuned. Following the submission, our focus shifted towards improving and adjusting the Contrastive Learning approach. The subsequent model, named **BART with CL**, was trained using improved contrastive learning techniques. However, due to resource constraints, it was trained solely on **1000** instances of data.

3.4 Contrastive Loss

Our proposed Contrastive Learning enhanced model was implemented on End-to-End Seq2Seq

[1]You are the examiner. Examine the text. If the number in any form appears in the text, change the number into another number. Return the revised text only.

generation model. For the implementation of CL, positive and negative samples of headlines were explicitly constructed. Given news and headline, we trained End-to-End Seq2Seq models to generate headlines based on ground truth headlines. For the CL part, the model uses news, 2 positive and 2 negative headline samples. Given that our main task is specifically numerical aware headline generation, the sampling method was chosen to put more attention to numbers. That is why during the model training, the samples for the batch were exclusively formed from the 2 positive and 2 negative distortions of the same headline. This encourages the model to preserve the semantic content of the headline while allowing variations in numerical values. By explicitly focusing on numerical distortions in the loss function, the model learns to generate headlines that are robust to variations in numerical values. The loss function of the positive pair of examples (i, j) is defined as:

$$\mathrm{L}_s = -\lambda \log \frac{\exp(\tau^{-1} sim(z_i, z_j))}{\sum_s I(s \neq i) \exp(\tau^{-1} sim(z_i, z_j))})$$

where: $I(\cdot)$ is an indicator function such that $I(s \neq i) = 1$ and $I(s = i) = 0$, and τ is a temperature parameter and (s) is an index variable representing the current sample being considered during the training process.

This loss function penalizes the model if the distance between the news and positive headline embeddings is not closer than the distance between the news and negative headline embeddings by a certain margin. The final loss function for the numeric headline generation task will consist of a combination of model loss L_{model} and contrastive loss L_{CL} where the β is hyperparameter. Model Loss is the loss calculated from the model's forward pass using the ground truth labels.

$$Loss = L_{model} + \beta \times L_{CL}$$

3.5 Evaluation Metrics

For the evaluation of trained models, the automatic evaluation metric that the task organizer proposed was utilized. It consists of the ROUGE metric, incorporating ROUGE-1, ROUGE-2, and sentence-level ROUGE-L. For the BERTScore it incorporates BERT Precision, BERT Recall, and BERT F1. Also, the overall, copy and reasoning numerical accuracies were calculated.

3.6 Implementation and Hyperparameters

Due to resource constraints, all our models were trained only on **1000** instances of training data. For each model, we established the maximum length for both the article and the target headline, with values set at 512 and 16 respectively. In our trials, we adapt BART-large, T5-large and our newly introduced CL-augmented model. When tackling the headline generation task, we utilize beam search with a beam size of 8 and configure our batch size to 4. For the contrastive loss, the margin was set as 0.5, and β of 0.5 was selected. We apply the Adam optimizer with a learning rate of 5×10^{-6}. The models undergo training for 10 epochs, with the validation set used to assess performance. All experiments were conducted on the Kaggle T4 GPU.

4 Experimental Results

Table 1 shows the performance from different headline generation models evaluated by ROUGE score. BART model trained with contrastive loss has achieved 35.74, which is higher than other baseline models, showing its effectiveness on headline generation. Comparing BART with and without contrastive loss (CL), we observe a notable improvement in ROUGE scores when contrastive loss is incorporated during training. BART with CL achieves the highest ROUGE-1 at 40.91 and ROUGE-2 at 17.49 scores. Results indicate that contrastive loss regularization enhances the model's ability to generate headlines with higher lexical overlap and coverage.

Table 2 is the BERTScore for each headline generation model. Its BERT F1 score of 41.77 reflects strong semantic similarity to reference summaries, indicating robust performance across both lexical and semantic dimensions.

Model	Rouge-1	Rouge-2	Rouge-L
BART	38.48	15.18	33.35
T5 with CL	36.72	14.31	32.58
BART(sub)	31.22	12.23	26.86
BART with CL	**40.91**	**17.49**	**35.74**

Table 2: ROUGE scores of Headline Generation Models

Model	P	R	F1
BART	33.4	45.61	33.46
T5 with CL	35.50	39.90	37.72
BART(sub)	19.53	**47.56**	33.13
BART with CL	**36.91**	46.67	**41.77**

Table 3: BERT scores of Headline Generation Models

Model	Overall	Copy	Reasoning
BART with CL	72.956	82.170	56.176

Table 4: Numerical accuracy evaluation results

Additionally, BART with CL exhibits a BERT Precision of 36.91 and a BERT Recall of 46.67, further emphasizing its balanced performance in capturing semantic content accurately.

5 Conclusion

Resolving Task 7 at SemEval-2024 as team Challenges, we applied contrastive learning techniques on several models, in order to see which obtain the model with highest performance. In the final submission we obtained the highest number accuracy in the COPY category, up to 82.170, and got the second place in overall score, also up to 72.956. In our human evaluation process, our headline generation model achieved the third-highest level of numerical accuracy by reaching 1.70 score. It thus proves that our approaches can help train the model in numerical reasoning and numerical headline generation. However, this model is merely trained on the **small part of dataset**. Therefore, in future work, it is suggested that more instances might help all the conventions. If we enlarge the data size, it is possible that the performance may get higher. Augmenting positive and negative headline samples artificially may enhance the effectiveness of numeric-based headline generation. In our future work, we are planning to generate positive and negative samples for the whole dataset, and train models.

Abstract

The prevalence of fluent over-generation hallucinations, grammatically correct but nonsensical text, poses a significant challenge to the reliability of Natural Language Processing (NLP) systems. These fabricated constructs, arising from factors like overfitting or data sparsity, can mislead users and undermine system efficacy. The SemEval-2024 Task 6, SHROOM, addresses this concern by offering a comprehensive evaluation platform. For our own contribution to the task we make use of a logistic regression classifier and a feed-forward ANN in order to provide a computationally economical, yet reliable solution to the the Task at hand.

1 Introduction

Fluent over-generation hallucinations, grammatically correct yet factually incorrect or contextually irrelevant text outputs, remain a persistent obstacle in NLP systems, particularly large language models (LLMs). Moreover, the coherent aspect of the output means that hallucinations are harder to detect than other types of erroneous generation,as discussed in (Guerreiro et al., 2022), particularly in tasks like machine translation, especially considering most metrics for measuring performance only account for fluency rather than correctness (Guerreiro et al., 2022) . In order to ensure that tools like LLMs, which are becoming increasingly popular among the general population, provide the user base with information that is faithful and coherent in the context of various language tasks, research in identifying instances of hallucinations has become necessary. In this paper, we present our contribution for the SemEval 2024 task [1], SHROOM, where we work on solutions for detecting and categorizing hallucinations, using the data made available for different types of language generation tasks, stemming from a model-aware and a model-agnostic track. Additionally, taking into account the fact that earlier studies have adopted a LLM-based few or zero shot learning approach to the problem, we opt for a computationally economical approach instead, using a two-pronged model making use of logistic regression and a simple feed-forward network.

2 Task Description

SHROOM challenges participants to develop a model-agnostic or model-aware binary classification system capable of identifying fluent overgeneration hallucinations in diverse NLP tasks like definition modeling, machine translation, and paraphrase generation.

The data consists of 61,080 text outputs, of which 1,080 are manually annotated instances (the rest being unlabeled).

3 Background

SHROOM represents a pivotal benchmark for advancing NLP systems' ability to discern and categorize fluent over-generation hallucinations. Its focus on real-world applicability through the model-agnostic track and its diverse dataset empower researchers to assess the limitations and strengths of current techniques. Ultimately, SHROOM contributes to the broader mission of enhancing the trustworthiness and resilience of NLP systems, a crucial aspect for applications like machine translation, text summarization, and chatbot interactions.

The task requires participants to develop a binary classification system which successfully identifies hallucinations for different types of language generation tasks: definition modeling, machine translation and paraphrase generation. The data was generated from two different tracks, model-aware, meaning knowlegde of the model which produced

[1]Our code is available for replication purposes at https://github.com/cicl-iscl/SemEval2024$_T$6$_S$$HROOMS$

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1663–1666

the output is accessible, and model-agnostic, where the model which generated the ouput is unknown. The generated outputs are provided in JSON format, containing source text, generated text and golden standard prompt, aswell the model name when applicable. 61080 datapoints are obtained in this way, from which 1080 are annotated (Mickus et al., 2024). A baseline was made available, using a zero-shot model with calls to LLAMA (Mickus et al., 2024).

4 Our System Strategy

Considering the likely instances where a system to detect hallucinations would find practical use and how current approaches to hallucination detection work (Friel and Sanyal, 2023), we decided that we wanted to make reduced inference time a goal of our system. Our primary strategy for detecting hallucinations involves a two-pronged approach utilizing either logistic regression or a small feed-forward neural networks trained on a labeled dataset as classification model. This leverages the strengths of each model for efficient and accurate hallucination detection. As input to our classification model we use sentence embeddings generated by SBERT (Reimers and Gurevych, 2019).

Using a logistic regression model as a baseline helps us to quantify the advantages of using a neural network as a classification model instead of simpler approaches.

4.0.1 SBERT

In order to enrich our understanding of the text and capture deeper semantic relationships beyond surface-level similarities, we incorporate Sentence-BERT (SBERT) embeddings into our system. SBERT generates high-dimensional vector representations of text, encoding semantic meaning and context.

We obtain reliable vector representations of our data utilizing a pre-trained SBERT model (e.g., all-mpnet-base-v2, all-MiniLM-L6-v2), we generate vector representations for each the source, target and hypothesis fields of our inputs. These vectors can be envisioned as high-dimensional fingerprints capturing the semantic essence of each sentence and its relationship to others. These SBERT-derived features are integrated with features such as task and model. This enriched feature set provides a comprehensive representation of the text, capturing deeper semantic information.

SBERT enables us to transcend basic word-level comparisons, allowing us to capture meaning and context within text more comprehensively. SBERT takes into account the context surrounding each sentence during analysis, which aids in identifying variations from the intended meaning and inconsistencies within the text. We anticipate that combining traditional features with those derived from SBERT will enhance the accuracy and generalizability of hallucination detection.

Additionally, using SBERT fits into our lightweight approach to the task, by offering a fast tool for inference, being more lightweight than newer state-of-the-art models.

4.0.2 Logistic Regression

For the initial layer of analysis, we employ logistic regression as a robust baseline model. Its interpretability allows us to gain insights into the key features distinguishing genuine and hallucinated text. We use SBERT to encode a prompt that incorporates Source, Target and Hypothesis. This provides the logistic regression model with single vector as input. The logistic regression model is then trained on these features to learn the underlying patterns that differentiate hallucinated and non-hallucinated text. This simple method provided us with a simple baseline.

4.0.3 Artificial Neural Network

The classification network is a simple multilayer feed-forward network. Its input are three sentence embeddings generated by SBERT from the Source, Target and Hypothesis fields of the input, as well as other features that the input provides. The usage of a neural network allows us to capture non-linear relationships and hidden patterns within the data that might be missed by the logistic regression model. The ANN architecture is designed with multiple hidden layers and non-linear activation functions, enabling it to learn intricate feature interactions and representations.

4.1 Key Discoveries and Challenges

The task presented us with two small datasets containing labeled instances and a bigger dataset without labels. Our main challenge therefore was to make the best use of a very limited dataset or find ways to leverage the not annotated data.

In regards to the following step in our approach, namely feature extraction, while many of the instances contained in the dataset seem to require

deep semantic analysis of the input data, much simpler features of the input can also be useful to identify hallucinations: word repetitions, n-gram counts, output length, unexpected characters, etc. (Huang et al., 2023)

Pertaining to supervised learning, while the approach proved itself to be useful, it also revealed its limitations. The reliance on pre-labeled data can restrict the generalizability of the model to new domains or tasks. Additionally, the quality of the pre-labeled data can impact the model's performance.

One of the main challenges we encountered was the lack of labeled data. Classifying hallucinations in unlabeled data remains a challenging task. The absence of explicit labels hinders the model's ability to definitively determine whether an instance is a hallucination. This problem highlights the need for more sophisticated methods for dealing with unlabeled data. However, the inclusion of the pre-labeled data which was made available for training our hallucination detection model proved to be an effective strategy. The model was able to generalize well to unseen data and achieve significant accuracy in identifying hallucinations, indicating that access to annotated datasets documenting cases of over generation will of course improve classification.

Our exploration of the dataset revealed that over-generation, the production of excessive or irrelevant text, is a significant aspect of hallucinations. The ability to distinguish between fluent over-generation and genuine hallucinations poses an additional challenge for our system, and is an aspect which would need to be further explored.

5 Key Algorithms and Modeling Decisions in Our SHROOM System

Our hallucination detection system employs a hybrid approach that combines both a pretrained LLM and a small classification model. The system's core components include:

1. Pre-trained Language Model (LM): We utilize a pre-trained BERT (Bidirectional Encoder Representations from Transformers) model to extract linguistic features from the text outputs ((Reimers and Gurevych, 2020)). BERT's ability to capture contextual information and semantic relationships is crucial for understanding the nuances of language and identifying deviations from the intended meaning. We use SBert for its ability to provide meaningful sentence embeddings and while being faster and less resource intensive than the newest LLMs openly available. This would make running our model in practical applications more realistic.

2. Classification Model: The sentence embeddings produced by the BERT-Model are given to 1) a logistic regression model or 2) a small feed-forward network producing a label probability.

3. Supervised Learning from Hallucination Annotations: The feed-forward network is trained using the labeled data provided in the SHROOM dataset. The model learns to classify text outputs as either containing hallucinations or being truthful to the Source.

6 Results

We achieved an accuracy of 0.57 on the model-aware track, and an accuracy of 0.63 on the model-agnostic track, placing us at respectively rank 32 and rank 27 on the competition leaderboard. Additionally, we scored 0.24 for accuracy for the model-agnostic track.

7 Experimental Setup

Because of our approach based on supervised learning we used the development dataset provided by the task organizers as training dataset, using cross validation to gain insights into our systems' performance before the actual test dataset was available.

We used PyTorch: 1.10.2 [2] in order to build our neural network. Transformers 4.12.2 [3], more specifically SBERT [4], was used in order to extract the sentence embeddings. Finally, in order to organize and process the data, we also made use of NumPy (1.22.3) [5] and Pandas (1.4.2)[6]. In order to run our code in an efficient manner, we used Colab[7].

8 Conclusion

By using a simple model exploiting feature extraction to aid in identifying hallucinations in a dataset containing data from different tasks, we

[2]https://pytorch.org/
[3]https://github.com/huggingface/transformers/
[4]https://www.sbert.net/
[5]https://numpy.org/
[6]https://pandas.pydata.org/
[7]https://colab.research.google.com/

have achieved an accuracy of 0.628. This could potentially indicate that for this type of task, it might be worthwhile to take into consideration approaches which do not exclusively rely on zero-shot classification, but instead make use of less computationally costly techniques. We have shown that such methods are not only efficient, but also present the advantage of being easily reproducible with fewer resources.

9 Going Forward

While our system is, at its current state, not usable in production systems, it shows that computationally less expensive methods can still lead to working systems in a task as complex as hallucination detection. Our implementation still leaves room for improvement and some unexplored possibilities: Our system does not leverage the unlabeled training data provided with the task. Using an encoder-decoder architecture to pretrain an encoder layer for the classification model might improve its training results on the small labeled data set. SBERT embeddings can be used to detect meaning similarities of texts, adding combinations of different embeddings (Source+Hypothesis, Target+Hypothesis, ...) may provide useful features to the classification layer. Our aim for a lightweight and fast system also makes manual approaches of hallucination detection as described in (Bruno et al., 2023) attractive.

Abstract

This paper describes AIpom, a system designed to detect a boundary between human-written and machine-generated text (SemEval-2024 Task 8, Subtask C: Human-Machine Mixed Text Detection). We propose a two-stage pipeline combining predictions from an instruction-tuned decoder-only model and encoder-only sequence taggers. AIpom is ranked second on the leaderboard while achieving a Mean Absolute Error of 15.94. Ablation studies confirm the benefits of pipelining encoder and decoder models, particularly in terms of improved performance.

1 Introduction

SemEval-2024 Task 8 (Wang et al., 2024a) focuses on multigenerator, multidomain, and multilingual machine-generated text detection based on the M4 corpus (Wang et al., 2024b). The shared task offers three subtasks, which correspond to standard task formulations in the rapidly developing field of artificial text detection (Jawahar et al., 2020; Uchendu, 2023): (A) classifying if a given text in a particular language is human-written or machine-generated, (B) attributing the author of a given text, and (C) detecting a boundary between human-written and machine-generated text. Developing generalizable solutions to these problems helps mitigate the risks of misusing generative language models (LMs) for malicious purposes (Weidinger et al., 2022) and improve human performance in identifying AI-produced content (Gehrmann et al., 2019).

This paper proposes AIpom[1], a novel method for human-machine mixed text detection (Subtask C). The boundary detection setup aligns with common user scenarios for applying generative LMs in practice, e.g., text continuation, creative writing, and story generation. The standard approach to this task is training a linear classifier or a regression model over encoder representations (Cutler et al., 2021; Dugan et al., 2023). In contrast, AIpom leverages a pipeline of decoder and encoder models to detect machine-generated text, utilizing them sequentially. AIpom takes second out of 33 participating teams on the Subtask C leaderboard by achieving a Mean Absolute Error (MAE) of 15.94 on the official evaluation set. After the official evaluation phase, we develop a better-performing solution with an MAE score of 15.21.

Our ablation studies confirm that using decoder or encoder models individually leads to lower performance. Thus, employing the pipeline of decoder and encoder models proves to be an effective solution. Additionally, these studies highlight domain shift issues, as there is a significant score disparity between the development and official evaluation sets. Future efforts should focus on enhancing the AIpom robustness with respect to the text domain and text generator. The codebase and models are publicly released[2].

2 Background

The M4 corpus consists of human-written and machine-generated texts in six languages (English, Chinese, Russian, Urdu, Indonesian, and Arabic) across various domains, ranging from Wikipedia to academic peer reviews. The generative LMs include the OpenAI models (ChatGPT and text-davinci-003), LLaMA-1 (Touvron et al., 2023), FLAN-T5 (Chung et al., 2022), Cohere, Dolly-v2[3], and BLOOMZ (Muennighoff et al., 2022). The organizers provide 3649, 505, and 11123 dataset instances in Subtask C training, development, and official evaluation sets, respectively.

[1]AIpom is named after a simian pokémon *aipom*, and stands for detecting **AI**-**p**roduced **o**utputs in **M**4.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1667–1672

Task Formulation Human-machine mixed text detection requires predicting the index corresponding to the first machine-generated word, as shown below:

- `text:` "👨‍💼We have added a 2+ page 🤖discussion on the experimental results, highlighting the superiority of the ARC-based models and their impact on the field of deep learning."
- `label: 6`

Performance Metric MAE measures the absolute distance between the predicted word and the word where the human-machine transition occurs.

3 AIpom

First, we overview the AIpom pipeline. Next, we detail the fine-tuning procedures for encoder and decoder models.

Overview The AIpom pipeline (see Figure 1) consists of multiple consecutive steps of fine-tuning language models:

(a) The decoder is fine-tuned on the training set to predict the change point from a human-written text to a machine-generated text.
(b) The decoder makes predictions and outputs the source texts with predicted change points.
(c) The first encoder model is fine-tuned on the texts with predicted change points from step (b).
(d) The second encoder model is fine-tuned on the mixture of texts from the training set and the texts with predicted change points from step (b).
(e) Two encoders are used to predict the indices of change points in test texts.
(f) The predicted change points from step (e) are aggregated by averaging.

Decoder The decoder is fine-tuned as follows: the input comprises the prompt and the training text. We experimented with various prompts, including instructing the model to output only the human-written text, the text with an inserted symbol representing the change point, and the machine-generated text alone. Our preliminary experiments suggest that instructing the decoder to output only the machine-generated text yields better results. Therefore, we use this option in subsequent experiments. Table 1 describes the prompt, and Figure 2 illustrates fine-tuning the decoder. The decoder is used in the first step of the AIpom pipeline: we utilize it to generate initial predictions, which are then further processed by two encoders.

```
As an output, write only the machine-generated part of the provided text. Output must start with "Answer: ". Separate tokens by " ". If the whole text is human-written, output "None". Here is the text: example["text"]
```

Table 1: The prompt used for fine-tuning the decoder.

After receiving the predicted text from the decoder, we post-process the original training text and insert a special token <BREAK> directly before the first machine-generated word predicted by the decoder. This allows us to pass the prediction further to the encoder.

Encoder The encoder is fine-tuned to label input texts on a token-wise way. Each token in the human-written segment is labeled with a zero, while each machine-generated token is labeled with one. In our final prediction, we determine the position of the word in which the first "1" label appears, indicating machine-generated text. See Figure 3 for illustration.

The AIpom pipeline involves fine-tuning two encoders. The first encoder is trained on a dataset consisting of texts labeled by the decoder. In contrast, the second encoder is fine-tuned using a dataset that includes both the decoder's predictions and the original source texts from the training set. we receive the predicted change point from each encoder, which we aggregate by averaging.

4 Experiments

Overview We design a series of experiments using two recent language models, a decoder *Mistral-7B-OpenOrca*[4] (Jiang et al., 2023) and an encoder *DeBERTaV3-Large*[5] (He et al., 2023), selected based on their performance on standard NLP benchmarks and computational requirements.

First, we establish a baseline for the decoder model by zero-shot prompting and then compare it to Low-Rank Adaptation (LoRA) tuning (Hu et al., 2021), which yields significantly better results. Second, we look into improving the performance of the

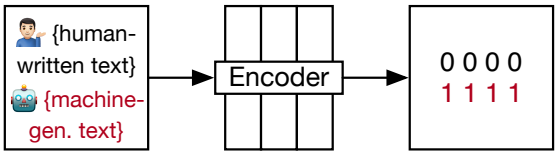

Figure 3: We fine-tune the encoder for token labeling. Human-written tokens are assigned zeros, while machine-generated tokens are assigned ones.

encoder model. We experiment with hyperparameter selection and feeding the encoder model with texts labeled by the decoder model. The combination of the decoder and encoder model outperforms each pipeline component individually.

We only use the development set to evaluate our pipeline and choose our final submission based on the MAE on the development set. In §5, we report the ablation studies results on both development and official test sets[6].

Decoder fine-tuning and inference To fine-tune the Mistral model, we employ LoRA layers tuning with the `SFTTrainer` class from the transformers library (Wolf et al., 2020). The model is fine-tuned on to output machine-generated texts, that is the loss functions are computed only on the model-generated parts. We experimented with learning rates in the range $[1e\text{-}5, 5e\text{-}5]$ with an increment of `1e-5`, and `warmup_ratio` $\in \{0.01, 0.03, 0.05\}$. Based on the results observed on the development set, we select a learning rate of `2e-5`, combined with a `warmup_ratio=0.03` and the `CosineLRScheduler`. For the Parameter-Efficient Fine-Tuning (PEFT) configuration, we adhere to the recommended parameters for Mistral: `rank=32`, `lora_alpha=64`, and `lora_dropout=0.05`. The batch size is set to 4 and the model is fine-tuned for 4 epochs.

We fine-tune the model to start its response with the `"Answer: "` template. This helps improve performance at the inference stage by providing easier-to-clean-up predictions, ensuring they always start the same way. We use the vLLM framework[7] (Kwon et al., 2023) for text generation, with default hyperparameters, the sampling temperature of 1, and `top_p` of 1.

Data labeling with decoder To prepare the training set for the encoder, we split the training set into two folds and perform LoRA tuning on two Mistral models with the same hyperparameters on each fold. Then, each fold is labeled using the decoder fine-tuned on the other fold. This helps us track the decoder's performance and reduce overfitting. During testing, we fine-tune another Mistral model on the entire training set and assess its per-

7.	DeBERTa	Training set + pred. from Mistral		1.91	16.49

Table 2: MAE scores on the development and official test sets for different setups and ablation experiments. Setup details include the model used, fine-tuning setup, and presence of <BREAK> in the input data at the inference stage. The top table shows each language model's performance in the AIpom pipeline. The bottom part shows ablation experiments.

formance on the development set. It is worth noting that we apply the post-processing step described in §3, specifically in the "Decoder" paragraph, to the predicted text before passing it to the encoder.

Encoder fine-tuning We build upon the baseline code provided by the task organizers[8], enhancing it to effectively fine-tuning the DeBERTa model. We explore a range of learning rates [1e-5, 5e-5] with an increment of 1e-5 to identify the optimal value for fine-tuning our model. Our final fine-tuning strategy utilizes the Adam optimizer (Kingma and Ba, 2015), with a learning rate of 3e-5 and the default CosineLRScheduler. To ensure consistency across all experiments, we use a maximum sequence length of 1024 for text tokenization, maintain a constant batch size of 64, and limit the maximum number of epochs to 6. To reduce overfitting, we freeze a certain number of bottom DeBERTa layers. Specifically, we experiment with fine-tuning only the top $N \in \{6, 12, 18\}$ layers out of the total 24. Through experiments, we determine that fine-tuning only the top 12 layers produces the best results.

Hardware specification We run experiments on a single GPU TESLA A100 80 GB. Model fine-tuning is conducted using the transformers library. The fine-tuning for DeBERTa requires approximately 3.5 hours to complete, while the inference on the official test set runs within 15 minutes. The LoRA tuning for Mistral lasts approximately 12 hours, with the inference on the official test set taking a few hours. To speed up the prediction phase, we employ the vLLM framework, designed specifically for optimizing the inference. This implementation significantly reduces inference time, with the official test set predictions generated in just 30 minutes.

5 Results

Table 2 provides a detailed comparison of the performance metrics across different models and experimental setups. The key results are:

- Fine-tuning Mistral with LoRA tuning (setup 1) on the training set outperforms zero-shot prompting (setup 5) by a wide margin.
- Fine-tuning DeBERTa using the Mistral predictions (setup 2) leads to higher results than fine-tuning DeBERTa on the training set (setup 6).
- Adding a <BREAK> token to the input at the inference stage improves the performance of the DeBERTa model (setup 3 vs. setup 7).
- Averaging predictions of two DeBERTa models (setup 4) leads to the best results on the development set.

The overall best results on the official test set are achieved with setup 3, where the DeBERTa model is fine-tuned on a dataset consisting of both the training set and predictions from the Mistral model, and the <BREAK> token is added to the input at the inference stage.[9]

Decoder vs. encoder Fine-tuned encoder models exhibit inferior performance compared to LoRA-tuned decoder. Specifically, the decoder struggles to comprehend the task in a zero-shot setting, evidenced by a high MAE of 80.81 on the official test set. However, with LoRA tuning, the decoder achieves a significantly lower MAE of 17.00, outperforming the single encoder model's MAE of

[8] github.com/mbzuai-nlp/SemEval2024-task8

[9] These results are achieved after the shared task submission deadline and hence not submitted for the official evaluation stage.

19.97. The encoder models are adaptable and integrate diverse inputs, including prompts and predictions from additional decoder models.

Benefits of pipelining We hypothesize that encoder models benefit from integrating inputs from a decoder. Our pipeline yields the final MAE of 15.94 while fine-tuning only the single encoder model results in a higher MAE score of 19.97.

Robustness While averaging predictions helps improve the overall performance, we find that the AIPom's robustness has room for improvement. In particular, we observe the performance decrease when comparing the results on the development and official test sets. Setup 3, with an MAE of 1.74 on the development set, performs better than an MAE of 15.21 on the official test set. At the same time, Setup 4 (our final submission) achieves a slightly better development MAE but a worse MAE on the official test set. Setup 3 involves finetuning on a mixture of data, showing how using more data can boost the performance and improve the robustness, especially when the dataset is small. We leave improving the out-of-domain robustness for future work.

6 Conclusion

This paper presents the AIpom system submitted to SemEval-2024 Task 8. Our solution achieves 2nd place out of 33 participating teams in Subtask C. We introduce a novel method that utilizes a pipeline of decoder and encoder models. The advantage of this approach is that the models are exposed to both the original data and the predictions from previous steps. We believe this approach holds significant potential, as it allows for creating pipelines comprising various models, mimicking the transfer of learned knowledge. We plan to further improve our system by exploring different combinations of models and longer pipelines. Additionally, we aim to enhance the system's robustness to handle domain-shift scenarios.

Abstract

This paper presents the methodology used for our participation in SemEval 2024 Task 2 (Jullien et al., 2024) – *Safe Biomedical Natural Language Inference for Clinical Trials*. The task involved Natural Language Inference (NLI) on clinical trial data, where statements were provided regarding information within Clinical Trial Reports (CTRs). These statements could pertain to a single CTR or compare two CTRs, requiring the identification of the inference relation (entailment vs contradiction) between CTR-statement pairs. Evaluation was based on F1, Faithfulness, and Consistency metrics, with priority given to the latter two by the organizers. Our approach aims to maximize Faithfulness and Consistency, guided by intuitive definitions provided by the organizers, without detailed metric calculations. Experimentally, our approach yielded models achieving maximal Faithfulness (top rank) and average Consistency (mid rank) at the expense of F1 (low rank). Future work will focus on refining our approach to achieve a balance among all three metrics.

1 Introduction

Clinical trials serve as the cornerstone for evaluating the efficacy and safety of novel medical interventions, playing a pivotal role in advancing healthcare practices (Avis et al., 2006). Clinical Trial Reports (CTRs) encapsulate crucial information regarding trial methodologies and outcomes, serving as indispensable resources for healthcare professionals in treatment decision-making (Bastian et al., 2010). However, the sheer volume of available CTRs, coupled with their rapid proliferation, poses significant challenges for comprehensive literature review and evidence synthesis in clinical practice (DeYoung et al., 2020). Natural Language Inference (NLI) emerges as a promising approach to address this issue (Bowman et al., 2015; Devlin et al., 2018; Raffel et al., 2020), facilitating the scalable interpretation and retrieval of medical evidence (Davari et al., 2020; Sutton et al., 2020; Davari et al., 2019). The SemEval 2024 Task 2 (Jullien et al., 2024) on *Safe Biomedical NLI for Clinical Trials* extends this paradigm to enable automated inference of relationships between statements and CTRs, thus streamlining evidence extraction and enhancing decision-making processes in healthcare.

The 2024 task is a continuation of the one introduced by Jullien et al. (2023b,a), specifically it focuses on Track 1, which focuses on NLI in the context of clinical trials. In this task, the input consists of pairs of Clinical Trial Reports (CTRs) and corresponding statements, where the statements make claims about the information contained within the CTRs. The objective is to determine the inference relation between each CTR-statement pair, classifying them as either entailing or contradicting each other. For instance, given a statement "Drug X is effective in treating condition Y" and a CTR outlining a clinical trial testing Drug X's efficacy, the task is to determine whether the statement is entailed by the CTR or contradicted by it. The datasets used are similar to those introduced by Jullien et al. (2023b), and further details can be found in there work.

Our system primarily focuses on maximizing Faithfulness and Consistency in the context of SemEval 2024 Task 2 (Jullien et al., 2024). To achieve this goal, we adopt a strategy centered around introducing controlled input noise during model training. This approach is based on the hypothesis that a certain level of tolerance towards input perturbations could enhance the faithfulness and consistency of the generated models. Specifically, we experiment with randomly masking a percentage ($k\%$) of tokens in both Clinical Trial Reports (CTRs) and the corresponding statements, thereby exposing the model to varying degrees of input uncertainty.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1673–1677

Through these experiments, we aim to optimize model performance in capturing the relationships between statements and CTRs, ultimately improving the system's effectiveness in clinical trial inference tasks.

Through our participation in SemEval 2024 Task 2 (Jullien et al., 2024), we observed a notable trade-off between different evaluation metrics. While our approach successfully improved Faithfulness and Consistency metrics, it came at the expense of F1 scores. This finding underscores the challenge of balancing these evaluation criteria and thus the need for future refinement to achieve a more harmonious optimization across all relevant metrics. Specifically, our models achieved top-ranking levels of Faithfulness but demonstrated only average performance in Consistency metrics, resulting in lower ranks in F1 assessment. See Sec. 4 for details.

2 System Overview

In our system, we leverage BART (Lewis et al., 2019) as the primary model for all experiments due to its robustness and effectiveness in various natural language processing tasks, particularly in Natural Language Inference (NLI) (Lewis et al., 2019; Barker et al., 2021; Farahnak et al., 2020). To streamline the fine-tuning process and enhance efficiency, we adopt the LoRA technique proposed by Hu et al. (2021), which significantly reduces the fine-tuning time without sacrificing performance. Additionally, we incorporate the Contrastive Tension loss function introduced by Carlsson et al. (2020). to guide the fine-tuning process. This loss function promotes contrastive learning by separately encoding the Clinical Trial Reports (CTRs) and their associated statements using two copies of BART (Lewis et al., 2019) during each training instance. By allowing only one copy to update its parameters at a time, the model is encouraged to focus on learning the essential semantic relationships between the CTRs and the statements.

Moreover, we introduce a novel approach to enhance the robustness of the model by incorporating random token masking during each training instance. Specifically, we randomly mask a percentage ($k\%$) of tokens in both the CTRs and their associated statements. This introduces noise in the input data, forcing the model to adapt to varying degrees of input uncertainty and preventing it from relying solely on superficial patterns. The rationale behind this approach is to encourage the model to concentrate on the fundamental semantic content of the input rather than exploiting surface-level correlations.

Balancing between the three required metrics—Faithfulness, Consistency, and F1—proved to be the primary challenge in our experimental setup. While optimizing for one metric often led to improvements in its performance, it frequently came at the expense of others. We explored different strategies to strike a balance between these metrics. However, finding an optimal solution that simultaneously maximized all three metrics remained unsolved. Our system struggled to maintain high levels of F1 score while simultaneously improving Faithfulness and Consistency metrics. Further exploration of optimization strategies and leveraging ensemble methods may offer potential avenues for achieving a better balance between the metrics.

3 Experimental setup

Training Details The training, validation, and test data for our experiments were all provided by the organizers of the SemEval 2024 Task 2, as outlined by Jullien et al. (2024). We trained our model for a total of 40 epochs, employing the Adam optimizer (Kingma and Ba, 2014) with a learning rate of 0.0001, with a batch size of 32. To stabilize and accelerate training, we implemented gradient clipping (Zhang et al., 2019) with a maximum norm of 1.

Additionally, we incorporated a linear warmup stage consisting of 40 gradient steps followed by a Cosine Annealing learning rate schedule (Loshchilov and Hutter, 2016). This strategy enabled gradual adjustment of the learning rate during the initial phase of training, allowing the model to converge more smoothly towards an optimal solution.

Furthermore, we limited the maximum sequence length to 256 tokens for both CTRs and their corresponding statements, aligning with the model architecture and computational capabilities. Consequently, each sequence pair was truncated to a total maximum of 512 tokens. This limitation on sequence length helped in handling memory constraints and optimizing the processing of input sequences during training. Exploring larger context sizes could be advantageous for future improvements in the task.

Evaluation Metrics Our system's performance is measured through three key metrics: (1) Faithfulness, (2) Consistency, and (3) F1 score.

Faithfulness: Faithfulness measures the degree to which a given system arrives at the correct prediction for the correct reason. Intuitively, this is estimated by assessing the model's ability to correctly change its predictions when subjected to a semantic altering intervention. Let N denote the number of statements x_i in the contrast set (C), y_i represent their respective original statements, and $f()$ denote the model predictions. Faithfulness is computed using Equation below:

$$\text{Faithfulness} = \frac{1}{N}\sum_{1}^{N} |f(y_i) - f(x_i)| \quad (1)$$

where $x_i \in C$, $\text{Label}(x_i) \neq \text{Label}(y_i)$, and $f(y_i) = \text{Label}(y_i)$.

Consistency: Consistency aims to measure the extent to which a given system produces the same outputs for semantically equivalent problems. It assesses the system's ability to predict the same label for original statements and contrast statements for semantic preserving interventions. Even if the final prediction is incorrect, the representation of the semantic phenomena should be consistent across the statements. Let N denote the number of statements x_i in the contrast set (C), y_i represent their respective original statements, and $f()$ denote the model predictions. Consistency is computed using Equation below:

$$\text{Consistency} = \frac{1}{N}\sum_{1}^{N} 1 - |f(y_i) - f(x_i)| \quad (2)$$

where $x_i \in C$, $\text{Label}(x_i) = \text{Label}(y_i)$.

F1: The F1 score is a commonly used metric in NLP tasks (Yang et al., 2023; Davari, 2020), measuring the balance between precision and recall of a model's predictions. It is calculated based on the geometric mean of precision and recall, where precision represents the ratio of true positive predictions to the total number of predicted positive instances, and recall represents the ratio of true positive predictions to the total number of actual positive instances.

4 Results

Our experimental results demonstrate a clear trade-off between the level of token masking (k) and the performance metrics of F1, Faithfulness, and Consistency. As we increase the masking level, we observe a consistent trend of decreasing F1 scores alongside increasing Faithfulness and Consistency metrics.

For $k = 0$, representing no token masking, we observe an F1 score of 0.65 (ranking 22 out of 32), a Faithfulness score of 0.51 (ranking 21 out of 28), and a Consistency score of 0.54 (ranking 25 out of 30). As we progressively increase k, we observe a gradual change in the metrics, specifically decrease in F1, and increase of the other 2 metrics. At $k = 30\%$, the highest masking level tested, we observe a significant drop in F1 score to 0.06 (ranking 28 out of 31), accompanied by substantial increases in Faithfulness (0.95, ranking 1 out of 28) and Consistency (0.6, ranking 22 out of 32) metrics.

Given the substantial decrease in F1 scores beyond a masking level of $k = 30\%$, we did not explore higher masking levels. This decision was made due to the observed trade-off, where increasing token masking beyond a certain threshold led to disproportionately low F1 scores, potentially indicating a loss of model generalization and predictive performance.

5 Conclusion

Our experiments underscore the intricate balance between token masking levels and performance metrics in biomedical NLI for clinical trials. We observed a discernible trade-off: while increasing token masking improves Faithfulness and Consistency, it results in diminished F1 scores. This finding highlights the necessity of exploring future approaches that could better optimize the model with multiple evaluation criteria as their objective function. Additionally, another potential avenue for improvement would involve examining alternative metrics to provide further insights into the behaviour of the model (Davari et al., 2022a; Farahnak et al., 2021; Steck et al., 2024; Davari et al., 2022b). Based on our findings, one avenue of research involves refining token masking strategies to achieve a more optimal balance between F1, Faithfulness, and Consistency metrics. Furthermore, exploring ensemble methods and alternative fine-tuning strategies could provide valuable insights into enhancing the overall performance of the model.

MALTO at SemEval-2024 Task 6: Leveraging Synthetic Data for LLM Hallucination Detection

Federico Borra* **Claudio Savelli*** **Giacomo Rosso**

Alkis Koudounas **Flavio Giobergia**

Politecnico di Torino, Italy

Abstract

In Natural Language Generation (NLG), contemporary Large Language Models (LLMs) face several challenges, such as generating fluent yet inaccurate outputs and relying on fluency-centric metrics. This often leads to neural networks exhibiting "hallucinations". The SHROOM challenge focuses on automatically identifying these hallucinations in the generated text. To tackle these issues, we introduce two key components, a data augmentation pipeline incorporating LLM-assisted pseudo-labelling and sentence rephrasing, and a voting ensemble from three models pre-trained on Natural Language Inference (NLI) tasks and fine-tuned on diverse datasets.

1 Introduction

Natural Language Generation (NLG) models are AI systems that use neural networks to produce human-like text. They have shown significant advancements in recent years, particularly with the advent of transformer-based architectures such as GPT (Generative Pre-trained Transformer) (Radford et al., 2018). These models offered unprecedented levels of fluency and coherence in generated text (Han et al., 2021). However, a critical challenge arises: these models can produce linguistically fluent but semantically inaccurate outputs, a phenomenon referred to as *hallucination* (Ji et al., 2023). This may also lead to the generation of offensive, misleading, or factually incorrect content, as highlighted in previous studies (Engstrom and Gelbach, 2020; Bender et al., 2021). Such issues could have profound repercussions, especially for marginalized or under-resourced communities (Surden, 2020; Volokh, 2023; Koudounas et al., 2024).

To address this challenge, the Shared-task on Hallucinations and Related Observable Overgeneration Mistakes (SHROOM) has been proposed at SemEval 2024 (Mickus et al., 2024). In particular, the Shared task aims to address the existing gap in assessing the semantic correctness and meaningfulness of NLG models. The ever-increasing adoption of such models makes it necessary to automatically detect and mitigate semantic hallucinations (Huang et al., 2023).

Some examples to tackle hallucination detection tasks in literature (Ji et al., 2023) are: (i) *Information Extraction and Comparison* between a generated text and a ground truth, (ii) *Natural Language Inference Metrics* that express the entailment between generated text and a ground truth or (iii) *Faithfulness Classification Metrics* that leverage upon knowledge-grounded datasets.

In this work, we address the SHROOM shared task by introducing an automatic pipeline of hallucination detection through the comparison between a generated text and a ground truth text. We propose enriching the original data available using different augmentation techniques, including LLM-aided pseudo-labeling and sentence rephrasing. Additionally, we suggest using an ensemble of three different approaches, incorporating a simple BERT-based classifier, a model trained through Conditioned Reinforcement Learning Fine Tuning (C-RLFT) (Wang et al., 2023), and a sequential model based on iterative fine-tuning. We show how this ensemble benefits from using different, complementary approaches, particularly in recall. Our methodology obtained an accuracy of 80.07% in the SemEval-Task 6 SHROOM.

1.1 Dataset

The dataset available for the SHROOM challenge is a collection of objects. Each object represents a solution of a generative language model to either of the three tasks. The first is *Definition Modeling* (DM) (Noraset et al., 2017), the task of providing a definition for a given word. The second is *Machine Translation* (MT), i.e., translating from a source

*These authors contributed equally to this work.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1678–1684

language to a target one: this has been shown to be a challenging task that can be addressed from both statistical (Koehn, 2009) and, in recent years, neural perspectives (Bahdanau et al., 2014; Giobergia et al., 2020). Finally, the task of *Paraphrase Generation* (PG) consists of paraphrasing, i.e., producing an alternative version, of a source sentence (Zhou and Bhat, 2021). Each solution has been annotated, based on its contents, as either a *hallucination* of the generative model or *not hallucination* by 5 human annotators.

For each object, the available information includes (i) the *source (src)*, which is the input text given to the generative language model, (ii) the *hypothesis (hyp)*, which represents the generated textual output of the model, and (iii) the *target (tgt)* which is the intended reference or "gold" text that the model is supposed to generate. Additionally, the task field indicates the type of task being solved, either DM, MT, or PG. The label, either *"hallucination"* or *"not hallucination"*, is determined through majority voting among five annotators, with *p(hal)* indicating the proportion of annotators who labeled the data point as a hallucination.

The gold (and augmented) data cardinalities are defined in Table 1. The training dataset comprises 500 instances with gold labels, denoted as $\mathcal{D}_g$, and 30,000 unlabelled instances, referred to as $\mathcal{D}_u$ (10,000 for each of the three tasks). The evaluation split contains 1,500 labelled samples, with 500 instances used for validation ($\mathcal{D}_v$) and 1,000 for testing ($\mathcal{D}_t$). We use the validation set for fine-tuning the ensemble layer (refer to Section 2.3), while the final test set provides overall results (see Section 3).

We further rephrase the original 500 labelled sentences of the training set ($\mathcal{D}_r$ in the table, see Section 2.1.2), while applying weak labelling to the 30,000 unlabelled instances ($\mathcal{D}_{pl}$, see Section 2.1.1).

2 Methodology

The main goal of this work is to propose a binary classification model to predict whether the answer to a given query is a hallucination or not. Figure 1 presents the main architecture adopted to address this task[1]. We propose (i) using a data augmentation pipeline (see Section 2.1) consisting of Large Language Model (LLM)-aided pseudo-labelling and sentence rephrasing and (ii) adopting an ensemble model (see Section 2.3) based on the results of three models, defined as follows:

- *Baseline* model, a binary classifier based on a semantic-aware embedding (e.g. BERT-based (Devlin et al., 2019)). The baseline model is presented in Section 2.2.1
- *C-RLFT* (Conditioned Reinforcement Learning Fine Tuning (Wang et al., 2023)), based on the introduction of pseudo-labels and augmented data, with different weighting schemes based on the quality of each data point. We cover C-RLFT in more detail in Section 2.2.2
- *Sequential* model, based on the iterative fine-tuning of the baseline model with increasingly higher-quality data, as detailed in Section 2.2.3

2.1 Data Augmentation

Due to the scarcity of data, we developed an approach to extend the number of labelled samples we could use to train our models. We specifically leverage two distinct techniques: pseudo-labelling and sentence rephrasing. Both approaches are based on LLMs and, as such, may themselves be subject to hallucinations or inaccuracies. As detailed next, we mitigate this problem by (1) using the C-RLFT technique (Wang et al., 2023), which involves assigning different weights to mixed-quality samples, and (2) with a sequential training that introduces different-quality labels at different training stages.

2.1.1 Pseudo Labeling

As stated in Section 1.1, only a small fraction of the dataset available is labelled. We introduce additional pseudo labels, as obtained by querying an LLM in a few-shot learning setting. Based on the hardware available, we tested several LLM models to assess the reliability of the pseudo labels produced (in terms of accuracy). We identified SOLAR (Kim et al., 2023) as being the best-performing model among the pool of candidates. Thus, we leverage it to generate synthetic labels for unlabelled data through a few-shot learning approach. We refer to this augmented dataset as $\mathcal{D}_{pl}$.

2.1.2 Sentence Rephrasing

We utilized sentence rephrasing based on GPT-4 as an additional data augmentation technique. We

[1]The code to replicate the experiments can be found at https://github.com/MAL-TO/shroom

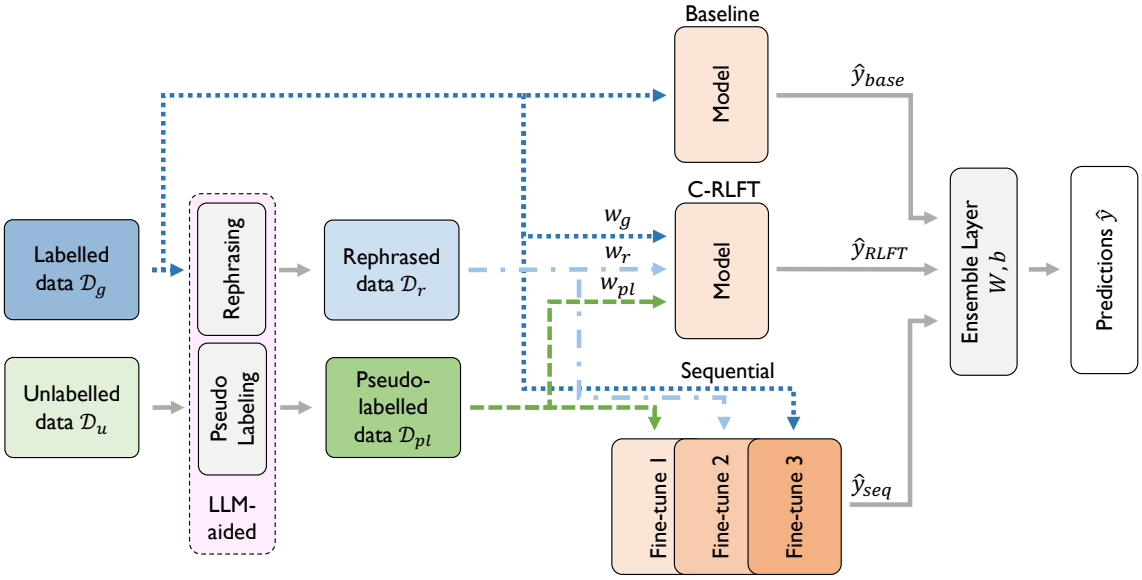

Figure 1: Pipeline architecture depicting data augmentation techniques and weighted ensemble of strategies.

do so by rephrasing both the model output and the target output of each gold sample. This approach aims to provide the model with diverse data while maintaining the reliability of the labels. We refer to this dataset as $\mathcal{D}_r$.

2.2 Models

We adopt an ensemble of three models, as described below. All models are based on DeBERTa (**?**). More specifically, we use a baseline model that has been fine-tuned in different ways.

2.2.1 Baseline

We employed a baseline model utilizing the DeBERTa encoder pre-trained on the Natural Language Inference (NLI) task, with a binary classification head. We fine-tune this model on the provided classification task using only data with the gold labels available, referred to as $\mathcal{D}_g$. The training approach involved minimizing the Binary Cross Entropy (BCE) loss.

We use the probability $p(hal)$ as the ground truth instead of the binary label. This is done to better reflect the distribution of votes of the human annotators in the output logits of the model.

2.2.2 C-RLFT

Conditioned Reinforcement Learning Fine Tuning (C-RLFT) is a technique that refines models using coarse-grained reward labels, allowing fine-tuning with both expert and sub-optimal data lacking preference labels. In our specific scenario, we fine-tuned the model by assigning different weights to data based on their label type, i.e., synthetic or gold. The weight assigned to each data sample influences the contribution to the final BCE loss.

We define a weighting scheme for the gold dataset $\mathcal{D}_g$, the pseudo-labelled dataset $\mathcal{D}_{pl}$ and the rephrased dataset $\mathcal{D}_r$, as follows:

$$w(x_i) = \begin{cases} w_g & \text{if } x_i \in \mathcal{D}_g \\ w_r & \text{if } x_i \in \mathcal{D}_r \\ w_{pl} & \text{if } x_i \in \mathcal{D}_{pl} \end{cases}$$

We choose weights $w_g > w_r > w_{pl}$. In this way, we aim to assign a higher importance to gold labels due to their reliability. The lowest weight is assigned to the pseudo-labelled points because of the lower quality of the automatically assigned labels. An intermediate weight is given to rephrased sentences due to the higher quality of the ground truth w.r.t. the pseudo-labelled points. The weighted loss is thus defined as follows, for a point x_i with ground truth y_i, as computed for a binary classifier $f(\cdot)$:

$$\begin{aligned} wBCE(x_i, y_i) = &- w(x_i) \cdot (y_i \; log \; f(x_i) \\ &+ (1 - y_i) \; \log(1 - f(x_i))) \end{aligned}$$

2.2.3 Sequential

The third model used is based on a sequential strategy that uses both generated and augmented data. We introduce three fine-tuning steps, performed sequentially on the initial model. The model initially underwent fine-tuning using the pseudo-labelled dataset $\mathcal{D}_{pl}$, which is the lowest-quality dataset

among the three available. Subsequently, we fine-tuned the resulting model on the rephrased data $\mathcal{D}_r$, which benefits from the original, correct, labels. The final fine-tuning step is then executed on the golden truth dataset $\mathcal{D}_g$. This approach is inspired by curriculum learning (Soviany et al., 2022), with data being ordered by veracity instead of difficulty.

This strategy aims to enhance the model's understanding of the task by starting with a substantial amount of data, including the less reliable synthetic labels, and progressively updating the model parameters with increasingly consistent data. This sequential approach allows the model to first adapt to the task using a broader dataset and then refine its knowledge with the highest quality data available.

2.3 Ensemble

The final step in the proposed pipeline involves creating an ensemble of results from the previously-introduced techniques, which has already proven to be effective in other NLP tasks (Jia et al., 2023; Koudounas et al., 2023). We trained three distinct models (*baseline*, *C-RLFT*, *sequential*) with specific strategies, and we generated their outputs ($\hat{y}_{base}$, $\hat{y}_{RLFT}$, $\hat{y}_{seq}$) on a validation set of previously unseen gold data. We obtain a single result $\hat{y}$ from the previous ones by using a single-layer network ($W \in \mathbb{R}^3$ and $b \in \mathbb{R}$), as follows:

$$\begin{aligned} \hat{y}_{models} &= (\hat{y}_{base}, \hat{y}_{RLFT}, \hat{y}_{seq}) \\ \hat{y} &= \sigma(W^\intercal \hat{y}_{models} + b) \end{aligned} \tag{1}$$

This network is trained to predict a single output from the three models' predicted probabilities. We trained this network by minimizing a BCE function.

3 Experimental Results

This section presents the experimental setup used, and the main results obtained.

3.1 Experimental Setup

The dataset used to train and validate the model is the one made available in the SHROOM challenge's model agnostic track (refer to Section 1.1). The augmentations are specified in Section 2.1.

For the model backbone and synthetic labelling we leverage Huggingface pre-trained models[2]. We also leverage *GPT-4* for sentence rephrasing. All the experiments' results are obtained based on 5 different runs. For C-RLFT, we identified the best performance for weights $w_g = 1.01, w_r = 0.4, w_{pl} = 0.1$.

Dataset Type	Label	Split	#Samples
$\mathcal{D}_g$	yes	Train	500
$\mathcal{D}_r$	yes	Train	500
$\mathcal{D}_u$	no	Train	30,000
$\mathcal{D}_{pl}$	weak	Train	30,000
$\mathcal{D}_v$	yes	Val	500
$\mathcal{D}_t$	yes	Test	1000

Table 1: Dataset type, labelling, and number of instances for each considered split.

3.2 Model performance

We summarize the results obtained on the test set in Table 2. We report the results in terms of F_1 score, precision, and recall on the "Hallucination" class, as well as overall accuracy.

We use as backbone both DeBERTa and a version of DeBERTa that has been fine-tuned on the Machine Natural Language Inference (MNLI) task. Further discussions on the choice of the backbone are presented in Section 3.3.

Section 3.4 highlights the result differences for each of the considered strategies and includes additional considerations on the ensemble of the approaches. Finally, we provide qualitative examples of the results in Section 3.5.

3.3 Backbone impact

We start by examining the differences between two backbone models, both fine-tuned on the gold data only – these are referred to as the *baseline* models in Table 2.

There is a notable increase of 0.09 in the F_1 score for the MNLI-fine-tuned model compared to the original DeBERTa. Interestingly, all the proposed DeBERTa-based approaches are still outperformed by the baseline DeBERTa+MNLI-based model (although to a lesser extent). This highlights the close relationship between the tasks of *Hallucination Detection* and *Natural Language Inference*.

3.4 Strategies comparisons

The *baseline* strategy, which utilizes all available labelled gold data, establishes a lower bound in the expected performance. Both *C-RLFT* and *sequential training* exhibit substantial performance

[2]We use *deberta-xlarge* and *deberta-xlarge-mnli* as encoders, *TheBloke/SOLAR-10.7B-Instruct-v1.0-GPTQ* for pseudo labelling.

Model	Method	F_1 score	Precision	Recall	Accuracy

Король Харальд Гормссон, более известный как Харальд Синезубый, ввёл в Дании христианство.	King Harald Hormsson, better known as Harald Sinezubii, introduced Christianity to Denmark.	King Harald Gormsson, better known as “Harald Bluetooth", introduced Christianity to Denmark.	0.40	0.40
Why’d you got to go and do that?	Why did you have to go do that?	Why would you say that?	0.00	0.91

Table 3: Examples of correctly and wrongly predicted as *“Hallucination”* or *“Not Hallucination”*. The model output is *p(hal)* and must be confronted with gold *p(hal)*. The first example proposed is a Russian to English *Machine Translation* (MT), and the second is an English *Paraphrase Generation* (PG).

improvements.

Regarding the *ensemble* strategy, the results in terms of F_1 score outperform individual techniques. We observe a trade-off where the precision of the final result is slightly compromised in exchange for an improved recall. This suggests that the *ensemble* effectively identifies instances of hallucination overlooked by the standalone approaches. These advantages are consistent across both backbones implementations, with and without the additional MNLI fine-tuning.

In a setting where detected hallucinations are shown to the final user with a warning, we argue that the recall is a metric of greater interest (w.r.t. precision). A false negative could be potentially harmful since final users are not warned of the presence of possible hallucinations. A false positive would raise a warning that may be inspected by the final user and safely ignored.

The weights learned for the ensemble layer, based on Equation 1, are $W = (0.52, 1.7, 1.82)$, $b = -1.7$. This shows how both C-RLFT and the sequential models are weighted similarly and more heavily w.r.t. the baseline. The baseline is assigned a non-zero weight: it is considered, although to a lesser extent, in the final vote. The negative bias implies a learned prior: without further knowledge, the initial prediction is of a negative one (i.e., the majority class).

3.5 Qualitative Example

Table 3 demonstrates the effectiveness of the applied strategies through some qualitative examples. We specifically showcase the sentences with the minimum (first row) and maximum (second row) errors.

The first instance depicts a partial hallucination, attributed to the transliteration of “Sinezubii” instead of the translation “Bluetooth,” which is absent from the translation hypothesis. In the second example, despite a paraphrased similarity between the source and hypothesis, the target introduces an action (“saying”) not present in the source (“doing”). As such, we argue that this might be a case of incorrectly labelled ground truth.

4 Conclusions

This work tackles the SHROOM Task 6 challenge at SemEval 2024, focusing on semantic hallucination in NLG models. We propose an automatic

pipeline for hallucination detection, utilizing data augmentation and an ensemble of three different methodologies. The ensemble of the approaches obtained an accuracy of 80.07% in the task's leaderboard. Particular attention should also be paid to the results obtained with the novelty method *sequential*, which was able to outperform the results of the other two methods due to the proposed sequential training.

Abstract

In recent studies, the extensive utilization of large language models has underscored the importance of robust evaluation methodologies for assessing text generation quality and relevance to specific tasks. This has revealed a prevalent issue known as hallucination, an emergent condition in the model where generated text lacks faithfulness to the source and deviates from the evaluation criteria. In this study, we formally define hallucination and propose a framework for its quantitative detection in a zero-shot setting, leveraging our definition and the assumption that model outputs entail task and sample specific inputs. In detecting hallucinations, our solution achieves an accuracy of 0.78 in a model-aware setting and 0.61 in a model-agnostic setting. Notably, our solution maintains computational efficiency, requiring far less computational resources than other SOTA approaches, aligning with the trend towards lightweight and compressed models.

1 Introduction

The contemporary landscape of Natural Language Generation (NLG) is marked by a confluence of complexities, wherein two primary challenges emerge as focal points of concern. Firstly, the prevalent neural models within NLG frameworks consistently produce outputs that exhibit linguistic fluency yet suffer from inaccuracies (Huang et al., 2023). Secondly, the current evaluation metrics, vital for evaluating the effectiveness of NLG systems, demonstrate a significant inclination towards fluency measures while neglecting to prioritize accuracy. So, this highlights the need to consider the "truthfulness" of the model's output, i.e its alignment with the source to ensure a comprehensive assessment.(Dale et al., 2022)

In the realm of NLG applications, the criticality of output accuracy cannot be overstated. A divergence between the fluency and factual correctness of generated content not only undermines the utility of NLG systems but also engenders substantial risks across various domains. Consider, for instance, the domain of machine translation,the production of seemingly plausible yet inaccurate translations not only compromises the integrity of the translated content but also defeats the purpose of facilitating correct translations.

Likewise, in tasks like definition modeling and paraphrase generation, where accurately conveying semantic meaning is crucial, the presence of incorrect outputs presents notable challenges in upholding the integrity and dependability of the generated content.

2 SHROOM Dataset

SHROOM (a Shared-task on Hallucinations and Related Observable Overgeneration Mistakes) dataset is a task-based hallucination detection dataset which is divided into two major categories:

2.1 Model Aware (MAw)

Model Aware (MAw) refers to situations where the model under study is known.

2.2 Model Agnostic (MAg)

Model Agnostic (MAg) refers to situations where the model under study is not known.

The dataset encompasses three major Natural Language Generation tasks, namely:

1. Definition Modeling (DM): In this task, models are trained to generate a definition for a given example in context.

[†]The authors contributed equally to this work.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1685–1689

2. Machine Translation (MT): In this task, models aim to generate translations of the given samples.

3. Paraphrase Generation (PG): In this task, models aim to produce paraphrases of the given text samples.

Further, each sample in the train set is populated with information such as task ($task$): indicating what objective the model was trained for, source (src): the input passed to the models for the generation, target (tgt): the intended reference "gold" standard text that the model ought to generate, hypothesis (hyp): the actual model production,also the model-aware dataset is populated with model name ($model$) used for the task, with the val set additionally being populated with majority-based gold-label ($label$), based on the annotator labels along with the probability values of the sample being hallucination ($p(Hallucination)$) based on the proportion of annotators who claim that the sample is an hallucination.

3 Definitions

As described earlier, the SHROOM shared task encompasses of three different taks, Definition Modelling (DM), Paraphrase Generation (PG), and Machine Translation. We define the **Hallucination** in the context of the specific task at hand. Defining hallucinations individually in the context of a specific task enables detecting hallucinations quantitatively and qualitatively. We offer distinct definitions of hallucinations and methodologies for detecting hallucinations within the context of each of the aforementioned task.

In the context of definition modelling, the model is expected to generate the definition of a word which has been used in the provided context by making use of distributional semantics. Definition modelling models such as flan-t5-definition-en-base (Giulianelli et al., 2023) are not fully capable of making use of distributional semantics to define a word as used in a context. In a sample where the word W has been used in a setting contrasting to the definition the model has learnt during its training process, the models fails to provide a contextual definition of the word W. Examples for the same have been demonstrated in Table 1 and Table 2. We observe the model outputs a definition of word W which is very similar what it has learnt during its training process. Based on this observation, we assume that the targets provided in the SHROOM dataset have been extracted from the training data of the definition modelling dataset. With this assumption, we define **"Hallucination to be an instance where the output generated by the definition modelling model *does not* entail the target output."** Thereby reducing the hallucination detection task to a Natural Language Inference task in the context of definition modelling.

In the context of paraphrase generation and machine translation, the model's inputs and outputs are anticipated to exhibit semantic equivalence. If the generated paraphrase or translation diverges from semantic equivalence with the source text, they are deemed imperfect paraphrases or translations. Therefore, in the context of paraphrase generation and machine translation, we define **"Hallucination to be an instance where the paraphrase or translation generated by the model is *not semantically equivalent* to the source."** This reduces the hallucination detection in the context of given tasks to a semantic equivalence detection task, which could also be framed as bidirectional entailment detection, a variation of the Natural Language Inference task.

The aforementioned definitions of hallucination allow us to simplify the hallucination detection task to a Natural Language Inference task, thereby enabling us to qualitatively and quantitatively detect hallucinations.

In a more generic setting, we provide a definition of hallucinations that can be adapted to any task to effectively detect them. We define **"hallucinations as instances where the output generated by the model is *not faithful* to the input or the training data of the model. If the model generates information that is contradictory to the model's training data or the input to the model, it can be termed as a hallucination."**

4 Methodology

Grounding to the above definitions, the experimental setup we designed goes on to quantify the alignment of the model's output (hyp) with either the source (src) or the target (tgt) based on the task ($task$) the data sample corresponds to.

We propose that examining the **entailment** relationship between the model's output (hyp) and either the source (src) or the target (tgt) (which is

Example 1: Definition Modeling (DM)
Model Input: I went into the *water bottle* to withdraw cash. What is the definition of *water bottle*?
Model Output: A container for holding liquids.
Expected Output: A financial institution such as a bank or ATM to withdraw cash
Model: flan-t5-definition-en-base

Table 1: A Table showing distinction between the model output and the expected output where the model fails to understand the contextual definition of the term *water bottle*

Example 2: Definition Modeling (DM)
I jumped into the flaxcron to do some swimming. What is the meaning of *flaxcron*?
Model Output: A slender, slender
Expected Output: A pool of water.
Model: flan-t5-definition-en-base

Table 2: A Table showing distinction between the model output and the expected output where the model fails to understand the contextual definition of the term *flaxcron*

also inherently linked to the source (src)), depending on the task, sheds light on data samples that are **not** "detached" from the source. Consistent with our initial hypothesis that hallucinations occur when samples are "detached" from the source, this approach based on Natural Language Inference (NLI) can effectively aid in hallucination classification.

- In the context of definition modelling, **if the** hyp **does not entail the** tgt, the sample has been classified as **Hallucination**.
- In the context of machine translation and paraphrase generation, we check equivalence through bidirectional entailment. **If the** hyp **does not bidirectionally entail the** src, the sample has been classified as **Hallucination**
- In the context of machine translation and paraphrase generation, we verify our hypothesis of semantic equivalence between the src and hyp by comparing the performance metrics in the case of both unidirectional and bidirectional entailment.

Recent research heavily relies on large language models (LLMs) to benchmark various natural language understanding and generation (NLG) tasks. However, this practice extends to hallucination detection as well, which we find ironic and counterproductive, considering LLMs' inherent tendency to hallucinate. Using LLMs for hallucination detection presents two major drawbacks. Firstly, their computational demands are significant, making them an expensive solution (Bai et al., 2024). Secondly, the lack of complete interpretability in LLMs renders them unreliable for this task (Singh et al., 2024).

5 Results

After several experiments with the above methodology, leveraging the accuracy and the Spearman correlation (ρ) metrics, we have bench-marked the hallucination detection task on the SHROOM validation and test sets to achieve an accuracy of 0.78 in model-aware and 0.61 on model-agnostic test sets respectively. For our analysis let us take only the accuracy metric into account.
The bench-marking saw a utilisation of open-source pre-trained Natural Language Inference (NLI) models available on Hugging Face. Several experiments brought out interesting observations which are worthy discussing.

We evaluated the following models:

1. MoritzLaurer/DeBERTa-v3-base-mnli-fever-anli **(DeBERTa-1)** (He et al., 2020)
2. MoritzLaurer/mDeBERTa-v3-base-xnli-multilingual-nli-2mil7 **(DeBERTa-2)** (He et al., 2020)

5.1 Definition Modelling

For the task of definition modelling, our approach achieves a peak accuracy of 0.748663 using the DeBERTa-2 model in a model-agnostic setting and a peak accuracy of 0.755319 using the RoBERTa-1 model in a model-aware setting. These results are in accordance with our hypothesis that when the model hallucinates, it does not entail the target.

5.2 Paraphrase Generation and Machine Translation

For the paraphrase generation and machine translation tasks, the observed results confirm our hypothesis that if the source (src) and hypothesis (hyp) are not semantically equivalent, the hypothesis is a hallucination. In hallucination detection for the paraphrase generation task, we observe that bidirectional entailment (semantic equivalence) outperforms the unidirectional entailment approach for all models. Similar results can also be observed for the machine translation task. This provides evidence that in machine translation and paraphrase generation, hallucinations can be detected by checking for semantic equivalency between the source and hypothesis.

Model	Unidirectional	Bidirectional
DeBERTa - 1	0.728	0.752

RoBERTa - 1	0.711230	0.834224	0.712

Table 7: Model-agnostic evaluation on individual tasks.

5.3 Overall Analysis

In the model-agnostic setting, we achieve a peak accuracy of 0.783567 using the DeBERTa-1 model and a peak accuracy of 0.612774 in a model-aware setting using the RoBERTa-1 model. These scores exhibit satisfactory performance of models pretrained on the Natural Language Inference task for Hallucination Detection.

6 Conclusion

Our work makes two significant contributions to the study of hallucinations in language models. First, we provide a concrete definition of the term "hallucination," enabling both qualitative and quantitative study and detection of such phenomena. Second, we offer a computationally efficient approach to detect hallucinations in tasks such as definition modeling, machine translation, and paraphrase generation. We frame the hallucination detection task as a function of the input to the generation model and the data used to train it. Our definitions and approaches also provide a framework that can be utilized for hallucination detection in

various Natural Language Generation tasks across the spectrum.

Abstract

This paper presents our solution for subtask A of shared task 8 of SemEval 2024 for classifying human- and machine-written texts in English across multiple domains. We propose a fusion model consisting of a RoBERTa-based pre-classifier and two MLPs that have been trained to correct the pre-classifier using linguistic features. Our model achieved an accuracy of 85%.

1 Introduction

After rapid developments in large language models (LLMs) and generative AIs in the last years, the detection of machine-generated content has become one focus of study as deepfakes, machine-generated lawyer statements and even libel suits (Superior Court of Gwinnett County) concerning language machines stress the importance of detecting texts not written by humans. The SemEval shared task 8 in 2024 aims at multi- and monolingual machine-generated text (MGT) detection from various domains by multiple models.

For the monolingual English data in subtask A (Wang et al., 2024) we propose a fusion model built using pre-trained RoBERTa word embeddings specialized for AI-generated text detection and correction MLP classifiers, supported by the additional computation of linguistic, stylistic and probabilistic features selected based on their informational value. With this system design, our model ranked at position 25 out of 124 with an 0.855 accuracy score on the task. The only data used for training was the one provided by the organizers without further data augmentation. Because of the different distributions of the data in the development and test data sets several strategies were tested and a fusion model was chosen as the best strategy. The fine-tuned RoBERTa Base OpenAI Detector alone performed well but developed a bias towards the machine class. To stabilize the model linguistic, probabilistic and stylistic features were added, which improved the overall F1 score of the fusion architecture.

2 Background

Over the last years, numerous approaches have been proposed to tackle the task of MGT detection. Some models, such as DetectMGT (Mitchell et al., 2023), focus on detecting texts from a specific source, such as GPT-family LLMs, while other approaches are specialized in texts from a specific genre, such as Shijaku and Canhasi (2023) for TOEFL essays. Other architectures, like ensemble models combining different classifiers (del Campo-Ávila et al., 2007) have been successfully used for machine-generated text detection to improve out-of-distribution performance (Lai et al., 2024).

Guo et al. (2023) show that, overall, deep-learning approaches, and in particular a RoBERTa-based-detector, are one of the best individual models for MGT detection. The RoBERTa-based-detector was shown to be particularly robust against oov scenarios in both Chinese and English, compared to a machine learning model. Moreover, Wang et al. (2023) and He et al. (2024) conducted large-scale bench-marking on existing approaches for MGT detection across multiple domains, models, and languages and concluded that the RoBERTa language model, especially the variants that have been optimized for AI detection tasks, consistently outperforms most other methods across evaluation metrics.

[†]Equal contribution.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1690–1697

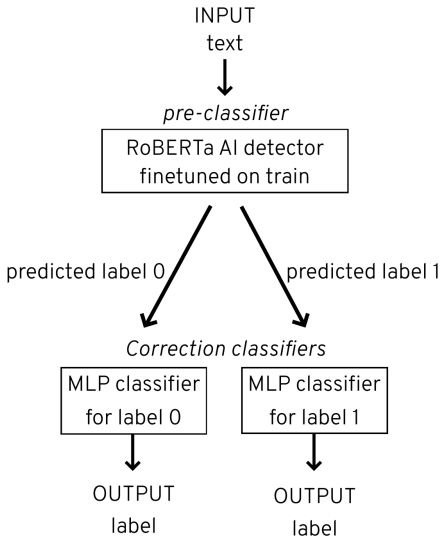

Figure 1: Model architecture used to obtain submission results.

3 System overview

Our system is based on a pre-classifier that is a RoBERTa model fine-tuned for AI generated text detection. In order to correct the predictions of the pre-classifier, two correction classifiers have been trained that are based on linguistic, stylistic and probabilistic features. An overview of the system setup is given in Figure 1.

Our RoBERTa pre-classifier is based on the RoBERTa Base OpenAI Detector[1] (Solaiman et al., 2019), a RoBERTa model fine-tuned for AI generated text detection. This model has been further fine-tuned on 10% of the training data. A prediction was then generated for each text in the train, dev and test set. In order to improve the predictions, two correction Multi-layer Perceptron (MLP) classifiers, one for each label, were trained on the training and development data of their respective label (see Figure 1) as well as on a range of features outlined in Section 4.2.1. To generate the final classification, all texts were classified again by the correction MLP that corresponded to the label predicted by the RoBERTa pre-classifier. This provided an opportunity for the more specialized classifier to correct the initial prediction.

4 Experimental setup

The M4 dataset consists of both machine (label 1) and human-generated texts (label 0). The dataset features texts from six different LLM generators (Davinci, chatGPT, Dolly, Cohere, BLOOMz and GPT4) and five different genres (Reddit, WikiHow, ArXive, Wikipedia, and peerRead). Participants were provided first with a train and dev set and later with a test set with 119,757, 5,000, and 34,272 texts in total, respectively.

Roughly 53% of the documents in the train set are machine generated (DaVinci: 14,343, chatGPT: 14,339, Dolly: 14,046, Cohere: 13,678), and 47% are human-written. In the dev set, exactly half of the texts were machine-generated by the BLOOMz model, the other half was human-written. The test set contains 18,000 (53%) machine-generated texts from Davinci, chatGPT, Dolly, Cohere, BLOOMz and GPT4 (3,000 texts each) and 16,272 (47%) human-written texts. An overview of the data is provided in Table 1. Since we did not include genre- or machine-specific information for our approach, this information is excluded from the table.

	train	dev	test
machine	53%	50%	53%
human	47%	50%	47%
total texts	119,757	5,000	34,272

Table 1: Label distribution across train, dev and test set.

4.1 RoBERTa pre-classifier

We used a fine-tuned RoBERTa Base OpenAI Detector as our pre-classifier. Because the OpenAI Detector had already been fine-tuned for human-machine classification, and to facilitate replication of the experiment, we used only 10% of the training data to further fine-tune the model[2].Training was done for 3 epochs with a learning rate of $2e^{-5}$ on Google Colab using a T4 run-time and took 45 minutes.

4.2 Correction classifiers

4.2.1 Feature extraction

To capture characteristics of machine-generated and human-written texts, the data was analyzed for various linguistic features. Altogether 70 features, widely used in NLP and easy to compute, were extracted, 35 of which exhibited a high to medium correlation with the gold label (see Table 4 in the Appendix). All features were computed on a 24GB

[1] https://huggingface.co/openai-community/roberta-base-openai-detector

[2] The data for fine-tuning consisted of 2,000 texts of each author category (Davinci, Cohere, Dolly, chatGPT, and human).

RAM machine with a Ryzen 7 7730U, which took up to 6 hours for all texts depending on the feature.

Count-based features. The texts were split into words and punctuation using regular expressions to derive the following features: mean sentence length, ratio of punctuation to words, ratio of word types to tokens, ratio of vowels to words and mean word length. The NLTK stopword list was used to get the ratio of content words to other words. Additionally the number of hapax legomena per text and the number of negation words (manually compiled list) per text were computed.

Syntactic features. All texts were POS-tagged with the NLTK part of speech tagger to compute syntactic features: ratio of nouns, verbs, adjectives, adpositions, adverbs, conjunctions, numerals, pronouns and determiners to words alltogether, ratio of adjectives to nouns and ratio of verbs to nouns.

Using the dependency parser of Spacy (Honnibal and Montani, 2017) we extracted the maximum depth of a dependency tree, mean depth of all dependency trees in a text, and number of passive constructions (determined by the number of *nsubjpass* POS tags) per sentence.

Frequency features. To capture whether the texts differ in word use, the logarithmic frequency of all content words in the human texts were computed. Additionally, lists of frequent words (frequency $\geq$ 12) and hapax legomena (frequency = 1) have been computed. From this the following features were extracted for all texts: mean log frequency of content words, ratio of frequent words to content words, ratio of hapax legomena to content words and number of hapax legomena.

Additionally, we used the Wiktionary frequency lists for English[3] and extracted a list of high frequency words (top 10%), mid-high frequency words (top 20%) as well as field specific word lists, namely the most frequent words in fantasy texts and in Wikipedia articles. For each list and each text in the datasets we extracted the ratio of words belonging to the lists to the content words as a feature.

Word difficulty features. The CEFR-J[4] project provides vocabulary lists for the different proficiency levels of the Common European Framework of Reference for Languages (CEFR)[5]. We used these lists[6] to compute the following features: ratio of A1/A2/B1/B2/C1/C2-level words to content words. This was done twice: once on the basis of the stemmed and once on the lemmatized words. We used the Porter stemmer and the WordNet lemmatizer from NLTK.

Stylistic and sentiment features. A number of features concerning text style and text sentiment were extracted. Using the same method as for the difficulty features above, we extracted the ratio of words in the list of negative opinion words compiled by Liu et al. (2005) as well as the readability score of the texts according to the Flesch reading-ease test[7] . The other features in this subset have been extracted by using available fine-tuned classifiers. Emotion English DistilRoBERTa-base[8] is a classifier that predicts Ekman's six basic emotions, plus a neutral class (cf. Hartmann, 2022). The logit for each class provides one feature (anger, disgust, fear, joy, neutral, sadness, surprise). As a standard sentiment analyzer we used the sentiment-analysis-pipeline from Hugging Face[9] and, using the logits, extracted two features (positive, negative). Analogously, the features 'formal' and 'informal' were extracted using the formality ranker by Babakov et al. (2023), which is a RoBERTa model trained to predict to which register a sentence belongs. Finally, we used a toxicity classification model[10] that is a RoBERTa model fine-tuned to predict whether a text is toxic or not.

Features extracted from the pre-classifier. In order to inform the correction classifiers on the basis of the decision of the pre-classifier, we extracted the logits and the last hidden state of our RoBERTa pre-classifier for each text. The last hidden states were reduced from 768 to 2 dimensions using PCA (principal component analysis) and UMAP (uniform manifold approximation and projection). For UMAP the hyperparameters `min_dist`, `n-neighbors` and `metric` were tuned by a combination of random search and grid search

[10] https://huggingface.co/s-nlp/roberta_toxicity_classifier

and evaluated on the accuracy of a logistic regression classifier that predicts the label from the 2 dimensions. The extracted features included in our feature set are the logits, the 2-dimensional PCA representation of the last hidden state and the 2 UMAP dimensions gained by setting `min_dist` to 0.01 and `n-neighbors` to 100. We kept two metrics, namely `cosine` and `jaccard`.

4.2.2 Feature selection

To account for the variability in features, we initially scaled all 70 features using the Standard Scaler from scikit-learn (Pedregosa et al., 2011). During the collection of the 70 features, no attention was paid to whether they contained quasi-duplications. Features which were highly correlated with other features (>0.9) were removed subsequently using a correlation matrix. After this removal, 51 features remained.

In the next step, only features with high or medium correlation with the gold label (Pearson correlation ≥ 0.1 or ≤ -0.1) were retained in order to choose the features most relevant for the classification task. Table 4 in the Appendix shows all features (including those which are highly correlated to each other) that have at least a medium positive or negative correlation with the gold label. After both selection steps, 26 features remained (see Table 5).

4.2.3 Model selection and training

In a comparison of various classifiers from scikit-learn (i.e. Random Forest, Logistic regression), MLPs performed best in most settings: whether trained on all features, trained only on at least medium correlated features, or trained only on features that are not extracted from the pre-classifier. We therefore chose MLP as our correction classifiers.

Before conducting training on the combined train and dev dataset, we separated the texts for which the RoBERTa pre-classifier had predicted the human label from those for which it had predicted the machine label, thus creating two splits. Then, we trained two separate MLPs on the two splits of the training data using the 26 features identified as relevant in the feature selection process (4.2.2). The idea behind this approach was that the models might learn in which cases the fine-tuned transformer classified the data incorrectly, and would thus have to be corrected. The test data was then prepared by calculating the 26 features, on which the pair of MLP correction classifiers made the final predictions.

model	label	prec.	rec.	f1
fusion model	human	0.85	0.85	**0.85**
	machine	0.86	0.86	**0.86**
accuracy: **0.85**				
pre-classifier	human	**0.99**	0.48	0.64
	machine	0.68	**0.99**	0.81
accuracy: 0.75				
MLP	human	0.53	0.89	0.67
	machine	0.75	0.30	0.43
accuracy: 0.58				

Table 2: Precision, recall, f1-score, and overall accuracy for the submitted fusion model and two models for comparison: the RoBERTa pre-classifier and an MLP model trained with the selected linguistic features. The support for the 'human' class is 16,272 and for the 'machine class 18,000.

5 Results

Table 2 shows the performance of the submitted fusion model, obtained using the `classification_report` from scikit-learn. Overall, the fusion model achieves an accuracy of 85%. The table additionally shows the performances of two other models on the test data in comparison: (i) the RoBERTa pre-classifier; (ii) an MLP model that was trained with the same hyperparameters as used for the correction classifiers and the same features selected in the feature selection process (see Section 4.2.2), except for the ones extracted from the pre-classifier (see Section 4.2.1).

Although the pre-classifier performed fairly well on the dev data (accuracy: 0.89, for more details see Table 6 in the Appendix), we opted for a fusion model with a correction layer in order to improve robustness for data from new generators and domains. The implementation of the two correction MLPs corroborated the hypothethis. On the test data, the accuracy of the pre-classifier drops to 0.75, while the addition of the correction layer improved the accuracy to 0.85.

A closer look at the recall and precision for the two classes 'human' and 'machine' reveals that the fusion model balances out the problems of the pre-classifier and the MLP. The high precision and low recall of the pre-classifier for 'human' and vice versa for 'machine' indicate that it is biased

towards the 'machine' class. Accordingly the relatively high precision and low recall of the MLP classifier for 'machine' and vice versa for 'human' indicate that it is biased towards the 'human' class. In contrast, the fusion model shows equally high precision and recall for both classes.

As described in Section 4.1, the pre-classifier is obtained from the RoBERTa base OpenAI detector by further training. Comparing its performance to the original model (see Table 7, Appendix), fine-tuning has led from a bias towards the 'human' class to a bias towards the 'machine class'. This is likely due to the fact that the fine-tuning data had an imbalance towards machine-generated texts.

5.1 Error Analysis

An error analysis was completed in three parts: We examined the influence of the different labels, the features, and the correctional classifiers on accuracy. The influence of the domain was not examined since there was only one domain present in the test data.

When inspecting the label distribution for the misclassified texts, we can see an almost perfect 50% split between human and machine-labeled texts. Between the models, the errors are not distributed as evenly, as shown in Figure 3 in the Appendix. GPT4 and dolly texts were misclassified most often, followed by Cohere, DaVinci, and chatGPT, while BLOOMz texts were rarely classified incorrectly. Since GPT4 texts were not seen in the train or dev data, it is not unsurprising that those texts were classified least accurately. A further reason could be that GPT4-generated texts are known to be very 'human-like', hence harder to differentiate from human texts.

Figure 2 shows the classification by the pre-classifier and whether it was modified by the correction classifier (the same data in numbers is given in Table 3). A text identified as human by the pre-classifier was typically classified accurately and only rarely adjusted by the correcting classifier. For the texts where the pre-classifier predicted a machine label, the prediction was corrected often. However, as shown in table 3, 2,308 cases should have been corrected and were not. The machine label predictions by the pre-classifier have caused most errors, as that label was predicted so often. This is also reflected in the recall of the pre-classifier-only model in Table 2.

Finally, we correlated all features used in the

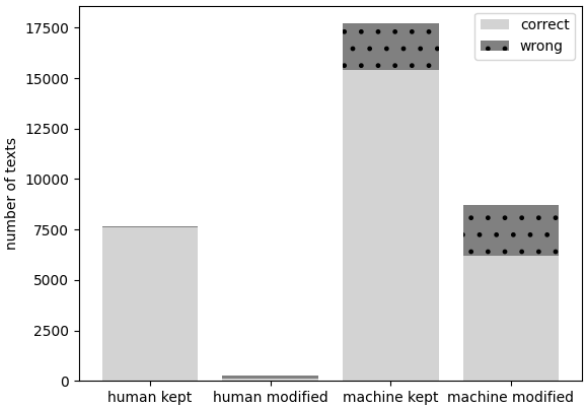

Figure 2: Left two bars: predictions by correction classifier correcting texts pre-classified as "human", right two bars: predictions by correction classifier correcting texts pre-classified as "machine".

pre-classifier	h		m	
correction classifer	h	m	m	h
correct	7622	86	15402	6189
wrong	12	153	2308	2500

Table 3: Classification errors split by prediction by the pre-classifier and correction classifier (h = human, m = machine).

fusion model with the labels that were predicted incorrectly. The strongest correlation was shown by the features *1st UMAP-dimension (Jaccard)* (- 0.82), *ratio of CEFR-B1 words (stem)* (- 0.71), *ratio of CEFR-B2 words (stem)* (- 0.57), *neutral sentiment score* (- 0.51), and *ratio of pronouns to content words* (0.55). Since the correlations are on the wrong predictions, a strong negative correlation indicates a correlation with an incorrectly predicted human label (label 0), while a strong positive correlation implies the opposite. It is possible that the low correlation threshold chosen for feature acceptance led to the inclusion of features initially weakly correlated with the labels in the training and development data, which may have adversely affected the correctional classifiers' decisions. Alternatively, the test set data might exhibit a different distribution for those features compared to the training and development data.

6 Conclusion and Limitations

Overall, this study has highlighted the benefit of using a fusion architecture consisting of a pre-classifier and linguistically informed correctional classifiers. By adding syntactic, stylistic, sentiment, frequency- and word difficulty-based features, we

were able to improve the performance of a fine-tuned pre-trained RoBERTa model for AI generated text detection and adjust the bias towards the machine label. Because our fusion model uses a pre-trained RoBERTa model, all computations for this paper can be run locally or, in the case of the RoBERTa fine-tuning, using a free Google Colab account. This means that our model can be easily expanded and leaves a smaller environmental footprint.

Future studies could expand our fusion model by incorporating more semantic-level or complex features such as contextual predictability, as well as fine-tuning the pre-classifier using more, balanced data. Our code is available on GitHub[11].

Abstract

The SemEval-2024 Task 3 presents two subtasks focusing on emotion-cause pair extraction within conversational contexts. Subtask 1 revolves around the extraction of textual emotion-cause pairs, where causes are defined and annotated as textual spans within the conversation. Conversely, Subtask 2 extends the analysis to encompass multimodal cues, including language, audio, and vision, acknowledging instances where causes may not be exclusively represented in the textual data. Despite this, our model addresses Subtask 2 using the same architecture as Subtask 1, focusing solely on textual and linguistic cues. Our architecture is organized into three main segments: (i) embedding extraction, (ii) cause-pair extraction & emotion classification, and (iii) post-pair-extraction cause analysis using QA. Our approach, utilizing advanced techniques and task-specific fine-tuning, unravels complex conversational dynamics and identifies causality in emotions. Our team, AIMA (MotoMoto at the leaderboard), demonstrated strong performance in the SemEval-2024 Task 3 competition ranked as the 10^{th} rank in subtask 1 and the 6^{th} in subtask 2 out of 23 teams. The code for our model implementation is available on https://github.com/language-ml/SemEval2024-Task3.

1 Introduction

The task of Emotion-Cause Pair Extraction in Conversations holds significant importance in advancing the field of emotion analysis. Unlike previous endeavors that primarily focused on recognizing emotions, this task delves deeper into understanding the underlying causes behind emotional expressions within conversational contexts (Wang et al., 2023). Recognizing that emotions are conveyed not only through words but also through vocal intonations and facial expressions, the field has shifted towards multimodal emotion recognition. This move aims to understand how emotions are interwoven with text, sound, and visual cues in dialogue (Wang et al., 2023).

The SemEval-2024 Task 3 (Wang et al., 2024, 2023; Xia and Ding, 2019) encompasses two subtasks aimed at extracting emotion-cause pairs in conversational contexts. Subtask 1 focuses on textual emotion-cause pair extraction, where causes are defined and annotated as textual spans within the conversation. In contrast, Subtask 2 broadens the analysis to incorporate multimodal cues, including language, audio, and vision. The task is based on the multimodal conversational emotion cause dataset ECF (Wang et al., 2023). Figure 1 illustrates an example of the task and the annotated dataset.

In this paper, we introduce an approach based on a model architecture consisting of three key components: (i) embedding extraction, (ii) cause-pair extraction & emotion classification, and (iii) cause extraction via QA post-pair detection. Utilizing advanced techniques and fine-tuning on specific datasets, our goal is to dissect complex conversational dynamics and pinpoint nuances that indicate emotional causality.

Although our architecture supports multimodal data—including text, audio, and video through concatenations of the embeddings of these modalities using pretrained models—this study specifically harnesses textual data, as our primary focus is on addressing subtask 1.

2 Related Work

This section provides an overview of two key areas in the field of emotion analysis: Emotion Recognition in Conversation and Emotion-Cause Pair Extraction in Conversations.

Emotion Recognition in Conversation: Emotion recognition in conversation, a burgeoning field, aims to decipher and understand the complex interplay of emotions within dialogues. ERC has seen significant advancements in recent years (Kim

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1698–1703

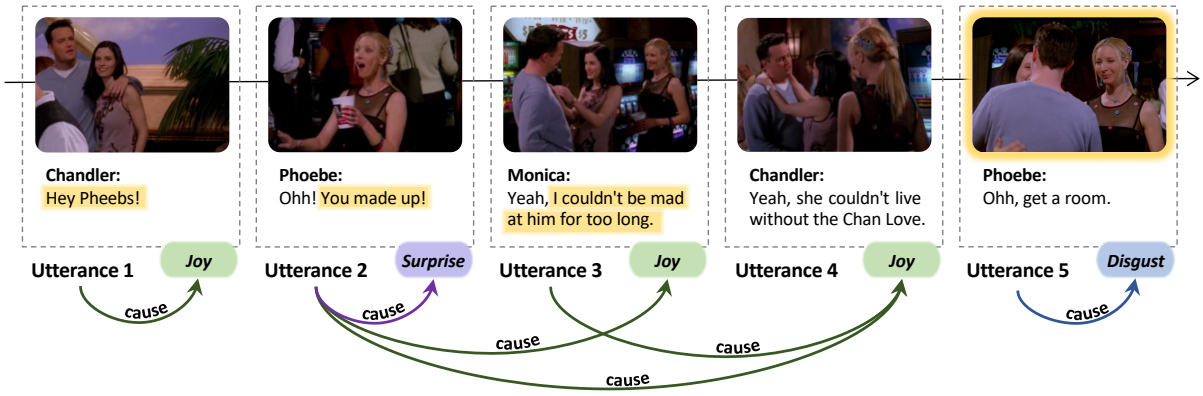

Figure 1: An example of the annotated conversation in ECF (Wang et al., 2023) dataset, illustrating the multimodal nature of emotion causes. Each arc points from the cause utterance to the emotion it triggers. The cause spans have been highlighted in yellow.

and Vossen, 2021; Zheng et al., 2023). These approaches have shown promising results on popular datasets such as IEMOCAP (Busso et al., 2008) and MELD (Poria et al., 2019).

EmoBERTa (Kim and Vossen, 2021) enhances RoBERTa (Liu et al., 2019) for emotion recognition in conversation (ERC) on datasets IEMOCAP (Busso et al., 2008) and MELD (Poria et al., 2019), by incorporating speaker information and dialogue context. It preprocesses dialogues, representing them as sequences with speaker annotations and context segments. EmoBERTa extends RoBERTa to handle multiple segments and utilizes a linear layer with softmax nonlinearity for sequence classification.

The FacialMMT (Zheng et al., 2023) framework comprises two key stages. Initially, a pipeline method is employed to isolate the face sequence of the real speaker within each utterance. Following this, a multi-modal facial expression-aware emotion recognition model is applied. This model utilizes frame-level facial emotion distributions and incorporates multi-task learning to improve utterance-level emotion recognition. Experimental evaluations conducted on the MELD (Poria et al., 2019) dataset validate the effectiveness of FacialMMT.

Emotion-Cause Pair Extraction in Conversations: The task of Emotion-Cause Pair Extraction in Conversations is pivotal for advancing our understanding of the nuanced interplay between emotions and their underlying triggers within dialogues, offering insights into human communication, cognition, and interpersonal dynamics.

The paper (Wang et al., 2023) introduces a baseline system, MC-ECPE-2steps, comprising two steps. Firstly, it employs multi-task learning to extract emotions and causes separately, utilizing word-level encoding and utterance-level encoders to derive representations specific to each. Secondly, it combines the predicted emotions and causes into pairs and employs BiLSTM and attention mechanisms to obtain pair representations. Subsequently, non-causal pairs are filtered out using a feed-forward neural network. Additionally, the system incorporates multimodal features from text, audio, and video modalities to enhance the extraction process. In addition to this approach, there exist other methodologies for Emotion-Cause Pair Extraction in Conversations (Xia and Ding, 2019; Zheng et al., 2022), some of which leverage question answering techniques (Nguyen and Nguyen, 2023).

3 System Overview

Our model architecture, illustrated in Figure 2, is designed with the capacity to incorporate a diverse set of inputs from various sources such as text, video, and audio to perform emotion-cause analysis within conversational contexts. However, for the purpose of addressing subtask 1, we specifically utilized textual data.

Embedding Extraction and Emotion Classification: In the Embedding Extraction phase, we leverage the EmoBERTa (Kim and Vossen, 2021) model specifically designed for text embedding. EmoBERTa's selection is based on its proven effectiveness in capturing the nuanced emotional dynamics inherent in conversational data, thereby facilitating precise emotion classification of the utterances.

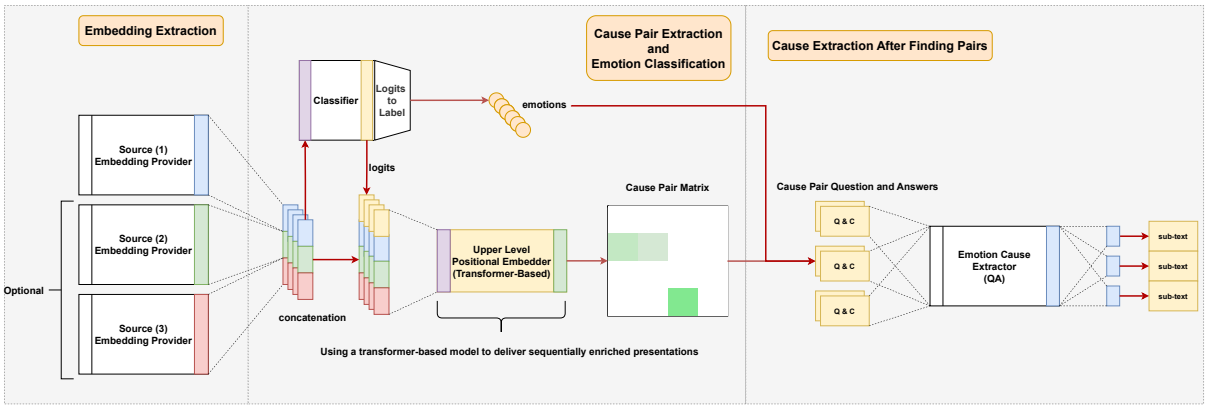

Figure 2: The schema of our proposed model for emotion-cause analysis, meticulously partitioned into three core segments: **Embedding Extraction**, **Cause Pair Extraction and Emotion Classification**, and **Cause Extraction After Finding Pairs**

Additionally, it's noteworthy that EmoBERTa's emotion classification schema encompasses classes such as "neutral, joy, surprise, anger, sadness, disgust, and fear," mirroring the emotion categories present in the task dataset. This alignment ensures consistency in emotion classification across datasets. Moreover, we fine-tune EmoBERTa on the task dataset, further enhancing its ability to capture emotion-specific nuances within conversational utterances. Notably, the original model (before fine-tuning) achieves an accuracy of 67% on the training data, indicating a good performance in emotion classification.

Causality Matrix Extraction: The embeddings of utterances, combined with logits from the classification task, are processed by a Transformer-based Encoder. This includes positional embeddings added to input vectors and a sequence of transformer encoder layers. The model's output, derived from the attention weights of the final layer, forms a causality matrix. This matrix highlights potential causal relationships within dialogue utterances, capturing the complex dynamics of conversation. The approach enriches data with emotion-specific insights, streamlining the identification of diverse emotion classes directly within the embeddings. In the following, the process of extracting the causality matrix is explained in detail.

Causality Matrix Extraction Process:

1. Initial combination of embeddings and logits:

$$combined = [s_1, s_2, s_3, logits] \quad (1)$$

where s_1, s_2, and s_3 are embeddings for an utterance, and $logits$ are the output from the classification model M_c, computed as $logits = M_c([s_1, s_2, s_3])$.

2. Application of dropout and addition of positional embeddings:

$$input = dropout(combined) + e_{pos} \quad (2)$$

Here, e_{pos} represents the positional embeddings, which are added to the dropout-modified combined inputs to incorporate positional information into the sequence representation. Specifically, e_{pos} encodes the position of each utterance within the conversation, enriching the model's understanding of dialogue structure and the sequential context of each utterance.

3. Generation of the causality matrix through the transformer encoder layers:

$$C_m = A_N(l_{1:N-1}^{encoder}(input)) \quad (3)$$

Here, $l_i^{encoder}$ denotes the i-th transformer encoder layer, with $N-1$ indicating that the input sequentially passes through all layers up to the $N-1$-th layer. A_N refers to the attention weights from of the N-th (last) encoder layer. The causality matrix, C_m, is specifically derived from these attention weights applied to the output of the $N-1$-th layer, which has been processed by all preceding encoder layers and enhanced with positional embeddings. This matrix captures the causal interactions within the dialogue, as inferred from the attention mechanism of the transformer's final layer.

Question Generation for Causality Pairs: Following the emotion classification task, where emotions within the dialogue are identified, a causality matrix is created. For each emotion-cause pair detected in this matrix, the system generates a structured query to facilitate the extraction of the causal text segment. The prompt, constructed only for these detected pairs, follows the template:

"Which part of the text {target_utterance} is the reason for {speaker}'s feeling of {emotion} when {main_utterance} is said?"

The Cause Extraction After Finding Pairs phase utilizes a question-answering model to interrogate the text, pinpointing exact sub-texts that substantiate the identified emotional triggers. (see Figure 3).

This study undertook a thorough evaluation of various question-answering (QA) models, uncovering areas where each model could be enhanced. Among the models examined, DistilBERT (Sanh et al., 2019) and BERT (Devlin et al., 2018) showed considerable promise for application within our research framework. Ultimately, we selected the deepset/deberta-v3-base-squad2, a pre-trained QA model, for our specific task requirements. This choice was informed by the model's foundation on the DeBERTa-v3-base architecture (He et al., 2021) and its prior fine-tuning on the SQuAD2 dataset (Rajpurkar et al., 2016), which includes both answerable and unanswerable questions. By further fine-tuning this model on our dataset, we ensured its proficiency in accurately extracting causal text segments from conversational contexts, a critical capability for our emotion-cause analysis.

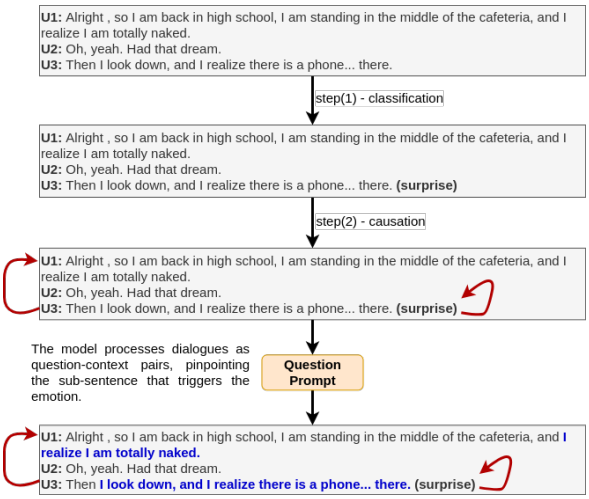

Figure 3: An example of the model's question-answering mechanism in action. After classifying emotions in the dialogue and creating the causality matrix, a question prompt is generated only for detected emotion-cause pairs. This diagram demonstrates the process of identifying the causative segment within the dialogue that led to the emotional response, with the causative text being highlighted in the context of the detected pairs.

4 Experimental Setup

4.1 Dataset Preparation

Dataset Preparation for Attention Model: The dataset preparation for cause pair extraction and emotion classification procedure commenced with the loading of conversation data and emotion-cause pairs, accompanied by preprocessing steps tailored for model training. A custom dataset class facilitated the loading and processing of data, extracting essential details like conversation ID, utterances, and emotion-cause pairs. Subsequently, a collate function was employed to organize individual samples into batches suitable for model input, focusing solely on text and generating attention targets based on the presence of cause pairs within the textual data.

Dataset Preparation for QA Model: The dataset preparation for subtext emotion cause extraction using question answering involved constructing samples for question answering by generating questions and contexts solely from text data. Each sample comprised a question formulated with a predefined prompt, the context concatenating all utterances from the conversation, and the answer containing the cause subtext. The dataset then underwent preprocessing to train the question-answering model, utilizing a pre-trained tokenizer to align tokenized inputs with the original text and determine the start and end positions of the answers within the textual context.

4.2 Training

Training the Attention Model: The attention model was optimized using mean squared error loss and the AdamW optimizer with a learning rate of 1e-4.

Training the QA Model: The QA model was trained over 25 epochs with a batch size of 8.

4.3 Evaluation Metrics

Our models' performance was gauged using F1 scores across the six primary emotion categories, with additional emphasis on weighted averages to account for class imbalances. Subtask 1 evaluations incorporated both Strict Match and Proportional

Match metrics to assess the accuracy of textual span identification for emotional causes.

Metric	Strict	Proportional	Weighted
Precision	0.0217	0.2018	0.2779
Recall	0.0217	0.2081	0.2486
F1-Score	0.0217	0.2049	0.2584

Table 1: Performance metrics for team AIMA (MotoMoto) in SemEval-2024 Task 3.

5 Results

5.1 Quantitative Findings

Our team, MotoMoto, participated in the SemEval-2024 Task 3 competition and secured the 10th rank in Subtask 1 and 5th rank in Subtask 2. The official metrics for our team's performance are as shown in Table 1 To explore the effectiveness of our approach, we compare it with the MC-ECPE-2steps (Wang et al., 2023) method, which represents our baseline. The comparison is based on the weighted average F1 scores achieved by both approaches, as presented in Table 2.

Approach	Weighted-average F1
MC-ECPE-2steps	0.3000
-Audio	0.2764
-Video	0.2993
-Audio - Video	0.2625
Ours	0.2584

Table 2: Comparison of Approaches with Baselines based on Weighted Average F1

5.2 Error Analysis

Our investigation into the discrepancies between our system's predictions and the ground truth leveraged the detailed insights from the confusion matrix (Table 3). The analysis underscores our emotion classification module's exceptional performance, notably in accurately identifying 'Neutral' and 'Joy' emotions with 4400 and 1576 correct instances, respectively. This substantiates our model's adeptness at recognizing emotions within conversations. Despite these strengths, the emotion-cause pair extraction component displayed variations, such as over or under-identification of causes compared to the ground truth annotations. Nevertheless, the precision of our model in identifying correct causes, as highlighted by specific successes in the confusion matrix, confirms its effectiveness in discerning emotions. These observations suggest that while our model excels in accurately identifying emotions, there is a valuable opportunity to refine the identification of causal factors within conversations for further improvement.

Table 3: Confusion Matrix for 13,619 dialogues. The model demonstrates no signs of overfitting, hence the entire train dataset is utilized to report this table.

	Neutral	Joy	Surprise	Anger	Sadness	Disgust	Fear
Neutral	4400	610	242	218	307	31	121
Joy	392	1576	136	82	70	19	26
Surprise	154	134	1380	77	34	17	44
Anger	168	180	192	823	88	71	93
Sadness	203	79	82	94	581	29	79
Disgust	83	34	41	77	25	143	11
Fear	70	36	42	24	35	8	158

6 Conclusion

Our investigation into emotion-cause pair extraction presents a paradigm shift towards simplicity and efficiency without compromising performance. By adopting a streamlined approach, we have demonstrated that high-impact emotion analysis does not necessarily require heavy computational resources or complex multimodal data integration. Our participation in the SemEval-2024 Task 3 competition has validated our methodology, securing commendable rankings and highlighting the efficacy of our model. The results underscore the potential of cost-effective solutions in the realm of emotion analysis, opening doors to wider applicability in resource-constrained environments. Looking forward, we aim to further optimize our model's efficiency and explore the integration of lightweight multimodal data processing techniques. This endeavor not only reinforces the viability of minimalist approaches but also sets a new benchmark for future research in emotion-cause analysis.

Abstract

In this study, we introduce a solution to the SemEval 2024 Task 10 on subtask 1, dedicated to Emotion Recognition in Conversation (ERC) in code-mixed Hindi-English conversations. ERC in code-mixed conversations presents unique challenges, as existing models are typically trained on monolingual datasets and may not perform well on code-mixed data. To address this, we propose a series of models that incorporate both the previous and future context of the current utterance, as well as the sequential information of the conversation. To facilitate the processing of code-mixed data, we developed a Hinglish-to-English translation pipeline to translate the code-mixed conversations into English. We designed four different base models, each utilizing powerful pre-trained encoders to extract features from the input but with varying architectures. By ensembling all of these models, we developed a final model that outperforms all other baselines.

1 Introduction

The first subtask of SemEval 2024 Task 10 focuses on Emotion Recognition in Conversation (ERC) (Kumar et al., 2023). This subtask requires the design of a model capable of predicting an emotion for each utterance. Our final system is an ensemble of four high-performing models we developed in this paper. Our primary strategy involves leveraging powerful pre-trained models and utilizing the context of preceding and succeeding utterances in the conversation. We also consider the sequential information of the conversation to accurately predict emotions. The final system is designed to work with Hindi-English code-mixed conversations. A detailed description of the task is available in (Kumar et al., 2024).

ERC is an emerging research frontier in Natural Language Processing (NLP), that aims to identify emotions in conversational data. The ability to accurately recognize emotions in conversation is crucial for a variety of applications, including opinion mining from social media platforms (Poria et al., 2019). ERC is also extremely important for generating emotion-aware dialogues that require an understanding of the user's emotions. It is useful in various sectors, such as healthcare for psychological analysis and education to aid in understanding student frustration (Antony et al., 2021).

ERC presents several research challenges due to the complexity and rapid changeability of emotions in conversation. The same words can convey different emotions depending on the context, adding a layer of complexity to the task (Kumar et al., 2023). This complexity is further amplified in code-mixed conversations, a common phenomenon in multilingual societies and online social media platforms where two or more languages are used interchangeably. The challenges in ERC for code-mixed conversations include **(i) Linguistic Complexity**, due to complex linguistic structures and sentence or word-level language switches; **(ii) Insufficient Training Data**, as the scarcity of annotated datasets hampers the training of deep learning models; **(iii) Cultural Nuances**, since emotions can be expressed differently across cultures and languages; and **(iv) Ambiguity and Context-Dependence**, as word meaning and emotions vary based on context and language.

2 Background

The official dataset for this task is the MaSaC dataset (Bedi et al., 2023), a mixed Hindi-English language dataset relevant to our study of emotion recognition in code-mixed dialogues (Kumar et al., 2023). This dataset consists of approximately 8506 train, 1354 validation, and 1580 test sentences. ERC has garnered significant attention in the NLP community due to its potential applications.

Recent research in ERC has attempted to ad-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1704–1710

dress these challenges, but there are still many areas for improvement. For instance, most current approaches to ERC focus on text-based data, overlooking the rich emotional information that can be gleaned from other modalities such as voice tone and facial expressions (Kumar et al., 2023).

With recent advances in Large Language Models (LLMs), many works leverage the power of these large models for ERC task (Tu et al., 2023). (Lei et al., 2023) introduced a novel approach, which leverages LLMs to reformulate the ERC task from a discriminative framework to a generative one. This approach has shown significant improvements over previous models on several ERC datasets. While considerable research has focused on discerning the emotions of individual speakers in monolingual dialogues, understanding the emotional dynamics in code-mixed conversations has received relatively less attention. This is the gap our study aims to address. (Kumar et al., 2023) proposed an innovative approach that integrates commonsense information with dialogue context to interpret emotions more accurately in code-mixed dialogues. They developed a pipeline based on a knowledge graph to extract relevant commonsense facts and fuse them with the dialogue representation. (Wadhawan and Aggarwal, 2021), the closest work to ours, introduced a new Hinglish dataset for emotion detection in Hindi-English code-mixed tweets. They trained various deep learning approaches, including transformer-based models, for emotion recognition task performance on this dataset.

This paper aims to delve deeper into the current state of ERC and propose models to take a step toward solving these challenges. Our method differs from existing approaches in that it incorporates both context and sequential information to improve emotion prediction performance.

3 System Overview

3.1 Preprocessing Data

In the preprocessing stage, we implement a two-step translation process due to the unique nature of our data, which comprises Hindi-English mixed conversations. At present, there are no robust models trained specifically in this mixed language, nor are there translators capable of directly translating Hindi-English mixed text to English with acceptable performance. As a result, we first need to translate our data to English. In the first step, we transform our Hindi-English mixed conversations into Hindi using the indic-trans transliteration module (Bhat et al., 2015), a tool proficient in cross-transliteration among all Indian languages. Following this, we employ SeamlessM4T Medium (Communication et al., 2023) to translate these Hindi conversations into English. The English conversations obtained from this process serve as our preprocessed data.

3.2 Model Architecture

In this section, we propose the model architectures that were used to construct our final ensemble model. We designed three distinct architectures, and the final model is an ensemble of four models trained based on these architectures. The second model follows the same architecture as the first, but it is trained on an augmented dataset. Our system predicts the emotion of the current sentence using majority voting based on the predicted emotions from four base models.

Given the specific domain of the task and the limited number of samples in the dataset, it is crucial to strike a balance between model complexity and performance. Overly complex models may lead to overfitting, especially given the unique distribution of our dataset. Conversely, overly simple models may not capture the complexity of this particular task. Therefore, we aimed to find a balance, ensuring adequate model complexity to learn effectively from the data without leading to overfitting. Furthermore, due to the limited dataset for this task and the special domain and emotions that are used, such as contempt, we leveraged the encoder component of a pre-trained RoBERTa-based model (Liu et al., 2019) for the emotion recognition task in sentences, and fine-tuned it for our specific task and domain. This model was trained on the GoEmotions dataset (Demszky et al., 2020), allowing us to employ the capabilities of pre-trained models for our task. This encoder was incorporated into all of our base models for sentence encoding. In the following parts, each of our base models is explained in detail. An overview of architectures is shown in Figure 1.

3.2.1 Simple History-Based Model

This model leverages both the current sentence, for which we aim to predict the emotion, and the preceding sentence along with its associated emotion as historical information to enhance the model's prediction. Both the current and previous sentences are processed through our pre-trained encoder to

obtain their respective embeddings. We then employed a multi-head attention mechanism (Vaswani et al., 2017) with 8 heads. In this mechanism, the keys are derived from the embeddings of the previous sentence, while the queries and values are derived from the current sentence. The use of 8 heads in the attention mechanism enables the model to capture information from different representational spaces at various levels of abstraction. This design allows the model to focus on the most relevant parts of the current sentence based on the context provided by the previous sentence.

For emotion representation, we utilized a 50-dimensional embedding space learned by our model. The embedding of the previous emotion and the output of the attention mechanism are concatenated and passed through a feed-forward classifier to predict the emotion. This classifier consists of two linear layers, a LeakyReLU activation function, and a Softmax layer for output normalization.

3.2.2 Simple History-Based Model + Data Augmentation

This model architecture is identical to the base model described earlier. The key difference lies in the training data. We used a Pegasus paraphrase model (Zhang et al., 2019) to augment our dataset and increase its size. We expanded our dataset by randomly selecting three sentences from the first ten paraphrases of each original sentence. Given the limited size of the original dataset, this augmentation method should enhance the model's learning capability by exposing it to a wider range of data.

3.2.3 Full History-Based Model

This model, which is an extension of the Simple History-Based model, aims to leverage more historical information for improved performance. In addition to the current sentence, previous sentence, and previous emotion, we also incorporated the concatenated string of all previous sentences in the conversation into our model. The rationale behind this is to enable the model to access additional information and gain a better understanding of the context of the current sentence within the conversation. The concatenated string of all previous sentences is processed through our pre-trained encoder to obtain the history embedding. This encoding is then passed through a simple feed-forward neural network, which consists of two linear layers, a batch normalization layer, a dropout layer, and a LeakyReLU activation function. This network transforms the 768-dimensional input into a 128-dimensional space.

The processing for the current sentence, previous sentence, and previous emotion remains the same as in the Simple History-Based Model. For the classifier network, we concatenated the output of the feed-forward network for previous sentences with the output of the attention mechanism and the emotion embedding. This concatenated vector is then passed to the classifier to predict the current emotion. The classifier comprises three linear layers, a batch normalization layer, two dropout layers, a LeakyReLU activation function, a ReLU activation function, and a Softmax layer for output normalization.

3.2.4 Context-Aware GRU-Based Model

This model, more complex than its predecessors, introduces several key modifications. Firstly, it incorporates information from both the preceding and succeeding sentences in a conversation, allowing the model to leverage both past and future contexts. Secondly, in contrast to previous architectures that use the emotion of the previous sentence, this model omits this feature to prevent error propagation during the inference phase. If a model incorrectly predicts the emotion of one sentence, it could potentially use this incorrect information when predicting the emotion of the next sentence, leading to further errors. Lastly, this model employs a Gated Recurrent Unit (GRU) (Chung et al., 2014; Cho et al., 2014), enabling it to leverage the sequential information in the conversation.

The model processes all sentences up to and including the current one (for which we want to predict the emotion) and the next sentence through our pre-trained encoder to obtain their embeddings. If the current sentence in the conversation has more than three previous sentences, only the last three are considered, making the model focus on the most recent context. These embeddings are then passed through a stacked GRU, consisting of two GRUs with a hidden dimension of 256 and a dropout rate of 0.25. Both the current and next sentences went through a transformation via a linear layer and a dropout layer to generate output encodings in a common 256-dimensional space. The last two hidden layers of the GRU are concatenated and passed through a multi-head self-attention mechanism, similar to our previous models.

The output of the last layer of the GRU, the output of the attention mechanism, and the trans-

formed outputs of the current and next sentences are concatenated and passed to a feed-forward classifier to predict the current emotion. The classifier comprises two linear layers, a dropout layer, a LeakyReLU activation function, and a Softmax layer for output normalization.

4 Experimental Setup

We utilized the official dataset provided for the task as the only data source for our system. The default split provided for the task was also used. During the development phase, the validation set was exclusively used for evaluating various steps and experimental configurations. For the final submission, models were fine-tuned on both the training and validation splits. For evaluation purposes, our primary metric was Weighted F1. However, to provide a more comprehensive analysis, we also reported three additional metrics, as detailed in Table 1. Our training process primarily employed the PyTorch and Transformers libraries. All base models were trained using the early stopping method and the AdamW (Loshchilov and Hutter, 2019) optimizer. A learning rate scheduler was used, with a lower learning rate set for the pre-trained encoder (5e-6) compared to other parameters (1e-4). The batch size was set to 1 for the Context-Aware GRU-Based model and 4 for other models during training. The cross-entropy loss function was used for the training.

5 Results

Table 1 presents SubTask 1 results. We compare our approach with four baseline models. The first baseline is GPT 3.5 Turbo, for which we used its API key to input the entire conversation and predict the emotion for each sentence. The results of this baseline model illustrate that this task is much more challenging than general sentence emotion recognition because it is domain-specific. The next two models are traditional ones, namely Linear Regression and Decision Tree, that utilize embeddings extracted from the LaBSE sentence encoder (Feng et al., 2022). The LaBSE model serves as a powerful encoder for our text data, enabling us to achieve comprehensive and multilingual text embeddings. The final baseline model is similar to a Simple History-Based model. It employs our pre-trained encoder but does not use any context, such as the previous sentence, and relies solely on the current sentence.

Moving on to the comparison of our models, we first consider the Simple History-Based model. By comparing its results with the Full History-Based model, we find that most of the information for predicting the emotion is contained in the current and the previous sentence. Therefore, information from all of the previous sentences is not as useful for predicting emotion. Our second model, which uses data augmentation, does not perform well. This is likely due to overfitting and the domain-specific nature of the conversations, making data augmentation less effective. As can be seen in our models, the Context-Aware GRU-Based model outperforms the others. This is because it incorporates information from both the preceding and succeeding sentences and the GRU can leverage the sequential information in the conversation. The closeness of

the results between the Context-Aware GRU-Based model and the Simple History-Based model reinforces our assumption that most information for predicting emotion is in the current and previous sentence. All of our models outperform the baselines. For our final model, we create an ensemble of these four models using majority voting. This ensemble model outperforms each individual model, achieving an F1-score of 0.4080.

6 Conclusion

In this paper, we proposed a novel method to address the Code-Mixed Emotion Recognition in Conversations (ERC) challenge. Our approach leverages the power of pre-trained large models and incorporates both previous and future context information of the current utterance, as well as sequential information of the conversation up to that point, to recognize each utterance's emotion. In addition to our primary model, we utilized other base models with different architectures based on various Deep Learning components to tackle this problem. By ensembling all of these models, we developed a final system that outperforms previous models.

Despite these advancements, Code-Mixed ERC remains a challenging task with significant potential for further investigation. Future research directions could include designing robust encoders capable of processing code-mixed dialogues and predicting emotions in an end-to-end manner. Moreover, collecting more data on these code-mixed dialogues is necessary to improve the performance of models. Furthermore, we can explore more complex models that incorporate different information from various modalities to achieve better performance. This work serves as a stepping stone towards more sophisticated emotion recognition systems for code-mixed dialogues.

Abstract

This paper outlines our approach to SemEval-2024 Task 8 (Subtask B), which focuses on discerning machine-generated text from human-written content, while also identifying the text sources, i.e., from which Large Language Model (LLM) the target text is generated. Our detection system uses Transformer-based techniques and incorporates various pre-trained language models (PLMs), which are tools that help understand and process language, including sentence transformer models. Additionally, we incorporate Contrastive Learning (CL) into the classifier to improve the detecting capabilities and employ Data Augmentation methods. Ultimately, our system achieves a peak accuracy of 76.96% on the test set of the competition, configured using a sentence transformer model integrated with CL methodology.

1 Introduction

The emergence of sophisticated Large Language Models (LLMs) has significantly blurred the lines between human-written and machine-generated texts, prompting an urgent need for systems capable of accurately distinguishing between the diverse sources.

In response, our team participated in SemEval-2024 Task 8: Multigenerator, Multidomain, and Multilingual Black-Box Machine-Generated Text Detection, as defined by Wang et al. (2024). This task aims to identify the origin of texts across various languages and domains, addressing critical concerns around the misuse of LLMs. We focused on Subtask B, which involves classifying English texts by their generative sources. This task adopted a fine-grained label set, for distinguishing not only between human-written and machine-generated texts, but also among texts generated by different machines. Our system leveraged Transformer-based pre-trained language models (PLMs) as well as its variant, Sentence Transformer models (Reimers and Gurevych, 2019). By applying Contrastive Learning (CL) approaches, which aimed at enhancing model robustness and generalization to our system, our best approach yielded a modest improvement over the baseline on the test set, achieving an accuracy of 76.96% compared to the baseline's 74.61%, and ranking 20th in the competition. The code for our system, detailed further in this paper, is made available at: https://github.com/banjuessing/adl_semeval24_mgtd.

2 Background and Related Work

The introduction of the M4 dataset by Wang et al. (2023) offers a comprehensive landscape for evaluating detection techniques across various generators, domains, and languages. The research done on the M4 dataset underscores the difficulties in generalizing detection across different domains and generators, highlighting the limitations of current approaches.

Data for Subtask B of SemEval-2024 Task 8, focusing on the detection of human-written against machine-generated texts from multiple generators across monolingual (English) contexts, is derived from the original M4 dataset. The dataset comprises 71,027 training and 3,000 development/test samples, distributed across multiple sources — Wikipedia, Reddit, arXiv, and wikiHow — with the testing data focused on the out-of-domain PeerRead domain. The task demands the identification of text origins, whether human or machine-generated by models. This underscores the necessity for systems that are adept at handling multi-class and out-of-domain classification challenges. In response to these challenges, our approach builds upon the insights from prior work. Abdalla et al. (2023), for instance, applied linguistic- and transformer-based method to detecting the author-

[†] Corresponding author.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1711–1718

ship of text. We also considered the methods used in the M4 dataset paper to compare with.

3 System Overview

Having outlined the urgency and relevance of distinguishing machine-generated text, we now describe our Transformer-based approach to tackle this issue. Our system tackles machine-generated text detection by carefully selecting a suite of transformer models (RoBERTa$_{\text{BASE}}$, RoBERTa$_{\text{LARGE}}$ (Liu et al., 2019), GPT-2 Small (Radford et al., 2019), XLNet-Base (Yang et al., 2019)), sentence transformer models (all-mpnet-base-v1[1], all-mpnet-base-v2[2], all-roberta-large-v1[3]), and integrating two different Contrastive Learning techniques, namely Supervised Contrastive Learning (SCL) (Gunel et al., 2020; Khosla et al., 2020) and Dual Contrastive Learning (DualCL) (Chen et al., 2022), alongside data augmentation strategies, inspired by (Bhattacharjee et al., 2023). Initially, we conducted hyperparameter tuning across both transformer and sentence transformer models in their base forms with trivial cross-entropy (CE) loss to identify optimal configurations. Subsequently, we refined our model selection to GPT-2 Small, RoBERTa$_{\text{BASE}}$, RoBERTa$_{\text{LARGE}}$, and all-roberta-large-v1, based on performance metrics on the enriched test set, which is described in section 4.1, further experimenting with combination of contrastive learning technique variants to enhance detection accuracy. Our approach culminates in the additional application of data augmentations aiming to improve robustness and generalizability.

3.1 Transformers

We began our exploration with a diverse set of transformer models: RoBERTa$_{\text{BASE}}$, RoBERTa$_{\text{LARGE}}$, GPT-2 Small and XLNet-Base, distinguished by unique architectural designs and pre-training objectives. RoBERTa, as an encoder model enhanced with optimized training approach dynamic masking strategy on longer sequences, offers robustness and depth in understanding context. GPT-2 with its generative capabilities and autoregressive training objective, provides insights into the sequence prediction dynamics often employed by text generation models. XLNet, incorporating permutation-based training, may capture bidirectional context and outperform traditional unidirectional models in understanding complex sentence structures. The different characteristics of those models grant us a comparative edge in detecting generated content. We conducted extensive hyperparameter tuning to identify the configurations that yield optimal performance on the classification task, which was crucial for ensuring that each model was leveraged to its fullest potential.

3.2 Sentence Transformers

In parallel, we evaluated three sentence transformer models: all-mpnet-base-v1, all-mpnet-base-v2, and all-roberta-large-v1. The decision to incorporate sentence transformers alongside traditional transformers was driven by their further pre-training on sentence pairs for generating semantically rich embeddings (Reimers and Gurevych, 2019), which potentially offers a more nuanced understanding of the essence of entire sentences. The selection of the three variants was informed by their pre-training paradigms and underlying architectures, which may influence their performance on text classification tasks. The all-mpnet-base models with a relatively smaller model size of 420 MB and hidden dimension of 768, derived from the MPNet (Song et al., 2020), are notable for their optimized permuted language modeling pre-training upon XLNet. The distinction between v1 and v2 primarily lies in the maximum sequence length, with v1 having 512 tokens and v2 having 384 tokens. The all-roberta-large-v1 model, on the other hand, is built upon the RoBERTa architecture with a larger model size of 1360 MB, a larger hidden dimension of 1024 but a smaller context window size of 256 tokens. Similar to the transformer models, hyperparameter tuning was performed to fine-tune these models for our specific task, ensuring that the models' configurations were optimized.

3.3 Contrastive Learning

Based on the initial evaluations, we narrowed our focus to GPT-2 Small, RoBERTa$_{\text{BASE}}$, RoBERTa$_{\text{LARGE}}$, and all-roberta-large-v1. These models were subjected to further experiments to test the efficacy of Contrastive Learning methods in enhancing their performances.

Driven by the training objectives of the sentence transformers and the intuition that in the embedding space, examples from the same source tend to

[1]https://huggingface.co/sentence-transformers/all-mpnet-base-v1

[2]https://huggingface.co/sentence-transformers/all-mpnet-base-v2

[3]https://huggingface.co/sentence-transformers/all-roberta-large-v1

be grouped together, while examples from different generators or human could be potentially pushed apart to be distinguished, we integrated SCL loss and DualCL loss with our selected models. Both loss functions utilize Contrastive Learning in the supervised setting. Following Gunel et al. (2020), the SCL loss directly takes the samples from the same class as positive samples and the samples from different classes as negative samples, while the DualCL loss simultaneously learns from the features of input samples $\mathcal{L}_z$ and the parameters of classifiers $\mathcal{L}_\theta$ in the same space with label-aware data augmentation (Chen et al., 2022). The overall loss that we used to optimise the models is then one of the two following combinations of two losses, where the λ adjusts the balance between the primary loss function and the contrastive loss component:

$$\mathcal{L}_{overall}^{SCL} = (1-\lambda)\mathcal{L}_{\text{CE}} + \lambda\mathcal{L}_{\text{SCL}} \quad (1)$$

$$\mathcal{L}_{overall}^{DualCL} = (1-\lambda)\mathcal{L}_{\text{CE}} + \frac{1}{2}\lambda\mathcal{L}_{\text{DualCL}} \quad (2)$$

where $\mathcal{L}_{\text{DualCL}} = \mathcal{L}_z + \mathcal{L}_\theta$.

Each model was trained and evaluated using one of these Contrastive Learning methods, in addition to the traditional CE loss, to compare their effectiveness systematically. Hyperparameter tuning was again employed for each combination of model and loss to ensure optimal settings.

3.4 Hyperparameter Optimization

For hyperparameter optimization (HPO) within our detection system, we employed a grid search strategy. Specifically, when training our models using the conventional CE loss, our tuning focused solely on optimizing the learning rate of the optimizer. Conversely, in scenarios where models were trained with the incorporation of SCL loss or DualCL loss, we extended our tuning efforts to include both the learning rate and the λ value.

3.5 Data Augmentation

Finally, we investigated the role of data augmentation in further enhancing the models' ability to discern machine-generated text. Selecting the top-performing model configurations from the previous steps, we applied various data augmentation techniques using `nlpaug` library[4] (Ma, 2019), including synonym replacement and random word swap to enrich the training dataset. This step aimed to introduce variability and complexity to the training process, testing the hypothesis that augmented data could lead to better generalization and robustness.

4 Experimental Setup

4.1 Data

The dataset for SemEval-2024 Task 8 encompasses a broad spectrum of text generators, encompassing both human-authored and machine-generated sources. The machine generated texts include outputs from advanced LLMs: BLOOMz, ChatGPT, Cohere, Davinci-003, and Dolly-v2. The data features diverse domains, including arXiv, WikiHow, Wikipedia, Reddit and PeerRead. This composition challenges us to distinguish human-written text from machine-generated content and further identify the specific LLM responsible.

The dataset was strategically split by organizers to promote an out-of-domain testing scenario, with the test set solely containing PeerRead texts absent from training data, comprising only 500 samples evenly distributed across each generator. This limitation led us to enrich our test dataset by incorporating all available samples from the original M4 dataset specific to the PeerRead domain, thereby aiming for a comprehensive analysis within our experimental framework. Utilizing the full PeerRead dataset provided us access to 14,566 data points, significantly enhancing our ability to conduct a deeper exploration of text detection capabilities. The distribution of data points across each model/source is as follows:

Model/Generator	Number of Samples
BLOOMz	2,334
ChatGPT	2,344
Cohere	2,342
Davinci-003	2,344
Dolly-v2	2,344
Human	2,858

Table 1: Distribution of data points across models/sources for the Peerread domain in our enriched test dataset.

To address the requirements of our experimental setup, we partitioned the original training dataset, as provided by the organizers, into two subsets: 90% for training and 10% for validation, where the labels and source domains of the samples are evenly distributed. This division was consistently applied

across all experiments to maintain uniformity in the evaluation process. Additionally, the enriched test dataset, as previously described, was employed as the test dataset for all experimental validations.

4.2 Hyperparameters

Under the experimental setup, a consistent approach was adopted for hyperparameter selection across all models to ensure comparability of the results. We ultilized AdamW (Loshchilov and Hutter, 2017) optimizer with a default weight decay of 0.01 for training each model across all experiments. Training was conducted with mixed precision for 20 epochs, incorporating an early stopping mechanism triggered by 3 consecutive epochs of loss increase. For the hyperparameter tuning of all transformer models and sentence transformer models using CE loss, a grid search methodology was implemented. The learning rate parameters explored were {1e-5, 2e-5, 5e-5}, with the exception of the RoBERTa$_{\text{LARGE}}$ model, for which a range of {1e-6, 2e-6, 5e-6} was tested. When integrating either SCL loss or DualCL loss, We explored the learning rate combined with λ values of {0.02, 0.1, 0.2} to adjust the influence of contrastive loss. Our decisions of selecting best performed models based on the accuracy of each model's performance on our enriched test dataset.

5 Results and Discussions

In our analysis of the performance of four transformer models as our baseline on the task of detecting machine-generated text, distinct variations in accuracy underscore the impact of model design and size on effectiveness, as shown in Table 2. The GPT-2 Small model, achieving the highest accuracy at 73.25%, outperformed both XLNet-Base and RoBERTa models. This superior performance could be attributed to GPT-2's architecture, primarily designed as a decoder model for generating text, which may inherently provide it with a nuanced capability to distinguish between human and machine-generated texts. When comparing models within the same family, RoBERTa$_{\text{BASE}}$'s performance surpasses that of RoBERTa$_{\text{LARGE}}$. This observation suggests that increasing model size, and thereby complexity, does not necessarily translate to better performance in detecting machine-generated text and a smaller model might be more effective than its larger counterpart. This could be due to the diminishing returns of model capacity expansion in this specific task.

Model	Accuracy
XLNet-Base	64.22
GPT-2 Small	**73.25**
RoBERTa$_{\text{BASE}}$	67.31
RoBERTa$_{\text{LARGE}}$	64.29

Table 2: Accuracy of the transformer models on the enriched test set. The results are reported as the best performance among each model's hyperparameter configurations.

In our evaluation of three sentence transformer models, we observed distinct performance outcomes that offer insights into the influence of model architecture and input sequence length on accuracy, as shown in Table 3. Specifically, the all-mpnet-base-v1 and all-mpnet-base-v2, which share the same foundational model and architectural parameters including model size and hidden dimension, demonstrated only a marginal difference in accuracy (61.36% for v1 and 60.73% for v2). This slight discrepancy in performance, despite v1's capability to process longer input sequences than v2, suggests that an extended context window does not inherently guarantee superior detection efficacy in our task. Conversely, the all-roberta-large-v1 model, characterized by its robust architecture and a higher hidden dimension of 1024, although with a reduced context window size, markedly outperformed the aforementioned models, achieving an accuracy of 69.96%. This outcome underscores the observation that a larger context window, contrary to expectations, may not be as critical for enhancing machine-generated text detection as previously assumed.

Model	Accuracy
all-mpnet-base-v1	61.36
all-mpnet-base-v2	60.73
all-roberta-large-v1	**69.96**

Table 3: Accuracy of the sentence transformer models on the enriched test set. The results are reported as the best performance among each model's hyperparameter configurations.

Our explorations with selected best models from previous experiments further led to insightful observations regarding the performance of incorporating contrastive learning methods, as shown in Table 4. For GPT-2 Small model, both the CL losses corrupted the performance, indicating the

alignments of CL losses may not suitable for a decoder model. For the RoBERTa$_{BASE}$ model, integrating CL methodologies yielded results comparable to those obtained using traditional CE loss with a slight underperformance. Similarly, the RoBERTa$_{LARGE}$ model, when augmented with CL methods, demonstrated only a marginal improvement under 2% over the conventional CE loss approach. Conversely, the all-roberta-large-v1 sentence transformer model showed a strong contrast in performance when leveraging two contrastive learning losses. The model variant with additional SCL loss markedly outperformed the accuracy achieved with standard CE loss, resulting in the best model variant across all our experiments. However, incorporating DualCL loss resulted in substantially poorer performance compared to the baseline, hinting at potential mismatches between the DualCL objective and the sentence transformer model for the task-specific requirements. Upon comparing the overall performances, the all-roberta-large-v1 model outperformed remarkably both the RoBERTa$_{BASE}$ and RoBERTa$_{LARGE}$ models, indicating that the adaptation and specialization of sentence transformers significantly contribute to discerning the subtle intricacies of machine-generated texts with the SCL loss further enhancing this ability.

Model	Loss	Accuracy (%)
GPT-2 Small	CE	73.25
	CE+SCL	72.53
	CE+DualCL	58.15
RoBERTa$_{BASE}$	CE	67.31
	CE+SCL	66.85
	CE+DualCL	66.64
RoBERTa$_{LARGE}$	CE	64.29
	CE+SCL	64.94
	CE+DualCL	65.94
all-roberta-large-v1	CE	69.96
	CE+SCL	**74.60**
	CE+DualCL	53.16

Table 4: Accuracy of the selected best performed models with various loss functions on the enriched test set. The results are reported as the best performance among each combination's hyperparameter configurations.

Incorporating data augmentation techniques, as detailed in section 3.5, to further train the GPT-2 Small and all-roberta-large-v1 model, which demonstrated top-2 performances in previous experiments, resulted in a significant decrease in performance, details shown in Table 5 in Appendix A.1. This decline was observed across both configurations of utilizing CE loss and the combination of CE loss and SCL loss, despite their initially high accuracy on the enriched test set. A potential reason for this downturn could be the introduction of noise or irrelevant variations through data augmentation, which may have led to the models' reduced ability to generalize from the augmented data, ultimately detracting from its capability to accurately distinguish machine-generated texts.

As we analyse model performance dynamics, an intriguing pattern of overfitting emerged among some of the top-performing model configurations. Upon testing earlier checkpoints of these models against the enriched test set, it was observed that certain pre-final checkpoints exhibited superior performance compared to the final models, which had achieved the highest validation accuracy. This phenomenon suggests that models slightly earlier in their training phase, before reaching peak validation accuracy, may generalize better to unseen data when detecting the machine generated texts. We report the detailed performance dynamics in Table 6 in Appendix A.2.

As we observe our best model's performance on the enriched test dataset for each generator, we find that the model demonstrates a robust ability to accurately identify texts generated by Dolly-v2, BLOOMz, ChatGPT, and Cohere, indicating a strong alignment with the characteristics prevalent in the outputs from these sources. However, it encounters significant challenges when attempting to classify texts originating from human authors and the Davinci-003 model. We report the detailed confusion matrix in Appendix A.3. This insight points to the need for further model refinement and training to bridge the gap in detection capabilities across some certain text origins.

6 Conclusion

In conclusion, our paper presents a comprehensive approach to SemEval-2024 Task 8 (Subtask B), focusing on the detection of machine-generated text and its attribution to specific Large Language Models (LLMs). Leveraging Transformer-based methods, pre-trained language models (PLMs), Contrastive Learning (CL), and Data Augmentation techniques, we have developed a robust detection system achieving a peak accuracy of 74.69%. Our findings underscore the effectiveness of integrat-

ing CL into the classification process and highlight the strength of leveraging diverse PLMs for improved performance in discerning between human and machine-generated text.

Table 6: Accuracy(%) of the three selected model configurations' performances across different epochs on the enriched test set. We select $\text{RoBERTa}_{\text{BASE}}$ with DualCL(λ=0.02), all-roberta-large-v1 with SCL(λ=0.2) and GPT-2 Small with SCL(λ=0.2) to observe the performance dynamics, because among the best performed model configurations they have long enough converge processes. The dashes in the table indicate no model checkpoint is saved in that epoch due to no increase in the validation accuracy. Saved model checkpoints in the later epochs have higher validation accuracy.

ClusterCore at SemEval-2024 Task 7: Few Shot Prompting With Large Language Models for Numeral-Aware Headline Generation

Monika Singh, Sujit Kumar, Tanveen and Sanasam Ranbir Singh
Indian Institute of Technology Guwahati
{s.monika, sujitkumar, t.tanveen , ranbir}@iitg.ac.in

Abstract

The generation of headlines, a crucial aspect of abstractive summarization, aims to compress an entire article into a concise, single line of text despite the effectiveness of modern encoder-decoder models for text generation and summarization tasks. The encoder-decoder model commonly faces challenges in accurately generating numerical content within headlines. This study empirically explored LLMs for numeral-aware headline generation and proposed few-shot prompting with LLMs for numeral-aware headline generations. Experiments conducted on the *NumHG* dataset and NumEval-2024 test set suggest that fine-tuning LLMs on *NumHG* dataset enhances the performance of LLMs for numeral aware headline generation. Furthermore, few-shot prompting with LLMs surpassed the performance of fine-tuned LLMs for numeral-aware headline generation.

1 Introduction

News articles are one of the most important sources of information in everyday life. News headlines are vital in selecting which news seems relevant to read. As delineated in studies (Wei and Wan, 2017; Gabielkov et al., 2016), headlines play a significant role in making news viral on social media and influencing readers' opinions (Tannenbaum, 1953). Inaccurate, incongruent or misinformation headlines also lead to the spread of misinformation and disinformation over digital platforms (Chesney et al., 2017; Kumar et al., 2022, 2023). Consequently, generating an accurate headline for a news body is essential. Therefore, ensuring the accuracy of headlines is essential for maintaining the credibility and usefulness of news publications. The task of headline generation, which is a form of text summarization, aims to condense a lengthy source text into a concise summary. This summary, typically presented as a headline, encapsulates the main points of the original text, providing readers with a quick overview of the content (Huang et al., 2023).

In earlier studies on headline generation, various sequence-to-sequence and encoder-decoder methods have been employed to extract relevant headlines from news articles (Nallapati et al., 2016; Chen et al., 2020; Paulus et al., 2018; Song et al., 2019). However, encoder-decoder methods faced challenges in processing large sequences of text. To address these limitations, recent studies (Radford et al., 2018; Devlin et al., 2018; Lewis et al., 2019; Liu et al., 2019; Raffel et al., 2020) have proposed transformer-based models for headline generation by summarizing news articles. While transformer-based models have indeed showcased enhanced capabilities in handling longer text sequences and have exhibited promising outcomes in headline generation tasks; it is noteworthy that their performance in numeral-aware headline generation tasks need to be consistently superior. Despite their overall advancements, transformer-based models may face challenges in accurately incorporating and representing numeric information within generated headlines. Motivated by such observations, the study (Huang et al., 2023) proposed numeral aware headline generation datasets.

This paper introduces our proposed approach and provides a comprehensive analysis of the task of *Numeral-Aware Headline Generation* (Task 3 (2)). Our proposed methodology leverages Few-shot prompting with LLMs, which involves applying few-shot learning techniques to large language models (LLMs) for numeral-aware headline generation tasks. We conduct our experiments using the NumHG dataset (Huang et al., 2023) and the test set provided by the organizer of NumEval Task-3(2). Our experimental results suggest that few-shot prompting-based methods with LLMs are efficient for numeral-aware headline generation.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1719–1726

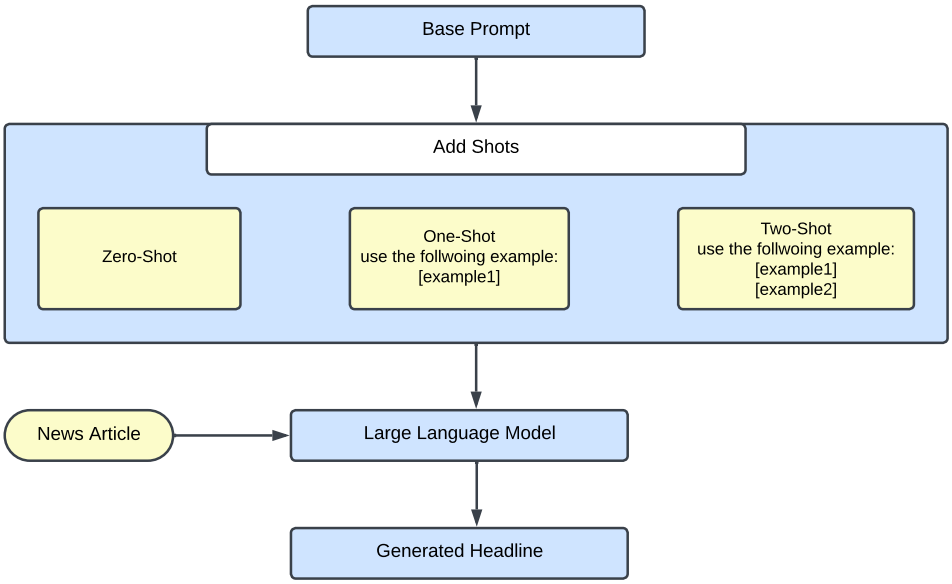

Figure 1: Working diagram of the proposed method.

2 Related Work

Headline generation, a type of text summarization, condenses lengthy source text into a brief summary, usually presented as a headline. This summary captures the main points of the original text, offering readers a quick overview (Huang et al., 2023). Summarization involves extractive and abstractive methods: Extractive selects key sentences, while abstractive generates novel summaries. In prior research investigating headline generation, a range of sequence-to-sequence and encoder-decoder approaches were employed to derive relevant headlines from news articles (Nallapati et al., 2016; Chen et al., 2020; Paulus et al., 2018; Song et al., 2019). However, these approaches encountered challenges, particularly in processing lengthy text sequences. The limitations of encoder-decoder methods in handling large sequences of text hindered their effectiveness in accurately summarizing news articles. To address these shortcomings and enhance the capability of headline generation models, recent research has focused on developing transformer-based architectures (Radford et al., 2018; Devlin et al., 2018; Lewis et al., 2019; Liu et al., 2019; Raffel et al., 2020). Similarly, Large Language Models LLMs such as GPT (Radford et al., 2019), BART (Lewis et al., 2020), T5 (Raffel et al., 2020) and LLaMA (Touvron et al., 2023) have also shown promising state-of-the-art models performance for text generation and summarization task.

Most studies above emphasize word selection and sentence structure, overlooking the significance of accurate numeric values in news headlines. Addressing this gap in the literature, a study (Huang et al., 2023) introduced numeral-aware headline generation datasets to facilitate the development of numeral-aware headline generation methods. Considering the superior performance of Large Language Models (LLMs) in text generation and summarization tasks (Basyal and Sanghvi, 2023), this study conducts an empirical study of LLMs for numeral-aware headline generation. Additionally, an error analysis is performed on the responses of LLMs for numeral aware headline generation. Subsequently, we propose Few-shot prompting with Large Language Models (LLMs) for numeral-aware headline generation.

3 Proposed Method

As mentioned above, the paper aims to study the effect of two important aspects of numeral aware headline generations. First, we study the effectiveness of large language models (LLMs) for numeral-aware headline generations. Second, we propose a few prompting-based methods for numeral-aware headline generations.

3.1 Large Language Models (LLMs):

Considering the effectiveness of LLMs in text summarization (Basyal and Sanghvi, 2023) and headline generations task (Ding et al., 2023). We fine-

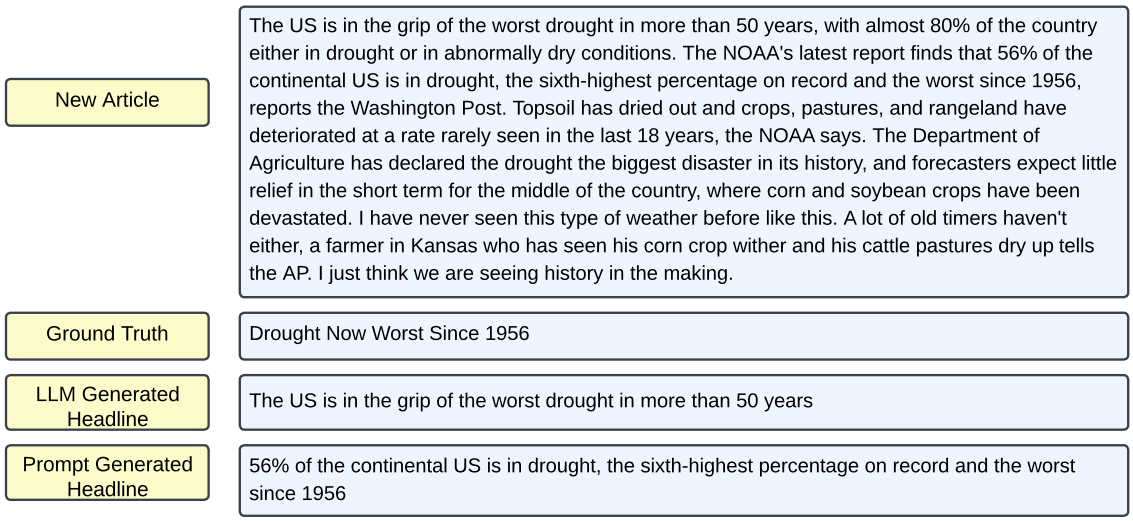

Figure 2: Presents an example comparison of a headline generated by a fine-tuned $T5$ model and a headline generated by a $T5$ model with three shot prompt

tune RoBERTa[1] (Rothe et al., 2020), *Generative Pre-trained Transformer* (GPT-2)[2] (Radford et al., 2019), *Bidirectional and Auto-Regressive Transformers* **BART**[3] (Lewis et al., 2020) and ***T**ext-**T**o-**T**ext **T**ransfer **T**ransformer* **T5**[4] (Raffel et al., 2020) for numeral aware headline generations.

3.2 Few Shot Prompting:

In-context learning denotes a methodology whereby language models acquire proficiency in tasks by utilizing a limited number of examples provided as demonstrations (Dong et al., 2022). The utilization of shot prompting guides the model's output. This approach encompasses three distinct strategies: zero-shot, one-shot, and few-shot prompting. Zero-shot prompting, also called direct prompting, entails assigning a task to the model without providing specific examples, relying solely on the knowledge the model has gained through its training. In contrast, one-shot and few-shot prompting involve presenting examples or 'shots' to the model during runtime, which are references for the expected response's structure or context (Reynolds and McDonell, 2021). The model then utilizes these examples to perform the task. Because these examples are presented in natural language, they offer an accessible method for interacting with language models and facilitate the integration of human knowledge into these models through demonstrations and templates. As evidenced by the findings of several recent studies (van Zandvoort et al., 2023; Schick and Schütze, 2021; Luo et al., 2022), the integration of few-shot learning techniques coupled with prompt instructions has demonstrated a noteworthy enhancement in the quality of text generated or summarized by large language models (LLMs). These observations underscore the potential effectiveness of leveraging few-shot learning methodologies alongside prompt guidance to augment the capabilities of LLMs in generating text of higher quality and relevance. Motivated by such observations regarding few-shot learning with quick text generation and summarization instructions, this study proposes few-shot and prompt engineering-based methods for numeral-aware headline generations. Figure 1 presents the working diagram of our few shot prompting with LLMs-based numeral aware headline generation method. There are three key components of our proposed method, namely:

1. **Few Shot:** We explore three distinct strategies of few-shot prompting: zero-shot, one-shot, and few-shot prompting. These strategies encompass varying degrees of example provision to guide the model's output, allowing for a comprehensive analysis of their respective efficacy in facilitating model performance across different tasks. We have used three examples for methods in our study, which will

[4] https://huggingface.co/Michau/t5-base-en-generate-headline

be considered three-shot prompting.

2. **Base Prompt:** Here, we provide instruction to a model which guides the model in numeral-aware headline generations. Below is one example of prompt instruction we provided to LLMs for generating numeral-aware headlines.
   Prompt (P1) : `Generate a short headline for a given news article. The headline should be concise and small but represent the content of the news body. The headline may contain a number that could be obtained by performing simple arithmetic operations like addition, subtraction, division, and multiplication or obtained by copying the same valid number from the news article if required to summarize the article.`

3. **Large Language models (LLMs):** This study considers three prominent large language models: GPT (Radford et al., 2018), T5 (Raffel et al., 2020), and LLaMA [5] (Touvron et al., 2023). These models generate headlines that accurately represent given news bodies, utilizing input consisting of the news body itself, prompt instructions, and a few-shot example.

4 Experimental Results and Discussions

4.1 Dataset

We consider the NumHG dataset curated by study (Huang et al., 2023) for training models and the test set provided by *NumEval* organizers for evaluating models. Table 4 presents the characteristics of experimental datasets.

4.2 Experimental Setups

This study incorporates several performance evaluation metrics to assess the effectiveness of models, namely *Recall-Oriented Understudy for Gisting Evaluation* (ROUGE)[6] (Lin, 2004), BERTScore[7] (Zhang* et al., 2020), MoverScore(Zhao et al., 2019) and Num Acc. (Huang et al., 2023) as performance evaluation metrics to evaluate the performance of models. These metrics provide comprehensive insights into various aspects of model performance, including linguistic quality, content overlap, semantic similarity, and numeral accuracy, respectively. Table 3 presents the details of experimental hyperparameters. To replicate the findings in this work, visit GitHub `https://github.com/MONIKASINGH16999/ClusterCore_SemEval2024Task7` to access our code repository.

4.3 Results and discussion

Table 1 illustrates the performance metrics of large language models (LLMs) across various configurations, including *Pretrained*, *Fine-tuned*, and *Shot Prompting*, evaluated on a designated test dataset. This evaluation aims to provide insights into the efficacy and adaptability of LLMs in different settings for numeral-aware headline generation. Initially, we examine the response of LLMs in both the *Pretrained* and *Fine-tuned* setups for numeral-aware headline generation. From Table 1, it is evident that the $T5$ model consistently outperforms the $RoBERTa$, GPT, and $BART$ models across the test dataset in both the *Pretrained* and *Fine-tuned* setups. From such observations, we can claim that the $T5$ model is more suitable for the headline generation tasks compared to $RoBERTa$, GPT, and $BART$. Referring to Table 1, it becomes apparent that fine-tuning these models over the training set enhances their performance and headline generation capability. Subsequently, we curate a subset of the dataset consisting of fifty news headlines and corresponding news bodies. This subset is formed by selecting pairs from the validation dataset where the presence of numeral figures in the headline is deemed particularly significant in accurately representing the content of the news body. Upon manual inspection of the news headlines generated by fine-tuned $RoBERTa$, GPT, $BART$, and $T5$ models over the subset of the dataset comprising fifty samples, our observations suggest that while the generated headlines are contextually similar to the ground truth headlines and effectively represent the content of the news body, the accuracy in representing numeral figures is notably average. From these observations, we can conclude that fine-tuned $RoBERTa$, GPT, $BART$, and $T5$ models exhibit high efficiency in headline generation but display slightly lower efficiency in numeral-

aware headline generation. One possible reason behind this discrepancy could be the requirement for complex mathematical reasoning capabilities in numeral-aware headline generation tasks. To enhance the performance of models in numeral-aware headline generation tasks, this study employs shot prompting methods. Shot prompting methods offer several advantages, primarily providing prompts to models that serve as instructions, guiding them on what specific task needs to be performed and how to approach it. Additionally, shot prompting methods supply a few examples to the models, aiding them in inference and comprehension for the underlying task. This approach enables the models to better understand the task and generate more

Table 4: present the characteristics of experimental datasets. Here, #sample indicates the number of news headlines and body pairs in the dataset. Similarly, #head and #Word indicate the average number of words in the headline and news body. Whereas #sent indicates the average number of sentences in the news body and #num indicates the average number of numeric figures in the news body.

accurate and contextually relevant headlines containing numeral figures. We consider GPT, $T5$ and $LLaMA$ in few shot prompt settings. From Table 1 it is apparent that $LLaMA$ the model outperforms GPT and $T5$ with few shot prompting. Similarly, it is also evident that $LLaMA$ a model with few shot prompting outperforms $RoBERTa$, GPT, $BART$, and $T5$ models in *Pretrained* and *Fine-tuned* setups. Our manual inspection of the news headlines generated by the GPT, $T5$, and $LLaMA$ models utilizing few-shot prompting over a subset of the dataset containing fifty samples suggests that the implementation of few-shot prompting enhances the efficiency of numeral-aware headline generation by the models. Based on the findings presented in Table 1, it's clear that few-shot prompting using the $LLaMA$ model outperforms both few-shot prompting with $T5$ and GPT. As a result, we chose to submit headlines generated by the few-shot prompting with the $LLaMA$ model as our final system for evaluation at NumEval-2024. We could have fine-tuned the $LLaMA$ model for better results, but we have only used the pre-trained $LLaMA$ model due to resource constraints.

Table 2 presents the human evaluation of headlines generated by our proposed system (few-shot

prompting with $LLaMA$), which were submitted to NumEval-2024. The organizers of NumEval-2024 conducted this human evaluation of the generated headlines. It is apparent from Table 2 that our proposed system (few-shot prompting with $LLaMA$) achieved the top rank in recommending 100 news.

5 Error Analysis

This study also conducts an error analysis to examine the strengths and weaknesses of large language models (LLMs) across different setups for numeral-aware headline generation. Through this analysis, we aim to identify patterns of errors and limitations inherent in the models, providing valuable insights into areas for improvement and optimization in future model development and training methodologies. We selected fifty news headline-body pairs, where numeral figures in the headline are crucial for accurately representing the news content. Our examination of the generated headlines by the models revealed the following insights: (i) $RoBERTa$ the model generates a headline, which is representative of the news body, however in some instances is failed to consider the numeric value for headline generation. Consequently, $RoBERTa$ is deemed unsuitable for numeral-aware headline generation. However, fine-tuning the $RoBERTa$ model enhances generated headline quality, which is also evident by the performance comparison between its *Pretrained* and *Fine-tuned* setups. (ii) The $BART$ models, whether in the *Pretrained* or *Fine-tuned* setups, demonstrate proficiency in generating efficient headlines that include valid numeric values. However, it is noteworthy that the inclusion of valid numeric values in headlines is more prevalent in the fine-tuned models compared to those without fine-tuning. (iii) The $T5$ models, in both the *Pretrained* and *Fine-tuned* setups, consistently produced headlines with more efficient and valid numerical values compared to $RoBERTa$, $BART$, and GPT. This indicates that $T5$ models are particularly more effective in numeral aware headline generations. (iv) The $LLaMA$ model stands out for its ability to generate accurate and efficient headlines containing valid numerical values when compared to $RoBERTa$, $BART$, GPT, and $T5$. This suggests that the $LLaMA$ model excels in incorporating precise numeric information into its generated headlines, surpassing other models in this aspect. Figure 2 presents an example' comparison between headline generated by fine-tuned $T5$ model and headline generated by $T5$ with three shot prompt. From Figure 2, it is apparent that the headline generated by $T5$ with three three-shot prompts better represents the news body compared to the headline generated by the fine-tuned T5 model. This further validates our claim that a few-shot prompt helps the LLMs generate headlines.

6 Conclusion and Future work

This study conducted an empirical research on LLMs for numeral-aware headline generation and proposed a few shots prompting with LLMs for numeral-aware headline generation. We conduct our experiments on *NumHG* and test set data provided by the organizer of NumEval-2024. Our experimental results suggest that finetuning LLMs over *NumHG* dataset improves the performance of numeral-aware headline generation. Further, few shot prompting with LLMs outperform fine-tuned LLMs for numeral-aware headline generation. This study identifies prompt tuning using LLMs for numeral-aware headline generation.

Abstract

Text classification is an important task in natural language processing. **H**ierarchical **T**ext **C**lassification (**HTC**) is a subset of text classification task-type. HTC tackles multi-label classification challenges by leveraging tree structures that delineate relationships between classes, thereby striving to enhance classification accuracy through the utilization of inter-class relationships. Memes, as prevalent vehicles of modern communication within social networks, hold immense potential as instruments for propagandistic dissemination due to their profound impact on users. In SemEval-2024 Task 4, the identification of propaganda and its various forms in memes is explored through two sub-tasks: (i) utilizing only the textual component of memes, and (ii) incorporating both textual and pictorial elements. In this study, we address the proposed problem through the lens of HTC, using state-of-the-art hierarchical text classification methodologies to detect propaganda in memes. Our system achieved first place in **English Sub-task 2a**, underscoring its efficacy in tackling the complexities inherent in propaganda detection within the meme landscape.

1 Introduction

1.1 Propaganda Techniques in Memes

Propaganda can be defined as the deliberate dissemination of information, often with a biased or misleading nature, aimed at promoting or publicizing a particular political cause, ideology, or viewpoint. This communication tactic takes various forms, including persuasive messaging, advertising campaigns, and the dissemination of ideas through media channels. The primary objective of propaganda is to influence people's beliefs, attitudes, or behaviors towards a specific agenda or ideology. Examples of propaganda can range from political advertisements designed to sway voters, to ideological messaging spread through social media platforms.

Memes have emerged as one of the most prevalent communication tools in digital media. Their utilization of both text and image allows for the transmission of substantial information, underscoring the critical need for detecting propaganda within them.

1.2 Task Overview

SemEval-2024 Task 4 (Dimitrov et al., 2024) addressed the challenge of propaganda technique detection within memes in three sub-tasks (**1**, **2a**, **2b**) and four languages (**English**, **Bulgarian**, **North Macedonian**, **Arabic**). The organizers focused on different aspects of meme analysis: **Task 1** concentrated on detecting propaganda techniques from the textual content of memes, while **Tasks 2a** and **2b** respectively tackled the identification of techniques and the presence or absence of propaganda in a multimodal format. The SemEval-2024 Task 4 introduced three distinct sub-tasks across four languages. **English** language data was provided in supervised learning, whereas **Bulgarian**, **North Macedonian**, and **Arabic** language datasets were presented in a zero-shot learning framework. It is important to note that this task presented propaganda techniques in the form of a hierarchy, illustrated in Figure 1.

1.3 Hierarchical Text Classification

Hierarchical **T**ext **C**lassification (**HTC**) is a method wherein classes are organized in a hierarchical structure. This approach aims to enhance the accuracy of text classification models by leveraging the relationships within this hierarchy. We used the previous state-of-the-art (SOTA) hierarchical text classification model (**HPT** (Wang et al., 2022b)) to identify propaganda techniques in memes based on the hierarchical structure of propaganda techniques.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1727–1732

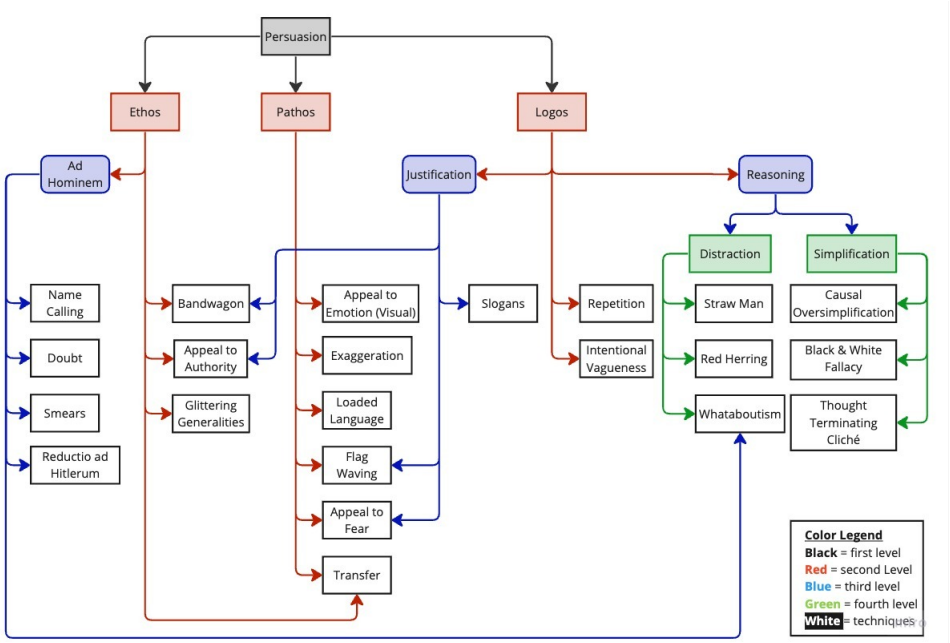

Figure 1: The diagram depicts propaganda techniques, represented as white nodes, organized in a directed acyclic graph (DAG). This image is sourced from the task description paper (Dimitrov et al., 2024)

In the multimodal section, we focused only on the textual content of memes, disregarding the accompanying images.

1.4 Our Discoveries

Our investigation revealed that employing hierarchical text classification models significantly enhanced text classification accuracy compared to various other methodologies and baseline approaches. Intriguingly, our decision to exclude the image component from consideration in **Task 2** resulted in the highest accuracy among all participating teams in **Task 2a**. We attribute this outcome to the inherent limitations of multimodal models in comprehending the intricate semantic relationships between images and text, particularly in the context of propaganda detection. Incorporating the image data would likely have increased model complexity and reduced accuracy, as observed in the performance of other teams. For the multilingual part, we rely on translation for non-English memes.

We utilized the HPT (Wang et al., 2022b) model source code[1], making necessary modifications to adapt it to our specific use case. The final version of our system's code has been made publicly available on GitHub for transparency and reproducibility[2].

[2]https://github.com/language-ml/SemEval-2024-Task-4

2 Background

2.1 Dataset

The dataset utilized in this study comprises both textual and pictorial content extracted from memes along with associated propaganda technique tags (Dimitrov et al., 2024). Specifically, **Task 1** involves texts extracted from memes alongside propaganda technique tags, except **Loaded Language** and **Name Calling/Labeling** techniques, which are not included in the tags. **Task 2a** expands upon **Task 1** by incorporating images of memes, thereby presenting a multi-label classification task in a multi-modal format. **Task 2b** is similar to **Task 1a**, except that it involves binary classification regarding the presence or absence of propaganda. The organizers released the three tasks for the English language in a supervised manner and for **English**, **Bulgarian**, **North Macedonian**, and **Arabic** language in a zero-shot manner. The organizers released the dataset in three parts: training, validation, and testing sets.

2.2 Propaganda Detection

In recent research, the task of detecting propaganda in various forms of media has gained significant attention. (Da San Martino et al., 2020) introduce a task focused on identifying propaganda in news articles, comprising two subtasks: detecting spans containing propaganda and identifying

specific propaganda techniques from a predefined set of 14 techniques. On the other hand, (Dimitrov et al., 2021) presents a task aimed at detecting propaganda techniques in memes, without considering the hierarchy relation between techniques.

2.3 Hierarchical Text Classification

In this paper, we categorize existing hierarchical text classification models into three main categories: local methods, global methods, and generative methods.

1. **Local Methods**: Local methods tackle the hierarchical classification problem by addressing individual categories within the hierarchy. (Banerjee et al., 2019) employ binary classifications for each category and mitigate the issue of data scarcity at lower levels through transfer learning from parent to child categories. (Kowsari et al., 2017) adopt a strategy of training a multi-label classifier for each node, while (Dumais and Chen, 2000) employ SVM per level. (Shimura et al., 2018) leverage multiple CNNs to address classification at each level of the hierarchy.

2. **Global Methods**: Global methods take a holistic approach by employing a single classifier to predict all classes within the hierarchical structure. HiAGM (Zhou et al., 2020) utilizes two encoders, TreeLSTM and GCN, to derive the tree representation. They introduce two models, HiAGM-LA and HiAGM-TP, which respectively utilize attention mechanisms on classes and text propagation within the graph encoder. (Deng et al., 2021) aims to enhance the HiAGM by using information theory. (Mao et al., 2019) frame the hierarchical classification as a reinforcement learning problem, seeking an optimal policy for traversing suitable labels within the tree. (Zhu et al., 2023) employ structural entropy to construct the code tree, followed by using HiAGM-TP. (Wang et al., 2022a) introduce contrastive learning and positive samples to incorporate hierarchy into the text encoder. (Chen et al., 2021) attempt to unify label embedding and text embedding in a single space using triplet loss. In (Wang et al., 2022b), soft prompt tuning is employed, whereby each row of the hierarchy is fed into a graph attention network. Subsequently, the representations obtained from each row are provided as input to the BERT model. The model is trained to predict the correct label corresponding to the output of these tokens.

3. **Generative Methods**: (Yu et al., 2022) addressed the challenge of hierarchical classification by employing a method that generates a sequence of labels. Their approach involves training a T5 model to generate paths within the hierarchy. (Kwon et al., 2023) also tackled hierarchical classification through label generation. Notably, their approach enabled the model to generate n-grams not explicitly present in the predefined problem categories.

3 System overview

In **sub-task 1**, we addressed the proposed problem using hierarchical text classification and used a state-of-the-art (SOTA) HTC model for propaganda technique detection with some modifications. We utilized HPT (Wang et al., 2022b) as the hierarchical text classifier.

Convert Task to HTC Problem: The hierarchical structure of propaganda techniques was represented as a **D**irected **A**cyclic **G**raph (DAG). The hierarchy of propaganda techniques is depicted in Figure 1. To use the HPT model (Wang et al., 2022b), it was imperative to transform this DAG into a hierarchical tree. This transformation involved converting nodes with multiple parents into new nodes. For instance, the node "Whataboutism" with two parents, "Distraction" and "Ad hominem" was split into two nodes labeled "Distraction_Whataboutism" and "Ad hominem_Whataboutism". Two methods can be employed for organizing the first level of the hierarchy tree: **(1)** placing two nodes labeled "propagandistic" and "non-propagandistic" at the initial level, followed by the entire hierarchy of propaganda techniques under the "propagandistic" node, or **(2)** directly utilizing the hierarchy tree without this initial categorization. Our observations indicate that **method 1** yields superior performance.

Additional Datasets: We utilized two additional datasets, (Da San Martino et al., 2020) and (Dimitrov et al., 2021), as supplementary sources for training our model. In employing the data from (Da San Martino et al., 2020), we focused on its **TC sub-task**, which involves identifying propaganda techniques within news articles. The format of the data provided by (Da San Martino et al.,

	Baseline	0.22705	0.29375	15/15

Table 2: The table presents the performance results of the hierarchical text classification model in comparison to both the baseline model and the best-performing model in sub-task 2b across four different languages: English, Bulgarian, North Macedonian, and Arabic. For each sub-task, the Macro F1 and Micro F1 are reported.

2020) consists of spans within the news text annotated with corresponding propaganda techniques. To integrate this data into our model, we adopted an approach where if a span within a news article contained a propaganda technique, we assigned that particular technique to the entire article. It's important to note, however, that the dataset from (Da San Martino et al., 2020) does not encompass all the propaganda techniques featured in the SemEval-2024 task 4 dataset. Our analysis revealed that utilizing the data from (Da San Martino et al., 2020) in this manner led to a decrease in model accuracy. We attribute this reduction to two primary factors: **(1)** the broad attribution of propaganda techniques to entire news articles and **(2)** the differing distribution characteristics between news articles and meme text. The task of detecting propaganda techniques from memes, as outlined in (Dimitrov et al., 2021), served as another additional dataset for our study. Our analysis revealed that incorporating the data provided by (Dimitrov et al., 2021) enhanced the accuracy of our model.

[CLS] Token: Many memes comprise multiple sentences distributed across different picture boxes, delineated by "\n\n" in the dataset. To establish coherence between sentence boundaries, we utilized **"[CLS]" Token** between sentences. We observed that the inclusion of this token between sentences improves the performance of the model.

Other Tasks: In subtasks **2a** and **2b**, the image component of memes was disregarded, and only the textual content was provided to the model. Furthermore, for all the sub-tasks that are non-English, we used Google Translation API to translate them into English and used the model of the previous part

Baseline: According to the task description, the baseline for each sub-task is the most common label.

4 Experimental Setup

The organizers provided the data in three parts: training, evaluation, and testing sets. We employed the HPT model, utilizing the **bert-base-uncased** language model for our study. For training purposes, we combine the training and evaluation data, randomly picking **10%** for evaluation, and reserving the remaining **90%** for training. Our training comprised a batch size of **8** and a learning rate of **3e-5**. The remaining hyperparameters are similar to the HPT paper. To use additional data, we initially trained the model on this additional dataset before continuing training on the task data.

5 Results

The results for **sub-tasks 1** and **2a** are presented in Table 1, while the outcomes for **sub-task 2b** are shown in Table 2. Our system has exhibited strong performance in English language Task 1. In **sub-task 2a** for English, despite our model solely leveraging textual content from memes without considering images, it achieved the top ranking. We attribute this observation to two main factors: **(1)** The challenge of discerning the connection between images and text in propaganda detection **(2)** A substantial portion of the requisite information for propaganda detection likely resides within the textual component in addition to the image itself.

However, our system encountered challenges in non-English sub-tasks, displaying poor performance. We attribute this to potential translation errors and the absence of a pre-processing pipeline for these languages.

6 Conclusion

In this study, we addressed the challenge of detecting propaganda techniques in memes through two distinct sub-tasks: textual and multimodal analysis, conducted in both supervised and zero-shot settings across various languages. To tackle this issue, we employed hierarchical text classification. In the multimodal sub-tasks, we focused solely on the textual content of memes, achieving notable performance. However, when dealing with sub-tasks in languages other than English, our system's performance suffered. We concluded by presenting the metrics and conducting a thorough analysis of the results. Moving forward, our next objective is to develop a better hierarchical text classification model with better performance.

Abstract

In this paper, we outline our submission for the SemEval-2024 Task 9 competition: 'BRAIN-TEASER: A Novel Task Defying Common Sense'. We engage in both sub-tasks: Sub-task A-Sentence Puzzle and Sub-task B-Word Puzzle. We evaluate a plethora of pre-trained transformer-based language models of different sizes through fine-tuning. Subsequently, we undertake an analysis of their scores and responses to aid future researchers in understanding and utilizing these models effectively. Our top-performing approaches secured competitive positions on the competition leaderboard across both sub-tasks. In the evaluation phase, our best submission attained an average accuracy score of 81.7% in the Sentence Puzzle, and 85.4% in the Word Puzzle, significantly outperforming the best neural baseline (ChatGPT) by more than 20% and 30% respectively.

1 Introduction

In Natural Language Processing (NLP), reasoning serves as the cognitive backbone, enabling systems to transcend mere language comprehension and delve into sophisticated understanding. Despite the excellence of Large Language Models (LLMs) in several linguistic tasks, their reasoning capabilities are still questionable to a non-negligible extend (Floridi and Chiriatti, 2020; Bender et al., 2021; Kauf et al., 2022; Zhang et al., 2023; Shi et al., 2023; Tyen et al., 2024; Giadikiaroglou et al., 2024), often posing the fundamental concerns of whether they can indeed reason or memorize exhaustively (Yuan et al., 2022).

Such limitations can be probed via well-crafted datasets and benchmarks, showcasing varying LLM deficiencies at a time. As the core of the current paper, BrainTeaser (Jiang et al., 2023b, 2024b) incorporates problems that stress models to think "out-of-the-box"; to this end, the key novelty of BrainTeaser is that in order to answer correctly, models need to defy default senses of concepts and common associations. Surprisingly, state-of-the-art (SoTa) LLMs, such as ChatGPT can only exhibit a maximum accuracy of ∼60% when solving BrainTeaser riddles, demonstrating an inherently limited reasoning ability in unconventional thinking.

Thus, assuming that large-scale training and prompting may not always serve as universally applicable solutions towards flexible reasoning, we move one step back and leverage transfer learning techniques starting from smaller models based on masked language modelling, such as BERT (Devlin et al., 2019) and consequent BERT-based encoders. Then, we proceed with similar techniques on LLMs, aiming to showcase that significant performance advancements using a small set of in-domain data for parameter updating can be achieved in comparison to merely querying the model's prior knowledge via prompting. Therefore, our contributions are:

1. We perform lightweight tuning on smaller encoder models and LLMs, significantly outperforming the reported baselines.
2. We transform the multiple-choice problem to a binary classification one, aiming to explore diverging reasoning paths for models.
3. We ground final performance on the models' "prior knowledge" in related problems.
4. We delve into models' frequent failures to obtain a deeper understanding of reasoning cues that make models struggle the most.

Our code is available on GitHub [1].

els and especially LLMs (Sun et al., 2023). Reasoning challenges incorporate commonsense reasoning (Richardson and Heck, 2023), involving inference regarding everyday situations, mathematical reasoning (Lu et al., 2023), referring to the ability of solving mathematical problems, logical reasoning (Yang et al., 2023), which includes the systematic deduction of conclusions based on established principles and formal rules, causal reasoning (Gendron et al., 2024), which studies cause-and-effect relationships explaining why an event leads to another, and several other sub-tasks (Vashishtha et al., 2020; Wei et al., 2023; Petersen and van der Plas, 2023). In terms of reasoning evaluation, BigBench (Srivastava et al., 2023) comprises 204 reasoning tasks, targeting to explore the related capabilities of recent LLMs. Several dedicated datasets have been developed to tackle different reasoning challenges, including commonsenseQA (Talmor et al., 2019), WinoGrande (Sakaguchi et al., 2019), RiddleSense (Lin et al., 2021) and others; most of these datasets are incorporated in Tasksource (Sileo, 2023). Especially RiddleSense questions aspects of reasoning close to BrainTeaser (Jiang et al., 2023b, 2024b).

3 Task and Dataset Description

The BrainTeaser task at SemEval-2024 (Jiang et al., 2023b, 2024b) features lateral thinking puzzles presented as multiple-choice questions (QAs). Each question offers four options, with one being the correct answer and the others serving as distractors. Additionally, the final option is always "None of above". It consists of two sub-tasks, *Task A*: **Sentence Puzzle** and *Task B*: **Word Puzzle**. In addition to the original puzzles, the dataset includes adversarial subsets created by manually modifying the original brain teasers while preserving their reasoning paths. The original data were perturbed in two ways: First, there is *semantic reconstruction* of each original question without altering the answers or the distractors. Second, the original data underwent *context reconstruction*, wherein the original reasoning path remains intact, but the brain teaser describes a new situational context. Overall, the dataset used for training and evaluation consists of triplets of data: original, semantic, and context reconstruction. Table 1 provides an example of the triplets of data that constitute the dataset.

***Task A*: Sentence Puzzle** In this sub-task, the sentence pairs are crafted in a manner that makes it relatively easy for humans to discern the correct statement, yet challenging for systems, even those equipped with commonsense understanding. Table 2 contains examples of the Sentence Puzzle dataset (on the left). The training data consists of 169 distinct multiple-choice QA sets, each accompanied by its semantic and context reconstructions, resulting in a total of 507 multiple-choice questions (3×169).

Question	Choice
Original	
What kind of nut has no shell?	A peanut.
	A doughnut.
	A walnut.
	None of above.
Semantic Reconstruction	
Which nut doesn't have a shell?	**A doughnut.**
	A walnut.
	A peanut.
	None of above.
Context Reconstruction	
Which type of bell doesn't make a sound?	A fire bell.
	A cow bell.
	A bluebell.
	None of above.

Table 1: Illustration of the structure of each sub-task's dataset, showcasing the original statement along with its two adversarials.

***Task B*: Word Puzzle** involves word-type brain teasers, where the answer defies the default meaning of the word and focuses on the letter composition of the question. The training dataset comprises 132 multiple-choice QAs, each accompanied by its semantic and context reconstructions, resulting in a total of 396 multiple-choice QAs (3×132). These brain teaser categories include puns, homophones, ambiguous words, and various other linguistic puzzles, as showcased in the examples provided in Table 2 on the right-hand side. The Word Puzzle sub-task pose challenges not only for systems but also for humans in discerning the correct answer.

Data statistics The BrainTeaser dataset comprises 3 data splits, namely train, development (used during the practice phase), and the hidden test set, which was used for evaluation. Statisics are provided in Table 3. Throughout the evaluation phase, the leaderboard was kept concealed.

Evaluation Metrics Both sub-tasks are assessed via accuracy metrics to gauge the performance of participating systems in two ways. First, instance-based accuracy evaluates each question individually, considering original questions and their seman-

Sentence Puzzle		*Word Puzzle*	
Question	**Choice**	**Question**	**Choice**
A man shaves everyday, yet keeps his beard long.	**He is a barber.**	What has toes but no feet or legs?	Cabbages.
	He wants to maintain his appearance.		**Tomatoes.**
	He wants his girlfriend to buy him a razor.		Onions.
	None of above.		None of above.
You go to the doctor because you're sick, and he gives you three medicines to take every half hour. How long do the drugs keep you going?	One and a half hours.	What did the little lobster get on its math test?	**Sea-plus.**
	Two hours.		Very-bad.
	An hour.		Very-Good.
	None of above.		None of above.
How many times can you deduct 10 from 100?	**Once.**	What's the beginning of an argument?	The letter T.
	Infinite time.		**The letter A.**
	Twice.		The letter U.
	None of above.		None of above.

B - Word Puzzle	396	96	96

Table 3: Data statistics.

tic and context adversarials. This metric provides a detailed understanding of a model's proficiency in reasoning through various scenarios. In contrast, group-based accuracy takes a broader perspective, assessing questions and associated adversarials as cohesive groups. Each group consists of three questions, and a model scores 1 only if it correctly solves *all* questions in a group. This approach evaluates the system's holistic performance in navigating through lateral thinking challenges. The combined use of instance-based and group-based accuracy metrics provides comprehensive insights into the capabilities of participating systems in tackling the complexities of both sub-tasks.

4 Methods

We focus on tuning language models belonging into two categories. First, we fine-tune variations of *encoder* models, namely BERT (Devlin et al., 2019), RoBERTa-large (Liu et al., 2019) and DeBERTaV3-base (He et al., 2023), to assess the impact of transfer learning using various datasets requiring similar reasoning abilities, apart from BrainTeaser. We study the problem using the provided *multi-choice* setup, but we also transform it into a *binary* classification task. Secondly, the encoders' results are compared with those obtained from *fine-tuned LLMs* using the BrainTeaser dataset. To achieve this, we fine-tune Llama 2 (Touvron et al., 2023b), Phi-2 (Gunasekar et al., 2023) and Mistral-7b (Jiang et al., 2024a), which have already demonstrated enhanced reasoning abilities. In this regard, we examine the effect of the model size on our task, which has already been reported in the literature to significantly influence the reasoning abilities of the models (Touvron et al., 2023b; Wei et al., 2022), along with other tuning hyperparameters. Model details are presented in App. A.

4.1 Encoder models

Pre-training First, we evaluate the effects of the pre-training on our task. Thus, we select two variations of each encoder: the *vanilla* one (using the default pre-trained basis and fine-tuned on BrainTeaser data only) and one that has undergone additional pre-training using supplementary commonsense reasoning datasets before fine-tuned on BrainTeaser. In the second case, we use the following pre-trained models: (1) BERT-SE: a BERT-base-uncased version pre-trained on the multiple-choice dataset used in SemEval-2020 Task 4b (Wang et al., 2020) (2) RoBERTa-WNGRD: a RoBERTa-large version pre-trained on the WinoGrande dataset, and (3) DeBERTaV3-TS: a DeBERTaV3-base model, pre-trained on diverse commonsense reasoning datasets, and fine-tuned with multi-task learning on over 600 tasks from the Tasksource collection.

Multi-class Classification task This strategy involves treating the problem as multi-class classification: all four provided options are combined with the given question, and consequently these concatenated inputs are fed into the model, which is fine-tuned to select one of the four options as part of a multi-class classification problem.

Binary Classification task Each sample originally consisting of multiple-choice QAs with four available options, underwent the following transformation: each candidate answer (excluding the

"None of above" option) was paired with the question receiving the label 0 if the choice was incorrect, or the label 1 for the opposite. In case all the 3 pairings returned 0, it is directly implied that "None of above" is the correct answer.

4.2 LLMs

We demonstrate an in-depth examination of fine-tuning SoTa LLMs (Llama 2, Phi-2, and Mistral-7b) in the context of multi-class classification. Note that during inference, the models prompted to provide an *explanation* along with the label. This experimental step, which we have observed to improve the performance of the model, also provides a qualitative identification of flaws in the models' reasoning process. In our experiments, we explore various combinations of LoRA (Hu et al., 2021) a and r hyperparameters, using values of 16, 32, 64, and 128. For the analysis ahead, LLMs are denoted as model_r_a, reflecting these hyperparameters. Additional technical information, including prompting details and specifics about QLoRA hyperparameters, is available in App. B, C, D.

5 Experimental Results

Our metrics for the Sentence Puzzle sub-task are presented in Table 4 and for the Word Puzzle sub-task in Table 5 along with their baselines. Interestingly, the performance of the binary classification problem is significantly lower than that of the multi-class classification task. Initially, this behavior seemed counterintuitive since it appeared easier to determine whether a question is correct or not than to select the correct answer from four different options. However, this assumption is not accurate. Consider the word riddle: *'What is the capital in France?"* At first glance, the option 'F' seems incorrect, but when considering the options 'F,' 'E', 'A', and 'None of the above', 'F' emerges as the only correct answer, as it becomes apparent that the question refers to the capital *letter* rather than the capital *city*. Therefore, the diverse options provide crucial context to the models, explaining the superior performance of multi-class models. This lack of context is why we refrain from further exploring this methodology across all models in our study.

***Task A*: Sentence Puzzle** Table 4 illustrates minimal fluctuations among all instance-based metrics. This consistency extends to the associated group-based metrics for all models, highlighting a systematic behavior towards detecting various reasoning paths. This observation holds for both the encoder-based classifiers and LLMs utilized in this sub-task. Sentence puzzles inherently offer more detailed information, enabling models to detect and identify the same reasoning patterns more readily, regardless of changes in context, in contrast to word puzzles, which typically feature shorter contextual statements, presenting a greater challenge for models to discern consistent reasoning patterns.

Initially, it becomes apparent that pre-training encoders across various commonsense reasoning datasets results in substantial performance enhancements, as it enables the system to grasp domain-agnostic features which prove advantageous for the subsequent task. Additionally, several commonsense pre-trained encoders fine-tuned on BrainTeaser data outperform Llama 2 and Phi-2.

Another noteworthy observation from Table 4 is that only Mistral-7b from LLMs is able to surpass the encoder-type networks, while both Llama 2 and Phi-2 consistently scored lower. Unlike Llama 2 and Mistral-7b, Phi-2 has not undergone instruction fine-tuning (Gunasekar et al., 2023), which, coupled with the limited number of examples in the BrainTeaser Sentence Puzzle dataset, contributes to its lower performance, as a result of Phi's incapability to capture the complexities of the BrainTeaser data. In this regard, Mistral-7b, which has already demonstrated superior performance compared to every Llama 2 variation when tested in commonsense reasoning benchmarks (Jiang et al., 2023a), is also capable of solving this task more accurately.

***Task B*: Word Puzzle** In Table 5, we observe a stark contrast in the models' performance in understanding and detecting reasoning paths when the context changes. There are notable discrepancies in accuracy between original and semantic contexts when compared to context reconstruction, particularly evident in the case of smaller encoder models.

Regarding encoders, it is evident that, especially vanilla RoBERTa-large lacks robust commonsense reasoning and struggles to systematically handle ambiguity; in contrast, RoBERTa-large pre-trained on WinoGrande presents competitive performance. This notable enhancement (over 40%) due to WinoGrande pre-training suggests that this particular dataset effectively equips the model with the ability to understand word puzzle-related reasoning complexities, making its scores competitive with DeBERTaV3 in this sub-task, despite the higher

System	Original	Semantic	Context	Ori. + Sem.	Ori. + Sem. + Con.	Overall

Table 5: Model performance for *sub-task B: Word Puzzle*. More results in Table 7.

DeBERTaV3-base performance over RoBERTa-large in baseline reasoning benchmarks (He et al., 2023). Other than that, pre-training on other commonsense reasoning datasets does not significantly improve the overall performance for encoders. Conclusively, apart from WinoGrande the rest of the extra pre-training datasets do not hold reasoning cues close to BrainTeaser's word puzzles.

Regarding LLMs, Mistral-7b notably outperformed all others by a significant margin, even surpassing the 8 times larger model tuned using the same hyperparameters (*Mixtral-8x7b*). Llama 2

Example of correct prediction with explanation	
Question	**Choice**
If a dog is tied to a piece of rope that is 6m long how can it reach a bone that is 7m away?	**The other end is not tied to anything.**
	The rope stretches proportionally, providing the extra length needed for the horse to reach the hay seven meters away.
	The dog dug a 1m tunnel underground to reach the bone that was 7m away while still tied to the 6m long rope.
	None of above.
Explanation: A dog cannot reach a bone that is 7m away if it is tied to a piece of rope that is 6m long. This is because the distance between the dog and the bone is greater than the length of the rope. Therefore, the dog will not be able to reach the bone unless the rope is untied.	
Example of misprediction with explanation	
Question	**Choice**
How can you drop a raw egg onto a concrete floor and not crack it?	You need to drop the egg gently.
	You need to drop the egg hard.
	No problem, because concrete floors are very hard to crack.
	None of above.
Predicted Answer: None of above. **Explanation:** There is no way to drop a raw egg onto a concrete floor and not crack it. Concrete is a very hard material and will easily break any object that falls on it. The only way to avoid this would be to use some sort of protective covering for the egg before dropping it.	

Table 6: An example of explanations generated by Mistral-7b, while addressing the multi-class classification problem. The explanations, regardless of their validity, are detailed and showcase a high level of comprehension and reasoning. Correct answers are indicated in bold, while mispredictions reference the predicted answer by the model.

exhibited the worst results regardless of size (7/13 billion) and LoRA hyperparameters (r and a). Conversely, Phi-2 demonstrated relatively better performance, particularly considering its smaller parameter count (2.7 billion) compared to the other LLMs. However, both models performed worse compared to most fine-tuned encoders. This observations strongly confirms that word puzzles possess a distribution that diverges from the analytical commonsense reasoning required for sentence puzzles, entailing a unique set of cognitive demands.

Mistral-7b exhibits a trend where higher quality explanations were generated with higher values of lora rank r. However, the top-performing model showcased a configuration with r=16 and a=64. The QLoRA method (Hu et al., 2021) explains why our top model has a rank of 16 instead of 128, contrary to common expectations (more details reagrding QLoRA hyperparameters in App. C). Drawing from the widespread presence of low-rank structures, as highlighted by prior studies (Li et al., 2016, 2019; Grasedyck et al., 2013), we leverage the intrinsic low-rank structure in our problem, as emphasized in Hu et al. (2021). It is well-established that many tasks, particularly involving heavily overparametrized models, exhibit low-rank properties post-training (Oymak et al., 2019).

Overall, our systems demonstrate remarkably high overall accuracy, being less than 10% lower than human performance and more than 30% greater than ChatGPT. This suggests our methods' proficiency in understanding and detecting wordplay patterns, consistently addressing ambiguity irrespective of contextual and semantic variations in brain teasers. Upon reviewing the short explanations provided with each prediction (Table 6), we note thorough justifications even for incorrect answers. Errors typically adhere to specific wordplay patterns across original, semantic, and context multiple-choice questions (details in App. E).

6 Conclusion

In this study, we systematically evaluate pre-trained and fine-tuned encoders, along with instruction-tuned Large Language Models (LLMs), against two multi-class classification sub-tasks within the "BRAINTEASER: A Novel Task Defying Common Sense". We achieve competitive performance in both sub-tasks, accompanied by a plethora of insights regarding the influence of leveraging in-domain data, the variability model scale and architecture introduce, as well as the examination of diverging reasoning paths. As future work, we will delve into further reasoning patterns LLMs tend to follow with regard to lateral thinking challenges.

A Model Selection

A.1 Encoder

BERT (Devlin et al., 2019): Bidirectional Encoder Representations for Transformers, is a pretrained deep bidirectional transformer model producing context representations. Using a fine-tuning setting, BERT has advanced state-of-the-art performances on a wide range of NLP tasks.

RoBERTa-large (Liu et al., 2019): Robustly Optimized BERT pre-training Approach (RoBERTa) is an adaptation of BERT architecture trained with larger batches on 160 GB data from various domains. RoBERTa-large was trained by dynamically modifying language masking while the next sentence prediction loss used in BERT was dropped. Other improvising techniques like larger input text sequences, byte pair encoding are used in training which seemingly improved the model performance in downstream tasks.

DeBERTaV3 (He et al., 2023): Decoding-enhanced BERT with disentangled attention is an extension of the original DeBERTa model. It builds upon the BERT (Bidirectional Encoder Representations from Transformers) architecture, aiming to enhance its decoding capabilities and overall performance across various natural language processing (NLP) tasks. DeBERTaV3 further improves the efficiency of DeBERTa (He et al., 2021) using ELECTRA-Style pre-training with Gradient Disentangled Embedding Sharing. Compared to DeBERTa, V3 significantly improves the model performance on downstream tasks. It incorporates a disentangled attention mechanism to allow the model to focus on different aspects of input independently, improving its ability to capture diverse linguistic patterns. The model also features enhancements in the decoding process, enabling more accurate text generation and sequence classification.

A.2 LLMs

Mistral-7b (Jiang et al., 2023a): Developed by EleutherAI, is a language model tailored for large-scale natural language processing tasks. With its 7 billion parameters, it excels in handling complex language understanding and generation tasks. Designed to perform exceptionally well across various NLP applications such as text generation, comprehension, and summarization, Mistral-7b surpasses the best open 13b model, Llama 2 (Touvron et al., 2023b), and the best released 34b model, Llama 1 (Touvron et al., 2023a), in reasoning, mathematics, and code generation tasks. Leveraging grouped-query attention (GQA) and sliding window attention (SWA), Mistral-7b ensures efficient inference and can handle sequences of arbitrary length with reduced inference cost. Its performance across a wide range of benchmarks makes it a promising solution for our sub-tasks, given its extensive task capabilities and superior performance in baseline benchmarks compared to similar or larger language models. While we considered experimenting with its larger variant, Mixtral-8x7b (Jiang et al., 2024a), limitations on available resources forced us to deal in depth only with the small variant, Mistral-7b.

Llama 2 (Touvron et al., 2023b): A language model that represents a significant advancement in natural language processing. It is a collection of pre-trained and fine-tuned large language models (LLMs) ranging in scale from 7 billion to 70 billion parameters. With its large parameter count and advanced architecture, Llama 2 is designed to tackle complex language understanding and generation tasks effectively. It outperforms many other mod-

els, including its predecessor, Llama 1, in various benchmarks, demonstrating superior capabilities in reasoning, mathematics, and code generation. Leveraging its extensive parameterization and innovative techniques, Llama 2 offers state-of-the-art performance across a wide range of NLP applications, making it a notable contender in the field. For our experiments we were able to experiment with various configurations wit the 7 billion and the 13 billion models. Our involvement with the 70 billion parameter model has been restricted due to limitations associated with the extensive parameter count, particularly during the fine-tuning process.

Phi-2 (Gunasekar et al., 2023): An advanced language model designed to address complex natural language processing tasks efficiently. It is part of the small language models (SLMs) released by Microsoft Research team. With its innovative architecture and extensive parameter count, Phi-2 surpasses its predecessor, Phi-1, in various benchmarks, showcasing superior performance in reasoning, comprehension, and text generation. Leveraging cutting-edge techniques and a comprehensive understanding of language patterns, Phi-2 demonstrates remarkable capabilities across a diverse range of NLP applications, solidifying its position as a prominent model in the field. Given its 2.7 billion-parameter architecture, which exhibits exceptional reasoning and language understanding abilities in comparison to various Llama 2 iterations and Mistral-7b, we are confident that this model will deliver noticeable performance for both of our sub-tasks.

B Experimental Setup

In our experiments, we employed the Google Colab platform and Kaggle, leveraging various open-source Python packages such as Transformers, TRL (Transformer Reinforcement Learning) (von Werra et al., 2020), PEFT (Parameter-Efficient Fine-Tuning) (Mangrulkar et al., 2022), BitsAndBytes, Accelerate (Gugger et al., 2022), and Sentence-Transformers.

Encoders BERT-SE[2]: During fine-tuning, a learning rate of $3e^{-5}$ was used, with a batch size of 16 samples processed in each iteration, over the course of 3 epochs. This process aimed to adapt the pre-trained model to better suit our sub-task. Our optimizer was AdamW and our learning scheduler was linear. Same setup was used for the fine-tuning of the BERT encoder.

RoBERTa-WNGRD[3] underwent fine-tuning on the train split of each dataset, utilizing a learning rate of $3e^{-5}$, a batch size of 16, and running for 3 epochs. The opptimizer was also AdamW and the learning scheduler was linear. RoBERTa-large was fine-tuned on the train split of each sub-task's specific dataset using identical configurations.

DeBERTaV3-TS[4], like DeBERTaV3-base, underwent a fine-tuning process similar to the RoBERTa-WNGRD system, differing only in the batch size, which was set to 4.

LLMs Phi-2[5] underwent fine-tuning using the prompt format outlined in Section *Prompting Details*. The fine-tuning process involved setting a learning rate of $2e^{-5}$ and a batch size of 2, with the model trained for 250 steps. We conducted experiments with different configurations of r and lora_alpha, encompassing combinations such as r = 64, 128 and lora_alpha = 64, 128. The dropout rate was consistently set to 0.1 across all experiments. We used an AdamW optimizer and a constant learning scheduler. Despite promising benchmarks accompanying its release, the model's performance during inference on the test split of both sub-tasks' datasets was subpar, scoring lower compared to the encoders mentioned above. This discrepancy raises the possibility, supported by various reports, that the model's training process using methods like quantization and LoRA may not be fully optimized yet, particularly given its recent introduction.

Both variations of Llama 2[6], with 7 billion and 13 billion parameters, underwent the same fine-tuning pipeline described earlier, utilizing the QLoRA technique. The fine-tuning process followed the prompt format outlined in Section D (*Prompting Details*), employing a learning rate of $2e^{-5}$ and a batch size of 1, with each model trained for 250 steps. Despite experimenting with various combinations of values for r and a (32, 64, 128), while the dropout rate was consistently set to 0.1, the results were disappointing. As a text generation model, Llama 2 provided explanations for each multiple-choice prompt. However, even when

[2] https://huggingface.co/JazibEijaz/bert-base-uncased-finetuned-semeval2020-task4b-append-e3-b32-l4e5

[3] https://huggingface.co/DeepPavlov/roberta-large-winogrande

[4] https://huggingface.co/sileod/deberta-v3-large-tasksource-nli

[5] https://huggingface.co/microsoft/phi-2

[6] https://huggingface.co/docs/transformers/en/model_doc/llama2

incorrectly predicting a choice as correct, the generated explanations often lacked logical coherence. Many explanations produced during the inference phase were irrelevant to the context of the brain teaser, indicating a failure to capture the reasoning path of most multiple-choice questions. In summary, both variations of Llama 2, despite their large scale, proved incapable of effectively understanding and reasoning through the multiple-choice questions provided.

The Mistral-7b[7] model outperformed all others significantly. Prior to fine-tuning, we applied the QLoRA technique. Using a learning rate of $2e^{-5}$ and a batch size of 2, each model underwent fine-tuning for 250 steps using the train split of the sub-tasks' dataset. The initial results were promising. During experimentation with the r and a parameters, while maintaining a dropout of 0.1, certain patterns emerged. Specifically, we observed higher quality explanations and scores when using higher rank values, ranging from (16, 32, 64, 128). This outcome was expected, as higher rank values correspond to higher precision weight changes, resulting in superior weight tuning and overall model performance. Interestingly, when the ratio of a/r was low (0.5 - 1), explanations maintained high quality irrespective of predictions, implying a coherent reasoning path even if the predicted choice was incorrect. However, setting the a/r ratio to 2 or 4 potentially enhanced results, signifying a stronger influence from QLoRA layers on the base model. However, this adjustment led to a decline in the quality of explanations. The improvement could be attributed to the model's low intrinsic dimensionality. Despite having many parameters, the effective dimensionality of the model's learned representations is low. Consequently, after conducting several experiments, the best-performing model regarding word puzzles aligns with this concept. After conducting numerous tests, we achieved our best performances with the first model using r=128 and alpha=128, and the third best using r=64 and alpha=32. These models are denoted as Mistral-7b_lora_r_lora_a, representing Mistral-7b_128_128 and Mistral-7b_64_32 configurations, respectively.

Our exploration of Mistral-8x7b[8] was constrained, yet initial results were promising, despite the limited configurations. Further experimentation with various hyperparameter settings may yield improved performance. In our single attempt with this system, we employed a learning rate of $2e^{-5}$ and a batch size of 2, fine-tuning the models for 250 steps using the train split of the sub-task's dataset. Both r and a were set to 128, accompanied by a dropout rate of 0.1. This configuration was selected based on the r and a values of the best-performing model across both sub-tasks, Mistral-7b. Despite its larger scale, Mistral-8x7b achieved the second-best accuracy during inference on the test split regarding the first subtask, trailing behind its smaller variation, Mistral-7b. This model is referenced in the results table of both sub-tasks as Mistral-8x7b_128_128. Further experimentation with various configurations may yield improvements, particularly when leveraging the low intrinsic dimensionality and redundancy inherent in the model.

C QLoRA hyperparameters

Initially, we employed the QLoRA technique (Dettmers et al., 2023) for optimization. The QLoRA technique entails the following steps. First we quantized the models using 4-bit precision to reduce memory usage and computational requirements. The quantization process was facilitated by the BitsAndBytes library. Following quantization, we implemented the LoRA technique (Hu et al., 2021) using the PEFT library. LoRA, applied to the quantized model, resulted in the creation of Quantized LoRA (QLoRA). This pipeline effectively addresses the challenges posed by memory-intensive models on hardware with limited capabilities, ensuring optimized performance and resource utilization. Regarding the hyperparameters of the QLoRA, the rank *(r)* determines the dimensionality of the low-rank approximation used in the adapter layers, while alpha *(a)* is the scaling factor that determines the magnitude of the newly learned weights compared to the original model's weights. The choice of alpha influences how much emphasis is given to the task-specific information compared to the pre-trained knowledge encoded in the original model.

In our experiments, we observed that lower values of r occasionally yielded slightly superior results. This phenomenon can be attributed to the regularization effect introduced by lower-rank approximations. Essentially, lower-rank approximations act as a form of regularization, discouraging

[7] https://huggingface.co/mistralai/Mistral-7B-v0.1

[8] https://huggingface.co/mistralai/Mixtral-8x7B-v0.1

the model from memorizing the training data and instead promoting the learning of more generalizable patterns. This regularization effect becomes particularly significant when dealing with small datasets, as the risk of overfitting is heightened in such scenarios. By limiting the model's capacity through lower-rank approximations, we encourage it to focus on learning essential features and avoid capturing noise or idiosyncrasies present in the training data. Therefore, in our case where the dataset size is small, the regularization provided by lower-rank approximations becomes crucial. It helps prevent overfitting and encourages the model to generalize better to unseen data, ultimately leading to improved performance in certain cases.

Table 7 depicts further analysis of LoRA hyperparameters for Mistral and Mixtral models, which have exhibited the best results among all other models and across the two tasks. Due to computational restrictions, we trained the Mixtral model, which is eight times larger, only for the best performing hyperparameters of Mistral, as a proxy for the performance difference.

D Prompting Details

Here, we provide a comprehensive overview of the prompt utilized consistently throughout the fine-tuning process of the LLMs, which ultimately led to optimal performance across both sub-tasks. Prompt:

```
### Instructions:
Below is an instruction that describes a
multiple choice task. Answer the following
multiple choice question by giving the
most appropriate response. Answer should
be one among options provided after the
question. Select the most suitable answer
while making the necessary assumptions.
Give only answer and a short explanation
of two or three sentences. Nothing else.

### Input:
Question: {question}
1) {a}
2) {b}
3) {c}
4) {d}

### Answer:
The correct answer is: {label}) {answer}
```

In the *Instructions* section, we define the task and provide detailed steps for the system. Results varied depending on the content of the *Instructions* section. It's important to note that our model isn't just tasked with selecting the most appropriate choice from the given options; it's also instructed to generate a brief explanation. This additional step aims to assess the model's ability to identify and comprehend a logical reasoning path that can justify its chosen answers for each multiple-choice problem. Given that the questions are brain teasers that challenge common sense, this approach helps us gauge the model's understanding and reasoning capabilities more effectively. In the *Input* section, we structure the provided dataset into a multiple-choice question format. Each component serves a specific purpose:

Question {question} This section contains the main question extracted from the dataset.

Choices ({a}, {b}, {c}, {d}): These represent the options provided as answers for the question within the dataset.

Correct Answer {label}) {answer} This section indicates the correct label and its corresponding answer from the dataset.

This structured format enables the model to comprehend and process each question along with its associated choices and correct answer during the fine-tuning training process. During the *inference phase*, the same prompt is reproduced, with the sole distinction of a blank space within the Answer section. This deliberate inclusion of a blank space aims to support the model's text generation process. In inference, the model is tasked with generating the correct answer using the information presented in the prompt. This setup enables the model to dynamically generate responses, utilizing its comprehension of the question and the contextual details provided within the prompt.

E Assessment and Insights on Dataset Quality

Upon reviewing our incorrect predictions across both sub-tasks, subsequent to the task organizer releasing the labels for the test split of the datasets, we reached several conclusions. Across all triplets, encompassing original, semantic, and context reconstruction statements, we observe a considerable degree of ambiguity in various patterns. This ambiguity often leads to inconsistent selection of correct answers, even when answered by humans. This underscores the need for clearer formulation of ques-

System	Original	Semantic	Context	Ori. + Sem.	Ori. + Sem. + Con.	Overall
Task A						
Mistral-7b_64_128	**.850**	**.825**	**.775**	**.825**	**.700**	**.817**

Mistral-7b_128_64	.850	.800	.725	.775	.625	.792
Mistral-7b_64_32	.850	.775	.725	.750	.675	.783
Mistral-7b_8_16	.800	.800	.700	.750	.625	.767
Mistral-7b_128_32	.825	.775	.725	.750	.600	.775
Task B						
Mistral-7b_128_128	**.844**	**.844**	**.813**	**.719**	**.625**	**.833**
Mistral-7b_8_16	.781	.938	.781	.719	.562	.833
Mistral-7b_16_16	.812	.812	.875	.688	.625	.833
Mistral-7b_8_8	.875	.812	.812	.750	.688	.833
Mistral-7b_16_32	.875	.812	.781	.750	.594	.823
Mistral-7b_64_32	.844	.875	.719	.750	.562	.812
Mistral-7b_128_64	.844	.812	.781	.688	.531	.812
Mistral-7b_64_64	.719	.812	.625	.625	.406	.719
Mixtral-8x7b_128_128	.625	.719	.625	.531	.375	.656

Table 7: The performance of various LoRA hyperparameters for Mistral and Mixtral in both sub-tasks.

tions and unambiguous expression to enhance the accuracy of model predictions. Another notable pattern we identified pertains to the quality control of semantic reconstruction in certain questions. In these instances, some words were not replaced with accurate synonyms, resulting in a shift in the definition of the brain teaser presented by the question. While this may not inherently be problematic, the dataset's correct answers remained unchanged compared to the original version of the question. This discrepancy suggests that the alteration in question definition went unnoticed by the task organizers, leading to some erroneous predictions by our model, when in reality the correct context of the provided multiple-choice statement was captured by our system. The two observations above highlight the inherent difficulty in generating clear and precise brain teasers, as well as the challenge that models face in understanding them. In the above scenarios, our top-performing model either detects the presence of a contradiction in the questions and opts to select "None of above," as elucidated in its brief and explanatory justification, or it provides an incorrect answer based on the dataset's answer but correctly reflects the problem context, which may have been altered due to inadvertent synonym usage.

DeepPavlov at SemEval-2024 Task 3: Multimodal Large Language Models in Emotion Reasoning

Julia Belikova and **Dmitrii Kosenko**
Moscow Institute of Physics and Technology
belikova.iua@phystech.edu, kosenko.dp@mipt.ru

Abstract

This paper presents the solution of the DeepPavlov team for the Multimodal Sentiment Cause Analysis competition in SemEval-2024 Task 3, Subtask 2 (Wang et al., 2024). In the evaluation leaderboard, our approach ranks 7th with an F1-score of 0.2132. Large Language Models (LLMs) are transformative in their ability to comprehend and generate human-like text. With recent advancements, Multimodal Large Language Models (MLLMs) have expanded LLM capabilities, integrating different modalities such as audio, vision, and language. Our work delves into the state-of-the-art MLLM Video-LLaMA, its associated modalities, and its application to the emotion reasoning downstream task, Multimodal Emotion Cause Analysis in Conversations (MECAC). We investigate the model's performance in several modes: zero-shot, few-shot, individual embeddings, and fine-tuned, providing insights into their limits and potential enhancements for emotion understanding.

1 Introduction

In the dynamic domain of artificial intelligence, the emergence of MLLMs has gained significant interest due to integrating input from different modalities, such as audio, vision and language, opens up in-depth perceptual and interpretive capabilities in dialogues instead of chat-based dialogue systems (Konovalov et al., 2016).

These models exhibit impressive potential in resolving a lot of challenges and have been deployed across various sectors, including banking support systems, social services, and as adjuncts in psychological assistance. In these applications, the deciphering of user intent and emotions is crucial for generating pertinent responses. Consequently, one of the most important domains within MLLM research is emotion reasoning.

This paper explores a specific facet of emotion reasoning: Multimodal Emotion Cause Analysis in Conversations (MECAC) (Wang et al., 2024). This task involves emotion recognition and matching emotional states with their causes in the context of a conversation, leveraging inputs from different modalities such as text, audio, video and more.

Despite the remarkable advancements in MLLMs, their capabilities and limitations in the high-potential area of emotion reasoning remain active topics for research. One of the seminal contributions to the investigation of MLLMs capabilities within the area of emotional reasoning is delineated in (Lian et al., 2023). The authors introduce a novel task, Explainable Multimodal Emotion Reasoning (EMER), and proceed to evaluate the efficacy of modern multimodal models in addressing EMER. Their research focuses on the integration and interpretability of emotional cues across diverse modalities, thereby advancing the understanding of emotion reasoning.

To address the described issue, we propose to continue research of the MLLMs capabilities in emotion reasoning by evaluating one of the most promising models, Video-LLaMA (Zhang et al., 2023), also explored in Lian et al. (2023), for MECAC on the Emotion-Cause-in-Friends dataset.

The work evaluates the performance of the model in three modes:

1. *Zero-shot and Few-shot modes*. These modes are utilized to evaluate the model's initial capabilities in emotion reasoning.

2. *Individual Embeddings mode*. In this mode, embeddings from individual modalities are employed alongside trained basic heads to address MECAC.

3. *Fine-tuned mode*. This mode is used to evaluate specialized emotion reasoning capabilities.

Experimental results demonstrate the considerable potential of MLLMs in the domain of emotion reasoning.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1747–1757

2 Related Work

2.1 Multimodal Large Language Models

The ascent of Large Language Models such as LLaMA2 (Touvron et al., 2023), Qwen (Bai et al., 2023), Mistral (Jiang et al., 2023) has marked a significant milestone in the field of artificial intelligence. These models have demonstrated exceptional capabilities in language reasoning and decision-making, closely mirroring human-level performance.

The integration of adapters to align pre-trained encoders from different modalities with textual LLMs has given rise to a new class of MLLMs such as: Flamingo (Alayrac et al., 2022), BLIP-2 (Li et al., 2023a), MiniGPT-4 (Zhu et al., 2023), mPLUG-Owl (Ye et al., 2023), VideoChat (Li et al., 2024a), InstructBLIP (Dai et al., 2023), Video-ChatGPT (Maaz et al., 2023), Video-LLaVA (Lin et al., 2023), VideoChat2 (Li et al., 2024b), Video-LLaMA (Zhang et al., 2023) (Table 1).

Model	Modality
Flamingo	I, V, T
BLIP-2	I, T
MiniGPT-4	I, T
mPLUG-Owl	I, V, T
InstructBLIP	I, T
Video-ChatGPT	I, V, T
VideoChat2	I, V, T
Video-LLaMA	I, V, A, T
Video-LLaVA	I, V, T

Table 1: Multimodal Large Language Models. T, A, I, and V stand for text, audio, image and silent video, respectively

These models have gained impressive results in well-known general domains (Wu et al., 2023): temporal perception and reasoning, casual inference, and spatial perception and analysis.

2.2 Emotion Reasoning in Conversation

Our work delves into MECAC, a derivation of ECPE (Xia and Ding, 2019), the downstream task of emotion reasoning. Given a conversation sequence consisting of N utterances, $U = \{U_1, U_2, \ldots, U_N\}$, where each utterance U_i is accompanied by a corresponding speaker identity, textual content, and an associated audio-visual clip.

The task is to output a set of emotion-cause pairs $E = \{(e_i, c_i)\}_{i=1}^{M}$, where each pair contains:

- e_i: an emotion utterance U_j that expresses an emotion.
- c_i: a cause utterance U_k that is identified as the cause of the emotion expressed in U_j.

Additionally, each emotion utterance e_i is tagged with an emotion category EC from a predefined set of emotion categories $EC = \{EC_1, EC_2, \ldots, EC_K\}$.

The exploration of emotion reasoning within the context of conversations has traditionally been addressed using various classical approaches. Recurrence-based or graph-based methods have been particularly popular due to their ability to capture sequential and relational data effectively. Notable methods in this domain include: MC-ECPE-2steps (Wang et al., 2023), which focuses on two-step recurrence-based emotion-cause pair extraction; Joint-GCN (Li et al., 2023b), which leverages recurrent and graph convolutional networks for joint emotion-cause detection; ECQED (Zheng et al., 2023), which extends the emotion-cause pair extraction to a quadruple extraction task and structural and semantic heterogeneous graph for conversation representation; CORECT (Nguyen et al., 2023), which enhances conversation understanding through relational temporal graph neural networks; and COGMEN (Joshi et al., 2022), which utilizes contextualized graph neural networks for multimodal emotion recognition.

In this paper, we investigate the capabilities of MLLMs for solving MECAC by evaluating the state-of-the-art model, Video-LLaMA. It is pertinent to acknowledge the application of MLLMs in a variety of sentiment and emotion recognition (Aslam et al., 2023), in the domain of EMER. Previous works indicate that MLLMs demonstrate notable efficacy in these complex tasks, which highlights their potential for advancing the frontier of emotion reasoning research.

2.3 Video-LLaMA architecture

Next, we summarize the key points of Video-LLaMA's architecture.

Video-LLaMA is a multimodal framework designed to extend the capabilities of frozen LLMs by enabling them to process and respond to audio-visual content.

Visual Encoder. The visual encoding component employs a pre-trained image encoder to compute representations from individual frames of a video. It introduces a frame embedding layer to

provide temporal information and incorporates a video Q-former to generate visual query tokens that encapsulate the temporal dynamics of visual scenes. A linear layer is introduced to transform video embedding vectors into query vectors that are compatible with the embedding space of LLMs.

Audio Encoder. For audio processing, Video-LLaMA leverages ImageBind (Girdhar et al., 2023). It also uses a similar architecture to the visual encoder to obtain audio embeddings for the LLM module.

Cross-Modal Training. The training process involves multi-branch, cross-modal pre-training to achieve both vision-language and audio-language alignment. The vision-language pre-training includes a video-clips-to-text generation task and static image-caption learning. The audio-language pre-training leverages the audio encoder and vision-text data to align with the LLM's embedding space.

Standard Inference. During inference, Video-LLaMA is capable of zero-shot video and audio understanding. It processes video frames and audio signals, converts them into query representations that are concatenated with textual input embeddings of LLMs, and generates responses grounded in the video's visual and auditory content.

3 Methods

3.1 Zero-shot and Few-shot

Today's LLMs are developed using extensive datasets and are further fine-tuned to comprehend and follow instructions, granting them the capacity to perform certain tasks in a zero-shot fashion (Tirskikh and Konovalov, 2023). Investigating how these capabilities are exhibited in multimodal models represents an active area of research.

To evaluate the capabilities of Video-LLaMA in the zero-shot emotion reasoning subtasks, we use structured templates such as the one detailed in Appendix A, Listing 4

While LLMs demonstrate remarkable zero-shot capabilities, they still fall short on more complex tasks within the zero-shot setting. Consequently, it is essential to evaluate their few-shot capabilities as well. To achieve this, we employ prompt templates, such as the one described in Appendix A, Listing 5.

3.2 Individual Embeddings

In this work, we also investigate the capabilities of embeddings obtained from the output of Video-LLaMA. Specifically, we extract multimodal embeddings corresponding to each fragment of the conversation. These embeddings are derived from the last semantic token of the last hidden state during the generation of responses to prompts formatted as shown in Listing 1.

```
# First option
<Item Value> Describe the behavior of
the speaker in this <Item Name> in one
word:
# Second option
<Item Value> Describe what is happening
in this <Item Name> in one word:
# Third option
<Item Value> Describe the emotional
state of the speaker in this <Item Name>
in one word:
```

Listing 1: Prompt templates for multimodal embeddings generation

To utilize these embeddings for our task, we integrate classical heads based on Multi-Layer Perceptron (MLP), Bidirectional Long Short-Term Memory (BiLSTM), and Self-Attention mechanisms. In the context of MLP, we adopt a straightforward approach for multi-class classification of emotions and binary classification of causes. Importantly, for the binary classification of causes, we consider all possible pairs of utterances. The probability that a pair belongs to a specific class is computed based on the output from the linear layer, which receives a concatenated representation of the utterance pairs as its input.

The BiLSTM head is implemented similarly to the MLP. For the self-attention mechanism, we employ multiple layers of a classical architecture. For both approaches — the MLP and BiLSTM-based heads — we utilize Cross-Entropy as the loss function.

It is also worth noting that there is a class imbalance in the case of binary causes classification. According to the authors of the dataset about 55.73% of the utterances are annotated with one of the six basic emotions, and 91.34% of the emotions are annotated with the corresponding causes in the ECF dataset. As a result, the matrices of some conversations divided into utterances become quite sparse. To mitigate the impact of imbalance, we propose several balancing methods: simple weighting of the loss function and adaptive weighting. In the first case, a constant scaling factor is chosen to increase the influence of the minority class, while in the

second case, balancing is done for each individual batch based on the current class frequency.

3.3 Fine-tuning

The fine-tuning stage employs Low-Rank Adaptation (LoRA) (Hu et al., 2021) to modify the pre-trained parameters of the LLaMA module within Video-LLaMA, while the visual and audio encoders remain unchanged. We design prompts for fine-tuning, outlined in Listings 2 and 3, that closely align with the format proposed in (Lei et al., 2023).

```
You are expert of multimodal emotion
classification and emotion cause
recognition.

The following is a conversation that
involves several speakers.

Here is a conversation that is described
in several fragments and includes

Listing 3: Response format for the fine-tuning stage

4 Experiments

For the experiments described below, we use the Emotion-Cause-in-Friends (ECF) dataset (the official train part), which is divided into train, validation, and test sets in accordance with the proportion 8:1:1. We used train part due to test split is not officially available for extensive experiments.

4.1 Zero-shot and Few-shot

In the zero-shot experiments, the model exhibits a loss of ability to follow general instructions and ceases responding to the guidelines provided, instead demonstrating a tendency for a detailed description of the events observed in the video. Examples of this behavior are visible in the experimental data presented in Appendix B. In few-shot experiments with Video-LLaMA, we observe the same pattern.

4.2 Individual Embeddings

Metrics. In evaluating the model's performance on the emotion classification subtask, we utilize two principal metrics: the macro F1-score, which provides a balanced measure of precision and recall across all classes, and Accuracy, reflecting the overall proportion of correctly identified instances. For the causal classification subtask, we similarly measure performance using the binary F1-score, which is tailored to binary classification problems, alongside Accuracy to determine the proportion of true results in the dataset.

Training configuration. Each training session is run in 50 epochs. For emotion classification, 32 utterances are used as one batch. For cause classification, one batch describe one conversation and an accumulation of 6 batches for gradient optimization is used.

To address the challenges presented by MECAC, our approach encompassed two distinct training schemas: joint and separate training for the dual classification objectives, namely emotions and causes. The joint training final loss function was composed as a linear combination of the individual losses from both classification heads as in MTL systems (Karpov and Konovalov, 2023).

Initial observations from the joint training indicated that the combination of loss functions from the emotion and cause components was instrumental in enhancing the model's generalization capabilities. However, this joint strategy appeared to reach a plateau, failing to deliver the maximum attainable performance in the later stages of training.

Further experimentation yielded additional insights, particularly in the domain of model convergence. For the emotion classification task, the MLP head emerged as the superior architecture, leading to the most optimal model convergence. Conversely, the BiLSTM head demonstrated a marked advantage in the cause classification domain.

Also, as mentioned above for the training of cause classification it is suggested to perform balancing of the loss function. In practice, the assumption to mitigate class imbalance has proven to be highly significant. According to the experimental results, the best convergence was provided by the use of a constant weight coefficient, notably a value of 3, to give greater emphasis to predictions of the minor classes within the loss function.

Prompt optimization. We evaluate three distinct prompt configurations to derive embeddings for each modality under consideration. The experimental results reinforce the notion of textual content as a leading modality, with the third prompt configuration demonstrating particular efficacy. Accordingly, the tables in Appendix C present the training results as evaluated on the test subset, including all combinations of the prompts applied to the audio and video modalities.

Modality impact. To evaluate the contribution of each modality to the overall effectiveness of the classification tasks, we conducted several experiments. The validation results are depicted in Figure 1, and the test results confirm the observed trend. The text modality emerges as the most influential, exerting the greatest effect on the model's predictive accuracy. In a secondary position, the audio modality is found to have a considerable impact, albeit less than that of text. The video modality, while still contributing to the overall model performance, is observed to have the least influence among the three.

The leading role of textual modality can also be substantiated by the information provided by the ECF authors, who state that approximately 8% of the emotion causes in the dataset are the events mainly reflected in the acoustic or visual modalities. It's also important to note the least valuable modality in these experiments: the visual modality. We suppose that this is justified by the lack of confidence of the models in visual feature space, which, most likely, can be eliminated by fine-tuning of the visual encoding branch.

4.3 Fine-tuning

In the fine-tuning phase of our experiments, we employ LoRA technique to fine-tune the parameters of the language model component, specifically, the 4-bit quantized Llama-2 7b model, it's selected due to resource constraints. We configure LoRA with an alpha value of 16 and a low-rank factor of 8, while a dropout rate of 0.1 is utilized to prevent overfitting. Our method focuses on selectively adapting only the self-attention projection modules within the transformer architecture. This refines the model's focus on salient features for the tasks at hand without necessitating a comprehensive retraining of the entire network. Training batches are set to a size of 4, and the fine-tuning process is conducted over a single epoch, covering the full training dataset.

The fine-tuning strategy yields notable improvements in the model's performance across two distinct classification tasks. For the emotion classification task, the model achieves a macro F1-score of 0.6500 and an Accuracy of 0.7412. This represents a significant enhancement in the model's ability to discern and categorize emotional content within the input data accurately. In the causal classification task, the model demonstrates a binary F1-score of 0.3824 and an Accuracy of 0.9220. While the binary F1-score appears modest, the high Accuracy underscores the model's effectiveness in identifying causal relationships within the tested dataset.

5 Conclusion

In this paper, we conduct an analysis of the MLLM Video-LLaMA with an emphasis on its emotion understanding capabilities in MECAC. Our experiments show that multimodal models, in their current iteration, exhibit limitations in deciphering emotional states under zero-shot and few-shot modes.

To enhance the capabilities of such models in emotion understanding, our findings indicate that task-specific dataset fine-tuning is an essential step. Despite the challenges observed, the raw embeddings generated by the Video-LLaMA model show promising potential as a foundation for improving emotion recognition performance.

The implications of this research highlight the necessity for continued development and refinement of multimodal learning frameworks. Future work may concentrate on expanding the diversity of the datasets used for fine-tuning to include a broader spectrum of emotional expressions and cultural contexts. This could mitigate existing biases and enhance the model's generalizability across various demographics and scenarios. Moreover, incorporating advanced techniques such as transfer learning and domain adaptation could further enhance the model's proficiency in interpreting nuanced emotional states (Chizhikova et al., 2023).

Abstract

This paper describes our approach for SemEval-2024 Task 9: BRAINTEASER: A Novel Task Defying Common Sense. The BRAINTEASER task comprises multiple-choice Question Answering designed to evaluate the models' lateral thinking capabilities. It consists of Sentence Puzzle and Word Puzzle subtasks that require models to defy default commonsense associations and exhibit unconventional thinking. We propose a unique strategy to improve the performance of pre-trained language models, notably the Gemini 1.0 Pro Model, in both subtasks. We employ static and dynamic few-shot prompting techniques and introduce a model-generated reasoning strategy that utilizes the LLM's reasoning capabilities to improve performance. Our approach demonstrated significant improvements, showing that it performed better than the baseline models by a considerable margin but fell short of performing as well as the human annotators, thus highlighting the efficacy of the proposed strategies. We have made our code open-sourced for the replicability of our methods. [1]

1 Introduction

Human cognition is characterized by two distinct modes of thinking: vertical and lateral (Waks, 1997). Vertical thinking, often called logical or convergent thinking, follows a structured analytical process based on reasoning and established rules. By contrast, lateral thinking, or "thinking outside the box," is a creative and divergent process that challenges conventional assumptions and explores novel perspectives.

Vertical thinking and lateral thinking are both complementary (Dingli, 2008). Vertical thinking is known for its selectivity and focus, while lateral thinking is known for its creativity and ability to generate alternative approaches and perspectives. It is crucial to recognize the value of both types of thinking and utilize them in a balanced manner to achieve optimal results.

We work on two subtasks (Sentence Puzzle and Word Puzzle) introduced as part of the SemEval-2023 Task 9: BRAINTEASER: A Novel Task Defying Common Sense (Jiang et al., 2024). The Sentence-type brain teasers contain puzzle-defying common sense teasers centred around sentence snippets. For instance, the question "What has a bed but no head, a mouth but no teeth?" challenges the default association of beds with people and forces the solver to consider other possibilities, such as a river (which has a riverbed but no heads or teeth). In Word-type brain teasers, the answer violates the default meaning of the word and focuses on the letter composition of the target question. For example, the question "What word becomes shorter when you add two letters to it?" challenges the assumption that adding letters to a word would make it longer and requires the solver to recognize that the word "short" becomes "shorter" when "er" is added to it.

We used the Gemini 1.0 Pro Model (Team et al., 2023) to evaluate the model's performance in zero-shot and few-shot settings. We also make notable enhancements in the few-shot setting. Firstly, by employing contextualized question selection, we ensure that the model is exposed to more relevant examples by identifying questions from the training set that closely resemble those in the test set. Secondly, we enable the model to generate explanations for correct answer choices during training through reason generation, thereby deepening its comprehension of the examples. These approaches have demonstrated improvements in the evaluation scores.

2 Related Work

Martinez-Gil et al. (2019), Hendrycks et al. (2021),

[1] https://github.com/TheAthleticCoder/iREL-at-SemEval-2024-Task-9.git

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1758–1766

and Singhal et al. (2023) demonstrate recent advancements in multiple-choice question answering. They achieve this by developing new datasets and evaluating large language models (LLMs) on them, thus contributing significantly to the field's progress.

Xie et al. (2023) presents OlaGPT, an innovative framework designed to enhance the reasoning capabilities of large language models (LLMs) by drawing inspiration from human cognitive architecture. OlaGPT integrates cognitive modules such as attention, memory, reasoning, and learning, emphasizing a reasoning module that simulates human-like thought processes. The module then enables OlaGPT to create multiple agents and utilize various thinking templates, including lateral and integrative thinking, to solve reasoning problems effectively.

Huang et al. (2023) introduces a novel evaluation benchmark to assess a model's lateral thinking abilities in an interactive framework, utilizing Lateral Thinking Puzzles as the context.

Meng et al. (2024) proposes a divide-and-conquer approach to LLM reasoning. It involves categorizing questions into subsets based on statistical confidence scores (CS), followed by targeted interventions such as Prior Knowledge-based Reasoning (PKR) and Filter Choices-based Reasoning (FCR) to address nuanced and demanding tasks.

3 Data

The primary dataset (Jiang et al., 2023a) used in this study encompasses data pertinent to two subtasks: sentence puzzles and word puzzles. The puzzle is presented in a single correct MCQ format, where each puzzle consists of a question and several options. Among these options, only one is the correct answer to the puzzle. Creating multiple-choice questions challenges balancing fairness and intellectual engagement (Ma et al., 2021). This necessitates carefully curating distractors that are not only incorrect but also sufficiently challenging. It is worth noting that within the training data for both puzzles, every brainteaser was accompanied by two distractor options alongside the correct option. Please refer to Table 1 for specific sample numbers.

Table 1: Dataset Details

Type of Puzzle	Train Samples	Test Samples
Sentence Puzzle	507	120
Word Puzzle	396	96

4 Methodology

4.1 Zero-Shot Prompting

Initially, we conducted experiments using a zero-shot approach(Brown et al., 2020). In this method, we presented the model with questions and their multiple-choice options and asked it to identify the correct option. Subsequently, we improved the zero-shot approach by introducing the model to a sentence or word puzzle concept depending on the specific subtask under evaluation. We provided the model with the puzzle definition and then asked it to select the correct option from the choices. This modified zero-shot prompt template can be found in App.A.

4.2 Few-Shot Prompting

To enhance the model's performance, we implemented a few-shot prompting technique (Brown et al., 2020). This methodology involved presenting a variable number of examples to the model to facilitate in-context learning for the lateral thinking task. Subsequently, the model was prompted to identify the correct option among the provided choices. App.B shows examples of few-shot prompt templates.

4.3 Contextualized Example Selection

The method outlined above relies on a fixed set of examples for model prompting. We modify this by applying a Dynamic Few-Shot prompting approach inspired by Nori et al. (2023), which enables in-context learning. This method involves selecting samples from the train data that closely match the semantic content of the samples posed in the test data. Initially, all questions from both the training and testing datasets undergo encoding using BERT-Large (Devlin et al., 2019), a pre-trained transformer-based language model. Subsequently, Cosine Similarity is utilized to calculate similarity scores between each question in the testing dataset and all questions in the training dataset.

Based on these similarity scores, we select the $top - n$ most similar examples from the training dataset for each question in the testing dataset, where n varies based on the desired number of

examples to be used in the prompt. This dynamic selection process aims to leverage more relevant examples from the training data to allow for better in-context learning while evaluating each test sample.

4.4 Self-Generated Reasoning

In Section 3 of this paper, we discuss how our training data contains the correct option and two distractor options for each question. We utilize this information to prompt the Gemini Model(Team et al., 2023) and GPT-4 Model (Achiam et al., 2023) to produce detailed reasoning about why the correct option is correct and why the distractor options are incorrect, highlighting potential confusion for test-takers. We include the models' reasoning and examples from the training data during inference on the testing data. This approach aims to improve the quality and precision of the models by providing detailed insights into the reasoning behind the options making up the example. The prompt template used to generate the reasons and some examples of model-generated reasons for the samples from the training data are provided in App.C,D.

4.5 Model and Hyperparameters

The Gemini Pro 1 Model (Team et al., 2023) was used as the primary model in this study. The temperature parameter(Brown et al., 2020) was set to 0.1, to guide the model to indicate its belief regarding the correct option based solely on its pre-existing knowledge base. This low-temperature setting was chosen to minimize the generation of creative or unexpected outputs. Additionally, we set both the top_p and top_k parameters (Brown et al., 2020) to 1. By restricting the model in this manner, we aimed to maintain the relevance and coherence of the responses within the context of our research tasks.

5 Results

The results of our experiments and ablation studies conducted for the Sentence Puzzle and Word Puzzle subtasks are presented in Tables 2 and 3, respectively. The baseline scores from the best-performing model in the Instruction, Commonsense, and Human categories, as provided by Jiang et al. (2023b), serve as benchmarks for comparison. Notably, across all six columns of scores, the Zero-Shot approaches and Few-Shot approaches outperform the baseline Chat-GPT 0 Shot and Roberta-L models by a significant margin.

3 Shot + DE + Reason	0.750	**0.812**	0.750	0.656	0.594	0.771
5 Shot + DE + Reason	0.750	**0.812**	0.812	0.688	0.594	0.792

Employing the zero-shot approach of providing the model with the definition of the sentence or word puzzle (Definition Prompting) yields superior performance across both subtasks compared to simply prompting it to indicate the correct option (Direct Prompting). The significant improvement contributing factor to the overall score is evident in the significant improvements observed in the context reconstruction scores(Con).

Based on the results shown in Figure 1 and Table 2, it appears that incorporating GPT-4's reasoning alongside static examples (SE) proved to be the most effective strategy for tackling Sentence Puzzles. The tested strategies also demonstrated improved outcomes when more examples were employed, emphasizing the crucial role of using more in-context examples. However, it is noteworthy that adding self-generated reasoning to the few-shot strategy with dynamic examples did not yield a commensurate improvement; instead, it resulted in a trade-off. While it enhanced the scores for semantically related questions, it came at the expense of the performance on other question types.

Contrary to expectations, the findings in Figure 2 and Table 3 reveal that static examples and reasoning work just as well and even better than dynamic examples and reasoning in the few-shot learning context for the Word Puzzle task. Specifically, incorporating self-generated reasoning alongside dynamic examples led to no significant advancements, indicating that the presumed benefits of dynamic examples did not materialize as expected.

6 Conclusion

In our work, our extensive experimentation demonstrates that the Gemini Pro 1 Model can perform lateral thinking tasks and demonstrate significant improvements in both Sentence Puzzle and Word Puzzle subtasks by employing static and dynamic example selection coupled with self-generated reasoning strategies. We achieved notable enhancements over the baseline models and observed minor improvements as we increased the number of examples used for prompting. While our approach demonstrates notable progress, it still falls short of the performance of human annotators, indicating that further research and development are necessary to bridge this gap.

A Zero-Shot Prompt Template

Here, we provide the modified zero-shot prompt templates for the sentence and word puzzles.

A.1 Sentence Puzzle

```
Welcome to the sentence-play puzzle challenge! You are presented with a question based on a sentence-play puzzle. It means that the question is a sentence-type brain teaser where the puzzle-defying commonsense is centered on sentence snippets. Remember to pay attention to the details mentioned and indicate the option number you believe is correct for the question:
Question: {question}
Choices:{choices}
```

A.2 Word Puzzle

```
Welcome to the word-play puzzle challenge! You are presented with a question based on a word-play puzzle. It means that the question is a brain teaser where the answer violates the default meaning of the word and focuses on the letter composition of the target question. Remember to pay attention to the details mentioned and indicate the option number you believe is correct for the question:
Question: {question}
Choices:{choices}
```

B Few-Shot Prompt Template

We provide the 2-shot prompt templates for both puzzles here as an example of the few-shot prompting approach.

B.1 Sentence Puzzle

```
Welcome to the sentence-play puzzle challenge! Here, you will be presented with a question based on a sentence-play puzzle. It means that the question is a sentence-type brain teaser where the puzzle-defying commonsense is centred on sentence snippets.
We have given you two examples below to help you understand the puzzle challenge better.
Example 1:
Question: {question}
Choices:{choices}
Correct Option: {correct choice}
Example 2:
Question: {question}
Choices:{choices}
Correct Option: {correct choice}
Now, we shall be giving you the puzzle you need to solve. Remember to pay attention to the details mentioned and indicate the option number you believe is correct for the question:
Question: {question}
Choices:{choices}
```

B.2 Word Puzzle

```
Welcome to the word-play puzzle challenge! Here, you will be presented with a question based on a word-play
```

puzzle. It means that the question is a brain teaser where the answer violates the default meaning of the word and focuses on the letter composition of the target question.
We have given you two examples below to help you understand the puzzle challenge better.
Example 1:
Question: {question}
Choices:{choices}
Correct Option: {correct choice}
Example 2:
Question: {question}
Choices:{choices}
Correct Option: {correct choice}
Now, we shall be giving you the puzzle you need to solve. Remember to pay attention to the details mentioned and indicate the option number you believe is correct for the question:
Question: {question}
Choices:{choices}

C Prompt Template for Self-Generated Reasoning

We provide the self-generated reasoning prompt template for the sentence and word puzzles.

C.1 Sentence Puzzle

CONTEXT
We are presented with a question based on a sentence-play puzzle. It means that the question is a sentence-type brain teaser where the puzzle-defying commonsense is centered on sentence snippets.
OBJECTIVE
We have provided you below with the question, the answer choices and the correct option number and choice. We have also provided you with what the distractor choice was. This distractor was aimed to throw you off the correct answer. You need to provide the reasoning for why the option is correct.
Question: {question}
Choices:{choices}
Correct Option: Option {option number} : {relevant content}
Distractor Choice: {distractor option content}
RESPONSE
Provide the reasoning for why the given correct option is correct and what should be taken care of so that the distractor choice is not chosen.
REASONING

C.2 Word Puzzle

CONTEXT
We are presented with a question based on a word-play puzzle. It means that the question is a brain teaser where the answer violates the default meaning of the word and focuses on the letter composition of the target question.
OBJECTIVE
We have provided you below with the question, the answer choices and the correct option number and choice. We have also provided you with what the distractor choice was. This distractor was aimed to throw you off the correct answer. You need to provide the reasoning for why the option is correct.
Question: {question}
Choices:{choices}
Correct Option: Option {option number} : {relevant content}
Distractor Choice: {distractor option content}
RESPONSE
Provide the reasoning for why the given correct option is correct and what should be taken care of so that the distractor choice is not chosen.
REASONING

D Examples of Self-Generated Reasoning

We have provided examples of the reasoning generated by the Gemini Pro 1 and GPT-4 Models over the training data.

D.1 Reasoning using Gemini Pro 1

D.1.1 Example 1

Question: There was once a bad wizard. He abducted three women from their homes and transformed them into identical rose plants. They were placed in his garden. One of the women pleaded with the magician to allow her to see her husband and kids. He concurred. He took the woman to her

home at night. He arrived early in the morning and drove her home. The spouse made the decision to go get her one day. He entered the wizard's garden as a result. He kept glancing at the three identical rose bushes, trying to determine which one might be his wife. He took his wife home as soon as he realized the solution. How did he recognize his wife among the rosebushes?
Choices:
Option 1: The husband knew which rose bush was his wife because it was the only one that still had her distinctive scent.
Option 2: The wizard brought the rosebush to her home at night and returned her to the garden in the morning. Therefore, she was the only plant without dew.
Option 3: The husband knew which rose bush was his wife because it was the only one that leaned towards him as he approached.
Option 4: None of above.
Correct Option: 2
Reason for Correct Option: Reasoning for the Correct Option:
Option 2: "The wizard brought the rosebush to her home at night and returned her to the garden in the morning. Therefore, she was the only plant without dew." is correct because:
- The passage states that the wizard took the woman to her home at night and returned her to the garden in the morning.
- This means that the rosebush that was his wife would be the only one without dew on it in the morning, as it had been indoors all night.
- The other rosebushes would have dew on them because they had been outside all night.

Distractor Choice Analysis:
Option 1: "The husband knew which rose bush was his wife because it was the only one that still had her distinctive scent." is a distractor choice because:
- The passage does not mention anything about the women retaining their distinctive scents after being transformed into rosebushes.
- Therefore, it is not possible for the husband to identify his wife by her scent.

Conclusion:
Therefore, the correct option is Option 2: "The wizard brought the rosebush to her home at night and returned her to the garden in the morning. Therefore, she was the only plant without dew." because it is the only option that is supported by the information in the passage.

D.1.2 Example 2

Question: What is the most shocking city?
Choices:
Option 1: Urban city.
Option 2: Inner city.
Option 3: Electricity.
Option 4: None of above.
Correct Option: 3
Reason for Correct Option: Reasoning:
The question is "What is the most shocking city?". The correct answer is "Electricity". Electricity is a form of energy that can cause shocks. A city is a large urban area. Therefore, the most shocking city is Electricity.
Distractor Choice:
The distractor choice is "Inner city". Inner city is a part of a city that is typically characterized by poverty and crime. Inner city is not a form of energy that can cause shocks. Therefore, inner city is not the most shocking city.
To avoid choosing the distractor choice, one should:
- Pay attention to the question and the answer choices.
- Understand the meaning of the words in the question and the answer choices.
- Use logic and reasoning to eliminate the incorrect answer choices.

D.2 Reasoning using GPT-4

D.2.1 Example 1

Question: An electric train is going south at 98 mph. The wind is blowing northeast. Which direction is the smoke blowing?
Choices:
Option 1: Northeast.
Option 2: West.
Option 3: South.
Option 4: None of above.
Correct Option: 4

Reason for Correct Option: To solve this sentence-play puzzle, let's analyze the key elements of the question:
Electric Train: This is a crucial piece of information. Electric trains do not produce smoke as they do not burn fuel in the same way that steam or diesel trains do.
Direction of Train: The train is going south. This would only be relevant if we were dealing with a train that produces smoke.
Wind Direction: The wind is blowing northeast. Normally, this would affect the direction of the smoke if the train produced any.
Given these points, the key detail here is that the train is electric. Therefore, the direction of the smoke is a trick question because there would be no smoke produced by an electric train.

D.2.2 Example 2

Question: What kind of lamp emits no light?
Choices:
Option 1: Oil lamp.
Option 2: LED lamp.
Option 3: Clamp.
Option 4: None of above.
Correct Option: 3
Reason for the Correct Option: This puzzle requires us to think beyond the literal uses of the words provided, focusing on the play on words involved in the question and the choices given. The question asks, "What kind of lamp emits no light?" Here are the steps to analyze the choices:
1. Oil lamp. An oil lamp is designed to emit light using oil as fuel. Therefore, it does not fit the criteria as it indeed emits light.
2. LED lamp. An LED lamp uses light-emitting diodes to produce light. Like the oil lamp, it is designed to emit light, so it also does not fit the criteria.
3. Clamp. This option is a play on words. While "clamp" contains the word "lamp," it is not a type of lamp at all; instead, it's a tool used for holding objects tightly together. Since it's not a device designed to emit light, it technically "emits no light."
4. None of above. This option would be correct if none of the first three choices were accurate. However, based on the analysis, there is an option that meets the criteria of emitting no light in the context of the puzzle.
Given the play on words and focusing on the criteria of emitting no light, the correct option is:
3. Clamp. This is because it's the only choice among the options that, despite containing "lamp" in its spelling, does not function as a light-emitting device.

uTeBC-NLP at SemEval-2024 Task 9: Can LLMs be Lateral Thinkers?

Pouya Sadeghi*[1], Amirhossein Abaskohi*[2], and Yadollah Yaghoobzadeh[1,3]

[1]Department of Electrical and Computer Engineering, University of Tehran
[2]Department of Computer Science, University of British Columbia
[3]Tehran Institute for Advanced Studies, Khatam University, Tehran, Iran
[1]{pouya.sadeghi,y.yaghoobzadeh}@ut.ac.ir
[2]aabaskoh@student.ubc.ca

Abstract

Inspired by human cognition, Jiang et al. (2023c) create a benchmark for assessing LLMs' lateral thinking—thinking outside the box. Building upon this benchmark, we investigate how different prompting methods enhance LLMs' performance on this task to reveal their inherent power for outside-the-box thinking ability. Through participating in SemEval-2024, task 9, Sentence Puzzle sub-task, we explore prompt engineering methods: chain of thoughts (CoT) and direct prompting, enhancing with informative descriptions, and employing contextualizing prompts using a retrieval augmented generation (RAG) pipeline. Our experiments involve three LLMs including GPT-3.5, GPT-4, and Zephyr-7B-β. We generate a dataset of thinking paths between riddles and options using GPT-4, validated by humans for quality. Findings indicate that compressed informative prompts enhance performance. Dynamic in-context learning enhances model performance significantly. Furthermore, fine-tuning Zephyr on our dataset enhances performance across other commonsense datasets, underscoring the value of innovative thinking.[1]

1 Introduction

Human cognition provides the foundational framework for understanding large language model (LLM) development, incorporating two critical thinking modes: vertical and lateral (Waks, 1997). Vertical thinking, synonymous with logical reasoning, relies on structured analysis and established principles. Conversely, lateral thinking, known for its creativity, challenges conventions and fosters innovative perspectives, enriching language processing capabilities. Recognizing and leveraging the synergy between vertical and lateral thinking are essential in maximizing LLMs' cognitive potential.

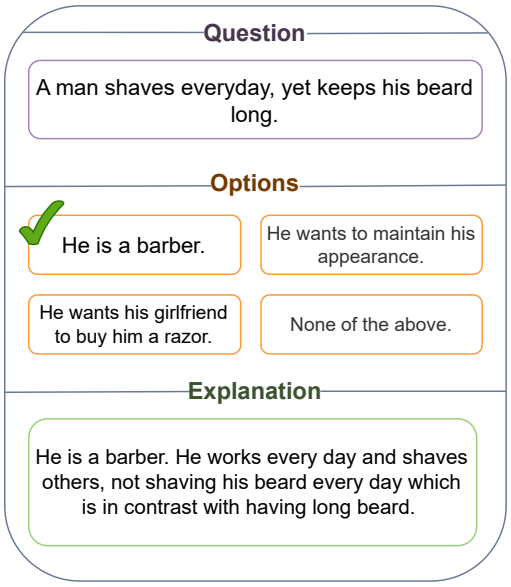

Figure 1: A sample from the sentence puzzle sub-task with an explanation of how this puzzle deprecates default commonsense.

Integrating both strategies facilitates adaptability and ingenuity in addressing linguistic challenges.

Despite LLMs' success and the abundance of reasoning benchmarks (Ho et al., 2023; Abaskohi et al., 2023; Yasunaga et al., 2024), understanding their reasoning remains incomplete. Many benchmarks prioritize vertical over lateral thinking (Waks, 1997), inherent in LLMs' pre-training data. Jiang et al. (2023c) introduces a challenging dataset, yet thorough analyses of prompting methods are lacking.

Building on previous research examining the impact of prompts on LLMs' performance (Webson and Pavlick, 2022), our study aims to validate the genuine lateral understanding capability of LLMs. We participated in SemEval-2024, shared task 9, utilizing various prompts to assess LLMs' lateral thinking abilities in the BrainTeaser multiple-choice QA task (Jiang et al., 2023c, 2024). The task focuses on the Sentence Puzzle (see Fig-

*Equal Contribution
[1]Our codes and data are publicly available at: https://github.com/Ipouyall/Can-LLMs-be-Lateral-Thinkers

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1767–1778
June 20-21, 2024

ure 1) and Word Puzzle sub-tasks[2], challenging common sense associations.

Our team, **uTeBC-NLP**, employs three different methods to evaluate LLMs' lateral thinking ability: (I) chain of thoughts (CoT)-based strategies, (II) enhancing prompts with a detailed task description and prompt compression, and (III) in-context learning ability, using retrieval-augmented generation (RAG) to select dynamic samples. We conducted these experiments on three LLMs: GPT-3.5[3], GPT-4[4], and Zephyr-7B-β (Tunstall et al., 2023), a fine-tuned version of Mistral-7B (Jiang et al., 2023a) trained on a combination of publicly available, synthetic datasets using direct preference optimization (DPO) (Rafailov et al., 2024).

Our contributions include: (I) exploring the impact of incorporating task information on lateral thinking, (II) developing a thesis-based approach wherein we delineate a path between each question-option pair separately, utilizing this thesis as contextual information in subsequent runs—termed as *external-CoT*, (III) leveraging RAG for generating few-shot examples to assess the efficacy of dynamic few-shot inference (IV) employing the generated thesis context to fine-tune Zephyr-7B-β and evaluating its impact on the model's comprehension of commonsense datasets.

In summary, our findings reveal that not all LLMs possess lateral thinking capabilities, with the ability more prominent in models with a greater number of parameters and exposure to extensive data. Proper prompting and introducing unconventional patterns would enhance this capability, by moving beyond conventional linear thinking. Models tend to prefer brief and informative prompts over lengthier alternatives. Notably, we excelled in the Sentence Puzzle sub-task, achieving a remarkable score of 0.975 in solving sentence puzzles, surpassing the baseline of 0.608, and securing the second-highest score.

2 Background

Chain of Thoughts Prompting. In-context zero-shot and few-shot learning play crucial roles in the success of LLMs. To enhance LLM performance across various tasks, including reasoning tasks, as proposed by Wei et al. (2022), we employ the CoT methodology. Replicating Wei et al. (2022)'s setup with sample shots and ensuring their quality can be challenging, so, to ensure fairness and rely on LLMs' knowledge, we adopt Kojima et al. (2022)'s zero-shot-CoT approach and referred to as Simple-Internal-CoT. In our simple-Internal-CoT experiments, we allow LLMs to autonomously handle the problem, thereby separating their performance from the quality of the provided samples. We introduced other variations for CoT, (I) Specifiec-Internal-CoT, in which we explain thinking steps to the LLM, and (II) External-CoT, in which we externally help the LLM to follow the steps by asking it to do only one step in each inference, and preserve results use in next steps' prompts.

Enhanced Prompting Strategies. Prompt strategies, particularly CoT, prove effective in enhancing LLMs' performance across tasks. However, our experiments demonstrate that CoT may not consistently yield better results. Another approach is boosting the model's performance, using informative prompts, inspired from Fernando et al. (2023). We developed a detailed prompt to familiarize LLMs with diverse riddle approaches in a simple and informative manner, aiming to prevent hasty answers and help them to know how should be faced with riddles. Acknowledging the lengthiness of our detailed prompt and to prevent this factor from limiting LLMs' performance, we created a highly compressed version following Jiang et al. (2023b), retaining essential details to improve LLMs' performance while minimizing prompt length.

In-context Learning. In-context learning proved to be one of the most powerful methods to enhance LLMs' performance (Brown et al., 2020). Few-shot prompting with static samples is examined by Jiang et al. (2023c) and shown not to work well. We Employed a RAG pipeline to dynamically select samples from the training split of the dataset. We focused on a three-shot manner and examined different ways of using our RAG pipeline to achieve the best performance. We also explore whether we need to explicitly mention the relation between the question and its answer or whether it can be inferred that effectively.

3 Methodology

This section begins with an overview of the dataset, followed by a detailed exposition of our methodology. We will start by elucidating the task information context. Subsequently, we will explore

[2]We just participated in the Sentence Puzzle sub-task.
[3]We used the gpt-3.5-turbo-0125 version.
[4]We used the gpt-4-0613 version.

different variations of CoT before concluding with an explanation of our RAG methods.

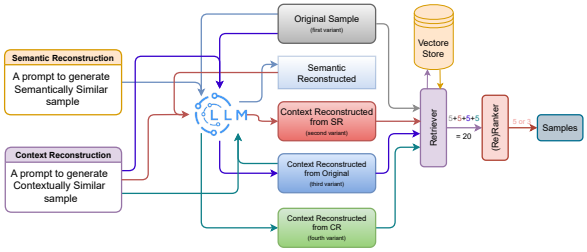

Figure 2: An illustration of our rag-fusion setup. Using an LLM, we generate four variations of the original sample to identify similar ones in the dataset, then rank them to find the closest matches. See appendix D for more details and used prompts.

3.1 Dataset

BrainTeaser. The BrainTeaser dataset (Jiang et al., 2023c) is a multiple-choice question-answering task, designed to evaluate a model's capability for lateral thinking and its ability to challenge default commonsense associations. Created to address the gap in the NLP community's attention towards tasks requiring implicit and intricate reasoning, the dataset relies on human-like commonsense mechanisms. The authors devised a three-step approach to create the first lateral thinking benchmark, involving data collection, distractor generation, and making adversarial examples. They produced 1,100 puzzles with detailed annotations. Assessing models' lateral reasoning consistency, they enhanced BrainTeaser questions with semantic and contextual adjustments. Experiments with top-notch language models showed a significant performance difference from humans, particularly evident across adversarial formats, which aim to avoid cheating in scores by memorizing or previously seen examples. The dataset includes 627 samples for sentence puzzles [5] and 492 samples for word puzzles [6]. In the case of sentence puzzles utilized in our experiments, the average number of tokens in questions is 34.88, with an average of 9.11 tokens in the answers. Our experiments are focused on the Sentence Puzzle sub-task and report our results on test split (post-evaluation phase).

Additional Datasets. We generated a dataset based on BrainTeaser's train data that contains a thinking path between a riddle and each of its options, prompting GPT-4 and revised by authors to avoid any bias. Then fine-tuned Zephyr on this dataset. As explored by Jiang et al. (2023c), Fine-tuning models on vertical thinking and traditional commonsense datasets can't improve performance on BrainTeaser and the model's lateral thinking ability. We aim to evaluate whether the fine-tuned model demonstrates an improvement in general commonsense knowledge and examine how lateral thinking ability could affect the model's performance. We utilized SWAG (Zellers et al., 2018) and CommonsenseQA (Talmor et al., 2019) for this purpose, as they don't need lateral thinking.

SWAG is a vast and diverse dataset designed for grounded commonsense inference, comprising over 113,000 sentence-pair completion examples sourced from internet text. Each example presents a context sentence followed by a partial continuation, prompting the selection of the most plausible completion among four choices.

CommonsenseQA (CSQA) serves as a rigorous benchmark for commonsense reasoning, featuring multiple-choice questions requiring an understanding of everyday situations, world facts, and causal relationships. Questions are associated with concepts from a large commonsense knowledge graph, interconnected through various relations, challenging models to engage in complex commonsense reasoning. Our evaluation incorporates 150 random samples from each of these datasets.

3.2 Task Informative Context

One approach to evaluating whether LLMs possess lateral thinking abilities is to prompt them explicitly for such capabilities. A key strategy involves providing hints about the task, signaling to the model that it should engage in unconventional thinking. In pursuit of this, we design three variations for task description: **(I) Simple**, which doesn't provide any special detail and serves as a base to provide evidence of how description could affect the model's performance, **(II) Detailed**, which would provide detailed information for the task and introduce common tricks to the LLM, and **(III) Compressed**, which is generated from the detailed variation and it just point out instead of detailed explanation. See Appendix A for more details.

3.3 Thinking Strategy

Many different thinking styles are recommended to enhance LLMs' ability to better perform on difficult tasks. CoT prompting has emerged as a potent

[5] Train: 507, Validation: 120, Test: 120
[6] Train: 396, Validation: 96, Test: 96

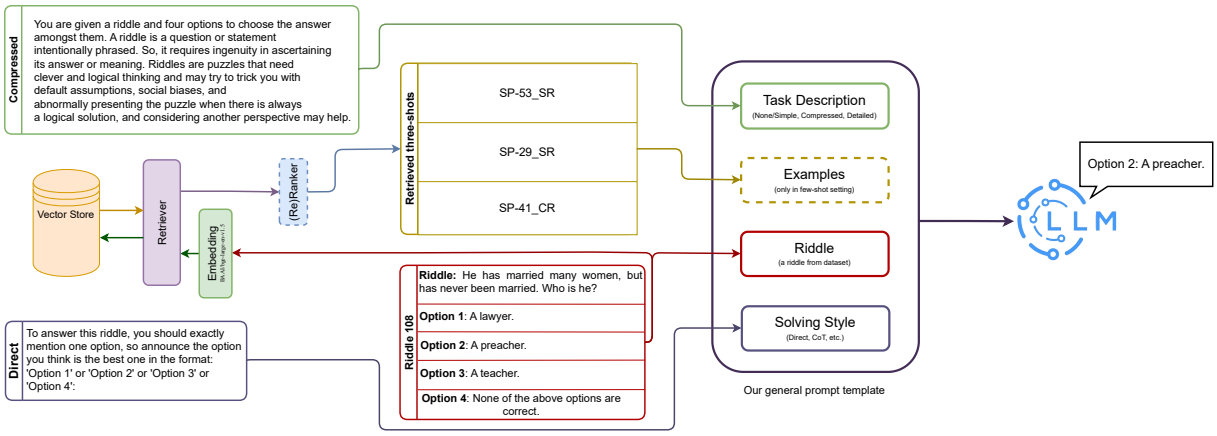

Figure 3: An overview of our approaches in solving the BrainTeaser riddles. In this setup, we have a **direct** prompt that asks the model to find the appropriate answer. To provide more information to the model, we can offer some task explanation, with the **compressed** version depicted in this figure. Finally, we utilize our RAG setup to provide the model with in-context examples. In some experiments, we also include the **theses** for each question-option pair in the prompt, serving as an unbiased link between the question and the option.

strategy for enhancing the LLMs' performance, particularly in tasks requiring complex reasoning such as arithmetic and commonsense reasoning (Zhang et al., 2022; Diao et al., 2023; Zou et al., 2023) and known as a popular choice for these complex tasks. However, the question of how CoT should be implemented remains an open challenge. Moreover, we should be aware that CoT won't achieve the best results in all cases, and use it or not, depends on the task and model.

We consider CoT prompting as two main approaches: **(I) Internal CoT** and **(II) External CoT**. Internal CoT involves guiding the model through step-by-step thinking or incrementally posing questions to facilitate analytical consideration of each option. Our exploration of internal CoT encompasses two types: (I) Simple, and (II) Specified. In Simple Internal CoT, the model is prompted to think step-by-step without explicit specification of each intermediate step. Specified Internal CoT provides the model with explicitly outlined steps to follow in reaching its answer. Conversely, in External CoT, similar to specified-internal-CoT, we defined steps that the model should pass to reach the final answer, but instead of letting the model control the process, we prompt it to do one step in each inference and use the model's response to generate next prompts till we reach to the final answer. Our suggested intermediate reasoning steps, "*find a path between the question and each answer option and then select the most logical one*," are independent for each question-option pair, and referred to as "*thesis*". Then we would use them as context for each option of the riddle and prompt model to solve the riddle regarding provided contexts. In Section 4.1 and Figure 4a, various CoT methods along with direct prompting, are compared.

3.4 In-context Learning

In this method, we let the model learn the task, using sample(s), known as few-shot prompting. In our few-shot experiments, we individually utilized three samples per question (Figure 3). We observed that employing static samples, as traditionally done in few-shot prompts (Brown et al., 2020), did not yield a significant performance boost, supporting few-shot results examined by Jiang et al. (2023c). To overcome this limitation, we developed a RAG pipeline to select shots dynamically based on each question. Our experiments involved three RAG methods: Ordinary RAG, Ranked RAG (RAG+ReRanker), and RAG-Fusion. Our experiments are all the same for these approaches and samples are selected from train split. Our shot instances are available with three entities: question, ground-truth answer, and explanation. Our explanations are sampled using GPT4, and they are a logical thinking path from question to answer. We also generated another variant for explanation named Summarized, which compressed long explanations. See Appendix D for more detail.

Ordinary RAG. Within the ordinary RAG approach, we employed the established RAG framework (Lewis et al., 2020) to generate contextualized representations for the question. The RAG model retrieved relevant passages from a knowl-

edge source, supplying contextual information crucial to the model's decision-making process.

Ranked RAG. The Ranked RAG approach (Lewis et al., 2020) entailed enhancing the RAG framework by incorporating a reranking mechanism. In this variant, retrieved passages would be reranked based on their relevance to the given question, prioritizing those deemed most relevant. This integration is aimed to enhance the quality and relevance of contextual information provided to the model and GPT-4's contexts had the most positive impact[7] on this approach.

RAG Fusion. The RAG-Fusion method (Rackauckas, 2024) seamlessly integrates elements from both ordinary RAG and Ranked RAG. In this methodology, we generate three distinct variants derived from the original riddle, which are subsequently input into the RAG pipeline for sample retrieval. After this step, a ranker[8] is employed to prioritize these samples (Figure 2). This multi-step process is meticulously designed to capture diverse contextual nuances and semantic variations, thereby significantly enhancing the overall effectiveness of the RAG-Fusion method. The most important weakness of this approach is that it is time-consuming as we need many LLM inferences that would take a long time.

Benchmarking. We designed a benchmark, in which we used samples from the train split, and retrieved 5 unique samples at the end, to observe each variant's performance on different setups. for each retrieved sample from the same group, including the sample itself, the method would give one point for that sample[9]as shown on 2 ordinary RAG can satisfy our needs in a more sample-efficient manner.

4 Experiments and Results

In this section, we report and discuss our results. Table 1 shows our submission scores during the competition. We first report and discuss our results on different methods (See Appendix C for full results). Next, we will discuss the effect of fine-tuning on our lateral thinking dataset.

[7]Help this method to provide more helpful samples for our purpose.

[8]The same reranker used as Ranked RAG.

[9]Max points for one sample: 3, as we have three variations in each group.

Metric	Score (%)
Ori	97.5
Sem	87.5
Con	82.5
Ori&Sem	85.0
OriSemCon	75.0
Overall	89.2

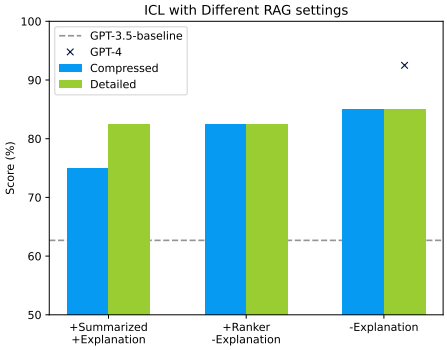
(a) Effect of different thinking (solving) styles on model's performance. Bars belong to GPT-3.5.



(b) Our proposed RAG-pipelines for dynamic in-context learning(Direct Prompting) and its effect on the model's performance. Bars belong to GPT-3.5.

Figure 4: Different prompting approaches and how they affect the model's performance. GPT-3.5-baseline reported by Jiang et al. (2023c).

Used Samples	RAG Type	Hit Rate
20	Ordinary	0.65
	Fusion	**0.767**
	Ranker	0.65
507	Ordinary	**0.753**
	Ranker	0.73

Table 2: Results of RAG's variants on the train split.

4.1 Prompting Methods

In this section, we detail our exploration of various prompting methods, as outlined in Section 3. Figure 4a presents a comparative analysis, revealing that, among different CoT methodologies, simple internal CoT exhibits superior performance. However, it scores lower than direct prompting, without any CoT variation employed. Notably, external CoT outperforms specifying steps in one prompt (specified internal CoT) but falls short compared to simple internal CoT and direct prompting. This is attributed to the impact of prompt length, where longer prompts with similar information weaken performance.

Prompt Length In task descriptions, providing hints consistently aided the model, with the condensed and detailed versions excelling in different scenarios. Our hypothesis, supported by the results, posits that both prompt and cognitive pathway length significantly influence performance. Extensive factors lead the model to favor concise yet informative prompts, as evidenced by the superior performance with the compressed descriptions.

In-context Learning As explained in Section 3, we focused on repeating experiments with Ordinary RAG and RAG+(Re)Ranker in three-shot format, leveraging three entities: question, ground-truth answer, and explanation.

Our explanations, sampled using GPT-4, represent a logical thinking path from question to answer. Additionally, we introduced a summarized variant, generated through Cohere's summarize API [10] [11] for explanations exceeding 250 words. As depicted in Figure 4b, using (Re)Ranker does not significantly enhance performance. Increasing task description details improves performance. Interestingly, we observed that excluding explanation and letting the model infer the thinking path between riddles and their answer will boost LLMs' performance, proving LLMs' ability to extract relations and thinking paths independently.

Examining three semantically similar questions in a three-shot format, the LLMs' performance converges to a certain score, independent of the task description. The optimal performance is achieved when excluding explanations and using a simple RAG pipeline without using (re)ranker. See Appendix D for more details on settings.

[10] https://cohere.com/summarize

[11] Settings: length="short", extractiveness="high"

4.2 Lateral Thinking Tuning

Fine-tuning is a core strategy for refining model performance in specific tasks. However, as noted in Jiang et al. (2023c), fine-tuning on other commonsense datasets may not guarantee performance improvements; potentially, it may even lead to a decline in the overall model's performance. This experiment focuses on fine-tuning the model using the dataset generated by GPT-4 and revised by authors, where the model discerns paths between each riddle and its options. The goal is to assess the impact of lateral thinking on model performance by evaluating it on other commonsense datasets. We tried to keep the dataset unbiased, enabling LLM to learn lateral thinking ability.

Model	Dataset	Tuned	Accuracy
Zephyr-7B-β	SWAG	No	38
		Yes	**46**
	CSQA	No	31.33
		Yes	**36**

Table 3: Fine-tuning experiments, observing model's performance improvement in commonsense.

Table 3 showcases that fine-tuning with a lateral thinking approach significantly enhances the model's performance on other commonsense datasets. This result challenges the conventional belief that linear thinking might constrain the model in scenarios requiring unconventional solutions. Adopting an out-of-the-box thinking approach proves beneficial, emphasizing the importance of lateral thinking across diverse contexts.

5 Conclusion

In conclusion, our study emphasizes the crucial role of prompting methods in augmenting the lateral thinking capabilities of LLMs. Through diverse CoT-based strategies, prompt refinements, and RAG techniques for in-context learning, we showcase the efficacy of well-structured prompts and thinking styles in elevating LLM performance. Additionally, fine-tuning models on a lateral thinking dataset proves advantageous, leading to improved performance on various commonsense tasks. This underscores the significance of integrating out-of-the-box thinking in model training, opening promising avenues for future research to enhance LLMs' reasoning abilities.

A Task description Prompts

During our analysis, we explored various combinations of prompting methodologies. Table A.1 presents our prompts for task description. The initial prompt solely defines what a riddle entails. In the compressed version, we provide general hints, such as avoiding bias. The final prompt includes eleven potential tricks that may occur in the question, along with instructions for the model to evade biases and consider superpower abilities used in the questions. These eleven hints were extracted from other sources.

Prompt
A riddle is a question or statement intentionally phrased so as to require ingenuity in ascertaining its answer or meaning.
A riddle is a question or statement intentionally phrased so as to require ingenuity in ascertaining its answer or meaning. Riddles are puzzles that need clever and logical thinking, and may try to trick you with default assumptions, social biases, and abnormally presenting the puzzle when there are always a logical solution, and considering another perspective may help.
A riddle is a question or statement intentionally phrased so as to require ingenuity in ascertaining its answer or meaning. Different ideas can be used in riddles to trick you: 1. Riddles often employ misdirection, leading you away from the actual solution. 2. They include elements with double meanings, requiring a keen eye for words with dual interpretations. 3. Metaphorical wordplay adds another layer, urging you to decipher figurative language. 4. Look out for exaggeration, as riddles may present overly dramatic details to divert your attention. 5. Common phrases and sayings may hide within the puzzle, demanding familiarity. 6. Associations and irony play a crucial role, introducing unexpected connections. 7. Numerical puzzles can also be part of the mystery, requiring you to decode their significance. 8. Elemental imagery, drawn from nature, might hold key descriptors. 9. Rhyming and sound clues can add a poetic dimension. 10. Avoid sexism and sex cliché, for example, gender bias for jobs, based on their positions or their outcome. 11. Riddle may try to present something impossible or in contradiction with the reality. Just consider alternative perspectives.

Table A.1: Our task description prompts. The first prompt lacks task details, the second is compressed, and the last is detailed, covering all potential tricks.

B Generating Path Between Question and Answer

One of the methods that was used both in external CoT and step-by-step internal CoT was asking the model to generate a thinking path between a question-option pair. To do that, we asked the model to generate a path between question and option, without giving any judgment on the answer and considering every option can be an answer to the question. To prompt we used to was: "`Your task is to generate a descriptive explanation from a question to an answer option. In the following, a question and an option as the answer to the question are provided. The provided option might or not be a correct answer. Write a descriptive explanation in at most one paragraph and 200 words to show the thinking path from the question to the option.`." To avoid hallucination, we tried to limit the model's description to 200 by asking the model to do so. Although it does not work all the time,

it limits the model's generated words. This limitation would be later beneficial as long input prompts could decrease the model's performance.

C Complete experiments and results

In this section, we will show our complete results for the sentence puzzle sub-task. Our scores on different experiments are shown in Table C.1 and each experiment's descriptions are available in Sections 3 and 4.

D RAG extensive experiments

In this section, we discuss our rag experiments in more detail. First, we mention the common setting between different methods, then we will mention each method and explain its specific experimental setup in more detail.

Commonly, we used the Chroma [12] as our vector store. We employed "bge-large-en-v1.5"(Xiao et al., 2023) as our embedding. Our final samples are chosen as the first three unique[13] samples retrieved from our vector store.

Our initial Explanations are selected from the same dataset used for lateral thinking tuning, using ground-truth answers instead of all options. Also for our summarized variant, for explanations longer than 250 words, we used summarizer (in this case, Cohere's summarize API) to summarize explanations.

Overall, our RAG methods can extract different variations in a group, as seen in Table 2 and Origian and SR variations seem to be closely related, but in some cases, it face problems to related CR variation into two other variations.

Ordinary RAG. We have used it as its ordinary usage. Despite having a close performance to RAG+Ranker, we decided to use this method, reducing the ranker's effect on our performance.

RAG+Ranker In this method, we first use a normal retriever as Ordinary RAG to retrieve 25 samples from our vector store. Then we fed our query and retrieved 25 samples to reranke(ranker)[14] and kept the first 3 samples with the highest scores.

RAG Fusion In this method. We designed two prompts to generate semantically or contextually related (see Table D.1). Using those two prompts, by prompting Zephyr-7B-β, we generate three new variations from the original, and counting the original sample, we feed each variation to the retriever to retrieve 5 samples, which provides 20 samples. Then we would run deduplication to eliminate duplicated samples, which may caused by employing multiple retrieval phases, and rank remained samples using a ranker(re-ranker) and keep the first five samples with the highest score (see Figure D.1). The we just continue with the first three samples as our shots.

[12] https://github.com/chroma-core/chroma

[13] The "unique" term comes meaningful with rag-fusion, as it may retrieve the same samples in each retrieval phase

[14] We used Cohere's reranker: https://txt.cohere.com/rerank/

Table C.1: Our complete submission result for the post-evaluation phase on test split. In-context learning means using three shots dynamically selected by our RAG's pipeline, in which: **E**) use Explanation, **S**) use Summarizer, **R**)use Ranker, and **ord**) using ordinary rag without explanation and ranker. Our final submission is underlined.

	Prompt
Semantically Related	Semantic reconstruction involves rephrasing a given text while preserving its original meaning. In this context, you are presented with a riddle. The task is to rephrase the riddle without altering the correct answer. Perform a semantic reconstruction of the following riddle. ORG Riddle: "Four men were in a boat on the lake. The boat turns over, and all four men sink to the bottom of the lake, yet not a single man got wet! Why?" SR Riddle: "A boat on the lake included four men. All four men on the boat sink to the bottom of the lake when it flips over. However, not a single man gets wet! Why?" ORG Riddle: "A plane crashed, and every single person on board this flight was killed, yet there were survivors. Explain how?" SR Riddle: "Despite the fact that the entire flight was lost in a plane crash and each single person is killed, there were survivors. Describe how?" ORG Riddle: "{riddle}" SR Riddle:
Contextually Related	Context reconstruction involves maintaining the original reasoning path while changing both the question and the answer to describe a new situational context. In this context, you are presented with a riddle. The task is to reconstruct the context of the riddle while keeping the original reasoning intact. Ensure that the reconstructed context maintains the same reasoning path as the original riddle and also it is reasonable. You should change the context and try to avoid it by just replacing some entities and trying to convey the question to another scenario. Perform a context reconstruction of the following riddle. ORG Riddle: "A woman shoots her husband. Then she holds him underwater for over 5 minutes. Finally, she hangs him. But 5 minutes later, they both go out and enjoy a wonderful dinner together. How can this be?" CR Riddle: "A woman shoots publicly at people at a National Park. The park is full of people, but no one gets killed. How is that possible?" ORG Riddle: "There are 3 apples available for 2 fathers and 2 boys to consume. They each receive a single apple. How is it a mathematical possibility?" CR Riddle: "Two mothers and two daughters were asking for new state IDs, but the agent only gave out three forms and instructed them on how to fill them out. Why?" ORG Riddle: "{riddle}" CR Riddle:

Table D.1: Prompts that are used to generate SR and CR-related samples for the RAG-Fusion method.

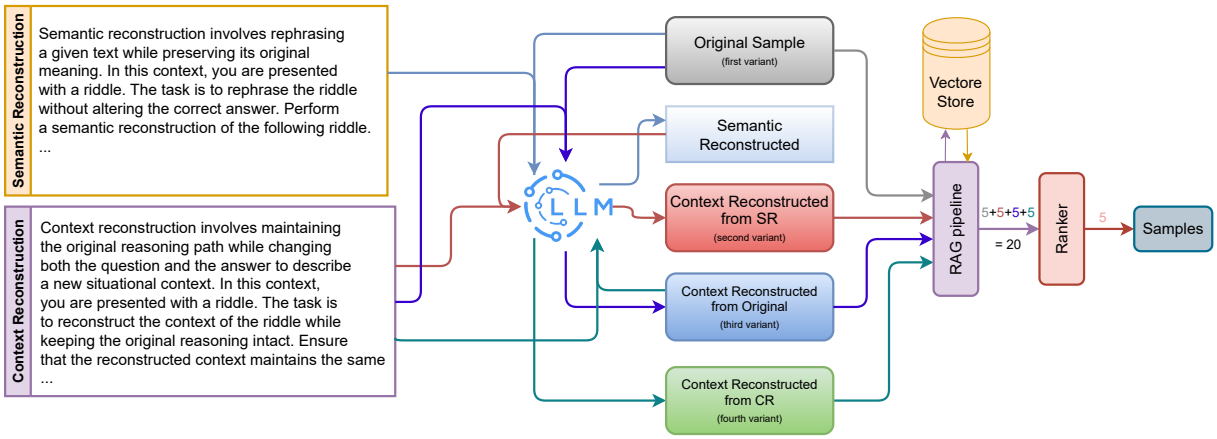

Figure D.1: RAG Fusion. The four used variants include: (I) The original riddle, (II) Context reconstruction obtained from semantically reconstructed samples originating from the original riddle, (III) Context reconstruction derived from the original riddle, (IV) Context reconstructed from step 3, then we retrieve similar samples for each variant. In the end, we feed retrieved documents to a ranker to filter them based on similarity and usefulness.

IITK at SemEval-2024 Task 4: Hierarchical Embeddings for Detection of Persuasion Techniques in Memes

Shreenaga Chikoti **Shrey Mehta** **Ashutosh Modi**
Indian Institute of Technology Kanpur (IIT Kanpur)
chikoti20@iitk.ac.in
ashutoshm@cse.iitk.ac.in

Abstract

Memes are one of the most popular types of content used in an online disinformation campaign. They are primarily effective on social media platforms since they can easily reach many users. Memes in a disinformation campaign achieve their goal of influencing the users through several rhetorical and psychological techniques, such as causal oversimplification, name-calling, and smear. The SemEval 2024 Task 4 *Multilingual Detection of Persuasion Technique in Memes* on identifying such techniques in the memes is divided across three sub-tasks: (**1**) Hierarchical multi-label classification using only textual content of the meme, (**2**) Hierarchical multi-label classification using both, textual and visual content of the meme and (**3**) Binary classification of whether the meme contains a persuasion technique or not using it's textual and visual content. This paper proposes an ensemble of Class Definition Prediction (CDP) and hyperbolic embeddings-based approaches for this task. We enhance meme classification accuracy and comprehensiveness by integrating HypEmo's hierarchical label embeddings (Chen et al., 2023) and a multi-task learning framework for emotion prediction. We achieve a hierarchical F1-score of 0.60, 0.67, and 0.48 on the respective sub-tasks.

1 Introduction

Memes are popular among people of all age groups today through different social media platforms (Keswani et al., 2020; Singh et al., 2020). These memes help people know about the trends around them and can influence their decisions. Memes are one of the popular modes for spreading disinformation among people (examples in Figure 1), as studies have suggested that people tend to believe what they see frequently in such memes spread over the internet (Moravec et al., 2018). As evidenced by research (Shu et al., 2017) during the 2016 US Presidential campaign, nefarious actors, including bots, cyborgs, and trolls, leveraged memes to evoke emotional reactions and propagate misleading narratives (Guo et al., 2020).

Figure 1: Sample set of memes showing the multi-modal setting

In this respect, SemEval-2024 Task 4 (Dimitrov et al., 2024) focuses on predicting the persuasive technique (from the visual and textual content) used in a meme across four different languages: English, Arabic, North Macedonian and Bulgarian. The task is divided into three sub-tasks: (**1**) Hierarchical multi-label classification using only textual content of the meme, (**2**) Hierarchical multi-label classification using both textual and visual content of the meme and (**3**) Binary classification of whether the meme contains a persuasion technique or not using it's textual and visual content. The training data is provided for each sub-task but only in English. Taxonomy of various persuasion techniques (Figure 2) and their respective definitions are provided.

To address sub-task **1**, we employed a dual approach involving definition-based modeling for each class and hierarchical classification using hyperbolic embeddings, as proposed in Chen et al. (2023). Based on hyperbolic embeddings, the

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1779–1787

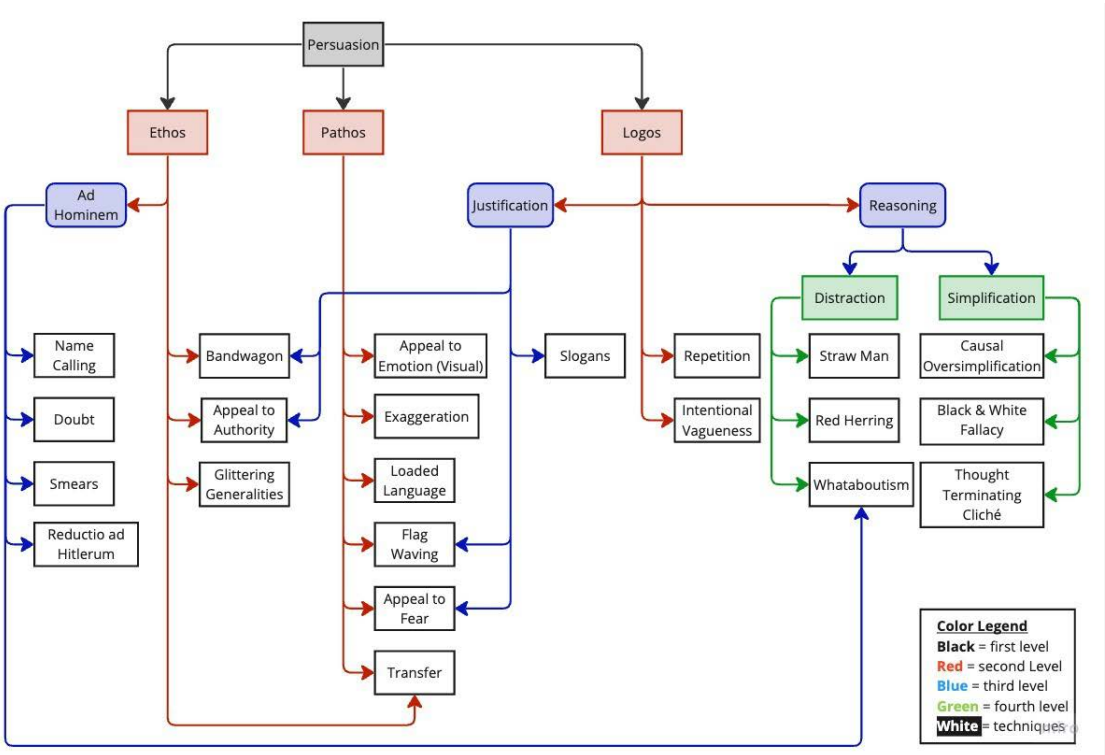

Figure 2: Taxonomy of persuasion techniques for sub-task **2**

method facilitates a nuanced classification of persuasion techniques by leveraging hierarchical structures. The incorporation of definition-based modeling allows for a dataset-agnostic approach, enhancing the precision of classification without reliance on hierarchical structures.

For sub-task **2**, we augmented our methodology by integrating CLIP embeddings (Radford et al., 2021) to capture essential features from memes' textual and visual components. This fusion of textual and visual information enables a more comprehensive analysis of meme content.

In addressing sub-task **3**, we adopted an ensemble approach, leveraging transfer learning from both the DistilBERT (Sanh et al., 2019) and CLIP embeddings (Radford et al., 2021). This ensemble technique enhances the robustness and effectiveness of our classification system by amalgamating insights from both pre-trained models. We release the code via GitHub.[1]

2 Background

The goal of propaganda is to enhance people's mindsets (Singh et al., 2020), especially at the time of elections, where the trends in the media influence the votes of the people (Shu et al., 2017). Propaganda uses psychological and rhetorical techniques to serve its purpose. Such methods include using logical fallacies and appealing to the audience's emotions. Logical fallacies are usually hard to spot since the argumentation, at first sight, might seem correct and objective. However, a careful analysis shows that the conclusion cannot be drawn from the premise without misusing logical rules (Gupta and Sharma, 2021). Another set of techniques uses emotional language to induce the audience to agree with the speaker only based on the emotional bond that is being created, provoking the suspension of any rational analysis of the argumentation (Szabo, 2020).

Corpora development has been instrumental in advancing deception detection methodologies. Rashkin et al. (2017) introduced the TSHP-17 corpus, providing document-level annotation across four classes: trusted, satire, hoax, and propaganda. However, their study on the classification task revealed limitations in the generalizability of n-gram-based approaches. Building on this, Barrón-Cedeno et al. (2019) contributed the QProp corpus, which specifically targeted propaganda detection, employing a binary classification scheme of propaganda versus non-propaganda. Similarly, Habernal

[1] https://github.com/Exploration-Lab/IITK-SemEval-2024-Task-4-Pursuasion-Techniques

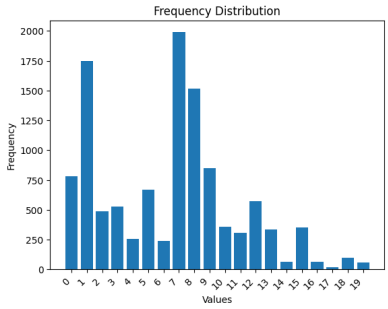

Figure 3: The frequency Distribution of Labels in the training dataset

et al. (2018) developed a corpus annotated with fallacies, including *ad hominem* and *red herring*, directly relevant to propaganda techniques.

BERT-based variants have emerged as promising methodologies for classification tasks in tandem with corpus development. Yoosuf and Yang (2019) proposed a fine-tuning approach post-world-level classification using BERT, while Fadel et al. (2019) presented a pre-trained ensemble model integrating BiLSTM, BERT, and RNN components. Further extending the capabilities of BERT, Costa et al. (2023) advocated for a multilingual setup, employing translation to English before utilizing RoBERTa. Additionally, Teimas and Saias (2023) proposed a hybrid technique combining CNN with DistilBERT for improved detection accuracy.

Exploring multimodal content, Glenski et al. (2019) delved into multilingual multimodal deception detection, mainly focusing on hateful memes. Leveraging visual and textual content, they utilized fine-tuning techniques with state-of-the-art models like ViLBERT and VisualBERT and transfer learning-based approaches (Gupta et al., 2021).

3 Data Description

The competition consisted of two different phases mainly the development phase which we refer to as the development set and for the development phase we were provided the training and validation sets for benchmarking our models

All three sub-tasks have different sets of memes split across training, validation and Develepmont sets as shown in Table 2. We have also plotted the Distribution of the labels across the Figure 3 training data and the Figure 4 validation data.

Our analysis used a dictionary to map various rhetorical techniques to numerical values for plotting. This dictionary is as follows:

Persuasion Technique	**Number mapped to**
Presenting Irrelevant Data (Red Herring)	0
Bandwagon	1
Smears	2
Glittering generalities (Virtue)	3
Causal Oversimplification	4
Whataboutism	5
Loaded Language	6
Exaggeration/Minimisation	7
Repetition	8
Thought-terminating cliché	9
Name calling/Labeling	10
Appeal to authority	11
Black-and-white Fallacy/Dictatorship	12
Obfuscation, Intentional vagueness, Confusion (Straw Man)	13
Reductio ad hitlerum	14
Appeal to fear/prejudice	15
Misrepresentation of Someone's Position (Straw Man)	16
Flag-waving	17
Slogans	18
Doubt	19

Table 1: Dictionary Mapping for different persuasion techniques for Subtask 1

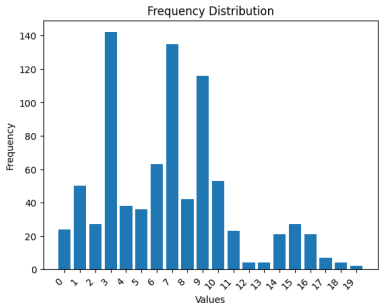

Figure 4: The frequency Distribution of Labels in the validation dataset

4 System overview

The proposed system for all the sub-tasks involves task-specific modifications made to the BERT model and earlier proposed works including CLIP Model (Radford et al., 2021), Class Definition based Emotion Predictions (Singh et al., 2021, 2023) and HypEmo model (Chen et al., 2023) (described below).

4.1 Data Pre-processing

To ensure consistency and standardization, we begin by pre-processing the text. This involves removing newline characters, commas, numerical values, and other special characters. Additionally, the entire text is converted to lowercase. In our approach, we leverage the Development (Dev) and Training sets, focusing solely on samples containing non-zero classes.

Figure 5: The meme sarcastically suggests that individuals who oppose Trump are being unfairly equated with terrorists, highlighting the absurdity of such comparisons. Two persuasion techniques are used: (i) *Loaded Language*, and (ii) *Name calling* that can be inferred from the text and the visual content.

Sub-task	Train Data	Validation Data	Development Data
Sub-task 1	7000	500	1000
Sub-task 2	7000	500	1000
Sub-task 3	1200	300	500

Table 2: Distribution of data across sub-tasks

4.2 Sub-task 1: Hierarchical Multi-label Text Classification

We present a novel approach to meme classification, drawing upon the methodologies of two key frameworks: HypEmo and a multi-task learning model focused on emotion definition modeling.

HypEmo (Chen et al., 2023) utilizes pre-trained label hyperbolic embeddings to capture hierarchical structures effectively, particularly in tree-like formations. Initially, the hidden state of the [CLS] token from the RoBERTa backbone model is projected using a Multi-Layer Perceptron (MLP). Subsequently, an exponential map is applied to project it into hyperbolic space. The distance from pre-trained label embeddings is the weight for the cross-entropy loss function, enhancing the model's sensitivity to label relationships.

To implement the HypEmo architecture, we transform the Directed Acyclic Graph (DAG) (Figure 2) into a tree structure. This involves duplicating children with multiple parents, resulting in distinct embeddings for each label. For example, a sentence with various labels is converted into separate samples, each assigned one label. Utilizing the Poincaré hyperbolic entailment cones model (Ganea et al., 2018) with 100 dimensions, the constructed tree undergoes training, with predictions generated via softmax. Peaks are identified through Z-score analysis associated with each class, with thresholds set accordingly.

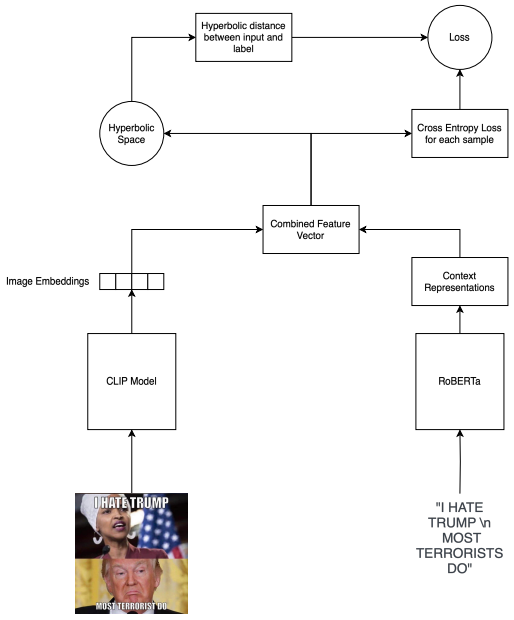

Figure 6: Proposed architecture for sub-task **2**

Singh et al. (2021, 2023) have introduced a complementary approach focusing on emotion prediction through a multi-task learning framework. This model incorporates auxiliary tasks, including masked language modeling (MLM) and class definition prediction, to enhance the understanding of emotional concepts. In our setup, class definitions are merged using a [SEP] token, with the model trained to predict whether the conjoined definition matches the actual definition. Binary cross-entropy loss is employed for this task, along with MLM for fine-tuning the model. Additionally, binary cross-entropy loss is used for each class during training. We utilize class definitions provided by the meme classification competition for the auxiliary task of class-definition prediction.

Finally, we merge the predictions generated by both models (HypEmo, Fine-grained class-definition based model) to compute the final predictions. This integrated approach aims to leverage the strengths of each framework, enhancing the accuracy and comprehensiveness of meme classification outcomes.

4.3 Sub-task 2: Hierarchical Multi-label Text and Image Classification

We model this sub-task by experimenting with using an ensemble of HypEmo (Chen et al., 2023)

and the class definition-based multi-task learning model (Singh et al., 2021, 2023) for the textual content of the meme and using the CLIP model (Radford et al., 2021) embeddings for extracting the relevant features from the visual content of the meme. We construct a similar DAG structure for sub-task 1 and generate the hyperbolic embeddings. The image embeddings obtained from the CLIP model are concatenated with the embeddings generated for the textual contents before sending the combined feature vector for training. Then, the model is trained, and the predictions are generated using the softmax activation function. The Z-score analysis is done on the resulting predictions to make the classification, similar to task 1. An overview of the architecture of the modified HypEmo model is shown in Figure 7.

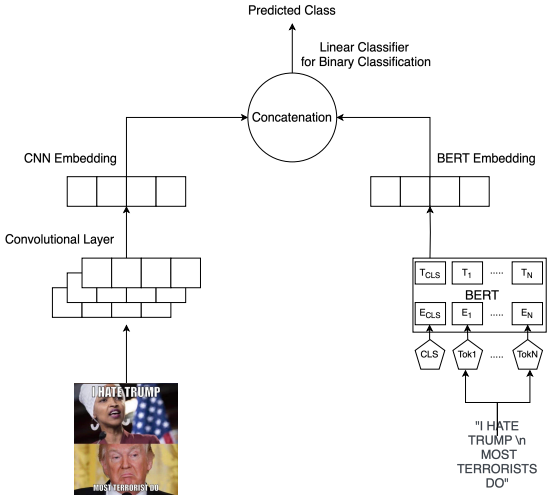

Figure 7: Proposed architecture for sub-task **3**

4.4 Sub-task 3: Binary Text and Image Classification

In this task, we must classify whether a meme contains a persuasion technique based on its textual and visual content. We use the pre-trained $\text{BERT}_{\text{BASE}}$ model (Devlin et al., 2019) and the Convolution Neural Network (CNN) (O'Shea and Nash, 2015) layer to extract the features from the text and image, respectively. We attach a feed-forward $[CLS]$ token embedding along with two linear layers connected by the $sigmoid$ activation function in between, which generates the sentence embeddings corresponding to the textual content in the meme. We use a network of four CNN layers connected through the ReLU activation function, which progressively extracts features from the input image. Max pooling layers are used to downsample the feature maps, increasing robustness to minor variations. The resultant image embeddings are concatenated with the sentence embeddings, and a linear classifier is applied to the combined feature vector with the $sigmoid$ activation function. We use the binary cross-entropy loss function to train the model and tune the hyperparameters on the validation set. An overview of the model architecture is shown with an example in Figure 8.

Since the training data is in a 2:1 ratio for the "persuasive" (positive, labeled as 1) and "not-persuasive" (negative, labeled as 0) class, which leads to an imbalance in the dataset, we use the weighted binary cross entropy loss function as shown below:

$$L(\mathbf{x}, \mathbf{y}) = -\frac{1}{N}\sum_{1}^{N}(w * y_i * log(x_i) + (1-w) * (1-y_i) * log(1-x_i))$$

$$w = \frac{1}{f}(K - f)$$

where N is the batch size, i is the index of the i^{th} batch element, f is the frequency of the positive class, $\mathbf{x}$ is the output of the last $sigmoid$ layer, $\mathbf{y}$ is the vector of the ground truth labels, and K is the total size of the training dataset. Finally, by choosing the one with a higher probability, we use the output probabilities of the final $sigmoid$ layer to predict whether a persuasion technique is present in the meme.

5 Experimental setup

5.1 Implementation Details

We have used the official PyTorch implementation (Paszke et al., 2019) for implementing all the models across sub-tasks. We have used the HypEmo[2] model and the Class Definition Prediction (CDP)[3] model for generating the hyperbolic embeddings and class-definition based features of the textual contents, respectively and the CLIP[4] mainly the 'clip-ViT-B-32' model for generating embeddings for the visual features of the meme. Some portions of the test set have languages other than English for

[2]HypEmo, https://github.com/dinobby/hypemo

[3]CDP, https://github.com/Exploration-Lab/FineGrained-Emotion-Prediciton-Using-Definitions

[4]CLIP, https://github.com/openai/CLIP

testing purposes. Since the models described earlier were trained in English, we translated the non-English data into English language using the implementation of the OPUS-MT model (Tiedemann and Thottingal, 2020) from the HuggingFace[5] library and inference was done on the translated text. We created an ensemble of classes predicted by all the models and took a union of the predicted labels to produce the final predicted set of labels to which the meme belonged.

We have used the data in the same ratio provided in the task to train the models. We combine the train validation dataset for training in each subtask and test it in the four languages.

5.2 Evaluation Metrics

Sub-tasks 1 and 2 depend on a hierarchy, as shown in Figure 2. Hierarchical-F1 (Kiritchenko et al., 2006) is used as the evaluation metric for these two sub-tasks. In these two, the gold label is always a leaf node of the DAG, considering the hierarchy in Figure 2 as a reference. However, any node of the DAG can be a predicted label with:

- If the prediction is a leaf node and it is the correct label, then a full reward is given. For example, *Red Herring* is predicted and is the gold label.
- If the prediction is NOT a leaf node and an ancestor of the correct gold label, then a partial reward is given (the reward depends on the distance between the two nodes). For example, if the gold label is Red Herring and the predicted label is *Distraction* or *Appeal to Logic*.
- If the prediction is not an ancestor node of the correct label, then a null reward is given. For example, if the gold label is *Red Herring* and the predicted label is *Black and White Fallacy* or *Appeal to Emotions.*

Sub-task 3 uses macro-F1 as the evaluation metric for the binary classification task. This ensures equal importance to the "persuasion technique present" and "no persuasion technique" classes, regardless of potential data imbalance.

6 Results

We conducted several experiments across all the sub-tasks, and the detailed information can be seen in Table 3,Table 4,Table 5,Table 8 and Table 9.

Table 4: Macro F1 scores for different persuasion classes for the given languages for Subtask 1

For Task 1, we started experimenting with the BERT and RoBERTa models, achieving a hierarchical F1 score of 0.55 and 0.60 on the test set of the English language. But, in this approach, we did not take the hierarchy and the definitions of the classes into consideration. We tried to accommodate that using the combination of HypEmo and CDP models.

For the HypEmo model, the model was trained to prioritize higher-level labels in the Directed Acyclic Graph (DAG). During this process, we explored two options: eliminating children when the model predicted the parent label and retaining the children. We observed a significant impact on the hierarchical F1 score, with the first formulation

Language	Base F1	Hierarchical F1	Hierarchical Precision	Hierarchical Recall
English	0.37	0.60	0.53	0.69
Arabic	0.37	0.42	0.32	0.60
Bulgarian	0.28	0.48	0.40	0.62
North-Macedonian	0.30	0.41	0.33	0.56

Table 5: Hierarchical-F1 scores computed across four languages of the test set for sub-task 1. Base F1 score here is the Baseline F1 score

Language	Baseline F1	Hierarchical F1	Hierarchical Precision	Hierarchical Recall
English	0.44	0.67	0.67	0.67
Arabic	0.57	0.53	0.50	0.57
Bulgarian	0.50	0.65	0.66	0.63
North-Macedonian	0.55	0.67	0.72	0.62

Table 6: Hierarchical-F1 scores calculated for four languages within the test set for sub-task 2, with Base-F1 denoting the Baseline F1 score depicted on the leaderboard

yielding 0.45 F1 and the second approach resulting in 0.59 on the test set. We also tried to predict the labels utilizing only the definitions of the classes, using the CDP model, which yielded a hierarchical F1 score of 0.57 and 0.59 on the dev set and the test set, respectively.

For constructing an ensemble, one approach considered concatenating embeddings or softmax predictions from both models for further classification using a neural network. However, this approach was not viable due to limited samples for generalization. The most effective model emerged from utilizing the ensemble with fine-tuning of hyperparameters. Combining predictions from both models yielded a hierarchical F1 score of 0.60.

Table 8 shows that the best generalizability across all tasks is achieved via the HypEmo + CDP(Union) for subtask1.

For sub-task 2, we trained the model from scratch after including the two labels used in the ensemble used in sub-task 1 and changed the feature embeddings being trained by considering the features from the visual content. However, as you can see, there is very little to no difference between the results using CLIP and not using CLIP. We can also see that, unlike the first subtask, they perform better due to more data.

We can see the F1-score analysis tables for each subtask, i.e., in Table 4, Table 3 for subtask1 and subtask2.

For sub-task 3, we trained the model on an ensemble of BERT and CNN models to consider the textual and visual features. It was seen that the ensemble performs just slightly better than using the BERT model, that is, considering only the textual cues. Visual cues are considered significantly when persuasion techniques like $Smears$ are used, as seen in sub-task 2. For the rest of the persuasion techniques, the visual cues were seen not to make a significant impact on the classification task. On the gold labels of the dev set, the ensemble gave a macro-F1 score of 0.67, which is a slight im-

Model	English	Arabic	Bulgarian	North-Macedonian

provement from the BERT model, which showed a macro-F1 score of 0.63 on the dev set.

7 Conclusion

Detection of persuasion techniques in memes is seen in a multi-modal setting in this task, but the significant features are drawn from the textual cues in the memes, which can be seen in the results of sub-tasks 1 and 2. The CLIP and other visual language models still need considerable development, and visual cues are helpful for only specific input-output pairs. Identifying whether a persuasion technique is present in the meme but does not apply to the multi-label classification task can be beneficial. Also, we have used a basic ensemble of the latest works in this area and modified them for task-specific requirements. Still, other complex architectures can be explored to get better results.

Abstract

This paper describes our submission for SemEval-2024 Task 6: SHROOM, a Shared-task on Hallucinations and Related Observable Overgeneration Mistakes. We propose four groups of methods for hallucination detection: 1) Entailment Recognition; 2) Similarity Search; 3) Factuality Verification; 4) Confidence Estimation. The four methods rely on either the semantic relationship between the hypothesis and its source (target) or on the model-aware features during decoding. We participated in both the model-agnostic and model-aware tracks. Our method's effectiveness is validated by our high rankings 3rd in the model-agnostic track and 5th in the model-aware track. We have released our code on GitHub.[1]

1 Introduction

In tasks related to natural language generation, the output of a model may be fluent but may suffer from inaccuracies or inconsistencies with the input, a phenomenon referred to as "hallucination." For instance, Lee et al. (2021) and Müller et al. (2020) noted that in machine translation tasks, translated text is regarded as a "hallucination" when it exhibits a complete disconnect from the source text. Such discrepancies can mislead users and potentially lead to severe consequences. However, current evaluation metrics such as perplexity and BLEU (Papineni et al., 2002a) concentrate more on fluency rather than the accuracy or fidelity to the original input. Therefore, hallucination detection poses a big challenge and has gathered attention from research community.

SemEval-2024 Task 6 (Mickus et al., 2024) presents a testbed to evaluate whether the model outputs are hallucinating or not. The task comprises a total of three kinds of subtasks, which are definition modeling (DM) (Noraset et al., 2017), machine translation (MT) and paraphrase generation (PG). Each subtask involves triplet data with a source, which is the input to the model; a target, which represents the "gold" text that the model is expected to produce; a hypothesis, which is the actual output of the model. For all subtasks, the objective is to evaluate whether the hypothesis exhibits hallucinations according to the source or the target. More specifically, the hallucination of the hypothesis is verified based on target for DM and MT tasks, and source for PG task.

This paper presents the participation of HIT-MI&T Lab in the shared task in detail. We introduce four distinct hallucination detection methods, which transform the problem into different tasks:

1) Entailment Recognition: Hallucination is determined by analyzing the entailment relationship between the hypothesis and its source (target). Our approach mainly involves fine-tuning large language models (LLMs) and DeBERTa (He et al., 2020). An annotation dataset is constructed automatically to address data scarcity. We also devise an optimized loss function to handle noisy annotations during the fine-tuning of DeBERTa.

2) Similarity Search: Hallucination is gauged based on the semantic similarity between the hypothesis and its source (target). We mainly leverage SBERT (Reimers and Gurevych, 2019) to derive sentence representations for similarity search.

3) Factual Verification: Hallucination is detected by identifying factual inconsistencies between the hypothesis and its source (target). We mainly employ UniEval (Zhong et al., 2022) to assess the factual consistency.

4) Confidence estimation: Hallucination is evaluated based on the model's confidence in its answer. We mainly rely on two methods to estimate the model's confidence: a) analyzing the softmax distribution during decoding; b) assessing prediction consistency among multiple samplings.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1788–1797

Finally, different groups of methods are ensembled for further enhancement, based on the accessibility of model-aware features. With our proposed framework, we achieved the third position in the model-agnostic track and the fifth position in the model-aware track, validating its effectiveness.

2 Related Work

With the success of ChatGPT (OpenAI, 2022) and GPT-4 (OpenAI, 2023), natural language generation has gained significant prominence within the broader domain of artificial intelligence. Its applicability spans a diverse array of tasks, including machine translation, summarization, and story continuation, etc. However, these models are sometimes prone to generating outputs that are fluent yet factually inaccurate, a phenomenon referred to as "hallucination". This phenomenon poses a substantial challenge to the reliability of language generation in real-world scenarios.

In the domain of hallucination detection methods, there has been considerable work by predecessors. Some people rely on semantic similarity measures for detection, such as N-gram-based Metrics (ROUGE (Lin, 2004) and BLEU (Papineni et al., 2002b)). However, these metrics only evaluate the lexical overlap between generated texts and reference texts by measuring the n-gram co-occurrence, and cannot discern fine-grained contextual semantic mismatch. Other studies(Laurer et al., 2023; Zha et al., 2023; Vectara, 2023) have fine-tuned BERT models using entailment datasets. These fine-tuned models are then utilized to detect hallucinations in specific scenarios. However, the fine-tuning process requires annotation data and can not generalize well among different scenarios.

As the hallucination mainly comes from the decoding procedure, some people propose to rely on uncertainty measures to detect hallucination. Some research (Guerreiro et al., 2023; Fu et al., 2023) proposed to calculate the log-probability or its entropy of translations for language generation tasks, and a lower probability indicates a lack of confidence, suggesting a potential hallucination. However, access to token-level probability distributions, essential for these approaches, is limited to open-source models and unavailable for models accessed solely through APIs, such as GPT-4.

Recently, with the popularization of LLMs, several LLM-based methods have been proposed. SelfCheckGPT (Manakul et al., 2023), employs a sampling-based strategy, which involves the generation of multiple stochastic samples. This approach hypothesizes that a model with a good understanding of the concept is less likely to generate significant hallucinations. Mündler et al. (2023) has explored the examination of self-contradiction within the context generated by an LLM as another aspect of hallucination detection. Their experiments, which involved prompting the LLM to perform a detection task, have demonstrated successful detection across various LLMs.

3 Methods

In this section, we will introduce our proposed four groups of methods for hallucination detection. The overall framework is shown in Figure 1.

3.1 Entailment recognition

While the objective of hallucination detection is to discern whether there is semantic mismatch between the hypothesis and the source (target), it resembles the objective of entailment recognition. Therefore, we decide to leverage entailment recognition models for detection.

3.1.1 LLM-based Data Construction

When employing entailment recognition model for hallucination detection, task specific fine-tuning is necessary to cope with the domain difference. However, organizers only provide unannotated training data in the form of [source, target, hypothesis], which cannot be directly leveraged for fine-tuning. Therefore, we propose deriving entailment annotations ourselves, leveraging the intelligence of proprietary LLMs like GPT-4. Specifically, we provide the paired text to the LLM, and design the prompt template to utilize GPT-4 to detect hallucinations in the hypothesis[2].

3.1.2 Fine-Tuning DeBERTa

As entailment recognition is inherently a text classification problem, we believe encoder-only understanding models may be more suitable. Therefore, we propose to apply fine-tuning on DeBERTaV3 (He et al., 2021), which has achieved good results especially in the text entailment task. The hypothesis, combined with the source (target) is fed to the entailment model, and a binary label is derived as the detection result.

[2]The detailed prompt is shown in Appendix A due to space limitations.

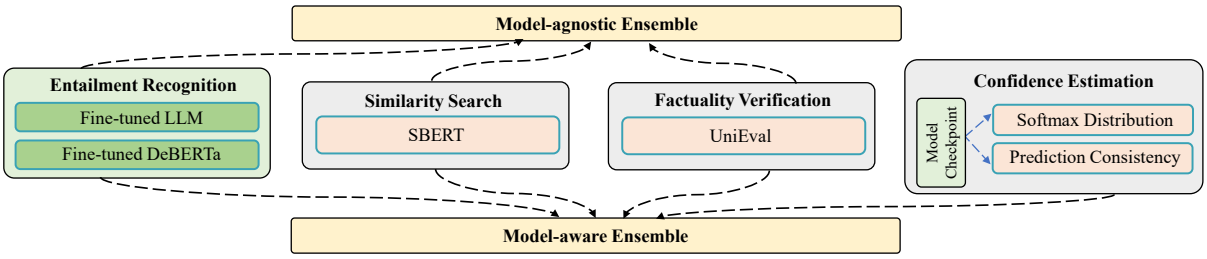

Figure 1: Overall framework of our proposed hallucination detection methods. We ensemble different groups of methods in different tracks, depending on the accessibility of model checkpoints.

As we mainly rely on automatically annotated data for fine-tuning, which the labels are generated by GPT-4 and may contain noise. Therefore, we introduced an auxiliary confidence loss that considers both the annotated labels and the difference between the model's prediction and its own confidence, following the work on weak-to-strong supervision by Burns et al. (2023). The optimized loss is formulated as follows:

$$L_{\mathbf{conf}}(f) = (1-\alpha)\cdot \mathrm{CE}(f(x), f_d(x)) \\ +\alpha \cdot \mathrm{CE}(f(x), \widehat{f}_t(x)) \quad (1)$$

with symbols denoted as follows:

- $\mathrm{CE}(\cdot,\cdot)$ is the cross-entropy loss between the ground truth labels and the predicted probabilities.
- $f(x)$ belongs to [0,1] and represents the model's prediction distribution for input x.
- $f_d(x)$ represents the label for the input x.
- α is a weight used to balance the two losses.
- $\hat{f}_t(x)$ is a special version of $f(x)$, defined as follows:

$$\hat{f}_t(x) = \begin{cases} 1 & \text{if } f(x) > t \\ 0 & \text{if } f(x) \leq t \end{cases} \quad (2)$$

3.1.3 Fine-Tuning LLM

Given the superior performance of open-source LLMs across a diverse array of tasks, we also employ LLM for hallucination detection, which is fine-tuned on the annotated data.

We employ the recently released InternLM-20B (Team, 2023), due to its superior performance across various benchmarks and relatively modest parameter count. Our fine-tuning follows the instruction fine-tuning process, where the hypothesis combined with the source (target) is fed to the model to yield predictions indicative of entailment. Notice as the InternLM has gained massive linguistic knowledge, we only perform fine-tuning on the human annotated validation set. Moreover, we employ Q-LoRA (Dettmers et al., 2023), a parameter-efficient fine-tuning method to reduce the demand for training resources and time.

3.2 Similarity search

Since the hallucination mainly signifies the semantic mismatch between the hypothesis and the source (target), we believe that the mismatch can also be measured by sentence similarity. With contextual sentence embedding models, the hallucination can be discerned by a delicately designed threshold.

Specifically, we use SBERT to derive the semantic representations. SBERT model is an adapted version of BERT (Devlin et al., 2018) which is specifically designed to extract contextual text embeddings. In this work, we construct the sentence representations using the SBERT models for both hypothesis and source (target). After that, the cosine similarity scores are then calculated between the representations, to measure their semantic similarity.

3.3 Factual verification

As hallucinations often relate to factuality contradiction, we think the hallucination can be determined by evaluating the factual consistency between the hypothesis and the source (target).

Specifically, we use the UniEval framework to calculate the factual consistency score. UniEval is a comprehensive framework designed to evaluate generated text across multiple explainable dimensions, including factual consistency assessment. We feed the combined hypothesis and source (target) to the UniEval framework, and a continuous score is derived indicating the factual consistency.

3.4 Confidence Estimation

Hallucination in model output often signifies a lack of confidence. Therefore, we propose to apply

confidence estimation techniques to detect hallucinations. By quantifying the model's confidence in its predictions, we can discern whether the output contains hallucination or not.

Specifically, we employ two confidence estimation techniques: analyzing softmax distribution of output tokens and assessing prediction consistency among multiple samplings. It is important to note that these methods are used only in the model-aware track due to the inherent requirement for checkpoints of the model that generates the output.

3.4.1 Softmax Distribution

One way to estimate model confidence is to analyze the softmax distribution over the vocabulary during the generation process. If the probability mass is highly concentrated on a few words, this suggests the model is confident in its predictions. Conversely, if the softmax probabilities approach a uniform distribution, where picking any word from the vocabulary is equally likely, then the quality of the hypothesis is expected to be low with hallucinations included. Therefore, we propose to incorporate the softmax distribution for hallucination detection.

In particular, we use two groups of features: token-level probability and entropy. For token-level probability, we calculate the average probability and minimum probability of each token. For entropy, we calculate the average entropy and maximum entropy at each position.

This method is primarily applied to DM and MT tasks, as these two subtasks tend to produce fixed outputs for fixed inputs.

3.4.2 Prediction Consistency

When the model lacks confidence with its own prediction, different predictions among different samplings might differ a lot. Based on this premise, we resort to the work of SelfCheckGPT (Manakul et al., 2023), using the model itself to quantify the confidence of the prediction among multiple samplings, thereby detecting hallucinations.

Specifically, we first invoke the model to generate n drawn samples S^n. For the hypothesis and the i-th S^i sample, we invoke the prompt to query LLM and discern their consistency. After that, the hallucination probabilities can be calculated as $\sum_{i=1}^{n} x_i$, with the result x_i for each sample i mapped to a value between 0 and 1. If most of the samples are consistent with the original hypothesis, then the model is confident with its own prediction, and the hypothesis is likely not hallucinated, and vice versa.

We apply this method mainly to the PG task, as this task tends to produce different outputs for fixed inputs. Notice this method does not require the accessibility of glass-box features such as softmax distribution.

4 Experiments

4.1 Experiment-Setup

4.1.1 Data

As shown in Table 1, the organizers provided a validation set with manual annotations and an unannotated training set. As described in Section 3.1.2, for the entailment recognition method, we explore using LLMs like GPT-4 to automatically annotate the unannotated training data. For similarity search, factuality verification, and confidence estimation methods, we mainly rely on the validation set.

Dataset	Track	Task	Quantity
training	model agnostic	DM	1000
		MT	750
		PG	1000
		Total	2750
validation	model agnostic	DM	187
		MT	187
		PG	125
		Total	499
	model aware	DM	188
		MT	188
		PG	125
		Total	501

Table 1: Data Statistics

4.1.2 Pretrained Checkpoints

Regarding the DeBERTa-based entailment model, we mainly rely on DeBERTa-MoritzLaurer, which has already been trained on a diverse range of entailment datasets. For the InternLM-based entailment model, we utilize both the un-instructed and instructed tuned versions for comparison. To derive sentence embeddings from SBERT, we employ three high-performing variants from the text embedding leaderboard[3]. The specific links for all incorporated models are provided in Appendix B.

4.1.3 Task Tracks

This shared task is divided into two tracks: model-agnostic and model-aware. The former operates

[3] https://huggingface.co/spaces/mteb/leaderboard

without knowledge of the hypothesis-generating model. The latter, on the other hand, is informed about the model and can access its checkpoints.

4.2 Main Results

The experimental results are shown in Table 2. The following is a detailed analysis for both model-agnostic and model-aware tracks.

1) DeBERTa-based entailment model performs the best on hallucination detection.

As can be seen, among the four groups of methods, the entailment recognition model performs the best on hallucination detection, across both model-agnostic and model-aware tracks, especially DeBERTa-based entailment model. Although DeBERTa is 50 times smaller than InternLM, it generally outperforms InternLM, possibly due to its encoder-only structure being well-suited for language understanding tasks. Additionally, as the DeBERTa we used is pre-finetuned on various entailment datasets, knowledge can be transferred from other datasets to boost its performance.

Interestingly, the un-instruction tuned InternLM performs better than its instruction tuned version. This indicates the instruction tuning process is inconsistent with our objective and may cause catastrophic forgetting.

2) Similarity-based and factuality-based methods underperform.

In contrast to the entailment-based approaches, similarity-based and factuality-based approaches markedly underperform, potentially due to their mismatches with hallucination detection.

Regarding the similarity-based model, hallucinated sentences might still be similar in the embedding space, as SBERT can only provide general semantic representations. Besides, the Siamese architecture of SBERT also disables in-depth interaction between the source (target) and hypothesis within the multi-layer neural network.

As for the factuality-based model, it mainly aims to evaluate the factual consistency between the source (target) and the hypothesis text, which is a broader task than detecting specific hallucinations. Hallucinations can sometimes be factually consistent with the source information but still contain invented details or distortions, which UniEval's factuality evaluation may not be sensitive enough to capture, leading to poor performance.

3) Confidence estimation performs noticeably worse than other methods.

In the model-aware track, we employ confidence estimation method across all subtasks. We found that this method performed poorly in terms of acc and rho for the DM and MT subtasks. It achieved good acc but poor rho for the PG subtasks. Overall, confidence estimation performed noticeably worse. This can be attributed to two main reasons:

a) The softmax distribution contains insufficient information. The softmax distribution provides a probability distribution over the output vocabulary, but it may not capture all the nuances and uncertainties present in the model's predictions, especially when it comes to hallucinated content.

b) The model fails to provide an accurate evaluation for its prediction. As the prediction is made by the model itself, it is unable to provide an accurate evaluation for the consistency. The consistency verification can only be achieved with the help of external resources among multiple samplings.

Therefore, relying solely on confidence estimation methods may not be effective in detecting hallucinations, as the model itself can be overconfident for its hallucinated outputs.

4) Ensemble of multiple models can enhance performance to some extent.

In the model-agnostic track, the ensembled model achieves an improvement of 0.6 points in acc and 1.5 points in rho. However, in the model-aware track, while the ensemble model surpasses the performance of most models, it is slightly inferior to the best result of the DeBERTa model. We think this might be due to the underperformance of some ensembled methods.

4.3 Analysis of the DeBERTa-based Entailment Model

1) Rationale for not directly utilizing the DeBERTa in entailment model.

As mentioned before, we adopted DeBERTa-MoritzLaurer which is pre-finetuned on various entailment datasets rather than the original DeBERTa model for entailment-based methods. To verify the effectiveness of the pre-finetuning, we perform an ablation study based on the training set and SNLI (Bowman et al., 2015). As can be seen in Table 4, if directly fine-tune DeBERTa on either training set or SNLI, the accuracy on the validation set can achieve only 70%. However, we observe significant performance improvement by employing a two-stage fine-tuning approach, using these datasets sequentially.

Model Type	Model	Description	model-agnostic		model-aware	
			acc	rho	acc	rho
Baseline	Mistral-7B	not train	69.66	40.29	74.53	48.78
Entailment Recognition	InternLM2-20B	train	78.86	67.30	78.20	62.70
	InternLM2-20B-sft	train	63.53	50.35	64.86	46.77
	DeBERTa-MoritzLaurer	train and loss optimization	**82.46**	**75.20**	**80.46**	**71.23**
Similarity Search	SBERT	not train	76.80	63.73	75.66	62.65
Factuality verification	UniEval	not train	72.00	58.04	73.13	54.43
Confidence Estimation	Softmax Distribution	for DM task			59.07	26.08
	Softmax Distribution	for MT task			66.07	37.87
	Prediction Consistency	for PG task			81.33	7.91
Ensemble		ensemble all model	**83.06**	**76.77**	79.73	72.37

Table 2: Experimental results were compared with the baseline of prompting the Mistral-7B model. We use accuracy (which is abbreviated as acc) as the primary evaluation metric and employ Spearman's correlation (which is abbreviated as rho) to comprehensively assess our model's performance.

Model Type	Model	Description	model-agnostic		model-aware	
			acc	rho	acc	rho
Baseline	Mistral-7B	not train	69.66	40.29	74.53	48.78
Entailment Model	DeBERTa-MoritzLaurer	not train	78.00	67.96	63.26	8.21
	DeBERTa-MoritzLaurer	train	81.20	**75.80**	80.13	**71.65**
	DeBERTa-MoritzLaurer	train separately for each task	79.00	66.60	76.40	60.27
	DeBERTa-MoritzLaurer	train and loss optimization	**82.46**	**75.20**	**80.46**	**71.23**

Table 3: Results of different DeBERTa-based entailment models with the following configurations: 1) no training, using the pre-trained model directly; 2) direct fine-tuning using cross-entropy loss; 3) separate fine-tuning on each subtask using cross-entropy loss; 4) fine-tuning with loss optimization.

Model	Description	acc
DeBERTa	fine-tuning on training set	71.23
DeBERTa	fine-tuning on SNLI	72.12
DeBERTa	two stage fine-tuning	78.21

Table 4: DeBERTa model's performance with different fine-tuning settings.

Therefore, instead of directly utilizing the original DeBERTa model, we opted for models pre-finetuned on entailment tasks. Specifically, we selected the DeBERTa-MoritzLaurer model, which is pre-trained on 33 entailment-related datasets, leveraging its transferable entailment recognition knowledge for effective hallucination detection.

2) Loss optimization improves the fine-tuning on LLM-annotated data.

To demonstrate the effectiveness of our proposed loss optimization method, we contrast it with various training methods. As shown in Table 3, while the original model can perform detection to some extent, fine-tuning on annotated data improved the performance. Based on that, our proposed loss optimization method takes into account not only the label but also the model's prediction situation, effectively mitigating overfitting, thereby further improving the performance.

5 Conclusion

In this study, we aimed to address the hallucination detection problem in SemEval-2024 Task 6. We established an ensemble model that includes entailment recognition, similarity search, and factuality verification models. For the model-aware track, we further leveraged confidence estimation for augmentation. Our approach proved effective as we ranked 3rd in the model-agnostic track and 5th in the model-aware track.

Although several methods were incorporated in our experiments, we realized that the best result was achieved primarily by relying on the DeBERTa-based entailment model. Given its portability and generalizability, we plan to further explore its use in hallucination detection in the future.

Table 5: Details of the utilized model and corresponding download URL

Prompt about task MT:

This is a machine translation task. Given a standard translation, and a model output translation, determine if the model output is subject to hallucination.
your task:
standard translation: {ref}
model output translation: {hyp}
The criteria for judging are as follows:
Check if the model output translation is fluent and answers the question.
Compare the model output translation with correct examples. If inconsistencies are found or it can't be inferred from the standard translation, it's likely hallucination.
If the model output translation aligns with the standard translation or has a similar meaning, it's likely not hallucination.
If the standard translation is "unanswerable" and the model output translation is "I don't know," it's likely not hallucination.
please only return 0 or 1. Return 1 for hallucination; return 0 for not hallucination.

Prompt about task DM:

This is a definition modeling task. Given a standard definition of a word, and a model output definition of this word, determine if the model output is subject to hallucination.
your task:
standard definition: {ref}
model output definition: {hyp}
The criteria for judging are as follows:
Check if the model output definition is fluent and answers the question.
Compare the model output definition with correct examples. If inconsistencies are found or it can't be inferred from the standard definition, it's likely hallucination.
If the model output definition aligns with the standard definition or has a similar meaning, it's likely not hallucination.
If the standard definition is "unanswerable" and the model output definition is "I don't know," it's likely not hallucination.
please only return 0 or 1. Return 1 for hallucination; return 0 for not hallucination.

Prompt about task PG:

This is a paraphrase generation task, which transforms a original sentence into a new sentence. Given a original sentence, and a model output new sentence, determine if the model output is subject to hallucination.
your task:
original sentence: {ref}
model output new sentence: {hyp}
The criteria for judging are as follows:
Check if the model output new sentence is fluent and answers the question.
Compare the model output new sentence with correct examples. If inconsistencies are found or it can't be inferred from the original sentence, it's likely hallucination.
If the model output new sentence aligns with the original sentence or has a similar meaning, it's likely not hallucination.
If the original sentence is "unanswerable" and the model output new sentence is "I don't know," it's likely not hallucination.
please only return 0 or 1. Return 1 for hallucination; return 0 for not hallucination.

Abstract

We describe our systems for SemEval-2024 Task 1: Semantic Textual Relatedness. We investigate the correlation between semantic relatedness and semantic similarity. Specifically, we test two hypotheses: (1) similarity is a special case of relatedness, and (2) semantic relatedness is preserved under translation. We experiment with a variety of approaches which are based on explicit semantics, downstream applications, contextual embeddings, large language models (LLMs), as well as ensembles of methods. We find empirical support for our theoretical insights. In addition, our best ensemble system yields highly competitive results in a number of diverse categories. Our code and data are available on GitHub.

1 Introduction

In this paper, we describe our submission for SemEval-2024 Task 1: Semantic Textual Relatedness (STR) (Ousidhoum et al., 2024b), which is based on the SemRel2024 dataset (Ousidhoum et al., 2024a). Each instance consists of a pair of sentences in the same language, annotated with a score that quantifies their semantic relatedness. SemRel2024 was annotated by native speakers of the dataset's 14 languages, which span five language families. An example English instance consists of the sentence pair *"the story is gripping and interesting"* and *"it's a brilliant, compelling, and heartfelt story"*, which is annotated with a relatedness score of 0.64. We participated in all three tracks (supervised, unsupervised, and cross-lingual) on all 14 languages.

Semantic relatedness is distinct from semantic similarity. Sentences that express opposite propositions, such as *"it is raining"* and *"it is not raining"*, exhibit low similarity but high relatedness. The impact of relations such as antonymy and meronymy (Budanitsky and Hirst, 2001) make semantic similarity a more specific task: similarity implies relatedness, but not vice versa. Nevertheless, many traditional algorithms make no attempt to distinguish between the two tasks (Jurafsky and Martin, 2009). For example, the word overlap baseline in this shared task could also be applied to measure semantic similarity. The extent to which semantic similarity and relatedness correlate in practice remains an important open question.

In this paper, we test the hypothesis that *similarity is a special case of relatedness* (Pedersen et al., 2007) through implementing an array of methods that are designed to measure similarity, and applying them to the task of measuring relatedness. We experiment with several different approaches: (1) methods that create and compare semantic representations of each input sentence; (2) methods that use the output of systems designed for other semantic tasks, such as paraphrase identification and entailment detection; (3) methods based on prompting large language models using in-context learning; and (4) methods that combine multiple individual methods. We further posit that *semantic relatedness is preserved under translation*. We investigate both hypotheses via supplementary experiments on datasets from the Semantic Textual Similarity (STS) task at SemEval 2017, as well as new cross-lingual datasets that we construct ourselves by translating parts of the SemRel2024 dataset.

Our experimental results provide support for our theoretical insights. The experiments on the supplementary datasets demonstrate a high correlation between the STR and STS tasks. Out of 51 competing teams, we rank among the top three entries in 16 of the language/track settings. In particular, our best-performing supervised ensemble system achieves the highest score in the English Track A among the teams that submitted a system description paper (Ousidhoum et al., 2024b). Taken together, these results support the idea of using similarity as a proxy for relatedness, as predicted by our hypotheses.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1798–1805

2 Methods

We investigate ten different methods, divided into four types. Each method takes as input a pair of sentences, and produces a scalar value, which, possibly after some normalization to place it within the range specified for this shared task, is used as a measure of STR. Thus, each individual method is a complete, functional STR method; our principal innovation is the ensembling of these methods into a single STR system.

2.1 Explicit Semantic Methods

Concept overlap We hypothesize that the number of shared lexical concepts correlates with the relatedness between two sentences. On the basis of this hypothesis, we tag the words in each sentence with WordNet senses (Miller, 1995) using the offline AMuSE-WSD large model Docker image (Orlando et al., 2021). Each such sense corresponds to a unique lexical concept. The concept overlap score is calculated by dividing the number of shared concepts, with a WordNet synset path similarity greater than 0.8, by the total number of unique concepts in both sentences.

AMR similarity We approximate the relatedness of two sentences by measuring the similarity of their abstract meaning representations (AMRs). The AMR of a sentence is a structured labeled graph that represents its meaning (Banarescu et al., 2013). After converting each input sentence into an AMR using the SapienzaNLP API[1], the similarity between the two AMRs is computed as the Smatch F1-score (Cai and Knight, 2013), a metric devised explicitly for analyzing the overlap between graph-based representations. This score is then used as a measure of the relatedness of the sentences.

2.2 Extrinsic Methods

Paraphrase identification (PI) We reduce STR to paraphrase identification, a binary classification task to determine the approximate semantic alignment between two sentences (Bhagat and Hovy, 2013). By utilizing a dedicated PI model, we first compute the probability that one sentence is a paraphrase of the other. The intuition is that a higher probability of a positive classification indicates greater semantic relatedness. While paraphrasing is, in theory, a symmetric relation on sentences, in practice, the order in which sentences are provided to the model impacts its output. We compute the paraphrase identification probability for both orderings of the two sentences, and use their average as the score for STR.

Taking RoBERTa (Liu et al., 2019) as the backbone, we fine-tune a paraphrase classifier on a combined dataset, including six datasets: PIT (Xu et al., 2015), QQP (Iyer et al., 2017), MRPC (Dolan and Brockett, 2005), PAWS QQP (Zhang et al., 2019), PAWS Wiki (Zhang et al., 2019), and PARADE (He et al., 2020). We follow dataset splits and training configurations as established in prior research (He et al., 2020; Peng et al., 2022).

Textual entailment Similar to PI, we use textual entailment as an indicator of sentence relatedness. In particular, we aim to reduce STR to recognizing textual entailment (RTE) or natural language inference (NLI). Both tasks evaluate whether the meaning of one sentence (the hypothesis) can be inferred from another (the premise). RTE frames this as a binary task and NLI expands it into ternary classification with the addition of a neutral label (Dagan and Glickman, 2004). Recognizing that entailment in either direction signifies potential relatedness, we use an off-the-shelf RoBERTa NLI classifier (Nie et al., 2020) to estimate the probability of entailment in both directions. The final STR score is the average of these two probabilities.

2.3 Distributional Methods

Embeddings In this method, we use an LLM to produce dense semantic embeddings representing the meaning of each input sentence. We then compute the cosine similarity between their respective embeddings, and use this as a measure of relatedness. This simple embedding-based approach allows a language model to be used "as-is", with no need for additional fine-tuning.

We experiment with two variants based on BERT (`Embed-B`) (Devlin et al., 2019) and RoBERTa (`Embed-R`), respectively. For each sentence, hidden states are obtained from the LLM, and an attention mask is applied to ensure the model focuses on meaningful tokens and excludes the other special ones such as the padding token. The resultant hidden states are aggregated into a single vector through average pooling.

2.4 Large Language Models

Prompting We utilize a few-shot prompting strategy to estimate STR between sentence pairs. We

[1] `nlp.uniroma1.it/spring/api/text-to-amr`

use in-context learning (Brown et al., 2020), providing first a small set of examples from the training data, consisting of two sentences and an STR value (i.e., the correct output from the data). For each pair of sentences, To facilitate few-shot prompting, we sample example sentence pairs from the training dataset and query ChatGPT through its API.[2]

Fusion This approach makes use of contextualized embeddings from a variety of open-source LLMs. For each sentence, we extract its sentence embeddings from each LLM, and concatenate them. The result is a "fusion" vector embedding of sentences whose dimensionality is the sum of the dimensionality of the embeddings produced by each LLM. We apply a trainable point-wise linear operation with bias to the fusion embeddings. We train this layer to minimize the distance between the cosine similarity of the fusion embeddings of each sentence pair in the training data and their gold-standard STR scores. In other words, we train this layer to produce the cosine similarity as the STR scores given pairs of fusion embeddings.

We integrate embeddings derived from a range of sentence transformer models (Reimers and Gurevych, 2019). While several of them are multilingual, our training process is exclusively focused on the English dataset. It aims to minimize the mean squared error (MSE) loss between the cosine similarity of the fusion embeddings for sentence pairs and their corresponding gold-standard STR scores. We adopt early stopping to mitigate the risk of overfitting.

Fine-tuning We add a linear regression head to a pre-trained language model, and fine-tune it for STR using the training data. The resulting regression model is therefore optimized for predicting the relatedness score given a pair of sentences. This provides another approach for leveraging the semantic capabilities of modern language models.

We investigate three distinct regression models, with one variant. Each regression model takes an LLM as the backbone with a randomly initialized regression head. We proceed to fine-tune the entire model, both the backbone and the regression head, The AdamW optimizer (Loshchilov and Hutter, 2019) is configured with an initial learning rate of 2e-5 and a batch size of 24. For the backbone, we experiment with T5 (`FT-T5`) (Raffel et al., 2020), GPT-2 (`FT-GPT2`) (Brown et al., 2020), and RoBERTa (`FT-R`). The variant `FT-MPNet` uses MPNet (Song et al., 2020), aligning more with the training process of SBERT. While most models are trained to minimize the MSE loss, MPNet uniquely targets minimizing the cosine similarity loss. This positions the MPNet one as a form of continued pre-training. We categorize this as a variant within our fine-tuning method for better presentation.

[2]GPT-3.5-turbo-1106. Our experiments with LLaMA-2 (Touvron et al., 2023) were unsuccessful.

2.5 Ensemble Modules

To combine the advantages of the methods above, we assess two ensembling strategies: *unsupervised linear combination* and *supervised regression*.

Linear combination Our first approach is to compute the average of the STR scores produced by the individual methods. We first normalize the scores, based on the observation that some methods tend to produce higher or lower scores (i.e., scores with very different distributions). For instance, one method might typically produce scores between 0.7 and 0.9, while another might tend to produce scores in the range of 0.2 to 0.6. Our normalization is intended to give each method a similar distribution, with the lowest scores being normalized to 0 and the highest scores being normalized to 1. Once normalization is complete, for a given pair of sentences, the final ensemble STR score is obtained by computing the average score across all methods.

Our official submission for Track B is a linear ensemble system `Linear-2Ms` applied to synthesize the results of `Embed-B` and `Embed-R`. It operates entirely unsupervised, meaning it does not require exposure to any samples from the training set.

Regression One limitation of the linear combination is that it makes no distinction between methods; each method contributes equally to the average, regardless of how reliable it is in practice. Our second method combines the scores from the individual methods by treating each score as a feature in a linear regressor. Once trained, the method is applied by first computing the outputs of each method in the ensemble, and then applying the regression model to obtain the final score.

Our official submission for non-English languages in Track C, as well as English in Track A, is a regression ensemble system `XGB-4Ms` designed to synthesize the outputs from fine-tuning T5, GPT2, RoBERTa, and MPNet. At the heart of this ensemble system, we deploy an XGBoost regressor (Chen and Guestrin, 2016) as the central

model, tasked with integrating the results of the four individual systems as input features to predict the STR score. The XGBoost regressor is configured with a squared error regression objective and tailored configurations to optimize performance: a column sample by tree of 0.1, a learning rate of 0.1, a maximum depth of 8, an alpha value of 0.1, and 128 estimators. Training will stop if there is no improvement during validation for 32 consecutive rounds. This set of hyper-parameters is optimized on the English development set and remains constant throughout experiments.

Our official submission for non-English languages in Track A is Target-XGB, a tailored variant of the XGB-4Ms system, which is specifically engineered to navigate the linguistic distribution shifts inherent across languages. Underpinning this approach is the assumption that STR between sentence pairs remains consistent across languages. To this end, we fine-tune each individual system and the XGB regressor on English translations within the target language. Recognizing the potential introduction of noise from imperfect machine translation systems, we implement a data augmentation technique. To be specific, we merge the English training and development sets with the translated training set of the target language. The translated development set of the target language is kept as it is out of the training. By that, we intend to treat the English dataset as a stabilizing anchor, mitigating translation noise and ensuring that our system still remains sensitive to the target language.

3 Semantic Textual Relatedness

Our principal evaluation is on Tracks A, B, and C of the shared task datasets. The evaluation results are reported in Table 1, excluding Punjabi (pan), where most results are negative without any observable pattern. Our results may differ from those submitted due to adjustments in methods. We report the Spearman correlation (%) between the prediction and the golden STR scores.

We employ several baseline methods. Overlap, LaBSE-Cross and LaBSE-Sup are the official baselines reported by Ousidhoum et al. (2024a); the key distinction between the last two lies in whether the backbone LaBSE (Feng et al., 2022) is fine-tuned or not. WordOvlap is our re-implementation of Overlap; EngWordOvlap is its variant which requires translating sentences into English first. Most of our systems are English-specific; we translate sentences in other languages into English via the Google Translate API.

Explicit methods ConceptOvlap performs comparably to WordOvlap, indicating a similar level of efficacy in capturing semantic relatedness. However, AMR lags behind, suggesting that representing sentences as semantic graphs may introduce information that does not contribute to determining semantic relatedness, or that the quality of the AMR representations is insufficient.

Extrinsic methods Reducing the STR task to either PI or NLI yields markedly distinct outcomes. While PI approaches the performance level of the WordOvlap baseline, NLI generally underperforms. This discrepancy may be attributed to the inherent unidirectional nature of entailment. Our implementation takes the average of two entailment probabilities, and thus imposes strict constraints on the relatedness of sentences.

Distributional methods We can see that both Embed-B and Embed-R secures commendable results, matching the overall performance of the WordOvlap baseline. The observed superiority of BERT over RoBERTa could stem from differences in their score distributions. The predictions of Embed-R tend to be more clustered (e.g., ranging from 0.84 to 0.99 on eng). We found that simply rounding its results to two decimal places could reduce its performance from 75.2 to 72.4 on eng. In contrast, the predicted score distribution of Embed-B is relatively more dispersed.

LLM methods Prompt is competitive with LaBSE-Cross, but well below other LLM methods, such as Fusion and FT. This shows that, despite its strong performance on many other tasks, ChatGPT's STR capabilities are still limited. Furthermore, training on the provided dataset is observed to be pivotal in enhancing performance. Overall, our findings underline that there remains considerable scope for exploring and enhancing the application of LLMs in this field.

Ensemble modules Target-XGB obtains the best results across most languages. It surpasses LaBSE-Sup and consistently exceeds XGB-4Ms across all evaluated languages by a significant margin. These results show the importance of additional fine-tuning using the translations of the target language. Furthermore, incorporating the English dataset alongside the translated dataset proves to be advantageous. Notably, our ensemble systems, using either linear or regression modules, demonstrate superior performance over the individual systems they comprise, supporting the efficacy of our proposed ensemble approach.

4 Cross-Lingual Textual Relatedness

In this section, we discuss our experiments on new cross-lingual datasets which we created from the shared task data. The purpose of these experiments is to test our hypothesis that *semantic relatedness is preserved under translation*. Our bilingual dataset contains pairs of sentences from English and Spanish, respectively. The Spanish sentences are obtained by alternately translating one of the two English sentences from each instance of the SemRel2024 development set. The task is to determine the cross-lingual STR score, which is assumed to be the same as that for the original monolingual English sentence pair.

Method	eng	esp*	eng-esp	eng-esp*
WordOvlap	62.7	57.8	33.1	62.5
ConceptOvlap	63.4	62.1	51.5	64.1
AMR	66.1	61.4	-	64.2
PI	71.6	40.3	-	71.5
NLI	62.0	38.2	-	61.6
Embed-B	72.4	71.0	-	70.9
Embed-R	72.1	**72.0**	-	67.0
Prompt	79.0	67.5	77.1	78.7
Fusion	82.5	68.2	**80.4**	81.7
XGB-4Ms	**85.6**	68.4	-	**84.9**

Table 2: Results of primary methods evaluated using Spearman correlation (%) in our cross-lingual setting. Translating inputs into English is denoted by "*".

Table 2 shows the experimental results on our cross-lingual STR dataset. The eng-esp column shows the results of those methods that can be directly applied to languages other than English. The eng-esp* column shows the results of a larger subset of methods obtained after translating the Spanish sentence in each instance back into English. For reference, we also include the results on the official English (eng) and Spanish (esp*) development sets, of which the latter is translated into English.

The WordOvlap baseline performs poorly when applied to the eng-esp dataset because orthographic forms rarely match across languages even if they have the same meaning. In contrast, ConceptOvlap performs much better, as it is entirely multi-lingual and independent of orthography and script. However, both methods obtain similar results on eng-esp*, where the Spanish text is translated into English. Our AMR, NLI, and XGB-4Ms systems cannot be applied to cross-lingual pairs, but when Spanish is translated into English, their performance on eng-esp* is comparable to what is observed on the English test set.

The most interesting findings emerge from the results of Prompt and Fusion. Both are applicable directly to cross-lingual data, without translating the Spanish sentences into English. Surprisingly, for both methods, we observe only small differ-

Method	eng-eng	eng-esp	eng-esp*
ECNU	85.2	81.3	-
WordOvlap	72.8	13.5	64.4
ConceptOvlap	74.8	50.3	69.0
AMR	71.5	-	59.2
PI	76.9	-	72.2
NLI	68.4	-	69.7
Embed-B	73.5	-	63.4
Embed-R	71.5	-	59.2
Prompt	89.2	**87.9**	**88.4**
Fusion	90.3	84.4	87.8
XGB-4Ms	**91.0**	-	87.6

Table 3: Evaluation results of our primary methods using Spearman correlation (%) for the STS task. Translating inputs into English is denoted by "*". ECNU (Tian et al., 2017) ranked first in the SemEval 2017 Task 1.

ences between the relatively high numbers in the three columns. This finding supports our hypothesis that translation does not affect the degree of relatedness between a pair of sentences.

5 Semantic Textual Similarity

Another hypothesis that we investigate is that *similarity is a special case of relatedness*. Therefore, we expect a strong correlation between the two concepts: sentences that are highly similar should also be considered highly related. In this section, we test this hypothesis by applying our methods to STS datasets (i.e., track 5 and 4a) from SemEval 2017 Task 1 (Cer et al., 2017).

Since both STR and STS tasks output numerical scores on pairs of sentences, our methods can be directly applied to STS without modification. For supervised methods, we apply the models to STS in the same way as to STR, without any additional training or fine-tuning. This approach can be viewed as transfer learning: models trained on STR datasets are tested on the STS task. For cross-lingual datasets, we again experiment with both direct application to different languages (eng-esp) and pre-translation into English (eng-esp*).

Table 3 shows the results of our STS experiments. While these STS results are not directly comparable to any STR results, we observe that the best three methods are the same for both mono-lingual and bilingual STS and STR. As shown in Figure 1, the progressive improvement from left to right across methods indicates a strong correlation between STR and STS. Furthermore, the overall alignment between the blue and green lines, as well as between the red and yellow lines, support our hypothesis that both STR and STS are preserved

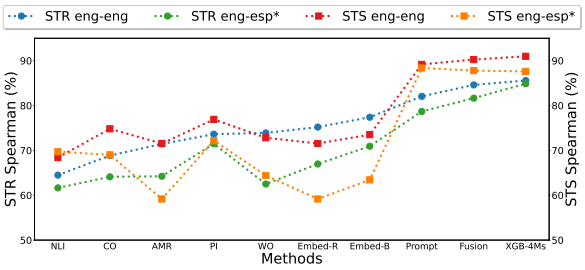

Figure 1: Summary of evaluation results for our primary methods in both STR and STS, Methods are ordered by their performance on STR eng-eng.

under translation.

A more detailed analysis of the individual methods reveals several additional insights. Among the explicit methods, WordOvlap and AMR are both outperformed by ConceptOvlap on STS, which is likely due to their lack of robustness in cross-lingual settings. Among the extrinsic methods, PI works better than NLI, exhibiting remarkable stability across tasks, likely due to the training of our PI model on diverse benchmark datasets, including adversarial examples from PAWS QQP and PAWS Wiki. Among the distributional methods, while Embed-B consistently outperforms Embed-R, both experience a decline in cross-lingual performance, revealing sensitivity of sentence embeddings to translation noise. Among LLMs-based methods, Prompt excels on cross-lingual STS benchmarks, possibly because of data leakage in training ChatGPT, as well as its multilingual design. Our ensemble system XGB-4Ms generally delivers the best results.

6 Conclusion

We have investigated a wide array of methods on two of sentence-level semantic tasks in both mono-lingual and cross-lingual settings. In the process, we assembled a comprehensive benchmark of datasets for future explorations in this domain. The experiments furnish evidence for two hypotheses: (1) semantic similarity is a special case of semantic relatedness, and (2) both similarity and relatedness are preserved under translation. In practical terms, the evaluation results indicate that ensembling LLMs with diverse architectural designs yields the most robust and effective performance across languages and tasks. Notably, our strongest system is at the top of the ranked teams in English Track A, the setting with the highest number of participants.

Abstract

In this article, we present an effective system for semeval-2024 task 5. The task involves assessing the feasibility of a given solution in civil litigation cases based on relevant legal provisions, issues, solutions, and analysis. This task demands a high level of proficiency in U.S. law and natural language reasoning. In this task, we designed a self-eval LLM system that simultaneously performs reasoning and self-assessment tasks. We created a confidence interval and a prompt instructing the LLM to output the answer to a question along with its confidence level. We designed a series of experiments to prove the effectiveness of the self-eval mechanism. In order to avoid the randomness of the results, the final result is obtained by voting on three results generated by the GPT-4. Our submission was conducted under zero-resource setting, and we achieved first place in the task with an F1-score of 0.8231 and an accuracy of 0.8673.

1 Introduction

In 2023, a significant event in the field of artificial intelligence (AI) was the widespread adoption of ChatGPT, particularly the introduction of GPT-4 (OpenAI, 2023), which revolutionized perceptions of AI. GPT-4 exhibited a notable advancement of 11.2 points on the MMLU benchmark (Hendrycks et al., 2021) and demonstrated superior performance on various question answering (QA) and natural language inference (NLI) datasets. Large-scale language models (LLM) represented by GPT-4 have sprung up, including LLaMa-2 (Touvron et al., 2023), Falcon (Almazrouei et al., 2023), Gemini (Anil et al., 2023), Baichuan-2 (Yang et al., 2023) , ChatGLM (Du et al., 2022), etc. There are many researchers have explored NLP task leveraging GPT-4 in zero-resource and low-resource scenarios. GPT-4 is pretrained on a large amount of Internet data initially, and refined through supervised fine-tuning and reinforcement learning from human feedback (RLHF) (Ouyang et al., 2022). Despite these advancements, limited research exists on the direct application of GPT-4 to NLP tasks within the legal domain. This paper aims to comprehensively address this research gap.

2 Task Description

This task aims to assess system's ability to reason about legal arguments. The task organizers have introduced a dataset (Bongard et al., 2022) of civil litigation cases from the U.S. legal system. Each instance comprises of an overview of the case, a question, a proposed solution (an answer candidate), and analysis justifying the solution. Systems are required to determine if the solutions and analysis are correct (True) or incorrect (False). While similar to a typical classification task, this task demands strong causal reasoning and practical application of knowledge. As shown in Figure 1, evaluating the correctness of an answer candidate demands not only a logical assessment of the question and response but also the application of legal knowledge provided in the introduction.

Further, this task requires expertise with legal terminology and concepts. An experienced law professor, armed with deep understanding of relevant legal statutes and extensive knowledge in the field, would likely be able to swiftly assess the accuracy of answer candidates and the soundness of their analysis, even with minimal background information. Conversely, for those less familiar with the field, even being provided with comprehensive information, identifying key details and reaching the correct conclusion remains a challenging task. Notably, the training dataset and development dataset provide analysis of the labels, whereas the test dataset does not.

This dataset is extracted from real law teaching books and includes a total of 666 training sets, 84 development sets, and 98 test sets. The training set and development set provide analysis of labels, but

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1806–1810

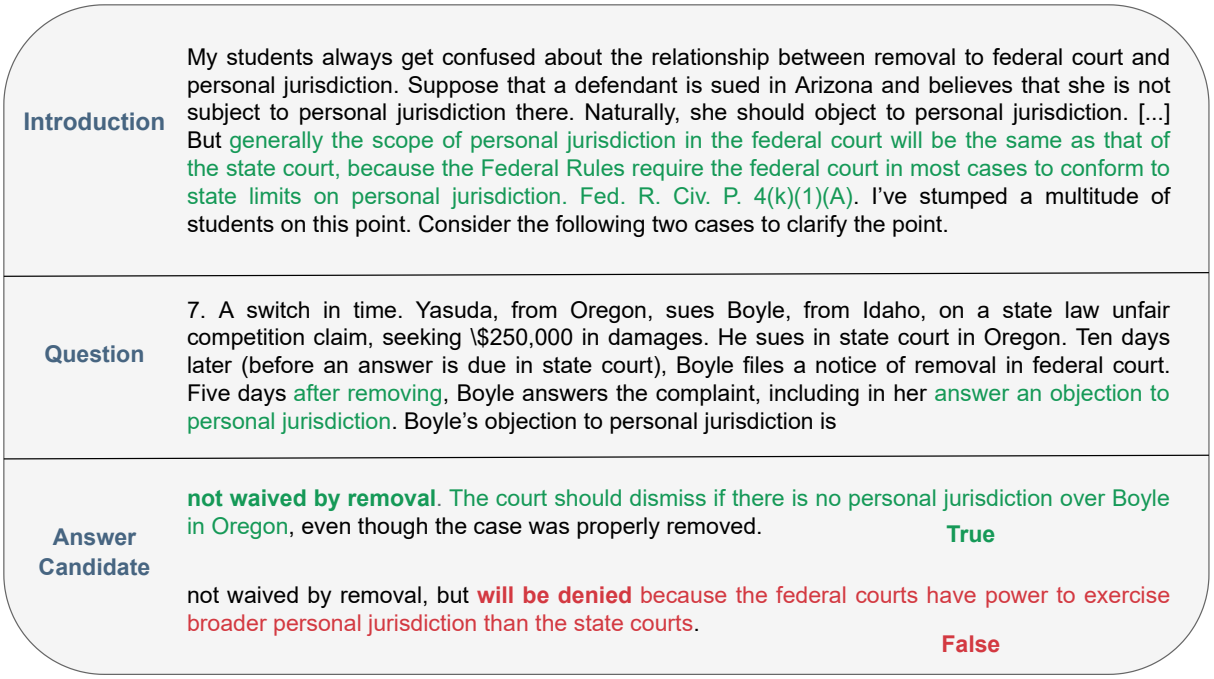

Figure 1: Data Example

the test set is not provided. The goal is to predict the label of the test set.

3 System

3.1 Method Overview

For this task, we have designed a Self-Eval LLM system that utilizes LLM (e.g. GPT-4) for reasoning to obtain answers. However, the responses generated by LLM can sometimes be ambiguous. Therefore, we have incorporated a confidence detection task to enable the LLM to evaluate the reliability of its own answers, and stimulate the LLM's potential. We use one specifically designed prompt for the model to perform both tasks — judging answer candidate and providing answer confidence. Furthermore, we have employed two strategies: converting judgments into selections and ensemble learning. As shown in Figure 2, we depict a workflow with and without confidence.

3.2 Inference with Confidence

This task demands strong causal reasoning skills and specialized knowledge in the legal domain, intutively beyond the capabilities of small models like BERT. LLMs are trained with vast Internet-based corpora, obtaining extensive knowledge and causal reasoning capabilities. Hence, we opted to utilize LLM, specifically the GPT-4, the model name is "gpt-4-0125-preview" and all hyperparameters use the default. Furthermore, in response to the ambiguity in LLM's responses, we proposed the Self-Eval mechanism, wherein the LLM is required to assess the confidence of its answer candidates while generating outputs. Our prompt took the following form: [*You are an AI assistant with reasoning and distinguishing abilities in the legal field. I have a new NLP task and dataset from the domain of the U.S. civil procedure. As a legal assistant, you can help me decide whether the relevant answer is correct or not. I will provide an explanation, an analysis, a question, and an answer. Please analyze to see if the answer is correct and give your confidence on a scale of 0-5, where the higher the score, the more accurate you think your answer is. The output format is: Analysis:, Is correct (Yes/No):, Confidence score:*].

Additionally, we found that LLM performs better in choice tasks than in judgment tasks. By examining task data examples, we noticed that some examples had the same introduction and question. Therefore, we converted data from true or false questions to multiple-choice questions. Specifically, we assigned numbers to answer candidates for LLM to choose from. If all options are incorrect, it returns None. For choice tasks, the prompt format we used was as follows: [*You are an AI assistant with reasoning and distinguishing abilities in the legal field. I have a new NLP task and dataset from the domain of the U.S. civil procedure. As a*

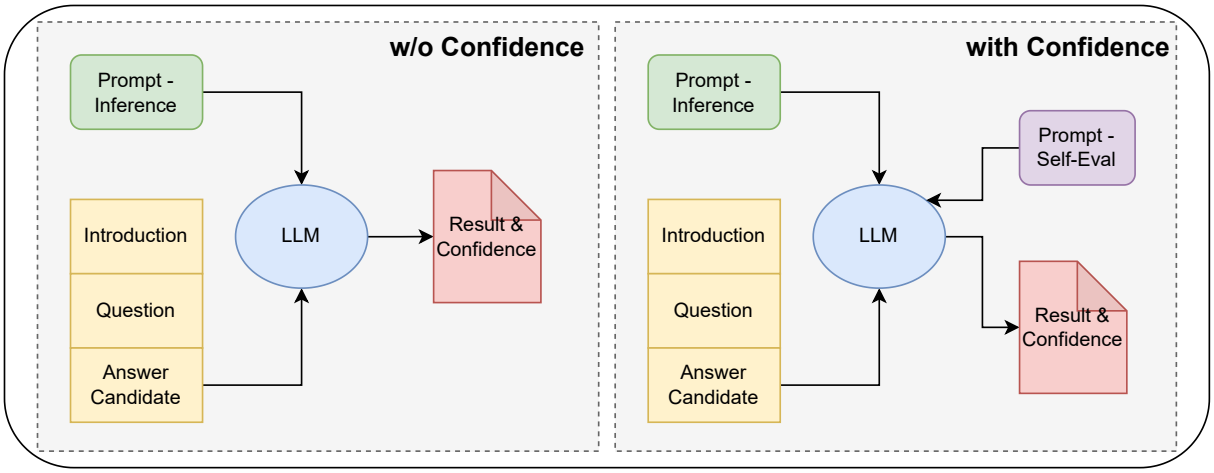

Figure 2: Flowchart of LLM System w/o Confidence and with Confidence

legal assistant, you can help me decide whether the relevant answer is correct or not. I will provide an explanation, an analysis, a question, and a few answers. Only one or none of these answers is correct. Please determine which answer is correct, Note that there may be cases where none of the answers are correct. Give a confidence score (0-5) on the larger model's answer, with higher scores indicating that you think the answer is correct. The output format is: correct answer: answer-id, confidence: score:]. Ultimately, to alleviate the model's stochastic nature, we implemented an ensemble strategy where, for each LLM, we ran it three times and aggregated the inference results, which is the final version we used in the evaluation. Due to cost constraints, we only implemented an ensemble strategy in the experimental group with the highest performance results.

3.3 Inference without Confidence

In addition to the previously mentioned LLM system equipped with the Self-Eval mechanism, we also conducted experiments involving direct inferring. The experimental parameters were kept consistent with the previous settings. When assessing judgement tasks, we utilized the following prompt format: [*You are an AI assistant with reasoning and distinguishing abilities in the legal field. I have a new NLP task and dataset from the domain of the U.S. civil procedure. As a legal assistant, you can help me decide whether the relevant answer is correct or not. I will provide an explanation, an analysis, a question, and an answer. Please analyze to see if the answer is correct. The output format is: Analysis:, Is correct (Yes/No):*]

When tackling choice tasks, the prompt we utilize is as follows: [*You are an AI assistant with reasoning and distinguishing abilities in the legal field. I have a new NLP task and dataset from the domain of the U.S. civil procedure. As a legal assistant, you can help me decide whether the relevant answer is correct or not. I will provide an explanation, an analysis, a question, and a few answers. Only one or none of these answers is correct. Please determine which answer is correct, Note that there may be cases where none of the answers are correct:*]

3.4 2Pass Strategy

In addition to the above experiments, we also designed a 2pass LLM reasoning and evaluation experiment to verify the self-evaluation ability of LLM. We take true or false questions as an example. First, we prompt the LLM to provide reasoning-only answers. Next, we ask the LLM to provide confidence scores for its answers, and gain the final result based on the confidence score. If confidence exceeds 3, we maintain the original result given by the LLM, otherwise we flip it. The prompts for the first pass are the same as the judgment only, and the prompts for the second pass are as follows: [*You are an AI assistant with reasoning and distinguishing abilities in the legal field. I have a new NLP task and dataset from the domain of the U.S. civil procedure. I will provide an explanation, an analysis, a question, and an answer. And analysis and judge of LLM, Give a confidence score (0-5) on the larger model's answer, with higher scores indicating that you think the answer is correct. The output format is: confidence: score:*].

Model	F1 Score	Accuracy
GPT-4-judgement only	0.7061	0.7551
GPT-4-judgement with confidence	0.7211	0.7653
GPT-4-2pass	0.6984	0.7341
GPT-4-choice only	0.7644	0.8163
GPT-4-choice with confidence	**0.8012**	**0.8649**
irene.benedetto's System	0.7747	0.8265
GPT-4-choice with confidence (Ensemble)	**0.8231**	**0.8673**

Table 1: Results of different models for test

4 Results and Analysis

4.1 Overview

Table 1 shows the results of different strategies on the test set of this task, where the representatives not marked with the Ensemble flag only run a single experiment. The evaluation metrics are F1 score and accuracy. As it is shown in the table, our final system, GPT-4-choice with confidence (Ensemble), has achieved the highest scores on both metrics, outperforming the best system from other participants, irene.benedetto, by absolute margins of 4.08 percentage points on F1 score and 2.65 percentage points on accuracy. Even without ensembling, our approach still improves F1 score by 2.65 percentage points and accuracy by 3.84 percentage points. This can prove the effectiveness of our system on the Legal Argument Reasoning task.

Table 1 presents a comparison between the performance of GPT-4 with and without Self-Eval. The results indicate a notable improvement when real-time confidence assessment is implemented. Specifically, for true or false questions, the F1 score of GPT-4 with confidence assessment is 1.50 percentage points higher than that without confidence assessment, with a corresponding 1.02 percentage point increase in accuracy. Similarly, in the case of multiple-choice questions, the F1 score for GPT-4 with confidence assessment outperforms the model without by 3.68 percentage points, while accuracy improves by 4.86 percentage points. This significant enhancement in performance underscores the value of integrating real-time confidence assessment into the model. The observed effect is attributed to the Self-Eval mechanism, which appears to stimulate the latent capabilities of the LLM. By prompting the LLM to evaluate its own confidence levels, it performs reasoning tasks more diligently, resulting in more accurate answers.

From Table 1, we can also see that on F1 score, 2Pass prompting underperforms the judgment-only and judgment-with-confidence versions of GPT-4 by 0.77 and 2.27 percentage points respectively. This suggests that ex-post confidence assessment does not benefit the model's answers. Confidence assessment only improve performance if conducted concurrently with inference. While surprising, this indicates promise for further exploration.

4.2 Case Study

As we mentioned in Section 3.1, the output of LLM is sometimes ambiguous. To address this, we introduced a self-evaluation mechanism. The following case illustrates its impact. As shown in figure 3, before the Self-Eval mechanism was introduced, when posed with a true of false question, the model replied "not entirely correct" — an ambiguous response falling between true and false. In contrast, analysis of multiple responses after incorporating the self-assessment mechanism revealed no ambiguous statements. These results demonstrate the effectiveness of the self-evaluation task at reducing ambiguity in LLM's responses.

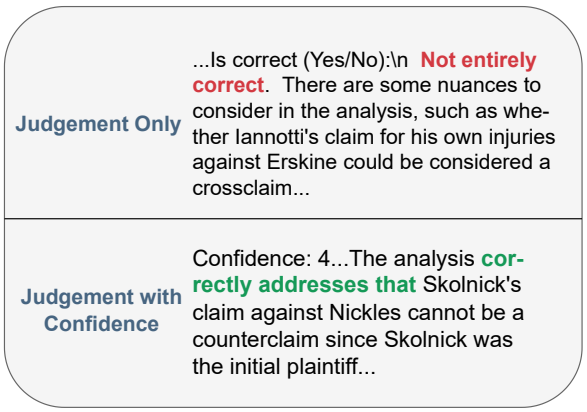

Figure 3: Case about Ambiguous with Self-Eval

5 Conclusion

In this article, we propose an LLM system with Self-Eval mechanism for SemEval-2024 Task 5. We explore the potential for using GPT-4 and prompt learning to obtain causal reasoning capabilities in the field of civil litigation. We have proven that the Self-Eval mechanism can alleviate the problem of unclear output and can also significantly improve performance. Additionally, we found that GPT4 demonstrates greater aptitude for choice tasks than for judgement tasks. With the prompts we provide, the experiment is fully reproducible and the experimental results can be extracted through regular expressions.

Due to time and space limitations, we leave some questions unresolved. For example, we only used GPT-4 for experiments. The broader applicability of the Self-Eval mechanism to other LLMs and its effectiveness in diverse tasks present room for further investigation. We intend to dive deeper into these questions in future work.

IITK at SemEval-2024 Task 10: Who is the speaker? Improving Emotion Recognition and Flip Reasoning in Conversations via Speaker Embeddings

Shubham Patel* **Divyaksh Shukla*** **Ashutosh Modi**
Indian Institute of Technology Kanpur (IIT Kanpur)
{devang21, divyakshs23}@iitk.ac.in
{ashutoshm}@cse.iitk.ac.in

Abstract

This paper presents our approach for the SemEval-2024 Task 10: Emotion Discovery and Reasoning its Flip in Conversations. For the Emotion Recognition in Conversations (ERC) task, we utilize a masked-memory network along with speaker participation. We propose a transformer-based speaker-centric model for the Emotion Flip Reasoning (EFR) task. We also introduce *Probable Trigger Zone*, a region of the conversation that is more likely to contain the utterances causing the emotion to flip. For sub-task 3, the proposed approach achieves a 5.9 (F1 score) improvement over the task baseline. The ablation study results highlight the significance of various design choices in the proposed method.

1 Introduction

Conversations between participants carry information that evokes emotions. Emotions include personality, character, temper, and inspiration as the primary psychological parameters that drive them (P S and G S, 2017). Analyzing emotions through language helps uncover the interpersonal sentiments in a conversation at a finer level. This can help build better affective generative models (Goswamy et al., 2020), like chatbots that understand emotion and respond according to a person's behaviors and personality (Kumar et al., 2021; Colombo et al., 2019).

The SemEval-2024 Task 10 (Kumar et al., 2024) aims at Emotion Recognition (ERC), sub-task 1, and Emotion Flip Reasoning (EFR), sub-tasks 2 and 3, in conversations for two languages, namely English and Hindi-English Code-Mixed. ERC refers to identifying the emotion of different utterances. EFR is about identifying those utterances in the dialogue that caused the emotion of a speaker to change.

We build upon the models presented in Kumar et al. (2021) for ERC and EFR. A speaker's personality is likely to influence the emotions developed in other participants (Hazarika et al., 2018a). This inspired us to include information regarding speaker participation to improve the analysis of the emotion of an utterance in conversations. Additionally, for Emotion Flip Reasoning, we propose the Probable Trigger Zone (PTZ), a region of the conversation more likely to consist of the utterance that caused an emotional change in the target participant. This helps us filter out significant non-trigger utterances, reducing the skew in the data. We utilize pre-trained models for computing text embeddings to obtain better representations of utterances.

In sub-task 1, we achieved a weighted F1 score of 45 and 9th rank. For sub-tasks 2 and 3, we secured 5th and 10th position with F1 scores of 56 and 60, respectively. The top scores for each sub-task were 78, 79, and 79, respectively. For sub-task 3, our model improves 5.9 F1 over the baseline model presented in Kumar et al. (2021). The proposed changes have assisted in improving the performance of the system. A limitation of our model is knowing speakers. It might not be possible in all circumstances that this information is available. Also, despite trying to reduce the skew in the data, our model's performance was still impacted. Our models and code can be found here.[1]

2 Related Work

2.1 ERC

The task of emotion prediction has been of active interest in recent years (Witon et al., 2018; Kumar et al., 2020; Keswani et al., 2020; Singh et al., 2021b, 2023, 2021a), including the development of

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1811–1820

models like ICON (Hazarika et al., 2018a), COGMEN (Joshi et al., 2022), Instruct-ERC (Lei et al., 2023) and the models by Kumar et al. (2021). Also, there has been active research in affective text generation (Goswamy et al., 2020). Several datasets exist (Bedi et al., 2023; Poria et al., 2019; Busso et al., 2008) that use one or more additional emotions along with Ekman's scheme (Ekman, 1992) of emotion representation via six emotion classes, namely, *fear*, *anger*, *joy*, *sad*, *disgust*, and *surprise*.

Hazarika et al. (2018a) and Li et al. (2020) highlight the importance of inter and intra-speaker interactions in a conversation. Li et al. (2020) achieves this by using three separate transformer-encoder blocks: (1) Conventional masking: masked multi-head self-attention, (2) Intra-speaker masking: all utterances from other speakers are masked, and (3) Inter-speaker masking: all utterances from the current speaker are masked. While this captures relationships, it does not capture the speaker's personality or presence. Hazarika et al. (2018a) also considers speakers, but it was modeled on the IEMOCAP dataset (Busso et al., 2008) that contains only two participants.

Shapes of Emotion (Bansal et al., 2022), ICON (Hazarika et al., 2018a) and its derived model ERC_MMN (Kumar et al., 2021) proposed the concept of speaker-level outputs, which means that during conversational flow, there is a speaker-level GRU to encode the currently spoken utterance. They achieve this by storing vectors representing each speaker and updating them using the speaker-level GRUs' hidden outputs, which are initialized to 0 during the start of a dialogue.

COGMEN (Joshi et al., 2022) introduces the concept of graphs to conversation flow for emotion recognition. They represent a graph in which each utterance is a node and is related to past or future utterances of the same or different speaker within a time window. CORECT (Nguyen et al., 2023) leverages on COGMEN and introduces speaker embeddings from MMGCN (Wei et al., 2019) to encode each speaker in the conversation for graph-based interaction and pairwise cross-modal feature interaction.

2.2 EFR

Kumar et al. (2021) introduces the relatively new Emotion-Flip Reasoning (EFR) task, which aims to identify past utterances in a conversation that have triggered one's emotional state to flip at a certain time. The task of Emotion-Cause Pair Extraction (ECPE) (Xia and Ding, 2019) and Emotion Cause Extraction (ECE) (Gui et al., 2016) are similar to EFR, but they aim to extract the causes of emotions from a given text instead of conversations. Kumar et al. (2021) present a transformer-based model for EFR and also measure the performance of baseline models CMN (Hazarika et al., 2018b), ICON (Hazarika et al., 2018a), DGCN (Ghosal et al., 2019), AGHMN (Jiao et al., 2019), and Pointer Network (Vinyals et al., 2017).

2.3 Embeddings

The performance of models on tasks is influenced by the quality of text representation it uses (Asudani et al., 2023). Nayak and Joshi (2022) release HingBERT, a BERT model that has been fine-tuned on Hindi-English Code-Mixed corpus. Muennighoff et al. (2023) introduce the Massive Text Embedding Benchmark (MTEB), which evaluates the performance of text embeddings through different tasks across several datasets. One of the top performers, the `voyage-embeddings`[2], utilize neural-net models to encode the text into text embeddings.

3 Task

SemEval-2024 Task 10: "**E**motion **Di**scovery and its **Re**asoning it **F**lip in Conversations" (Kumar et al., 2024), EDiReF, consisted of three sub-tasks:

1. ERC in Hindi-English Code-Mixed.
2. EFR in Hindi-English Code-Mixed.
3. EFR in English.

Emotion Recognition in Conversations (ERC) is classifying the utterances in a dialogue into one of the given emotion categories. An emotion flip is said to have occurred when a speaker's utterance differs from his/her previous utterance's emotion. Emotion Flip Reasoning (EFR) refers to identifying the utterances (triggers) that caused an emotional flip. These utterances could have been spoken either by the speaker himself or someone else. For the task of ERC, given the utterances in the conversation and corresponding speaker names, the emotion label for each utterance has to be predicted. For the task of EFR, the emotion labels of utterances have also been provided, and the triggers for a given emotion flip have to be predicted.

Utterances	8506	11260	8747
Triggers	-	6542	5575

Table 1: Statistics of the Training Dataset.

Sub-Tasks 1 and 2 tailor the Hindi-English Code-Mixed dataset - MaSaC (Bedi et al., 2023). The training dataset consists of utterances in Roman script (e.g., "*yah plastic ke stickers tumne kahan se khariden?*"). Sub-Task 3 uses the MELD-FR dataset presented in Kumar et al. (2021) built upon the MELD dataset (Poria et al., 2019). Table 1 highlights the overall statistics regarding the training set for each sub-task. Figure 1a and Figure 1b show the distribution of the triggers as a function of the distance from the target utterance for the sub-task 2 and sub-task 3 training datasets, respectively.

4 System overview

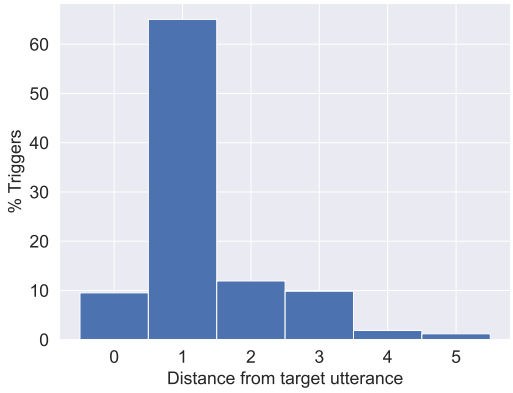
Inspired by the use of memory networks by Hazarika et al. (2018a) and Kumar et al. (2021) for emotion recognition, in 4.2 we present our model for the task of ERC, sub-task 1. Inspired by a transformer-based (Vaswani et al., 2017) approach for emotion flip reasoning presented by Kumar et al. (2021), in 4.3 we present our models for sub-tasks 2 and 3.

4.1 Utterance Embeddings

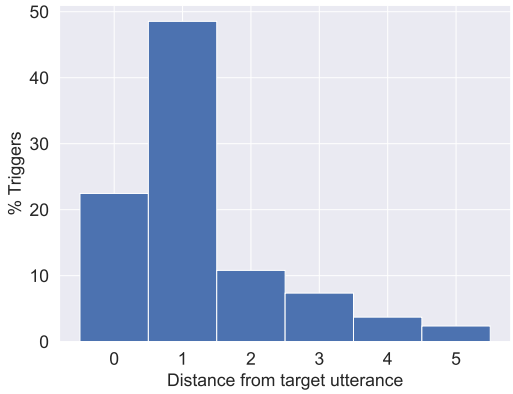
We utilize pre-trained models to compute representations of the utterances in the conversation. Sub-tasks 1 and 2 required the computation of utterance embeddings for code-mixed Hindi-English sentences. We utilized HingBERT to compute the utterance embedding as an average of all the token embeddings in an utterance. Sub-Task 3 consists of utterances in English. We referred to the Massive Text Embedding Benchmark to determine an efficient method to compute utterance embeddings. We experimented with the embeddings presented in Li and Li (2023) and voyage-embeddings, out of which the latter performed better. Hence, we used the `voyage-lite-02-instruct` model with `query_type` as a `document`.

4.2 ERC

We take inspiration from the Masked Memory Network architecture presented by Kumar et al. (2021)



(a) Sub-Task 2.



(b) Sub-Task 3.

Figure 1: Distribution of the distance between the target utterance and the causal utterance for emotion flip.

and speaker-specific GRUs proposed by Kumar et al. (2021) and Hazarika et al. (2018a). We used HingBERT to encode each utterance and then pass them through a dialog-level GRU and a speaker-level GRU. The vectors from the global-level GRUs are passed through a memory network through multiple hops (a cycle of reading from memory and writing back to memory is called a hop. The output is taken from the final memory read operation.) Then, attention is computed between the memory and speaker-level outputs while masking future utterances and concatenating with speaker-level outputs to compute conversation-level outputs. Finally, the obtained features are passed through a trainable linear layer for predicting emotion class. Figure 2 shows the model architecture.

Notations: u_t denotes the embedded utterance at time t in a dialogue, while $s_t^{(k)}$ denotes the k^{th} speaker embedding for utterance u_t. $attention(q, k, v)$ is the attention operator applied on query q, key k and value v. r is the number of

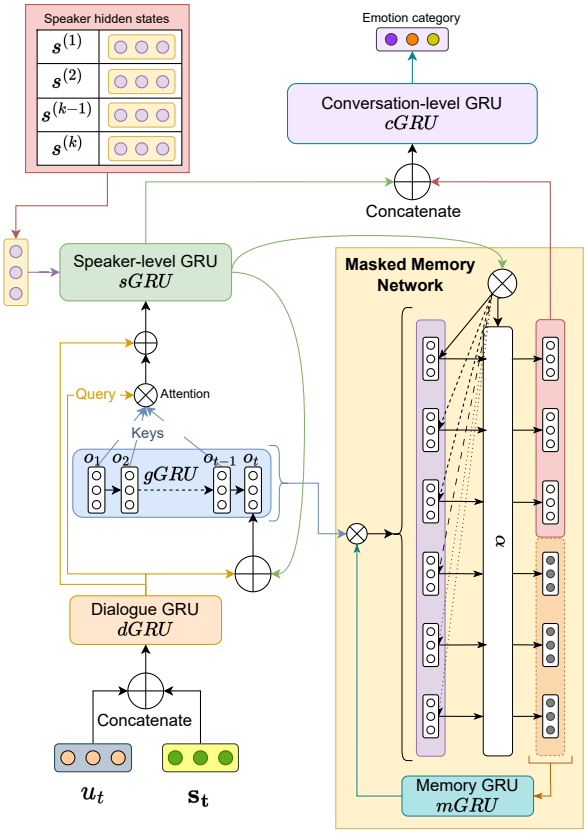


Figure 2: Masked Memory Network with Speaker-Embeddings concatenated with utterance embeddings. Speaker-embeddings are one-hot vectors of 6-dimensions which store 1 at the index of the top-6 speakers, otherwise 0.

hops in the memory layer, inspired from Hazarika et al. (2018a).

Dialogue-level GRU $dGRU$**:** This recurrent unit gives a dialogue-level representation of the u_t and gives output as do_t.

$$do_t = dGRU(u_t \oplus s_{kt})$$

Global-level GRU $gGRU$**:** This recurrent unit gives a global-level representation of the utterances $u_{(1:t)}$ till time step t, as $o_{(1:t)}$.

$$o_t = gGRU(do_t \oplus so_{t-1})$$

Attention Module: Attention is computed between do_t as query and value and $o_{(1:t-1)}$ as keys to obtain attention-based context for speaker-level GRU layer.

$$attention(do_t, o_{(1:t-1)}, do_t)$$

Speaker-level GRU $sGRU$**:** This gives a speaker-level recurrent unit that takes inputs $attention$ and speaker hidden state $s^{(k)}$ (taken from a dictionary of size k) and gives outputs so_t. The hidden output replaces the dictionary entry for $s^{(k)}$. At the start of a dialogue, the dictionary is empty, and the default hidden state for a new speaker is a zero vector.

$$so_t = sGRU(attention(do_t, o_{(1:t-1)}, do_t) + do_t)$$

Masked-Memory Attention: A memory vector, which represents the previous dialogues and utterances, is obtained by passing $o_{(1:t)}$ through a memory GRU ($mGRU$). This then goes through masked attention with the so_t while masking future utterances and a softmax activation α to give attention weights to each utterance in $o_{(1:t-1)}$. This is then used to update the memory vectors via the $mGRU$ and is concatenated with so_t as an input to $cGRU$.

$$temp = mGRU(o_{(1:t)})$$
$$mem^r = masked\_attention(temp, so_t)$$
$$temp = mGRU(mem^{r-1})$$

Conversation-level GRU $cGRU$**:** This layer represents the conversation flow of the dialogue and takes inputs as the concatenation of so_t and masked attention output, to give conversation-level features.

$$co_t = cGRU(mem^r + so_t)$$

Finally, the outputs of the $cGRU$ are used to compute the emotion class.

$$e_t = W.co_t + b$$

4.3 EFR

4.3.1 Baseline

In Kumar et al. (2021), the authors propose a transformer-based model for the task of EFR, whose architecture is as follows. Utterance embeddings for each utterance are computed using BERT (Devlin et al., 2019). The utterance embeddings of a conversation are passed through a transformer to compute a contextualized utterance embedding for each utterance. The emotion classes for each utterance are encoded as a one-hot vector and passed through a GRU to compute the emotion-history vector. For each utterance, its contextualized embedding, the contextualized embedding of the target utterance, and the emotion-history vector are passed through a linear layer to make a prediction.

4.3.2 Speaker-Aware Embeddings

As highlighted by Li et al. (2020) and Hazarika et al. (2018a), speaker interaction also drives the emotion of an utterance. Unlike their approach for modeling intra and inter-speaker interaction, we believe that the participation of certain speakers in the conversation drives the flip in the emotion of an utterance. Providing information regarding the speaker will help the model learn the nature of the specific speakers. To incorporate this, we utilize that the speakers in the test and the train set overlap.

An aspect of the conversation that has not been captured by the baseline model regarding the speakers of an utterance. In the baseline model, each utterance is treated as an independent text, and its embedding has been computed. This has failed to incorporate the information regarding who the speaker of a given utterance was. To incorporate this aspect, we concatenate the utterance embeddings with a one-hot vector denoting the speaker to create speaker-aware embeddings. This equips the model with the ability to capture the behavioral trends of specific speakers.

4.3.3 Probable Trigger Zone (PTZ)

We propose a hypothesis regarding the possible location of triggers. We divide the conversation into two parts. The first part consists of the utterances before the target speaker's previous utterance. The second part consists of utterances from the target speaker's previous utterance to his target utterance. We call the second part the Probable Trigger Zone (PTZ).

We hypothesize that no triggers lie in the first part of the conversation. Since the target speaker's emotion has flipped during the second part of the conversation, it is more likely that the causes for the emotion flip lie in the second part. Suppose the trigger causing the target emotion had been in the first part. In that case, it is more likely that it would have already caused the emotion of the previous utterance of the target speaker to flip. Then, the same emotion would have been carried to the target utterance, wrongly implying that no emotion flip occurred at the target utterance. To incorporate the hypothesis, we mask any predictions made by the model outside the Probable Trigger Zone. In section 5, we discuss how PTZ helps to reduce skew in the dataset.

For example, consider the conversation in Figure 3. Here, the target speaker is *Ross* with the target

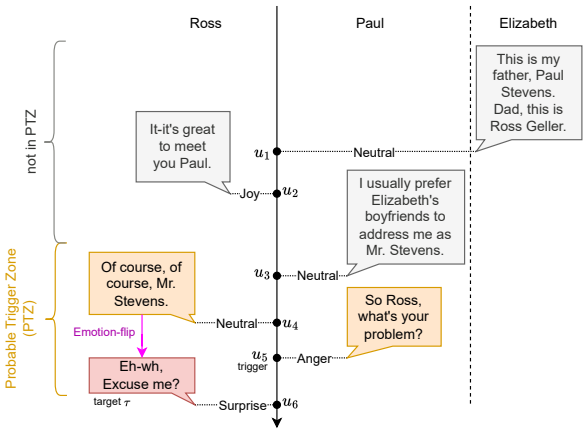

Figure 3: Probable Trigger Zone.

utterance u_6 and his previous utterance u_4. The probable trigger zone consists of utterances from u_4 to u_6. Due to the "surprise-causing" statement u_5 in PTZ, *Ross's* emotion flips from *Neutral* to *Surprise*. If this "surprise-causing" statement had been present outside the PTZ, i.e., before the previous utterance u_4, then the emotion of u_4 would likely have been *Surprise*.

4.3.4 Emotion-Aware Embeddings

Using an Emotion-GRU, the baseline model computes an emotion-history vector from the emotion labels. It uses this emotion-history vector in the final linear layer to predict the utterance label. A possible shortcoming of the above is that the linear layer has access only to the emotion history rather than to the emotion labels of the individual utterances. Also, the transformer layer cannot access the emotion labels while computing the contextualized utterance embeddings. Providing those to the transformer will also allow the embeddings to be emotion-aware. We concatenate our speaker-aware utterance embeddings and one-hot emotion labels to incorporate the above.

4.3.5 Model Functioning

Figure 4 presents the model architecture used for the task of EFR. The target utterance is denoted by the subscript τ. Each utterance u_t of a dialogue d is concatenated with its true emotion label e_t and one-hot speaker embedding s_t. This is then passed through the transformer to take into account the context. The Emotion-GRU computes the emotion-history vector. For each utterance, its and the target utterance's contextualized representation and the emotion-history vector are passed through a linear layer to make the prediction.

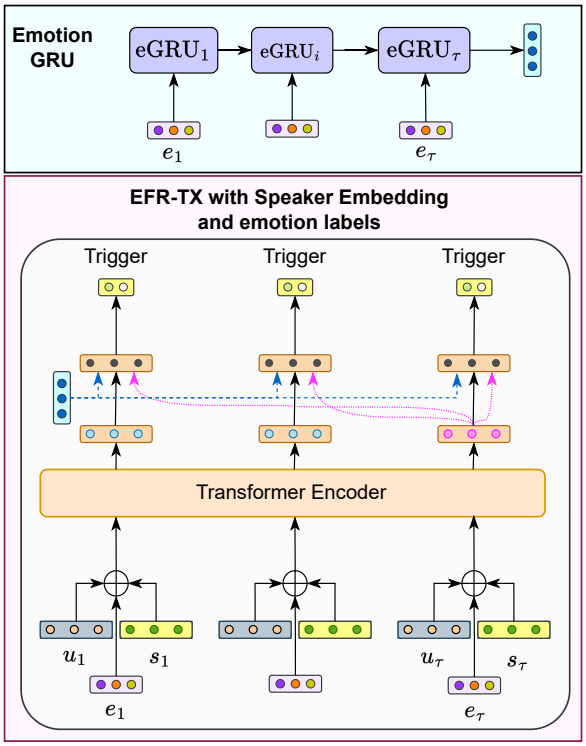

Figure 4: Architecture of the model proposed for the task of Emotion Flip Recognition.

5 Experimental setup

5.1 Training Details

For sub-task 1, we chose a sequence length seq_len of 15, i.e., we break a long conversation into disjoint smaller conversations with utterances less than equal to seq_len. For sub-tasks 2 and 3, we use a window size w of 5. We consider only the last w utterances in a conversation to predict the trigger, i.e., $U_{n-w+1}, U_{n-w+2}...U_{n-1}, U_n$. Table 2 contains details of the hyperparameters we used to train the models. To limit the size of the vector denoting the speaker, keep retained information regarding the top $k = 6$ speakers. We chose the top 6 speakers since this covered nearly $80 - 85\%$ of utterances in the corpus. We used Adam optimizer (Kingma and Ba, 2017) for all the sub-tasks, with a weight decay of 1e-5. Training of models has been done using Kaggle[3] P100 GPUs.

5.2 Effect of Hypothesis and Sequence Length

In Table 3 and Table 4, we highlight the impact of the hypothesis and selection of sequence length on the datasets. On reducing the window size w to 5, a significant number of negative labels have been eliminated, while there has not been much impact on the number of positive labels. Applying the hypothesis has helped mitigate the skew in the data, although there has been a slight impact on the number of positive labels. *Setting 1* refers to considering only the utterances within the window size $w = 5$. *Setting 2* refers to considering utterances that are both within the window and in the probable trigger zone.

6 Results

For Sub-Task 1, the dataset consisted of a non-uniform distribution of labels, with *neutral* being the most frequent. A model that predicts the emotion category of each utterance to be *neutral* achieves a weighted F1 of 24.36. We consider this as a simple *neutral* baseline for sub-task 1. For Sub-Task 2, we have kept the baseline as a rule-based model that predicts the previous utterance to be a trigger and the rest of all utterances non-triggers. The data for the second sub-task is highly skewed

as can be seen in Figure 1a. Due to this baseline performs exceptionally well, as can be observed in Table 5. For Sub-Task 3, we use ERC$^{\text{True}}$ EFR-TX from Kumar et al. (2021) as the baseline.

Sub-Task	Model	Metric	Value
2	Rule-Based	F1	79.15
3	ERC$^{\text{True}}$ EFR-TX	F1	53.9

Table 5: Baselines for various Sub-Tasks.
Rule-Based: A rule-based model that predicts the previous utterance as a trigger and the rest as non-triggers.

6.1 Model Performance

We have highlighted the performance of our models on the test data in Table 6. For sub-task 2, we get precision and recall scores of 0.73 and 0.83, respectively. For sub-task 3, we get precision and recall scores of 0.74 and 0.80, respectively.

6.2 Error Analysis

For sub-task 1 and sub-task 3, our model performed better than the baselines, but not for sub-task 2. For sub-task 1, the dataset consisted of a non-uniform distribution of labels in the training dataset. Due to this skew in the data, the model has shown different performances for different labels. The predictions for sub-task 1 have been highlighted in Figure 5. For EFR, the usage of a window size $w = 5$ utterances has helped to eliminate a large number of non-triggers. Due to this, the model's predictions have many true negatives, as can be seen in Table 7 and Table 8. But despite this, there was still skew in the data, which impacted the model's performance in predicting the minority class of triggers. The data for sub-task 2 is highly skewed, as can be seen in Figure 1a. We suspect this is why our model has performed poorer than the baseline.

Figure 6 is an example of an erroneous emotion labeling of the model on the test set of sub-task 1 (ERC). Here, the utterance marked in red has the true label as 'Fear,' but the model predicts 'Neutral.' This is due to the sharp change in conversation context at u_5. Also, 'hahhaha' directly corresponds to laughing, but in this case, the speaker at u_6 utters 'hahhaha' as he is worried that the inspector is looking for 'Sharman'. The speaker, Indravardhan, who continuously interacted with the inspector, showed neutral emotion. This led to storing vectors corresponding to neutral for Indravardhan in the memory network, leading to misclassification of emotion at u_6.

Sub-Task	Metric	Our	Best	Rank
1	Weighted F1	44.80	78	9
2	F1	56.35	79	5
3	F1	59.78	79	10

Table 6: Results on the Test Set.

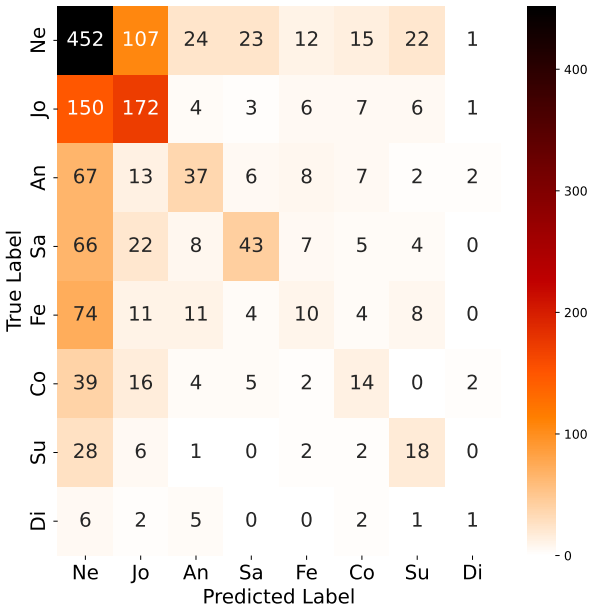

Figure 5: Confusion Matrix for Sub-Task 1.

6.3 Ablation Study

The application of the hypothesis has assisted in removing a few of the wrongly guessed triggers. This has improved the model's performance, as seen in Table 9. We also experimented with another approach of making predictions only inside the PTZ instead of masking the outside labels. This was done by training in the model and making predictions only using the utterances within the probable target zone. In this case, the model's performance was poorer. We suspect this is because the context the model gets in the latter is more restricted than in the first case. Due to this, the model is not able to make predictions effectively.

7 Conclusion

In this paper, we discussed approaches to improve the masked memory network architecture for emotion recognition (ERC) and transformer-based architecture for emotion flip reasoning (EFR) by incorporating speaker information into the embeddings and making better use of the emotion labels. We also employed an approach of focusing the

		Predicted

Table 8: Confusion Matrix Sub-Task 3.

model's prediction on more likely regions to identify triggers by defining the Probable Trigger Zone in conversations. This, along with considering a window of last-few utterances, assisted in reducing the bias in the data.

Limitations: Our model assumes that the training and testing data consist of the same speakers. While this would be true for many benchmark datasets of emotion analysis in conversations, it might not be true in all real-world circumstances. Another limitation of the proposed approach is the training time.

Future Work: In the future, we can include speaker information across dialogues for ERC to capture better speaker semantics by using learnable embeddings for each speaker updated by the hidden outputs of the speaker-level GRU. However, to apply the above, we need to know the number of speakers in the datasets, training, and testing. Additionally, the model becomes dependent on the number of speakers.

A possible approach to help mitigate the assumption of having common speakers and knowing the number of speakers in the training and test time could be exploring further modeling inter and intra-speaker dependencies, as shown in Li et al. (2020) and Hazarika et al. (2018a). They propose models that capture speaker relationships but are not dependent on the number of speakers.

Mitigating the issues of skewed data can be further explored to enhance the system's performance. Also, addressing other aspects of conversations, such as whom the statement is being told to and treating names of speakers in utterances differently from simple pronouns, can be explored.

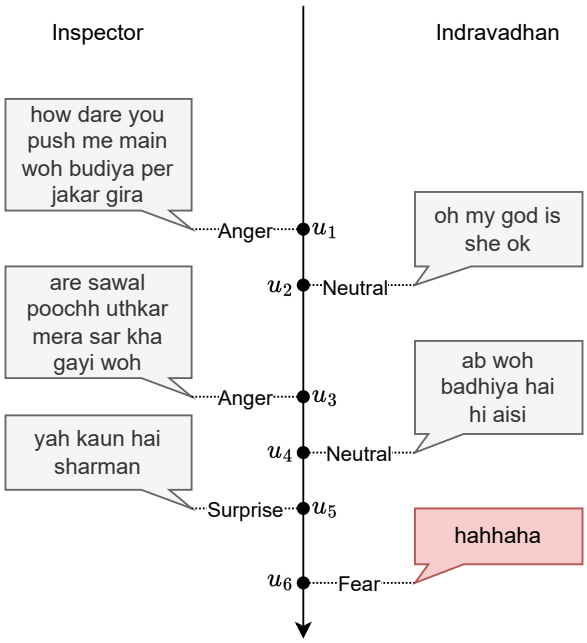

Figure 6: Example of an erroneous emotion labeling from the model. The true label is 'Fear,' but the model predicted 'Neutral.'

{vozniuk.ae, vasily.konovalov}@phystech.edu

Abstract

The Multigenerator, Multidomain, and Multilingual Black-Box Machine-Generated Text Detection shared task in the SemEval-2024 competition aims to tackle the problem of misusing collaborative human-AI writing. Although there are a lot of existing detectors of AI content, they are often designed to give a binary answer and thus may not be suitable for more nuanced problem of finding the boundaries between human-written and machine-generated texts, while hybrid human-AI writing becomes more and more popular. In this paper, we address the boundary detection problem. Particularly, we present a pipeline for augmenting data for supervised fine-tuning of DeBERTaV3. We receive new best MAE score, according to the leaderboard of the competition, with this pipeline.

1 Introduction

Recently, there has been a rapid development of auto-regressive language models, for example, GPT-3 (Brown et al., 2020), GPT-4 (OpenAI, 2023), and LLaMA2 (Touvron et al., 2023). These models are trained on enormous amounts of data and are able to produce coherent texts that can be indistinguishable from human-written texts (Dugan et al., 2022).

The SemEval-2024 Task 8 competition suggests to tackle the problem of detecting machine-generated texts. This problem has become more relevant recently due to the release of ChatGPT[1], a model by OpenAI that simplified the access to the large language models (LLM) and their usage. For example, LLM can be maliciously used to generate fake news (Zellers et al., 2019). There are also some concerns raised among scientists (Ma et al., 2023) and educators (Zeng et al., 2023) that the usage of LLMs will devalue the process of learning and research.

The commonly used approach to formulate the task of detecting machine-generated texts is a binary classification task (Jawahar et al., 2020). In this case, a text can be attributed to either a human or a LLM. Otherwise, the task can be formulated as a multiclass classification or an authorship attribution task (Uchendu et al., 2020), where it is needed to determine which one of the k authors is the real author of the given text. Finally, the trend toward human-AI collaborative writing is rising, which highlights the importance of the boundary detection task. In this setup, text contains consecutive chunks of different authorship, and it is required to detect where the boundaries between chunks lie and who is the author of every chunk. Due to its complexity, it is usually assumed the text has a human-written prefix and the rest of the text is AI-generated (Dugan et al., 2022; Cutler et al., 2021; Kushnareva et al., 2023).
Our main contributions are three-fold:

1. We receive the new best MAE score on the task of detecting the boundary between human-written and machine-generated parts of the text.

2. We present a new simple yet effective pipeline of augmenting data for the task of boundary detection, which allows us to get more data for training and improve the results of fine-tuning large language models.

3. We compare the performance of several fine-tuned models with different architectures on various amounts of training data.

Additionally, we've made the code of augmentation publicly available.[2]

2 Related Work

Most of approaches (Jawahar et al., 2020) for machine-generated text detection are based on calculating linguistic (Fröhling and Zubiaga, 2021), stylometric, and statistical features, as well as on using classical machine learning methods like logistic regression, random forest, and gradient boosting as classifiers. Among commonly used features are word and n-gram frequencies (Manjavacas et al., 2017), and tf-idf (Solaiman et al., 2019).

An alternative strategy is to use zero-shot techniques based on the internal metrics of the texts. For example, token-wise log probability can be evaluated by models like GROVER (Zellers et al., 2019) or GPT-2 (Solaiman et al., 2019). A probability threshold is established to distinguish writings produced by machines from those written by humans. Moreover, rank (Gehrmann et al., 2019) or log-rank (Mitchell et al., 2023) can be calculated for each token and compared for consistency with the prior context.

It's shown by Ippolito et al. (2020) that feature-based methods are inferior to methods based on using encoders of pretrained language models like BERT (Devlin et al., 2019) as a basis for fine-tuning on the selected domain. Representations from auto-regressive language models can be used as input for the classification head. Such transformer-based methods require supervised detection examples for further training. Among the models commonly used for fine-tuning are RoBERTa (Liu et al., 2019) and XLNet (Yang et al., 2019). Fine-tuned RoBERTa has shown the state-of-the-art results on the problems of authorship attribution (Uchendu et al., 2021).

To tackle the problem of mixed human-machine writing, Dugan et al. (2022) introduces the Real Or Fake Text (RoFT) tool, where humans were asked to detect the sentence where the text transitions from human-written text to machine-generated text. One of the possible formulations of this task is multilabel classification (Cutler et al., 2021), where the boundary detector needs to determine the first generated sentence, and the number of this sentence is considered the label of the text. In that work, each sentence is processed separately with shallow classification and regression models based on RoBERTa and SRoBERTa (Reimers and Gurevych, 2019). That solution perform well in an in-domain setup, but is limited in an out-of-domain setup.

Any solution for tasks about detecting machine-generated texts should be robust to domain change. The organisers of the SemEval-2024 Task 8 competition claimed to have added new domains to the test set for testing the robustness of participants' solutions. There are several works on performance of detecting methods on out-of-domain setup, such as Kushnareva et al. (2023) and Zeng et al. (2023). Kushnareva et al. (2023) conclude that perplexity-based and topological features appear to be helpful in case of domain shift.

3 Data and Task Description

3.1 Task Description

The Multigenerator, Multidomain, and Multilingual Black-Box Machine-Generated Text Detection (Wang et al., 2024) is focused on challenging detectors of machine-generated texts. The dataset, provided by organisers, consists of 3 parts:

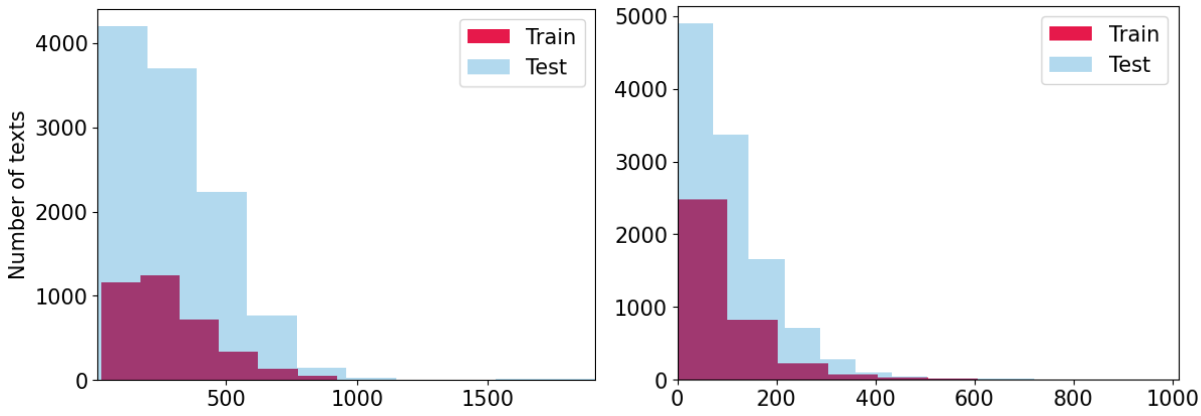
1. texts of different authorship for subtask A and subtask B;

2. texts with collaborative human-AI writing for subtask C.

This paper focuses only on subtask C, suggesting a solution to differentiate a human-written prefix from the rest of the AI-generated text. The texts for this subtask are generated in the following way: the language model should continue the human-written text, which is given as a prompt. Several examples of texts are presented in Appendix A. The designated evaluation metric for this task is Mean Absolute Error (MAE), which quantifies the absolute distance between the predicted word and the actual word where the switch of authorship between human and LLM occurs.

3.2 Data Description

The dataset for this task is derived from the M4 (Wang et al., 2023) dataset, which contains texts of various domains, various languages, and generators. The authors show that current detectors tend to misclassify machine-generated texts as human-written if they're given a text from a different domain. The texts in the train and validation datasets are generated from scientific paper reviews from PeerRead (Kang et al., 2018). The test set partially consists of texts generated from PeerRead. In order to check the robustness of the solutions to domain shift, texts from Outfox, a dataset of LLM-generated student essays (Koike et al., 2023), are



(a) Distribution of lengths of tokenized texts

(b) Distribution of boundary subtoken positions

Figure 1: Statistics of the texts in the datasets

added to the dataset. All data sets contain English texts only.

3.3 Data Analysis

The distribution of lengths of texts in train and test data sets, tokenized by DeBERTa-V3-base models, is shown in Figure 1a. The majority of the texts in the test set are shorter in length, but there are several texts that exceed 1,000 subtokens. The distribution of positions of a boundary subtoken in texts is shown in Figure 1b. A boundary subtoken is the first subtoken of a boundary word. In both datasets, there is a distinguishable disproportion in the position of a boundary subtoken, as most of them have the boundary subtoken within the first 200 subtokens. Thus, a model, trained only on this data, will give limited results when encountering longer texts with longer human prefixes in them.

4 Proposed Method

The provided train dataset consists only of 3,649 texts. It's well known that an abundance of in-domain training data is crucial for classifier performance (Konovalov et al., 2016). However, during the competition period, it was prohibited to use any external data for training, and thus we were limited to working only with the provided dataset. In this case, getting more training data with some kind of augmentation plays a crucial role. We designed an augmentation pipeline and ran all our experiments on two sets of data: the one provided by the organisers of the competition, described in Section 3, and our augmented data.

4.1 Data Augmentation

The general idea of our augmentation pipeline is to split the text into distinct sentences and take several consequent sentences from the text with authorship change. It will make new texts coherent and will not mislead models during training (Ostyakova et al., 2023). In addition, to be useful for training, each sequence should contain a sentence with an authorship change.

Another nuance about the augmentation process is the need to correctly determine the boundary label. The boundary label is calculated as a number of whitespace-split words in the human-written prefix. However, the initial dataset contains texts where a pair or even a sequence of words is split only by line breaks or punctuation symbols. Such a sequence of words should be considered as one word when calculating the boundary label. Thus, we have to pay a lot of attention to whitespace characters during augmentation and do not mistakenly append new whitespace characters between words.

We preprocess each text in the dataset for augmentation in the following way:

1. Split the text into sentences by punctuation symbols.
2. Split the sentences themselves by whitespaces into lists of whitespace-split words.
3. Compare the list of whitespace-split words from previous step with the list of whitespace-split words obtained by splitting the text itself. In case of discrepancy, fix it, depending on its type.

See example of preprocessing for the text from train set in Appendix D.

In the third step of preprocessing, there are two main types of discrepancies: lost whitespace characters and words sequences, originally separated by line breaks only that were split during sentence split process. The former is solved by inserting the missing whitespace characters, while for the latter we merge the split words into one sequence. The last step of preprocessing is crucial and skipping it will result in the incorrect calculation of the boundary label for augmented text, as the label directly depends on the number of whitespace characters in the text.

After preprocessing, we take a number of consecutive sentences to the left and to the right from the boundary sentence, combine them in a text and determine the label of the boundary word in this new text.

4.2 Model Comparison

We used only the transfer learning approach, where a pretrained transformer-based model is fine-tuned on our task in a supervised way. We would like the model to be able to work with long enough sequences because we want the whole human-written prefix to fit in the encoder. Thus, we've determined three models that showed good results on the task of machine-generated text detection:

1. RoBERTa (Liu et al., 2019) has shown good performance in both tasks of boundary detection (Kushnareva et al., 2023) and machine-generated text detection (Macko et al., 2023).

2. Longformer (Beltagy et al., 2020), which was suggested as a baseline by organisers of the task. This model is based on pretrained RoBERTa with novel attention mechanism with a sliding window to long sequences.

3. DeBERTa (He et al., 2021b), which is the state-of-the-art model for machine-generated text detection (Macko et al., 2023). It overcomes the BERT and RoBERTa by introducing a disentangled attention for encoding the position and content of each token separately into two vectors. We decided to test it in the boundary detection task to understand whether it outperform RoBERTa. In our experiments, we fine-tuned DeBERTaV3 (He et al., 2021a) which is an enhanced version of DeBERTa.

All three models are fine-tuned for token classification task. For each token, models predict the probability of being a boundary token and output the most probable token.

Model	dev	test
RoBERTa-base	9.04 \ 5.78	31.56 \ 30.71
RoBERTa-large	6.72 \ 4.18	25.25 \ 20.66
longformer-base	5.10 \ 5.67	23.16 \ 22.94
longformer-large	4.54 \ 4.40	22.97 \ 20.33
DeBERTaV3-base	3.66 \ 3.15	16.12 \ 13.98
DeBERTaV3-large	2.38 \ 2.54	15.16 \ **13.38**
Top-1 Submission	-	15.68

Table 1: MAE on original \ augmented dataset and comparison with Top-1 submission on the leaderboard. Longformer-base is suggested as a baseline solution by organisers of competition.

5 Experimental Setup

We have used pretrained `longformer-4096-base` and `longformer-4096-large` with default hyperparameters to fine-tune Longformer. For experiments with RoBERTa, we have chosen two models: `roberta-base` and `roberta-large`. The models were fine-tuned with the set of custom hyperparameters, taken from the original paper (Liu et al., 2019). Finally, for experiments with DeBERTa, we have also chosen two models: `deberta-v3-base` and `deberta-v3-large`. The models were fine-tuned with the set of custom hyperparameters taken from He et al. (2021a). All custom hyperparameters are listed in Appendix B.

For all models we set the maximum length of context in tokenizer equal to 512 as there are only few text items in both train and test set with tokenized text length greater than 512. Additionaly, we've used the early stopping method for all of our experiments to get rid of epochs dependency.

6 Results and Discussion

6.1 Main Results

In Tables 1, we compare MAE scores of different models from Section 4.2. There are experiments with models fine-tuned on the original dataset provided by organisers and on the extended dataset with both augmented and original texts.

All models perform better when they are fine-tuned on the extended dataset rather than only on original texts. It clearly shows that even such a simple data augmentation provides a significant boost in performance.

If we compare the results among the models, we will clearly see the dominance of DeBERTaV3 models. For both setups DeBERTaV3-large has shown the best performance and the lowest MAE score on the validation and test datasets. On the setup with the extended dataset, DeBERTaV3-large gets new best MAE score for the competition, which is equal to 13.375. It improves MAE score of the top-1 submission by more than 2 points, from 15.683 to 13.38.

6.2 Discussion

Results in Section 6.1 show the importance of both the variety of the data in the dataset and a pretrained model. Leveraging augmented training data significantly increases performance on the task, because it introduces variety in lengths of texts and boundary token positions while preserving the coherence of the texts. We believe that to be the reason why the models perform better when they are fine-tuned on the dataset with augmented data rather than on the original dataset.

Apart from various data, it is also important for the pretrained model to have great generalization capabilities. DeBERTaV3-large has better generalization capabilities than other tested models (He et al., 2021b). The advanced architecture of DeBERTaV3 helps to significantly improve the MAE score in comparison with both RoBERTa and Longformer.

For all three models, large vesion of each model outperforms base version on both the original and the extended dataset. The reason to this is, greater number of trainable parameters allows models to generalize on training set better.

6.3 Error Analysis

We manually inspected texts from the test set on which the best-performing model, DeBERTaV3-large, made serious mistakes. We've limited our inspection set to the texts where the distance between the predicted label and the true label was more than 100 tokens. Thus, we got 276 texts. Only 75 out of these 276 texts were from PeerReview domain, so model made most of its mistakes on the Outfox domain, texts from which are not present in the train set.

These two domains presented in the test set are very different: they vary in the style of formatting, punctuation, and text structuring. The second domain of LLM-generated student essays have a lot of spelling and punctuation problems and it may confuse the models, as they trained on more formal and literate texts. It would be interesting to evaluate models on each of these domains separately. However, because we do not have domain classification lables in the test set, it is not yet feasible.

6.4 Anomalies in Texts

In the majority of texts from the original dataset, the model generates a coherent continuation of the human-written prefix, and it may be hard for a human to guess the boundary word without knowing it. However, there are a number of texts in the data sets that have some flaws in the generated parts.

There are texts in which LLM hallucinated. It either repeated the human prefix or went into a loop where it generated excessive lists with the same beginning. See example of it in Appendix A and in Appendix C. Such hallucinations can be an immediate hint for detector model to put the label boundary near this anomaly. Also, sometimes machine-generated text can have some distinguished features that imply the artificial nature of a particular part of the text. For example, in a number of cases the model begins the generation with the """ (three double quotation marks). It may also be a hint for the detector. A list of other common features we've encountered while examining the test set is provided in Appendix C.

7 Conclusion

In this paper we describe the system submitted for SemEval2024-Task 8, the subtask dedicated to hybrid human-machine writing detection. We present a simple yet effective augmentation pipeline. We explore how adding this pipeline to the process of fine-tuning can significantly increase the performance on the task, and provide an analysis of performance of various models with and without our augmentation pipeline. The best model, which is DeBERTaV3-large fine-tuned on a large set of augmented data, receives a new best score according to the leaderboard of the competition. Other fine-tuned models achieve competitive results, ranking in the upper half of the leaderboard and beating the organisers' baseline. As the provided data was limited to English language only, future work might include training multilingual boundary detection solution by mixing training data of different languages and using a multilingual encoder (Chizhikova et al., 2023). Such a system can be used for hybrid AI-writing detection as a standalone solution or can

be integrated into existing NLP frameworks like DeepPavlov (Burtsev et al., 2018).

A Examples of Texts

Table 2 contains three examples of how authorship change occurs in the texts from the train set. While

the first text contains no signs of a flawed generation, the second and third texts have some flaws. In the second text, the model begins to generate from the capital letter, and its generation is incoherent with the human-written prefix. In the third text, the model starts to repeat the end of the human part, which is a glaring sign of machine-generated text.

Model
I noticed that in Figure 2, the two quantization factors for quantized layers are missing labels. It would be helpful for the reader to understand which layers are being quantized in the figure
Hi Authors, You seem to have submitted two of the same paper? Pls advise Could you please clarify if this is a mistake or if there are any differences between the two submitted papers?
There has been prior work on semi-supervised GAN, though this paper is the first context conditional variant. The novelty of the approach was the novelty of the approach was leveraging in-painting using an adversarial loss to generate contextually relevant images.

B Hyperparameters

For fine-tuning DeBERTaV3 we use hyperparameters, listed by model authors in He et al. (2021a). Table 3 lists these hyperparameters.

Hyperparameters	Large	Base
Optimizer	AdamW	AdamW
Adam β_1, β_2	0.9, 0.999	0.9, 0.999
Adam ϵ	1e-6	1e-6
Warm-up step	50	50
Batch size	4	32
Learning rate (LR)	5e-6	2e-6
Learning rate decay	Linear	Linear
Weight decay	0.01	0.01
Gradient clipping	1.0	1.0

Table 3: Hyperparameters for fine-tuning DebertaV3-large and DebertaV3-base

Table 4 contains hyperparameters for fine-tuning RoBERTa, also taken from original paper (Liu et al., 2019).

Hyperparameters	values
Optimizer	AdamW
Warm-up steps	50
Batch size	16
Learning rate (LR)	5e-6
Learning rate decay	Linear
Weight decay	0.01

Abstract

In this paper, we describe the methods used for Quantitative Natural Language Inference (QNLI), and Quantitative Question Answering (QQA) in task1 of Semeval2024 NumEval. The challenge's focus is to enhance the model's quantitative understanding consequently improving its performance on certain tasks. We accomplish this task from two perspectives: (1) By integrating real-world numerical comparison data during the supervised fine-tuning (SFT) phase, we enhanced the model's numerical sensitivity. (2) We develop an innovative reward model scoring mechanism, leveraging reinforcement learning from human feedback (RLHF) techniques to improve the model's reasoning completeness. The experimental results demonstrate that our methods achieve outstanding performance. Our code could be found at https://github.com/Bit-numeval/NumEval.

1 Introduction

Numeral-aware language understanding plays a crucial role in narratives when contexts contain numerical comparison, implication, definition etc (Chen et al., 2023a). This importance is especially revealed in real-world applications, such as law, finance, and clinical documentation (Chen et al., 2024b). Large Language Models (LLMs) demonstrated impressive performance in various NLP tasks, but they still suffer from challenges such as hallucination of weak numerical reasoning (Zhuang et al., 2024). In this paper, we delve into solving the numerical hallucination problem, evaluated by the QNLI (Ravichander et al., 2019) and QQA (Mishra et al., 2022) subtasks in the Quantitative Understanding (QU) task (Ravichander et al., 2019) of the Semeval Numeval Task (Chen et al., 2024a). QNLI involves inferring relationships based on numerical clues, and QQA requires quantitative reasoning. Table 6 in Appendix A.1 shows examples of each task.

QQA

prompt: I will first raise a question and then provide two options. Please choose the correct answer after providing the inference process step by step, in the format of 'the answer is option 1. ####_1'.
question: "The ranger and the rustler both were riding horses that galloped at the same speed. The rustler left at 01:00 where as the ranger left at 05:00. Who has traveled further??"
option1: the ranger
option2: the rustler
Response: Let's think step by step.

label: the answer is option 2. #### 2

Solution with inaccurate steps
[1]. The ranger and the rustler both were riding horses that galloped at the same speed. The rustler left at 01:00 where as the ranger left at 05:00 hours. [2]. Since the ranger left at 05:00 hours and the rustler left at 01:00 hours, **the ranger has traveled for 4 hours more than the rustler.** [3]. As they were riding at the same speed, the ranger has traveled further in the given time period. [4]. Therefore, the answer is option 1. #### 1

Solution with incomplete reasoning
[1]. Given that both the ranger and the rustler were riding horses at the same speed. The rustler left at 01:00 and the ranger left at 05:00 hours. [2]. Therefore, the answer is option 2: the rustler. #### 2

Correct solution
[1]. Given that both the ranger and the rustler were riding horses at the same speed, the distance traveled is directly proportional to the time traveled. Distance = Speed * Time. [2] . The rustler left at 01:00 and the ranger left at 05:00 hours. Since the rustler started 4 hours earlier, the rustler has traveled for 4 hours more compared to the ranger. [3] . As they were riding at the same speed, the rustler has traveled further in the given time period. [4] . Therefore, the answer is option 2: the rustler.#### 2

Figure 1: An example from QQA dataset. LLMs may not be able to generate an accurate and complete process during quantitative reasoning. Specifically in this example, the first solution has an error in step[2] where the model confuses the concept of time period and time point, resulting in a wrong answer. And the second solution simply jump to the final answer after summarizing the problem, which is incomplete and unreasonable.

Based on our investigation and preliminary evidence of promise, we attribute LLMs' limitations on the QU tasks to two key aspects: (1) *Numerical Sensitivity*: LLMs, trained on vast quantities of text, often fail to accurately capture numerical information (Chen et al., 2023b). (2) *Reasoning Accuracy and Completeness*: as illustrated in Figure 1, LLMs may struggle to generate a comprehensive and precise step-by-step reasoning process, particularly in numerical reasoning contexts (Bílková et al., 2023).

To improve models' numerical sensitivity, Chen et al. (2023b) fine-tuned them using the Comparing

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1830–1841

Numbers Dataset, which comprises numerical comparison statements. However, solely tuning models using the comparing number data may lead to an overfit issue. Meanwhile, recent efforts on enhancing reasoning accuracy such as process supervision by reinforcement learning on every reasoning step (Lightman et al., 2023). Nevertheless, in our cases, numerical reasoning involves a variable number of reasoning steps. Therefore, multiplying reward scores for each step (Lightman et al., 2023) reduces the overall multi-step reasoning score, which results in incomplete reasoning steps.

To address these limitations, we propose utilizing numerical comparisons of real-world contexts for more robust fine-tuning. In addition, we introduce a reasoning completeness reward designed to improve the precision of viable reasoning processes. The contributions of this paper include: (1) By integrating the comparing numbers task during the fine-tuning, we enhance the model's numerical sensitivity. Specifically, we use GPT-3.5 to integrate comparing numbers data into the real-world context, effectively preventing overfitting during training. Additionally, we reduce the long-tail effect by balancing between comparing numbers data and QU task data. Ablation studies show significant performance improvements with this method. (2) To the best of our knowledge, our study is the first time to enhance the model's reasoning completeness by RLHF. By introducing a fine-grained Reasoning Completeness Reward method, we emulate the complexity of human reasoning processes, aligning the model's accuracy and step rationality with human feedback. Experimental results confirm that our approach effectively improves the performance by ensuring a reasonable number of reasoning steps. (3) Our approach outperforms the other models of the same size across all test datasets, demonstrating strong generalizability. Furthermore, even compared to the state-of-the-art LLMs such as GPT-3.5 (Ouyang et al., 2022) and Llama2-70B (Touvron et al., 2023), our method also achieves better performance on four datasets.

2 System Overview

As shown in Figure 2, we highlight to enhance the model's *numerical sensitivity* and *reasoning completeness*. Specifically, we first use GPT-3.5 (Ouyang et al., 2022) to extend comparing numbers data into real-world contexts and fine-tune the model with this data to enhance numerical sensitivity. To prevent model overfitting, we mix 50% of the QNLI and QQA task data and 50% comparing numbers data into the SFT training dataset. Furthermore, we employ RLHF method to align every reasoning step with human-labeled process supervision. To leverage a more profitable Reward model for RLHF, we manually score the reasoning steps of the augmented positive and negative cases. In particular, we propose a newly Reasoning Completeness Reward for the PPO algorithm to encourage a complete reasoning procedure. The following subsections will detail our method.

2.1 Comparing Numbers Task for Numerical Sensitivity Enhancement

The comparing numbers task is proven to enhance the numerical sensitivity of the model (Chen et al., 2023b). Nevertheless, traditional comparing numbers data only involves the comparison of two numbers and lacks real-world contexts, which can lead to model overfitting and impairing its comprehension and generation capabilities. To address this, we use GPT-3.5 to put comparing numbers data into real-world contexts for training. Additionally, we introduce training data balance to avoid overfitting and long-tail problems. The following will provide a detailed explanation.

Comparing Numbers in Real-world Contexts The comparing numbers task was first proposed by Chen et al. (2023b), statements in the format "[Num 1] is equal to [Num 2], the answer is True/False." We further improve the statements by using GPT-3.5 to incorporate comparing numbers data into real-world contexts, thereby increasing the diversity and reality of the data. Additionally, randomly generating [Num 1] and [Num 2] overlooks the realistic numerical ranges in real-world contexts (e.g. human ages cannot reach 100,000 years old). Therefore, we restrict the numerical range to ensure that 90% of the numbers are randomly generated within the range of 0 to 10,000, thus aligning more closely with real-world contexts. Details and an example are shown in Appendix A.

Training Data Balance To balance the data and avoid long-tail problems caused by varying dataset sizes in QNLI and QQA tasks, we generate additional data by using GPT-3.5, which has increased the number of cases in each dataset to approximately 1000. Moreover, during the training phase of the comparing numbers task, we mix 50% of

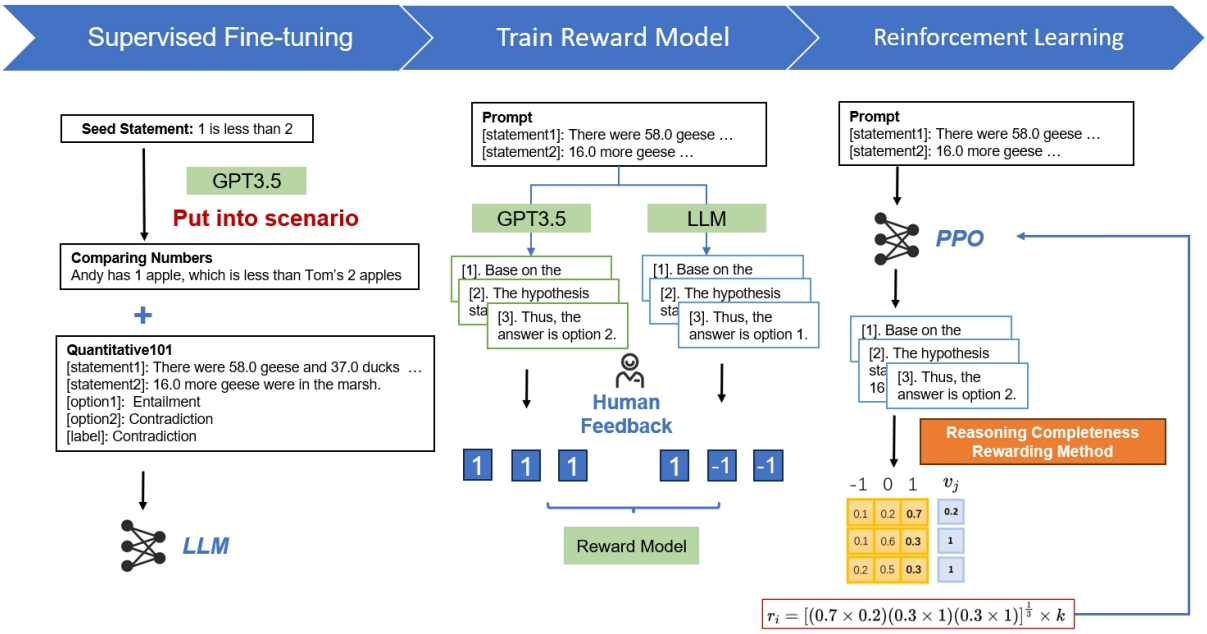

Figure 2: An overview of our system: (1) supervised fine-tuning with comparing numbers task for numerical sensitivity enhancement, (2) reward model training. (3) reinforcement learning via proximal policy optimization with Reasoning Completeness Reward.

the QU training data and 50% comparing numbers data to avoid overfitting the model to the comparing numbers task. Details on the specific expansion methods and prompt specifics can be found in the Appendix C.

2.2 RLHF-based Reasoning Completeness Alignment

To enhance the model's reasoning accuracy and completeness, we first employ human-labeled process supervision signals to align every reasoning step generated by the LLMs; then, we propose a new Reasoning Completeness Reward (RCR) model to improve the RLHF's performance to encourage generating complete reasoning steps.

2.2.1 Human-data Collection for Training Reward Model

To train a profitable reward model (RM), balanced labels need to be collected. While the number of positive labels far exceeds other labels among the steps generated by GPT-3.5, we have also used other open-source LLMs, such as Abel-7b, to generate candidates of reasoning steps, which may contain more negative examples to balance the labels' polarities. Human labelers would evaluate the given steps by their correctness, and correct answers to the question are provided as a reference. The statistics of datasets are shown in Table 1.

Datasets	Cases	Human labeled			
		Pos.	Neu.	Neg.	Steps
AwpNLI	1622	4334	822	1669	7109
NewsNLI	1643	3358	910	2870	7502
RedditNLI	1152	3074	507	958	4674
RTE_Quant	1324	3363	290	914	4817
StressTest	1369	2598	723	1921	5696
QQA	1394	3937	184	1778	6424

Table 1: The step data labeled by human. "Cases" is the number of solutions generated by models, "Pos.", "Neu.", and "Neg." are the number of positive, neutral, and negative labels after labeling, respectively, "Steps" is the total number of reasoning steps taken to solve all the questions in the dataset.

Step Labelling Criteria Each step is classified as either 'positive', 'neutral', or 'negative' due to its correctness, corresponding to three labels: "1", "0", and "-1". The correct steps must first meet the requirements of accurate logic and calculation within the steps (correct object of operation and correct result). At the same time, it is necessary to be consistent with and correctly use the results of the previous step for subsequent reasoning. If the correct conditions are met but there is no help in obtaining the correct answer, 0 points will be given. On this basis, if the task requirements are correctly understood and helpful in obtaining the correct answer, 1 point can be given. Steps with

logical, computational, or factual errors that are completely unrelated to the context and question, or incorrect answers, will receive a score of -1.

2.2.2 Reasoning Completeness Reward

Lightman et al. (2023) proposed a process supervision method by scoring the correctness probability of each reasoning step. The score is implemented as the multiplication of probabilities of all reasoning steps:

$$r_i^1 = \prod_{j=1}^{N} P(y_j = 1|x_j) \tag{1}$$

where N is the number of steps for the i-th solution, x_j is the input of RM, and y_j is the classification.

However, when the number of reasoning steps is not fixed, the score of (1) is influenced by the number of reasoning steps. As the correctness probability is decimal, the more steps involved in reasoning, the smaller the product of probabilities, resulting in lower rewards, which leads to a tendency for the model to subsequently generate less reasoning steps. To mitigate this, we applied geometric mean to the product:

$$r_i^2 = \left(\prod_{j=1}^{N} S_j \right)^{\frac{1}{N}} \tag{2}$$

where $S_j = P(y_j = 1|x_j)$ is the score for j-th step.

We observed that despite using the scoring method of (2), the model still failed to generate complete reasoning steps. Further analysis revealed that the model often simply repeats the question in its first reasoning step, resulting in a high score for the first step, which in turn leads the model to refrain from generating subsequent steps. Therefore, we propose the **reasoning completeness reward**, including a weighted geometric mean and a penalty coefficient. First, the importance of steps at different positions can be adjusted by setting weight v_j.

$$r_i^3 = \left(\prod_{j=1}^{N} v_j S_j \right)^{\frac{1}{N}} \tag{3}$$

In addition, as we hope that the solutions are around 4 steps, and solutions guessing the result from the first step without reasoning is not encouraged, a penalty coefficient k is introduced to constrain it.

$$k = \begin{cases} \frac{5}{\sigma\sqrt{2\pi}} e^{-\frac{(N-\mu)^2}{2\sigma^2}} & , N > 1 \\ 0 & , N \leq 1 \end{cases} \tag{4}$$

where $\mu = 4$, $\sigma = 2$. So the reward from the reward model is

$$R_i = r_i - \beta KL(x, y) \tag{5}$$

$$r_i^4 = \left(\prod_{j=1}^{N} v_j S_j \right)^{\frac{1}{N}} \times k \tag{6}$$

where $KL(x, y)$ is the KL-divergence between the current policy and the reference model in reinforcement learning.

Upon achieving the RM, we employ RLHF with PPO (Schulman et al., 2017) in a step-by-step manner, which is implemented with TRL[1].

3 Experimental Setups

Datasets We adopted the Quantitative101 dataset provided for SemEval 2024 Task7 and then expanded it using the GPT-3.5 API, in Table 1. From these data, three datasets were obtained for SFT, reward model training, and reinforcement learning, respectively. The prompts used during training and testing can be found in the Appendix D. Due to a large amount of labeled "1" data in the RM training dataset, each step of "0" and "-1" was repeated 2-3 times, resulting in 16587 positive steps, 11072 neutral steps, and 16236 negative steps in total. When dividing the datasets, 20% of the data is used as test sets in all three periods.

Metrics and Parameters setting The metric is the average micro-F1 score of the testing dataset in QNLI and QQA tasks. Our CN-SFT model is trained on Abel-7B (Chern et al., 2023) with a learning rate of 3e-5, a warmup rate of 0.03, and a model max length of 1024. As for the RM, we choose to train on BERT-large model (Devlin et al., 2018) as it well complete the classification tasks (Gao et al., 2022). It is trained with a learning rate of 2e-5, warmup rate of 0.05, and a model max length of 256, and is trained for 10 epochs. The PPO training is implemented with Lora, where the learning rate=1.41e-5, max new tokens=512. On a dataset of size 5470, each training epoch takes around 55 hours on 4 A100s.

4 Experimental Results

4.1 Overall Results

Main Results Table 2 compares the performance of our method with that of current mainstream

StressTest	37.32%	**53.57%**
QQA	51.23%	**56.68%**
Score	65.57	**71.84**
Steps (avg)	2.624	**2.844**

Table 3: Comparison results indicate that our proposed RCR-improved RLHF outperforms over all datasets and can generate more completed reasoning steps.

LLMs on the QU tasks. Our model achieved optimal performance in the AwpNLI, NewsNLI, RedditNLI, and RTE_Quant tasks. It also showed comparable results in the StressTest and QA tasks, only falling short of Llama2-70B and GPT-3.5. However, it is worth emphasizing that our model has only 7B parameters. At this scale, its performance significantly surpasses that of other models.

Specifically, compared to our baseline model Abel-7B, by solely employing the CN-SFT method, our model achieved significant accuracy improvements of 15.26%, 15.92%, 17.12%, 15.86%, 21.87%, and 8.03% across six tasks. Upon further integrating the RLHF, the accuracy additionally gained 16.17%, 4.96%, 10.8%, 14.46%, 0.83%, and 0.51% improvement. These results validate the effectiveness of the methods proposed in this study.

The Effect of the Reasoning Completeness Reward (RCR) It is aimed at enhancing the completeness of the reasoning steps. Table 3 shows the comparison of our method's effectiveness and the number of reasoning steps against the baseline. The results demonstrate that the proposed RCR significantly increases the performance. Furthermore, the number of reasoning steps generated by our proposed enhances the reasoning completeness indicated by reasoning steps.

4.2 Ablation Analysis

We further conduct ablations to analyze the contribution of our methods' components.

Comparing numbers task can enhance the model's numerical sensitivity. We first verify whether the comparing numbers task enhances the model's numerical sensitivity. As shown in Table 4, By comparing the results of SFT (column 2) and CN-SFT (column 3) as well as PPO (column 4) and CN-PPO (column 5), we observe that models integrating the comparing numbers task exhibit superior performance in all datasets.

RLHF-based reasoning completeness alignment is valid. As shown in Table 4, the comparison of the PPO (column 4) to the SFT (column 2), and the comparison of the CN-PPO (column 5) to the CN-SFT (column 3) indicate that reasoning completeness alignment based on the proposed RLHF can effectively improve the model's performance on numerical understanding.

4.3 Comprehensive Analysis

4.3.1 Error Analysis

As shown in Table 2, the system performs relatively weakly on the QQA and StressTest datasets. The weak accuracy in the QQA task may be attributed to a lack of physical common sense in our 7B LLM. For instance, the question `"An apple is`

Dataset	SFT (w/o CN and RL)	CN-SFT (w/o RL)	PPO (w/o CN)	CN-PPO
AwpNLI	58.82%	**71.08%**	80.67%	**87.25%**
NewsNLI	55.87%	**66.67%**	59.62%	**71.36%**
RedditNLI	51.60%	**64.40%**	71.20%	**75.20%**
RTE_Quant	68.40%	**72.53%**	80.72%	**86.99%**
StressTest	52.57%	**52.74%**	53.40%	**53.57%**
QQA	50.62%	**56.17%**	**59.26%**	56.68%
Score	56.31	**63.93**	67.48	**71.84**

Table 4: Ablation studies of our method. SFT means the model is fine-tuned only on QU training data, while PPO refers to reinforcement learning training based on this model. CN-SFT means the model was fine-tuned on both QU training data and comparing numbers data, and CN-PPO refers to reinforcement learning training based on this model.

`sitting 15 meters away from Harry, and a watermelon is sitting 110 cm away. Which item looks larger?`". Another example is shown in Appendix B.1. Solving such a problem not only relies on numerical logical reasoning, but also requires understanding the conversion relationship between 'meters' and 'cm', and the physical principle that objects appear smaller the further away they are. This common sense is often acquired by knowledge injection for LLMs, which is out of our research scope in this paper.

The objective of the StreesTest dataset is to determine the relations of two sentences. Most of the sentences always contain multiple numbers whereas only one or two numerical information is valuable for classifying the sentences' relations. An example is shown in Appendix B.2. However, our models as well as other LLMs (i.e. GPT3.5 and Llama-70B) hardly capture the most valid numbers to predict the outcomes. As a result, the improvement of our model on the StressTest dataset is not as significant as in other datasets.

4.3.2 Strengths and Weaknesses

Strengths This study firstly integrates comparing numbers data into real-world contexts, thereby avoiding model overfitting and the deterioration of linguistic capabilities typically caused by solely using formatted data. This approach not only enhances the model's numerical sensitivity but also effectively prevents overfitting issues. Moreover, we propose a new reasoning completeness reward scoring method, suitable for more complex reasoning tasks, particularly those featuring a variable number of reasoning steps. The effectiveness of this method lies in rewarding each step of reasoning and considering the number of reasoning steps into the reward calculation, thus preventing the generation of reasoning processes that are either too brief or excessively lengthy. Finally, In the majority of tasks, our 7B model outperforms super LLMs such as GPT-3.5 (Ouyang et al., 2022) and Llama2-70B (Touvron et al., 2023).

Weaknesses First, in Section 4.3.1, We noted that the model generates incorrect answers for certain tasks due to the absence of essential physical common sense and demonstrates suboptimal performance in identifying and predicting relationships involving multiple numbers. Second, our approach substantially mitigates the model's hallucination of weak numerical reasoning but doesn't eliminate the hallucination that existed in LLMs' outcomes. Third, this study employs the PPO algorithm for the RLHF to validate its effectiveness. Nevertheless, the learning efficiency and convergence problems of the PPO algorithm have not been fully explored.

Therefore, future work is directed to the following aspects. The first one is knowledge injection (Lauscher et al., 2020; von Rueden et al., 2023), especially numerical-relevant knowledge, could be further employed to improve the numerical-aware language understanding capability of the LLMs. Second, the most valuable numbers during the reasoning process could be identified and weighted. Third, employing Score Normalization and Clipping to constrain the reward scores can resolve the training instability (Zheng et al., 2023). Last, utilizing the DPO algorithm (Rafailov et al., 2023), which implements an implicate reward, enhances training stability and its efficiency.

5 Conclusion

In this paper, we described the systems used for QNLI, and QQA in task1 of Semeval2024 NumEval. We select the Abel-7B model as the baseline model. To address the quantitative understanding problem, we first integrate comparing numbers data from real-world contexts to enhance the model's numerical sensitivity. During this process, we devise an effective data mixer to prevent overfitting and the long-tail problem. Subsequently, by employing process supervision from human feedback, we develop an innovative reward model scoring mechanism to improve the model's reasoning completeness using RLHF. Test results demonstrate that our 7B model exceptionally outperformed, surpassing LLMs such as GPT-3.5 on 4 tasks and Llama2-70B on 6 tasks, respectively.

A Construction Process for Our Comparing Numbers Task

To create our Comparing Numbers data, we first automatically generate seed statements and then put them into natural language paragraphs by GPT3.5.

As Table 5 shows, there are three templates for seed statements. We randomly select two numbers from 0 to 9,999 and insert them into the template, note that the distributions of each template and answers are balanced. Finally, 5059 instances are obtained, small amount of duplication in numbers is acceptable as they will be placed into different scenarios afterwards.

Considering most scenarios in the QU tasks are daily situation and financial news, we adopted the following two prompts to generate statements respectively.

Prompt for daily situations: Rewrite the sentence containing numerical comparison relationships into a paragraph describing daily situations about numbers, with a length of no more than 50 words, comparative relationships must be included: (seed statement). For example : 'There were 128,695 students in the large university, which exceeded the 107,736 count of another university.'

Prompt for financial news: Rewrite the sentence containing numerical comparison relationships into a paragraph of financial news, with a length of no more than 50 words, comparative relationships must be included : (seed statement) For example: 'In the stock market, stock A's price at 183.146 increase, surpassing stock B's price at 115.877.'

A.1 Examples of Different Tasks

As shown in Table 6, the comparing numbers task involves a statement with a numerical relationship, which requires the model to determine if it is true.

In the QNLI task, there are two statements, the first is the premise, and the second is the hypothesis. The model needs to determine the correct relationship (entailment/neutral/contradiction) between the two statements, that is, to determine whether the hypothesis can be inferred from the premise. In the QQA task, there is a question with two options, and the model's task is to work out the correct answer.

These tasks require models to interpret quantities expressed in language, perform basic calculations, judge their accuracy, and justify quantitative claims using both verbal and numeric reasoning.

B Examples of Model Results

B.1 Example from QQA task

As shown in Table 7, in QQA tasks, the model sometimes becomes confused about the knowledge required for this problem, unable to analyze based on common sense that lightweight paper airplanes can fly faster, but instead conducts analysis unrelated to the problem, resulting in incorrect answers.

B.2 Example from StressTest

From Table 8 we can see that although the model correctly extracted quantitative information, it misses the key numeral and is distracted by the text, conducting calculations unrelated to the question, resulting in wrong answer.

C Dataset Extending

C.1 QNLI tasks

For the QNLI task, first automatically generate a set of numerals which will be contained by the premise and generate the premise with GPT3.5, then rewrite the statement based on the "entailment", "neutral"or "contradiction"relationship as hypotheses.

For example, when expanding the NewsNLI dataset, we use the following prompts in sequence.

To generate a premise: " Write a piece of news in 30 words or less that contains the message "[number]"

To generate an entailed hypothesis: "Abbreviate this paragraph and keep its original meaning unchanged:" [premise] "

To generate a neutral hypothesis: " Add some numerical information to this paragraph:[statement] "

If a contradicted statement needs to be generated, simply replace the numbers in the premise, such as replacing" 30 people "with" 40 people "," more than 50 people ", or" less than 20 people ".

When expanding the AwpNLI dataset, we can first generate a pair of statements with entailment relationships, the prompt is as follows: "Generate two statements, the first being a promise that contains some quantitative information, and the second statement is a quantitative inference based on the premise. For example: [statement1]: A restaurant baked 5.0 cakes during lunch and sold 6.0 during dinner today and the restaurant baked 3.0 cakes yesterday." [statement2]: 2.0 cakes are left," and

Seed statement	Question	Label
200 **is less than** 215	At the cafe, a line of 215 individuals formed, exceeding the queue at the bakery, where 200 people were waiting.	True
83.146 **is larger than** 115,899	In the stock market, stock A's price at 83.146 increase, surpassing stock B's price at 115,877.	False
147,254 **is equal to** 32.567	There were 147,254 votes for candidate A, which was equal to 32,567 votes for candidate B.	False

Table 5: Examples of our Comparing Numbers task. The seed statements and labels are generated by randomly selecting two numbers between 0 and 9,999 to create comparison statements. The questions are then formulated by GPT-3.5 by specific prompts.

Task	Question	Label
Comparing Numbers	At the cafe, a line of 200 individuals formed, exceeding the queue at the bakery, where 215 people were waiting.	True/False
QNLI	statement1: The fighting ended with all seven attackers dead, Afghan officials said. statement2: All seven militants are dead , authorities say.	Entailment/ Contradiction/ Neutral
QQA	The beauty queen glided across the marble floors with a speed of 15 m/s but at a speed of 1000 cm/s on the wooden floors because it had? Option1: more resistance. Option2: less resistance	Option1

Table 6: Examples of Comparing Numbers, QNLI, and QQA task.

then replace the numerical information in statement 2 to obtain the conflicting statement.

C.2 QQA task

For QQA tasks, most of the questions in the dataset are simple physics multiple choice questions, including knowledge of friction and kinematics. To maintain a balanced proportion of answers, specify the answer option in the prompt of the generated question: "Generate a physics multiple choice question with a quantitative relationship, consisting of two options. The correct answer is option [ans], avoid using markers or latex markers. For example:" question ":" James is watching it rain one day. He notes that the rain travels over the driveway in 5 seconds and the bump "shingles of his house's roof in 10 seconds, the driveway and the shingles are all similar in size. Which surface is more smooth?," option1 ":" roof "," option2 ":" driveway. ".

D Prompts Used in Our Work

Table 9 shows all the prompts we used during the training process.

QQA
question: Two paper planes are thrown at a time, into the air. One is made of thick cardboard and has a weight of 200 gms, one is made of thin paper and weighs 40 gms. Which paper plane flies faster? **option1:** cardboard plane **option2:** paper plane **label:** Thus, the answer is option2. #### 2
SFT output [1]. The flight speed of a paper plane could be given by the equation: S = faultincline * cos(theta) * times filled, where fill time = t, S is the flight speed, and proprietor elevation. [2] . As the Fuji Schoolcogel 2424 AppColl Maybe is a smaller number, we can assume it's an inertial force. [3] . We can calculate the weight using the equation: W = m * g / W, where W is the wheel weight, m is the mass, g is the acceleration, and D is the diameter of the wheel. [4] . Finally, we can determine the acceleration of a cardboard plane using the equation: Continuous acceleration = (m * g) / times filled, where W is the weight, m is the mass, and D is the diameter of the wheel, w_c = 200 g. [5]. Calculating the acceleration of the cardboard plane: Continuous acceleration = (200 g * g) / 10 sec = 200 g * g / 10 sec = 200(g) / 10 sec. [6] . Calculating the acceleration of the thin paper plane: Continuous acceleration = (40 g * g) / 10 sec = 40 g * g / 10 sec = 40(g) / 10 sec. [7] . There is no difference in acceleration between the cardboard plane and the thin paper plane, so they will fly at the same speed. Thus, the answer is option 1. #### 1

Table 7: An error example from QQA task. Model sometimes becomes confused about the knowledge required for this problem, unable to analyze based on common sense that lightweight paper airplanes can fly faster, but instead conducts analysis unrelated to the problem, resulting in incorrect answers.

StressTest
statement1: If Danny **scored 86** , 75 , 52 , 87 , 85 and 82 marks (out of 100) in English , Social Studies , Art , Music , Biology and French **statement2:** If Danny **scored more than 76** , 75 , 52 , 87 , 85 and 82 marks (out of 100) in English , Social Studies , Art , Music , Biology and French **option1:** Entailment **option2:** contradiction **option3:** neutral **label:** Thus, the answer is option1. #### 1
CND-PPO output [1]: Given the numbers 86, 75, 52, 87, 85, and 82, it can be calculated that the average mark is (86 + 75 + 52 + 87 + 85 + 82) / 6 = 485 / 6 = 77.5.[2] : The hypothesis states that Danny scored more than 76, 75, 52, 87, 85, and 82 marks.[3] : As the average mark approximately equals 77.5, and each mark is rounded to the nearest whole number before factoring, the hypothesis is 'not car more than 76, 75, 52, 87, 85, and 82 marks' in the given context.Thus, the answer is option 3. #### 3 **reward:** 0.28299634026503834
Correct solution [1]: The premise states that Danny scored 86 , 75 , 52 , 87 , 85 and 82 marks (out of 100). The hypothesis states that Danny scored more than 76, 75, 52, 87, 85, and 82 marks. [2]: **86 is indeed more than 76**, so the hypothesis can be infered to be true. [3] Thus, the answer is option 1. #### 1

Table 8: An error example from StressTest dataset. Although the model correctly extracted all the quantitative information, it misses the key point and conducted analysis and calculations unrelated to the question, resulted in wrong answer.

QQA I will first raise a question and then provide two options. Please choose the correct answer after providing the inference process step by step, in the format of 'the answer is option 1. #### 1'. If calculation is involved, please provide the equations during the calculation process. Using numbers like '1.' or '[1]' to mark steps. question: option1: option2: Response: Let's think step by step.
AwpNLI I will first raise two statements and then provide two options which are entailment and contradiction. The first statement is the given premise, the second statement is the hypothesis. You should determine if the hypothesis can be justifiably inferred to be true (option 1 : entailment) or false (option 2 : contradiction) base on the premise. Please choose the correct answer after providing the inference process step by step, in the format of 'the answer is option 1. #### 1'. If calculation is involved, please provide the equations during the calculation process. Using numbers like '1.' or '[1]' to mark steps. Abstract

This paper presents our system developed for the SemEval-2024 Task 1: Semantic Textual Relatedness (STR), on Track C: Cross-lingual. The task aims to detect semantic relatedness of two sentences in a given target language without access to direct supervision (i.e. zero-shot cross-lingual transfer). To this end, we focus on different source language selection strategies on two different pre-trained languages models: XLM-R and FURINA. We experiment with 1) single-source transfer and select source languages based on typological similarity, 2) augmenting English training data with the two nearest-neighbor source languages, and 3) multi-source transfer where we compare selecting on all training languages against languages from the same family. We further study machine translation-based data augmentation and the impact of script differences. Our submission achieved the first place in the C8 (Kinyarwanda) test set.

1 Introduction

The task of semantic textual relatedness (STR) has a long-standing tradition in NLP (e.g., Mohammad, 2008). It consists of predicting a score that reflects the closeness in semantic meaning between two given sentences. For example, consider the following examples extracted from the actual shared task data (Abdalla et al., 2023) shown in Figure 1. For English, the annotators scored the first pair higher than the second sentence pair. Similarly, for Afrikaans the annotators scored the first example higher than the second one. As further described in Abdalla et al. (2023), all sentence pairs were annotated manually in a pairwise fashion to obtain semantic textual relatedness (STR) scores between 0 (completely unrelated) and 1 (maximally related).

While previous work has largely focused on English, the SemEval-2024 shared task 1 (Ousidhoum et al., 2024b) aims to extend the language coverage. It proposes datasets to evaluate the relatedness of sentence pairs for a total of 14 languages, including low-resource tail languages such as Kinyarwanda (kin) or Marathi (mar) (Abdalla et al., 2023) (see §2.1). The shared task includes three subtracks, each with a focus on supervised, unsupervised and cross-lingual STR, respectively. In this paper, we focus on Track C, *cross-lingual STR*. In this track, the goal is to develop a system to predict STR scores *without* access to any labeled data for the target language (importantly, also no target development data). That is, Track C requires the development of a regression model for 12 target languages, without relying on any labeled datasets in the target language (or pre-trained language model fine-tuned on other STR tasks). Instead the cross-lingual task allows to utilize training datasets from at least one other language from the other tracks (which includes training data of up to 9 languages). Returning to our running example in Figure 1, the task is to develop a system for example for Afrikaans as target by transferring knowledge from one or more source languages (which may include English).

Pair	STR	Sentence Pair
eng-25	0.88	"It is better known as a walk." "It is also known as a walk ."
eng-31	0.30	"But, of course, it's not that simple" "However, this is not for me."
afr-87	0.72	"ols totdat dit n bal vorm." "Dit moet n stywe bal deeg vorm."
afr-78	0.09	"Stel jou voor jou kind skryf elke week n opstel." "Washington is ook n fietsryer-vriendelike stad."

Figure 1: Examples from the dev sets for Semantic Textual Relatedness (STR). eng: English, afr: Afrikaans.

Previous work on multilingual NLP has illustrated the *curse of multilinguality* (Conneau et al., 2020), that is, diminishing returns for training a

[*] Both authors contributed equally.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1842–1853

single system on many languages due to language interference. This shared task has a focus on low-resource languages and languages typologically distant to English, a setup in where cross-lingual transfer has shown to be particularly challenging (Lauscher et al., 2020). Motivated by these two aspects, we set out to study the use of fewer but more relevant *source* languages for a given target language. More specifically, we aim to find good "donor language(s)" (Malkin et al., 2022) and compare those to baselines that either only use English, or a multi-source model trained on all source languages (except the target). We aim to answer the following research questions: **RQ1** To what extent does knowledge transfer from source languages improve STR models? **RQ2** Do multilingual STR models exhibit language interference (Wang et al., 2020), i.e., performance drops when training data from heterogeneous languages are combined? **RQ3** To what extent do script differences play a role in STR ("script gap"), and can we narrow the script gap by using a foundation model specialized to align transliterated data and data written in different scripts? **RQ4** Can we further improve the transfer performance by relying on machine translation to augment existing training data?

To study RQ1, we make use of typological information available in language vectors. For RQ2, we opt for a multi-source approach, that combines the training data for all languages (except the target). To study the impact of scripts (RQ3), we make use of transliteration, and further compare a BERT-based model to FURINA (Liu et al., 2024), a recently proposed language model that aims to better align languages across scripts. Finally for RQ4, we investigate the use of machine translation (MT) for data augmentation. We apply ours methods to 12 target languages in Track C. The specific details about languages are presented in §2.1.

2 Background

2.1 STR Task Setup and Datasets

The STR task (Ousidhoum et al., 2024b) aims to measure the extent to which two linguistic elements share semantic proximity (Ousidhoum et al., 2024a). These elements may be associated through various means, such as conveying similar ideas, originating from the same historical period, complementing each other's meaning, and so forth. It offers 3 tracks to follow: supervised (Track A), unsupervised (Track B), cross-lingual (Track C). In Track C, participants must provide systems developed without relying on any labeled datasets specifically tailored for semantic similarity or relatedness in the target language. Instead, they are required to employ labeled dataset(s) from at least one other language.

The STR task involves 14 monolingual datasets for Afrikaans (`afr`), Amharic (`amh`), Modern Standard Arabic (`arb`), Algerian Arabic (`arq`), Moroccan Arabic (`ary`), English (`eng`), Spanish (`esp`), Hausa (`hau`), Hindi (`hin`), Indonesian (`ind`), Kinyarwanda (`kin`), Marathi (`mar`), Punjabi (`pan`), and Telugu (`tel`). Among these, Track A and Track C comprise 9 and 12 languages respectively (see Table 1). In the training datasets, each instance consists of a sentence pair and is assigned a golden STR score as judged by native speakers. The score ranges between 0 and 1, with higher values indicating greater relatedness between the sentence pairs. For details on the data collection, we refer the reader to the shared task overview paper (Ousidhoum et al., 2024a).

As per requirement, we designate the 9 languages in Track A as source languages and those in Track C as the 12 target languages. An overview of the resulting train/dev/test data statistics for the 14 languages is provided in Table 1.

2.2 Evaluation Metric

The evaluation metric used in this shared task is Spearman's rank correlation coefficient. It evaluates the strength and direction of the monotonic relationship between two variables with a range from -1 to 1. In the context of our task, as previously mentioned, the scoring has been adjusted to range between 0 and 1. We use the evaluation script provided by the organizers (Ousidhoum et al., 2024b).

2.3 Baselines

The organizers fine-tuned LaBSE (Feng et al., 2022) on the English training set to get baselines for all target languages except English (cf. §3.1). For English, they fine-tuned LaBSE on Spanish as a baseline. Since the test dataset for Spanish has not been made publicly available, all models aimed at Spanish evaluation are conducted solely on their respective validation datasets. In order to ensure a more equitable comparison with other findings, we reproduce the baseline LaBSE model utilizing the methodology provided by the organizers. It yields a baseline score of 0.687 on the Spanish validation

	eng	esp	afr	hin	pan	amh	arb	arq	ary	hau	ind	kin	mar	tel	total

Table 1: STR Dataset statistics. Indo-European lanuguages including esp, afr, hin, ind, pan and mar: 10,424 train instances; 1,811 dev instances; 5,357 test instances. Afro-Asiatic languages including hau, amh, arb, ary and arq: 3,921 train instances; 411 dev instances; 2,197 test instances. Out of 14 languages, 5 languages including amh, hin, arb, arq, ary are in non-latin script, all the rest of languages are in latin script.

dataset.

3 Methods

We opt for two RoBERTa-based (Liu et al., 2019) models for the regression task trained with a mean-squared error (MSE) loss. More specifically, we use the XLM-RoBERTa base model, and FURINA (Liu et al., 2024), which is a XLM-R derivative based on Glot-500 (ImaniGooghari et al., 2023), further detailed below. We adopt a multi-source approach that involves individually fine-tuning a model for each target language in Track C. This fine-tuning process utilizes the training datasets from all languages available in Track A, explicitly excluding the dataset of the test language itself. For baseline comparisons, we use XLM-RoBERTa (Conneau et al., 2020) and FURINA (Liu et al., 2024) models fine-tuned solely on English datasets.

3.1 Model Selection

XLM-RoBERTa. The multilingual masked language model XLM-RoBERTa (XLM-R) (Conneau et al., 2020) pre-trained on 2.5TB of filtered CommonCrawl data containing 100 languages has shown superior performance compared to Multilingual BERT (mBERT) (Devlin et al., 2019) across a range of cross-lingual benchmarks. In the experiment, we utilize the base version of XLM-R.[1] XLM-R has seen all SemRelEval languages except for Algerian Arabic (arq), Moroccan Arabic (ary), Kinyarwanda (kin) at pre-training time.

FURINA. FURINA (Liu et al., 2024) covers 511 low-resource languages. It was fine-tuned on Glot500-m (ImaniGooghari et al., 2023). The training data consists of 5% of Glot500-m's pretraining sentences in original script as well as their corresponding Latin transliterations. At pre-training time FURINA has been exposed to all SemRelEval languages except for Algerian Arabic (arq).

LaBSE. The organizers provide cross-lingual baselines for each target language by fine-tuning Language-agnostic BERT Sentence Embeddings (`LaBSE`) (Feng et al., 2022), which supports 109 languages. LaBSE was pre-trained using Translation language modeling (TLM) (Conneau and Lample, 2019), which included bilingual translation sentence pairs for training. The bilingual corpus is constructed from web pages using a bitext mining system, filtered by a pre-trained contrastive data-selection scoring model, and manually curated to create a high-quality collection of 6 billion translation pairs. Out of those, LaBSE has been exposed to different amounts of parallel data (`eng-xxx`) from SemRelEval languages. The largest amount of parallel text involves Spanish with over 375M sentence pairs (`eng-esp`), followed by Indonesian with over 250M sentence pairs (eng-ind), followed by Hindi and Arabic (`eng-{hin, arb}`) with over 125M language pairs. All other languages (`afr`, `pan`, `amh`, `haus`, `tel`, `kin`, `mar`) appear in the TLM training corpus with less than 125M sentence pairs.

3.2 Source Language Selection

Single-Source Transfer. In our first approach, we follow the standard single-source zero-shot cross-lingual transfer setup and fine-tune pre-trained language models on English data ($\texttt{XLM-R}_{\texttt{eng}}$, $\texttt{Furina}_{\texttt{eng}}$). This is a common evaluation approach adopted in standard natural language understanding and generation benchmarks (Liang et al., 2020; Ruder et al., 2023). However, English has been shown to not always be the best source language (Turc et al., 2021). To investigate if this also true for SemRelEval, we further experiment with selecting for each test language its closest (i.e., most similar) source language. Here, we measure language similarity according to typological features from the lang2vec library (Littell et al., 2017).

[1] https://huggingface.co/FacebookAI/xlm-roberta-base

K-nearest-neighbor languages. In this approach we augment the English training dataset with the datasets of k languages that are closest to the target language, dubbed kNN. To determine suitable source languages for each target language, we assess language similarity by calculating the cosine similarity between language vectors learned by a multilingual neural MT model provided by Malaviya et al. (2017). We specifically use the cell_state language vectors, which are computed by encoding all sentences in a given language and then computing the average hidden cell state of the encoder LSTM.[2] These vectors can be seen as language embeddings encoding latent typology features (Östling and Tiedemann, 2017; Yu et al., 2021). With our kNN-models we aim for a good balance between large amounts of training instances (English) and positive transfer from similar languages.

Multi-Source Transfer. The STR dataset contains languages from different language families. To investigate whether training a single model on a disverse set of languages leads to negative interference (Wang et al., 2020) we compare two multi-source models. In the first model, dubbed MS-All, we fine-tune XLM-R and Furina on the concatenation of all training sets from Track A (excluding the target language). Inspired by previous work on combining *multiple related* source languages (Snæbjarnarson et al., 2023; Lim et al., 2024), we further evaluate multi-source models trained on languages from the same language family (MS-Fam).

3.3 Other Approaches

Machine Translation. For the purpose of data augmentation and balance of languages, we translate selected languages into each other using NLLB (Costa-jussà et al., 2022), ensuring that each language contributes equally to the training dataset. Taking Kinyarwanda as an example, we select Hausa and Spanish as the two languages closest to it, based on dense language vector similarity as outlined above (kNN), along with English, as training dataset. We translate among these three languages mutually, thus tripling the size of the training dataset while ensuring a balanced representation of all languages.

Transliteration. Additionally, we attempt to further facilitate multilingual transfer learning by standardizing script across languages. Utilizing the tool Uroman[3] (Hermjakob et al., 2018), which was also used by FURINA (Liu et al., 2024), we transliterate the train and test datasets of languages written in non-Latin scripts, including both the original datasets and the translated datasets, into Latin script. We evaluate the models fine-tuned on Romanized training data on the Romanized test dataset. This attempt only involves non-Latin script languages (amh, arb, ary, arq, hin).

4 Experimental Setup

The detailed setting are listed in Appendix A. As baseline, we exclusively train a model on the English dataset ($\texttt{XLM-R}_{\texttt{eng}}$, $\texttt{Furina}_{\texttt{eng}}$) and assess its performance across all target languages. Subsequently, for each target language, we fine-tune a multi-source model: if the target language is not within the 9 training datasets, we train on the union of all $n = 9$ training languages. Otherwise we train a multi-source model on $n - 1 = 8$ source languages, excluding the target ($\texttt{XLM-R}_{\texttt{MS-All}}$, $\texttt{Furina}_{\texttt{MS-All}}$). Following this, we explore whether it is helpful to prune certain languages, retaining only English and the two closest to the target languages according to lang2vec (Littell et al., 2017)[4] as source languages ($\texttt{XLM-R}_{\texttt{L2V}}$, $\texttt{Furina}_{\texttt{L2V}}$). Due to the reduction in the training set, which significantly decreased the size of the data, we attempted to expand the dataset through cross-translation ($\texttt{XLM-R}_{\texttt{L2V-Aug}}$, $\texttt{Furina}_{\texttt{L2V-Aug}}$; cf. §3.2).

5 Results and Discussion

Our main results are presented in Table 2 and are discussed in the following section.

Single-source versus multi-source transfer. We first compare the performance of a zero-shot STR model trained on English ($\texttt{XLM-R}_{\texttt{eng}}$, $\texttt{Furina}_{\texttt{eng}}$) against a multi-source model trained on the concatenation of all available languages from Track A ($\texttt{XLM-R}_{\texttt{MS-All}}$, $\texttt{Furina}_{\texttt{MS-All}}$). Our results reveal that knowledge transfer from multiple source languages (**RQ1**) improves STR models, affirming the potential of multi-source training to enhance cross-lingual capabilities. On average, both MS-All models outperform their single-source counterparts by 0.02 and 0.09 respectively. This is expected since

[2] https://github.com/chaitanyamalaviya/lang-reps/

[3] https://github.com/isi-nlp/uroman

[4] We compare the similarity of languages based on three criteria: lang_cell_states, lang_vecs and language typological vectors

Table 2: Spearman's rank correlation of zero-shot transfer experiments on SemRelEval 9 test languages. The organizers decided to keep the test set for Spanish private, we therefore report the performance on the validation set. We exclude English from the average result (avg). **bold**: Best result for each language. Languages not covered by all L2V features are excluded from the average (eng, pan, arq, ind, kin). For our kNN-variants we opt for $k = 2$.

the multi-source training dataset is with 15,123 instances almost three times larger than the English dataset with 5,500 instances (cf. Table 1). When trained solely on English data, FURINA performs substantially worse than XLM-R. However, this performance gap narrows when transitioning from single-source to multi-source training.

Transfer from language families. After showing that models trained on all languages outperform the single-source baseline, we now investigate the effect of training on languages from the same family as source languages. Here we experiment with two multi-source models specialized only on Indo-European and Afro-Asiatic languages respectively (MS-Fam). Importantly, for each target language we train a multi-source model on all other languages in the same language family.[5] On Indo-European languages, we find that $\text{XLM-R}_{\text{MS-Fam}}$ and $\text{Furina}_{\text{MS-Fam}}$ yield similar results with much less training data (i.e., 4,913 fewer instances belonging to other language families). For Spanish, our models show performance gains of +0.8 and +0.13 for XLM-R and FURINA respectively, when compared to models trained on all languages. This underscores the presence of language interference (Wang et al., 2020) in multilingual STR models when the training data from dissimilar languages are combined (**RQ2**). On Afro-Asiatic languages, we observe average performance drops of -0.09 and -0.06 for XLM-R and FURINA when moving from MS-All to MS-Fam. We hypothesize that this can be attributed to the amount of training data available. In fact, there are 28% fewer training instances for all Afro-Asiatic languages than for English (5,500).

Transfer from nearest language neighbors. We now investigate the transfer performance when training STR models on their two closest languages according to cosine similarity of language cell state vectors, i.e. learned language vectors presented in (Malaviya et al., 2017). As mentioned earlier, we add English due to its large scale as a third training language. Our submitted system, $\text{Furina}_{\text{eng+esp+hau}}$, is trained on the two closest training languages of Kinyarwanda (kin) and has been ranked first place on the shared task leaderboard. Applying the same approach for each test language ($\text{XLM-R}_{\text{kNN}}$, $\text{Furina}_{\text{kNN}}$) shows mixed results. This indicates that the strong performance on kin can be attributed to the fact that, contrary to XLM-R, kin has been seen by Furina during pretraining.

Transliteration and cross-translation. The STR dataset contains six test languages in non-Latin scripts: Hindi (hin), Punjabi (pan), Amharic

[5] Indonesian and Kinyarwanda are the only SemRel languages in their family, we therefore cannot evaluate multi-source for those languages.

MAX	0.82	0.69	0.83	0.80	0.04	0.79	0.61	0.63	0.74	0.66	0.49	0.65	0.73

Table 3: Single-source transfer results in terms of spearman correlation. The language selection is based on the cosine similarity of different typological features obtained from lang2vec (L2V). We additionally report the lower (MIN) and upper bound (MAX) obtained from selecting the best and worst source language. Languages not covered by all L2V features are excluded from the average: eng, pan, arq, ind, kin. For L2V-Phon, both tel and mar are closest to hin. For L2V-Fam amh and arq are the closest languages, we report their average score (0.595). In single-source transfer with XLM-R$_{kNN}$ we use $k = 1$ and do not combine the selected language with eng training data.

(amh), Standard Arabic (arb), Algerian Arabic (arq), and Moroccan Arabic (ary). Zero-shot cross-lingual transfer of models fine-tuned on English performs worse for Arabic scripts than for amh and hin. Punjabi shows the lowest results by a large margin. When fine-tuned on on multiple source languages (MS-All), XLM-R improves the performance on four out of six languages while Furina yields improvements on all five languages. We find that (1) there is no clear winner between XLM-R and FURINA when applied on text written in different scripts, and (2) romanizing all training and test languages did not improve zero-shot cross-lingual transfer for STR (**RQ3**).

Next, we investigate the impact of augmenting the training data with translated data. The varied outcomes of augmenting data indicate that while machine translation can enhance transfer performance for certain languages. Performance drops in others may stem from shifts in label semantics and the degree of relatedness between original and translated sentence pairs (**RQ4**). Appendix C (Table 14) shows an example where MT fails to capture nuanced differences between closely, but not perfectly related sentences, leading to near-identical translations and inconsistent labels.

Single-source transfer results. We now select the most similar source languages based on different typological features obtained from the lang2vec (L2V) library. We obtain L2V vectors for Phonology (Pho), Syntax (Syn), Inventory (Inv), Family (Fam), Geography (Geo) and learned (LRN) features.

Table 3 shows our results for XLM-R.[6] Overall, a careful selection of a single-source language is crucial for zero-shot cross-lingual transfer. There is a substantial gap between the worst possible result (0.58) and the best possible result (0.73). On average, English is the most effective source language with a correlation of 0.71. A closer analysis reveals that English is the best language only for half of the target languages, despite being the language with the largest training dataset (cf. Table 13 in Appendix). Interestingly, the best possible single-source language selection (MAX) results into the same performance as XLM-R$_{MS-All}$ (cf. Table 2).

6 Conclusion

In this paper, we investigate source language selection for cross-lingual transfer for Semantic Textual Relatedness (STR). We evaluate three different language selection strategies: single-source, multi-source transfer and transfer from English and two nearest language neighbors. We find that the transfer performance crucially depends on the size of the training dataset and the linguistic proximity to the test language. We further show that script differences cause high variance transfer performance and MT-based data augmentation can lead to shifts in label semantics. Fine-tuning FURINA on eng, esp, and hau, we achieve first place in the SemEval-2024 Task 1, Track C8 (kin).

[6] FURINA results can be found in Appendix Table 12.

A Hyperparameters

We employed identical hyperparameters across all variants of XLM-R and FURINA. We train our models for at most 30 epochs with a batch size of 32 and a learning rate of 2e-5 and use AdamW (Loshchilov and Hutter, 2017) with a weight decay of 1e-3. We evaluate the dev set performance every 200 steps and stop early based on the spearman correlation on the validation set (patience counter: 8, patience threshold: 1e-4).

B Language Similarities

Table 4 shows for each test language its two closest source languages (`kNN`) according to cell state vectors from (Malaviya et al., 2017) and learned vectors from lang2vec (`L2V-LRN`) (Littell et al., 2017). We find both language vectors lead to similar results. Here, we further show the selected languages for our multi-source model (`MS-Fam`), which outperforms both `L2V-LRN` and `kNN`.

In Table 5-11 we show cosine similarities between all train and test languages according to different typological features extracted from L2V and learned vectors from (Malaviya et al., 2017). We use the similarities to select source languages for our `kNN` and single-source model variants.

Model Variant	Source languages	Target language	# Train Instances	FURINA	XLM-R
Based on cell state vectors (kNN) (Malaviya et al., 2017)

Table 13: Each cell shows a given test language and lang2vec (L2V) feature the closest source language used for single source transfer in Table 3 and Table 12. We further show the closest languages according to cell-state vectors obtained from a multilingual MT system (kNN) (Malaviya et al., 2017), see §3.2 for details. MIN and MAX show the source language for which best transfer and worst transfer performance is achieved.

Pair	**Sentence Pair**
esp-182	"Un hombre está saltando a una pared baja." "Un hombre está saltando a un muro bajo."
translated	"A man is jumping into a low wall." "A man is jumping into a low wall"

Table 14: An example from Spanish training dataset with its English translation, the label is 0.80.

C Translation quality.

We reviewed some machine-translated examples and noticed that subtle differences in the original language can be lost during translation. As shown in Table 14, the two translated sentences, apart from punctuation, share no differences while the label assigned is 0.8. This undoubtedly has the potential to interfere with the model's learning process for the STR task.

NLP_Team1@SSN at SemEval-2024 Task 1: Impact of language models in Sentence-BERT for Semantic Textual Relatedness in Low-resource Languages

Abstract

Semantic Textual Relatedness (STR) will provide insight into the limitations of existing models and support ongoing work on semantic representations. Track A in Shared Task-1, provides pairs of sentences with semantic relatedness scores for 9 languages out of which 7 are low-resources. These languages are from four different language families. We developed models for 8 languages (except for Amharic) in Track A, using Sentence Transformers (SBERT) architecture, and fine-tuned them with multilingual and monolingual pre-trained language models (PLM). Our models for English (eng), Algerian Arabic (arq), and Kinyarwanda (kin) languages were ranked 12, 5, and 8 respectively. Our submissions are ranked 5^{th} among 40 submissions in Track A with an average Spearman correlation score of 0.74. However, we observed that the usage of monolingual PLMs did not guarantee better than multilingual PLMs in Marathi (mar), and Telugu (tel) languages in our case.

1 Introduction

Prior NLP work has largely focused on semantic similarity, a subset of relatedness, because of a lack of relatedness datasets. The first dataset for Semantic Textual Relatedness, STR-2022 was introduced by Abdalla et al., 2023, which has 5,500 English sentence pairs manually annotated using a comparative annotation framework, resulting in fine-grained scores. The semantic relatedness of two units of language is the degree to which they are close in terms of their meaning (Mohammad and Hirst, 2012). The linguistic units can be words, phrases, sentences, etc.

The most semantic similarity datasets were annotated using coarse rating labels such as integer values between 1 and 5 representing coarse degrees of closeness. These datasets suffer from issues arising due to the fixed granularity which intuits fuzzy boundaries between related and unrelated notions. The following subsection describes the difference between similarity and relatedness which is crucial in understanding the textual semantics.

1.1 Similarity versus Relatedness

As discussed in Abdalla et al., 2023, the following are the characteristics of similarity versus relatedness:

1. Two terms are considered semantically similar if there is a synonymy, hyponymy, or troponymy relation between them whereas for semantic relatedness, it's enough to have any lexical semantic relation at all between them. (example: money-cost is related whereas price-cost is similar)

2. All similar pairs are also related, but not all related pairs are similar. For example, `surgeon-scalpel`, and `tree-shade` are related, but not similar.

3. If units are sentences, then the similarity between sentence pairs exhibits paraphrase or entailment property whereas the relatedness does not support that property since it accounts for all of the commonalities that can exist between two sentences.

The analysis showed that the presence of proper nouns (PROPN), nouns, and other coarse-grained POS categories in a sentence pair impact semantic relatedness much more than any other POS. We evaluated the semantic textual relatedness of 8 languages (Algerian Arabic (arq), Moroccan Arabic (ary), Kinyarwanda (kin), Hausa (hau), Marathi (mar), Telugu (tel), English (eng) and Spanish (esp)) in Track A of SemEval Task 1: Semantic Textual Relatedness for African and Asian Languages (Ousidhoum et al., 2024b).

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1854–1859

2 Related Work

Similarity task is originally proposed to mimic human perception of the similarity level between word or sentence pairs. The first, word similarity dataset was collected in Rubenstein and Goodenough (1965), which consisted of 65-word pairs with human annotations. In general, the datasets consist of pairs of words (w1, w2) (or sentences) and human-annotated similarity scores S_h.

Abdalla et al. (2023) measured the semantic relatedness using Contextual versus Static embeddings and Unsupervised versus Supervised approach to sentence representation. In an unsupervised approach, the embedding of a sentence is derived from that of its constituent tokens. They used Word2Vec, GLoVe, and Fasttext static embeddings in unsupervised settings and the majority of the static embedding models failed to obtain better correlations with human annotation scores. The contextual embeddings from BERT and RoBERTa do not perform better than the Word2vec embeddings.

Finally, the supervised approach by finetuning the SBERT with the STR-2022 dataset captured high semantic relatedness and the Spearman correlation is 0.82 and 0.83 for BERT-based and RoBERTa-based respectively. The supervised approach using the SBERT framework by formulating a regression task leads to a better correlation score of 0.20 than the unsupervised approach.

This motivated us to use the SBERT framework to score the semantic relatedness between the pairs of sentences across 6 low-resource languages and English, and Spanish in the Track A dataset. We used 2 multilingual pre-trained language models ($LABSE, pp-mpnet-v2$) and language-specific monolingual LM for each of the languages. The following subsections describe the reason behind the selection of particular pre-trained LMs that are used in our models.

2.1 LaBSE

Multilingual pre-trained models such as mBERT (Devlin et al., 2019) and XLM-R (CONNEAU and Lample, 2019) have led to exceptional gains across a variety of cross-lingual natural language processing tasks. However, without a sentence-level objective, they do not directly produce good sentence embeddings.

Language-agnostic BERT Sentence Embedding (Feng et al., 2022) is a multilingual BERT embedding model, called LaBSE, that produces language-agnostic cross-lingual sentence embeddings for 109 languages. The model is trained on 17 billion monolingual sentences and 6 billion bilingual sentence pairs using MLM and TLM pre-training, resulting in a model that is effective even on low-resource languages for which there is no data available during training.

It was trained on parallel sentence pairs from 109 languages using a Siamese network based on the BERT architecture. The model's ability to support 109 languages makes it a powerful tool for multilingual applications and cross-lingual natural language processing tasks. This multilingual PLM is used across all the 8 models in our experiment.

PLM Type	Language Model
Monolingual	MahaSBERT, TeluguSBERT
	DziriBERT
Multilingual	Sentence-T5, LaBSE
	AfroXLMR, IndicSBERT
	pp-mpnet-v2

Table 1: Types of pre-trained LM

2.2 paraphrase-multilingual-mpnet-base-v2

This is based on the multi-lingual model of `paraphrase-mpnet-base-v2`, extended to 50+ languages by Reimers and Gurevych 2020. It uses a multilingual knowledge distillation method that allows extending existing sentence embedding models to new languages. It has achieved state-of-the-art performance on the paraphrase identification task on several benchmark datasets.

2.3 AfroXLMR

Alabi et al. (2022) proposed multilingual adaptive fine-tuning (MAFT) as a method for simultaneously adapting multilingual pre-trained language models (PLMs) on 17 of Africa's most resourced languages and three other high-resource languages widely spoken on the African continent to encourage cross-lingual transfer learning. This approach was more competitive than the AfriBERTa (Ogueji et al., 2021) pre-trained LM on various NLP tasks. We used this pre-trained LM for Kinyarwanda (kin) and Hausa (hau) languages.

2.4 IndicSBERT

The IndicSBERT exhibits strong cross-lingual capabilities and performs significantly better than

Pre-trained LM	English	Spanish
LaBSE	0.802	**0.68**

alternatives like LaBSE, LASER, and paraphrase-multilingual-mpnet-base-v2 on Indic cross-lingual and monolingual sentence similarity tasks.

The authors Deode et al. (2023) proposed a simple strategy to train cross-lingual sentence representations using a pre-trained multilingual BERT model and synthetic NLI/STS data. This is the first multilingual SBERT model trained specifically for Indian languages. However, monolingual models are typically found to be performing better than multilingual ones. Hence publicly released monolingual SBERT models for 10 Indic languages. We used `MahaSBERT` for Marathi(mar), and `TeluguSBERT` for Telugu(tel) in evaluating the STR score in Track A.

2.5 DziriBERT

The Algerian dialect is mainly inspired by standard Arabic but also from Tamazight, French, Turkish, Spanish, Italian, and English. Thus the Algerian dialect has several specificities that make the use of Arabic or multilingual models inappropriate. To address this issue the authors (Abdaoui et al., 2022) collected more than one million Algerian tweets and pre-trained the first Algerian language model: DziriBERT.

DziriBERT is a BERT-based model for the Algerian dialect which was trained using the Masked Language Modeling (MLM) task. It handles Algerian text contents written using both Arabic and Latin characters. We used this model for evaluating the semantic relatedness score for the Semitic languages group - Algerian Arabic(arq), and Moroccan Arabic(ary).

3 System Overview

Given a human-annotated dataset for semantic textual relatedness, the participants are allowed to submit systems that have been trained using the labeled training datasets. Apart from that, the participating teams are also allowed to use any other publicly available datasets. We restrict the use of only the dataset provided by the task organizers so that the impact of pre-trained language models on Sentence Transformers can be analyzed for the semantic relatedness task across different low-resource languages. We used the plain vanilla SBERT architecture for fine-tuning with pre-trained LMs for text processing.

In our experiment, predicting semantic relatedness is treated as a regression task, where each sentence is represented as a vector. We use the cosine similarity between the vectors to predict their semantic relatedness, S_p, the Spearman score predicted by the system. Finally, the correlation between S_h, the Spearman score manually annotated by humans, and S_p is computed, and a higher correlation suggests good alignment with human annotations and a better embedding model. Usually, the Spearman correlation between the prediction and gold relatedness scores is used to measure the goodness of the relatedness predictions.

3.1 Dataset

The authors Ousidhoum et al. (2024a) presented SemRel2024 dataset - the first benchmark on semantic distance (similarity or relatedness) that includes low-resource African and Asian languages from five different language families. We used the sentence pairs of 8 languages from the dataset for Track A. Refer Ousidhoum et al. (2024b) to the dataset split size for training, development, and test instances for Track A. The dataset contains semantic relatedness scores for each of the pairs of sentences of 8 languages.

3.2 Training and Testing

During the development phase, only the training and development datasets are given to construct the model for each language. The training data is used to fine-tune the model and development data is used to evaluate the model performance. We report the results using the default hyperparameters

set in the sentence transformer. The PLMs are fine-tuned on training data using cosine similarity loss with batch size as 8, and number of epochs as 20. The official evaluation metric is the Spearman correlation between the predicted similarity scores and the human-annotated gold scores.

During the test phase, we combined the training data + development data to fine-tune the model, and the unseen test data was used to predict the semantic relatedness score. Models using various pre-trained LMs are evaluated using Spearman correlation during the development phase. The model with the maximum Spearman correlation score is used during the testing phase to submit our results. The table 1 lists the types of pre-trained LMs and the corresponding LMs used in our study.

4 Experimental Setup

We aim to focus on the impact of the Sentence-BERT deep neural network in semantic textual relatedness scoring tasks, and the benefit of multilingual/monolingual pre-trained LMs over the task especially for the low-resource languages.

4.1 SentenceBERT

Unlike BERT, SentenceTransformer or SBERT by Reimers and Gurevych (2020) uses a Siamese architecture, where it contains two BERT architectures that are essentially identical and share the same weights. It processes two sentences as pairs during training. This neural network architecture is appropriate for pair-wise semantic sentence tasks such as Sentence Textual Similarity (STS), Semantic Textual Relatedness (STR), Natural Language Inference (NLI), and paraphrase identification tasks. This network leverages the two BERT architectures in parallel to compute/score the similarity/relatedness of pair-wise sentences.

Consider a pair of sentences S1 and S2 that are to be fed into the network. Feed a sentence S1 to BERT A and S2 to BERT B in the SBERT network. Each BERT outputs pooled sentence embeddings u and v respectively. The cosine similarity between these two embeddings (u, v) is computed by using mean-squared error loss as the objective function. This outputs the regressive score between 0 to 1. This is the predicted semantic relatedness score by the model between a pair of sentences S1 and S2. We developed all the models using SBERT for each of the 8 languages (except for Amharic) in Track A.

Pre-trained LM	Algerian Arabic	Moroccan Arabic
LaBSE	0.58	**0.799**
pp-mpnet-v2	0.53	0.73
DziriBERT	**0.67**	0.64

LaBSE	0.579	0.715
pp-mpnet-v2	0.58	0.67
AfroXLMR	**0.61**	**0.73**

Table 5: Evaluation of African languages during development

4.2 Evaluation during development phase

The train ad development split data for each of the languages are as mentioned in the Ousidhoum et al. (2024a). We used two multilingual pre-trained LMs: LaBSE[1] and paraphrase-multilingual-mpnet-base-v2[2] (in short `pp-mpnet-v2`) across all the models. The idea behind using multilingual PLM for all 8 languages is primarily to check the performance of MLM for semantic textual relatedness tasks in low-resource languages. Apart from that, language-specific monolingual pre-trained LMs are also used in each of the models. During the development phase, the model that scored the maximum Spearman correlation is selected and applied during the testing phase. The models developed for each of the languages along with the pre-trained LMs used and its score are discussed below.

The table 2 shows that `sentence-t5-large` [3] (Ni et al., 2022), a text-to-text model showed better performance for the `English` language. The model using `LaBSE` scored higher than the other multilingual and monolingual LM for `Spanish` during evaluation in the development phase.

Table 3 shows that the monolingual models such as `MahaSBERT`[4] and `TeluguSBERT`[5] perform well than the multilingual models. The interesting fact to note is that even the `IndicSBERT`[6] - one of the popular multilingual models pre-trained on 14 Indian languages, scored poorly than the

Language	Model	Predict	Rank	baseline	LM type	diff.
English (eng)	SBERT-T5	**0.8352**	12	0.83	**MultiLM**	+0.0052
Spanish (esp)	SBERT-LaBSE	**0.7045**	9	0.7	**MultiLM**	+0.0045
Marathi (mar)	SBERT-MahaSBERT	0.8711	10	0.88	MonoLM	-0.0089
Telugu (tel)	SBERT-TeluguSBERT	0.7889	17	0.82	MonoLM	-.0.0311
Algerian Arabic (arq)	SBERT-DziriBERT	**0.6226**	5	0.6	**MonoLM**	+0.0226
Moroccan Arabic (ary)	SBERT-LaBSE	0.7446	16	0.77	MultiLM	-0.0254
Kinyarwanda (kin)	SBERT-AfroXLMR	**0.7233**	8	0.72	**MultiLM**	+0.0033
Hausa (hau)	SBERT-AfroXLMR	0.6281	11	0.69	MultiLM	-0.0619

Table 6: Evaluation of our SBERT-based models during the test phase. Boldface highlights the score more or equal to the baseline

LaBSE and pp-mpnet-v2 generic multilingual LM. IndicSBERT is one of the regional multilingual LMs trained in Indian languages.

Similarly for the Semitic languages such as Algerian Arabic and Moroccan Arabic, DziriBERT[7] PLM performed better than the generic multilingual LM in the Algerian Arabic language as shown in Table 4. The DziriBERT was specifically pre-trained on Algerian dialects. For Moroccan Arabic, a model with LaBSE had a better score than the model using DziriBERT LM. As per our knowledge, we do not find any monolingual pre-trained LM for Moroccan Arabic that improves the score than the LaBSE. This is one of the major drawbacks of low-resource languages. The availability of good pre-trained LM for task-specific or generic purposes is scarce in low-resource languages.

For African languages, the performance of the model using AfroXLMR[8] pre-trained LM scored better than the other models using generic pre-trained LMs as shown in table 5. This indicates that the use of appropriate pre-trained LMs is more important for semantic relatedness tasks than the generic pre-trained multilingual language models.

5 Result

During the testing phase, we combined the training + development data as training data to fine-tune the model that yielded the maximum score during the development phase. Then the model is tested with the test dataset of the corresponding language. The predicted sentence relatedness score by the models is submitted as a result and is evaluated using the Spearman coefficient. The results are shown in the Table 6. It is evident from the table 6 that almost 4 models had reached a score equal to or above the baseline score which is highlighted using boldface. The difference between the baseline and the model prediction is indicated with the + and - sign. The difference in Spearman correlation value with '+' indicates the improvement whereas the '-' sign indicates the poor performance of the model.

SBERT-based models for the languages English (eng), Algerian Arabic (arq), and Kinyarwanda (kin) performed more than the baseline Spearman score. SBERT-LaBSE model for Spanish (esp) scored almost equal to the baseline system. Even though the monolingual models SBERT-MahaSBERT for Marathi and SBERT-TeluguSBERT for Telugu showed better performance during the development phase, failed to score above the baseline during testing in respective languages. Similarly, SBERT-based models trained using multilingual pre-trained LM for Moroccan Arabic (ary) and Hausa (hau) languages scored lesser than the baseline model in the test phase.

5.1 Conclusion

Table 6 depicts the impact of pre-trained language models (LM) in SBERT for the various low-resource languages. The usage of monolingual LM in Marathi (mar) and Telugu (tel) did not guarantee a greater performance than the baseline system. This shows the limitations of existing state-of-the-art monolingual pre-trained LM MahaSBERT, TeluguSBERT for the STR task.

Apart from that, the multilingual pre-trained LM such as LaBSE, AfroXLMR did not perform well for Moroccan Arabic (ary) and Hausa (hau) which are from Afro-Asiatic language family. This shows the existence of poor resources such as pre-trained LM in those languages. By default, the monolingual LM did not guarantee better performance than the multilingual pre-trained LM, especially for the low-resource languages.

Abstract

This paper presents our findings for SemEval-2024 Task 4. We submit only to subtask 1, applying the text-to-text framework using a FLAN-T5 model with a combination of parameter efficient fine-tuning methods - low-rank adaptation and prompt tuning. Overall, we find that the system performs well in English, but performance is limited in Bulgarian, North Macedonian and Arabic. Our analysis raises interesting questions about the effects of label order and label names when applying the text-to-text framework.

1 Introduction

Social media platforms have become increasingly popular over time (Perrin, 2015). Whilst this enables greater public discourse, information and disinformation can also be presented purposefully to influence opinions online . Therefore, it is important to explore the detection of persuasion techniques. By fulfilling this goal, strategies that counteract false or misleading narratives can developed, and internet users can be empowered to think more critically about what they see online.

This paper describes our submission for SemEval-2024 Task 4: Multilingual Detection of Persuasion Techniques in Memes. We took a text only approach, and as such we only tackled subtask 1 - given only the "textual content" of a meme, our system must identify which persuasion techniques (of a possible 20) are used (Dimitrov et al., 2024). The labels are organized in a hierarchy (see figure 1) and multiple labels may apply to the same data point. For example:

> **Text:** HISTORY HAS SHOWN THAT THESE ARE THE FIRST TWO THINGS BANNED\\n\\nBY TOTALITARIAN GOVERNMENTS
>
> **Labels**: Loaded Language, Thought-terminating cliché

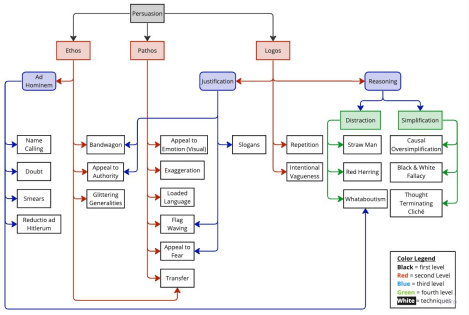

Figure 1: The hierarchical structure of the labels (Dimitrov et al., 2024).

In recognition of the diverse and intriguing use of language for manipulative communication, we target our exploration using a transformer-based architecture due to the ability of such models to capture linguistic intricacies (Plaza-del arco et al., 2023; Tenney et al., 2019). Specifically, we investigate this task using the text-to-text model FLAN-T5 (Chung et al., 2022).

2 Background

Research on identifying persuasion techniques in memes builds on the efforts of propaganda detection (Da San Martino et al., 2021; Dimitrov et al., 2021). Rashkin et al. (2017) trained models using n-gram TF-IDF feature vectors on a four category news reliability classification task. Barrón-Cedeño et al. (2019) both replicated the work of Rashkin et al. (2017) and applied n-grams to propaganda detection under binary classification. More recently, Da San Martino et al. (2019) took a more fine-grained approach. They developed a dataset of news articles with an annotation schema consisting of 18 propaganda techniques. They proposed a multi-granularity network using contextual embeddings derived with BERT (see also Da San Martino et al., 2020). Piskorski et al. (2023) presents a multilingual and multifaceted dataset of news articles, annotated with genre, framing and persuasion tech-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1860–1867

niques. They also evaluated the performance of a transformer model at various granularity levels - token-level, sentence-level, paragraph-level, and document-level.

To the best of our knowledge, there has been no work completed on exploring text-to-text (also known as sequence-to-sequence, or Seq2Seq) models for this multilingual, multi-label classification task in the domain of meme language. Text-to-text models take in text as input and output new text. Models such as T5 can be applied to many different tasks under the text-to-text framework (Raffel et al., 2019). They have also been shown to be effective in zero-shot settings (Chung et al., 2022; Plaza-del arco et al., 2023).

3 System Overview

We use FLAN-T5 (Chung et al., 2022) as our base model. FLAN-T5 was created by fine-tuning T5 (Raffel et al., 2019) on a mixture of tasks including text classification, question answering, and translation. The model regards every task as a text-to-text task.

We train in two steps:

1. LoRA; Low-Rank Adaptation (Hu et al., 2021)

2. Prompt Tuning (Lester et al., 2021)

For both steps all of the original FLAN-T5 parameters are frozen, lessening training time and hardware requirements. As both methods introduce their own set of distinct parameters, the LoRA parameters do not need to be trainable during prompt tuning. We first train using LoRA, then freeze the values of the introduced LoRA parameters and train using prompt tuning to produce the final model.

3.1 LoRA

Neural networks contain many dense layers, which transform input x to output h via matrix multiplication. Without model adaption, the pre-trained weight matrix $W_0 \in \mathbb{R}^{d \times k}$ produces output as follows:

$$h = W_0 x$$

After model adaptation, the updated output can be represented as follows:

$$h_{adapted} = W_0 x + \Delta W x$$

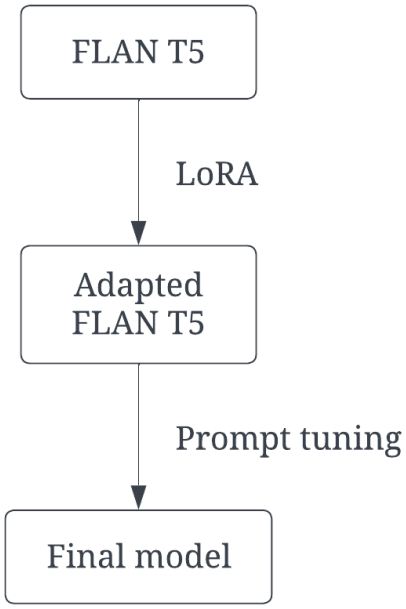

Figure 2: Training steps for our model.

where ΔW is the overall change to the weights, optimised during training. LoRA constrains ΔW by decomposing it into two low-rank matrices, $B \in \mathbb{R}^{d \times r}$ and $A \in \mathbb{R}^{r \times k}$, where $r << min(d, k)$:

$$h_{LoRA} = W_0 x + BAx$$

This process is summarised in figure 3. A and B are trainable parameters, initialised as a random Gaussian and 0 respectively to give an initial $BA = \Delta W$ of 0. $\Delta W x$ is scaled by $\frac{\alpha}{r}$, where α is a hyperparameter. Hu et al. (2021) applied LoRA to attention weights, achieving on par or better performance than full fine-tuning with only a fraction of the trainable parameters.

3.2 Prompt Tuning

In prompt engineering, a "hard prompt" is prepended to the input and used to guide the model to produce the desired output. Prompt tuning instead learns a "soft prompt", wherein the prompt tokens are taken as learnable parameters.

For input consisting of a token sequence $x_0, x_1, ..., x_n$, the tokens are first transformed to the embedding $X_e \in \mathbb{R}^{n \times e}$, where e is the dimension of the embedding space. The soft prompt, $P_e \in \mathbb{R}^{p \times e}$, where p is the length of the prompt, is concatenated to X_e to form new input matrix

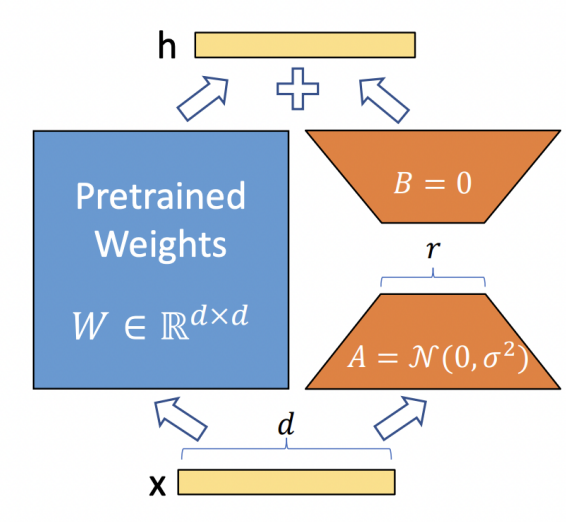

Figure 3: Overview of the LoRA method (Hu et al., 2021).

$[P_e; X_e] \in \mathbb{R}^{(p+n)\times e}$. During training, all model parameters are frozen and only P_e is optimised.

This method drastically reduces the number of required parameters, while achieving comparable performance to full fine-tuning when applied to very large models.

4 Experimental Setup

For hardware reasons, we use a sharded version of FLAN-T5-XXL[1] loaded in 8-bit precision.

The training set (size = 7000) was used for the LoRA training and the validation set (size = 500) was used for the prompt tuning.

Preprocessing was required to transform the data into an appropriate format for text-to-text training. We transform the input text to lower case, and for LoRA we prepended a simple task prompt. For example:

> NEW POLL\\n\\n82 percent of voters support TERM LIMITS ON CONGRESS\\n

becomes

> which persuasion techniques are in this text? text: new poll\\n\\n82 percent of voters support term limits on congress\\n

When preprocessing the labels, we observed that many original labels were metaphorical and/or lengthy, such as 'Glittering generalities (Virtue)'. Theorising that these sequences would be more difficult for the model to generate, we replace each label with a simplified (if applicable), lower case version. Finally, we concatenate the labels into a comma-separated list. Some examples are listed in table 1 - see Appendix A for a full list of simplified labels.

Original	Preprocessed
['Bandwagon']	'appeal to popularity'
['Repetition', 'Name calling/Labeling']	'repetition, labeling'
[]	'none'

Table 1: Examples of preprocessed labels for text-to-text training.

We use the PEFT implementation of LoRA and prompt tuning (Mangrulkar et al., 2022). For LoRA, we train for 5 epochs with a learning rate of 0.001. We mostly use the same hyperparameters for prompt tuning as Mozes et al. (2023) on T5-XXL. We initialise the prompt as:

> 'which persuasion techniques are in this text? text: '

More details on hyperparameters for both training steps can be found in Appendix B.

The evaluation measure used in this task is hierarchical F1 (Kiritchenko et al., 2006), which takes into account the tree structure of the labels when calculating model performance.

5 Results

Our final results are summarised in table 2[2]. Our English language result places us slightly above the centre of the leaderboard. Our Bulgarian result places lower, but is still superior to the baseline. Our North Macedonian result is below baseline performance. While FLAN-T5 was fine-tuned on a small number of Bulgarian language tasks during training, no North Macedonian language tasks were included. Likely due to the absence of Bulgarian and North Macedonian data in our training data and the small size of the corresponding test sets (size = 436 and 259 respectively), our results on these languages are much more variable than our English results.

Table 2: Hierarchical precision, recall, and F1 for our model on the test sets; average and range across two repeats.

The model failed to generalize to the fourth language, Arabic, despite its presence in the FLAN-T5 training data - we did not make a submission for this language as the model predicted no labels for all inputs.

5.1 Error Analysis

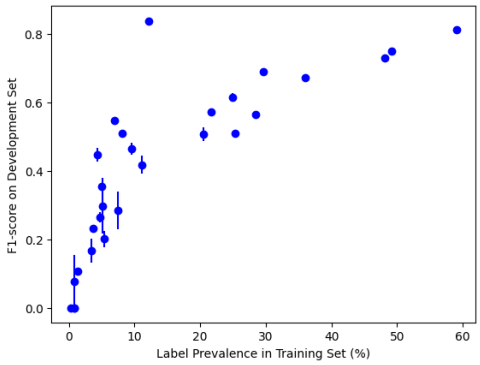

Figure 4: Prevalence of each label in the training set versus average F1 score on the English development set (size = 1000) over two repeats. Error bars show the range of values[3].

To investigate the errors of our model, we analysed the data on a per-label basis using our best performing language, English. Instead of using hierarchical F1, we split the multilabel task into 20 binary tasks (one for the prediction of each label) and calculated the average F1 score for each. In general, our system performed better on labels that were common in the training data (see figure 4). Several labels with very low training set prevalence had F1 scores of zero.

A notable result was the label 'Appeal to authority', which achieved a very high average F1 score of 0.838 while appearing in only 12.14% of the training data. Most data labelled with 'Appeal to authority' contains a quote, leading to the simplification of the label to 'quoting'. This clear pattern may have contributed to the higher average F1 score.

Other than 'Appeal to authority', the highest performing labels were non-leaf labels such as 'Ethos'[4]. These categories are very prevalent in the training data, so higher F1 scores are expected.

5.2 Further Analysis

We investigated two features of our system which may have affected the performance:

1. Ordered labels
2. Simplified label names

5.2.1 Ordered Labels

The text-to-text format necessitates that the labels be placed in an order (see table 1). This trains the model to associate an order with the labels - however, the order that the labels appear holds no semantic significance. For instance, "smears, slogans" is equivalent to "slogans, smears". In the data, there is a bias in the lists of labels in which certain labels ('Appeal to authority', 'Loaded Language', and 'Doubt') usually occur at the start. Labels such as 'Smears' usually occur at the end of the list, although the bias is not as strong as that of 'Appeal to authority'. Therefore, superfluous information may have been introduced to the model, decreasing the performance.

Alternatively, the model may leverage label order to reduce the number of possibilities while decoding, improving the performance. The typical positioning of 'Appeal to authority' at the start of the label list is another factor that may have made it an easier label to predict.

To investigate the effect of label order, we trained a separate version of our model, in which the labels of the training and validation sets (used for LoRA and prompt tuning respectively) were randomly shuffled. Our results are outlined in table 3[5], showing a slight increase in English hierarchical F1 and a much greater increase for Bulgarian and North Macedonian. This suggests that the bias in the label order may be detrimental to overall performance.

[3]As the range of F1 scores for some labels was zero or close to zero, not all error bars are visible.

[4]The model does not predict these labels directly. For the error analysis, the ancestor labels of each predicted label were added to the prediction in post-processing.

Table 3: Hierarchical precision, recall, and F1 on the test sets for our model trained using shuffled labels; average and range across two repeats.

5.2.2 Simplified Label Names

Simplified labels (see Appendix A) were manually determined and focused on semantic simplicity and length. Despite this, many simplified labels were long in order to convey the concept of the persuasion technique, and some labels could not be easily simplified, being left with metaphorical or vague meanings.

To investigate the effect of the label names on performance, we compared the simplified label names with the per-label F1 scores. Table 4 shows the average per-label F1 score for the English development set and the prevalence of each label in the training set. As is also shown in figure 4, there is a correlation between average F1 score and training set prevalence. However, there are exceptions - 'virtue', the simplification of 'Glittering generalities (Virtue)', is a short and semantically obvious label and performs better than expected. Meanwhile, the longer and more metaphorical 'black and white thinking' has a lower average F1 score than expected.

This evidence suggests that longer and more complex labels may compromise text-to-text model performance, but more study is needed to reach a definitive conclusion. For example, the unusually high performance of 'quoting' is likely influenced by other factors. Some persuasion techniques may be easier or harder to detect regardless of label name.

6 Conclusion

In this paper we present a case study for the application of the text-to-text framework to multilabel classification. While our model exhibits some strengths, it did not achieve performance on par with top-ranking results. However, our analysis shows the potential for label names to affect performance, and suggests that shuffling labels during training may lead to increased performance.

Simplified Label	F1	Prevalence (%)
quoting	0.838	12.14
loaded language	0.616	25.00
labeling	0.574	21.69
smears	0.564	28.43
virtue	0.547	6.97
appeal to identity	0.509	8.16
slogans	0.464	9.53
repetition	0.447	4.36
black and white thinking	0.418	11.14
doubt	0.355	5.00
exaggeration or minimisation	0.298	5.09
shutting down discussion	0.285	7.54
appeal to fear or prejudice	0.265	4.81
whataboutism	0.232	3.69
causal oversimplification	0.167	3.43
appeal to popularity	0.108	1.39
guilt by association	0.077	0.90
straw man	0.000	0.89
red herring	0.000	0.84
obfuscation	0.000	0.30

Table 4: Simplified label names, average F1 score on the English development set over two repeats, and the prevalence of each label in the training set. The labels are ordered by average F1 score.

Limitations

Our paper has several limitations. Firstly, we only report results for our model across two repeats. This means that by chance, our results may appear to be better or worse than they would be on average. We only use English training data, which likely led to lower performance on the Bulgarian, North Macedonian, and Arabic test sets. Finally, we did not use a full-precision version of FLAN-T5-XXL due to hardware concerns. This likely led to decreased performance across all languages.

A Simplified Labels

This appendix contains the simplified labels used in preprocessing. We did not remove all metaphorical references, leaving those which are relatively common (e.g. 'red herring') as FLAN-T5 is likely to have encountered them during training. As 'whataboutism' is difficult to explain succinctly, we left it as-is. All simplified labels are listed in table 5.

B Training Hyperparameters

Table 6 shows the training hyperparameters used in LoRA and prompt tuning. For our final output, we limit the length of the generated text to 20 tokens.

	Hyperparameter	**Value**
LoRA	Epochs	5
	Learning Rate	0.001
	Rank	16
	α	32
	Dropout	0.05
	Target modules	q,v
Prompt Tuning	Epochs	1
	Learning Rate	0.1
	Weight decay	0.00001
	Batch size	32
	Prompt tokens	10

Table 6: Hyperparameters used in LoRA training and prompt tuning.

Original Labels	Simplified Labels
Black-and-white Fallacy/Dictatorship	black and white thinking
Loaded Language	loaded language
Glittering generalities (Virtue)	virtue
Thought-terminating cliché	shutting down discussion
Whataboutism	whataboutism
Slogans	slogans
Causal Oversimplification	causal oversimplification
Smears	smears
Name calling/Labeling	labeling
Appeal to authority	quoting
Exaggeration/Minimisation	exaggeration or minimisation
Repetition	repetition
Flag-waving	appeal to identity
Appeal to fear/prejudice	appeal to fear or prejudice
Reductio ad hitlerum	guilt by association
Doubt	doubt
Misrepresentation of Someone's Position (Straw Man)	straw man
Obfuscation, Intentional vagueness, Confusion	obfuscation
Bandwagon	appeal to popularity
Presenting Irrelevant Data (Red Herring)	red herring

Abstract

This study presents a systematic method for identifying 22 persuasive techniques used in multilingual memes. We explored various fine-tuning techniques and classification strategies, such as data augmentation, problem transformation, and hierarchical multi-label classification strategies. Identifying persuasive techniques in memes involves a multimodal task. We fine-tuned the XLM-RoBERTA-large-twitter language model[1], focusing on domain-specific language modeling, and integrated it with the CLIP visual model's embedding to consider image and text features simultaneously. In our experiments, we evaluated the effectiveness of our approach by using official validation data in English. Our system in the competition, achieving competitive rankings in Subtask1 and Subtask2b across four languages: English, Bulgarian, North Macedonian, and Arabic. Significantly, we achieved 2nd place ranking for Arabic language in Subtask 1.

1 Introduction

Propaganda and advertising serve as examples of persuasive discourse, which aims to change another's behavior, feelings, intentions, or views through communication, often in a one-sided manner (Lakoff, 1982). Hence, the context in which the communication occurs is crucial alongside the actual content being conveyed.

Memes, combining persuasive discourse on social media platforms, prove particularly effective. They spread ideas or emotions online and are a popular tool in misinformation campaigns, using various rhetorical and psychological techniques to influence users. Memes' visual components either reinforce or convey persuasive tactics, thus playing a significant role in shaping public opinion and attitudes. To address these challenges, SemEval-2024 introduced a shared task focusing on detecting persuasion techniques from multilingual memes (Dimitrov et al., 2024). This task defines a hierarchy directed acyclic graph (HDAG) to represent a meme's persuasive techniques and highlights the challenges and importance of understanding the nuances of digital persuasion.

This study proposes exploring the effectiveness of multi-dimensional hierarchical classification (MDHC) strategies in identifying persuasive techniques in memes, based on previous research and the successful application of MDHC strategies in real-world HDAGs. The results from a competition show our approach's effectiveness, ranking first in a specific subtask and competitively across others, demonstrating the potential of MDHC strategies in analyzing persuasive discourse.

2 Background

In this study, we explore the application of Hierarchical Multi-label Classification (HMC) in the context of persuasive techniques, by structuring them within a hierarchical multi-label framework. This approach allows for the simultaneous handling of both textual and visual data through multimodal modeling.

Recent research (Montenegro et al., 2023) has demonstrated the efficacy of the MDHC approach for HMC, noting its simplicity and ease of implementation. HMC, an advancement of Multi-label Classification (MC), is designed to predict multiple labels that are organized hierarchically from general to specific categories. The incorporation of hierarchical knowledge is found to significantly improve the performance of classifiers.

The MC, which is applicable in a wide range of areas, involves the challenge of predicting multiple interrelated category variables. As highlighted by Alfaro et al. (Alfaro et al., 2023) and Bielza and Larrañaga (bie, 2011), the complexity of MC compared to single-dimensional problems is primarily

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1868–1875

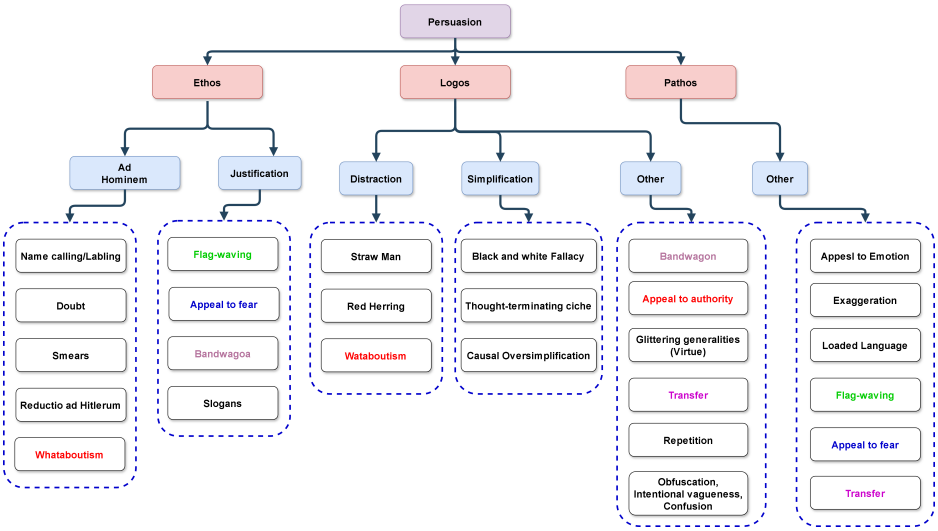

Figure 1: Hierarchy Multi-label Classification(HMC) with Persuasive Techniques

due to the vast combinations of class labels and the scarcity of relevant data.

We transform persuasive techniques into the HMC framework, this approach transforms persuasive technique graphs for application in specific subtasks. Given the necessity to analyze both textual and visual data for accurately identifying persuasive techniques, multimodal models become essential.

CLIP (Contrastive Language-Image Pre-Training) proposed by OpenAI (Radford et al., 2021), stands out for its independent text and image encoding capabilities, offering flexibility for various subtask types. In a study, (Kumar and Nandakumar, 2022) have suggested a range of techniques that combine textual and visual embedding vectors, leading to the effective detection of hateful memes. They also conducted various fusion experiments by switching different text encoders. Therefore, we refer to the authors' approach to combine the embedding vectors of the CLIP and the multilingual model with the aim of better adapting to Subtask 2ab, which involves tasks belonging to the multilingual domain and including datasets in three non-English languages (Bulgarian, North Macedonian, Arabic) in the test set.

3 Exploratory Data Analysis for Datasets

The dataset used in this study contains about 15,000 memes in English and other languages.

We have examined the label distribution for each task, and it is apparent that the data sets for subtask 1 and 2a are imbalanced, which differing numbers

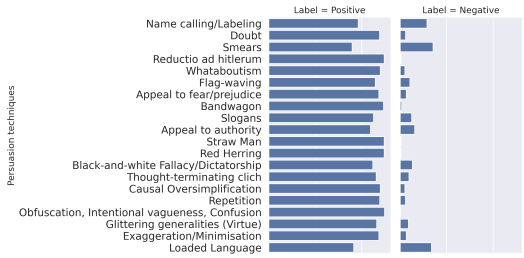

Figure 2: Data distribution of Persuasive Techniques on Subtask 1 Train Set

of Memes's persuasive techniques available for positive and negative are shown in Figure 2 and Figure 6. Further scrutiny, as delineated in Attachment Figure 5, it's evident that the datasets for Subtask 1 and 2a have a highly imbalanced distribution of data across 22 persuasion techniques, with Subtask 2a, in particular, showing a significant imbalance between positive and negative samples. We will describe how to address these imbalances in subsequent sections.

3.1 Transform the Structure of the Persuasive Techniques

The official release includes HDAG comprising 22 types of persuasive techniques. We have transformed this hierarchy into HMC. As shown in Figure 1, our reconstructed HMC has three levels: it includes 1 root node, the first layer has 3 child nodes, the second layer has 5 child nodes, and the bottom layer consists of 22 leaf nodes :

- **Root**: This describes whether a Meme image possesses any persuasive techniques.

- **First Layer Nodes**: There are 3 child nodes at this layer: Ethos, Logos, and Pathos. These nodes categorize the 22 types of persuasive techniques into 3 distinct classes of persuasive strategies.

- **Second Layer Nodes**: This layer includes 5 child nodes: Ad Hominem, Justification, Distraction, Simplification, and Other. We simplify the official hierarchy of persuasive techniques by using the "Other" node to encompass the Distraction and Simplification nodes, as they are redundant in the MDHC strategy.

- **Leaf Nodes**: There are 22 nodes at this level, corresponding to the 22 types of persuasive techniques that are the focus of this task. When a persuasive technique belongs to multiple categories in the first layer, it is represented by the same color.

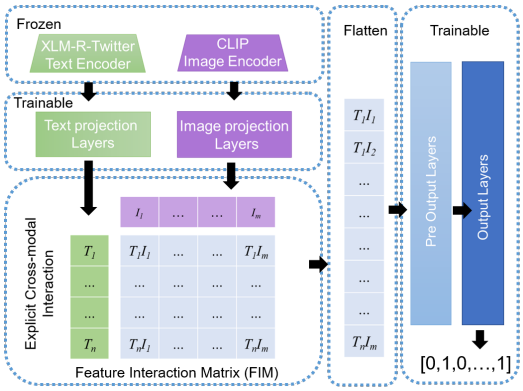

Figure 3: The Workflow for Multiclass Classification Task on the Multimodal Model

4 System Overview

In our research, we conducted an in-depth comparison of two MDHC strategies: Stacking+GC and Stacking+LCL, utilizing the same dataset for model training. The comparative analysis revealed that Stacking+GC demonstrated superior performance over Stacking+LCL. This superiority is attributed to its more effective handling of errors during the merging process of hierarchical levels, thereby enhancing the overall classification accuracy within the hierarchical structure of the data.

XLM-RoBERTA-large-twitter[1] For this system task, which is multilingual and specifically focused on the social media domain of Memes, we fine-tuned the domain-specific language model XLM-RoBERTA-large-twitter. This model was adjusted based on a corpus of over 156 million tweets in ten languages.

CLIP uses two distinct architectures as the backbone for encoding visual and textual datasets: image encoder, which represents the neural network architecture responsible for encoding images (e.g., ResNet or Vision Transformer), and text encoder, which represents the neural network architecture responsible for encoding textual information (e.g., BERT or Text Transformer). This structure is flexibly adapted to the subtasks of this project.

4.1 Detailed Description of the MDHC Strategy

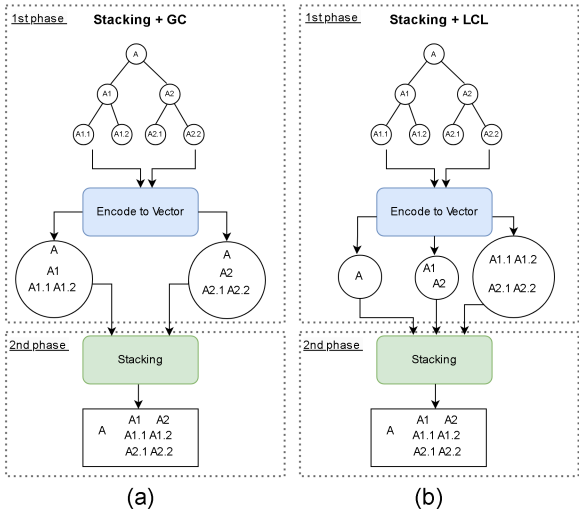

Figure 4: Illustration of the two DMC strategies. The feature vector is used on the 1^{st} phase as input, while the 2^{st} phase uses the outputs of the 1^{st} phase. it is to solve all the tasks associated with the internal nodes drawn inside the circle.

MDHC Strategies Incorporating the MDHC paradigm proposed by (Montenegro et al., 2023), our strategy selects an HMC classification approach suitable for this task, integrating both MC and HC strategies.

In MC strategy, we explore two solution algorithms: **Local Classifier per Level (LCL)**, which creates a model for each level of the hierarchy, and **Global Classifier (GC)**, a model that learns and predicts across the entire class hierarchy.

For HC strategy, we adopt *Stacking*, as introduced by (Wolpert, 1992), leveraging predictions from other labels to refine initial predictions, us-

ing average confidence scores to identify specific persuasive techniques with a threshold of 0.5 for determination.

To compare MDHC classification strategies, we integrate two MC strategies with an HC strategy, resulting in two distinct approaches.

Stacking + GC : this strategy applies the GC strategy to each dimension in the 1^{st} phase, utilizing feature vectors as inputs. The 2^{nd} phase employs the Stacking strategy, concatenating the probability vectors of the 1^{st} phase classifier's predictions for output. This strategy is shown in a Figure 4 (a)

Stacking + LCL : this strategy applies the LCL strategy to each dimension in the 1^{st} phase. In the 2^{nd} phase, it also adopts the Stacking strategy, using concatenated probability vectors from the first stage's predictions, with each circle representing a classifier addressing the classification problem of listed parent nodes. This strategy is shown in a Figure 4 (b)

4.2 Internal Negative Data Augmentation

In typical datasets, there is usually a similar ratio of positive to negative samples, even though they may not be evenly distributed. However, in the data distribution for Subtask 2b, there are only 2 samples that do not contain persuasive elements. Generally, one could use the PTC[2] dataset to augment this. However, the PTC dataset consists of news sentences with 18 types of persuasive techniques, and in hierarchical multi-label classification, the multiple labels have complex relationships.

When attempting to augment data by adding more examples for underrepresented labels, one must navigate the complex interplay between these labels carefully. Simply increasing the number of samples for a specific label can inadvertently exacerbate the imbalance for others. For example, if we augment the dataset with more instances of the 'Whataboutism' technique without considering its relationship with other techniques like 'Loaded Language' or 'Flag-waving,' we might skew the dataset further, making it even more challenging to train a balanced and accurate classifier.

To address this issue, we used two MDHC strategies. Firstly, we divided the entire hierarchy of persuasive techniques into six tasks based on the second-layer parent nodes: Ad Hominem, Justification, Distraction, Simplification, and Other (which was further split into two tasks). Each task independently applies the MC strategy, considering its specific persuasive techniques as positive examples and the others as negative examples, which approach we called **Internal Negative Data Augmentation(INDA)**, not only offers effective negative examples but also ensures consistency in labeling across various datasets. Ultimately, these six MC tasks determine the classification of the top-level parent node (indicating the presence of persuasive techniques) through a voting mechanism.

However, the INDA, while addressing the issue of imbalanced label distribution among samples without persuasive techniques, introduces the Long Tail Distribution problem. Long Tail Distribution is a probability distribution model characterized by lower probability density in its tail. In many cases, the distribution's right tail is considered more significant, but the left tail has a higher probability density. As shown in Attachment Figures 7, 8 and 9, the MDHC classification strategy we employed results in the positive distribution of a particular persuasive technique type being concentrated in the tail, forming a left-skewed long tail distribution.

The long-tail distribution presents two main challenges: Label co-occurrence and Dominance of negative labels:

Label co-occurrence : texts are often associated with multiple persuasive techniques simultaneously, making it difficult to accurately sample individual categories.

Dominance of negative labels : a text may only be associated with a small subset of persuasive techniques, resulting in the majority of labels being negative. However, Binary Cross-Entropy (BCE) treats positive and negative associated categories equally, leading to a shift in the boundary of negative associations.

To address the issues of Label co-occurrence and Dominance of negative labels, we introduce the Distribution-Balanced Loss (DBL) proposed by (Wu et al., 2020), the loss function employs re-balanced weighting and negative-tolerant regularization to mitigate the challenges posed by Label co-occurrence and Dominance of negative labels.

Therefore, without relying on external data augmentation, we utilize the MDHC strategy combined with the DBL loss function to address the sample imbalance issues in Subtask 1 and 2a. Additionally, we also introduce the DBL loss function to tackle the long-tail distribution problem.

4.3 Meme with Multimodal Learning

In Subtask 2a and 2b, we employ the CLIP multimodal model, which includes an image encoder and a text encoder. The image encoder is responsible for encoding images, while the text encoder handles encoding textual information. At this stage, we utilize the XLM-RoBERTA-twitter fine-tuned on Subtask 1 as the text encoder because this model already possesses a certain understanding of meme text. For the image encoder, we use the pre-trained CLIP image encoder provided by the official source. Through Feature-wise Linear Modulation (FIM), these two encoders encode to obtain a representation embedding vector containing both image and text, enabling the model to effectively comprehend memes reliant on the relationship between text and image, such as persuasive techniques like Transfer and Appeal to (strong) Emotions.

Specifically, as depicted in Figure 3, Subtask 2ab involves encoding Meme images using the image encoder (I) and Meme text using the text encoder (T). Thus, we obtain sets of image encoding vectors $I_1...I_N$ and text encoding vectors $T_1...T_N$. We compute the FIM by multiplying these two vectors to obtain a new set of feature vectors. Subsequently, we attach a linear layer for classification at the end of the model to output the correct classifications. Specifically, in Subtask 2a, the learning objective is multi-label (MC) persuasion techniques classification, while in Subtask 2b, the learning objective is binary classification to identify whether it contains persuasive techniques or not.

5 Experiment and Evaluate

In our experiments, we employed three MDHC classification strategies on subtasks. All tasks utilize the HierarchyF_1 evaluation metric, which is the unified evaluation metric provided by the official source. In the experiment setting, refer to Appendix A for details of the relevant parameters.

In **Subtask 1**, we compared the performance of two language models, XLM-RoBERTA and XLM-RoBERTA-Twitter, across Subtask 1 and 2a, to assess the impact of domain-specific pre-training. We explored three classification strategies: GC, Stacking + GC, and Stacking + LCL, to identify the most effective approach for Subtask 1. In **Subtask 2a**, we evaluated two multimodal models by combining CLIP with XLM-RoBERTA-Twitter from Subtask 1. The goal was to improve the comprehension of Meme's persuasive techniques by utilizing a fine-tuned text encoder. Additionally, we employed GC, Stacking + GC, and Stacking + LCL strategies to determine which one is more effective for subtask 2a. Our primary focus was on improving classification performance in a multimodal setting. In **Subtask 2b**, we explored multimodal model and classification strategy using the CLIP + XLM-RoBERTA-Twitter combination from subtask 1, applied to a binary classification framework. Utilizing a balanced dataset of hate Memes collected by Meta AI, as referenced in the Harmful Memes Dataset (Kiela et al., 2020), the goal was to train the model on balanced samples to prevent bias effectively.

Results Our study's evaluation of the official validation set showcases the impactful of domain knowledge in enhancing model performance for persuasive technique identification across various subtasks. **Subtask 1**: As shown in Table 1, the model fine-tuned with domain knowledge performs significantly better in identifying persuasive techniques. Among the three classification strategies, Stack + GC demonstrates superior performance compared to the other two strategies. **Subtask 2a**:

The evaluation results for this task, as depicted in Table 2, align with Subtask 1. The model fine-tuned with domain knowledge outperforms others in identifying persuasive techniques. Among the three classification strategies, Stack + GC exhibits superior performance. **Subtask 2b**: In Table 3, this task involves binary classification. We utilized a multimodal model for binary classification and achieved competitive scores through external data augmentation methods.

Bulgarian	Baseline	0.16667	0.20000
	Ours	**0.64706**	**0.82000**
North Macedonian	Baseline	0.09091	0.10000
	Ours	**0.52000**	**0.79000**
Arabic	Baseline	0.22705	0.29375
	Ours	**0.58518**	**0.59375**

In the test set of the competition, we propose a method that has demonstrated competitive performance on the official competition leaderboard. As shown in Table 4, our method outperforms all official baselines in Subtask 1, which involves the identification of meme persuasion techniques in four different languages at the text level. Our method ranks 4th on average across four languages (English, Bulgarian, North Macedonian, and Arabic), with rankings of 6th in English, 3rd in Bulgarian, 4th in North Macedonian, and 2nd in Arabic. These results indicating our method is competitive.

In the multimodal task, as shown in Table 5, We observe the performance of our method in Subtask 2a, where it demonstrates competitiveness in English memes. We attribute this to two main reasons. Firstly, our method only undergoes text-level domain pretraining on the English memes provided in the training dataset. As a result, it lacks the necessary representation capabilities for low-resource languages, such as North Macedonian. based on the above, our method does not improve cross-linguistic abilities; instead, it relies on the language representation capabilities of the multilingual model. Therefore, this makes it challenging to identify cross-lingual fine-grained persuasion techniques. Secondly, the inherent cultural differences in various languages may lead to discrepancies in the same set of memes presented in different languages, indicating a potential issue of cultural divergence.

Finally, in Subtask 2b, as shown in Table 6, although our proposed method falls short in the fine-grained cross-linguistic meme persuasion techniques identification, it remains competitive in tasks involving the identification of whether a meme, combining text and image, contains one of the persuasion techniques. Our method ranks 6th on average across four languages (English, Bulgarian, North Macedonian, and Arabic), with rankings of 7th in English, 5th in Bulgarian, 6th in North Macedonian, and 5th in Arabic. This demonstrates the competitive edge of our method in a multimodal context.

6 Conclusion

We conducted a detailed analysis of the HDAG containing persuasive techniques, transforming it into an HMC task. We also explored two MDHC strategies and highlighted the importance of addressing the long-tail distribution issue, proposing the use of the DBL loss function to mitigate this issue in HMC tasks. Regarding the models, we recommend utilizing domain-specific pre-training to detect memes containing persuasive elements and the effectiveness of domain-specific training was demonstrated across various experiments. Finally, we achieve competitive results in the competition.

Abstract

Extensive research exists on the performance of large language models on logic-based tasks, whereas relatively little has been done on their ability to generate creative solutions on lateral thinking tasks. The BRAINTEASER shared task tests lateral thinking and uses adversarial datasets to prevent memorization, resulting in poor performance for out-of-the-box models. We propose a system for iterative, chain-of-thought prompt engineering which optimizes prompts using human evaluation. Using this shared task, we demonstrate our system's ability to significantly improve model performance by optimizing prompts and evaluate the input dataset.[1]

1 Introduction

The ability for language models to reason or possess common sense knowledge has become a controversial topic with far-reaching implications (Bender and Koller, 2020). Large language models (LLMs) show remarkable results on *vertical thinking* tasks that require sequential logical inference (Liu et al., 2019) but there have been relatively few studies done on *lateral thinking* puzzles—tasks that require more creative, "outside the box" problem-solving processes. As larger LLMs with the ability to memorize large corpora (Hartmann et al., 2023) are developed, lateral thinking tasks become an increasingly important benchmark for analyzing and evaluating their reasoning capacities. The BRAINTEASER shared task (Jiang et al., 2023)(Jiang et al., 2024) is designed to elicit and evaluate lateral thinking through two English-language subtasks, using sentence puzzles and word puzzles respectively.

In this paper, we propose a novel method for optimizing chain-of-thought (CoT) prompting (Wei et al., 2023) on the `GPT-4` model which we use to tackle the sentence puzzle subtask. Our system iteratively optimizes CoT prompting by systematically evaluating input data and model output using human performance as a benchmark. We identify question types that are difficult for humans, informing the next iteration of prompt engineering. Not only does this process optimize CoT prompting for a specific task, our system also provides insights for improving future data collection and synthesis.

Our main contribution is the novel approach for identifying reasoning challenges to optimize prompting. For the sentence-based task, we develop a prompt engineering method which requires the model to reason over all answer choices and provide explanations for both correct and incorrect choices. In doing so, the model is more likely to refute choices that are semantically related to the question but logically incorrect. Our methodology significantly improves performance for adversarial datasets and achieves more consistent results, which suggests that the model relies less on memorization when using these CoT prompts.

As part of our evaluation of the data, we also identify several questions in the adversarial datasets that are difficult to solve due to having multiple logical options or are unanswerable with the provided premises. By combining model reasoning with human evaluation, we can quickly identify and evaluate problematic questions. This process can further explain model performance and provide guidance for future data collection/generation.

2 Background

Question Answering (QA) is a well-established task in natural language processing with broad applications both in academia and in industry (Hirschman and Gaizauskas, 2001). Recent work such as CommonSenseQA (CSQA) (Talmor et al., 2018) and StrategyQA (Geva et al., 2021) focus on reasoning questions that require logical inference

[1]Our code can be found at https://github.com/alvin-pc-chen/semeval_brainteaser.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1876–1888

in the form of vertical thinking. BRAINTEASER questions instead require lateral thinking to answer, much like questions in the traditional "brainteaser" style(Jiang et al., 2023)(Jiang et al., 2024):

Base: Samuel was out for a walk when it started to rain. He did not have an umbrella and he wasn't wearing a hat. His clothes were soaked, yet not a single hair on his head got wet. How could this happen?

1. His hair is dyed.
2. **This man is bald.**
3. This man walk upside down to avoid rain.
4. None of above.

SR: Rain began to fall as Samuel was taking a stroll. He wasn't wearing a hat, and he didn't have an umbrella. Even though his clothes were completely drenched, not a single hair on his head was moist. How is this even possible?

1. This man walk upside down to avoid rain.
2. His hair is dyed.
3. **This man is bald.**
4. None of above.

CR: Tom is a clean freak but he never dries his hair after a shower. How is this possible?

1. His hair is dyed.
2. He tries to stand upside down during shower to avoid rain.
3. **This man is bald.**
4. None of above.

The data for this subtask is drawn from online English-language riddles and brainteasers, with incorrect choices created by handpicking entailments generated by COMET (Bosselut et al., 2019) using incorrect premises. Each question has three unique answers, as well as a shared fourth option, "None of above". To counter memorization from LLMs trained on web crawls, the task authors generated two synthetic datasets using *semantic reconstruction* (SR) and *context reconstruction* (CR). The SR dataset rephrases the original question without changing the answer or premises while the CR dataset changes the situational context without changing the misleading premise. The SR dataset was generated with an open-source rephrasing tool while the CR dataset was generated using GPT-4; both sets were manually refined by human annotators. In total, 208 question/answer pairs were sampled for the base set resulting in 624 questions after SR and CR augmentation. The training set was split with 81.25% of the data with the same base/SR/CR questions kept together in the split.

Although the task is designed to elicit lateral thinking, we consider an alternative understanding of the task by thinking of the questions as *noisy*. Questions are loaded with irrelevant, contradictory, or misleading information to distract the respondent. Since transformers generally learn meaning by scoring tokens across the sentence or sentence pair, they are biased against long-tail knowledge (Li et al., 2023), which is knowledge that occurs infrequently in the training set.

Brainteasers, by their nature, rely on the unconventional interpretation of the question to stump the respondent. This same property can trick the model into selecting a semantically similar answer choice that is logically incorrect. Chain-of-Thought (CoT) prompt engineering (Wei et al., 2023) is a recent method that has been shown to not only improve outcomes on similar problems, but also to provide an interpretable window for human review. CoT prompts provide example questions with related reasoning to the model, which induces the model to provide reasoning for a given answer in the output. We utilize both of these properties to introduce an iterative method that optimizes CoT prompting for a given task.

3 System Overview

We propose an iterative system for optimizing the CoT prompt engineering process:

1. Randomly sample the training data and naively engineer CoT prompts.
2. Identify distinct categories in output reasoning to partition training data.
3. Perform independent human evaluation to isolate specific challenges in each category.
4. Use findings to inform the development of new CoT prompts.
5. Optionally, identify gaps in the data for future data collection/synthesis.

Each step of our process is iterative, although independent human evaluation should only be performed when novel problem categories are identified in the model reasoning. Once the human benchmark has been incorporated into the prompt engineering process, future iterations mainly rely on evaluating model outputs for gaps in logic. All evaluation steps can provide powerful insights into the dataset itself to inform future dataset creation,

and is particularly useful for real-world applications where data selection is an open-ended problem. By identifying gaps and problems in the data, more representative data can be collected to improve model performance on the given application. This can be thought of as a backpropagating human and model outputs back to the prompt engineering and data curation steps.

3.1 Naive Chain-of-Thought Prompting

In the first step, we randomly sample the training data to generate naive CoT prompts to use on the test set. This step eliminates a large portion of the dataset that naive CoT prompting already solves while also providing outputs with interpretable windows for identifying problem questions and corresponding failure in logic. For example, the topics (mathematics, physics, law, etc.) identified by the task authors in the training data were found to have minimal impact on model accuracy. Instead, we found that the construction type impacted model performance above all. By focusing on the model outputs, we determine that the type of reconstruction (base, SR, and CR) have the highest impact on model performance and require human analysis.

For the first round of CoT prompting, we randomly select 8 samples from the training set and generate the Naive CoT-Base prompt set based on the logical premises of the questions (all naive prompts in Appendices A):

```
Naive CoT Example Prompt:
Question: A horse is tied to a five-meter rope in front of an old saloon. Ten meters behind the horse is a bale of hay. Without breaking his rope, the horse is able to eat the hay whenever he chooses. How is this possible?
Choices:
0 = The rope stretches proportionally, providing the extra length needed for the horse to reach the hay ten meters away.;
1 = The rope is not tied to anything else.;
2 = The walls of the saloon retract or collapse inwards, creating more space for the horse to reach the hay.;
3 = None of above.;
Response: That the rope is not tied to anything else is the simplest choice. The horse can reach the hay whenever he chooses. The answer is 1
```

3.2 Human Evaluation Step

Based on model performance using the naive CoT prompts, we separate the test set along base, SR, and CR lines for human testing. When prompting `GPT-4`, each question is independently shown to the model with no retention in between. Humans are not under similar constraints and can easily identify reconstructions, especially the SR set which share the same answer choices with the base set. For accurate comparison, we select different participants to answer each dataset.

We selected 3 participants for each dataset in order to collect robust results while still maintaining consensus. All participants are graduate students with native proficiency in English, and surveys were completed using Google Forms with the same instructions, randomized question order, and constant answer choice order. An additional option "Unsure" was provided to uncover difficult questions which was counted as "None of above" for testing purposes.

We analyze accuracy along four metrics: mean, minimum score, maximum score, and consensus score. The minimum score is counted only when all participants answer correctly whereas the maximum score is counted when any participant answers correctly. The consensus score uses the answer selected by 2/3 participants; 4 questions had no consensus and were marked as incorrect. Through this process, we identified common errors for humans and models in each dataset which informed the second iteration of CoT prompting.

3.3 Iterated Chain-of-Thought Prompting

Besides the tricky CR questions uncovered in the human evaluation step, we also identified that our naive sample was overly weighted on base questions, which potentially serves to reinforce model memorization. To address both issues, we develop the CoT-Mix set, a new set of 8 prompts weighted towards SR and CR questions and tailored towards disproving incorrect answer choices. Since our human benchmark performed particularly poorly on CR questions, we also separately created CoT prompts comprised entirely of base, SR, and CR sets for further comparison. All prompt sets can be found in the Appendices B.

```
Iterated Chain-of-Thought Prompt:
Question: A horse is tied to a five-meter rope in front of an old saloon. Ten meters behind the horse is a bale of hay. Without breaking his rope, the horse is able to eat the hay whenever he chooses. How is this possible
Choices:
0 = The rope stretches proportionally, providing
```

System	Instance Based			Group Based		Overall
	Base	SR	CR	Base&SR	Adversarial	
abdelhak	100	100	95.0	100	95.0	98.3
Human (Jiang et al., 2023)	90.7	90.7	94.4	90.7	88.9	92.0
Human Consensus (Ours)	90.0	90.0	67.5	80.0	55.0	82.5
GPT-4 Zero Shot	87.5	72.5	70.0	72.5	60.0	76.7
GPT-4 Multi Shot Base	92.5	**90.0**	80.0	**87.5**	70.0	87.5
GPT-4 Multi Shot Mix	**95.0**	**90.0**	**85.0**	**87.5**	**80.0**	**90.0**
GPT-4 Naive CoT-Base	**95.0**	**87.5**	75.0	85.0	65.0	85.8
GPT-4 Naive CoT-Mix	92.5	**87.5**	**82.5**	**87.5**	**75.0**	**87.5**
GPT-4 New CoT-Base	**97.5**	85.0	80.0	85.0	70.0	87.5
GPT-4 New CoT-SR	90.0	90.0	75.0	85.0	67.5	85.0
GPT-4 New CoT-CR	92.5	90.0	77.5	87.5	67.5	86.7
GPT-4 New CoT-Mix	95.0	**92.5**	**82.5**	**92.5**	**77.5**	**90.0**

Table 1: Accuracy of each model; **Base**, **SR**, and **CR** are scored on individual datasets, **Base&SR** only counts if both the base and SR versions are correct for a given question, **Adversarial** only counts if all three versions are correct for a given question, and **Overall** counts base, SR, and CR separately.

```
the extra length needed for the horse to reach the
hay ten meters away.;
1 = The rope is not tied to anything else.;
2 = The walls of the saloon retract or collapse
inwards, creating more space for the horse to reach
the hay.;
3 = None of above.;
Response: Rope generally cannot stretch, and if it
could stretch the length would be variable. If the
walls collapse, the horse would be further from
the hay. The rope not being tied to anything else
is the simplest answer. The answer is 1
```

4 Experimental Setup

All experiments were performed using GPT-4 via the OpenAI API[2] with the same system prefix. Each question was called separately with the respective prefix. Initial experiments limited token count to 1 in order to force the model to output integer labels but the restriction was removed due to poor performance. Output text was logged and labels were extracted deterministically; labels that could not be extracted this way were reviewed and manually entered. Results shown in this paper were from API calls between 2024/01/15-2024/02/17; since OpenAI models are updated regularly replication results may differ.

The input data was first preprocessed by removing extra spaces, lines, punctuation, and spelling and grammatical errors. Due to the variety of sentence-based problems in the data, some answer choices were multiple sentences long while others were single words; this discrepancy could potentially affect model performance. Since semicolons do not occur in the data at all, they were selected as separators between answer choices for GPT-4 prompting to mitigate this issue. System prompts can be found in Appendix C.

5 Results

In this section, we compare results across four categories: human performance, zero/multi-shot performance, naive CoT prompt performance, and the iterated CoT prompt performance. For completion, we also provide the top competition result (abdelhak). Our official submission for the shared task leaderboard used the GPT-4 New CoT-Base prompts. With 31 participants, our results scored 2nd overall on the base data, 7th on SR, CR, and Base&SR accuracy, 9th on adversarial accuracy, and 9th overall.

5.1 Quantitative Benchmarks

As expected, the new CoT prompts show significant improvements along all metrics compared to their naive counterparts. Since the adversarial datasets are designed specifically to counteract model memorization, the gains made in the group-based metrics between the Naive and New CoT-Mix prompts in particular demonstrates the effectiveness of our system. The CoT-Base sets, on the other hand, likely still suffer from overweighting on the original questions crawled from online

sources. The fact that multi-shot prompting outperforms the Naive CoT prompts further supports this argument. Despite not receiving any guidance on logic, the model is still able to achieve strong results on the task. However, once we introduce the idea of disproving incorrect answers, the model is once again able to make gains in performance.

Interestingly, the SR and CR prompts did not show significant improvements compared to the base set and even performed worse on the CR questions. This could potentially be due to the fact that the model performs worse on these question types overall. Without base questions to provide a foundation, the model is unable to generate the most robust reasoning. While this finding provides grounds for further exploration, the results from the New CoT-Mix prompting shows consistent improvements across the board, suggesting that there are commonalities within each adversarial dataset that can be identified by the model.

5.2 Human Performance Evaluation

Dataset	Mean	Min.	Con.	Max.
Base	84.2	65.0	87.5	100.0
SR	85.8	70.0	90.0	97.5
CR	60.0	30.0	65.0	80.0

Table 2: Human participant accuracy for each dataset; **Min.** is only counted when all three participants answer correctly, **Con.** is counted when 2/3 agree on an answer, and **Max.** is counted when any participant scores correctly.

When evaluating human performance, we find that there were significantly higher rates of "Unsure" answers in the CR set which contributes to the lower overall score. Along with other observations, the greater rate of "Unsure" answers supports the idea that the CR questions are more difficult to reason over. However, there were no cases where all respondents selected "Unsure" for the same question, making this metric a weak indicator of problematic questions. One possible explanation suggests that the wording for the answers in the CR set are less well-formed than the other sets, leading to greater confusion among respondents.

For human performance, none of our CoT results were able to beat the task paper human benchmark on the CR dataset, although our iterated CoT results did surpass the human benchmark on SR. Our human results only drastically differ on the CR set with those found in the task paper, which could be influenced by several factors. A major factor is the fact that we use independent human annotators for each of the datasets, meaning that those working on the CR set have no reference to the original question. For questions with multiple valid answers or unclear logic, our annotators would not be able to reference the base and SR versions for clues. Out of 14 incorrectly answered CR questions, we identify 5 such questions.

Specifically, we discovered several questions in the CR set with multiple logical responses. In the example below, the correct answer is "two and a half hours" with the assumption that each stop is meant to take half an hour. Ignoring that the premise itself is nonsensical (the driver would have simply been told to stop for the full two and a half hours), nowhere is it stated that the driver takes half an hour for each break. As a result, both (2.) and (4.) are viable candidates depending on reasoning. The rest of the problem questions can be seen in Appendix D.

```
Example Question: A driver is told to make a stop
every half an hour for the engine to cool down,
for five times. How long do the stops take?
Choices:
1. Three hours.
2. Two and a half hours.
3. Two hours.
4. None of above.
```

6 Conclusions

In this paper, we demonstrate a novel system for optimizing chain-of-thought prompt engineering using human evaluation. While Naive CoT prompts performed similarly to multi-shot prompting without guidance on reasoning, later iterations were able to approach state-of-the-art performance. Significant improvement on the SR, CR, and group-based metrics were shown on the test data, supporting the adoption for this method of prompt engineering. This system further provides guidance on identifying key problem areas in the dataset, specifically with regards to the generation of context reconstruction questions. This form of evaluation serves to inform decisions for improving dataset quality. For future work, we plan to implement different techniques to create synthetic data and perform the same evaluation across an open-ended dataset.

A Naive CoT Prompts

A.1 Naive Base Prompts

1. Question: Samuel was out for a walk when it started to rain. He did not have an umbrella and he wasn't wearing a hat. His clothes were soaked, yet not a single hair on his head got wet. How could this happen?
   Choices:
   0 = His hair is dyed.;
   1 = This man is bald.;
   2 = This man walk upside down to avoid rain.;
   3 = None of above.;
   Response: Samuel got wet from the rain, but no hair on his head got wet. If Samuel dyed his hair it would still be wet. Samuel is bald, so his hair didn't get wet. The answer is 1

2. Question: A horse is tied to a five-meter rope in front of an old saloon. Ten meters behind the horse is a bale of hay. Without breaking his rope, the horse is able to eat the hay whenever he chooses. How is this possible?
   Choices:
   0 = The rope stretches proportionally, providing the extra length needed for the horse to reach the hay ten meters away.;
   1 = The rope is not tied to anything else.;
   2 = The walls of the saloon retract or collapse inwards, creating more space for the horse to reach the hay.;
   3 = None of above.;
   Response: That the rope is not tied to anything else is the simplest choice. The horse can reach the hay whenever he chooses. The answer is 1

3. Question: A woman who lives in new york legally married three men, she did not get divorce, get an enrollment, or legally seperate. How is this possible?
   Choices:
   0 = The woman is not a good person.;
   1 = His husband is not a good husband.;
   2 = She is a minister.;
   3 = None of above.;
   Response: In new york it is not legal to be married to more than one person at a time. If the woman did not get divorced or legally separated, she cannot be legally married to more than one person. Ministers perform marriages, they do not get married. The answer is 2

4. Question: Why is the value of 1968 pennies higher than 1967 pennies?
   Choices:
   0 = Old money weight more than new money.;
   1 = Old money is dirtier than new money.;
   2 = Because there is one more penny in 1968 pennies than in 1967 pennies.;
   3 = None of above.;
   Response: 1968 and 1967 refer to the number of pennies. The value of 1968 pennies is higher than 1967 pennies because there is one more penny in 1968 pennies than in 1967 pennies. The answer is 2

5. Question: Not a single parent objected when the teacher spanked every child in the class. How come?
   Choices:
   0 = The teacher had informed all the parents in advance about the unique disciplinary approach.;
   1 = The teacher had informed all the children in advance about the unique disciplinary approach.;
   2 = The teacher was in an orphanage school.;
   3 = None of above.;
   Response: Even if the teacher had informed all the parents or all the students in advance about the unique disciplinary approach, it is unlikely that nobody would object. If the teacher is in an orphange school, there would be no parents to object. The answer is 2

6. Question: Twenty-seven ducks are going to the pond. Five of them got lost, thirteen of them are staying home, and nine of them are at the pond. Where are the rest of them?
   Choices:
   0 = Home.;
   1 = The way to the pond.;
   2 = Pond.;
   3 = None of above.;
   Response: Twenty-seven ducks are going to the pond. Five of them are lost, 27 - 5 = 22. Thirteen of them are staying home, 22 - 13 = 9. Nine of them are at the pond, 9 - 9 = 0. There are no more ducks so the question is invalid. The answer is 3

7. Question: How many birth days does the average person have?
   Choices:
   0 = People may celebrate their birthdays annually, so it depends on their life span.;
   1 = They technically only have one birth day in their lifetime.;
   2 = It can be zero as some people are too busy to celebrating their birthdays.;
   3 = None of above.;
   Response: Everyone is born only once so technically the average person has one birthday in their lifetime. The answer is 1

8. Question: The more you take, the more you leave behind
   Choices:
   0 = Love.;
   1 = Footsteps.;
   2 = Money.;
   3 = None of above.;
   Response: Footsteps. The more you walk, the more footsteps you leave behind. The answer is 1

A.2 Naive Mixed Prompts

1. Question: A horse is tied to a five-meter rope in front of an old saloon. Ten meters behind the horse is a bale of hay. Without breaking his rope, the horse is able to eat the hay whenever he chooses. How is this possible?
   Choices:
   0 = The rope stretches proportionally, providing the extra length needed for the horse to reach the hay ten meters away.;
   1 = The rope is not tied to anything else.;
   2 = The walls of the saloon retract or collapse inwards, creating more space for the horse to reach the hay.;
   3 = None of above.;
   Response: Rope generally cannot stretch, and if it could stretch the length would be variable. If the walls collapse, the horse would be further from the hay. The rope not being tied to anything else is the simplest answer. The answer is 1

2. Question: A woman who lives in new york legally married three men, she did not get divorce, get an enrollment, or legally seperate. How is this possible?
   Choices:
   0 = The woman is not a good person.;
   1 = His husband is not a good husband.;
   2 = She is a minister.;
   3 = None of above.;
   Response: In new york it is not legal to be

married to more than one person at a time, even if her husband is bad. If the woman did not get divorced or legally separated, she cannot be legally married to more than one person. Ministers perform marriages, they do not get married. The answer is 2

3. Question: Brad began by entering the office tower's 22nd story through the filthy common window. He slid the window open and leapt through it after becoming depressed. Outside the building, there was a cliff-like drop to the ground. Amazingly, he came to rest entirely unharmed. How could he have survived the fall if there was nothing to slow or cushion his descent?
   Choices:
   0 = Brad was so sick and tired of window washing, he opened the window and jumped inside.;
   1 = The ground outside the building is wet.;
   2 = Consistent exercise has made him a very strong man.;
   3 = None of above.;
   Response: Even very strong men would not survive a fall from a 22-story building. The ground outside the building being wet would not cushion his fall. Brad was so sick and tired of window washing, he opened the window and jumped inside. The answer is 0

4. Question: Danny had just passed under an overpass in his semi when he abruptly came to a stop. Danny accidentally drove under the overpass that was only just tall enough for his truck because he wasn't paying enough attention. He was unable to move forward or backward in the semi due to how tightly it was wedged. When another tracker passed by, he was told how simple it would be to remove the semi from underneath the bridge. What did he recommend?
   Choices:
   0 = He told Danny to left the bridge.;
   1 = He told Danny to overturn the track.;
   2 = He told Danny to let some air out of his tires.;
   3 = None of above.;
   Response: The bridge would not be lifted. Overturning the truck would not help. Letting some air out of his tires would help. The answer is 2

5. Question: I excavate little caves and keep my gold and silver there. I also create gold crowns and silver bridges. They are the tiniest things you can imagine. Everyone will eventually require my assistance, but many people are reluctant to accept it. Why?
   Choices:
   0 = I am a dentist.;
   1 = I am a thief.;
   2 = I am a miner.;
   3 = None of above.;
   Response: Thieves and miners do not create gold crowns or bridges. Tiny crowns and bridges are dental work. People don't like going to the dentist. The answer is 0

6. Question: Each of the 30 participants in the masquerade had to wear a unique hat to distinguish themselves from one another. The host, however, only tallied 29 when he counted the number of hats to determine attendance. All 30 persons had signed their names on the spreadsheet, which confused him. He repeated the count. There are still 29. How is that even doable?
   Choices:
   0 = One person had a pretty beautiful hat.;
   1 = The host had a hat himself and he forget to count it.;
   2 = One person had moved away from the group when the host was counting.;
   3 = None of above.;
   Response: If one person had a pretty beautiful hat, then the host would still count 30 hats. If one person had moved away from the group when the host was counting, then the host would still count 30 hats. The host had a hat himself and he forget to count it. The answer is 1

7. Question: A certain kind of animal has parents but no children, lives happily but can not give birth to offspring. This kind of animal has existed on earth for a long history. How is that possible?
   Choices:
   0 = The animal is the dinosaur. Millions of years ago, dinosaurs roamed the Earth, but eventually, they became extinct due to various factors such as climate change or asteroid impact.;
   1 = The animal is the butterfly. During the

pupal stage of their life cycle, butterflies are inside a protective casing, and it may appear as if they have completely disappeared or been wiped out.;
2 = The animal is the Mule. Since all Mules are born sterile, you can only get a Mule by crossing a donkey with a horse.;
3 = None of above.;
Response: Dinosaurs are no longer alive, so they cannot live happily. Butterflies can give birth to offspring, so they are not the answer. Mules are born sterile, so they cannot give birth to offspring. The answer is 2

8. Question: Six women were hiking on a trail when a sudden snowfall began. Five of the women hurried along, but the sixth did not. Still, they all reached the cabin at the same time, and all but the sixth were cold. How is that possible?
Choices:
0 = The 6th woman beated them at the end.;
1 = The sixth woman was in a photograph that one of the others was carrying.;
2 = The 6th woman walked slowly to dodge the snow.;
3 = None of above.;
Response: If the sixth woman beat them or walked slowly to dodge the snow she would not have reached the cabin at the same time. If the sixth woman was in a photograph that one of the others was carrying, then she would not be cold and would not have to hurry. The answer is 1

B New CoT Prompts

B.1 New Base Prompts

1. Question: A couple is having a disagreement over the man's error. The man kept apologizing and pleading with the woman to allow him to see her directly. The woman was still upset. Thus, she wouldn't agree. The couple, though, was positioned on the same mat. How is that even doable?
Choices:
0 = The mat was folded in multiple times and end up with a special shape.;
1 = The woman kept turning her back to the man.;
2 = The couple was standing on two sides of the girl's apartment door, which had a rug under it.;
3 = None of above.;
Response: The couple are standing on the same mat but cannot see each other, which suggests that there is a barrier between them. Regardless of how the mat was folded, it would not prevent the couple from seeing each other. Even if the woman turned her back to the man he would still see her. Therefore, the couple was standing on two sides of a door, which had a rug under it. The answer is 2

2. Question: Eight people were sitting under a large tree. Suddenly, a gust of wind blows, yet none of them got hit by any falling leaves. How is this possible?
Choices:
0 = It was winter and the tree doesn't have any leaves.;
1 = People were camping under the tree.;
2 = The wind blows heavily.;
3 = None of above.;
Response: If the people were camping under the tree, they would still be hit by the falling leaves. The wind blowing heavily would cause the leaves to fall. If it was winter and the tree doesn't have any leaves, then the people would not be hit by any falling leaves. The answer is 0

3. Question: The ship was in the central Pacific Ocean. The ship suddenly began to sink without being crushed. However, each team was still preoccupied with its own tasks, so none was threatening. Why?
Choices:
0 = An underwater earthquake caused a rapid drop in the water level and resulted in the loss of buoyancy for the ship.;
1 = It was a Submarine.;
2 = There are too many fish around the ship.;
3 = None of above.;
Response: An earthquake would cause people to feel threatened, and fish around the ship would not matter. If the ship were a submarine, it would be designed to sink. The answer is 1

4. Question: Two mothers and two daughters were asking for new state IDs, but the agent only gave out three forms and instructed them on how to fill them out. Why?
Choices:
0 = They are one daughters, one mother and

one grandmother.;
1 = Two girls filled the from together.;
2 = One mother is too old to apply for new IDs.;
3 = None of above.;
Response: The agent only gave out three forms and instructed them on how to fill them out, which suggests that there are only three people. If they are one daughter, one mother, and one grandmother, then there would be three people. The answer is 0

5. Question: Every night, a man would sleep with a light on, as bright as the sun, dazzling the neighbors. But why did his neighbors never complain?
Choices:
0 = All his neighbors are blind.;
1 = The man would wake up early.;
2 = He lived in a light house.;
3 = None of above.;
Response: If all his neighbors are blind, they would not be dazzled by the light. If the man lived in a light house then the light would be expected. The answer is 2

6. Question: Each of the 30 participants in the masquerade had to wear a unique hat to distinguish themselves from one another. The host, however, only tallied 29 when he counted the number of hats to determine attendance. All 30 persons had signed their names on the spreadsheet, which confused him. He repeated the count. There are still 29. How is that even doable?
Choices:
0 = One person had a pretty beautiful hat.;
1 = The host had a hat himself and he forget to count it.;
2 = One person had moved away from the group when the host was counting.;
3 = None of above.;
Response: If one person had a pretty beautiful hat, then the host would still count 30 hats. If one person had moved away from the group when the host was counting, then the host would still count 30 hats. The host had a hat himself and he forget to count it. The answer is 1

7. Question: A certain kind of animal has parents but no children, lives happily but can not give birth to offspring. This kind of animal has existed on earth for a long history. How is that possible?
Choices:
0 = The animal is the dinosaur. Millions of years ago, dinosaurs roamed the Earth, but eventually, they became extinct due to various factors such as climate change or asteroid impact.;
1 = The animal is the butterfly. During the pupal stage of their life cycle, butterflies are inside a protective casing, and it may appear as if they have completely disappeared or been wiped out.;
2 = The animal is the Mule. Since all Mules are born sterile, you can only get a Mule by crossing a donkey with a horse.;
3 = None of above.;
Response: Dinosaurs are no longer alive, so they cannot live happily. Butterflies can give birth to offspring, so they are not the answer. Mules are born sterile, so they cannot give birth to offspring. The answer is 2

8. Question: Six women were hiking on a trail when a sudden snowfall began. Five of the women hurried along, but the sixth did not. Still, they all reached the cabin at the same time, and all but the sixth were cold. How is that possible?
Choices:
0 = The 6th woman beated them at the end.;
1 = The sixth woman was in a photograph that one of the others was carrying.;
2 = The 6th woman walked slowly to dodge the snow.;
3 = None of above.;
Response: If the sixth woman beat them or walked slowly to dodge the snow she would not have reached the cabin at the same time. If the sixth woman was in a photograph that one of the others was carrying, then she would not be cold and would not have to hurry. The answer is 1

B.2 New Mixed Prompts

1. Question: A horse is tied to a five-meter rope in front of an old saloon. Ten meters behind the horse is a bale of hay. Without breaking his rope, the horse is able to eat the hay whenever he chooses. How is this possible?
Choices:
0 = The rope stretches proportionally, provid-

ing the extra length needed for the horse to reach the hay ten meters away.;
1 = The rope is not tied to anything else.;
2 = The walls of the saloon retract or collapse inwards, creating more space for the horse to reach the hay.;
3 = None of above.;
Response: That the rope is not tied to anything else is the simplest choice. The horse can reach the hay whenever he chooses. The answer is 1

2. Question: A woman who lives in new york legally married three men, she did not get divorce, get an enrollment, or legally seperate. How is this possible?
Choices:
0 = The woman is not a good person.;
1 = His husband is not a good husband.;
2 = She is a minister.;
3 = None of above.;
Response: In new york it is not legal to be married to more than one person at a time. Ministers perform marriages, they do not get married. The answer is 2

3. Question: Brad began by entering the office tower's 22nd story through the filthy common window. He slid the window open and leapt through it after becoming depressed. Outside the building, there was a cliff-like drop to the ground. Amazingly, he came to rest entirely unharmed. How could he have survived the fall if there was nothing to slow or cushion his descent?
Choices:
0 = Brad was so sick and tired of window washing, he opened the window and jumped inside.;
1 = The ground outside the building is wet.;
2 = Consistent exercise has made him a very strong man.;
3 = None of above.;
Response: A person cannot jump out of a 22 story building without injury. Brad must have jumped into the building. The answer is 0

4. Question: Danny had just passed under an overpass in his semi when he abruptly came to a stop. Danny accidentally drove under the overpass that was only just tall enough for his truck because he wasn't paying enough attention. He was unable to move forward or backward in the semi due to how tightly it was wedged. When another tracker passed by, he was told how simple it would be to remove the semi from underneath the bridge. What did he recommend?
Choices:
0 = He told Danny to left the bridge.;
1 = He told Danny to overturn the track.;
2 = He told Danny to let some air out of his tires.;
3 = None of above.;
Response: Danny has to reduce the height of his truck to pass the bridge. Letting the air out of his tires reduces the truck's height. The answer is 2

5. Question: I excavate little caves and keep my gold and silver there. I also create gold crowns and silver bridges. They are the tiniest things you can imagine. Everyone will eventually require my assistance, but many people are reluctant to accept it. Why?
Choices:
0 = I am a dentist.;
1 = I am a thief.;
2 = I am a miner.;
3 = None of above.;
Response: Tiny crowns and bridges are dental work. People don't like going to the dentist. The answer is 0

6. Question: Each of the 30 participants in the masquerade had to wear a unique hat to distinguish themselves from one another. The host, however, only tallied 29 when he counted the number of hats to determine attendance. All 30 persons had signed their names on the spreadsheet, which confused him. He repeated the count. There are still 29. How is that even doable?
Choices:
0 = One person had a pretty beautiful hat.;
1 = The host had a hat himself and he forget to count it.;
2 = One person had moved away from the group when the host was counting.;
3 = None of above.;
Response: The host is the one counting the hats. The host had a hat himself and he forget to count it. The answer is 1

7. Question: A certain kind of animal has par-

ents but no children, lives happily but can not give birth to offspring. This kind of animal has existed on earth for a long history. How is that possible?
Choices:
0 = The animal is the dinosaur. Millions of years ago, dinosaurs roamed the Earth, but eventually, they became extinct due to various factors such as climate change or asteroid impact.;
1 = The animal is the butterfly. During the pupal stage of their life cycle, butterflies are inside a protective casing, and it may appear as if they have completely disappeared or been wiped out.;
2 = The animal is the Mule. Since all Mules are born sterile, you can only get a Mule by crossing a donkey with a horse.;
3 = None of above.;
Response: The animal is still alive, has parents, but cannot have children. Mules are born sterile, so they cannot give birth to offspring. The answer is 2

8. Question: Six women were hiking on a trail when a sudden snowfall began. Five of the women hurried along, but the sixth did not. Still, they all reached the cabin at the same time, and all but the sixth were cold. How is that possible?
Choices:
0 = The 6th woman beated them at the end.;
1 = The sixth woman was in a photograph that one of the others was carrying.;
2 = The 6th woman walked slowly to dodge the snow.;
3 = None of above.;
Response: All the women hurried except the sixth and were cold. The sixth woman is not physically present. She must be in a photograph one of the others was carrying. The answer is 1

C System and User Prompts

"role": "system", "content": "You are a Question Answering Model that answers questions by finding logical entailments between the question and answer choices."

D Problematic CR Questions

1. SP-120_CR: Mark was in a playground where somebody noticed a great player playing and with the announcements, gathered a lot of people. There were many great players from basketball, volleyball, football, and even swimmers, But Mark directly went to the footballer and took a photo with him. How did he know who was the person that people got excited for in the first place?
"Since the playground was a football playground and the other players could've not been playing in the playground at the time of the announcement.",
"Since Mark was a crazy fan of football, only a football player can be considered as great player in his mind.",
"Since Mark stood closest to the football players, he only focused on football players and didn't notice others.",
"None of above."

2. SP-30_CR: Why do old people consume more food than young people.
"Older adults may have specific dietary requirements to address age-related issues",
"Older people require increased nutrient intake to support overall health and well-being.",
"Because older people live longer.",
"None of above."

3. SP-184_CR: Five people were at a football match, and a sudden shower started. The four that rushed to take cover still got soaked, but the one who didn't move stayed completely dry. Why didn't he get wet?
"The man is an excellent football player that can avoid rain in high speed."
"The man was lucky enough to avoid all the rain.
"He was a photograph, the other people were there to honor a former player.",
"None of above."

4. SP-166_CR: A farmer has 11 sheep. Half of them are white. How is this possible?
"One sheep is regarded as both white and other colors same time.",
"A famer raises his sheep in both white way and another way.",
"They are all white.",
"None of above."

5. SP-156_CR: A driver is told to make a stop every half an hour for the engine to cool down, for five times. How long do the stops take?
   "Three hours."
   "Two and a half hours.",
   "Two hours.",
   "None of above."

Zero Shot is All You Need at SemEval-2024 Task 9: A study of State of the Art LLMs on Lateral Thinking Puzzles

Erfan Moosavi Monazzah* and **Mahdi Feghhi***
Iran University of Science and Technology
moosavi_m, feghhi_me@comp.iust.ac.ir

Abstract

The successful deployment of large language models in numerous NLP tasks has spurred the demand for tackling more complex tasks, which were previously unattainable. SemEval-2024 Task 9 introduces the brainteaser dataset that necessitates intricate, human-like reasoning to solve puzzles that challenge common sense. At first glance, the riddles in the dataset may appear trivial for humans to solve. However, these riddles demand lateral thinking, which deviates from vertical thinking that is the dominant form when it comes to current reasoning tasks. In this paper, we examine the ability of current state-of-the-art LLMs to solve this task. Our study is diversified by selecting both open and closed source LLMs with varying numbers of parameters. Additionally, we extend the task dataset with synthetic explanations derived from the LLMs' reasoning processes during task resolution. These could serve as a valuable resource for further expanding the task dataset and developing more robust methods for tasks that require complex reasoning. All the codes and datasets are available in paper's GitHub repository[1].

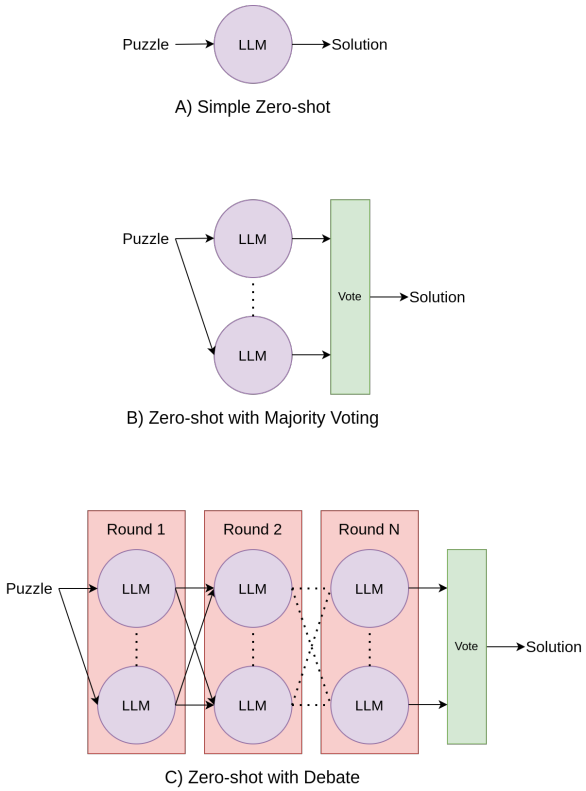

Figure 1: Different zero-shot configurations are shown. Figure A depicts the simple zero-shot usage of a Large Language Model. Figure B depicts the application of majority voting to a pool of LLMs. Figure C depicts a debate among a pool of LLMs over multiple rounds.

1 Introduction

In the domain of cognitive science, human reasoning is characterized by two distinct processes housed within the brain: 1) Vertical thinking and 2) Lateral thinking (Waks, 1997). Vertical thinking, also known as linear, convergent, or logical thinking, is an analytical process that progresses in a sequential manner. It is rooted in rationality, logic, and established rules, and is typically associated with the left hemisphere of the brain. Conversely, lateral thinking, colloquially referred to as "thinking outside the box", is a divergent and creative process. It entails approaching a problem from a novel perspective and challenging pre-existing assumptions, and is linked with the right hemisphere of the brain (Jiang et al., 2023). To solve a vertical puzzle, the model could follow a linear solution path and provide a step-by-step reasoning for the solution. However, the model was unable to provide a step-by-step solution for solving the lateral puzzle. Instead, it offered a fresh perspective on the puzzle and explained why the answer might be unreasonable when considering common sense. With the expansion of the LLMs market and re-

Table 1: Zero-Shot models benchmarks over Brainteaser dataset. Values are the accuracy of the model over the dataset. Our submission on leader board is the output of the Bing.

search community, the demand for more complex benchmarks and tasks has increased as previous tasks become trivial for each new generation of models. As proposed by (Jiang et al., 2023), examining the ability of current state-of-the-art LLMs to reason on lateral thinking puzzles is a crucial aspect of their reasoning capabilities, which is the primary focus of this paper. We investigate a set of LLMs in a single model zero-shot, multi-agent voting, and multi-agent debate setup (**?**). To diversify our experiments, we studied both state-of-the-art production-level LLMs like ChatGPT and Gemini, and open ones like Microsoft Phi-2 and Mixtral 8x7B. We also publish an extended brainteaser dataset, which contains the detailed answers from all the models and techniques we tested. This dataset could be used for further analysis of these models and help to expand this relatively small dataset into a comprehensive benchmark for lateral reasoning evaluation. Interestingly, we found that current state-of-the-art models, despite having errors when it comes to lateral thinking, show very promising results. Even smaller LLMs like Phi-2 were able to demonstrate lateral thinking procedures in some cases. We submitted our best results which are produced by Microsoft Bing Chat to the task leader-board and ranked 2nd and 10th for Word Puzzle and Sentence Puzzle, respectively. (Jiang et al., 2024b)

2 System Overview

2.1 Zero-Shot

(Jiang et al., 2023) frames the puzzles as multiple-choice question-answering tasks. Each question or riddle is accompanied by four potential answers, with the last option always being "None of the above". Among the remaining three choices, one is invariably correct, while the others are guaranteed to be incorrect. Empirical experiments reveal a significant challenge with the current formulation, specifically the last choice. For most of these riddles, the solution is not a logical expression but often involves wordplay or clever misconceptions. Due to these factors, LLMs tend to favor the last choice *"None of the above"* since none of the other answers make sense in the conventional vertical thinking manner. For example when we asked Mixtral model, *"What animal keeps the best time? 1) A watchdog. 2) An elephant. 3) A whale. 4) None of above."* the model responded *"The correct answer is 'None of the above'. The reasoning behind this is that animals do not keep time in the sense of telling the exact hour and minutes like a clock or watch does. However, some animals such as certain bird species and insects are known for their keen sense of timing when it comes to activities such as migration and hibernation."*. Moreover, this option comprises a negligible portion of the Train and Validation dataset. Assuming that this is also the case for the Test dataset (since the la-

Zero-shot Prompt	Which option is the answer to this riddle, explain in a step by step manner:
	What clothing does a house wear?
	1) Address.
	2) Suit.
	3) Wedding dress.
	please place your answer in a json format:
	{
	"explanation":
	"option_number":
	}

Model Response	{
	"explanation": "The phrase 'what clothing does a house wear?' is intentionally misleading because houses do not physically wear clothes. The answer lies within option (1): an address. In essence, you can think of an address as the 'clothing' a house wears since it identifies and distinguishes each building from another.",
	"option_number": 1
	}

Table 2: A sample prompt provided to the model and the corresponding response generated by the model.

bels were not available at the time), we modify the formulation and remove the last option to compel the models to provide an answer to the riddle. We prompt the models with this new formulation and request them to "solve the riddle", explicitly asking for an explanation of the reasoning procedure. To simplify the evaluation of their answers, we also ask them to provide their answers in JSON format which make it easier to parse their responses. A sample prompt and model response is illustrated in Table 2.

2.2 Majority Voting

Different answers can be extracted from the same model while sending the same prompt by merely adjusting the model generation temperature to high values. This technique allows us to create a pool of models, pose the exact same question to them, and expect to receive different answers. Having a set of answers for the same question enables us to conduct a vote among them and select the most voted answer. To prevent a tie between the three choices in each question, we pose the same question to four language models with different temperatures. This approach ensures that one choice has at least one more vote than the others. Although asking the same question from the same LLM with different temperatures multiple times increases the chance of getting the right answer, it also increases the cost and resource usage, especially in the case of production LLMs like ChatGPT.

2.3 Debate

In majority voting, each LLM is independent from the others that are trying to solve the same question. But what if we group them together and attempt to solve the problem in a debate? Specifically, we define a finite number of debate rounds. In the first round, we pose the same question to each model, and they begin to answer the question individually (exactly the same as in majority voting). Having the initial responses at hand, in each subsequent round, we can ask the model to reconsider its reasoning based on the response (both answer and reasoning) of other LLMs. This may help the current LLM to identify any flaws in its solution (if any flaws are present) and attempt to correct it (Du et al., 2023). The debate continues until all the LLMs at the debate table reach a consensus or a maximum number of rounds pass. In that case, majority voting will be used to determine the final answer of the debate.

3 Experimental Setup

We carry out experiments with five distinct LLMs. For more information about each of them, refer to Table 1. We interact with these models through APIs, with the exception of Microsoft Phi-2, for which we utilize a Google Colab session equipped with a T4 GPU. In the Zero-Shot and Majority Voting experiments, each riddle is presented once to each model, and the answer is recorded. However, for the Debate experiment, we maintain a history of the conversation with the model, which serves as

	Sentence Puzzle				
Model	Original	Semantic	Context	Ori Sem	Overall
ChatGPT	56.1	52.4	51.8	43.9	53.5
Human	91.7	91.7	91.7	91.7	91.7
Bing (ours)	95	82.5	82.5	80	86.7
	Word Puzzle				
Model	Original	Semantic	Context	Ori Sem	Overall
ChatGPT	60.8	59.3	67.9	50.7	62.7
Human	90.7	90.7	94.44	90.7	92
Bing (ours)	100	100	93.8	100	97.9

Table 3: Detailed accuracy computation for each part of the dataset.

What was the result of the tiny lobster's math test?			The phrase 'sea plus' sounds similar to 'A+', a common grading symbol indicating excellent performance. However, since the subject of the question is a 'tiny lobster', it seems more appropriate to give a humorous response rather than a literal interpretation. Therefore, the best answer is likely 2) Sea-plus.
Very-bad	Sea-plus	Very-Good	
What kind of tree is most safe?			At first glance, this appears to be a botany-related question asking about different kinds of trees. However, the term 'safe' suggests another dimension to the query. Oaks were commonly used for building ships and houses, providing shelter from environmental elements. Thus, out of the provided options, oak seems to fit best.
Pine	Hemlock	Oak	
What is the capital in Washington?			This question plays with words related to the state of Washington and its capital city, Olympia. If we look at the word 'Washington', the letters N, T, and W appear as individual characters. Among those choices, the first letter N stands for the correct answer—Olympia, the capital of Washington State.
The letter N	The letter T	The letter W	

Table 4: There are different types of answers. The first type is when the model responds correctly. The second type is when the model attempts vertical thinking instead of lateral thinking and fails. The third type is when the model becomes confused and generates a nonsensical explanation.

additional context containing the model's previous answers and reasoning from earlier rounds. We explicitly instruct each model to provide its answer in JSON format. Due to lack of resources we could only test ChatGPT with voting and debating.

4 Results

The majority of our models outperformed the paper baselines, as shown in Table 1. This superior performance was not confined to Production Level models like Bing or Gmini. Surprisingly, the open model Mixtral performed on par with ChatGPT. Among the smaller models, Phi-2 performed commendably well, considering it only has 2.7 billion parameters compared to FlanT5 or T0PP, which have 11 billion parameters. It outperformed those models on the Word Puzzle. Bing also surpassed human performance on Word puzzles, as shown in Table 2. We observed that voting can positively impact accuracy. However, when it comes to debating, the results are less robust. Although it performs reasonably well on the Word puzzle, its performance deteriorated on the Sentence puzzle. During the inspection of the results, we encountered three types of answers. The first type is where the model understands that it's dealing with lateral thinking puzzles. Not only does it solve the puzzle correctly, but it also mentions something like 'The puzzle is a play on words,' which indicates that the model grasped the concept of the puzzle. In the second type, the model attempts a vertical thinking procedure and tries to solve the puzzle in a literal sense. It tries to assign an answer and justify it using complex logic. In the third type, the models were unable to come up with any good explanation. It seems they got confused by the nature of the puzzle and started to generate nonsense. See table 4.

5 Conclusion

Although there is still a gap between the accuracy of LLMs and humans when it comes to solving challenging puzzles that require lateral thinking, they currently perform well considering the difficulty of this task. Our results indicate a promising path for using an ensemble of large language models to collaborate and solve a problem together, whether they are fine-tuned for this collaboration, like Mixtral, or we use prompting ideas like voting or debating. We believe this path still requires thorough research, specifically in the quality of the

reasonings generated by each model.

Abstract

The NLI4CT task assesses Natural Language Inference systems in predicting whether hypotheses entail or contradict evidence from Clinical Trial Reports. In this study, we evaluate various Large Language Models (LLMs) with multiple strategies, including Chain-of-Thought, In-Context Learning, and Parameter-Efficient Fine-Tuning (PEFT). We propose a PEFT method to improve the consistency of LLMs by merging adapters that were fine-tuned separately using triplet and language modelling objectives. We found that merging the two PEFT adapters improves the F1 score (+0.0346) and consistency (+0.152) of the LLMs. However, our novel methods did not produce more accurate results than GPT-4 in terms of faithfulness and consistency. Averaging the three metrics, GPT-4 ranks joint-first in the competition with 0.8328. Finally, our contamination analysis with GPT-4 indicates that there was no test data leakage.[1]

1 Introduction

Extracting insights from Clinical Trial Reports (CTRs) is vital for advancing personalised medicine, yet manual analysis of these vast datasets is impractical. The Natural Language Inference for Clinical Trial Data (NLI4CT) task (Jullien et al., 2024)[2] addresses this challenge by evaluating Natural Language Inference (NLI) systems' ability to understand and reason within this domain.

In this study, we evaluate various LLMs, such as LLaMA2 (Touvron et al., 2023b), Mistral (Jiang et al., 2023), MistralLite (Yin Song and Chen Wu and Eden Duthie, 2023), and GPT-4 (OpenAI, 2023). We employed prompting strategies like In-context Learning (ICL) and Chain-of-Thought (CoT) to improve their accuracy. We also proposed a Parameter-Efficient Fine-Tuning (PEFT) method that merges independently fine-tuned adapters trained with distinct objectives, namely a triplet loss and a language modelling (LM) loss, to improve the consistency of the LLMs.

Our findings reveal that our novel PEFT method improves the F1 and consistency scores of the LLMs. However, GPT-4 produces more accurate results than all of the models we considered, co-leading the competition leaderboard. Although GPT-4 places fifth in the F1 score, its high faithfulness and consistency scores highlight its potential for a reliable prediction in the clinical domain. Lastly, we conduct a contamination analysis of GPT-4 to check whether instances of the NLI4CT dataset were included in GPT-4's pre-training data.

2 Background

2.1 Task overview

The NLI4CT task leverages a collection of CTRs and expert-annotated hypotheses. This iteration places a heightened emphasis on faithfulness (robustness to semantic changes) and consistency (stability against semantic preserving alterations). Aside from this focus, the composition of the dataset and the task objective remains identical to the previous iteration (Jullien et al., 2023a,b). Table 1 contains statistics for each data split, organised by sample, section, and label types.

Section Types Each CTR consists of four sections: "Eligibility criteria", "Intervention", "Results", and "Adverse events". Hypotheses are sentences claiming information in a CTR section.

Sample Types The task presents two sample types: "Single" and "Comparison". "Single" samples provide all relevant evidence within one CTR, while "Comparison" samples require cross-referencing information from two CTRs.

Task Objective The task objective is to classify the relationship between hypotheses and corre-

sponding CTR(s) as "entailment" or "contradiction". "Entailment" implies that the hypothesis is supported by the CTR(s), while a "contradiction" classification suggests inconsistency.

2.2 Related work

LLMs demonstrated promising results in the medical domain. For example, Liévin et al. (2022) conducted evaluations on LLMs, including Codex (Chen et al., 2021) and InstructGPT (Ouyang et al., 2022) using zero-shot, few-shot, and CoT prompting. These LLMs show comprehension of complex medical questions, recall of domain knowledge, and nontrivial reasoning.

Despite the increasing use of general LLMs, domain adaptive fine-tuning remains a prevailing approach in the medical domain (Lehman et al., 2023). As LLMs continue to grow in size, PEFT gains preference over full-parameter fine-tuning due to its resource efficiency. Gema et al. (2023) proposed a two-stage PEFT framework, one for domain-adaptive pre-training and one for downstream fine-tuning, to adapt LLaMA (Touvron et al., 2023a) to the clinical outcome prediction tasks. Even though Gema et al. (2023) introduced the idea of combining multiple adapters, they did not explicitly merge the adapter weights. Chronopoulou et al. (2023) proposed AdapterSoup, which performs averaging of the weights of PEFT adapters trained on the same objective function and different domains to improve the model's performance.

Extending the adapter merging idea, we introduced a novel method to merge PEFT adapters that are trained on different training objectives: triplet loss and LM loss. We compared this method with strategies without parameter fine-tuning, such as zero-shot inference, ICL, and CoT.

3 System Overview

We experimented with two strategies. The first involved no fine-tuning, aiming to comprehend LLMs' inherent ability to solve clinical tasks. The second employed our proposed PEFT method to improve the consistency of the model. Both systems ingest CTR-hypothesis pairs, predicting the correct label one token at a time from left to right.

3.1 Without Parameter Fine-tuning

The system with no fine-tuning utilises the pre-trained general LLMs for prediction. We experimented with multiple prompting strategies:

Zero-shot Employing the LLMs without any fine-tuning and examples.

In-Context Learning (ICL) Adapting the LLMs by providing examples of how to perform a task. Due to the maximum context length of the LLMs, we limit experiments to two examples (2-shot).

Chain-of-Thought (CoT) Prompting LLMs with a phrase (e.g., *"Let's think step by step"*) (Kojima et al., 2022), encouraging a sequential reasoning.

ICL + CoT Adapting the LLMs with ICL examples that are augmented with reasoning steps.

Figure 1 shows the workflow of the system. Firstly, we prepare the ICL examples. The normal ICL strategy requires the CTR section, the hypothesis, and the true label. Meanwhile, the ICL+CoT strategy requires ICL examples with reasons. We use ChatGPT (`gpt-3.5-turbo-0613`) to generate reasoned ICL examples as it has demonstrated sufficient clinical understanding (Falis et al., 2024). Similar to He et al. (2023), We prompt ChatGPT with a phrase *"Reason the answer step by step"* along with the CTR section, statement, and true label from the training dataset. The true labels and generated explanations using the ICL strategy are then stored. See Appendix B.1 for ChatGPT's hyperparameters used for generating explanations.

Second, we retrieve the ICL examples using either a random or BM25 retriever. Random retriever fetches ICL examples randomly, while the BM25 retriever fetches the most similar training data to the hypothesis sentence in question. We skip this step if we do not intend to use ICL.

Third, we choose the prompt template. If CoT is not used, the ordinary prompt is employed. This prompt instructs LLMs to answer using only one word, either "Contradiction" or "Entailment". If

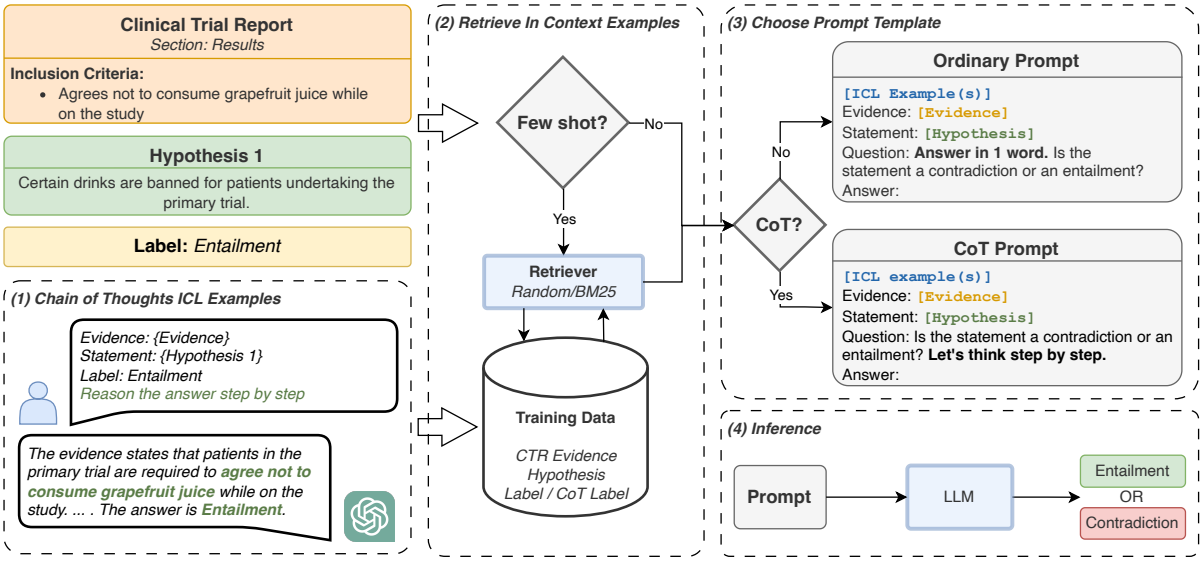

Figure 1: Our inference schema with multiple prompting strategies (without fine-tuning). For Chain-of-Thought examples, Natural Language Explanation was generated using ChatGPT (He et al., 2023).

CoT is used, the CoT prompt is used to instruct LLMs to think step by step. Refer to Figure 1.(3) and Appendix D for both final prompt designs.

Finally, the LLMs ingest the prompted input to generate an answer. To obtain the prediction, we checked which label appears last in the generated answer (either *"Entailment"* or *"Contradiction"*).

3.2 With Parameter Fine-tuning

We used LoRA (Hu et al., 2022) to fine-tune the parameters Φ_0 of a pretrained LLM $P_{\Phi_0}(y \mid x)$ on a training dataset $\mathcal{Z} = \{(x_i, y_i)\}_{i=1,\ldots,N}$. LoRA only trains a small number of additional parameters θ where $|\theta| \ll |\Phi_0|$; the parameters θ introduced by LoRA are used to define a new set of parameters Φ for the LLM, such that $\Phi = \Phi_0 + \Delta\Phi(\theta)$. The training objective for the additional parameters θ introduced by LoRA can be defined as:

$$\underset{\theta}{\operatorname{argmax}} \sum_{(x,y)\in\mathcal{Z}} f\left(P_{\Phi_0+\Delta\Phi(\theta)}\left(y \mid x\right)\right).$$

In our proposed method, we fine-tune two adapters using different training objectives, namely a Language Modelling objective (used to train the adapter parameters θ_{LM}) and a supervised learning objective based on the triplet loss (Balntas et al., 2016) (used to train the adapter θ_{triplet}).

In the supervised learning setting, we train LLMs using a triplet loss, with CTR serving as an anchor. Each CTR is associated with a pair of hypotheses, one contradiction and one entailment. The triplet loss encourages LLMs to map the entailment hypothesis closer to the CTR and the contradiction hypothesis to be far from the CTR.

$$L(a, p, n) = \max(0, d(a, p) - d(a, n) + \alpha),$$

where a, p, and n denote the averaged last hidden states of the LLM for the anchor (CTR), positive sample (entailment hypothesis), and negative sample (contradiction hypothesis), respectively. α is a margin.

We hypothesise that LM fine-tuning can improve the accuracy of the model on knowledge-intensive domain-specific downstream tasks, while supervised fine-tuning aids the model in distinguishing syntactically similar but semantically different data points and vice versa. Merging both adapters aims to achieve the best of both fine-tuning methods:

$$\theta_{\text{merged}} = \frac{1}{2}\left(\theta_{\text{LM}} + \theta_{\text{triplet}}\right).$$

This process resulted in one merged LoRA adapter, which can be re-attached to the original LLM. The base LLM, equipped with the merged LoRA, processes similarly prompted input, generating either *"Entailment"* or *"Contradiction"*. Refer to Figure 2 for an illustration of the workflow.

4 Results

The results shown in Table 2 can help us answer multiple research questions:

RQ 1: Can zero-shot LLMs perform well?

In a zero-shot setting, MistralLite-7B showed zero performance across all metrics due to it outputting

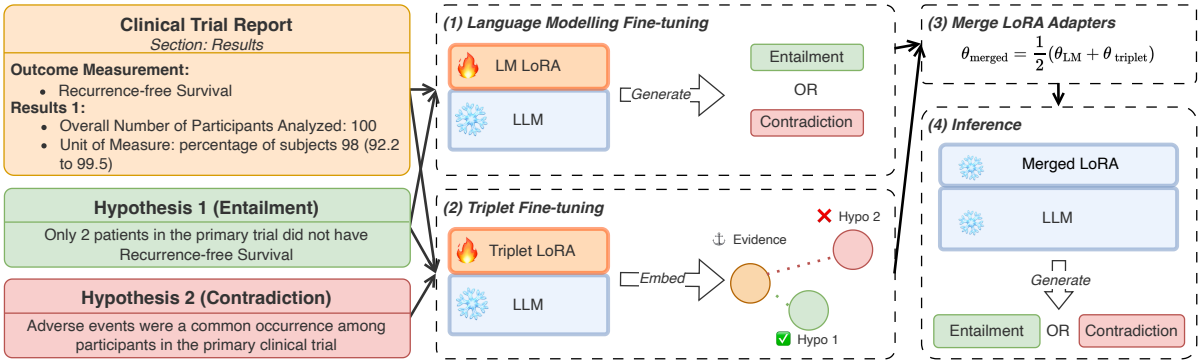

Figure 2: Our proposed fine-tuning scheme on SemEval 2024-Task 2. We suggested merging Adapters trained through Language Modelling (LM) Fine-tuning based on language modelling loss (in predicting either "Entailment" or "Contradiction") with Adapters trained through Triplet Fine-tuning based on triplet loss.

GPT-4	**0.7751**	**0.9479**	**0.7754**	**0.8328**

Table 2: Results on the test set across various LLMs with multiple prompting strategies (no fine-tuning).

an empty string. This suggests that, without any prompting strategies, it did not understand the given instruction. Mistral-7B-Instruct, LLaMA2-7B-Chat, and LLaMA2-13B-Chat show some degree of performance in the F1, faithfulness, and consistency metrics. Among the three, LLaMA2-13B-Chat achieved the highest faithfulness and consistency scores. GPT-4 stood out with the highest scores in all metrics, suggesting its strong performance even without any prompting strategies applied. This begs the question of whether any prompting strategies can be applied to help the relatively smaller LLMs perform better.

RQ 2: Can smaller LLMs perform on par with GPT-4 with prompting strategies?

In-Context Learning We investigated 1- and 2-shot settings using BM25. 1-shot setting consistently improved the performance of the LLMs (see Appendix C comparing random and BM25 ICL examples). With an ICL example, MistralLite-7B understood how to answer the prompted input. Mistral-7B-Instruct, LLaMA2-7B-Chat, and LLaMA2-13B-Chat also showed performance improvement compared to the zero-shot setting, albeit marginal. The 2-shot setting did not improve the LLMs consistently. Mistral-7B-Instruct showed an improvement in all metrics with 2-shot settings, while the other LLMs see F1 score drops, albeit the faithfulness and consistency may be improved.

Chain-of-Thought We investigated CoT in a zero-shot setting. Similarly to the zero-shot setting, MistralLite-7B showed zero performance in all metrics due to outputting an empty string. We saw drops in F1 scores for Mistral-7B-Instruct, LLaMA2-7B-Chat, and LLaMA2-13B-Chat, and improved the faithfulness and consistency scores. This indicates the efficacy of CoT in ensuring faithful and consistent answers from LLMs, albeit it may marginally harm the accuracy of the model.

In-Context Learning + Chain-of-Thought Since ICL improves the LLMs' F1 score, and CoT improves the faithfulness and consistency scores, we investigated the combination of both. The results show that ICL + CoT improves LLMs across metrics. Considering the averaged score,

2-shot ICL and CoT improve all LLMs except for MistralLite-7B.

Despite employing these strategies, the LLMs could not outperform GPT-4, particularly in terms of faithfulness and consistency. This suggests that while combining ICL and CoT is beneficial, it is still challenging to achieve parity with GPT-4.

RQ 3: Can fine-tuned smaller LLMs perform on par with GPT-4?

Model	F1	Faith.	Con.	Avg.
Mistral-7B-Instruct	**0.7689**	0.7662	0.7140	0.7497
MistralLite-7B	0.7478	0.8727	**0.7220**	**0.7808**
LLaMA2-7B-Chat	0.6073	0.7176	0.6146	0.6465
LLaMA2-13B-Chat	0.6766	0.7731	0.6610	0.7036
Meditron-7B	0.1980	**0.9560**	0.6165	0.5902

Table 3: Results on the test set across various LLMs with parametric-efficient fine-tuning.

As we may have reached the limit of performance using prompting strategies, we investigated employing fine-tuning the smaller LLMs.

Can LoRA fine-tuning improve the performance of LLMs? Table 3 presents the performance for each LLM fine-tuned with LoRA. Notably, fine-tuning leads to improvements across all metrics for all LLMs. MistralLite-7B is the best-performing LLM after fine-tuning with 0.7808 averaged scores, and it is notably better in terms of faithfulness and consistency scores compared to the other models. The fine-tuned Meditron-7B did not show a satisfactory overall performance. The subsequent experiment in merging LoRA adapters will focus on using MistralLite-7B as the base model.

Model	F1	Faith.	Con.	Avg
MistralLite-7B				
+ θ_{LM}	0.7478	0.8727	0.7220	0.7808
+ Avg (θ_{LM}, θ_{triplet})	**0.7824**	**0.8391**	**0.7372**	**0.7862**

Table 4: Results on the test set with our proposed merging adapters fine-tuning.

Can merging LoRA adapters improve the performance of LLMs? Table 4 displays results obtained through fine-tuning MistralLite-7B with only LM adapter θ_{LM} and the average of θ_{LM} and θ_{triplet} adapters. The merged θ_{LM} and θ_{triplet} adapters improve the overall performance of the LLM (joint-fourth in the competition). It achieves a better F1 score of 0.7824 (+0.0346), indicating that merging LoRA adapters may improve the predictive performance of LLMs. We noticed a lower faithfulness score (-0.0336) and a higher consistency score (+0.0152). This indicates the model struggles to understand semantic changes introduced by deliberate alterations but can understand semantically similar data better.

4.1 Contamination Analysis on GPT-4

Inspired by Carlini et al. (2022), we assessed whether instances of the NLI4CT dataset were included in GPT-4's pre-training data. We prompted GPT-4 with: 1) System instruction: *"You are a helpful assistant on the SemEval task. Complete the given statement."*, 2) Truncation of half of the statement to prompt GPT-4 to infer the remaining. (refer to Appendices B.7 and D.3 for details)

We define two metrics: *extractable match*, checking if the predicted half of the statement by GPT-4 is included in the original half, and *partial match*, assessing how sequentially each token of the predicted half of the statement is included in the original half. In the test set, GPT-4 recorded an extractable match score of 0.033 and a partial match score of 0.322. The low extractable match score may indicate that GPT-4 has not seen the test data during its pretraining, whereas the higher partial match score may indicate GPT-4's ability to identify keywords from CTRs.

5 Conclusion

This study assesses the performance of various LLMs, employing diverse strategies such as CoT, ICL, and PEFT. We propose a PEFT method, merging independent adapters fine-tuned separately using triplet and LM losses. Our proposed PEFT method improves the F1 and consistency scores but reduces faithfulness — our best fine-tuned model, MistralLite-7B + LM LoRA + Triplet LoRA, achieved an average score of 0.7862. However, it does not outperform GPT-4 in terms of faithfulness and consistency: GPT-4 ranks joint-first in the competition with an average score of 0.8328. A contamination analysis on GPT-4 revealed no NLI4CT test data leakage, indicated by a low extractable match score (0.033), and showcased its ability to identify keywords from CTRs with a relatively high partial match score (0.322).

Limitations

Due to the scope of the study and the limited resources, we opted to only experiment with GPT-4 in a zero-shot setup. However, our proposed strategies that improved the performance of smaller LLMs could also be used to enhance GPT-4. Albeit the promising performance of the LLMs, particularly GPT-4, the predictions may still be inaccurate and should not be used in a clinical setting without human supervision.

We conducted a contamination analysis inspired by Carlini et al. (2022) and concluded that there may be no test data leakage during the pretraining of GPT-4. However, we acknowledge that contamination analysis alone may not be sufficient in proving test data leakage.

Table 7: Triplet training hyperparameters.

A Experimental setup

We use HuggingFace's Transformers (Wolf et al., 2020) and PEFT (Mangrulkar et al., 2022) libraries for the experiments. All inferences and fine-tuning experiments were run on two NVIDIA A100-40GB GPUs.

For models without parameter fine-tuning (prompting strategies, subsection 3.1), in-context examples were retrieved from the Training set (for both random and BM25 retrievers). Additionally, the Dev set was used to evaluate and select the optimal prompt design. Models with parameter fine-tuning (subsection 3.2) were trained using the Training set, and the Dev set was utilised to determine the best checkpoint.

B Hyperparameters

B.1 ChatGPT Hyperparameters for the generation of Natural Language Explanation

We prompted GPT-3.5 (model name: `gpt-3.5-turbo-0613`) with hyperparameters as shown in Table 5. The generation process took approximately 2 hours and cost $2.

B.2 GPT-4 generation hyperparameters

We prompted GPT-4 (model name: `gpt-4`) with the ordinary prompt as shown in Figure 1. We set `temperature=0` to ensure that the model's generation is deterministic. The maximum generation length is 8. The generation process took approximately 2 hours and cost $77.

B.3 Non GPT-4 generation hyperparameters

All models (apart from GPT-4) were loaded in BFloat16 to ensure that they fit into our resources. We used `do_sample=False` to ensure that the model's generation is deterministic. The maximum generation length is 8 new tokens for non-CoT experiments and 100 for CoT experiments.

B.4 Language Modelling training hyperparameters

LM training used the hyperparameters detailed in Table 6. The LLM's maximum sequence length is adjusted to fit on two NVIDIA A100-40GB GPUs.

B.5 Triplet training hyperparameters

Triplet training used the hyperparameters detailed in Table 7. The LLM's maximum sequence length is adjusted to fit on two NVIDIA A100-40GB GPUs. Triplet training demands more memory because we need to generate three hidden representations during training (i.e., anchor, positive, negative), necessitating a reduction in sequence length.

B.6 PEFT Hyperparameters

All LLMs and training methods (i.e., LM and triplet training) used the same LoRA hyperparameters as shown in Table 8.

Hyperparameter	Value
r	16
alpha	32
dropout	0.0
target_modules	["k_proj", "q_proj", "v_proj"]

Table 9: Comparison of In-Context Learning Models Using Random and BM25 Retrievers on the Test set

B.7 Contamination Analysis on GPT-4

For the Contamination Analysis, we utilised the same settings as those described in Appendix B.2, specifically setting the maximum number of generated tokens to 8. This was done to prevent the incorrect biases due to excessively lengthy predictions by GPT-4, as our evaluation method focuses on determining whether the prediction is included within the ground truth.

C Ablation study on Random vs Relevance-based In-Context Examples

We also compared the performance of the model by using random and relevant ICL examples. As shown in Table 9, we found that relevant ICL examples helped the LLMs achieve better faithfulness and consistency scores, while the F1 scores may be impacted. For that reason, we opted to use relevance-based ICL examples for the ICL-based runs.

D Prompt Examples

Here, we provide examples of the prompts used in our experiments. The black text within the box represents the prompt input text, the red text represents the prediction of the models, and the blue text represents the ground truth.

D.1 Base Prompt for Zero-shot and In-Context Learning

Base Prompt

You are a helpful assistant.

«In-Context Learning Examples»

Evidence:
Primary trial:
Adverse Events 1:
Total: 0/15 (0.00%)
Adverse Events 2:
Total:

Secondary trial:
Adverse Events 1:
Total: 0/442 (0.00%)
Adverse Events 2:

Statement: the primary trial and the secondary trial do not have any recorded adverse events for their participants. crypt is a pitlike depression or tubular recess.
Question: Answer in 1 word. Is the statement a contradiction or an entailment?
Answer: Entailment

Ground Truth: Entailment

D.2 Chain-of-Thought for Zero-shot and In-Context Learning

Chain-of-Thought

You are a helpful assistant.

Abstract

Large language models (LLMs) have demonstrated state-of-the-art performance across multiple domains in various natural language tasks. Entailment tasks, however, are more difficult to achieve with a high-performance model. The task is to use safe natural language models to conclude biomedical clinical trial reports (CTRs). The Natural Language Inference for Clinical Trial Data (NLI4CT) task aims to define a given entailment and hypothesis based on CTRs. This paper aims to address the challenges of medical abbreviations and numerical data that can be logically inferred from one another due to acronyms, using different data pre-processing techniques to explain such data. This paper presents a model for NLI4CT SemEval 2024 task 2 that trains the data with DeBERTa, BioLink, BERT, GPT2, BioGPT, and Clinical BERT using the best training approaches, such as fine-tuning, prompt tuning, and contrastive learning. Furthermore, to validate these models, different experiments have been carried out. Our best system is built on an ensemble of different models with different training settings, which achieves an F1 score of 0.77, a faithfulness score of 0.76, and a consistency score of 0.75 and secures the sixth rank in the official leaderboard. In conclusion, this paper has addressed challenges in medical text analysis by exploring various NLP techniques, evaluating multiple advanced natural language models(NLM) models and achieving good results with the ensemble model. Additionally, this project has contributed to the advancement of safe and effective NLMs for analysing complex medical data in CTRs.

1 Introduction

Clinical trials play a crucial role in advancing medical knowledge, evaluating the safety and efficacy of new treatments, and improving patient care (Holford et al., 2010) which are essential for the development of new drugs, therapies, and medical interventions. Most importantly, they involve systematic investigations that aim to answer specific research questions and provide evidence-based guidance for medical decision-making (Tunis et al., 2003). Moreover, clinical trial reports (CTRs) have been published at an accelerated rate due to the rapid development of digital health. Currently, there are more than 10,000 CTRs just for breast cancer (Jullien et al., 2024; Bastian et al., 2010). Also, medical professionals have developed evidence-based clinical diagnoses through the increasing number of Clinical Trial Reports (CTRs) (Bastian et al., 2010), which serve as a broad source of factual and scientific information. Despite these CTRs, drawing valuable conclusions from these reports can be an uphill task due to the different medical domains and the unstructured nature of the report. Recent improvements in natural language processing (NLP) systems, on the other hand, have led to the idea of using multiple language models that have already been trained in the medical field to efficiently carry out medical NLP tasks. The growth of CTRs has also made it possible for a natural language inference (NLI) system to be created that can help with medical interpretation and finding evidence for individualized evidence-based therapy.(Agrawal et al., 2022) used InstructGPT with zero-shot and few-shot settings to extract information from clinical text. In addition, the authors introduced new datasets for benchmarking for few-shot clinical information extraction. The work in (Molinet et al., 2022) introduced a new tool, the ACTA automated tool, to support evidence-based clinical decision-making. The authors in (Yasunaga et al., 2022) proposed a new model, LinkBERT, that incorporates document link knowledge for medical domains. Despite substantial research on the use of advanced NLP approaches in the medical domain, evaluation benchmarks remain inadequate.

The SemEval 2024 Task 2: Safe Biomedical Natural Language Inference for Clinical Trials

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1905–1911

(NLI4CT) task is proposed by (Jullien et al., 2024) by building an efficient evaluation benchmark using a set of statements, explanations, and CTRs for breast cancer. This task is an extension of the previous year's shared task Multi-evidence Natural Language Inference for Clinical Trials. The purpose of the NLI4CT task is to entail a statement based on one or multiple clinical reports. NLI4CT is challenging because hypothesis verification sometimes requires integrating multiple pieces of data from the premise. In some instances, validating a hypothesis necessitates a comparison of two distinct premise CTRs. Validating hypotheses based on each premise type demands varying levels of inference skills (textual, numerical, etc.).

This paper presents work done in the NLI4CT to address these challenges owing to the complexity of the medical domain and text structure. The objective of this task is to develop a system capable of deducing conclusions or implications about various CTRs. The system consists of an ensemble of different experiments using different training approaches. The rest of the papers go as follows: section 3 discusses the proposed methods, section 4 shows experimental results, and section 5 concludes the paper.

2 Background

The main goal of the task is to determine the validity of a claim (hypothesis) based on a single section from one or multiple clinical trial reports (CTRs) of breast cancer (premises). There are two possible inferential relations for each statement: entailment and contradiction. The dataset[1] used is provided by the task organizers and it is divided into two parts: The first part is derived from a compilation of CTRs, which is categorized into four sections.: a) eligibility criteria required for participation in the clinical trial; b) intervention detailing the treatment type, dosage, frequency, and duration; c) results showing participant numbers, outcome measures, units, and findings; and d) adverse effects observed in patients during the trial. The second part compromises the claim about the information contained in a single section, either in one or two CTRs and information about which CTRs are targeted and which section. The dataset consists of 1700 training samples and 200 validation samples. The dataset supplied has an equal distribution of labels.

[1] https://github.com/ai-systems/Task-2-SemEval-2024

3 System overview

This section presents the various approaches used while developing the final models. This includes techniques for preprocessing and ingesting data. Moreover, it includes the paradigms used for training as well as the experimental setup. DeBERTa and Bert-based models are fine-tuned using a weighted ensemble of refined iterations, as well as prompt-based fine-tuning (Lester et al., 2021) for DeBERTa final models.

3.1 Data Preparation

Large Models (LM) have challenges doing reasoning tasks when presented with acronyms, numerical, and quantitative information. Large language models (LLM) can be used to answer numerical entities and improve performance through a chain of thought, which is a methodical process of reasoning and explaining things step by step (Wang et al., 2023a). We have implemented a comparable pre-processing procedure for converting numeric quantities into textual representations and providing explanations in the presence of mathematical formulas. Furthermore, abbreviations are expanded to their original full names. The process goes as follows: first numbers, operations and abbreviations are converted into textual representation. For example **"Arm/Group Description: Phase 1 Cyclophosphamide Dose Escalation: Fludarabine 5x25mg/m2 + Cyclophosphamide 2x60mg/kg + Cells intravenous (IV) "** is converted to **"Arm/Group Description: Phase one Cyclophosphamide Dose Escalation: Fludarabine five times twenty-five milligram/ meterstwo plus Cyclophosphamide two times sixty milligram/ kilograms plus Cells intravenous (IV)."** The next steps involve using LLM as chatGPT or Mistral 7b to give an explanation for the converted text. The following prompt is feed to the LLM ***" Explain the following sentences in five sentences: text".*** . ChatGPT provides the following explanation: " **The given sentence describes a specific group or category within a clinical trial referred to as "Arm/Group Description" during the phase one stage. This particular arm involves a treatment protocol called "Cyclophosphamide Dose Escalation," which aims to determine the optimal and safe dosage of Cyclophosphamide, a chemotherapy drug. The treatment**

regimen includes the intravenous administration (IV) of Fludarabine at a dose of twenty-five milligrams per square meter of body surface area, repeated five times over a specific time period or schedule. Additionally, Cyclophosphamide is administered intravenously (IV) at a dose of sixty milligrams per kilogram of body weight, repeated twice over the same time period or schedule. The treatment also involves the administration of cells intravenously (IV), although the specific type of cells is not mentioned in the provided sentence.". Finally, Both Converted text and explanation are concatenated.

3.2 Data Representation

In types of reasoning tasks such as hypothesis and premise reasoning, the intuitive step is to feed both texts separated by a model-separating token ***("hypothesis [SEP] premise")***. However, it is not yet clear if it is an optimal representation or not. To address this, different representations were used to assess model performance and sensitivity to data representations.

The following illustrates several data representations used. The challenge included two sorts of reasoning. The first type of reasoning is to check whether a given premise is correct based on one single report. The second type is to check whether a given premise is correct based on two different reports. Therefore the model was two different representations were designed for each type.

- The first common design is to feed in each premise section separated by a separator token, then the hypothesis section.
  - ***"First premise [SEP] Second premise [SEP] hypothesis".***
- The second design was adding special token information to indicate the following sections:
  - **token_first** for the first premise
  - **token_second** for the second premise
  - **token_hypothesis** for the hypothesis.
  - ***"token_first_section First premise [SEP] token_second_section Second premise [SEP] token_hypothesis".***
- The third design was inverting order first feed hypothesis followed by premise.
- The remaining design explored the impact of adding different prompts to encourage model correct classification to each sentence and understanding of the current problem.
  - ***"First premise [SEP] Second premise [SEP] Is this statement correct based on previous CTR reports: hypothesis?".***
  - ***"First premise [SEP] Second premise [SEP] Question: Does this imply that: hypothesis?".***
  - ***"Task: Determine Claim Validity \n \n n CTR Report \n First premise [SEP] CTR Report \n Second premise [SEP] Evaluate the Claim: \n hypothesis".***

Also, since the organizers offered the specific lines that contributed to reasoning in a given section presented in both training and validation data, another crucial data-feeding option is whether to feed an entire section for the premise or choose selected lines from a premise section. Some models were trained on the whole section, while others were trained on chosen premise lines.

3.3 Model Selection, Design and training

Based on the following papers results (Wang et al., 2023b; Kanakarajan and Sankarasubbu, 2023; Zhou et al., 2023), experiments were conducted with a variety of different models, including 1) GPT2 (Lagler et al., 2013) 2) Deberta large (He et al., 2020) 3) BioLinkBERT (Yasunaga et al., 2022) 4) Clinical BERT (Alsentzer et al., 2019) 5) Scifive (Phan et al., 2021) 6) BioGPT (Luo et al., 2022).

3.3.1 Model architecture

It is important to modify the model architecture by deciding whether to simply use the last layer and input them into the Fully Connected (FC) layer, or to use the last n-layers from the model and implement average pooling before feeding them to the FC layer, or to direct the output to a convolutional or LSTM layer followed by the FC layer. Experiments were conducted with two alternative options. The first option is to apply mean pooling to the last layer of the model, while the second option is to use GeM pooling on the same layer.

3.3.2 Model Training

BioLinkBERT, Clinical BERT, BioGPT, DeBERTa-large and GPT2 models: Several training approaches have been investigated to improve the generalizability of the model and

its performance. The first approach involves fine-tuning the whole model while using cross-entropy loss. The second approach involves fine-tuning the whole model while using two losses. To improve model performance. The first loss is a cross-entropy loss so penalize the model for wrong prediction; the second loss is contrastive (Chen et al., 2020). The reason behind it is to improve model representation for both classes in the embedding space. The following weights were used: 0.7 for cross-entropy loss and 0.3 for contrastive loss. Following recent practices from the literature, parameter-efficient tuning methodologies as prompt-tuning, LoRA, have been shown to improve model performance over conventional fine-tuning (Fu et al., 2023; Ding et al., 2023). Therefore, the third approach leverages prompt-fine-tuning (Lester et al., 2021) for LM. In prompt-fine-tuning, the data is fed with a prompt to encourage the model to understand the task well, as well as the **"[MASK]"** token. The model task is to predict the correct class in the **"[MASK]"** token. The challenge in prompting lies in the design of the prompt and the model's output. The prompt we used was: ***"First premise [SEP]. Can we infer the hypothesis from the text above? [MASK]".*** The model's output is a binary prediction of either **"yes"** or **"no."**.

Scifive model training: Scifive is based on the T5 (Raffel et al., 2020) generator type, which is an encoder-decoder that transforms all tasks into text-to-text. Instruction fine-tuning has been conducted on the Scifive model with the following template: ***"Determine Claim Validity \n \n. First premise \n \n. Second premise \n\n. Evaluate the following Claim: hypothesis \n \n. Is the assertion accurate? Options: [yes, no]."*** For the loss function of the model BLEU score have been used. The model was constrained to predict either **"valid/invalid"**, or **"correct/incorrect"**, or **"yes/no"**.

3.3.3 Experimental setup

Table 2 shows the hyperparameter setup used during training.

4 Results

In this section, the performance of the proposed models is reported based on the official metric during the dev-phase and test-phase. Error analysis (Lu et al., 2023) was conducted to identify the weaknesses of the proposed models. For the task, the official metric is based on the F1 score and the average faithfulness [2] and consistency [3] scores.

4.1 Dev-phase results

Table 3 shows the results of the developed models on the dev-set, with their training settings. Clearly, the DeBERTa model with different settings showed superior performance compared to other models such as BioGPT, BioLinkBert, ClinicalBERT, GPT2 and Scifive. The Scifive model showed huge performance degradation when compared to BioLinkBert.

The first observation is that changing the pooling technique from mean pooling to GeM pooling, improved model performance by a magnitude of 3%. The second observation is that having two loss function contrastive loss with cross entropy loss improved performance by a magnitude of 3%. The third observation is that building two models for the different cases of reasoning (case single premise, hypothesis, and case of two premises and hypothesis) and including a task description in the data fed improved model performance by 2%. The fourth observation is that prompt-based fine-tuning is better than conventional fine-tuning by magnitude of 1-2%. Another key observation during training is that the model scores a similar f1-score for both classes in most of the settings. The fifth observation is that having data processing as converting numerical quantities to textual representation along with an explanation improves model performance over conventional ones by a magnitude of 1-2%.

4.2 Test-phase results

The results of the proposed system are presented in table 1. Our system ranks in sixth place, with a 0.77 F1-Score, a 0.76 Faithfulness score, and a 0.75 Consistency score. There are correlations between the dev-phase f1-score and the test-phase f1-score, which suggests that a greedy approach to choosing models and their weights is a good approach.

5 Conclusion

The study tested different ways to prepare and load data, as well as more advanced NlM models. It came to the conclusion that the ensemble

[2] Faithfulness measures the extent to which a given system arrives at the correct prediction for the correct reason (Li et al., 2022)

[3] Consistency is a measure of the extent to which a given system produces the same outputs for semantically equivalent problems (Fan et al., 2023)

Combination of selected Models	Leaderboard Results F1-score/ Consistency/Faithfulness	Dev f1-score
BioLinkBert DeBERTa (model 5,8,11,6,10 from table 3)	0.75/0.75/0.79	**0.8945**
DeBERTa (model 8,12,6,9,10 from table 3)	0.743/0.75/0.76	0.8899
DeBERTa (model 8,6,9,11, 10 from table 3)	0.754/0.74/0.75	0.88497
DeBERTa (model 5,8,12,6,9 from table 3)	0.744/0.76/0.80	0.88492
DeBERTa (model 8,6,9,10 from table 3)	**0.765/0.76/0.75**	0.8799
DeBERTa (model 8,11,6,10 from table 3)	0.73/0.75/0.75	0.8749
BioLinkBert DeBERTa (model 8,9,6 from table 3)	0.744/0.75/0.75	0.87474
DeBERTa (model 8,6,9 from table 3)	0.742/0.74/0.78	0.8746

Table 1: Performance of the submitted models on the leaderboard

Hyperparameter	Value
Learning-rate	4e-5 or 5e-6

model worked well for medical text analysis. DeBERTA, ClinicalBERT, GPT2, Scifive, BioGPT, and BioLinkBert have been investigated and the results show that the DEBERTA model showed better performance compared to other models during the training phase. The final model submitted was an ensemble of various models and techniques. The best-performing model achieved an F1 score of 0.77, a faithfulness score of 0.76, and a consistency score of 0.75, securing the sixth rank in the official leaderboard. Overall, this study has enhanced safe and effective NLMs for complicated medical data analysis in clinical trial reports. Future recommendations could explore other large language models and training techniques, such as LoRA and prefix-tuning, for ingesting medical knowledge into CTRs.

CVCoders at SemEval-2024 Task 4: Unified Multimodal Modelling For Multilingual Propaganda Detection in Memes

Fatemezahra Bakhshande and Mahdieh Naderi and Sauleh Etemadi
Iran University of Science and Technology
{bakhshande.ghazal, mahdieh9816, sauleh}@gmail.com

Abstract

This paper presents our approach to the SemEval 2024 Task 4 on "Multilingual Detection of Persuasion Techniques in Memes." We address the challenge of identifying persuasion techniques in textual and multimodal meme content using a combination of preprocessing techniques and Uni-modal models. Leveraging advanced preprocessing methods, including the OpenAI API for text data, we achieved improved data quality. Our model architecture combines VGG for image feature extraction and GPT-2 for text feature extraction, yielding superior performance. To mitigate class imbalance, we employed Focal Loss as the loss function and AdamW as the optimizer. Experimental results demonstrate the effectiveness of our approach, achieving competitive performance in the task.

1 Introduction

The SemEval 2024 Task 4 [1] focuses on the multilingual detection of persuasion techniques in memes, a crucial endeavor in combating disinformation campaigns prevalent on social media platforms. Memes, being potent vehicles for influencing public opinion, necessitate robust methods for identifying rhetorical and psychological techniques embedded within their textual and visual content. This task spans multiple languages, including Bulgarian, English, and North Macedonian, underscoring the global significance of addressing online misinformation (Dimitrov et al., 2024).

Our system employs a combination of pre-trained models for text and image processing to tackle the challenge posed by Subtask 2b of Task 4. Specifically, we utilize pre-trained language models such as XLM-RoBERTa and GPT-2 for textual feature extraction, while employing VGG and ViT models for image feature extraction. This multimodal approach allows us to effectively capture both textual and visual cues present in memes.

Through our participation in this task, we discovered the importance of advanced preprocessing techniques, particularly in cleaning and standardizing textual data extracted from memes. Leveraging the GPT API for text preprocessing and NLTK for further cleaning proved instrumental in enhancing the quality of our training data. Additionally, we observed the significance of model selection and hyperparameter tuning in achieving competitive performance. Despite encountering challenges in cleaning textual data, our system achieved promising results, demonstrating the efficacy of our approach.

2 Background

The task at hand, Subtask 2b of SemEval-2024 Task 4, revolves around the multilingual detection of persuasion techniques in memes. Memes, which are widely circulated across social media platforms, often contain subtle rhetorical and psychological strategies aimed at influencing public opinion. The goal of the task is to develop models capable of identifying these persuasion techniques embedded within the textual and visual content of memes.

The input to the task consists of textual and visual data extracted from memes in various languages, including Bulgarian, English, and North Macedonian. The textual content of memes may contain linguistic elements such as catchphrases, slogans, or captions, while the visual component typically comprises images or graphics. For example, a meme may feature a humorous image accompanied by a caption containing persuasive language or propaganda.

As for our participation, we focused on Subtask 2b of Task 4, which involves analyzing the presence of persuasion techniques in memes using both

[1] https://propaganda.math.unipd.it/semeval2024task4

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1912–1918

textual and visual features. Our approach combines advanced preprocessing techniques with state-of-the-art models to effectively tackle this challenging task. We draw inspiration from related work in the fields of natural language processing and computer vision, leveraging pre-trained models and techniques to enhance the accuracy and efficiency of our system.

2.1 Related Work

Generative Pre-trained Transformer 2 (GPT-2) is a large language model developed by OpenAI, pre-trained on a dataset of 8 million web pages. It exhibits general-purpose learning capabilities, enabling various tasks such as text translation, question answering, summarization, and text generation (Vincent, 2019; OpenAI, 2019; Piper, 2019).

XLM-R, a large-scale multilingual language model, demonstrates significant performance gains across diverse cross-lingual tasks, outperforming mBERT on tasks such as XNLI and MLQA (Conneau et al., 2020).

Researchers have proposed modified VGG-16 architectures for datasets like CIFAR-10, achieving improved performance with stronger regularization techniques and Batch Normalization (Liu and Deng, 2015).

Vision Transformer (ViT) demonstrates the effectiveness of pure transformer architectures applied directly to image patches for image classification tasks, achieving excellent results compared to convolutional networks (Dosovitskiy et al., 2020).

In recent years, SemEval has incorporated memes into some of its projects, such as Task 6 in 2021[2].

SemEval-2021 Task 6 focused on detecting persuasion techniques in memes, attracting significant participation and highlighting the importance of modeling interactions between text and image modalities (Dimitrov et al., 2021).

SemEval-2023 Task 3[3]. addressed persuasion techniques detection with a multilingual dataset, achieving competitive results using a fine-tuned XLM-RoBERTa large model (Hromadka et al., 2023).

[3] https://propaganda.math.unipd.it/semeval2023task3/

3 System overview

Our system for Subtask 2b of Task 4 in SemEval 2024 employs a combination of algorithms and modeling decisions to detect persuasion techniques in memes based on both textual and visual content. In this section, we outline the key components of our system, including preprocessing steps, model architectures, and training procedures.

3.1 Text Preprocessing

The textual content extracted from memes often contains noise and irrelevant information, which can adversely affect the performance of downstream tasks such as persuasion technique detection. To address these challenges, we employ a series of preprocessing steps to clean and standardize the text data.

3.1.1 OpenAI API for Initial Preprocessing

We utilize the OpenAI API for initial text preprocessing, leveraging its advanced natural language processing capabilities to handle common challenges encountered in meme text extraction. The API effectively identifies and removes extraneous information such as dates, usernames, and additional text that may accompany the original meme content. By leveraging the power of the OpenAI API, we ensure that the text data fed into our system is clean and devoid of irrelevant noise.

3.1.2 Further Cleaning with NLTK

Following the initial preprocessing step, we employ the Natural Language Toolkit (NLTK) for further cleaning and normalization of the text data. The NLTK library provides a wide range of text processing tools, including tokenization, stemming, and stop-word removal, which help standardize the textual content extracted from memes.

3.1.3 Manual Data Correction

Initially, we trained the data without text and solely using images, achieving 45% F1 macro on dev set. So, the major challenge we faced was how to incorporate text.

In instances where the automated text extraction process yielded inaccurate results, manual intervention was necessary to correct these errors. This phase involved a meticulous review of the textual content of problematic memes by human annotators, who then made the necessary adjustments to rectify any discrepancies.

This manual correction process was crucial for ensuring the accuracy and reliability of the textual data used in our system. By meticulously aligning the extracted text with the actual content depicted in the meme images, we mitigated potential biases and inconsistencies that could adversely affect the performance of our system.

In Listing 1, it can be observed that the textual content provided in the 'text' field ("@:\nDer") differs from the text contained within the associated image ('prop_meme_4499.png').

```
{
    "id": "25064",
    "text": "@:\\nDer",
    "image": "prop_meme_4499.png",
    "label": "propagandistic"
}
```

Listing 1: Sample Data Illustrating Textual Content Discrepancy in Manual Data Correction

The actual text present in the meme image is as follows: "Donald Trump Jr. @DonaldTrumpJr.8s\nMuppets have races now? So based on the orange\nI'm guessing Ernie is a Trump and must be \ncancelled immediately!!!\n\nABC News @ABC.7h\nAt only 7 years old, Ji-Young is making history\nas the first Asian American muppet in the\n"Sesame Street" canon. abcn.ws/3FyppJx\n\n'SESAME STREET' DEBUTS\nASIAN AMERICAN MUPPET\nabc NEWS\n\nAP PHOTO/NOREEN NASIR"

3.2 Image Preprocessing

Image preprocessing involves standard techniques such as resizing and normalization to enhance the quality and diversity of the image data. We employ the PyTorch framework for image preprocessing, utilizing built-in functions for resizing and normalization.

In Figure 1, we illustrate the data structure and preprocessing steps employed in our approach.

3.3 Feature Extraction

For textual feature extraction, we fine-tune pre-trained language models, including XLM-RoBERTa and GPT-2, on the meme text data. These models capture semantic and syntactic information embedded in the textual content, enabling effective representation learning for downstream tasks. For image feature extraction, we explore both convolutional neural networks (CNNs) such as VGG and vision transformers (ViTs) to extract visual features from memes. The extracted features

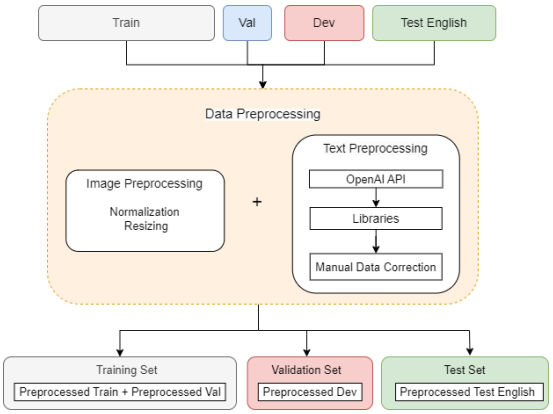

Figure 1: Diagram illustrating the Data structure and preprocessing steps

from both modalities are concatenated to form a multimodal feature representation of the memes.

3.4 Model Architecture

Our model architecture consists of a multimodal fusion layer followed by a classification layer. The multimodal fusion layer combines textual and visual features using concatenation to integrate information from both modalities. The classification layer employs a binary classification approach to predict the presence or absence of persuasion techniques in memes.

In Figure 2, we present the architecture of our Best model, which combines VGG-16 and GPT-2 for Subtask2b.

3.5 Multilingual Considerations

Given the multilingual nature of the task, one initial consideration was how to effectively handle language diversity within the dataset. Initially, we contemplated translating the data into English to leverage state-of-the-art monolingual language models such as BERT. However, inspired by insights from the top-performing submission in last year's TASK 3, (Hromadka et al., 2023) we recognized the efficacy of utilizing pre-trained multilingual models like GPT and XLM-RoBERTa.(Liu et al., 2019) This approach proved advantageous, allowing our system to effectively analyze memes across different languages without the need for explicit translation.

3.6 Overfitting Mitigation Strategies

During the development phase, we encountered challenges related to model overfitting, particularly when using complex architectures such as

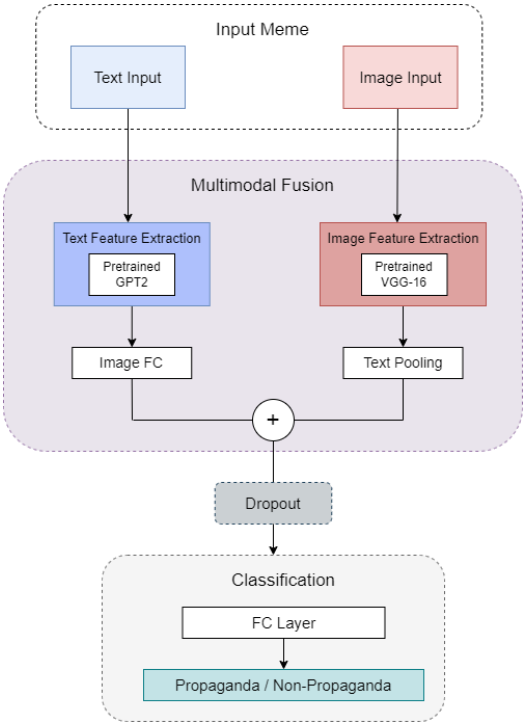

Figure 2: Model architecture combining VGG-16 and GPT-2 for Subtask2b.

a combination of XLM-RoBERTa for text processing and VGG for image analysis. Without proper normalization, our initial model exhibited signs of overfitting, compromising its generalization capabilities. To address this issue, we implemented regularization techniques, including dropout layers, to prevent overfitting and enhance the robustness of our model. These measures proved instrumental in stabilizing the training process and improving the overall performance of our system.

3.7 Training Procedure

We train our model using a combination of supervised learning and fine-tuning techniques. We train the model with the training data merged with the validation data. We employ Focal Loss as the loss function to address class imbalance and AdamW optimizer for gradient descent optimization. Hyperparameters such as learning rate, batch size, and dropout rate are tuned using grid search and cross-validation on the dev set.

3.8 Evaluation and Results

The performance of our system is evaluated using standard evaluation metrics such as macro-F1 score on the test set. We compare our results with baseline models to assess the effectiveness of our approach.

3.9 System Variants

We explore multiple system configurations, including variations in model architectures, preprocessing techniques, and hyperparameter settings. Each variant is evaluated and compared based on its performance on the validation set, allowing us to identify the most effective configuration for the task.

4 Experiment Setup

In this section, we detail the experimental setup used to train and evaluate our system for Subtask 2b of TASK4 2024. This task is a multi-model binary classification task.

4.1 Data Splitting

As shown in Table 1, in this task, we have 1200 samples in the train dataset, 150 samples in the validation dataset, and 300 samples in the `dev_unlabeled` dataset. Initially, the labels for the development dataset were unavailable to be used for testing purposes. However, eventually, these labels were fully accessible under the name of `dev_gold_labels` to the participants, and a dataset consisting of 600 samples was curated to serve as the test dataset, for which the labels have not yet been released.

Data Set/Label	Propagandistic	Non-Propagandistic
Train	800	400
Validation	100	50
Development	200	100

Table 1: Distribution of Datasets

At the beginning of our work, we utilized the same provided training dataset to train our initial model. However, we noticed that the model's accuracy on the training data reached 90% after 2 epochs, but the accuracy on the validation data was not as promising. Despite adjusting hyperparameters, this discrepancy in accuracy did not improve. Therefore, we decided to proceed by using the entire dataset for training our models. This expanded dataset significantly improved the model's performance on the test data.

4.2 Loss Function

After examining the labeled training and validation datasets, we noticed that the data distribution across classes is not uniform. Therefore, we opted to use focal loss alongside binary cross-entropy as the loss function.(Terven et al., 2023)

The formula for Binary Cross-Entropy (BCE) is given by:

$$BCE = -\frac{1}{N}\sum_{i=1}^{N}[y_i \log(\hat{y}_i) + (1 - y_i)\log(1 - \hat{y}_i)] \quad (1)$$

Where:

N is the number of samples,
y_i is the true label of sample i,
$\hat{y}_i$ is the predicted probability of sample i.

The formula for Focal Loss combined with Binary Cross-Entropy (BCE) is given by:

$$FocalLoss + BCE = -\frac{1}{N}\sum_{i=1}^{N}[(1 - \hat{y}_i)^{\gamma} y_i \log(\hat{y}_i) + (1 - y_i)^{\alpha}\hat{y}_i \log(1 - \hat{y}_i)] \quad (2)$$

Where:

N is the number of samples,
y_i is the true label of sample i,
$\hat{y}_i$ is the predicted probability of sample i,
α and γ are hyperparameters controlling the balance and focusing strength

4.3 Hyperparameter Tuning

Hyperparameter tuning played a crucial role in optimizing model performance. We experimented with various hyperparameters, including learning rates, batch sizes, and thresholds, to find the optimal configuration.

Further training parameters are specified in Table 2, in addition to those mentioned above.

Params	Value
number of train epoch	10
train batch size	32
validation batch size	32
weight decay	0.001
learning rate	$1e^{-3}$
threshold	0.39

Table 2: training hyperparameters

Moreover, In Figure 3, the impact of thresholds on Precision, Recall, F-score, and F1-macro metrics is visualized. This analysis provides insights into the trade-offs between these metrics, guiding the selection of an optimal threshold for model evaluation and decision-making.

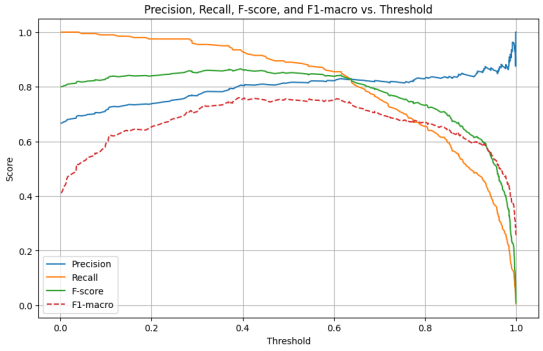

Figure 3: Precision, Recall, F-score, and F1-macro vs. Threshold on the Development Set

4.4 Tools and Libraries

Our system leveraged several external tools and libraries, including:

- OpenAI GPT API[4] for text preprocessing
- PyTorch[5] deep learning framework (v1.9.0) for model implementation
- Hugging Face Transformers[6] library (v4.11.3) for accessing pre-trained language models

4.5 Evaluation Measures

The evaluation of our system's performance was based on macro-F1 score, which accounts for precision and recall across all classes. This metric provides a comprehensive assessment of the model's ability to detect persuasion techniques in memes, considering both true positive and false positive rates (Powers, 2007).

The precision, recall, and F1 score are calculated as follows :

$$Precision = \frac{TP}{TP + FP} \quad (3)$$

$$Recall = \frac{TP}{TP + FN} \quad (4)$$

$$F\_1Score = 2 \times \frac{Precision \times Recall}{Precision + Recall} \quad (5)$$

Where:

TP is the total number of true positives,
FP is the total number of false positives,
FN is the total number of false negatives.

[4] https://openai.com/gpt
[5] https://pytorch.org
[6] https://huggingface.co/transformers

F1-macro is calculated as the average of the F1 scores for each class in the classification. It gives equal weight to each class, regardless of its size. The formula for F1-macro is:

$$F1_{\text{macro}} = \frac{1}{N} \sum_{i=1}^{N} F1_i \tag{6}$$

Where:

$$N \text{ is the number of classes,}$$
$$F1_i \text{ is the F1 score for class } i.$$

F1-micro is calculated by considering the total number of true positives, false negatives, and false positives across all classes. It gives equal weight to each instance, regardless of its class. The formula for F1-micro is:

$$F1_{\text{micro}} = \frac{2 \times TP}{2 \times TP + FP + FN} \tag{7}$$

Both F1-macro and F1-micro are commonly used to evaluate the performance of classification models, especially in situations where class imbalance exists.(Opitz and Burst, 2019)

5 Results

5.1 Main Quantitative Findings

Our system achieved moderate performance in Subtask 2b of TASK4 2024. On the English test dataset, it attained an F1 macro score of 0.67 and an F1 micro score of 0.74.

The evaluation results of four different model combinations, utilizing the best possible threshold based on the F1 macro on the English Dev dataset, are presented in Table 3. These combinations include VGG + XLM-RoBERTa, VGG + GPT-2, ViT + XLM-RoBERTa, and ViT + GPT-2.

Model	F1 macro	F1 macro Best Threshold
VGG + XLM-RoBERTa	0.58	0.63
VGG + gpt-2	0.71	0.76
ViT + XLM-RoBERTa	0.40	0.53
ViT + gpt-2	0.35	0.51

Table 3: Dev Set Result

Furthermore, the best model, GPT + VGG, was tested on the test data across three languages, and its results are shown in Table 4.

5.2 Quantitative Analysis

To gain deeper insights into our system's performance, we conducted ablation studies and compared different design decisions to identify optimal configurations. We utilized the entire training dataset for these analyses, employing a combination of train, validation, and gold_unlabeled data for training and validation purposes.

Through systematic experimentation, we observed that incorporating focal loss with sigmoid binary activation significantly improved the model's performance, particularly in handling class imbalance issues. Furthermore, training the model using gold_unlabeled data as an additional validation set resulted in notable enhancements in accuracy.

6 Conclusion

This paper presents our approach to the SemEval 2024 Task 4 on "Multilingual Detection of Persuasion Techniques in Memes." Leveraging preprocessing techniques and a multimodal model architecture combining VGG for image features and GPT-2 for text features, our system achieved competitive results on the test dataset in Subtask 2b.

Furthermore, our findings suggest that GPT-2 exhibits greater generalizability than XLM-RoBERTa, with a lower limit on the number of tokens. Insights from our experiments underscore the potential of pre-training models on similar data to enhance performance and generalization.

Looking ahead, future work could focus on pre-training models on meme-specific data and refining preprocessing techniques for extracted text. The large amount of available data presents an opportunity to delve deeper into this aspect, potentially improving model accuracy and robustness in meme analysis tasks.

Abstract

Large language models (LLMs) have shown remarkable capability of creating fluent responses to a wide variety of user queries. However, this also comes with concerns regarding the spread of misinformation and potential misuse within educational context. In this paper we describe our contribution to SemEval-2024 Task 8 (Wang et al., 2024), a shared task created around detecting machine-generated text. We aim to create several feature-based models that can detect whether a text is machine-generated or human-written. In the end, we obtained an accuracy of 0.74 on the binary human-written vs. machine-generated text classification task (Subtask A monolingual) and an accuracy of 0.61 on the multi-way machine-generated text-classification task (Subtask B). For future work, more features and models could be implemented.

1 Introduction

Recent large language models (LLMs), such as ChatGPT, have shown remarkable capability of creating fluent responses to a wide variety of user queries. This, in combination with increased accessibility to these models, has lead to an increase of machine-generated content over various channels. However, these LLMs come with concerns regarding the potential misuse of such tasks, like spreading misinformation and misuse within the education system (Wang et al., 2023). Therefore, detecting whether a text is human-written or machine-generated is extremely important.

Unfortunately, humans perform only slightly better than chance at this task, as found by Gehrmann et al. (2019). This introduces the need for developing automatic systems that can identify machine-generated texts, in order to mitigate their potential misuse (Wang et al., 2023).

While previous work has been done on identifying machine-generated texts, they either focused on only one or two particular languages, or focused on detecting machine-generated text for a specific LLM or a specific domain (Wang et al., 2023).

For instance, Macko et al. (2023) note that most of the research on machine-generated text detection uses systems that were trained on English datasets and that prior works show that detectors fine-tuned on English data fail to generalize to other languages. This can be seen in the results from Mitchell et al. (2023), where a decrease is seen from 0.946 AUC ROC to 0.537 when working with German data. In addition, Macko et al. (2023) get similar results.

Meanwhile, Sarvazyan et al. (2023) address the issue of detection systems not generalizing across different generation models and domains. They mention that most previous works often overlook that detection systems would be applied to a broad variety of domains, writing styles, and generation models.

Thus, the goal of Task 8 of SemEval 2024 (Wang et al., 2024) is to take a first step into creating a mono- or multilingual system that is able to detect machine-generated text created by different LLMs in different domains. The Task is divided into three subtasks, of which we participate in two. These subtasks are described in Section 2.

In order to tackle this task, we have created multiple feature-based models. The features on which the models have been trained will be described in Section 3. Our decision for creating these feature-based models is supported by our beliefs that a model with carefully crafted features is computationally less expensive than fine-tuning a LLM, while it may be able to achieve equal or better performance because of its ability to generalize (Wang et al., 2023), which is something that LLMs tend to struggle with (Lasri et al., 2022; Wilson et al., 2023). We focused on creating monolingual models for subtask A and B.

Eventually, we created a model that was ranked 95th out of 137 teams for the monolingual track of subtask A with an accuracy of 0.69. For subtask B,

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1919–1925

we ranked 50th out of 77 participating teams with an accuracy score of 0.61.

All of our code for this project can be found on our GitHub repository.[1]

2 Background

The goal of this shared task is to create machine-learning models that are able to detect machine-generated text across multiple languages, generators and domains. The datasets we used to train and test were provided by the task organizers. We took part in two subtasks: A and B.

2.1 Subtask A

The goal of subtask A is to detect whether the text is machine-generated or human-written. Every instance in the dataset contains the text generated by a machine or written by a human and its corresponding label, which is either *human* or *machine*. Besides this, it also includes the model that generated the data and the source of the text.

There is one monolingual dataset, which is made up of English texts only, and one multilingual dataset. We chose to only focus on the monolingual track of this subtask, since we can make language specific feature for this dataset. For the monolingual dataset, the source means the domain of the text, e.g. `reddit` or `wikipedia`. The train set for the monolingual track has 119,757 instances, while the development set contains 5,000 instances.

2.2 Subtask B

The datasets for subtask B are similar to those of subtask A, however, as the goal of this subtask is to detect by which specific text generator the text was created, there are more labels: `human`, `chatGPT`, `cohere`, `davinci`, `bloomz` and `dolly`. The train set consists out of 71,027 instances and the development set includes 3,000 instances. All instances are from sources in English.

3 System Overview

We experimented with four different kind of supervised models and the features that we created ourselves. We will describe each model and feature one by one.

[1] https://github.com/bbjoverbeek/SamEval-2024_Task-8_M4

3.1 Models

Support Vector Machine We chose to implement a Support Vector Machine (SVM; Cortes and Vapnik, 1995), because this has been one of the most fundamental models in statistical machine learning. It has become less popular with the uprising of neural networks, but we expect it will perform well on this task.

Naive Bayes Naive Bayes is a statistical machine learning model that is easy to implement and works well on large datasets. It is based on Bayes' Theorem which calculates the probability of something happening based on previous encounters.

K-Nearest Neighbors Lastly, we implemented the K-Nearest Neighbors algorithm (KNN; Fix and Hodges, 1989). This algorithm is also specialized in classification and is simple to implement.

Feed Forward Neural Network In an attempt to find more complex relationship between different features, we also implement simple neural networks whith several different architectures.

3.2 Features

The following section describes the set of features that we created and experimented with.

Personal pronouns vs. proper pames The first feature focuses on the difference in the usage of personal pronouns, like "he" or "she", versus the usage of proper names, like "Michael" or "Karen" within the text. According to Mitrovic et al. (2023), humans will usually switch to pronouns to refer to a person after using a proper name once or twice in a paragraph, while ChatGPT tends to refer to a person by their proper name more often. For this reason, we thought it would be interesting to see if this effect would be prevalent for other LLMs and if this would have an impact on the results.

Sentence tense This feature focuses on the tense that a sentence is written in. The three tenses we consider are *past*, *present* and *future*. Our goal with this feature was to discover if there are patterns in tense usage that are more commonly used in machine-generated text when compared to human-written text and vice versa.

Sentence voice For all of the sentences, we collect the voice that the sentence was written in. This could be either *passive* or *active*. Similarly to

the sentence tense, we hoped that we could discover patterns that are distinct to either machine-generated text or human-written text, since Mitrovic et al. (2023) mentioned that ChatGPT writes in the passive voice more often than active.

Sentence similarity The sentence similarity calculates how similar a sentence is to its previous and following sentence. In similar fashion to the sentence tense and sentence voice, we want to discover if there are any distinct patterns.

Sentiment We collect the sentiment on sentence level from the text to use as a feature. We believed that there might be a difference between human-written and machine-generated texts in terms of sentiment.

Domain The domain of the text in the train and development data was provided by the task organizers. However, we suspected that this might not be included in the final test set. Therefore, we also included domain as a feature that we could experiment with. We figured that if the domain had a positive influence on the final score, we could build our own classifier that predicts the domain of a text, which can then be used as a feature for our system.

POS-tags and dependency tags Finally, we also included the POS-tags and dependency tags as features. These features contain information about the structure of the text, which we believed could be helpful in distinguishing between machine-generated and human-written text.

4 Experimental Setup

In this following section, we will describe how we created the models and crafted the features.

4.1 Models

Support Vector Machine In order to run the SVM, we made use of the scikit-learn library (version 1.3.2) (Pedregosa et al., 2011).[2] In particular, we used `LinearSVC`. By using the built-in functions of scikit-learn we could train and test the model.

Naive Bayes To build the Naive Bayes classifier, we used the `GaussianNB` classifier from scikit-learn. This type of Naive Bayes classifier assumes that our data is normally distributed.

K-Nearest Neighbors For the KNN algorithm, we used `KNeighborsClassifier` from scikit-learn. When this model is used for subtask A, the number of neighbors is 5. In other cases, the number of neighbors was 15. It is trained and tested in a similar way to the SVM.

Feed Forward Neural Network With the Keras library we created a simple feedforward neural network (FFNN).[3] We experimented with different setups for the neural networks, ranging from 1 up to 4 hidden layers and giving the hidden layers from 8 up to 1024 nodes. The ones that worked best had two or three hidden layers. The size of the layers ranged from 16 up to 256 (depending on the model). All the models use softmax as their activation and Adam for optimization.

4.2 Features

4.2.1 Token-level

Pre-processing With the use of spaCy (version 3.7, using their trained pipeline called *en_core_web_sm*), we could split the full text into tokens.[4] After that, we used the tokens to create our token-level features which will be described below in the following two paragraphs.

Personal pronouns vs. proper names For this feature, we first count how many personal pronouns and proper names the text contains. In order to find the amount of personal pronouns in a text, we use spaCy to find every token that has the POS-tag *pron* (pronoun) and count the number of occurrences.

To collect the number of proper names, we use spaCy's entity recognizer and count every token that has the label *person*.

POS-tags and dependency tags The POS-tags and dependency tags can be easily extracted with spaCy. We use their built-in function to retrieve these tags and then use them as features. For both of these features, we created a bag-of-trigrams.

4.2.2 Sentence-level

Pre-Processing For the sentence-level features, we split the full text into sentences with spaCy. We then use these sentences to extract the features we describe in the remainder of this subsection.

Sentence tense In order to extract the sentence tense, we used spaCy's token-based matching. We

[2] https://scikit-learn.org/

[3] https://keras.io/

[4] https://spacy.io/

created multiple patterns for each sentence tense by using GitHub Copilot[5]. The patterns are made out of combinations of detailed POS-tags, dependency tags, and in some cases, words. The sentences are matched with these patterns and as a result they either get the label *past*, *present* or *future*.

After we collected all the sentence tense labels, we have created trigrams out of these labels and used these in a bag-of-words. We do this by using the `CountVectorizer` that can be found in the skicit-learn library (Pedregosa et al., 2011). The bag-of-trigrams is the feature we use that represents the sentence tense.

Sentence voice Collecting the sentence voice is done in a similar way as the sentence tense. We again use spaCy's token-based matching to determine if a sentence is written in *active* or *passive* voice. The patterns we used were adapted from an example implementation found on Stack Overflow[6]. We then create a bag-of-trigrams in the same way as for the sentence tense and use this as a feature.

Sentence similarity For the sentence similarity feature, the first thing that is done is that each sentence is compared to its previous and following sentence using a sentence-transformers model[7] from Hugging Face (Wolf et al., 2020). We then get two similarity scores per sentence, after which we check for each sentence whether it is most similar to the previous or following one and then give it the value *previous* or *next*, depending on which combination has the highest score. After that, the process is the same as for the sentence tense and voice: we create a bag-of-trigrams to use as a feature.

Sentiment In order to determine the sentiment of a sentence, we used a RoBERTa model from Hugging Face (Liu et al., 2019).[8] Each sentence was assigned one of the following labels: *positive*, *neutral* or *negative*. Afterwards, we again created a bag-of-trigrams so that we could actually use it as a feature.

4.2.3 Document-level

Domain Since domain was already given with the train and test data, we initially used this to experiment with this feature. We trained the models with and without domain to get an insight in the influence of this feature on the final scores. In some cases, the inclusion of domain as a feature improved the score, however, it was only very little. Therefore, we did not find it fruitful to build our own classifier that could predict the domain, especially considering that this classifier may not have been 100% accurate, which would increase the risk of wrong predictions negatively influencing the results.

Evaluation measures In order to evaluate the performance of the model, we calculate precision and recall, the f1-score, and the accuracy. Since the official metric used for subtask A and B is the accuracy, we considered the models with the highest accuracy our best performing models.

We train our different models with every possible combination of features on the training data and evaluate their performance on the development data given by the task organizers. The models with the highest accuracy are the ones we submitted to the shared task.

5 Results

5.1 Subtask A

For subtask A, we handed in three SVMs and three neural networks, since these models received the highest scores on the development set. We achieved the highest accuracy (0.74) on the final test set with a neural network using the sentence tense, sentence voice, sentence similarity and ratio of pronouns and named entities as features. The final ranking released by the task organizers however was not based on the submitted model with the highest score but on the last submitted model, which in our case was the SVM model using the sentence tense, sentence voice and ratio pronouns/named entities as features. This model ranked 95th out of 137 teams. The results of the models we handed in, including our best performing model, can be seen in Table 1. Even though our best performing model obtained an accuracy of 0.74, it is still lower than the RoBERTa baseline, which achieved an accuracy of 0.88.

5.2 Subtask B

For subtask B, we handed in three models, namely one SVM and two neural networks. Our best scoring model was the SVM with an accuracy of 0.61. This model used the sentence tense, sentence voice,

[8] https://huggingface.co/cardiffnlp/twitter-roberta-base-sentiment-latest

Model	Features	Precision	Recall	F1-score	Accuracy
RoBERTa (baseline)	-	-	-	-	*0.88*
SVM	Tense, Voice	0.73	0.64	0.68	0.69
SVM	Tense, Voice, Ratio PRON/NE	0.73	0.66	0.69	0.69
SVM	Tense, Voice, Similarity, Ratio PRON/NE	0.77	0.64	0.70	0.71
NN 12e-b64-l0.0001	Tense, Voice, Ratio PRON/NE	0.72	0.64	0.68	0.68
NN 8e-b32-l0.0001	Tense, Voice, Similarity, Ratio PRON/NE	0.79	**0.68**	**0.73**	**0.74**
NN 10e-b64-l0.0001	Tense, Voice, Similarity	**0.83**	0.57	0.68	0.72

Table 1: The results of our best models on the monolingual test data of subtask A. The numbers behind the neural networks (NN) stand for the number of epochs (e), the batch size (b) and the learning rate (l) respectively. All the other hyperparameters were the same. The highest scoring model is the neural network with four different features. It is only outscored by another neural network model on precision.

Model	Features	Precision	Recall	F1-score	Accuracy
RoBERTa (baseline)	-	-	-	-	*0.75*
SVM	Tense, Voice, Sentiment, POS DEP, Similarity, Ratio PRON/NE	**0.60**	**0.61**	**0.58**	**0.61**
NN 48e-b32-l0.0005	Tense, Voice, POS, DEP, Ratio PRON/NE	0.54	0.56	0.50	0.56
NN 48e-b32-l0.0005	Tense, Voice, POS, DEP, Similarity, Ratio PRON/NE	0.56	0.56	0.51	0.56

Table 2: The results of our best models on the test data of subtask B provided by the creators of the Shared Task. The numbers behind the neural networks (NN) stand for the number of epochs (e), the batch size (b) and the learning rate (l) respectively. The highest scoring model is the SVM with seven different features.

sentiment, POS-tags, dependency tags, sentence similarity and the pronoun/named entity ratio as features. This model scored the 50th place out of 77 models in total. The results of our best models can be seen in Table 2. Again, our best performing model scores lower than the RoBERTa baseline that has an accuracy of 0.75.

5.3 Discussion

We found that the SVMs and the feedforward neural networks gave the best results on the development set, while the KNN and Naive Bayes algorithms did not perform well. This can be seen in Table 3 in Appendix A, which shows the best results of the different models on subtask A monolingual. Because of these results we decided to focus our attention on feedforward neural networks and SVMs, for both subtask A as well as subtask B.

Our submissions for both subtasks ended up being in the bottom 50% of the total submissions. However, we used older techniques for this task, as we believed that carefully crafting our own features and training these on simpler models would still return good results while being less computationally expensive.

For both subtask A and B we can conclude that a simple FFNN or SVM performs well, but it does not outperform the current state-of-the-art models.

Overall, some features contribute more to the detection of machine-generated text than others. The features that perform well are the sentence tense, sentence voice, sentence similarity and the ratio of personal pronouns and proper names. The tense and the voice of the sentences even appear in all of our best scoring models.

We think that the reason of the effect of ratio of personal pronouns and proper names on the performance is due to the fact that machines tend to use named entities more often than humans, as we described in Section 3.2.

The feature that did not seem effective was sentiment, which only occurs in one of our top models. One of the reasons we think that the sentiment feature did not seem helpful is due to the fact that most of the texts come from sources that are naturally written in neutral tone, such as Wikipedia and arXiv.

6 Conclusion

To conclude, while we still gained quite good results, our models do not outperform the state-of-the-art models. We achieved an accuracy of 0.74 on subtask A and an accuracy of 0.61 on subtask B. Both scores are lower than the RoBERTa baseline.

We discovered that sentence tense, sentence

voice and the ratio between pronouns and named entities seemed to be effective for the classification task, while sentiment did not have that much influence.

In future research, there could be more experimentation with different kinds of machine learning models and more features could be created to further improve the models.

Acknowledgements

This submission has been carried out as a part of the 2023-2024 edition of the master course Shared Task Information Science (LIX026M05) at the University of Groningen. We want to thank Antonio Toral and Lukas Edman for teaching the course. As Antonio Toral was the teacher assigned to our group, we want to thank him especially for supervising our progress, steering us in the right direction and answering all of our questions.

Abstract

The emergence of generative language models has put in place the necessity of building models to discern between machine-generated and human-generated text. In this paper, we present our participation in subtasks A and B of the SemEval 2024 Task 8 shared task, which revolves around this problem. Our approach primarily centers on feature-based systems, where a diverse array of features pertinent to the text's linguistic attributes is extracted. Alongside those, we incorporate token-level probabilistic features which are fed into a Bidirectional Long Short-Term Memory (BiLSTM) model. Both resulting feature arrays are concatenated and fed into our final prediction model. Our method under-performed compared to the baseline, despite the fact that previous attempts by others have successfully used linguistic features for the purpose of discerning machine-generated text. We conclude that our examined subset of linguistically motivated features alongside probabilistic features was not able to contribute almost any performance at all to a hybrid classifier of human and machine texts. Our codebase is publicly available on GitHub.[1]

1 Introduction

Large language models capable of generating human-like text have become quite ubiquitous very quickly. There are now many such models which are commonly used to generate text across different domains and in different languages. With their increasing availability and capabilities, it has subsequently become necessary to find ways to distinguish machine-generated text from that which is produced by humans. Humans alone are not able to detect machine-generated text consistently, not even experts in this task (Guo et al., 2023), and current commercial solutions fall short (Chaka, 2023). It is natural then that this problem has seen wide discussion and participation over several domains and languages, including the creation of datasets and proposal of different feature sets and model types (Shamardina et al. 2022; Wang et al. 2024b to name a few), but it is still far from being solved. This leads us to the SemEval-2024 Shared Task 8 that this paper is concerned with "Multidomain, Multimodal and Multilingual Machine-Generated Text Detection" (Wang et al., 2024a). This task is about distinguishing human-written text from machine-generated text in multiple different domains, modalities and across different languages. The languages included in the task are: Arabic, Bulgarian, Chinese, English, Indonesian, Russian and Urdu. The domains are varied and range from Wikipedia pages to arXiv research papers to Reddit posts.

1.1 Research Question

The task of discerning machine-generated texts can be approached using classical feature-based methods or using recent neural methods. The inclusion of multiple domains, languages, and underlying models adds complexity to the problem, but also demands a more universal solution. We therefore find it important not only to strive for high accuracy, but also for explainability and universality based on linguistic concepts. Our research question thus read as the following:

- How well does the linguistically motivated probabilistic model perform for machine-generated text detection and model authorship attribution?

To answer this question, our main strategy uses a combined linear model with document-level features alongside token-level features which have been processed by a BiLSTM, resulting in a method which combines probability-based features with low-level and high-level linguistic features. Our method is inspired by Przybyła et al. (2023), which

[1] https://github.com/rug-1-at-semeval24-task8/code

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1926–1932

used a similar model structure for the AuTexTification shared task (Sarvazyan et al., 2023), achieving results that were close behind an LLM-based model. In our method, however, we employ a linear perceptron instead of a random forest classifier to combine the document-level and processed token-level features, in an attempt to enhance the model's performance and learning. A wide range of features is employed, with our system utilizing stylometric features, entity coherence features, information-theoretic features as well as complementary features such as TF-IDF features for word-level unigrams. An LSTM model proved to attain notably high accuracy in our baseline system, which led to us combining our extracted features with a BiLSTM model. The overview of our system is presented in Figure 1. Our system performs poorly in general and relative to other teams, where we rank at the bottom ten for all tasks that we participated in.

While our primary emphasis remained on feature-based models, we developed a separate model to explore potential performance variations compared to the feature-based approach. In this independent model, we employed a basic LSTM architecture with BERT (Devlin et al., 2018) serving as the embedding layer to acquire sentence embeddings. However, the inclusion of the embedding layer introduced computational overhead, resulting in prolonged processing times. Consequently, we were only able to obtain results for Task B on the test dataset using this architecture.

2 Related Work

Due to the similarities in the architecture and training of different text-generation machines, generated text may possess universal characteristics that distinguish it from text written by humans. Guo et al. (2023) set up a series of human evaluation and linguistics analyses to understand the characteristic features and patterns, where a study by Mitrović et al. (2023) looked at the differences in human vs AI-generated text. The studies found that humans tend to have much more diverse and expressive vocabulary, and often tend to diverge from the topic more than ChatGPT does (Guo et al., 2023; Mitrović et al., 2023). This idea is supported by Gehrmann et al. (2019), who performed a probabilistic analysis of the vocabulary in human- and machine-generated texts and found that generation models tend to have a relatively limited and predictable vocabulary. Some work focuses on stylometric features, as these may be productive in discerning the original author of a text (Li et al., 2014; Pearl and Steyvers, 2012). Wang et al. (2024b) show that models based on such feature sets perform strongly within the domain, but the choice of training dataset may have a notable effect on performance.

Feature-based detectors work fairly well for simple binary classifications in a single domain, but tend to fall short when attempting more complex problems which consist of additional styles and sources of texts (Wang et al., 2024b), where shorter texts can have a negative impact on performance Shamardina et al. (2022). Conversely, language models may prove to be the optimal tool for detecting machine-generated text. Recent attempts mostly use (Ro)BERT(a)-based models (Devlin et al., 2018; Liu et al., 2019) that are pre-trained for language understanding, and fine-tune them using datasets of human- and machine-generated text (Zellers et al., 2019; Shamardina et al., 2022; Guo et al., 2023). These models are then able to detect authorship with varying levels of success. Much of the focus in this area has been on developing useful datasets for fine-tuning and finding optimal models and methods of fine-tuning.

An LSTM, as introduced in Hochreiter and Schmidhuber (1997), is a version of a RNN (recurrent neural network) that utilizes *long term short memory* to deal with issues present in regular RNNs caused by larger gap lengths, which can be especially relevant in NLP tasks such as ours. LSTMs have been used with success to perform authorship attribution (Deibel and Löfflad, 2021; Gupta et al., 2019) which suggests they may be useful in distinguishing human and machine authors as well.

3 Shared Task Set Up

The SemEval-2024 shared task 8 revolved around distinguishing human-written texts and machine-generated texts. It was divided into multiple subtasks. The goal of subtask A was to perform binary classification on a given text to determine whether it is human-written or machine-generated. The monolingual track of this subtask only included text in English, whereas the multilingual track included text in English, Russian, Chinese, Arabic, Urdu, Indonesian and Bulgarian. Subtask B focused on multi-way machine-generated text, where the goal of the task was to determine whether a

given text is written by a human or generated by a machine, and if generated by a machine – which specific language model was it that generated the text?

For all subtasks, we used the datasets provided by the task organizers. These datasets are an extension of the M4 dataset from Wang et al. (2024b). The datasets include texts from multiple domains, such as Reddit discussions, Wikipedia pages and arXiv papers to name a few, as well as multiple languages as stated above. In addition, the dataset for subtask B contains machine-generated texts from multiple models. For more information about the shared task, see Wang et al. (2024a).

4 System Overview

The basic components of our design consist of both document-level and token-level features. Document-level features (detailed in Section 4.1) are extracted directly from the text, and the output features of document-level features are concatenated for further use in an MLP for classification. Token-level features, *i.e.,* the measure of predictability, are the probability of the input text according to a large language model, are fed into a BiLSTM network which converts sequences into a fixed-length representation by concatenating both directions; the details of token-level features are outlined in 4.2. Document-level and token-level features are concatenated and then passed to an MLP for classification. This design remains consistent for both subtask A and subtask B, differing only in the dimensionality of the MLP output representation, which requires adjustments to the number of output classes.

4.1 Document-level features

4.1.1 Perplexity feature

Perplexity serves as a crucial measure of a language model's predictive capability regarding word sequences. Essentially, it gauges the level of surprise a language model experiences when encountering a new sequence of words. A lower perplexity score indicates that the language model excels in predicting the next word in a sequence. It's shown in previous studies that generally the text perplexity generated by large language models (e.g. ChatGPT) is lower than that human written text (Liao et al., 2023). Numerous prior studies have either directly evaluated the efficacy of perplexity in discerning machine-generated data or incorporated it into their models (Liao et al., 2023; Mindner et al., 2023).

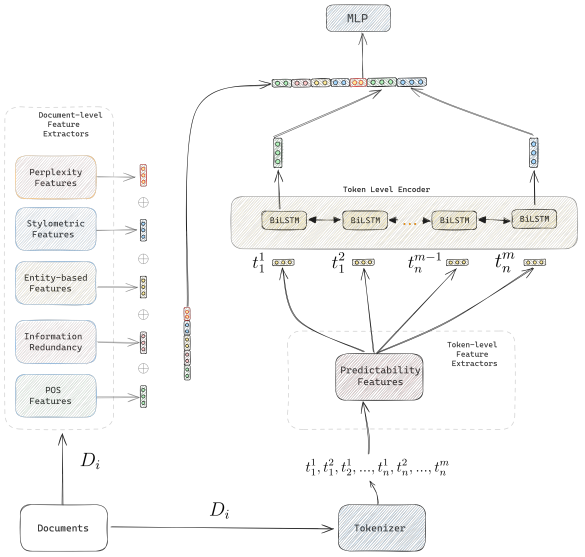

Figure 1: System architecture.

In this study, we employ the XLM-RoBERTa (Conneau et al., 2019) language model to compute the perplexity score for each document. Consequently, each document is represented by 1 perplexity feature.

4.1.2 TF-IDF

We use a text vectorizer to extract term frequency–inverse document frequency (TF-IDF) features based on word-level unigrams. The vocabulary and feature-set for each dataset (A monolingual, A multilingual, B) are calculated separately.

4.1.3 Simple stylometric features

We calculate a small subset of stylometric features. These include: average sentence length by word count; punctuation count, normalized by total number of tokens; number of capitalized words, normalized by total number of words; and the distribution of Part-of-Speech tags in the texts. We make use of the Stanza package (Qi et al., 2020) to perform tokenization, sentence segmentation, and PoS tagging.

4.1.4 Information redundancy

Information redundancy in text may be expressed as lexical or topical repetition. Recent comparisons suggest that machine-generated text is prone to this kind of repetition to some degree (Holtzman et al., 2019), possibly over-repeating words in the output compared to human text (Dou et al., 2021). To calculate information redundancy, we follow the method outlined by Fröhling and Zubiaga (2021).

4.1.5 Entity-based coherence

The inclusion of this feature is based on a hypothesis that human-written text and machine-generated text differ in their use of references to entities throughout the text (Fröhling and Zubiaga, 2021). We extract coherence features using a conventional method which relies on transitions of mention types between sentences (Lapata et al., 2005). An illustration of this process can be found in Figure 2. Due to the limitations of the current co-reference resolution availability, this feature was only used in the monolingual track of subtask A and in subtask B, as these only contained samples in English.

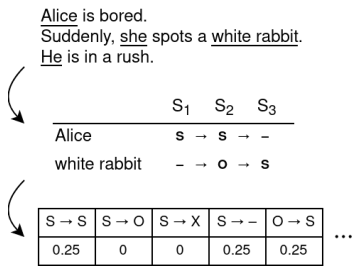

Figure 2: Entity-based coherence illustration.

4.2 Token-level features

4.2.1 Predictability feature

The predictability measurement method, the approach presented by (Przybyła et al., 2023), assesses the likelihood of token sequences using generative language models, distinguishing between machine-generated and human-authored text. Key components of the predictability measurement include:

- *Log-probability of the observed token* t_i^*:

  $\log p(i, t_i^*)$

  This feature measures the likelihood of the observed token given the model's predictions at a specific position in the sequence.

- *Log-probability of the most likely token* w_j *from dictionary* D:

  $\max_{j \in D} \log p(i, w_j)$

  This feature calculates the maximum log probability among all tokens in the model's dictionary, indicating the confidence of the model's top prediction at a particular position.

- *The entropy of the token probability distribution*:

  $-\sum_{j \in D} p(i, w_j) \log p(i, w_j)$

  This feature quantifies the uncertainty of choosing the next token according to the model at a given position.

The XLM-RoBERTa (Conneau et al., 2019) language model is utilized for both Subtasks A and B. Since we only employ the language model, each token is represented by 4 predictability features for all languages, and the maximum sequence length is limited to 128 tokens. The method employs a bidirectional LSTM to distinguish patterns from the sequence of features, without relying on averaging or aggregation functions.

4.3 BERT-LSTM model

Though we mainly focused on feature based system, we have worked on building a simple LSTM model independently as well. For this model, we have used BERT to get sentence embedding, as BERT provide different embedding for the same words based on their context in the sentence. After getting the sentence embedding, we fed it into an LSTM layer, which contains 128 hidden nodes. Subsequently, we have added a linear layer on top of the LSTM layer as the final output layer. The number of output nodes was related to the task it was assigned. For Task B, we have used 6 nodes in the output layer, as there are 6 possible classes. The overview of this system architecture is displayed in Figure 3.

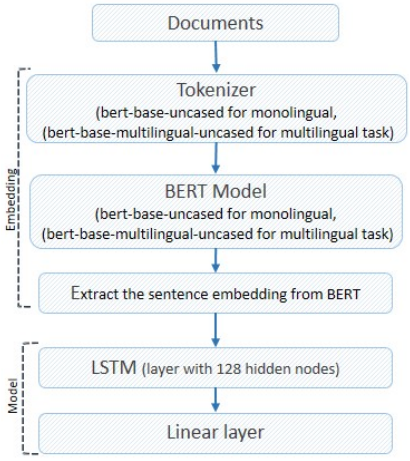

Figure 3: BERT-LSTM system overview.

5 Experimental Setup

We initially divided the training data into two subsets: training and development. We utilized the

development set for testing purposes during the model development phase. However, following the availability of the test data, we incorporated the entire training set for training and the development set for validation. We then evaluated the model's performance on the raw documents in the publicly available test set. For preprocessing, we employed the XLM-RoBERTa tokenizer for features related to perplexity and predictability. Additionally, we utilized the Stanza (Qi et al., 2020) tokenization pipeline for features such as stylometric analysis, entity coherence, information redundancy, and part-of-speech (POS) tagging. Our model was implemented using PyTorch. We employed accuracy as the official evaluation measure.

6 Results

6.1 Feature-based Model

Our numerical results on the test dataset are displayed fully in Table 1. Overall, our system did not perform very well in general or according to official metrics. Our monolingual subtask A model did not learn to differentiate between human and machine texts, and predicted all test examples to be machine-generated. Our subtask B model suffered a similar fate, predicting all test examples to be written by ChatGPT. Our multilingual subtask A was our only model which was able to distinguish between examples to some extent. However, this model also had an extreme bias towards the "machine" label.

Table 1: Overview of our results on each of the subtasks. Values represent accuracy of predictions made on the test set of each subtask.

Subtask	Task Baseline	Our Result	Our Ranking
A Mono.	.884	.525	128/137
A Multi.	.808	.512	61/68
B	.746	.166	74/77

In an attempt to further understand the lack of learning by our models, we examined the raw features produced by our feature extractors on the test set examples. Interestingly, we find that some features did actually differ notably in value for human and machine texts. We calculate means and standard deviations for the raw features on human and machine texts separately, and compare the results using the Cohen's d effect-size metric. Some notable results are shown in Table 3. As expected, the information loss, represented as the norm of the difference between the original document matrix and the truncated matrix, was higher in human texts than in machine texts in the test set, suggesting that the machine texts had more information redundancy, *i.e.,* repetition of information. We observe some interesting findings regarding PoS distribution in the texts, such as higher presence of pronouns, auxiliary verbs, and particles in human texts versus higher presence of nouns, adjectives, and adpositions in machine texts.

Table 2: Confusion matrix for predictions made by our subtask A multilingual model, comparing predicted labels with gold labels.

Subtask A Multi.		Predicted	
		Human	Machine
Gold	Human	406	16259
	Machine	460	17147

Note: Confusion matrices for other subtasks are redundant, as our models only predicted a single label for each of them ('Machine' for subtask A monolingual, and 'ChatGPT' for subtask B).

Table 3: Notable features with effect sizes > 0.3 as calculated on examples from the monolingual A test set. Positive values denote that these features were higher in human texts than in machine texts.

Feature	Effect size (d) (Human − Machine)
Frequency of pronouns	1.59
Frequency of auxiliary verbs	1.49
Frequency of particles	0.8
Frequency of adverbs	0.58
Frequency of verbs	0.54
$\|A - A_{\text{trunc}}\|$ (Information loss)	0.31
$\min(A_{\text{trunc}})$ (Info. redundancy)	-0.51
Frequency of adpositions	-0.75
Punctuation count	-1.03
Frequency of adjectives	-1.31
Frequency of nouns	-1.62

6.2 BERT-LSTM model

We employed BERT (Devlin et al., 2018) to obtain sentence embeddings, a process that significantly increased the computational complexity of our BERT-LSTM system. The model ended up pre-

dicting all the labels on the test set as the same. As a result this system get an 16.67% accuracy on the task B which is not better than a random selection. Due to the time constraint, we could not manage to experiment with Task A.

7 Conclusion

Our overall conclusion is that our examined subset of linguistically motivated features alongside probabilistic features was not able to contribute almost any performance at all to a classifier of human and machine texts. While some features did differ in value between human and machine texts, these differences did not translate into a learning advantage for a hybrid model. Our findings underscore the nuanced challenges inherent in developing robust detection mechanisms for machine-generated text, emphasizing the need for further exploration and refinement of feature engineering strategies to effectively address this evolving domain.

8 Acknowledgments

This submission has been carried out as part of the 2023-2024 edition of the master course Shared Task Information Science (LIX026M05) at the University of Groningen, taught by Lukas Edman and Antonio Toral. We want to humbly express our sincerest gratitude to both Antonio Toral Ruiz and Lukas Edman for their help and support during this task.

We thank the Center for Information Technology of the University of Groningen for their support and for providing access to the Hábrók high-performance computing cluster.

Finally, we would like to express our sincere gratitude to the Erasmus Mundus Masters Program in Language and Communication Technologies (LCT) for supporting students who participated in this project.

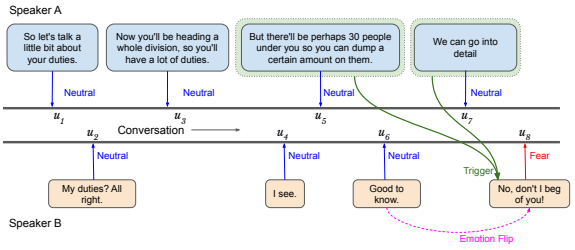
tanchak@iitd.ac.in

Abstract

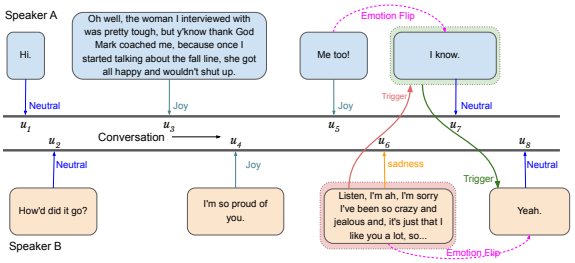
We present SemEval-2024 Task 10, a shared task centred on identifying emotions and finding the rationale behind their flips within monolingual English and Hindi-English code-mixed dialogues. This task comprises three distinct subtasks – emotion recognition in conversation for code-mixed dialogues, emotion flip reasoning for code-mixed dialogues, and emotion flip reasoning for English dialogues. Participating systems were tasked to automatically execute one or more of these subtasks. The datasets for these tasks comprise manually annotated conversations focusing on emotions and triggers for emotion shifts.[1] A total of 84 participants engaged in this task, with the most adept systems attaining F1-scores of 0.70, 0.79, and 0.76 for the respective subtasks. This paper summarises the results and findings from 24 teams alongside their system descriptions.

1 Introduction

In pursuit of one of AI's ultimate objectives, i.e., emulating human behaviour, machines must comprehend human emotions (Ekman, 1992; Picard, 1997). Consequently, Emotion Recognition in Conversation (ERC) has emerged as a vibrant domain within NLP (Hazarika et al., 2018b,a; Zhong et al., 2019; Ghosal et al., 2019; Jiao et al., 2020). The significance of emotion detection amplifies particularly during shifts in the speaker's emotional state. However, merely identifying an emotional transition is insufficient; understanding the catalyst behind the shift is crucial for facilitating informed decisions by other speakers. For instance, identifying the utterance responsible for a customer's transition from a positive emotional state (e.g., joy) to a negative one (e.g., disgust) due to a flawed dialogue system is critical in customer service. Such



(a) Emotion-flip is caused by more than one utterance.



(b) Emotion-flip is caused by the previous utterance. Out of five emotion-flips, we show only two of them ($u_5 \rightarrow u_7$ and $u_6 \rightarrow u_8$) for brevity. Other emotion-flips are $u_1 \rightarrow u_3$, $u_2 \rightarrow u_4$, and $u_4 \rightarrow u_6$ with triggers u_3, u_3, and u_6, respectively.

Figure 1: Examples of emotion-flip reasoning.

insights can serve as feedback to the dialogue system, enabling it to avoid (negative emotion-flip) or replicate (positive emotion-flip) similar utterances to enhance the customer experience in the future.

Emotion-Flip Reasoning (EFR), as outlined by Kumar et al. (2021), presents a novel endeavour aimed at pinpointing the trigger utterances responsible for an emotion-flip within the context of a multi-party conversation. Figure 1 provides illustrative scenarios depicting the essence of EFR. In Figure 1a, Speaker B undergoes a transition in emotion (*neutral→fear*) between utterances u_6 and u_8. Notably, this emotional shift can be attributed to the contributions of Speaker A through utterances u_5 and u_7. The fundamental objective of this task is to discern these trigger utterances (u_5 and u_7) given a target emotion-flip utterance (u_8) and the context preceding it ($u_1 \ldots u_7$).

As an effort to advance research within the do-

[1]The task data is available at https://github.com/LCS2-IIITD/EDiReF-SemEval2024.git.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1933–1946

main of ERC and EFR, this shared task at SemEval 2024 (Ojha et al., 2024) seeks to assess the efficacy of NLP systems in automatically addressing both of these tasks. Furthermore, as technological applications extend beyond English to encompass non-English, multilingual, and code-mixed populations, there is a growing need to broaden the scope of research. To support this cause and further the exploration of code-mixed languages, we advocate for the inclusion of ERC and EFR tasks within Hindi-English (Hinglish) code-mixed conversations. Specifically, the shared task is segmented into three distinct subtasks:

- ***Task A* – ERC in Hindi-English code-mixed conversation:** Given a multiparty code-mixed conversation, tag each utterance with one of the eight emotion labels – *anger*, *disgust*, *fear*, *sadness*, *surprise*, *joy*, *contempt*, and *neutral*.
- ***Task B* – EFR in Hindi-English code-mixed conversation:** Given a multiparty code-mixed conversation along with emotions for each utterance, the goal is to identify the trigger utterance for each emotion-flip in the dialogue.
- ***Task C* – EFR in English conversation:** It is similar to Task B but in monolingual English.

The decision to omit ERC for monolingual English stems from its thorough examination and the abundance of available datasets. Conversely, ERC in Hindi-English code-mixed conversation remains relatively unexplored, and as far as we are aware, no other dataset besides the one outlined in this article is publicly accessible.

Further elaboration on our task data and setting is provided in Sections 3 and Section 4, respectively. The participating teams are outlined in Section 5, with their task outcomes and assessments detailed in Section 6.

2 Related Work

Emotion recognition. Identifying emotions has been a focal point in prior research, with investigations into emotion analysis (Ekman, 1992; Picard, 1997; Cowen and Keltner, 2017; Mencattini et al., 2014; Zhang et al., 2016; Cui et al., 2020) initially centring on standalone inputs devoid of contextual cues. However, recognising the significance of contextual information, the emphasis shifted towards emotion detection within conversations, particularly ERC. Initially, ERC was tackled using heuristic approaches and conventional machine learning techniques (Fitrianie et al., 2003; Chuang and Wu, 2004; Li et al., 2007). However, the recent trend has witnessed a transition towards the adoption of a diverse array of deep learning methodologies (Hazarika et al., 2018a; Zhong et al., 2019; Li et al., 2020; Ghosal et al., 2019; Jiao et al., 2020; Hazarika et al., 2021; Shen et al., 2020; Poria et al., 2017; Jiao et al., 2019; Tu et al., 2022; Yang et al., 2022; Ma et al., 2022).

Emotion and code-mixing. Current studies addressing emotion analysis in code-mixed language primarily centre around isolated social media texts (Sasidhar et al., 2020; Ilyas et al., 2023; Wadhawan and Aggarwal, 2021) and reviews (Suciati and Budi, 2020; Zhu et al., 2022). Despite examinations into aspects like sarcasm (Kumar et al., 2022a,b), humour (Bedi et al., 2023), and offence (Madhu et al., 2023) within code-mixed conversations, the domain of emotion analysis remains largely uncharted, lacking pertinent literature, to the best of our knowledge. Our objective is to address this gap by delving into the under-explored realm of ERC, specifically within Hindi-English code-mixed dialogues in this shared task.

Beyond emotion recognition. The interpretability of emotion recognition within the linguistic domain represents a relatively uncharted avenue of research, with only a limited number of studies delving into this field. Previous works by Lee et al. (2010); Poria et al. (2021); Wang et al. (2023) have focused on investigating the root causes of expressed emotions in text, commonly referred to as 'emotion-cause analysis.' This task involves identifying a specific span within the text that elicits a particular emotion. While on an abstract level, both emotion-cause analysis and emotion-flip reasoning tasks may appear interconnected, they diverge significantly in practice. Emotion-cause analysis aims to pinpoint phrases within the text that provide clues or triggers for the expressed emotion. In contrast, our proposed EFR task pertains to conversational dialogues involving multiple speakers, with the objective of extracting the causes (Kumar et al., 2023a) or triggers behind emotional transitions for a speaker. The triggers comprise one or more utterances from the dialogue history, as illustrated in the two examples in Figure 1.

In this shared task, we tackle the challenge of automatically performing the task of ERC and EFR for code-mixed and monolingual English dialogues in order to further this research direction.

Table 1: Statistics of the English and Hindi datasets for ERC and EFR.

3 Data

English Conversations: We extend MELD (Poria et al., 2019), an established ERC dataset comprising monolingual English dialogues, by incorporating annotations for emotion-flip reasoning. These dialogues are sourced from the popular TV series *F.R.I.E.N.D.S*[2]. Each utterance u is attributed to a specific speaker s and assigned an emotion label $e \in$[*anger*, *disgust*, *fear*, *sadness*, *surprise*, *joy*, *neutral*]. In the context of a speaker's emotional transition, we designate and label trigger utterances as 1 if they induce the speaker's emotional shift – the emotion alters from the speaker's preceding utterance within the same dialogue. In contrast, a label 0 indicates that the utterance bears no responsibility for the emotional transition.

To facilitate the annotation of triggers, we establish a set of guidelines outlined below. Within this framework, a ***trigger*** is defined as any utterance within the contextual history of the target utterance (the utterance for which the trigger is to be identified) meeting the following criteria:

1. An utterance, or part thereof, directly influencing a change in emotion of the target speaker is designated as the trigger.
2. The speaker of the trigger utterance may be different from or the same as the target speaker.
3. The target utterance itself may qualify as a trigger utterance if it contributes to the emotional transition of the target speaker. For instance, if an individual's emotion shifts from *neutral* to *sad* due to conveying a sad message, then the target utterance is deemed responsible for the transition.
4. Multiple triggers may be accountable for a single emotional transition.
5. In cases where the rationale behind an emotional transition is not identifiable from the data, no utterance should be labelled as a trigger.

In total, we have annotated emotion-flip reasoning for $1,161$ monolingual English conversation dialogues, encompassing $8,387$ trigger utterances across $5,430$ emotion-flip instances. Three annotators carefully annotated these dialogues in accordance with the aforementioned guidelines for trigger identification. Among the three, two annotators were male while one was female, all possessing 3-10 years of research experience within the 30-40 age bracket. We calculated the alpha-reliability inter-annotator agreement (Krippendorff, 2011) between each pair of annotators, yielding $\alpha_{AB} = 0.824$, $\alpha_{AC} = 0.804$, and $\alpha_{BC} = 0.820$. By averaging these scores, we derived an overall agreement score of $\alpha = 0.816$. We call the resultant dataset as `MELD-FR`.

Hindi-English Code-mixed Conversations: For code-mixed tasks, we adhere to identical guidelines as those applied to English, selecting code-mixed conversations from a preexisting dialogue dataset called MaSaC (Bedi et al., 2023). The dialogues in the dataset are sourced from the popular Indian TV series '*Sarabhai vs Sarabhai*'[3]. Further, we annotated $11,908$ utterances spanning 449 dialogues, encompassing eight emotion labels (including '*contempt*' alongside the six basic emotions and *neutral*) for the ERC task, achieving a Krippendorff alpha-reliability inter-annotator agreement (Krippendorff, 2011) of 0.85. In the context of EFR, we annotated $7,550$ trigger utterances for $5,873$ emotion-flip occurrences. Mirroring our approach with the English dataset, we engaged experts fluent in both Hindi and English to ensure accuracy. As

[2] https://www.imdb.com/title/tt0108778/

[3] https://www.imdb.com/title/tt1518542/

a measure of quality assurance, the Krippendorff alpha-reliability inter-annotator agreement stands at $\alpha = 0.853$. The resultant dataset is denoted as E-MASAC and EFR-MASAC for the ERC and EFR tasks, respectively. A concise overview of both datasets is presented in Table 1.

4 Task and Background

The idea of the presented shared task is to delve into ERC and EFR within the domain of English and code-mixed dialogues. This section delves into our preliminary investigations for the three subtasks entailed in this collaborative endeavour.

4.1 Shared Task Settings

Task A. In the task of ERC within code-mixed dialogues, participants receive textual utterances as input along with their respective speakers for each dialogue. Their objective is to develop systems capable of autonomously predicting the emotion labels for each utterance. Essentially, the system is presented with a dialogue $D_{erc} = \{(s_1, u_1), (s_2, u_2), ..., (s_n, u_n)\}$, and it must anticipate the emotions e_i for each utterance u_i uttered by speaker s_i. Weighted F-1 score of the emotion classification is used as the evaluation metric for the task of ERC.

Task B. For the code-mixed EFR task, participants receive dialogues along with their corresponding utterances, speakers, and emotions, presented in the format $D_{efr} = \{(s_1, u_1, e_1), (s_2, u_2, e_2), ..., (s_n, u_n, e_n)\}$. Their objective is to anticipate trigger utterances, T, from the context whenever a speaker undergoes an emotion flip. In other words, $T \in \{u_i, ..., u_j\}$ if $s_i = s_j$ and $e_i \neq e_j$. The evaluation metric of choice for this task is the F1 score obtained for trigger utterances.

Task C. The input modelling for Task C mirrors that of Task B, as both tasks revolve around EFR. Here, the data comes from the `MELD-FR` dataset and is present in Monolingual English. Just like Task B, the evaluation is conducted based on the F1 score achieved for trigger utterances.

4.2 Pilot Study

Task A. Our preliminary investigation for the task of ERC in code-mixed setting (Kumar et al., 2023b), we integrate commonsense knowledge with the dialogue representation acquired from a backbone architecture designed for dialogue understanding. We leverage the COMET graph (Bosselut et al., 2019) to extract commonsense knowledge, and subsequently employ context-aware attention (Yang et al., 2019) to integrate this information with the dialogue context. This adaptable module, when combined with RoBERTa (Liu et al., 2019), yields a weighted average F1-score of 0.44 in performance.

Task B. For evaluating the feasibility of our second subtask, we employ FastText multilingual word embeddings[4] for the tokens and perform classification using the proposed model for Task C to obtain an F1-score of 0.27 for trigger identification.

Task C. In our initial exploration (Kumar et al., 2021), we explored a memory-network and transformer-based architecture to address each occurrence of emotion-flip. This approach yielded a trigger-F1 score of 0.53. While these findings surpassed various baselines, the overall performance remains inadequate from a practical standpoint, with an error rate of approximately 50%.

5 Participants

A total of 84 participants engaged in the CodaLab competition organised for the shared task[5], with 24 teams (Shaik et al., 2024; V et al., 2024; Liang et al., 2024; Venkatesh et al., 2024; Yenumulapalli et al., 2024; Niță and Păiș, 2024; Moctezuma et al., 2024; Vyas, 2024; Tareh et al., 2024; Garcia et al., 2024; Wan et al., 2024; Abootorabi et al., 2024; Patel et al., 2024; Siino, 2024; Nguyen and Zhang, 2024; Vaidya et al., 2024; Takahashi, 2024; Alexandru et al., 2024; Rajesh et al., 2024; Shanbhag et al., 2024; Creanga and Dinu, 2024; pan et al., 2024) submitting papers describing their systems. Among the submissions, a prevailing trend emerges with the widespread adoption of Large Language Models (LLMs) such as BERT (Devlin et al., 2018), RoBERTa (Liu et al., 2019), GPT (Radford et al., 2019), LLaMa (Touvron et al., 2023), and Mistral (Jiang et al., 2023). Techniques such as fine-tuning, instruction tuning, ensembling, and prompting significantly contribute to enhanced performance in the task. Moreover, many approaches utilise machine learning-based methods including linear regression and SVM. Additionally, some studies explore statistical and rule-based methods such as TF-IDF. While LLMs dominate the approaches for both ERC and EFR, machine learning methods

[4] https://fasttext.cc/docs/en/crawl-vectors.html

[5] https://codalab.lisn.upsaclay.fr/competitions/16769

also remain popular among the participants. Furthermore, there appears to be a notable preference among teams for Task A over Tasks B and C, as evidenced by the higher participation in Task A compared to the latter two. An overview of the top-performing models from various teams for ERC is provided in Table 2, while Table 3 presents the systems for EFR. We summarize some of the techniques used by the top performing systems below.

Using LLMs There exists a prevalent preference for LLMs among teams addressing the ERC and EFR tasks, with approximately 18 methods leveraging LLMs for these endeavours. Notably, BERT and its variants emerge as the most favoured models. Some teams explore larger open-source language models like Zephyr (Tunstall et al., 2023) and Mistral, while at least one team delves into closed-source alternatives such as GPT3.5 (Brown et al., 2020). In the realm of ERC, the leading system (refer to Table 4) integrates DistilBERT (Sanh et al., 2020) with classical machine learning techniques to execute emotion classification optimally. Although the authors experiment with BERT, RoBERTa, and GPT-4 (OpenAI et al., 2023), their most effective model combines DistilBERT with classical ML algorithms. They adopt a two-step approach, initially extracting contextual features from dialogues using an LLM, then inputting these features into classical ML algorithms such as random forests, SVM, logistic regression, and Naive Bayes. Notably, DistilBERT outperforms GPT-4, possibly attributed to the latter's extensive parameter count, necessitating substantial data for meaningful learning. However, our Task A dataset (E-MASAC) encompasses only $\sim$ 8500 utterances, limiting the efficacy of larger models. Conversely, lighter models like DistilBERT exhibit superior adaptability with limited data, capturing nuanced patterns effectively. This finding aligns with observations from various teams, including BITS Pilani, where BERT outperforms Llama.

For the task of EFR as well, LLMs appear to be the predominant choice among the teams. However, intriguingly, the most effective model for this task (refer to Table 5) adopts a classical machine learning approach - XGBoost. Further elaboration on this aspect is provided in Section 6.2.

Classical machine learning and deep learning methods Efficiently capturing context information is crucial in modelling conversations. Several teams explored this aspect, utilising Recurrent Neural Networks (RNNs) like LSTMs and GRUs. Specifically, at least three teams have integrated GRU with Transformers to enhance context capture. Conversely, team TECHSSN adopts a simpler approach, employing LSTM with intelligent embedding layers for both ERC and EFR tasks. However, these methods frequently fall short in comparison to utilising pre-trained LLMs, as outlined in Section 6.2.

Rule-based and statistical methods The surge in deep learning's popularity can be attributed to the remarkable advancements in LLMs. This has led to a decline in the usage of traditional rule-based or statistical approaches, despite their potential to perform comparably in certain scenarios

Rank	Team Name	Results
3	IASBS (Tareh et al., 2024)	0.70

alongside more intricate machine learning or deep learning methods. It was pleasant to observe numerous teams incorporating such traditional techniques into this shared task. Notably, at least four teams opted for methods like Bag of Words, TF-IDF, NER based, and rule based approaches. While these methods may not excel in the ERC task, they surprisingly demonstrate superiority in the EFR task. This is reasoned in detail in Section 6.2.

6 Results

In this section, we delve into the outcomes achieved by the participating teams in the shared task outlined earlier. Initially, we will examine the results submitted by the 24 teams, which provided detailed descriptions of their systems. Subsequently, we will present the leaderboard, showcasing the performance rankings of all participants.

6.1 Task A: ERC in Hindi-English code-mixed conversation

The results for Task A are compiled in Table 4. Out of the 24 submitted papers, 22 teams explored the code-mixed ERC task, attaining weighted F1 scores spanning from 0.70 to 0.18. Notably, the foremost twelve teams, up to SSN_Semeval10, opted for LLMs as their architectural preference, yielding top performances. Following closely, RNN-based approaches such as LSTM and classical ML methods like SVM emerged as the subsequent choices. A notable observation is the substantial disparity (approximately 37%) in performance between the leading model and the succeeding system.

Rank	Team Name	Results
1	TW-NLP (Tian et al., 2024)	0.79
2	Innovators (Shanbhag et al., 2024)	0.79
2	UCSC NLP (Wan et al., 2024)	0.79
2	GAVx (Nguyen and Zhang, 2024)	0.79
3	FeedForward (Shaik et al., 2024)	0.77
5	IITK (Patel et al., 2024)	0.56
6	UMUTeam (pan et al., 2024)	0.26
7	IASBS (Tareh et al., 2024)	0.12
9	SSN_ARMM (S et al., 2024)	0.11
11	TECHSSN (V et al., 2024)	0.1
21	YNU-HPCC (Liang et al., 2024)	0.01

Table 5: Results for Task B. F1 score for trigger utterances is our metric of choice. Rank is as mentioned in CodaLab. Team Name is as mentioned in the corresponding system description.

Both leading teams relied on LLMs as their primary architectural framework, yet IASBS diverged by integrating classical ML methods. Their innovative two-phase strategy, combining LLMs for contextual representations and ML techniques for classification, evidently yielded significant improvements. Conversely, the subsequent top model utilised LLMs without any ensembling. Team FeedForward, securing fifth place on the CodaLab leaderboard for Task A, implemented instruction-based finetuning and quantized low-rank adaptation alongside novel techniques like sentext-height and enhanced prompting strategies.

Another intriguing observation arises from the marginal discrepancy (approximately 2%) between strategies based on LLMs and those employing classical ML techniques. Team SSN_Semeval10 refined a BERT classifier, achieving a weighted F1-score of 0.40. Conversely, team Hidetsune took a different approach by translating all code-mixed data into English and employing data augmentation to bolster the 'English'-based ERC dataset. Subsequently, they trained a SpaCy-v3[6] classifier, resulting in a weighted F1-score of 0.39.

6.2 Task B – EFR in Hindi-English code-mixed conversation

Table 5 presents the outcomes for Task B, wherein the highest performance attained a trigger F1-score

[6] https://spacy.io/

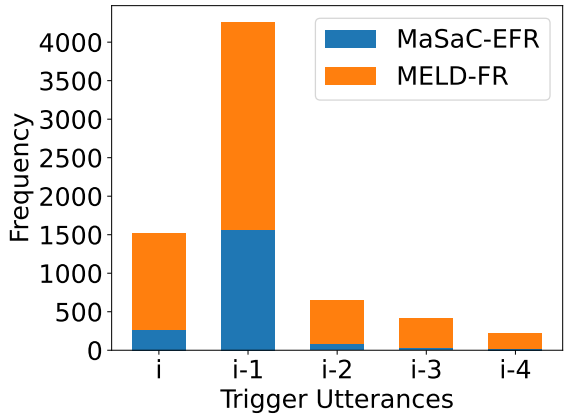

Figure 2: Distribution of triggers for the last four utterances from the trigger utterance i.

Rank	Team Name	Results
2	GAVx (Nguyen and Zhang, 2024)	0.76
3	FeedForward (Shaik et al., 2024)	0.74
5	TW-NLP (Tian et al., 2024)	0.71
7	Innovators (Shanbhag et al., 2024)	0.68
8	UCSC NLP (Wan et al., 2024)	0.68
10	IITK (Patel et al., 2024)	0.6
11	SSN_ARMM (S et al., 2024)	0.26
12	IASBS (Tareh et al., 2024)	0.25
13	TECHSSN (V et al., 2024)	0.24
15	UMUTeam (pan et al., 2024)	0.22
26	YNU-HPCC (Liang et al., 2024)	0.07

Table 6: Results for Task C. F1 score for trigger utterances is our metric of choice. Rank is as mentioned in CodaLab. Team Name is as mentioned in the corresponding system description.

of 0.79. Particularly intriguing is the fact that the leading four teams achieved identical F1-scores, with the top two teams opting for conventional ML and rule-based approaches. This phenomenon stems from the common occurrence wherein a speaker's emotional shift in a conversation at utterance i is predominantly triggered by the $i-1$ utterance. This pattern underscores the significance of the preceding utterance as a trigger. Illustrated in Figure 2 is the trigger distribution within the dialogues of EFR-MASAC and MELD-FR. Evidently, the majority of trigger utterances are the $i-1^{th}$ utterances. Employing XGBoost for trigger classification, the leading team, TW-NLP, secured their position, while the second-ranking team opted for a rule-based approach, designating all $i-1$ utterances as triggers. This strategy led to the attainment of the highest score of 0.79 F1.

6.3 Task C – EFR in English conversation

The outcomes for Task C are displayed in Table 6, revealing the top-performing system achieving an F1 score of 0.76 for the triggers. Impressively, the subsequent results closely trail the best one, exhibiting only a marginal gap of approximately $2\% to 4\%$. Notably, the leading two performers in the task predominantly utilise methods employing LLMs, while the third-best performance is attributed to XGBoost. Illustrated in Figure 2, MELD-FR also grapples with a skewed distribution of trigger utterances, thereby resulting in comparable performances between LLMs and ML-based systems.

6.4 Findings by Participants

Challenge of code-mixing. The dataset utilised in this shared task encompasses Hindi-English code-mixed instances for subtasks A and B, presenting the most formidable challenge of the competition. To address this hurdle, several teams, including TransMistral, FeedForward, and Hidetsune, opted for translation, converting all code-mixed instances into monolingual English before engaging in any classification process. Additionally, teams such as TW-NLP leveraged multilingual LLMs like MBERT to effectively manage code-mixed input.

Effect of data augmentation. Machine learning and deep learning techniques exhibit an insatiable appetite for data, giving rise to circumstances where an abundance of data tends to correlate with improved performance. In light of this conjecture, several teams, including Hidetsune, ventured into experimenting with data augmentation for the ERC task. The general observation revealed an enhancement in performance with the incorporation of more data during model training.

Required context for classification. Emotions are fleeting and are typically influenced by the immediate circumstances in which the speaker finds themselves. As a result, the nearby utterances within a dialogue exert a more pronounced impact on determining the emotional nuances of a speaker compared to utterances further removed in context. This phenomenon is depicted in Figure 2. Consequently, teams such as FeedForward and IITK initially ascertain the requisite extent of context needed for conducting ERC, before proceeding with classification, taking the computed context into consideration.

Challenge of implicit triggers. Emotion flips can generally be attributed to two scenarios: firstly, when something uttered in the dialogue directly prompts the emotion flip, constituting explicit triggers; and secondly, when events external to the

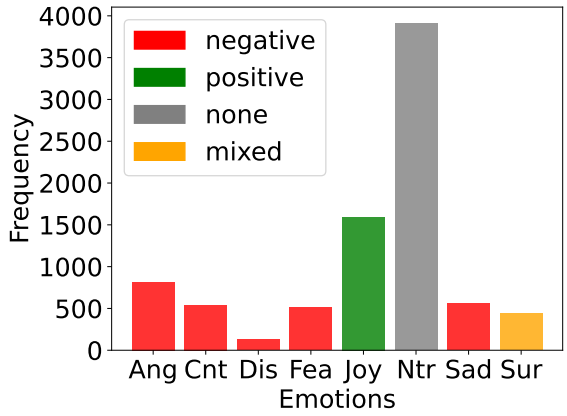

Figure 3: Emotion distribution in E-MASAC. The colors depict the distribution of emotions capturing positive, negative, mixed, and no feelings (Abbreviations: Ang: Anger, Cnt: Contempt, Dis: Disgust, Fea: Fear, Ntr: Neutral, Sad: Sadness, Sur: Surprise).

dialogue, such as an act of theft, occur without explicit mention in the dialogue, representing implicit triggers. In both the EFR-MASAC and MELD-FR datasets, instances of implicit triggers exist where no trigger utterances are marked in the dialogue. These instances present a challenge for the learned models of several teams, including GAVx.

Negative vs positive emotions. The dataset E-MASAC utilises Ekman emotions (Ekman, 1992) as its set of emotion labels, encompassing six emotions and one label for neutral emotions. These emotions include Anger, Contempt, Disgust, Fear, Joy, Neutral, Sadness, and Surprise. Notably, among these emotions, five portray negative feelings (Anger, Contempt, Disgust, Fear, and Sadness), while only one represents positive emotions (Joy). Surprise, on the other hand, can convey either positive or negative emotions depending on the context. Figure 3 displays the distribution of these emotions within E-MASAC. It's evident that as there's only one category for positive emotions, all such instances are classified as joy, leading to a higher frequency of joy compared to other emotions. Moreover, the neutral category has the most instances compared to the others. Consequently, many teams, like IITK, have noted that their models perform better for the neutral and joy labels than for any other emotion.

6.5 Leaderboard

In this paper, we have exclusively examined the outcomes of participants who provided a description of their system(s) for the shared task. The complete array of ranks, team names, and results

Table 7: Leaderboard from CodaLab. Rank for each task is mentioned in parenthesis. Top three systems are highlighted in green, yellow, and orange.

of the participants in the CodaLab competition, encompassing users who didn't submit a system description, is depicted in Table 7. Although not all teams attempted all three tasks, however, they obtained some score in the leaderboard since they submitted some values for the output. A glimpse at the leaderboard reveals that the best performance for tasks A, B, and C stood at 0.78, 0.79, and 0.79, respectively. One, four, and one team(s) achieved best performance of the three tasks.

7 Conclusion

This paper outlines SemEval 2024 Task 10, covering its goals, data, participants, and results. It

includes three subtasks: emotion identification in code-mixed dialogues and pinpointing triggers for emotion shifts in code-mixed and English dialogues. 84 participants competed on CodaLab, with 24 teams submitting system description papers. Top systems for Tasks A and C used LLM-based architectures, while Task B favored standard ML techniques. Leading systems achieved F1 scores of 0.70, 0.79, and 0.76 across subtasks, indicating impressive performance but also highlighting ongoing challenges for future research.

Abstract

Large Language Models (LLMs) are at the forefront of NLP achievements but fall short in dealing with shortcut learning, factual inconsistency, and vulnerability to adversarial inputs. These shortcomings are especially critical in medical contexts, where they can misrepresent actual model capabilities. Addressing this, we present SemEval-2024 Task 2: Safe Biomedical Natural Language Inference for Clinical Trials. Our contributions include the refined NLI4CT-P dataset (i.e. Natural Language Inference for Clinical Trials - Perturbed), designed to challenge LLMs with interventional and causal reasoning tasks, along with a comprehensive evaluation of methods and results for participant submissions. A total of 106 participants registered for the task contributing to over 1200 individual submissions and 25 system overview papers. This initiative aims to advance the robustness and applicability of NLI models in healthcare, ensuring safer and more dependable AI assistance in clinical decision-making. We anticipate that the dataset, models, and outcomes of this task can support future research in the field of biomedical NLI. The dataset[1], competition leaderboard[2], and website[3] are publicly available.

1 Introduction

Large Language Models (LLMs) excel in numerous Natural Language Processing (NLP) tasks, as evidenced by their state-of-the-art achievements (Brown et al., 2020; Chowdhery et al., 2022). Despite these advancements, LLMs are prone to several critical vulnerabilities. These include a tendency towards shortcut learning, which may compromise their learning process and accuracy (Geirhos et al., 2020; Poliak et al., 2018; Tsuchiya, 2018). Additionally, they exhibit factual inconsistencies (Elazar et al., 2021) and are sensitive to changes in word distributions (Miller et al., 2020; Lee et al., 2020), data transformations (Xing et al., 2020; Stolfo et al., 2022; Meadows et al., 2023; Rozanova et al., 2023), and adversarial attacks (Li et al., 2020). These issues are particularly concerning as they may lead to an overestimation of LLMs' capabilities in practical applications, a risk that is notably significant in fields requiring high reliability, such as healthcare (Patel et al., 2008; Recht et al., 2019).

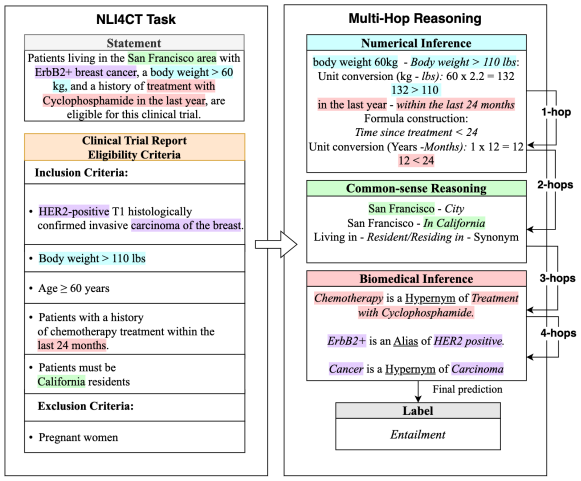

Figure 1: The goal of NLI4CT is to predict the relationship of entailment between a **Statement** and a **CTR** premise (Jullien et al., 2023a). In this task, we introduce a set of perturbations (NLI4CT-P) applied to the statements to test the semantic consistency and faithfulness of NLI models.

Clinical trials play a pivotal role in evaluating the efficacy and safety of novel treatments, thereby significantly contributing to the progress of experimental medicine (Avis et al., 2006). Clinical Trial Reports (CTRs) document the methodologies and outcomes of these trials, serving as a foundation for healthcare professionals to devise and administer experimental therapies. However, the sheer volume

[3]https://sites.google.com/view/nli4ct/

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1947–1962
June 20-21, 2024

of CTRs, exceeding 400,000 and continually growing (Bastian et al., 2010), renders it impractical for a manual comprehensive analysis of all pertinent literature in treatment planning (DeYoung et al., 2020). In this context, Natural Language Inference (NLI) (Bowman et al., 2015) emerges as a viable solution, facilitating the large-scale interpretation and synthesis of medical evidence. This approach effectively bridges the latest research findings with clinical practice, thereby supporting the delivery of personalized care (Sutton et al., 2020).

Previously, we created the Multi-Evidence Natural Language Inference for Clinical Trial Reports (NLI4CT) dataset, detailed in Jullien et al. (2023a). This dataset, enriched with Clinical Trial Reports (CTRs) and expert-annotated statements for entailment and contradiction, exemplified in Figure 1, served as the foundation for organizing "SemEval-2023 Task 7: Multi-Evidence Natural Language Inference for Clinical Trial Data".

While the preceding version of NLI4CT spurred the creation of models based on Large Language Models (LLMs) (Zhou et al., 2023; Kanakarajan and Sankarasubbu, 2023; Vladika and Matthes, 2023) that demonstrated commendable performance (i.e., F1 score $\approx 85\%$), deploying LLMs in sensitive areas like real-world clinical trials mandates additional scrutiny. This necessitates the invention of new evaluation frameworks that allow thorough behavioural and causal analysis (Wang et al., 2021).

In pursuit of these goals, we present the latest iteration of our dataset, NLI4CT-P, an extension of the original NLI4CT with data perturbations. Moreover, we provide a comprehensive analysis of the systems that participated in "SemEval-2024 Task 2: Safe Biomedical Natural Language Inference for Clinical Trials" a task conducted using the NLI4CT-P dataset. This initiative aims to improve our understanding of LLMs behaviour and advance evaluation methodologies for clinical Natural Language Inference (NLI).

The task is structured around the systematic application of controlled interventions, each designed to investigate specific semantic and numerical inference challenges typical of clinical NLI (see Table 1). The interventions enable a comprehensive evaluation of LLMs' reasoning capabilities within a clinical framework, emphasizing robustness, consistency, and faithfulness.

Our efforts aim to significantly contribute to the crafting of more dependable and insightful evaluation standards and metrics for NLI systems, ensuring their reliability and efficacy in healthcare applications.

Original Statement: The primary trial intervention protocol lasts a total of 14 days.
Label: Entailment

Perturbed Statement	Intervention	Type
The primary clinical trial's intervention treatment plan has a duration of 14 days.	Paraphrase	Preserving
The primary clinical trial intervention protocol spans an entire year	Contradiction rephrasing	Altering
Lacks energy refers to whether an individual has/had a lack of energy. The primary trial intervention protocol lasts a total of 14 days	Text appended	Preserving
The primary trial intervention protocol lasts 2 weeks	Numerical paraphrase	Preserving
The primary trial intervention protocol lasts a total of 3 hours	Numerical contradiction	Altering

Table 1: Example of perturbations applied to the statements with the type of intervention and its semantic effect (i.e., preserving vs. altering).

This second iteration is intended to ground NLI4CT in interventional and causal analyses of NLI models (YU et al., 2022). By enriching the original NLI4CT dataset with a novel contrast set derived from targeted interventions to statements in the NLI4CT test and development sets, we establish a direct causal link between these interventions and the anticipated labels. This enhancement introduces two innovative metrics, Consistency and Faithfulness. These metrics allow us to explore specific research objectives with a causal perspective:

- **Consistency:** To examine whether NLI models maintain uniformity in processing semantically equivalent phenomena crucial for inference within clinical NLI contexts.
- **Faithfulness:** To assess the capacity of NLI models to capture and interpret the underlying semantic features required for reasoning over clinical trials, and to change their predictions according to relevant changes of such features.

This paper introduces SemEval-2024 Task 2 – Safe Biomedical Natural Language Inference for Clinical Trials – (NLI4CT-P) presenting a detailed analysis of the performance of the participating systems. We report the following conclusions:

Challenges in Clinical NLI: Despite improvements achieved via the application of Large Language Models (LLMs), Clinical NLI remains a significant challenge. With the highest F1 score achieved in this task being 0.8 (Liu and Thoma, 2024; Guimarães et al., 2024) (FZI-WIM, Lisbon Computational Linguists), leveraging Mixtral-8x7B-Instruct models. This emphasises the necessity for the development of more robust and reliable systems capable of dealing with the challenges of real-world clinical application.

Importance of Faithfulness and Consistency Evaluation: The incorporation of Faithfulness and Consistency metrics into our evaluation framework underscores the unpredictability of current systems and the limitations inherent in relying solely on F1 score for comprehensive analysis.

Superiority of Generative Models: Generative models have been shown to outperform discriminative models in terms of F1 score (+0.025), Faithfulness (+0.15), and Consistency (+0.037).

Value of Additional Data: Leveraging additional training data in the form of instruction tuning or medical NLI datasets has been shown to produce significant performance gains. When augmented with extra data, systems exhibit notable enhancements, recording improvements of +0.056 in F1 score, +0.132 in Faithfulness, and +0.062 in Consistency relative to their counterparts.

Impact of Prompting Strategies: The study highlights that the choice of prompting strategy plays a crucial role in influencing model performance. Specifically, zero-shot prompting has been shown to provide notable enhancements, with an average increase of +0.025 in F1 score, and marginal gains of +0.001 in both Faithfulness and Consistency, compared to the outcomes achieved with few-shot prompting techniques.

Efficacy of Mid-Sized Architectures: Mid-sized architectures, possessing 7B to 70B parameters, offer a cost-effective alternative capable of matching or surpassing larger models in key performance metrics like F1, Faithfulness, and Consistency. Compared to models exceeding 70B parameters, these mid-sized models report a slight improvement of +0.01 in F1 score, albeit with minor reductions of -0.03 in Faithfulness and -0.01 in Consistency. Against models below 7B parameters, however, they show notable enhancements, achieving +0.10 in F1 score, +0.40 in Faithfulness, and +0.19 in Consistency.

2 Task Description

SemEval-2024 Task 2 is a textual entailment task, each instance in NLI4CT contains a CTR premise and a related statement. These premises range from 5 to 500 tokens in length and provide details about a trial's results, eligibility criteria, interventions, or adverse events. Corresponding statements are concise sentences, containing 10 to 35 tokens, that make some claim about the premise information (refer to Table 1 for examples). The task is to classify the inference relation between a CTR premise, and a statement as either entailment or contradiction, exemplified in Figure 1 The dataset features two distinct types of instances: single instances, where a statement discusses a single CTR, and comparison instances, which involve statements that compare and contrast two CTRs.

3 Dataset

The premises used in the NLI4CT dataset (Jullien et al., 2023a) are derived from 1,000 publicly accessible, English-language breast cancer Clinical Trial Reports (CTRs) published on ClinicalTrials.gov a resource managed by the U.S. National Library of Medicine. This dataset complies with the Health Insurance Portability and Accountability Act (HIPAA) Privacy Rule. The original NLI4CT collection includes 2,400 expert-annotated statements, premises and associated labels. These are distributed across training, testing, and development sets in a 70/20/10 ratio.

We have advanced the methodology of the previous NLI4CT dataset by incorporating interventions to create a contrast set, enabling a systematic behavioural and causal analysis of models evaluated in the competition. This enhanced version is referred to as NLI4CT-P (Perturbed). The construction of the contrast set involves four semi-automated, controlled interventions applied to the statements from the NLI4CT test and development set. It's important to note that the specifics of these interventions were kept undisclosed until the completion of the competition's testing phase on January 31st 2024.

3.1 Interventions

We delineate and implement the four interventions in the following manner:

Paraphrasing and Contradiction Rephrasing Clinical texts frequently contain acronyms and aliases, which can hinder the performance of clinical NLI models (Grossman Liu et al., 2021; Jimeno-Yepes et al., 2011; Pesaranghader et al., 2019; Jin et al., 2019). Moreover, these models can fall prey to shortcut learning, where they make inferences based on syntactic patterns rather than semantic understanding (Geirhos et al., 2020). To evaluate this phenomenon, original statements were rephrased using different vocabulary and syntax. Paraphrasing was employed to retain the original meaning and label (row 1 Table 1), while contradiction rephrasing created new statements that directly contradict the original statement, and are therefore always labelled as contradictions (row 2 Table 1).

Numerical Paraphrasing and Contradiction Large Language Models (LLMs) have shown limitations in consistent numerical and quantitative reasoning (Patel et al., 2021; Ravichander et al., 2019; Galashov et al., 2019), an essential aspect for tasks like NLI4CT that demand such inferences. To evaluate the models' capabilities in this area, operands and numerical units within the hypotheses were altered (rows 4 and 5 Table 1). This modification either preserved or inverted the initial entailment label.

Appending Text LLMs are often challenged by complex reasoning when dealing with extended premise-hypothesis pairs (Liu et al., 2021). We test this in a clinical setting by appending biomedical definitions from the NCI Thesaurus to the original statements (row 3 Table 1). The added definitions, ranging from 15 to 20 tokens in length, almost double the average statement token length. Despite the definitions not being independently verifiable against the premises, these definitions are regarded as 'ground truth', they are universally true and remain neutral in relation to the premises. Since they neither assert nor verify any premise-specific information, within the scope of our task, appending such neutral text is categorized as a 'preserving' intervention.

These interventions, other than the text appending, were performed by prompting ChatGPT 3.5 and Whisper APIs (Brockman et al., 2023) with human-in-the-loop correction to address any errors (Gilardi et al., 2023). Each statement in the test and development sets underwent each type of intervention process three times. This did not extend to the training set, as the aim was to prevent models from learning the patterns of intervention. Although attempts were made to apply numerical paraphrasing and contradiction interventions, they were not always feasible. This was due to the absence of numerical data or units in the original statements, and when the quality of the perturbed statements was deemed substandard, they were excluded during the manual review phase. consequently, this resulted in a markedly reduced count of numerically perturbed statements within the dataset. The prompts used to perform the interventions are available in the appendix.

4 Evaluation

SemEval-2024 Task 2 is devised as a binary classification challenge, with the Macro F1-score being utilized to gauge the foundational performance of the participating systems. This evaluation is conducted on the original NLI4CT test set, serving as a control metric, rather than on the NLI4CT-P test set, which contains exclusively perturbed statements. Although the Macro F1 score is instrumental in measuring overall model performance by highlighting precision and recall across various classes, it inherently lacks the capability to fully capture the sophisticated understanding and reasoning skills essential for effective Natural Language Inference (NLI). Specifically, the F1 score does not assess a model's capacity to adjust to subtle semantic shifts or evaluate the resilience of its predictions when faced with interventions that either modify or maintain the semantic integrity of statements. This gap highlights the necessity for more advanced metrics capable of offering deeper insights into a model's interpretative and reasoning proficiency. In response to this need and inspired by recent advancements in causal analysis within the NLP domain (Stolfo et al., 2022), we introduce two novel evaluation metrics aimed at examining the causal effects of interventions on model performance.

Faithfulness gauges the degree to which a system's predictions are both accurate and grounded in the correct rationale. Intuitively, this is estimated by measuring the ability of a model to correctly adjust its predictions when exposed to interventions that modify the meaning (semantic altering) of the statement. Specifically, for a set of N statements x_i in the contrast set (C), alongside their corresponding original statements y_i and the model predictions denoted as $f()$, faithfulness is quantified using the

Set	Original	Appended definition	Paraphrase	Contradiction rephrasing	Numerical paraphrase	Numerical Contradiction	Total
Dev	200	600	600	600	64	78	1942
Test	500	1500	1500	1500	224	276	5000

Table 2: Distribution of statement counts across the sets of NLI4CT-P

formula presented in Equation 1.

$$Faithfulness = \frac{1}{N}\sum_{1}^{N}|f(y_i) - f(x_i)|$$
$$x_i \in C : \text{Label}(x_i) \neq \text{Label}(y_i), \text{ and } f(y_i) = \text{Label}(y_i) \quad (1)$$

Consistency assesses a system's capability to generate identical outcomes for semantically equivalent inputs. This measure evaluates whether a system can uniformly predict the same label for both the original and contrast statements under interventions that do not alter the semantic content (semantic preserving) of the statements. The key aspect here is the uniformity in representing semantic concepts across different statements, irrespective of the correctness of the final prediction. For N statements x_i in the contrast set (C), alongside their original counterparts y_i, and model predictions $f()$, consistency is determined as follows:

$$Consistency = \frac{1}{N}\sum_{1}^{N}1 - |f(y_i) - f(x_i)| \quad (2)$$
$$x_i \in C : \text{Label}(x_i) = \text{Label}(y_i)$$

The Macro F1 score provides a foundational benchmark for basic model performance, serving as a control metric, the core objective of Task 2 is towards enhancing model quality and dependability through systematic causal analysis. The pursuit here is not only for high performance in a traditional sense but for models that demonstrate a more reliable and robust application of natural language, reflecting a more nuanced approach to evaluating system capabilities, and allowing for developing safer, ethical, and trustworthy clinical systems.

5 Results and Discussion

106 participants registered to the SemEval-2024 Task 2 competition contributing over 1200 individual submissions and 25 system overview papers, presented in Table 3. Please note that our analysis focuses exclusively on systems that are detailed in system overview papers and for which official leaderboard results have been provided. Generally, participants tend to submit the highest-scoring results to the leaderboard, regardless of whether the system achieving these results represents the primary contribution of their paper. This approach ensures that our report reflects the peak performance levels achieved, albeit potentially overlooking the main systems of interest described in the papers.

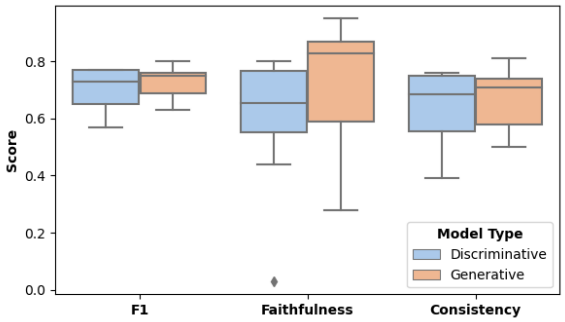

Figure 2: Comparative Analysis of F1, Consistency, and Faithfulness Across Model Types

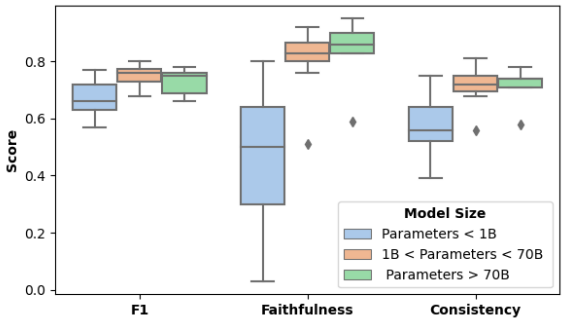

Figure 3: Comparative Analysis of F1, Consistency, and Faithfulness Across Model Parameter Numbers

5.1 Architectures

In the SemEval-2024 Task 2 submissions, a diverse range of 12 different architectures was employed, as detailed in Table 4. The predominant choice among participants was Mistral-based architectures, accounting for 7 out of 25 submissions, closely followed by DeBERTa with 5 out of 25. The majority of submissions utilised generative

Table 3: SemEval-2024 Task 2 Results, sorted by F1 (on the unperturbed subset of the test set), with Faithfulness (F), and Consistency (C)

models, with 17 out of the total, compared to 8 leveraging discriminative models. The F1 score suggests that GPT-4's performance is on par with considerably smaller models such as DeBERTa. However, a deeper evaluation using our novel metrics, especially Faithfulness, reveals a significant disparity, indicating that smaller models might be overfitting. This observation underscores the importance of employing these complementary metrics for a more comprehensive comparison of model capabilities. Despite the prevailing notion that larger models inherently perform better, this trend appears to be less pronounced than observed in this task's previous iteration (Jullien et al., 2023b), as illustrated in Figure 3. Notably, there seems to be a point of diminishing returns for model sizes between 7B and 70B, within the generative model category, shown in Figure 3. On average, models with sizes ranging from 7B to 70B parameters achieve +0.01 in F1 score but show decreases of -0.03 in Faithfulness and -0.01 in Consistency relative to models with more than 70B parameters. When compared to models with fewer than 7B parameters, these mid-sized models exhibit substantial improvements of +0.10 in F1 score, +0.40 in Faithfulness, and +0.19 in Consistency.

Table 4: Participant architectures by popularity, with average F1, Faithfulness (F) and Consistency (C)

Model	F1	F	C	Count
DeBERTa	0.76	0.76	0.75	5
Mistral 7B	0.75	0.84	0.69	4
Mixtral 8x7B	0.73	0.76	0.66	3
T5	0.66	0.36	0.53	3
Gemini Pro	0.70	0.77	0.68	3
GPT-4	**0.77**	**0.91**	0.76	2
SOLAR 10B	0.75	0.88	**0.77**	2
BERT base	0.62	0.44	0.54	1
Biolinkbert	0.72	0.59	0.64	1
BART	0.66	0.03	0.39	1
RoBERTa	0.57	0.64	0.56	1
Flan-T5 XL	0.76	0.84	0.75	1

Additionally, on average, generative models outperform discriminative ones across the board—with improvements observed in F1 scores (+0.025), Faithfulness (+0.15), and Consistency (+0.037), as depicted in Figure 2. Intriguingly, when comparing specific architectures, there is minimal correlation between model types and Faithfulness, Consistency, and F1, even though the top two performing systems in terms of F1 score are based on the Mixtral-8x7B-Instruct model (see Table 3).

5.2 Base F1 Performance

As previously mentioned the focus of this task extends beyond base performance. Nevertheless, it's noteworthy that the highest F1 score achieved in this iteration was 0.8 (Liu and Thoma, 2024; Guimarães et al., 2024) (FZI-WIM, Lisbon Computational Linguists) by two systems (Table 3). A figure that notably falls short of the previous iteration's top score of 0.856 (Zhou et al., 2023; Jullien et al., 2023b). This observed decline underscores a significant gap between the current capabilities of NLI systems and the performance required for practical application within clinical environments.

5.3 Faithfulness and Consistency

The overall average Faithfulness recorded at 0.719 significantly outperforms the average Consistency, which stands at 0.67. This disparity grows more pronounced within the subset of models within the top 10 F1 scores, where Average Faithfulness escalates to 0.835 and Average Consistency to 0.751.

Furthermore, a robust overall Spearman's correlation was identified between Consistency and F1 scores (0.8) and between Faithfulness and F1 scores (0.62). Intriguingly, this correlation inverts within the top 10 systems, where Spearman's Correlation between Consistency and F1 drops to -0.12, and between Faithfulness and F1 rises slightly to 0.319. Notably, the models with the highest Faithfulness (0.95) (Gema et al., 2024)(Edinburgh Clinical NLP) and Consistency (0.81) (Lee et al., 2024)(NYCU-NLP) scores achieve an average score of 0.84, surpassing systems ranked above them (with average scores of 0.81 and 0.78) yet both reporting a lower F1 score by -0.02. also Mandal and Modi (2024)(IITK) achieves a very high faithfulness of 0.9, while only managing an F1 of 0.69. These patterns underscore the limitation of F1 scores as sole indicators of model performance at the apex levels, accentuating the importance of considering Faithfulness and Consistency metrics in conjunction with F1.

The inversion of correlations among the top 10 models suggests a nuanced landscape of performance evaluation. While Consistency contributes broadly to high F1 scores, the top 10 models distinctly leverage Faithfulness, indicating that, at peak performance levels, perhaps accurate predictions rooted in correct premises are paramount over consistent responses to similar cases.

This phenomenon might also signify a ceiling effect for Consistency, suggesting that beyond a certain point, efforts to improve consistency do not translate into proportional performance gains. Such a scenario could inadvertently overshadow other critical model attributes like adaptability and nuanced comprehension, aspects more closely associated with Faithfulness. Alternatively, this situation could imply that models specifically optimized for F1 scores might inadvertently neglect Consistency, and to some degree, Faithfulness, as evidenced by the observed decline in their correlation with peak F1 scores.

Our analysis further elucidates the relationship between Consistency and Faithfulness in submitted systems, revealing an Overall Spearman Correlation of 0.708. This correlation slightly diminishes among the top 10 F1 scoring models to 0.39. While this represents a weaker correlation within the subset of the top 10 models, it importantly suggests the absence of a strict trade-off between Consistency and Faithfulness. Such a finding challenges the notion that improvements in one metric necessarily come at the expense of the other.

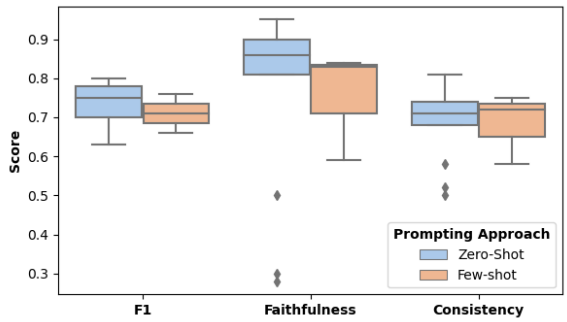

Figure 4: Comparative Analysis of F1, Consistency, and Faithfulness Across Prompting strategies

Among the participants, 4 out of 25 achieved a Faithfulness score of 0.9 or higher (Mandal and Modi, 2024; Liu and Thoma, 2024; Lee et al., 2024; Gema et al., 2024)(IITK, FZI-WIM, NYCU-NLP, Edinburgh Clinical NLP). Remarkably, only 1 out of 25 participants attained a Consistency score of 0.8 or higher (Lee et al., 2024)(NYCU-NLP). These results suggest a continued need for refining these models to achieve higher degrees of Faithfulness and Consistency if they are to be applied in real-world clinical environments.

5.4 Prompting Strategies

A variety of prompting strategies were used in the submitted systems. It is essential to acknowledge that variations in prompts can lead to significant differences in outcomes, even when employing the same architecture. For instance, within the Gemini Pro systems, a comparison between submissions by ALTINOK (2024)(D-NLP) and Kim et al. (2024)(Saama Technologies) from Saama Technologies reveals substantial disparities in performance metrics: F1 scores, Faithfulness, and Consistency differ by 0.09, 0.24, and 0.16, respectively. Similar patterns of variation were observed among submissions utilizing Mistral-based and T5-based approaches, underscoring the impact of prompting nuances.

Among the generative model submissions, 13 out of 16 employed a zero-shot approach, while the remaining three opted for few-shot prompting. Zero-shot prompting involves generating responses without any example-based guidance, relying solely on the model's pre-existing knowledge and the task description. Few-shot prompting, on the other hand, provides the model with one or more examples to guide its responses, traditionally anticipated to yield superior results.

Contrary to initial expectations, zero-shot prompting has shown a significant advantage, especially in achieving higher F1 scores and improving Faithfulness. Notably, four out of the top five models with the highest F1 scores utilized zero-shot techniques, as depicted in Figure 4. On average, zero-shot prompting yielded improvements of +0.025 in F1 score, +0.001 in Faithfulness, and +0.001 in Consistency, when compared to few-shot prompting methods.

Direct prompting is a straightforward method of querying a Language Model (LM). It involves posing a question to the model in a direct manner, without providing additional context or requesting intermediate steps. For example *"Given the CTR:* {Premise} *does the statement:* {Statement} *follow?"*

On the other hand, Chain of Thought (CoT) prompting represents a more elaborate technique designed to prompt the model to "show its work" by articulating the intermediate steps or reasoning that leads to its conclusion (Wei et al., 2022). This approach enables the model to break down the problem into smaller, more manageable parts, thereby facilitating more accurate or explainable predictions. For instance, the prompt could be structured as follows: *"Given the CTR:* {Premise} *and the statement:* {Statement}*, provide a step-by-step reasoning process to determine if the statement logically follows from the report."* Such a modification in the prompting strategy has been shown to produce significant differences in the model's outputs (Wei et al., 2022).

While direct prompting has been the predominant strategy among generative approaches, several teams have experimented with more nuanced strategies. Specifically, FZI-WIM (Liu and Thoma, 2024), IITK (Mandal and Modi, 2024), and Saama Technologies (Kim et al., 2024) have employed Chain of Thought prompting. Furthermore, IITK (Mandal and Modi, 2024) has also explored Tree of Thought (ToT) prompting. ToT prompting is an advanced technique aimed at improving the performance and interpretability of LMs, particularly in complex problem-solving tasks (Yao et al., 2023). It goes beyond the CoT approach by not merely listing reasoning steps linearly but by organizing these steps into a tree structure that represents different branches of reasoning or possible solutions. IITK (Mandal and Modi, 2024) applies this technique with the prompt *Imagine three different clinical experts are answering the question given below. All*

experts will write down first step of their thinking, then share it with the group. Then all experts will go on to the next step of their thinking. If any expert realises they're wrong at any point then they leave. They will continue till a definite conclusion is reached.. However, the ability to draw definitive conclusions about the relative efficacy of these prompting strategies is constrained given the considerable performance variability associated with each approach and the application of these strategies across diverse models, complicating efforts to ascertain the sources of performance gains or losses.

Two particularly intriguing prompting strategies emerged from the submissions. (Brutti-Mairesse, 2024)(CRCL) utilized an OPRO (Optimal Prompting for Response Optimization) technique (Yang et al., 2023), which leverages the model's ability to generate effective prompts from a small set of exemplars and prior instructions. This technique essentially tasks the model with creating its own instructions to tackle given problems. Additionally, (Lu and Kao, 2024) introduced a multi-agent debating framework, incorporating several custom agents with diverse expertise, including Biostatistics and Medical Linguistics, to enrich the model's output.

In summary, the submissions reveal a broad spectrum of prompting strategies, from zero-shot to more complex approaches like Tree of Thought and multi-agent frameworks. These strategies significantly influence model performance, underscoring the importance of prompt design in the development and evaluation of NLI systems. As the field progresses, further research is warranted to elucidate the optimal prompting strategies for enhancing model accuracy, reliability, and interpretability across various applications, in a controlled manner.

5.5 Fine-tuning strategies

Within the context of SemEval-2024 Task 2, a diverse array of fine-tuning strategies was employed across the 25 participating systems, revealing significant insights into their impact on model performance. Notably, 9 out of 25 systems, all of which were generative, did not undergo any form of fine-tuning. In contrast, 8 out of 25 systems were fine-tuned specifically on the NLI4CT-P training set, while the remaining 6 systems benefited from fine-tuning on additional datasets.

Interestingly, systems fine-tuned on the NLI4CT-P training set exhibited the lowest average performance across all three evaluated metrics, as detailed in Figure 5. Conversely, systems that underwent fine-tuning on external datasets demonstrated superior performance on all metrics, indicating a significant advantage of incorporating diverse training data.

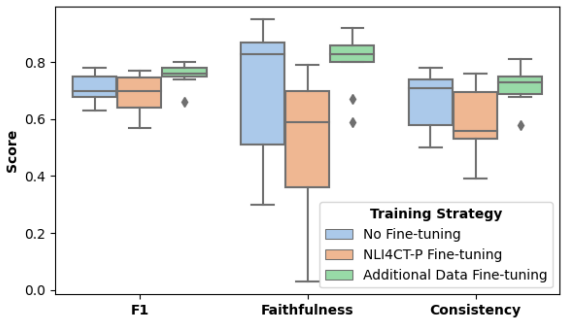

Figure 5: Comparative Analysis of F1, Consistency, and Faithfulness Across Training Strategies

The range of additional datasets leveraged for fine-tuning included various medical NLI datasets, such as MultiNLI, FeverNLI, ANLI, LingNLI, and WANLI, utilized by Zhang et al. (2024)(YNU-HPCC), and MedNLI by Verma and Raithel (2024)(DFKI-NLP). Moreover, some teams, including Sun et al. (2024)(LMU-BioNLP), Wang et al. (2024)(DKE-Research), Guimarães et al. (2024)(Lisbon Computational Lin- guists), Smilga and Alabiad (2024)(TüDuo), and Zhang et al. (2024)(YNU-HPCC), innovatively generated their data by applying interventions similar to those used in our task, thereby enriching their training material. Systems enhanced with additional data demonstrate significant improvements, achieving gains of +0.056 in F1 score, +0.132 in Faithfulness, and +0.062 in Consistency. These results suggest a substantial benefit from such tuning, particularly in terms of Faithfulness. This indicates that incorporating perturbed data into the training process not only enhances the model's inference ability but also significantly improves its reliability and adherence to the truthfulness of the clinical data it processes.

Instruction tuning emerged as a prevalent strategy, with datasets specifically crafted for this purpose by teams such as Liu and Thoma (2024)(FZI-WIM), Guimarães et al. (2024)(Lisbon Computational Lin- guists), Smilga and Alabiad (2024)(TüDuo), LUM-BIO, Wang et al. (2024)(DKE-Research), and (Lee et al., 2024)(NYCU-NLP). Notably, 3 out of the top 5 systems, as per F1 scores, employed instruction tuning, underscoring its effec-

tiveness in enhancing model performance, although notably producing minimal gains in consistency.

6 Related Work

The landscape of expert-annotated resources for clinical NLP is rich, with notable examples such as the TREC 2021 Clinical Track (Soboroff, 2021), which focuses on information retrieval from CTR data, highlighting eligibility criteria. Evidence Inference 2.0 (DeYoung et al., 2020) introduces a QA task alongside span selection based on CTR results, while the MEDNLI dataset (Romanov and Shivade, 2018) offers an entailment task using patient medical history notes. These datasets primarily aim to evaluate biomedical language understanding and reasoning. Despite neural architectures leading in biomedical NLI performance (Gu et al., 2021; DeYoung et al., 2020), challenges remain in quantitative reasoning and numerical operations within NLI (Ravichander et al., 2019; Galashov et al., 2019). Prior works experiment with biomedical pre-training strategies (Lee et al., 2020; Shin et al., 2020; Gu et al., 2021), and while ExaCT (Kiritchenko et al., 2010) automates information extraction from clinical trials, the integration of biomedical and numerical NLI effectively remains unaddressed. None of the aforementioned resources provide avenues for meaningful causal analysis, a gap NLI4CT-P aims to fill, through the application of targeted interventions and the introduction of novel evaluation metrics.

7 Conclusion

This study introduces the NLI4CT-P dataset and provides a comprehensive analysis of submissions to SemEval-2024 Task 2, underscoring the persistent challenges in Clinical Natural Language Inference (NLI) despite significant advancements in Large Language Models (LLMs). The incorporation of Faithfulness and Consistency metrics further highlights these challenges, shedding light on areas requiring additional focus, if these systems are to meet the requirements for real-world clinical implementation. Our key findings reveal that generative models markedly outperform discriminative models, particularly in terms of Faithfulness and Consistency. The utility of additional data is underscored, especially due to the limited size of the NLI4CT-P training set. Furthermore, our analysis reveals the substantial impact of prompting strategies on model performance, noting an intriguing preference for zero-shot approaches over few-shot methods. Additionally, mid-sized architectures, ranging between 7B and 70B parameters, demonstrate the potential to match or even exceed the performance of larger models (>70B) in F1 scores, Faithfulness, and Consistency, while being more resource and cost-effective. Conversely, models with fewer than 7B parameters face difficulties in achieving comparable results. We plan to perform a further analysis of the submitted systems' performance at an intervention level, identifying specific areas of weakness, such as numerical reasoning or handling longer premises, to refine and enhance Clinical NLI systems further.

8 Limitations

Despite not disclosing detailed specifics of the interventions, nor providing intervened training data, several participants generated their own interventions for data augmentation. As a result, some models were specifically trained on this intervened data. However, this approach raises concerns regarding their ability to generalize effectively to entirely new, unseen perturbations or adversarial datasets. The tailored training to specific interventions may limit the models' broader applicability and robustness on unseen perturbed or adversarial data.

A Intervention Prompts

A.1 Contradictory Rephrasing prompt

Your task is to provide 3 contradictory statements, given an original statement.

(Instructions) Ensure that the contradictory statements are factually opposed to the original statement. Do not mention the original statement in the contradictory statements. Use formal and straightforward language when writing the new statements, and avoid unusual or overly descriptive language. Make sure to retain the names 'Primary Clinical Trial' and 'Secondary Clinical Trial' in the contradictory statements, these names must be present in every statement. Provide 3 different options in a consistent JSON format with keys 'Statement_1', 'Statement_2', and 'Statement_3' followed by their respective paraphrased statements.

(Examples) 1. [original statement]:"the secondary trial requires patients to be over a certain age, but the primary trial does not specify an age range for participation." [ideal output]: "the secondary trial does not give an age limit for patients to participate, but patients must be between the age of 12-34 to be eligible for the primary trial"

2. [original statement]:"a patient that has received an organ transplant within the last month, and is still bedridden would be excluded from the primary trial but may be eligible for the secondary trial" [ideal output]: "a patient that has received an liver transplant in the last week, with an ECOG score of 4 would be eligible for the primary trial but excluded from the secondary trial"

3.[original statement]: "Women with Newly diagnosed stage IV breast cancer, confirmed as ER+ Considering a mastectomy are eligible for the primary trial" [ideal output]: "Women recently diagnosed with stage 4 ER-positive breast cancer and contemplating a mastectomy are excluded from the Primary Clinical Trial"

Input:

A.2 Paraphrasing prompt

Your task is to provide 3 paraphrased statements, given an original statement.

(Instructions) Use formal and straighforward language when writing the new statements, and avoiding unusual or overly descriptive language. Make sure to retain the name 'Primary Clinical Trial' in the statements, this name must be present in every statement. Provide 3 different options in a consistent JSON format with keys 'Statement_1', 'Statement_2', and 'Statement_3' followed by their respective paraphrased statements.

(Examples) 1. [original statement]:"the primary trial does not specify an age range for participation." [ideal output]: "patients aged between 30-60 years old can be eligible for the primary trial"

2. [original statement]:"a patient that has received an organ transplant within the last month, and is still bedridden would be excluded from the primary trial" [ideal output]: "a patient that has received an liver transplant in the last week, with an ECOG score of 4 would be excluded from the primary trial"

3.[original statement]: "Women with Newly diagnosed stage IV breast cancer, confirmed as ER+ Considering a mastectomy are eligible for the primary trial" [ideal output]: "Women recently diagnosed with stage 4 ER-positive breast cancer and contemplating a mastectomy are suitable for the Primary Clinical Trial"

Input:

A.3 Numerical Paraphrasing prompt

Your task is to modify the numerical values and units in an original statement while maintaining its original meaning, to generate 3 new statements.

(Instructions) Do not paraphrase the statements, You can only change numerical values or units, if you change the units you must also convert the measurement values. Provide 3 different options in a consistent JSON format with keys 'Statement_1', 'Statement_2', and 'Statement_3' followed by their respective paraphrased statements.

(Examples) 1. [original statement]: "Over 6 weeks of TAK-228 Plus Tamoxifen treatment patients in the primary trial experienced a 5% reduction in the Percentage of cells with Ki67 expression" [ideal output]: "Over 42 days of TAK-228 Plus Tamoxifen treatment patients in the primary trial experienced a 5% reduction in the Percentage of cells with Ki67 expression"

2.[original statement]: "in the primary trial there were 10 times the number of Hepatotoxicity cases as there were cases of hypertension and Pancreatectomy" [ideal output]: "in the primary trial there were 1000% the number of Hepatotoxicity cases as there were cases of hypertension and Pancreatectomy"

3.[original statement]: "2/73 the primary trial participants, and 0/1674 the secondary trial participants suffered an Acute myocardial infarction " [ideal output]: "2.74% the primary trial participants, and 0% the secondary trial participants suffered an Acute myocardial infarction "

Input:

A.4 Numerical Contradictory Rephrasing prompt

Your task is to modify the numerical values and units in an original statement to contradict the original statement, to generate 3 new statements.

(Instructions) Do not paraphrase the statements, You can only change numerical values or units, if you change the units you must also convert the measurement values. Provide 3 different options in a consistent JSON format with keys 'Statement_1', 'Statement_2', and 'Statement_3' followed by their respective paraphrased statements.

(Examples) 1. [original statement]: "Over 6 weeks of TAK-228 Plus Tamoxifen treatment patients in the primary trial experienced a 5% reduction in the Percentage of cells with Ki67 expression"

[ideal output]: "Over 50 days of TAK-228 Plus Tamoxifen treatment patients in the primary trial experienced a 105% reduction in the Percentage of cells with Ki67 expression"

2.[original statement]: "in the primary trial there were 10 times the number of Hepatotoxicity cases as there were cases of hypertension and Pancreatectomy" [ideal output]: "in the primary trial there were 30% the number of Hepatotoxicity cases as there were cases of hypertension and Pancreatectomy"

3.[original statement]: "2/73 the primary trial participants, and 0/1674 the secondary trial participants suffered an Acute myocardial infarction " [ideal output]: "9.74% the primary trial participants, and 8% the secondary trial participants suffered an Acute myocardial infarction "

Abstract

We present the first shared task on Semantic Textual Relatedness (STR). While earlier shared tasks primarily focused on semantic similarity, we instead investigate the broader phenomenon of semantic relatedness across 14 languages: *Afrikaans, Algerian Arabic, Amharic, English, Hausa, Hindi, Indonesian, Kinyarwanda, Marathi, Moroccan Arabic, Modern Standard Arabic, Punjabi, Spanish,* and *Telugu*. These languages originate from five distinct language families and are predominantly spoken in Africa and Asia – regions characterised by the relatively limited availability of NLP resources. Each instance in the datasets is a sentence pair associated with a score that represents the degree of semantic textual relatedness between the two sentences. Participating systems were asked to rank sentence pairs by their closeness in meaning (i.e., their degree of semantic relatedness) in the 14 languages in three main tracks: (a) supervised, (b) unsupervised, and (c) crosslingual. The task attracted 163 participants. We received 70 submissions in total (across all tasks) from 51 different teams, and 38 system description papers. We report on the best-performing systems as well as the most common and the most effective approaches for the three different tracks.

1 Introduction

Defining the relationship between two units of text is an important component of constructing text representations. Within this context, semantic textual relatedness (STR) aims to capture the degree to which two linguistic units (e.g., words or sentences, etc.) are close in meaning (Mohammad and Hirst, 2012). Two units may be related in a variety of different ways (e.g., by expressing the same view, originating from the same time period, elaborating on each other, etc.). On the other hand, semantic textual similarity (STS) considers only a narrow view of the relationship that may exist between texts (such as equivalence or paraphrase) which does not incorporate other dimensions of relatedness such as entailment, topic or view similarity, or temporal relations (Abdalla et al., 2023). For example, *'I am feeling sick.'* and *'Get well soon!'* would receive a low similarity score, despite the two being very related. In this shared task, we investigate the broader concept of semantic textual relatedness. STR is central to understanding meaning in text (Hasan and Halliday, 1976; Miller and Charles, 1991; Morris and Hirst, 1991) and its automation can benefit various downstream tasks such as evaluating sentence representation methods, question answering, and summarisation (Abdalla et al., 2023; Wang et al., 2022).

Prior shared tasks (Agirre et al., 2012, 2013, 2014, 2015, 2016; Cer et al., 2017) have mainly focused on textual similarity. In this work, we provide participants with SemRel (Ousidhoum et al., 2024), a collection of 14 newly curated monolingual STR datasets for Afrikaans (`afr`), Amharic (`amh`), Modern Standard Arabic (`arb`), Algerian Arabic (`arq`), Moroccan Arabic (`ary`), English (`eng`), Spanish (`esp`), Hausa (`hau`), Hindi (`hin`), Indonesian (`ind`), Kinyarwanda (`kin`), Marathi (`mar`), Punjabi (`pun`) and Telugu (`tel`). The datasets are composed of sentence pairs, each assigned a relatedness score between 0 (completely

*Equal contribution from first and second authors, authors 3 to 16 are alphabetically ordered.

Table 1: The language families and data split sizes of the different datasets. Datasets with no traning sets were only used in tracks B and C.

unrelated) and 1 (maximally related) with a large range of expected relatedness values. The pairs of sentences were first selected from pre-existing datasets covering various topics and formality levels, e.g., news data, Wikipedia, and conversational data. To generate the relatedness scores, the sentence pairs were then annotated by native speakers who performed comparisons between different pairs of sentences using Best–Worst Scaling (BWS) (Louviere and Woodworth, 1991; Kiritchenko and Mohammad, 2017a). The shared task included three main tracks: (1) supervised, (2) unsupervised, and (3) cross-lingual.

Each team could provide submissions for one, two, or all of the tracks in one or more languages. Our official evaluation metric was the Spearman rank correlation coefficient, which captures how well the system-predicted rankings of test instances aligned with human judgments. Our task attracted 163 participants, received 70 final submissions from 51 different teams, and 38 teams submitted system description papers. Track A (supervised) received the largest number of submissions: 40, followed by 18 submissions for track B (unsupervised) and 12 for track C (crosslingual). Most teams participated in multiple languages (more than eight on average). All of the task details and resources are available on the task website.[1]

2 Related Work

The field of semantic textual relatedness in natural language processing covers a variety of approaches and techniques designed to measure the closeness in meaning between units of text, specifically words (Miller, 1994) or sentences (Abdalla et al., 2023).

Most prior shared tasks focus on semantic textual similarity, a narrower subset of relatedness, and often only cover high-resource languages such as English (Agirre et al., 2012, 2013, 2014, 2015, 2016), Arabic, German, Spanish, and Turkish (Cer et al., 2017) with few exceptions such as Armendariz et al. (2020) who also included Slovene, Finnish, and Croatian.

By comparison, this shared task focuses on sentence-level STR in various low-resource languages. To our knowledge, the only corpora specially designed for semantic textual relatedness between pairs of sentences was created by Abdalla et al. (2023) for English. The core of Abdalla et al. (2023) approach served as the model for data annotations added to new ways of data collection–curation for several less-resourced languages.

3 Data

3.1 Data Collection

A key step in the data creation process was identifying text sources for each language and selecting sentence pairs. This was particularly challenging for low-resource languages such as Hausa, Telugu, or Algerian Arabic. Since most SemRel languages are low-resource, the domain, (in)formality, and diversity of the sentence pairs were highly dependent on the publicly available corpora. We aimed to collect datasets with average-length sentences, free of offensive utterances, and as diverse as possible. Thus, data instances were extracted for each language using a tailored combination of heuristics such as lexical overlap and paraphrases. We used further pre-processing, post-processing, and data analysis methods to avoid incoherence and unnaturalness.

Since arbitrarily selecting sentences and pairing them would lead to many unrelated instances, we relied on the following heuristics to pair sentences and ensure that the pairs would exhibit relatedness scores varying from completely unrelated to very related:

1. **Lexical Overlap** Select sentences with various proportions of lexical overlap, i.e., one or more words/tokens in common, with or without using TF/IDF normalisation.
2. **Contiguity/Entailment** Select adjacent pairs of sentences in a paragraph or a social media

Table 2: SHR (split-half reliability) scores for each of the created dataset splits and numbers of annotators per tuple (#Annotators).

thread, i.e., sentences that appear one after the other.

3. **Paraphrases or Machine Translation (MT) Paraphrases** Select pairs of sentences from paraphrase or MT data. For MT, we pivot across the translation and back to the source language to generate a new sentence and pair it with the original.
4. **Random selection** Random pairs of sentences are selected.

We elaborate on the detailed data collection and processing steps in Ousidhoum et al. (2024).

3.2 Data Annotation

As the notions of *related* and *unrelated* do not have clear boundaries with no unanimous definition in the literature, we use comparative annotations and rely on the intuitions of fluent speakers for each language to choose between sentence pairs. Therefore, instead of relying on vague class definitions, we capture common perceptions of semantic relatedness (i.e., what is believed by the vast majority) rather than "correct" or "right" rankings.

We used Best–Worst Scaling (BWS) (Louviere and Woodworth, 1991; Kiritchenko and Mohammad, 2017a), a form of comparative annotation that avoids various biases of traditional rating scales, to annotate our data instances and generate an ordinal ranking of instances. In BWS, annotators are given n items (an n-tuple, where $n > 1$ and commonly $n = 4$). They are asked which item is the *best* (highest in terms of the property of interest) and which is the *worst* (lowest in terms of the property of interest). When working on 4-tuples, best–worst annotations are particularly efficient because each best and worst annotation will reveal the order of five of the six-item pairs. Real-valued scores of association between the items and the property of interest can be determined using simple arithmetic on the number of times an item was chosen best and the number of times it was chosen worst (Orme, 2009; Flynn and Marley, 2014). It has been empirically shown that annotations for $2N$ 4-tuples are sufficient for obtaining reliable scores (where N is the number of items) (Louviere and Woodworth, 1991; Kiritchenko and Mohammad, 2016). Kiritchenko and Mohammad (2017b) showed through empirical experiments that BWS produces more reliable and discriminating scores than those obtained using rating scales. (See (Kiritchenko and Mohammad, 2016, 2017b) for further details on BWS.) We generated tuples using the BWS scripts provided by Kiritchenko and Mohammad (2017a)[2].

We report the number of annotators and the split-half reliability (SHR) scores (Cronbach, 1951; Kuder and Richardson, 1937) for each of the datasets in Table 2. SHR measures the degree to which repeating the annotations results in similar relative rankings of the instancesOverall the scores in Table 2 vary between 0.64 and 0.96, which indicates a high annotation reliability.

4 Task Description

In this task, we aim to predict the semantic textual relatedness (STR) of sentence pairs. Participants had to rank sentence pairs by their degree of semantic relatedness which varies between 0 (unrelated) and 1 (closely related). Each team could provide submissions for one, two, or all of the tracks presented below.

4.1 Track A: Supervised

Participants were to submit systems trained on the labeled training datasets provided. Participating teams were allowed to use any publicly available datasets (e.g., other relatedness and similarity datasets or datasets in any other languages). However, they had to report on additional data they used, and ideally report how each resource impacted the final results.

4.2 Track B: Unsupervised

Participants were to submit systems that were developed without the use of any labeled datasets

4	silp_nlp	0.740		UAlberta	0.481		MaiNLP	0.499
5	NLP_1@SSN	0.740		silp_nlp	0.400		ustcctsu	0.445

Table 3: Top 5 submissions per track. See Appendix for paper information about the different teams. * shows baseline results using lexical overlap, XLMR and LaBSE reported in the SemRel dataset paper (Ousidhoum et al., 2024).

pertaining to semantic relatedness or semantic similarity between units of text more than two words long in any language. The use of unigram or bigram relatedness datasets (from any language) was permitted.

4.3 Track C: Cross-lingual

Participants were to submit systems that were developed without the use of any labeled semantic similarity or semantic relatedness datasets in the target language and with the use of labeled dataset(s) from at least one other language. Using labeled data from another track was mandatory for a submission to this track.

4.4 Official Evaluation Metric

The official evaluation metric for this task is the Spearman rank correlation coefficient, which captures how well the system-predicted rankings of test instances align with human judgments. We provided the participants with an evaluation script on GitHub page[3].

4.5 Task Organisation

We released some pilot datasets before the start of the shared task for participants to have a better understanding of the task (i.e., the datasets, the languages involved, and the labels) and provided the participants with a starter kit on GitHub.

5 Evaluation

5.1 Our baselines

In Table 3, we report a simple lexical overlap baseline which consists of the Dice coefficient between two sentences A and B: the number of unique unigrams occurring in both sentences, adjusted by their lengths (Abdalla et al., 2023):

$$\frac{2 \times |unigram(A) \cap unigram(B)|}{|unigram(A) + unigram(B)|} \quad (1)$$

In addition, we used LaBSE (Label Agnostic BERT Sentence Embeddings) (Feng et al., 2020) which can map 109 languages into a shared vector space. With the embeddings covering all the SemRel languages, we report baseline results using the default hyperparameters set in the sentence-transformers repository[4]. We used:

- the predefined setup without further fine-tuning,
- the LaBSE model further fine-tuned on our training data using a cosine similarity loss.

For the crosslingual baselines, we fine-tuned LaBSE on the English training set and tested on all the other datasets except English while using the Spanish training set to fine-tune LaBSE when testing on English. We elaborate on the detailed baseline experiment in (Ousidhoum et al., 2024)

5.2 Participating Systems and Results

5.3 Participant Overview

During the evaluation phase, 163 people registered for the competition. Of these, 51 teams made 70 final submissions across tracks [5]. Track A received 40 final submissions, track B received 12 submissions, and track C received 18. For track A, most participants submitted systems for at least eight languages. We report the top–5 performing systems in all tracks in Table 3.

Table 4: Track A results. The best results are in bold, and NR stands for *not ranked*. As the methods are highly language-dependent, we only rank teams that participated in at least 8 sub-tracks, but we highlight in blue the best results achieved by non-ranked teams. (Non-ranked teams are sorted based on the number of languages they participated in.)

5.4 Task A: Supervised

5.4.1 Best Performing Systems

AAdaM They opted for data augmentation by translating the English SemRel dataset and STSB (semantic similarity) to create and augment data in other languages. The team explored both fine-tuning and adapter-based tuning. Given a target language, they first fine-tuned the cross-encoder-based AfroXLMR model (Alabi et al., 2022) on the augmented data as a warm-up or TAPT (Task-Adaptive-Pre-Training) and then continued the fine-tuning on the provided SemRel data.

NRK They ensembled various BERT-like models and used a weighted voting technique to improve the performance of their model.

PEAR They examined the effect of combining or using per-language data through 5-fold validation. They did not conduct any text preprocessing to maintain fairness across languages. They defined three model configurations: "base" with no training, "all" trained on all languages, and "lan" trained on one language. They experimented with multilingual embeddings, cross-encoders, and augmented data from bi-encoders.

5.4.2 Popular Methods

The general trend for the methods submitted to track A was (1) embedding sentence pairs into text and (2) training a regression model. Some teams used traditional embeddings and regression approaches (e.g., word2vec with support vector regressor – team 'Text Mining'). The majority used deep learning approaches (e.g., BERT, RoBERTa) or other large pre-trained transformer models (e.g., teams "IITK", "Fired_from_NLP, HausaNLP"). When using these models, the teams would often experiment with different hyperparameters. Some teams went further and modified the specific learning approach or representations learned through methods such as contrastive learning (e.g., team: IITK).

5.4.3 Most Effective and Original Methods

In track A, the participants used the provided training sets for each of the 9 languages included in the track (`amh`, `arq`, `ary`, `eng`, `esp`, `hau`, `kin`, `mar` and `tel`). Overall, the different teams explored several approaches to enhance the performance. For instance, the top performing team PALI, used MT-DNN (Multi-Task Deep Neural Networks for Natural Language Understanding) (Liu et al., 2019a) and outperformed all the other teams across all languages except for Spanish and Kinyarwanda. For Kinyarwanda, king001 who used MT for data augmentation and multilingual mixed training and XLM-R (Conneau et al., 2020) as a base model achieved the best performance, and AAdaM who used translation-based data augmentation and adapter-based tuning reported the best score.

Note. however, that since PALI and king001 did not submit system description papers, they are not ranked in Tables 3 and 4.

5.5 Task B: Unsupervised

5.5.1 Best Performing Systems

SATLab Team SATLab used a system based on a model developed for authorship identification of source code (Bestgen, 2019). The system processed each pair of utterances independently, generating a distance between them without relying on additional information. Their pre-processing involved lower-casing of texts and making use of character n-grams ranging from 1 to 5 characters, encompassing all characters including spaces, punctuation marks, symbols, and characters from different writing systems. All n-grams were retained without a frequency threshold. The frequency of each feature was weighted by a logarithmic function, and the features of each statement were weighted by the L2 norm. The semantic similarity between utterances was estimated using the Euclidean distance between sets of n-grams in each pair.

MasonTigers In the initial phase, team MasonTigers obtained the embeddings of training data instances and used TF–IDF, PPMI, LaBSE sentence transformer, and language-specific BERT models for multiple languages. Cosine similarity scores were then computed between pairs of embeddings, followed by the use of ElasticNet and Linear Regression separately to predict sentence pair similarity. Predicted values were clipped to ensure a range from 0 to 1.

HW–TSC Team HW-TSC's method included the N-gram chars utilising tokenizers from XLM-RoBERTa and m-BERT as key features to compute similarity scores based on n-gram dictionaries of sentences. They also used BERTScore to assess text quality based on the cosine similarity of token-level representations from the BERT model.

5.5.2 Popular Methods

As the main challenge with track B was the prevention of using any data of more than two words long related to semantics, many teams such as Hausa–NLP and Tübingen–CL used pre-trained language models such as All-MiniLM-L6-v2 (Reimers and Gurevych, 2019).

Most teams opted for language-specific data and models, if not trained on similarity data, and compared the performance to monolingual BERT models. However, none of these methods were used by the top three performing teams.

5.5.3 Most effective and Original Methods

The most effective methods for the unsupervised track for all languages were submitted by teams SATLab, MasonTigers, and HW–TSC (top–3). SATLab's approach involved processing pairs independently using character n-grams. MasonTigers, on the other hand, leveraged various embedding methods and statistical machine learning using simple features such as TF-IDF and BERT models to compute the cosine similarity between embeddings, further refined using ElasticNet. On the other hand, The HW–TSC team used innovative techniques

Table 5: Track B results. The best results are in bold, and NR stands for *not ranked*. As the methods are highly language-dependent, we only rank teams that participated in at least 8 sub-tracks, but we highlight in blue the best results achieved by non-ranked teams. (Non-ranked teams are sorted based on the number of languages they participated in.)

such as the N-gram chars method with XLM-R and m-BERT tokenizers, as well as the BERTScore to evaluate the text quality.

In Table 5, we also have honorable mentions for teams that did not participate in all the languages but achieved remarkable results in one or a few languages. Notably, team CAILMD–23 achieved the best results in Hindi by using Hindi-BERT-v2, and team Tübingen–CL achieved the best results in English.

5.6 Task C: Crosslingual

5.6.1 Best Performing Systems

AAdaM They experimented with full fine-tuning, adapter fine-tuning using MAD (Pfeiffer et al., 2020), and data augmentation using different language combinations to augment data in a given source language.

UAlberta They used an XGBoost regressor-based (Chen and Guestrin, 2016) ensemble approach to integrate the predicted relatedness scores of three distinct regression models, with one optional SBERT model, as input and returned the final relatedness score as output. They applied the English version of their method trained for Track A to the translations of the non-English test sets. The regression model fine-tuned on MPNet was used in the XGBoost ensemble only for `amh`, `hau`, and `hin`, but not for the other languages such as `esp`, `ary`, `kin`, `ind`, `arb`, `arq`, and `afr`. The pre-trained English language models that were used include RoBERTa Large, T5 Base, and GPT2 Base, as well as MPNet only for languages `amh`, `hau`, and `hin`.

silp_nlp They used the provided datasets and cross-lingual transferability with all the provided datasets, except data in the target language, as a source. Their cross-lingual transfer approach made use of MuRIL (Khanuja et al., 2021) which led to the best results for Hindi and XLM-R (Conneau et al., 2020) led to the best ones for all the other languages.

5.6.2 Popular Methods

For the crosslingual track, many teams including best-performing ones such as UAlberta chose approaches similar to the ones used for supervised sub-tracks (e.g., using an XGBoost regressor (Chen and Guestrin, 2016)). As the main challenge was to determine how to leverage data in languages other than the target, many teams combined the provided SemRel datasets in all possible languages (e.g., king001, AAdaM). Some used the training datasets without any modifications (e.g., team HausaNLP) and others experimented with different language combinations to use those that would lead to the best results (e.g., MasonTigers). Finally, some teams applied advanced techniques to modify the vector embedding space (e.g., by adjusting for the anisotropic nature of vector spaces – team: USTC-CTSU).

5.6.3 Most Effective and and Original Methods

Overall, applying methods that are similar to the ones used in the supervised track using data in different languages can indeed lead to good results (e.g., king001, AAdaM, UAlberta). In addition, combining data in different languages and testing on another could boost the performance of crosslin-

Table 6: Track C results. The best results are in bold, and NR stands for *not ranked*. As the methods are highly language-dependent, we only rank teams that participated in at least 8 sub-tracks, but we highlight in blue the best results achieved by non-ranked teams. (Non-ranked teams are sorted based on the number of languages they participated in.)

gual models for STR as shown by team sil_nlp who achieved the best results in Amharic and Moroccan Arabic. Further, we note that leveraging advanced features such as (1) linguistic features (e.g., language family) as performed by MaiNLP, who achieved the best results for Kinyarwanda, and (2) embedding features by adjusting the distribution of the similarity scores as experimented by USTCCTSU could also help boost the performance.

Besides reporting on the best-performing teams only, in Table 6, we also mention teams that did not participate in many sub-tracks but achieved good results such as team YSP, which outperforms all the other teams in English.

6 Discussion

We observe that in general, teams opt out of pretrained models, and in most cases, the methods do not perform equally well across languages. Hence, for a given track, performing well in a language does not mean performing equally well in another language.

Further, the results show that good scores are not only related to low vs. high-resourcedness. For instance, In tracks B and C, results for Modern Standard Arabic (arb), which is considered high resource, are sometimes worse than those for low resource languages such as Amharic (amh) and Kinyarwanda (kin).

Interestingly, although the participating teams rarely use language-specific features, such approaches lead to good and interpretable results, as reported by e.g., team MaiNLP, who leveraged information about language families in Track C. We also note that for Track C, using a simple LaBSE baseline can achieve results that are better or comparable to more sophisticated techniques (see Ousidhoum et al. (2024) for language-specific baseline results).

7 Conclusion

We presented the first shared task on semantic relatedness, covering three tracks and 14 languages in total. The submitted systems were ranked based on the ranking of their predicted relatedness scores compared to the gold labels.

We summarised the reported results, the best-performing methods, and the most effective, promising, and original ones. Overall, our findings on sentence representation techniques vary across the different languages and show that determining semantic textual relatedness is not a trivial task.

8 Limitations

As stated in Ousidhoum et al. (2024), we acknowledge that there is no formal definition of what constitutes semantic relatedness and that our annotations may be subjective. To mitigate the issue, we share our guidelines and annotated instances so researchers in the community can expand on our work, replicate it, and study the disagreements in our data. We are also aware of the limited number of data sources and data variety in some low-resource languages involved. We do not claim

that the datasets released represent all variations of these languages. However, they remain a good starting point as they were carefully picked, labeled, and processed by native speakers.

9 Ethics Statement

As stated in Ousidhoum et al. (2024), we acknowledge all the possible socio-cultural biases that can come with our data due to the data sources or the annotation process. When building our datasets, we did avoid instances with inappropriate or offensive utterances, but we might have missed some. Our goal was to identify common perceptions of semantic relatedness by native speakers, and our labels are not meant to be standardised for any given language as these are not fully representative of its usage.

A Appendix: Track A–Best Performing Teams

PALI and king001 Both teams PALI and king001 did not submit a task description paper. king001 chose to use translation for data augmentation and multilingual mixed training. The team used XLM–R as their base model and DeBERTa–v3 (He et al., 2021).

AAdaM Team AAdaM opted for translation-based data augmentation to increase the training data size for better performance. The English STR training data and STSB (semantic similarity) data were translated to create augmented datasets in other languages. The team explored both fine-tuning and adapter-based tuning, aiming to examine and compare their effectiveness on STR across the different languages. Given a target language, they first fine-tuned the cross-encoder-based AfroXLMR model on the augmented data as a warm-up or TAPT (Task-Adaptive-Pre-Training) and then continued the fine-tuning on the provided STR data.

NRK They used ensembling and various BERT-like models.

PEAR They examined the effect of combining vs. using language-specific data through 5-fold validation. No text preprocessing was conducted to maintain fairness across languages. Three model configurations were defined: “base” with no training, “all” trained on all languages, and “lang” trained on one language. They experimented with multilingual embeddings, cross-encoders, and data augmentation with bi-encoders. Parameter optimization was conducted using Optuna.

silp_nlp Team silp_nlp’s methodology for track A was a two-stage training. In the initial stage, they trained a model using all 9 languages covered in track A with MuRIL (Khanuja et al., 2021). They experimented with different hyperparameters on five epochs and selected the best multilingual checkpoint based on the average validation data loss. They fine-tuned the resulting model using the training data for each language in track A and ended up with monolingual models.

Each monolingual model was trained using different hyperparameters and they selected their final model based on the validation data loss of the corresponding language track.

NLP_1@SSN They used SBERT fine-tuned on multilingual and monolingual pre-trained language models Overall, they observed that the usage of monolingual PLMs did not guarantee better performance.

UAlberta They used an ensemble approach with an XGBoost regression (Chen and Guestrin, 2016) to integrate the predicted relatedness scores of three distinct regression models, with one optional SBERT model, as input and returned the final relatedness scores as output. Each of these models used a different pre-trained language model as its backbone, specifically RoBERTa Large (Liu et al.,

2019b), T5 Base, GPT-2 Base, and the optional SBERT (MPNet). They merged the English training and development sets with the translated training set of the target language. Then, they split them again via uniform random sampling according to their original sizes to establish new training and development splits. The did not use the data provided for arq, ary, and kin, and applied the English-trained version of their method to the English translations of the arq, ary, and kin test sets instead.

MBZUAI-UNAM They fine-tuned a paraphrase model architecture to train language-specific models, using a separate pre-trained model to embed each language. They also experimented with combined training sets based on the language families.

INGEOTEC For English and Spanish, they used embeddings (microsoft/mpnet-base, bert-base-multilingual-cased) to train an SVM classifier. For the other languages, they used prior work EvoMSA.

HausaNLP They used different base pre-trained models.

B Appendix: Track B

SATLab They proposed a system based on a model developed for the authorship identification of source code (Bestgen, 2019). It processed each pair of utterances independently, generating a distance between them without relying on additional information. Pre-processing involved lower-casing of texts. Character n-grams ranging from 1 to 5 characters are used, encompassing all characters including spaces, punctuation marks, symbols, and characters from different writing systems, all n-grams are retained without a frequency threshold. The frequency of each feature was weighted by a logarithmic function, and the features of each statement were weighted by the L2 norm. Semantic similarity between utterances was estimated using Euclidean distance between sets of n-grams in each pair.

MasonTigers In the initial phase, team MasonTigers obtained embeddings of training data and used various methods including TF-IDF, PPMI, LaBSE sentence transformer, and language-specific BERT models for multiple languages. Cosine similarity was then computed between pairs of embeddings, followed by applying ElasticNet and Linear Regression separately to predict sentence pair similarity in the development phase. Predicted values were clipped to ensure a range from 0 to 1.

HW–TSC The key features used by team HW-TSC's method included the N-gram chars method using XLM-RoBERTa and m-BERT tokenizers to compute similarity scores based on n-gram sentence dictionaries. They also used the BERTScore method to assess text quality based on the cosine similarity of token-level representations from the BERT model.

UAlberta They used a linear combination of two sets of normalized results, each derived from the cosine similarity measurements of sentence embeddings obtained from the hidden sentence representations processed by BERT Large and RoBERTa Large. They calculated the final relatedness scores by averaging the cosine similarity scores of sentence embeddings obtained from each set.

silp_nlp They converted the sentences into unigram and bigram representations and used Support Vector Regression (SVR).

Sentences were combined and transformed into a vector, and each sentence was indexed based on a value that represented the count of unigrams/bigrams present in it. The resulting vector was fed into the SVR model along with label values for training.

HausaNLP Team HausaNLP used a standard all-MiniLM-L6-v2 model to train a model for Track B.

IITK Team IITK uses SimCSE (Gao et al., 2021), or Simple Contrastive Learning of Sentence Embeddings that induced slight variations in its representation through dropout. TSDAE(Wang et al., 2021), a denoising autoencoder, was used to generate sentence embeddings by reconstructing original sentences in the presence of noise. They used BERT to construct the denoising autoencoder and TSDAE optimized the likelihood of reconstructing sentences during training, which led to compact embeddings.

Tübingen-CL Team Tübingen-CL opted for exploring features like cosine distance of average word embeddings and word overlap ratios, to potentially enhance performance. For English, they used two models: multi-qa-MiniLM-L6-cos-v1 trained on QA pairs and trained for semantic search and e5-

base-unsupervised trained on various pairs including question-answer and post-comment pairs, both refined with unsupervised transformation (PCA). Two additional features, PCA-transformed GloVe embeddings, and content word overlap ratios were incorporated into the unsupervised ensemble system. Similar methods were applied for Spanish and Hind using multilingual BERT embeddings and various feature combinations to predict relatedness.

CAILMD-23 Team CAILMD-23 participated in the English and Hindi sub-tracks of the unsupervised task. They experimented with a few models such as BERT-based and Hindi-Bert v2. The latter is trained on Hindi text comprehension with a training corpus of roughly 1.8 billion tokens.

C Appendix: Track C

AAdaM hey experimented with full fine-tuning, adapter fine-tuning using MAD (Pfeiffer et al., 2020), and data augmentation using different language combinations to augment data in a given source language.

king001 They did not submit a system description paper but they reported combining the training datasets provided for track A, and if one of them was in the target language, they translated it into English. Then, they run multi-task learning for 15 epochs.

UAlberta They used an ensemble approach with an XGBoost regressor (Chen and Guestrin, 2016) to integrate the predicted relatedness scores of three distinct regression models, with one optional SBERT model, as input. Each of their models used a different pre-trained language model as its backbone, specifically RoBERTa Large, T5 Base, GPT-2 Base, and the optional SBERT (MPNet).

They applied the English version of their method reported for Track A to the translations of the non-English test sets. The regression model fine-tuned on MPNet was used in the XGBoost ensembling method for amh, hau, and hin and not for esp, ary, kin, ind, arb, arq, and afr.

silp_nlp They used cross-lingual transferability on all the provided datasets except for the target language (e.g., when they test on Telugu, they use all languages except Telugu). In their cross-lingual transfer approach, MuRIL (Khanuja et al., 2021) led to the best results for Hindi and XLM-R (Conneau et al., 2020) for all the other languages.

USTCCTSU They used XLM-R (Conneau et al., 2020) trained on a combination of language inputs (chosen by trying different combinations with the best one including all the languages). They ranked in the top 5 for ind,arq, and esp.

They adjusted the similarity scores for the XLM-R base models by applying a technique called *whitening* that allowed them to change the non-uniform score distribution into multiple distributions, and eventually, into a uniform one.

MaiNLP They finetuned multilingual LLMs (XLM-R and Furina) using an upscaled version of the data from Track A. They assessed the linguistic similarity of the available Track A data to determine the most useful datasets and experimented with different language families. For pre-processing, they used tokenization, segmentation, and translation. They also experimented with transliteration to change the scripts into Latin. Translations helped them upscale the English, Hausa, and Spanish training data and then evaluate on the Track C data. They achieved the best results for Kinyarwanda.

umbclu They pre-trained T5 models with SemRel data. They used the English fine-tuned models for inference on all language test sets except English. On the other hand, they used Spanish models for inference on English.

HausaNLP They used a BERT-based model fine-tuned on the datasets in other languages. E.g., they trained on English data and tested on Spanish, trained on Kinyarwanda and tested on Hausa. They ranked in the top 5 in Task C for ind, pan.

MasonTigers They used statistical machine learning (Linear Regression, ElasticNet with TF-IDF and PPMI features) along with language-specific BERT-based models to predict the relatedness scores. The models were trained on dataset combinations of 5 languages other than the target language and used BERT-based models's similarity prediction on the target test data (e.g., they trained on amh, eng, esp, arq, ary and tested on afr). For language-specific BERT-like models, they used African language BERT-base models, Arabic BERT-based models, AfricanBERTa, and for eng, hin, ind, pun, esp, they used spanBERTa, BanglaBERT, RoBERTa-tagalog-base-BERT, HindiBERT, and RoBERTa.

Abstract

This paper presents the results of the SHROOM, a shared task focused on detecting hallucinations: outputs from natural language generation (NLG) systems that are fluent, yet inaccurate. Such cases of overgeneration put in jeopardy many NLG applications, where correctness is often mission-critical. The shared task was conducted with a newly constructed dataset of 4000 model outputs labeled by 5 annotators each, spanning 3 NLP tasks: machine translation, paraphrase generation and definition modeling.

The shared task was tackled by a total of 58 different users grouped in 42 teams, out of which 26 elected to write a system description paper; collectively, they submitted over 300 prediction sets on both tracks of the shared task. We observe a number of key trends in how this approach was tackled—many participants rely on a handful of model, and often rely either on synthetic data for fine-tuning or zero-shot prompting strategies. While a majority of the teams did outperform our proposed baseline system, the performances of top-scoring systems are still consistent with a random handling of the more challenging items.

1 Introduction

The modern NLG landscape is plagued by two interlinked problems: On the one hand, our current neural models have a propensity to produce inaccurate but fluent outputs; on the other hand, our metrics are most apt at describing fluency, rather than correctness. This leads neural networks to "hallucinate", i.e., produce fluent but incorrect outputs that we currently struggle to detect automatically. For instance, Dopierre et al. (2021) report that when trying to produce a paraphrase for the input "*I am not sure where my phone is*", they obtain the following 'hallucination' behavior: "*How can I find the location of any Android mobile*". For many NLG applications, the correctness of an output is however mission critical. For instance, producing a plausible-sounding translation that is inconsistent with the source text puts in jeopardy the usefulness of a machine translation pipeline.

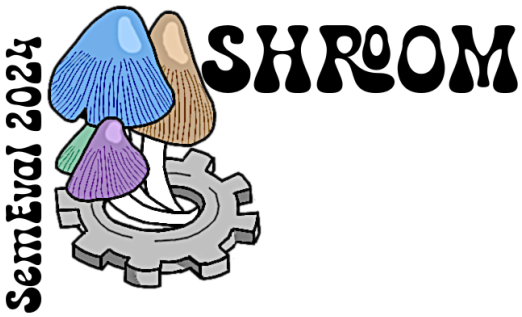

Figure 1: The SHROOM logo.

This motivates us to organize a **S**hared-task on **H**allucinations and **R**elated **O**bservable **O**vergeneration **M**istakes, or SHROOM. With our shared task, we hope to foster the growing interest in this topic in the community (e.g., Ji et al., 2023; Raunak et al., 2021; Guerreiro et al., 2023; Xiao and Wang, 2021; Guo et al., 2022). In particular, in the SHROOM we adopt a *post hoc* setting, where models have already been trained and outputs already produced. Participants were asked to perform binary classification to identify cases of **fluent overgeneration hallucinations** in two different setups: **model-aware** and **model-agnostic** tracks. That is, participants had to detect grammatically sound outputs which contain incorrect or unsupported semantic information, inconsistent

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1979–1993

with the reference input, with or without having access to the model that produced the output.

To that end, we constructed a dataset comprising a collection of checkpoints, inputs, references and outputs of systems covering three different NLG tasks: definition modeling (DM, Noraset et al., 2017), machine translation (MT) and paraphrase generation (PG) trained with varying degrees of accuracy. Datapoints were all annotated by 5 human annotators each resulting in 1000 validation items and 3000 test items.

Beyond simply detecting factually unsupported outputs, one of the goals of this shared task was to establish whether hallucinations are best construed as a categorical phenomenon or a gradient one. Similar remarks have been made with respect to textual entailment (Bowman et al., 2015). As such, participants' submission were scored both for accuracy (whether classifiers correctly identify hallucinations) and calibration (whether classifiers are confident about their prediction when they ought to be).

The shared task attracted a total of 58 different users grouped in 42 teams, out of which 26 elected to write a system description paper. Collectively, over the three weeks of the evaluation phase, participants submitted 300 valid sets of predictions on the model-aware track, and 320 on the model-agnostic track. We take this participation rate, along with the breadth of methodological approaches developed by participants, as clear signs of success for our shared task: This large pool of participants allows us to identify and discuss some key trends in how the task was tackled. Crucially, many participants rely on a handful of model, and often rely either on synthetic data for fine-tuning or zero-shot prompting strategies. In terms of raw performance, we note that while a majority of the teams (64 to 71%) did outperform our proposed baseline system, the performances of top-scoring systems are still consistent with a random handling of the more challenging items. In sum, this first iteration of the SHROOM underscores both an interest of the research community as well as the current limitations in our approaches.

The remainder of this article is structured as follows: Iin Section 2, we provide an overview of the current research landscape. Section 3 defines our theoretical framework, and Section 4 summarizes our data collection process. We then present and discuss shared task results in Sections 5 and 6 before concluding with a few thoughts on further research in Section 7.

2 Connecting with the past: related works and state of the art

It is now widely accepted that NLG models often generate outputs that are not faithful to the given input, commonly referred to in the community as hallucinations (Vinyals and Le, 2015; Raunak et al., 2021; Maynez et al., 2020). Yet there is minimal consensus on the optimal framework for its application. This lack of agreement is due in part to the diversity of tasks that NLG encompasses (Ji et al., 2023).

Guerreiro et al. (2023) propose a taxonomy of hallucinations that includes oscillatory productions, and fluent but strongly or fully "detached" outputs. While this taxonomy is well constructed, we find it inadequate for the needs of the community at large for four reasons: *(i)* It conflates some issues of fluency with semantic correctness (oscillatory productions are cases of non-fluent overgeneration where no extraneous semantic material is introduced); *(ii)* It only considers the most extreme cases of hallucinations (strongly or fully detached productions), whereas diagnosis of intermediary cases is bound to be more challenging and useful to the community; *(iii)* It focuses only on MT, although other tasks are also known to suffer from fluent overgeneration (e.g., Rohrbach et al., 2018), including the ones we propose to address; *(iv)* It uses only lowest scoring outputs, whereas any tool built to verify system outputs ought not to flag non-pathological outputs.

Alternative studies have built benchmarks for hallucination detection, with a predominant emphasis on dialogue systems. Li et al. (2023) propose the HaluEval benchmark using an annotation framework that does not necessarily center on the input given to the model and requires the annotators to search the internet for facts. Moreover, they opted to annotate the outputs of a popular LLM, with the major downsides that it is closed, not-transparent and commercial; rendering the research outputs that may stem from future studies less interesting. Other benchmarks include the works of Liu et al. (2022) and Zhou et al. (2021), which automatically insert hallucinations into training instances to generate syntactic data for token-level hallucination detection; Lin et al. (2022), which work with factual claims supported by reliable, publicly available

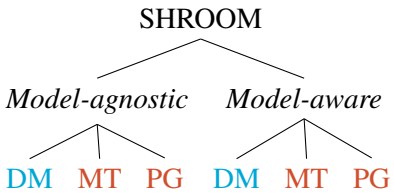

Figure 2: Shared task overview. Both tracks feature all three NLG tasks. Datapoints from systems in blue correspond to target-referential datapoints and in red the ones that are either target- or source-referential; which we refer to as *dual-referential*.

evidence; and Dziri et al. (2022), which focus on knowledge-based dialogue systems and base their annotation on NLI, relying only on the system's input, just as we do.

3 Tripping over hallucinations: task definition and annotation

In contrast with previous works (e.g. Guerreiro et al., 2023; Li et al., 2023), we focus on cases of fluent overgeneration since judgments pertaining to the over-generative nature of a production can be elicited by means of **inferential semantics**: if an output cannot be inferred from its semantic reference, then it contains some information that is not present in the reference—i.e., the model has generated more than we expected.[1] This approach connects with the theoretical framework sketched by van Deemter (2024), who likewise relies on inferential semantics but also considers undergeneration issues in NLG outputs. We provide multiple annotations and a gold majority label, given the low consensus on semantic annotations (Nie et al., 2020).

In Figure 2 we provide an overview of the task. The SHROOM is framed around two key distinctions: (i) model-aware vs. model-agnostic approaches, and (ii) source-referential vs. dual-referential datapoints. The former corresponds to whether participants have access to the model that generated the item: **Model-agnostic** approaches are practical, as models may not be accessible to end users; **Model-aware** approaches can lead to richer and more accurate diagnoses. The latter is a consequence of our inferential take on over-

[1]Note that if the output can be inferred from the reference but the information is not explicitly present in the reference, then the model is actually making a correct semantic inference: it is generating a semantically sound output. E.g., if the the model produces "my tie is blue" for the reference "my tie is the color of the sky", the model output is semantically sound.

```
{ "hyp":"A cigarette .",
  "ref":"tgt",
  "src":"I stepped outside to smoke myself a j .
         What is the meaning of J ?",
  "tgt":"( plural Js or J 's ) A marijuana
          cigarette .",
  "model":"ltg\/flan-t5-definition-en-base",
  "task":"DM",
  "labels":["Hallucination","Not Hallucination",
            "Not Hallucination", "Hallucination",
            "Hallucination"],
  "label":"Hallucination",
  "p(Hallucination)":0.6  }
```

Figure 3: Target-referential datapoint example from the validation set for the model-aware track.

generation: what can effectively serve as a semantic reference varies across NLP systems. For DM, where we fine-tune a language model to produce a definition for a given example of usage the datapoints are **target-referential**, i.e. the target is the sole usable semantic reference. In this context, the target serves as the sole usable semantic reference. Conversely, the target is expected to be semantically implied from the source in source-referential tasks, such as summarization. Note that we do not annotate source-referential tasks due to annotation challenges that make them unreliable for our purposes. In dual-referential tasks like PG & MT, this distinction bears no weight.

In Figure 3, we present an example datapoint displaying how we plan to encode all relevant information in a JSON format is provided. The datapoint keeps track of the source provided to the model as input (`src`), the intended target (`tgt`), the model production (`hyp`), the task this production was derived from (`task`), can correspond to DM, MT or PG), whether this datapoint is target-referential (`ref`), the annotations, the gold label and the proportion of annotators that labeled the utterance as a hallucination (`labels`, `label`, and `p(Hallucination)`). In the model-aware track, we will also provide a HuggingFace model name (`model`).

4 Foraging and harvesting season: Collected data

All SHROOM data (models, outputs and annotations) are available under a CC-BY license.[2]

[2]See helsinki-nlp.github.io/shroom

4.1 Data & model provenance

Participants have access to generated outputs from multiple systems trained to generate English output at various stages of their training, stemming from three sequence-to-sequence NLG tasks: DM, MT and PG. The SHROOM dataset consists of annotated *test* and *dev* sets, as well as a *unlabeled training split* of 30k datapoints per track and the full set of possible target references to allow corpus-wide approaches. To ensure effective annotation of the development and test sets, and to be able to guarantee a gradient in quality as measured by automated metrics, we pre-selected fluent outputs for the annotators, which we describe in the following.[3]

MT: For the model agnostic track we use the models from Mickus and Vázquez (2023). We compute perplexity for the all MT outputs and BERTScores with regards to the outputs and corresponding targets. We filter outputs with perplexity scores above the 2% quantile. From the filtered outputs, we randomly select 200 samples with BERTscores in the 1/7, 2/7, 3/7, 4/7, and 5/7 quantiles. For the model-aware track, we use the NLLB model (NLLB Team et al., 2022) and produce translations on the Flores-200 dataset from languages marked as low-resource to English. Next, we manually select a sample that is sufficiently fluent.

DM: We use the model of Segonne and Mickus (2023) for the model-agnostic track, and for the model-aware track we used the `flan-t5-definition-en-base` (Giulianelli et al., 2023). We generate outputs on the English portion of the CoDWoE dataset (Mickus et al., 2022), and manually select a sample that is reasonably fluent and contains no profanities.

PG: We used a pretrained and fine-tuned paraphrasing model[4] based on Pegasus (Zhang et al., 2020) for the model-aware track, and the controlled paraphrase generation model of Vahtola et al. (2023) for the model-agnostic track.

We generated paraphrase hypotheses using Europarl (Koehn, 2005) and Opusparcus (Creutz, 2018) for the model-aware and -agnostic tracks, respectively. For the model-aware setup, we generated 50 hypotheses for each source sentence using diverse beam search (Vijayakumar et al., 2016) using BLEU scores (Papineni et al., 2002) to select the least similar hypothesis for each source sentence to serve as its paraphrase. For the model-agnostic setup, we calculated control tokens for each source sentence as in Vahtola et al. (2023), scaled the length-controlling value in range (1, 1.5) with a uniform probability distribution to provoke hallucination in the generated sequences, and used beam search with a beam size of 5 to produce the paraphrases. We manually curated the final validation and test examples.

4.2 Annotation

We annotate a total of 4,000 items, which are split 25%–75% between development and test sets: 1000 datapoints come from PG, 1500 from DM and 1500 from MT. Each item is annotated by five annotators on whether the reference entails the output. Annotations are binary, for ease of dataset construction. Gold labels are defined with respect to the annotators' majority vote.

The annotators were enlisted via Prolific,[5] a paid platform specialized in gathering human data for research studies and AI dataset creation, among other purposes. We did not target any particular group of participants; the only screening prerequisites were that (i) participants had to be fluent in English and (ii) they should not have taken part in an initial pilot study.

We used Potato (Pei et al., 2022), an open-source annotation tool specifically designed to seamlessly integrate with Prolific. Annotators were first presented with a pre-annotation screen outlining the annotation guidelines, after which they commenced the annotation of items individually. Each item consisted of the Reference, the AI-generated output, and relevant context regarding the NLG task (DM, MT, or PG). The annotators were asked to answer the question *"Does the following AI output only contain information supported by the Reference?"* responding with either "yes" or "no," and were also given the opportunity to provide comments if necessary. Additionally, they could navigate back and forth through their assigned items. We set up a timer that notified the participants every 60 seconds of the time spent on an item. In Appendix B, we present a copy of the instructions we used.

To control for annotation quality, we manually reviewed annotations from two sets of selected an-

[3] Note that we do not warranty that the training split contains fluent outputs.

[4] https://huggingface.co/tuner007/pegasus_paraphrase

[5] https://www.prolific.com/

notators: (i) five randomly selected annotators; and (ii) the five annotators who completed the task the fastest (under 3.5 minutes). All 10 annotators completed 20 annotations each. We judged all 200 annotations to be sound, in that a reasoning could be reconstructed to explain the provided annotation.

Label distribution. Figure 4 provides an overview of the distribution of labels in the SHROOM dataset splits (validation and test), broken down per NLG task (MT, DM and PG) and track (model-aware vs. model-agnostic). In this figure, we consider the empirical probability that a given item is judged to be a hallucination, i.e., the proportion of annotators judging the NLG output is not supported by the intended semantic reference.

We can highlight two trends in this figure. The first one, and perhaps most important, is that hallucinations are not consensual among our annotators. If intuitions regarding hallucinations were clear-cut, we would strongly expect a bi-modal distribution of empirical label distributions being consistently judged as hallucinations or not hallucinations. Instead, we find a number of intermediate cases, where annotators are split: These account for 29–32% of the data, depending on the split (validation or test) and track (model-aware or model-agnostic). Given the small number of annotators per datapoint, we cannot confidently rule out the possibility of a sampling bias—it is plausible that a larger pool of annotator would yield more bimodal empirical distributions. On the other hand, this tentative evidence is also in line with what has been argued elsewhere for natural language inference (Nie et al., 2020; Zhou et al., 2022). This is in fact well exemplified by the datapoint provided in Figure 3: Whether the term *cigarette* is underspecified and can apply to any smokable substance, or whether it is to be understood as prototypically referring to tobacco cigarettes by default is, in fact, up for discussion—and it stands to reason that different speakers may form different opinions.

Second, it is difficult to find hallucinations: The higher the empirical probability, the fewer the datapoints. This is especially true in the PG task: these outputs rarely yields consensual hallucinations, whereas we can find such items in DM and MT much more frequently. Looking at the expected value of the empirical probability per task, we find that DM consistently ranks higher than MT, which in turns ranks higher than PG. Both of these differences are significant under a one-sided Mann-Whitney U-test in the two test tracks ($p < 0.0003$); in the model-aware validation dataset, only the difference between MT and PG is significant ($p < 2 \cdot 10^{-8}$), in the model-agnostic validation dataset, only the difference between DM and MT is ($p < 0.04$). We note that DM requires a more complex processing of its input, as it has to rely on facts captured by the underlying LLM during its pre-training phase; for MT and PG, the input of the NLG task contains the semantic information necessary to produce a valid output. As such, we conjecture that the difficulty of an NLG task fosters hallucinatory behavior.[6]

5 They got so high: shared task results

The competition was held via Codalab (Pavao et al., 2023). The leaderboard was left hidden during the evaluation phase (i.e., participants were not notified of their submissions' scores until the end of the evaluation phase) but users were allowed to make a high number of submissions (50).

Systems are evaluated according to two criteria: the **accuracy** that the system reached on the binary classification, and their **calibration**, measured as the Spearman correlation of the systems' output probabilities with the proportion of the annotators marking the item as overgenerating. We rank systems by accuracy and break possible ties using calibration.

5.1 Baseline system

As a baseline for the task, we use an LLM[7] to evaluate whether the generated hypotheses are coherent with the provided context. Drawing upon Manakul et al. (2023), we use the prompt template listed in Figure 5. The system of Manakul et al. (2023), which has gathered some attention from the community, constitutes a straightforward approach based on a modern LLM, and is therefore well-suited to serve as a baseline in our shared-task:

[6] We also remark that the two tracks are broadly comparable in terms of hallucinatory content. Two-samples Kolmogorov-Smirnov tests for either split (test or validation) do not provide sufficient grounds to suggest a difference of distribution in labels between model-aware and model-agnostic tracks—which again suggests that the relevant difference is at the task level, rather than at the model level.

[7] We use quantized `Mistral-7B-Instruct-v0.2` (Jiang et al., 2023), from the `Hugging Face hub` `huggingface.co/TheBloke/Mistral-7B-Instruct-v0.2-GGUF` or the `llamacpp` project `github.com/ggerganov/llama.cpp`.

it corresponds to a reasonable default approach to tackle the problem we challenge participants with.

The specific context varies depending on the task addressed, i.e. the source sentence for the paraphrase generation task, and the target sentence for machine translation and definition modeling tasks. As for the probability of hallucination, we rely on the probability assigned by the model to the first output word.[8] In cases where the output does not clearly indicate *yes* or *no*, we randomly select one, attributing a hallucination probability of 0.5.

On the model-agnostic track, our baseline system achieves an accuracy of 0.697 (with a calibration of $\rho = 0.403$), on the model-aware track, we observe an accuracy of 0.745 (with $\rho = 0.488$). We can also indicate some other simple heuristics, such as picking the most frequent label (viz., `Not Hallucination`): In this case, one would expect an accuracy of 0.593 on the model-agnostic track, and 0.633 on the model-aware track. A purely random guess between the two possible labels would result in an accuracy of 0.5. In short, our baseline systems systematically outperforms these crude heuristics.

5.2 Participating teams

A total of 59 individual users grouped in 42 teams participated in the shared task, out of which 26 elected to write a system description paper. During the evaluation phase, we received a total of 512 submissions, out of which 368 were successful. 264 of these submissions targeted both tracks, while 68 only targeted the model-agnostic track, and 36 only targeted the model-aware track. That is, we received 332 model-agnostic submissions and 300 model-aware submissions.

We present the model-agnostic track rankings in Table 1a and the model-aware track in Table 1b. As one might expect, there is a high correlation between the accuracy and calibration scores of each team's top ranking submission, which translates into a Spearman's ρ correlation of 0.909 on the model-agnostic track and 0.949 on the model-aware track. Most of the top submissions per team rank above our baseline ($30/42 \approx 71.4\%$ in the model-agnostic track, $25/39 \approx 64.1\%$ in the model-aware track). This appears roughly in line with all submissions globally: 69.9% of all model-agnostic submissions and 57.0% of all model-aware submissions score higher than our baseline.

Another point worth stressing is that teams that fare well on one track usually fare equally well on the other: For the 38 teams participating in both tracks, we find that the rank they obtain on the model-aware track correlates with the rank they obtain on the model-agnostic track (Spearman's $\rho = 0.884$). This would tentatively suggest that participants could not effectively leverage the supplementary data available in the model-aware track.[9]

Lastly, we note that there is a ceiling in terms

[8] We note that this simple heuristic may not accurately represent the true hallucination probability.

[9] An alternative account would be that all teams that participated in both tracks equally benefited from the access to the model weights, which we deem much less likely.

(b) Model-aware track rankings

Table 1: SHROOM team rankings. Codalab usernames are used to define teams when no other information was provided.

of performances: The most effective systems misclassify between 15 to 19% of all items, or almost one in every six or five datapoints. We have discussed above that, as hallucinations are a graded phenomenon, a large segment of our data (30%) corresponds to ambiguous cases where annotators are split 2 vs. 3. As such, it is worth stressing that top scores are consistent with models that classify consensual items well (where at most one annotator disagree), but perform at random chance on the more challenging ambiguous datapoints.

6 A bunch of fun guys: qualitative analysis of participants systems

We derive our analyses from system description papers as well as self-reports from a handful of participants who elected to not provide a full description of their systems. This corresponds to 33 systems

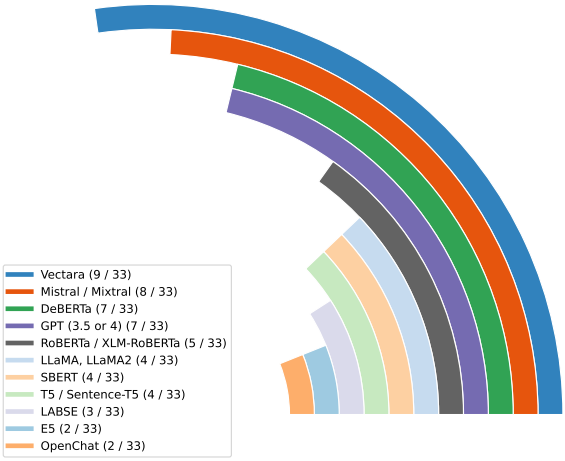

Figure 6: Known models used by more than one team. A full circle would correspond to a given model used by all of respondents, half a circle to 50% of respondents using said model. Best viewed in color.

out of the 42 identified teams that participated to the shared task, out of which 7 did not provide a full description. See also Table 2 in Appendix A for further details.

How the task was approached. The teams used a variety of methods to address the problem, ranging from ensemble techniques to fine-tuning pre-trained language models (LLMs) and prompt engineering. As expected, most teams used popular pre-trained LLMs such as GPT, LLaMA, DeBERTa, RoBERTa, and XLM-RoBERTa; Figure 6 provides a summary of which models were most popular among our teams. The Vectara hallucination evaluation model[10] turned out to be extremely popular, as more than 1 in 4 teams that provided information about their systems report having used it in their experiments. If we add other DeBERTa-based models, this number climbs to $16/33$, i.e. almost every other team used DeBERTa or a variant thereof.

Yet, the ways in which these LLMs were used cover a wide range of approaches: Some either fine-tuned on hallucination data or optimized with prompts; others employed in-context learning with role-playing, automatic prompt generation, and ensemble methods. Furthermore, some teams focused on zero-shot and few-shot approaches, while others focused on synthetic data generation and semi-supervised learning techniques to construct a labeled training set. Especially noteworthy, Rahimi et al. (2024) report constructing a manual dataset of 3000 datapoints for training their systems.

Teams predominantly relied on the data constructed for the SHROOM, although some teams added datasets such as QQP and PAWS. Interestingly, we also note five teams relying on NLI/entailment data or models, including some that achieved high results (Obiso et al., 2024; Sanayei et al., 2024; Borra et al., 2024; Liu et al., 2024 and Team Centre-Back)—and this matches the theoretical framework adopted in this shared task.

What worked well. We now turn to what distinguishes top scorers from other submissions. We note that systems based on the closed-source models GPT-3.5 and GPT-4 tend to fare well: 4 out of the 6 highest scoring systems on either track—Mehta et al. (2024); Obiso et al. (2024); Liu et al. (2024); Allen et al. (2024) and Alejandro Mosquera—all report using these models. This is however not a strict requisite as OPDAI (Chen et al., 2024) manages to rank high (2^{nd} on the model-agnostic track and 4^{th} on the model-aware track) without it. Neither does using closed-source models guarantee a high result: UCC-NLP and Markchom et al. (2024) also use GPT-3.5, and while the former is ranked 14^{th} on the model-agnostic track and 13^{th} on the model-aware track, the latter is ranked 30^{th} on the model-agnostic track and 21^{st} on the model-aware track, and only outperforms the baseline model in accuracy by 0.02 to 0.03 points.

Remarkably, many of the top-scoring approaches rely on fine-tuning (Liu et al., 2024; Obiso et al., 2024; Arzt et al., 2024; Chen et al., 2024) or ensembling (Mehta et al., 2024; Belikova and Kosenko, 2024, Alejandro Mosquera), suggesting that high performances do not come out of the box from off-the-shelf LLMs and systems. It is necessary to adapt existing models or establish to what extent their predictions are useful to the task at hand.

Another important trend we identify is that the number of submissions per team anti-correlates with the rank they obtain: The more participants submitted, the higher their best scores went. This is visualized in Figure 7: On both tracks, we find reasonable anti-correlations ($-0.58 < \rho < -0.44$) indicating that top-scorers tended to submit more. This might provide an alternative explanation for what distinguishes top-scorers from other participants: If we were to model participants' submissions as a random process, we would expect that sampling more often (i.e., submitting more) would mechanically yield a better rank.

[10] https://huggingface.co/vectara/hallucination_evaluation_model

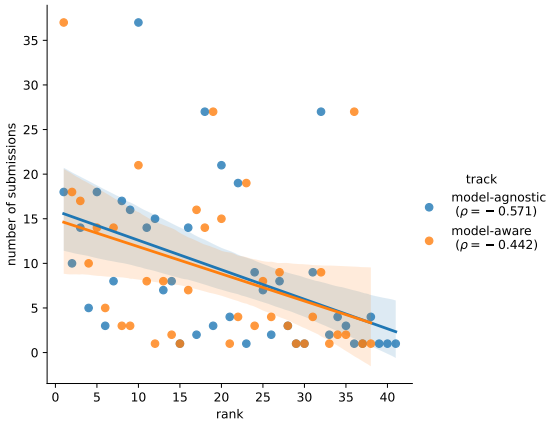

Figure 7: Rank obtained vs. number of submissions made on both tracks.

Overall, the high methodological diversity highlights the complexity of hallucination detection, even when contained the simple inferential semantics framework of our shared task: While a focus on NLI or using high-performance closed source models may help, the highest scores are obtained through thorough involvement—both in terms of model training and prediction set submissions.

7 Much room to grow: conclusions and future perspectives

This first iteration of the SHROOM shared task on detecting hallucinations has allowed us to make significant headway into understanding the confabulatory behavior of modern NLG systems. The data collected demonstrate that *hallucinations correspond to a gradient phenomenon*, and that different speakers form different opinions as to what counts as a hallucination. We were also able to showcase that *ambiguous items remain challenging*, and that the current state of the art on the dataset we provided is compatible with simple random guesses whenever the data is more ambiguous. This results underscore the massive gap that NLP research urgently needs to address: one out of every six items is still misclassified by the most effective systems showcased during this shared task.

The diversity of methodologies employed by participants underscores how *out-of-the-box solutions are not sufficient*: Highest scoring teams had to rely on fine-tuning or ensembling and made a high number of submissions. Relatedly, *access to the model parameters was of limited help*: Few approaches attempted to perform model-specific investigations, and performances on the model-aware track are in fact lower than what we observed on the model-agnostic track. Properly leveraging the parameter space for finer-grained hallucination detection remains a point for future research to investigate.

This shared task has not broached some crucial aspects and questions: How do these results translate insofar as modern LLMs—often much larger and better trained than the systems we studied here—are concerned? Can we leverage sentence-level predictions to pinpoint token-level issues with the output of our NLG systems? And will the difficulties that we underscored in this purely English be exacerbated when studying other languages—especially those that are less well-resourced and typologically different? Answering these questions and more will require further research—and perhaps future iterations of this shared task.

Overall, the success of this shared task is owed to its committed participants. We received over 350 submissions in the span of three weeks from across the world. The width of approaches studied and reported upon provides a useful snapshot of where the field is at, what approaches are favored, and what gaps still need to be overcome. We expect that the results of the SHROOM will provide a useful starting point for future work on hallucinations.

Doing SHROOM responsibly: ethical considerations

We strive to adhere to the ACL Code of Ethics.

Broader Impact. Hallucinated outputs from large language models can be used to further spread disinformation and advance misleading narratives. Detecting hallucinated outputs is an important step in elucidating the factors of this phenomena and contribute to ongoing efforts to mitigate hallucination. This leads to the development of more trustworthy generative language models.

Data and Annotators. Our annotators were suitably compensated for their work in excess of minimum wage. Due to the nature of the proposed task, the data we release might contain false or misleading statements. In the case of annotated data, these statements are labeled as such, but this does not for the unannotated portions of the data. We manually pre-filtered the data to remove profanities before providing them to annotators. Such precautions were not taken for the unannotated portion of the dataset, which might therefore contain offensive, obscene or otherwise unconscionable items.

Acknowledgments

The construction of the SHROOM dataset was made possible by a grant from the Oskar Öfflund Foundation. This work is also supported by the ICT 2023 project "Uncertainty-aware neural language models" funded by the Academy of Finland (grant agreement № 345999). We also thank the CSC-IT Center for Science Ltd., for computational resources.

The shared task logo (cf. Figure 1) uses the "Retro Cool" font from Nirmana Visual (https://nirmanavisual.com/), made available for personal / non-commercial uses.

A Shared consciousnesses: Overview of approaches used by SHROOM teams

In Table 2, we provide a short overview of the various teams, the resources they utilized (models & datasets), as well as a short description of their approach.

B What SHROOM makes you do: Annotation guidelines

In Figure 8, we provide an exact copy of the annotation guidelines given to the annotators. These guidelines are based on five of the organizers' experience of annotating the trial set, and were provided to annotators recruited for the validation and test splits.

Annotation guidelines for SHROOM

Thank you for agreeing to participate in the SHROOM survey! The present document will provide you some general guidelines as to what is expected of you.

What are we looking for?

Our goal is to assess the **truthfulness** of sentences and documents written with artificial intelligence. In particular, we are interested in cases when the **AI outputs** are not supported by the facts. Such unsupported outputs are colloquially referred to as **'hallucinations'**.
You will be presented with a series of items. Each item contains an **AI output**, as well as one or more **References**, i.e., examples of what the model should have produced in an ideal scenario. Outputs and references can correspond to different types of sentences and paragraphs: news headlines, dictionary definitions, movie subtitles…
We ask that **you mark for every item**, whether the output contains or describes facts that are **not supported by the provided reference**. Such items are instances of hallucinations.

In other words: **hallucinations are cases where the AI output is more specific than it should be, given the available reference**.

Some Examples and counterexamples Hallucinations

Hallucinations

Below are some examples of items our research team unanimously considered as hallucinations:

Example 1

```
Reference: The worship of trees.

AI output: (uncountable) The study of trees.
```

Example 2

```
    Reference: Why is everyone laughing?
    AI output: Why is everyone okay?
```

Example 3

```
    Reference: You’re a scam artist.
    AI output: You’re not a good scam artist.
```

Not Hallucinations

And next, here are a few items that we unanimously did not consider as hallucinations:

Example 1

```
    Reference: Capable of being deployed by parachute.
    AI output: Capable of being parachuted.
```

Example 2

```
    Reference: When did you see him?
    AI output:When was the last time you saw him?
```

One last thing: Hallucinations vs. undergeneration

In some instances, the AI output can contain **less** information than the reference. We refer to such items as cases of **“undergeneration”**. These are not necessarily cases of hallucinations: as long as what is stated in the AI output is supported by the reference, such items should not be marked as hallucinations.

Here is one straightforward example:

```
Reference: I can't do it alone. You have to help me.
AI output:I can't do it alone.
```

Given that all the information present in the AI output is also found in the reference, **this should not be marked as a hallucination**.

That's it!

Figure 8: Annotation guidelines.

Abstract

While vertical thinking relies on logical and commonsense reasoning, lateral thinking requires systems to defy commonsense associations and overwrite them through unconventional thinking. Lateral thinking has been shown to be challenging for current models but has received little attention. A recent benchmark, BRAINTEASER, aims to evaluate current models' lateral thinking ability in a zero-shot setting. In this paper, we split the original benchmark to also support fine-tuning setting and present SemEval Task 9: **BRAINTEASER(S)**,[1] the first task at this competition designed to test the system's reasoning and lateral thinking ability. As a popular task, BRAINTEASER(S)'s two subtasks receive 483 team submissions from 182 participants during the competition. This paper provides a fine-grained system analysis of the competition results, together with a reflection on what this means for the ability of the systems to reason laterally. We hope that the BRAINTEASER(S) subtasks and findings in this paper can stimulate future work on lateral thinking and robust reasoning by computational models.

1 Introduction

Vertical thinking requires logical and commonsense reasoning, i.e., making plausible sequential associations of different pieces of commonsense knowledge. As presented in Figure 1 (top), we can easily infer that flooding a room requires filling it with water, based on common sense, and inanimate objects with five fingers are gloves in the riddle. In contrast, lateral thinking is a creative and divergent process that requires thinking out of the box and defying common sense. For example, as shown in Figure 1 (bottom), one needs to overwrite the commonsense associations of *man shaves* to *he shaves himself*, and regard the man as somebody who shaves others all day (e.g., a barber) to answer the lateral puzzle.

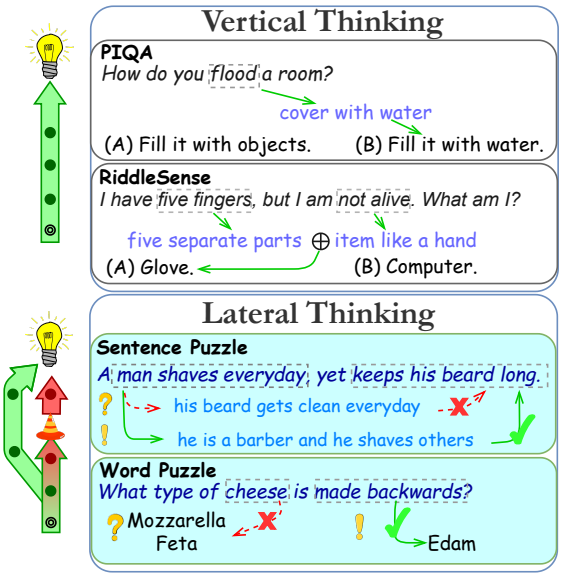

Figure 1: Figure from the first lateral thinking benchmark BRAINTEASER (Jiang et al., 2023c), contrasting existing Vertical Thinking tasks (PIQA (Bisk et al., 2020) and RiddleSense (Lin et al., 2021)) to lateral thinking. Solving BRAINTEASER's lateral puzzles requires default commonsense thinking to be deprecated.

While there are many datasets focusing on commonsense reasoning (Talmor et al., 2019; Bisk et al., 2020; Sap et al., 2019b) and numerous studies on improving commonsense reasoning ability of artificial systems (Ma et al., 2021a,b; Zhang et al., 2022), lateral thinking challenges have received little attention and are often filtered out as noise during preprocessing (Vajjala and Meurers, 2012; Speer et al., 2017; Sap et al., 2019a). Consequently, artificial systems' ability to solve lateral thinking problems remains understudied.

To bridge this gap, in (Jiang et al., 2023c), we introduce a novel BRAINTEASER benchmark with two tasks of different granularity: Sentence Puz-

[1]We use BRAINTEASER to represent the original benchmark and BRAINTEASER(S) to represent the data in SemEval task for clarity.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1994–2008

zles and Word Puzzles (cf. Figure 1). The task is formulated in a multiple-choice QA setting for a straightforward human and automatic evaluation. The dataset is constructed via a three-stage pipeline to ensure that the questions are valid and challenging.

We organize our SemEval Task with **BRAINTEASER(S)**, which contains the same data as the BRAINTEASER benchmark to *study model's lateral thinking ability*. Differing from the original benchmark that only focuses on the zero-shot setting, BRAINTEASER(S) divides this data into train/trial/test sets and has no limitation on the method adaptation. The goal of this paper is to describe the SemEval task and provide an analysis of the participant results. We provide details of the data construction pipeline in Section 2 and the SemEval Task description in Section 3. We present the overall leaderboard result and fine-grained method analysis in Section 4. Finally, we discuss the summarized result and conclude with high-level insight to stimulate future works on lateral thinking. For further information, we refer the reader to our source code,[2] task website,[3] and competition website.[4]

2 Source Dataset

We use our recently introduced BRAINTEASER dataset (Jiang et al., 2023c) as the basis for our evaluation. In this section, we briefly describe the data construction pipeline and we refer interested readers to (Jiang et al., 2023c) for full details.

The data construction pipeline has three stages. In the first stage, we collect lateral thinking puzzles from public websites such as `riddles.com` and `rd.com` and conduct filtering and deduplication. Then, the remaining questions are manually verified to ensure that they fit in the sentence or word puzzle categories.

Since the collected puzzles are open-ended questions, which poses great challenges for evaluation. These open-ended puzzles are then converted to multiple-choice questions in the second stage. Specifically, we leverage tools such as COMET (Hwang et al., 2021), WordNet and Wikipedia to construct distractors for every question. For sentence puzzles, we collect distractors that overwrite non-central premises of the question, and for word puzzles, we collect distractors that are semantically similar to the correct answer to ensure they are challenging for systems.

Table 1: Key statistics of the BRAINTEASER dataset. Choices combine the correct answer with all the distractors.

	Sentence	**Word**
# Puzzles	627	492
Average Question Tokens	34.88	10.65
% Long Question (>30 tokens)	48.32%	2.23%
Average Answer Tokens	9.11	3.0
Std of Choice Tokens	2.36	0.52

Finally, in stage three, we construct additional data to mitigate the risk of memorization by large pretrained language models. In particular, for each question, we rephrase the original question using an open-source rephrasing tool without changing its answers or distractors.[5] This set is referred to as *Semantic Reconstruction*. Additionally, we leverage GPT-4 to reconstruct each question into a new context such that the misleading question premise is kept. In this case, both the question and the correct answer become different, but the reasoning path remains the same. After reconstruction, the distractors are collected in the same way as described earlier. This set is referred to as *Context Reconstruction*. A strong reasoning model is expected to solve all variants of the question consistently, as their reasoning patterns are identical despite being phrased differently. In total, we construct 1,119 data samples, including reconstruction variants. We report the key statistics in Table 1.

3 Task Description

3.1 Task Definition and Organization

In BRAINTEASER(S), we utilize both subtasks in the BRAINTEASER benchmark for evaluation: Sentenze Puzzle (*SP*) and Word Puzzle (*WP*). Both subtasks are multiple-choice QA tasks. We run our SemEval task on CodaLab. Our task is divided into two primary phases: (i) The Practice Phase runs from September 2023 to January 2024, and (ii) The Evaluation Phase runs from 10th Jan 2024 to 31st Jan 2024. We open the Post-Evaluation Phase after 31st Jan 2024 to encourage further research.

3.2 Evaluation Metrics and Data Splits

Evaluation Metrics We evaluate all systems using the same accuracy metrics as Jiang et al. (2023c):

[2] https://github.com/1171-jpg/BrainTeaser
[3] https://brainteasersem.github.io/
[4] https://codalab.lisn.upsaclay.fr/competitions/15566
[5] `https://quillbot.com/`

Table 2: Data statistics of each data split and baseline of BRAINTEASER(S).

	SP	WP
BRAINTEASER	627	492
Data Split of BRAINTEASER(S)		
Train	507	396
↪ Trial (*subset of train*)	120	96
Test	120	120
Baseline overall accuracy		
Human	0.920	0.917
ChatGPT (BRAINTEASER)	0.627	0.535
RoBERTa-L (BRAINTEASER)	0.434	0.207

Instance-based Accuracy considers each (original or reconstruction) question separately. We report instance-based accuracy on the original puzzles and their semantic and context reconstructions. *Group-based Accuracy* considers each original puzzle and its variants as a group. The model will score 1 only when it successfully solves all three puzzles in the group, otherwise, its score is 0. *Overall Accuracy* computes accuracy over all instances.

Data Split To enable BRAINTEASER(S) to support both fine-tuning and zero/few-shot setting, we further divided the original BRAINTEASER dataset into 3 data splits: train, trial, and test set, as shown in Table 2. The train set consists of 507 sentence puzzles and 396 word puzzles. We reuse a portion of the train set as a trial set, which contains 120 sentence puzzles and 96 word puzzles. The test set has 120 data for both subtasks. We release questions and answers from the train and trial set during the Practice Phase. We only release the questions of the test set during the Evaluation Phase and release the whole dataset after the Evaluation Phase ends.

Baseline We provide three baselines (Table 2, see Appendix A for details) to show the gap between humans and SOTA models. To get a comprehensive and robust evaluation performance for each subtask, the human evaluation is computed over 102 data randomly sampled from the original **BRAINTEASER** benchmark, ChatGPT and RoBERTa-L (Liu et al., 2019) performance are also computed over the **BRAINTEASER** in zero-shot setting, i.e. the original unpartitioned data of (Jiang et al., 2023c).

4 Participant System and Results

4.1 Participant Overview

We have 182 participants in total. In the Practice Phase, we have no limitation on the number of submissions to support exploration and enable participants to understand the submission format. We receive 243 submissions for *SP* and 155 for *WP*. In the Evaluation Phase, we allow up to three submissions per team and keep the submission with the best overall accuracy. Our final leaderboard has 48 team submissions for *SP* and 37 for *WP*.

4.2 Leaderboard Results

Table 3 (see Appendix A for full table) displays the top ten models for each subtask, ranked by overall accuracy. The best-performing model in *SP* excels in all six metrics, whereas the leading models in *WP* excel in all but context reconstruction. In the **instance-based accuracy metrics**, most top-performing models (75%) in two subtasks show better performance on original and semantic reconstruction compared to context reconstruction. Most models (80% in *SP*; 70% in *WP*) show the same trend across the entire leaderboard. In the **group-based accuracy metric**, half of the top models in both tasks align with their original instance-based accuracy for the grouped original and semantic reconstruction (Ori&Sem). Only one model in *WP* maintains its performance on all reconstructions (Ori&Sem&Con). Across the leaderboard, more than 80 percent of models in both subtasks show a decrease in Ori&Sem accuracy, ranging from 0.025 to 0.175 in *SP* and 0.031 to 0.281 in *WP*. Nearly all models show a significant drop in Ori&Sem&Con accuracy, with declines varying from 0.025 to 0.275 in *SP* and 0.031 to 0.344 in *WP*.

4.3 Fine-grained System Analysis

In this section, we provide system analysis for the models from the 28 system description papers from participants.*

Method Adaptation and Architecture Selection For both subtasks, the chosen adaptation methods among participants are either fine-tuning models (60%) or prompting models (65%) in a zero-shot (Sanh et al., 2021) or few-shot manner (Brown et al., 2020). Half of the participants try multiple adaptations and submit the best one. For the fine-tuning architecture, participants select either small-size models (<1B) including BERT (Devlin et al., 2018), RoBERTa (Liu et al., 2019), DeBERTa (He et al., 2020) or large-size models (>=1B) such as FLAN-T5 (Chung et al., 2022) and Mistral

* The rank discussed later in this section is based on systems with description papers.

Table 3: Top ten leaderboard results for both subtasks, including user submissions without system description papers. Ori = Original, Sem = Semantic, Con = Context. Team name with (*) submit the system description paper. The first, second and third submissions per category are represented by highlight, **bold** and underline, respectively.

7B (Jiang et al., 2023a). For the prompting architecture, the majority (90%) use closed-source LLMs such as GPT-4 (OpenAI et al., 2023), GPT-3.5, GeminiPro (Team et al., 2023), Claude (Anthropic, 2024), and Copilot.[6] Techniques like Chain-of-Thought (Wei et al., 2022a), Ensemble (Wang et al., 2022), and RECONCILE (Chen et al., 2023) are widely adopted for prompt engineering. Figure 2 provides a visualization of the overall accuracy distribution for each architecture. For fine-tuning architecture, fine-tuning on large models shows better performance with a tight accuracy range compared to small ones. Fine-tuning on small models shows competitive performance (three in the top five*) in *SP* but a significant drop in *WP*. Among the prompting designs, both zero-shot and few-shot show promising results (seven in the top nine systems*) on two subtasks, with the latter one having a wider accuracy range.

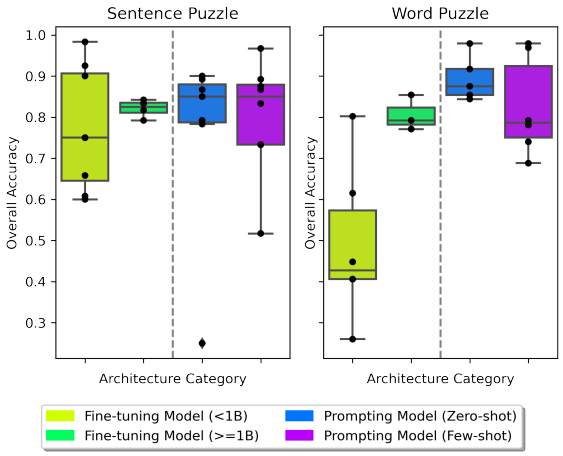

Figure 2: The overall accuracy distribution of each architecture selection.

External Dataset Half of the participants (54%) implement their systems only on the original target task, but some further introduce external datasets (35%) to enhance their models' performance. Participants generate humor-style synthetic data using LLMs, crawl riddle websites, or use RiddleSense (Lin et al., 2021) to invoke models' lateral thinking abilities. Other commonsense datasets such as BIRD-QA (Chen and Zulkernine, 2021) or knowledge graphs including ConceptNet (Speer et al., 2017) and WordNet (Miller, 1995) are used to provide general concepts of key instances in questions. Using humor-style datasets tends to be useful on both subtasks, especially for fine-tuning models. Meanwhile, synthetic explanations derived from LLMs are used in prompting to evoke chain-of-thought (Wei et al., 2022b) reasoning abilities.

Data Reconstruction Some participants (18%) reconstruct the original data or change the four-

[6]https://copilot.microsoft.com/

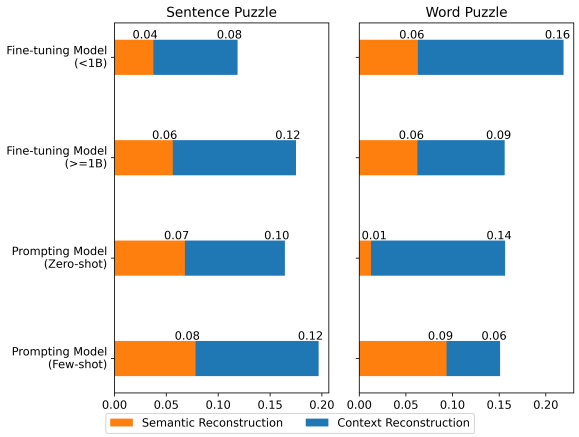

Figure 3: The drop in performance after introducing each reconstruction in group metric.

choice question format. Wang et al. (2024a) use back translation to enlarge the dataset size. Chakraborty et al. (2024) simplify each question into the binary choice problem and Reyes et al. (2024) solve the question under a classification approach with three class labels. Removing the unsure choice is also widely adopted for prompting, where the systems only choose unsure when they fail on the other three choices. Due to a limited number of data reconstruction samples, we cannot conclude which approach can improve performance.

Consistency of Model Predictions In Figure 3, we compare the drop in performance when considering reconstruction variants with group metrics to understand whether the models can solve lateral thinking puzzles by following a consistent reasoning path. On semantic reconstructions, the fine-tuning model has a smaller drop than zero/few-shot prompting in general. Fine-tuning on small models and zero-shot prompting work best on each subtask. On context reconstruction, all architectures show a more significant decline in performance. Fine-tuning on small models and few-shot prompting yield minimal drops in *SP* and *WP*, yet exhibit the largest declines in other subtasks.

5 Discussion

We start the discussion with the question: "*Is lateral thinking solved*?" The best-performing systems reach 100% on both tasks, making it seem that the task is solved. However, there remain many questions to explore. Our discussion targets 5 questions to provide overall insights: 1) What's the difference between the **BRAINTEASER(S)** SemEval Task and the original **BRAINTEASER** benchmark? 2) What's the difference between the best systems for sentence puzzles and word puzzles? 3) Are model predictions consistent with individual and group partitions? 4) What does fine-tuning mean for lateral thinking tasks? 5) What challenges still exist in the realm of lateral thinking?

5.1 Difference with the Original BRAINTEASER (Jiang et al., 2023c)

The **BRAINTEASER** benchmark (Jiang et al., 2023c) is proposed to evaluate LLMs' lateral thinking ability in **zero- and few-shot** settings while in **BRAINTEASER(S)** we release 80 percent of the data for training and we put no limitation on method adaptation. Although releasing data encourages more possibilities for participants, it also narrows down our hidden test set, making the comparison between system performance on BRAINTEASER(S) and the LLMs evaluation results on the BRAINTEASER benchmark unfair. With only 120 samples in the BRAINTEASER(S) test set, the probability of achieving high performance by some of the large number of systems becomes relatively large. Moreover, we expect that most of the lateral patterns will be recurring between the training and the test data, which especially benefits fine-tuning methods. With these caveats in mind, we hope the result and analysis on BRAINTEASER(S) can provide meaningful ideas and insight on lateral thinking and be verified systematically on the whole BRAINTEASER benchmark.

5.2 Effective System Choices and Differences

From subsection 4.3, we know architecture selection yields different distributions of performances on each subtask. On sentence puzzles, fine-tuning small models (Kelious and Okirim, 2024; Mishra and Ghashami, 2024; Farokh and Zeinali, 2024) with additional dataset providing competitive results. On word puzzles, either zero-shot (Moosavi Monazzah and Feghhi, 2024; Venkatesh and Sharma, 2024) or few-shot (Li et al., 2024; Raihan et al., 2024) prompting leads to top-performing results. In general, even small models obtaining language understanding during pre-training can adapt to sentence puzzles via fine-tuning, and additional humor-style datasets can evoke more lateral thinking abilities. On word puzzles, fine-tuned models have difficulties focusing on letter composition which hugely deviates from

their pertaining dataset. Even the top-scoring fine-tuning model (Kelious and Okirim, 2024) on *SP* fails to perform well on *WP*. On the other hand, the prompting method leverages the information stored in LLMs' parameters and their access to large pre-training data to mitigate the difficulty of word puzzles. However, the nature of the frozen model not only reduces the effectiveness of the external datasets but also limits further improvement and requires meticulous prompting engineering to ensure stable performance.

5.3 Prediction Consistency

Reconstruction of the original brainteaser puzzles allows us to distinguish between memorizing the training corpus and the ability of models to generalize to unseen samples. As indicated in subsection 4.2, most models struggle with consistent lateral thinking. Context reconstruction poses greater challenges than semantic reconstruction due to the need for lateral reasoning adaptation to novel settings. Context reconstruction of word puzzles is the most challenging, highlighting the risks of overfitting and memorization. Figure 3 shows architectures have different consistency issues. Fine-tuned models have a significant drop in context reconstruction in *WP* because the novelty of puzzles limits models to training corpus. Few-shot prompting can be beneficial for consistency in word puzzles but useless in sentence puzzles. LLMs' ability to follow pattern (Mirchandani et al., 2023) leads them to focus on the surface form in word puzzles, which brings improvement in consistency. Few-shot prompting can hardly provide general patterns of sentence puzzles due to its uniqueness, and the example in the demonstration can mislead the model.

5.4 Impact of Fine-Tuning

Even though recently in-context learning (ICL) (Brown et al., 2020) has achieved great progress on reasoning tasks (Talmor et al., 2019; Bisk et al., 2020), we are happy to see half of the participants implement their system in fine-tuning approaches and showing promising performance. Fine-tuning on small models can lead to a wide accuracy distribution, which requires careful design on hyperparameters and the training process. Exposure to external datasets can stabilize and enhance performance. Fine-tuning on large models shows tight accuracy distribution but lacks top-performing models, which suggests the need for more fine-tuning data to "distort" the default commonsense (Kumar et al., 2022) and evoke lateral thinking out-of-distribution (Jiang et al., 2023b). Also, the large gap between instance- and group-based metric (Figure 3) points out that short-cut learning still exists among these methods.

5.5 Challenges in Lateral Thinking

We summarize the discussion with the challenges that remain unsolved and require further effort to evoke the models' lateral thinking abilities. 1) The system performances and our analysis are based on a small set of original BRAINTEASER benchmark (subsection 5.1). A more general and systematic analysis should be performed with the entire original BRAINTEASER data or even an enlarged version of it, starting from prompting models. 2) There is still a lack of a general approach demonstrating a stable and competitive performance on both subtasks. No existing method can merge the advantages of each architecture on each subtask (subsection 5.2). 3) Each model fails to generate consistent predictions similar to humans, even under simple semantic reconstructions (subsection 5.3). 4) Fine-tuning methods suffer from learning shortcuts while prompting methods have problems finding general lateral thinking patterns akin to humans (see also (Lewis and Mitchell, 2024)) (subsection 5.4).

6 Conclusions and Future Perspectives

This paper summarizes SemEval 2024 Task 9, BRAINTEASER(S), a novel task defying common sense. We present the motivation, data design, data construction, evaluation process, competition systems, participant results, result analysis, and discussion. BRAINTEASER(S) was popular among participants and received 483 submissions from 182 teams during the competition, with various method adaptations and architecture selections demonstrating different advantages on each subtask and evaluation metric. The best-performing systems have impressive performance on both subtasks, which reach 100% accuracy on lateral thinking puzzles from the web. However, our fine-grained analysis highlights the remaining questions and challenges for further research. Importantly, BRAINTESER(S) SemEval result is evaluated over a subset (20%) of original BRAINTEASER benchmark. Even on this subset and despite the access to 80% of the data for training, models still strug-

gle to reason consistently on semantic and context reconstruction. Future work should investigate flexible ways to combine lateral and vertical thinking, construct better evaluation metrics for creative and open-ended generations, build connections within reconstruction based on analogical reasoning (Sourati et al., 2023) and explore a dynamic, multi-stage process where the model (or human) can request clarifications or obtain contextual hints. The BRAINTEASER(S) SemEval Task, together with its source BRAINTEASER task, is the first step toward injecting AI systems with lateral thinking ability. We hope that the competition results and analysis can inspire future research on developing and evaluating lateral thinking models.

Ethical Considerations

As our brain teasers are "folk knowledge" and are published on a range set of websites, it is hard to check their original licenses comprehensively. Yet, the website owners declare permission to print and download material for **non-commercial use** without modification on the material's copyright. Therefore, we provide the corresponding copyright statements and website URLs for each original brain teaser and its adversarial version. In addition, we ask the task participants to sign a document claiming that the only aim of the data usage is research. We note that, despite our best efforts, the task data may still contain bias in terms of gender or politics. We will indicate that future research should use the task data with caution.

7 Acknowledgements

We appreciate Baktash Ansari, Dilip Venkatesh, Soumya Smruti Mishra, Harshit Gupta, and Pouya Sadeghi for their support as emergency reviewers for the competition. This research was sponsored by the Defense Advanced Research Projects Agency via Contract HR00112390061, Defense Advanced Research Projects Agency with award N660011924033 and Strengthening Teamwork for Robust Operations in Novel Groups via number W911NF-19-S-0001.

A CodaLab Leaderboard

In the main part of the paper, we only analyse the results for part of the participants' submission due to page limitation. Table 4 and 5 show a complete set of user names and results of the participants in the CodaLab competition for two subtasks, including users who did not submit a system description. The human evaluation is computed over 102 data randomly sampled from the **whole dataset**. The random base is average over three different seeds. The ChatGPT and RoBERTa-L baseline is computed over the whole dataset using OPENAI API[7] from 2023/5/01 to 2023/5/15.

We visualize each team's overall accuracy in each subtask according to the model adaptation category in Figure 4. In Sentence Puzzle, 12 teams employed fine-tuning, and 15 adopted zero/few-shot approaches. Fine-tuning achieved 1st, 3rd, and 5th positions on the leaderboard, whereas zero/few-shot have 7 places in the top ten. For Word Puzzle, 9 teams used fine-tuning, and 11 opted for zero/few-shot, with the latter dominating the top five ranks, outperforming fine-tuning.

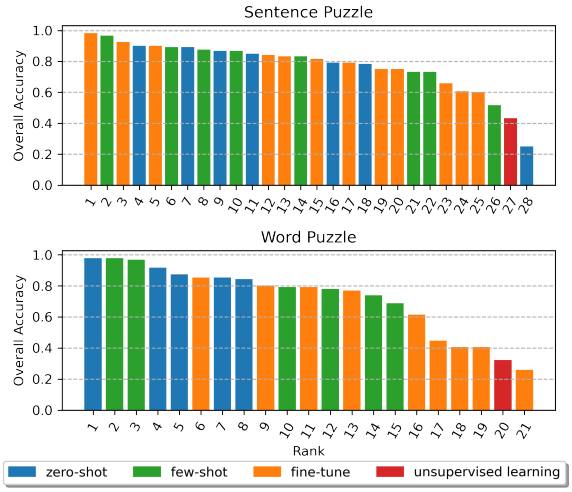

Figure 4: The overall accuracy performance of each team based on method adaptations.

B Participant Systems

In this section, we list the systems of all participants who submitted a system description paper. The **team name** represents each system, appended with the corresponding rank in [bracket], keywords in (parentheses), and a short description for further reference. *SP X* and*WP X* represent the ranks in sentence and word puzzles based on overall performance, respectively.

Abdelhak [SP 1;WP 16] (Kelious and Okirim, 2024) (*Fine-tuned*;*DeBERTa*;*Zero-shot*;*ChatGPT*;*Temperature Anlysis*) They fine-tuned the pre-trained language model DeBERTa-v3-base in the multiple-choice setting. They further experimented with the relationship between temperature and lateral thinking with ChatGPT in a zero-shot setting.

HW-TSC [SP 2;WP 3] (Li et al., 2024)(*Fine-tuned*;*Mixstral*;*Zero-shot*;*Few-shot*;*GPT-3.5*;*GPT-4*;*Prompting Engineering*;*Ensemble*) They first experimented with fine-tuning Mixtral overall whole training set. They turned to GPT-3.5 and GPT-4 due to poor fine-tuning results. They identified and categorized over 20 challenging training instances to include in an extended prompt. Finally, they submitted their result with GPT-4 in the few-shot setting with a well-designed prompting demonstration as well as the ensemble method.

AmazUtah_NLP [SP 6;WP 10] (Mishra and Ghashami, 2024) (*Fine-tuned*;*DeBERTa*;*BERT*;*External Data*;*Synthetic Data*;*RiddleSense*) They fine-tuned DeBERTa and BERT in the multiple-choice setting. They utilized the public puzzle dataset RiddleSense as well as creating humor-style data by prompting GPT 4 as the external dataset. They also experimented by adding commonsense datasets SWAG and CODAH but found the introduction reduced overall performance.

BITS Pilani [SP 7;WP 5] (Venkatesh and Sharma, 2024) (*Zero-shot*;*GPT-4*;*Prompting Engineering*) They used OpenAI's GPT-4 model along with prompt engineering in the zero-shot setting to solve these brainteasers.

ALF [SP 7] (Farokh and Zeinali, 2024) (*Fine-tuned*;*ALBERT*;*RoBERTa*;*DeBERTa*;*Flan T5*;*Unified QA*;*External Data*;*RiddleSense*) Their experiments focused on two prominent families of pre-trained models, BERT and T5, and fine-tuned ALBERT, RoBERTa, DeBERTa, Flan T5 and Unified QA in the multiple-choice setting. They explored the potential benefits of multi-task finetuning on commonsense reasoning datasets, including RiddleSense, CSQA, PIQA, SIQA, Hellaswag, and SWAG, to enhance performance.

uTeBC-NLP [SP 8] (Sadeghi et al., 2024) (*Fine-tuned*;*Zephyr-7B-β*;*Zero-shot*;*Few-shot*;*GPT-3.5*;*GPT-*

[7]https://platform.openai.com/docs/api-reference

4;*RAG*;*External Data*;*Synthetic Data*;*Prompting Engineering*;*COT*;*Lateral thinking enhancement analysis*) They explored Chain of Thought (CoT) strategies, enhancing prompts with detailed task descriptions, and retrieval augmented generation for generating in-context samples. Their experiments involve GPT-3.5 and GPT-4. They also showcased that fine-tuning Zephyr-7B-β with a lateral thinking approach significantly enhances the model's performance on other commonsense datasets.

yangqqi [SP 8;WP 6] (Yang et al., 2024) (*Zero-shot*;*ChatGPT*;*RAG*;*Self-Adaptive ICL*;*Prompting Engineering*;*External Data*;*ConceptNet*) They proposed the SHTL system to mimic human lateral thinking ability for solving brain teaser questions. They first retrieved related knowledge concepts from ConceptNet and used SAICL to find the optimal organization for each single test sample. At last, they provide ChatGPT with the related knowledge concepts and find the options to solve the conflicts contained in the related knowledge concepts effectively.

Mothman [SP 9] (Chen et al., 2024) (*Zero-shot*;*Few-shot*;*GPT-4*;*Prompting Engineering*;*COT*;) They proposed a system for iterative chain-of-thought prompt engineering which optimizes prompts using a flexible evaluation strategy on both model outputs and input data. They obtain feedback from human evaluation to modify the prompting demonstration interactively to guide GPT-4 to focus on challenging problems. They also proposed a new COT strategy requiring GPT-4 to produce rationals for both correct and incorrect options.

Zero_Shot_is_All_You_Need [SP 10;WP 2] (Moosavi Monazzah and Feghhi, 2024) (*Zero-shot*;*Bing*;*Gemini*;*Mixtral*;*Mixtral*;*ChatGPT*;*Phi-2*;*Prompting Engineering*;*Ensemble*;*Debate*) They examined the zero-shot ability of current state-of-the-art LLMs, Bing, Gemini, Mixtral, ChatGPT and Phi-2 to solve this task. They also tried ensemble and debate prompting engineering methods.

OUNLP [SP 10;WP 11] (Saravanan and Wilson, 2024) (*Zero-shot*;*Few-shot*;*GPT-3.5*;*GPT-4*;*Gemini*;*languagemodels*;*Prompting Engineering*;*COT*;*RECONCILE*;*External Data*;*crawled riddles*) They experimented with a series of structured prompts ranging from basic to those integrating task descriptions and explanations(COT). They use the most similar or the most different training example as the demonstration in the one-shot prompting. They downloaded a collection of riddles from the web as an external data source. In the end, they simulated a council scenario to evoke discussion between different models but didn't observe significant improvement.

BAMO [SP 11] (Ansari et al., 2024) (*Fine-tuned*;*RoBERTa*;*BERT*;*Zero-shot*;*Open Chat*;*Llama-2-70b*;*Mixtral*;*GPT3.5*;*Claud*;*Microsoft Copilot*;*Prompting Engineering*;*ReConcile*) They fine-tuned 2 models, BERT and RoBERTa Large, and employed a Chain of Thought (CoT) zero-shot prompting approach with 6 large language models, such as GPT-3.5, Mixtral, and Llama2. Finally, they utilized ReConcile prompting amount three models.

YNU-HPCC [SP 12;WP 13] (Wang et al., 2024a) (*Fine-tuned*;*DeBERTa*;*External Data*;*Back translation*) They fine-tuned DeBERTa in different training strategies and enhanced the training set with back translation.

FtG-CoT [SP 13] (Zhang et al., 2024) (*Fine-tuned*;*BERT*;*Zero-shot*;*Few-shot*;*GPT-3.5*;*Prompting Engineering*;*COT*) They first fine-tuned BERT in a multi-class classification setting and fine-tuned GPT-3.5 with chain-of-thought generated by zero-shot prompting. Then they picked the set of training demonstrations provided in the few-shot prompt based on the BERT encoding cosine similarity to the test question.

MasonTigers [SP 13;WP 2] (Raihan et al., 2024) (*Zero-shot*;*Few-shot*;*GPT-4.5*;*Claude*;*Mixtral*;*Prompting Engineering*;*COT*) They explored various prompting strategies to guide the models, including zero-shot, few-shot, and chain-of-thought prompting. The Ensemble method was adopted to enhance COT performance.

AILS-NTUA [SP 14;WP 7] (Panagiotopoulos et al., 2024) (*Fine-tuned*;*DeBERTa*;*RoBERTa*;*BERT*;*Mixtral*;*Llama 2*;*Phi-2*) They evaluated a plethora of pre-trained transformer-based language models of different sizes and pre-train dataset through fine-tuning. They also delved into models' frequent failures to obtain a deeper understanding of reasoning cues that make models struggle the most.

RiddleMaster [SP 15;WP 8] (Take and Tran, 2024) (*Fine-tuned*;*Mistral*;*Zero-shot*;*GPT-4*;*Prompting Engineering*;*COT*;*Ensemble*) They compared multiple zero-shot approaches using

GPT-4 as well as fine-tuned Mistral output.

UMBCLU[8] [SP 15;WP 11] (*Fine-tuned*;*Flan-T5*;*Data Augmentation*) They fine-tuned and evaluated various T5 family models on both the word and sentence puzzle tasks and showed that training on the alternative contexts improves a model's lateral reasoning capability.

KnowComp [SP 16;WP 7] (Wang et al., 2024b) (*Zero-shot*;*ChatGPT*;*Prompting Engineering*) They first prompted ChatGPT to identify relevant instances in the question and generate conceptualizations for the identified instances. They then converted each puzzle into a declarative format and modified the task to involve selecting the most plausible statement from the options.

NIMZ [SP 20;WP 19] (Rahimi et al., 2024) (*Fine-tuned*;*BERT*;*RoBERTa*;*T5*;*QA-GNN*;*External Data*;*ConceptNet*) They fine-tuned BERT, RoBERTa and T5 and evaluated their performance. They used ConceptNet as an external knowledge source and fine-tuned graph neural network QA-GNN and suggested its superiority on sentence puzzle.

Deja-Vu [SP 20;WP 20] (Chakraborty et al., 2024) (*Fine-tuned*;*BERT*;*RoBERTa*;*XLNet*;*BART*;*T5*;*Data Augmentation*) They fine-tuned five transformer-based language models and found the integration of sentence and word puzzles into a single dataset led to a noticeable decrease in accuracy.

GeminiPro [SP 21;WP 12] (Choi and Na, 2024) (*Zero-shot*;*Few-shot*;*Gemini*;*Prompting Engineering*) They tested Gemini's performance in zero-shot and few-shot settings. They experimented with whether tailor-made demonstrations to specific tasks can alleviate confusion and aid in 049 problem-solving.

iREL [SP 21;WP 14] (Gupta et al., 2024) (*Zero-shot*;*Few-shot*;*Gemini*;*Prompting Engineering*;*COT*) They tested Gemini's performance in zero-shot and few-shot settings. Especially in the few-shot setting, reasoning from Gemini and GPT-4 are integrated into the demonstration, selected by static or dynamic strategy.

IIMAS [SP 23;WP 22] (Reyes et al., 2024) (*Fine-tuned*;*BERT*;*RoBERTa*;*ChatGPT*;*Gemini*;*Data Augmentation*) They tackled this challenge by applying fine-tuning techniques with pre-trained models (BERT and RoBERTa Winogrande) while also augmenting the dataset with the LLMs ChatGPT and Gemini. During the training, they transformed the data format for specific templates.

IUST-NLPLAB [SP 24] (Abbaspour et al., 2024) (*Fine-tuned*;*MPNET*;*Zero-shot*;*GPT-3.5*) They first introduced a zero-shot approach leveraging the capabilities of the GPT3.5 model. Additionally, they presented three finetuning methodologies utilizing MPNET as the underlying architecture, each employing a different loss function.

ROSHA [SP 25;WP 20] (Rostamkhani et al., 2024) (*Fine-tuned*;*RoBERTa*;*Zero-shot*;*GPT-3.5*;*Gemini*;*Mixtral*;*GPT-4*;*External Data*;*BiRdQA*;*RiddleSense*;*Prompting Engineering*;*Reconcile*) They applied the XLM-RoBERTa model both to the original training dataset and concurrently to the original dataset alongside the BiRdQA dataset and the RiddleSense for comprehensive model training. They also tested the Reconcile prompting strategy with GPT-3.5, Gemini as well as Mixtral and zero-shot on GPT-4.

DaVinci [SP 26;WP 15] (Mathur et al., 2024) (*Few-shot*;*GPT-3.5*;*Prompting Engineering*) They used few-shot prompting on GPT-3.5 with rationale and gained insights regarding the difference in the nature of the two types of questions.

StFX-NLP [SP 27;WP 21] (Heavey et al., 2024) (*unsupervised*;*External Data*;*WordNet*) They explored three unsupervised learning models. Two of these models incorporate word sense disambiguation and part-of-speech tagging, specifically leveraging SensEmBERT and the Stanford log-linear part-of-speech tagger. The third model relies on a more traditional language modelling approach.

DeBERTa [SP 28] (Siino, 2024) (*Zero-shot*;*DeBERTa*) They used DeBERTa in zero-shot setting.

Abstract

The automatic identification of misleading and persuasive content has emerged as a significant issue among various stakeholders, including social media platforms, policymakers, and the broader society. To tackle this issue within the context of memes, we organized a shared task at SemEval-2024, focusing on the multilingual detection of persuasion techniques. This paper outlines the dataset, the organization of the task, the evaluation framework, and the outcomes.The task targets memes in four languages, with the inclusion of three surprise test datasets in Bulgarian, North Macedonian, and Arabic. It encompasses three subtasks: *(i)* identifying whether a meme utilizes a persuasion technique; *(ii)* identifying persuasion techniques within the meme's "textual content"; and *(iii)* identifying persuasion techniques across both the textual and visual components of the meme (a multimodal task). Furthermore, due to the complex nature of persuasion techniques, we present a hierarchy that groups the 22 persuasion techniques into several levels of categories. This became one of the attractive shared tasks in SemEval 2024, with 153 teams registered, 48 teams submitting results, and finally, 32 system description papers submitted.

1 Introduction

The rise of online social media platforms has enabled people to share their views and feelings openly. This increase in freedom of speech has significantly expanded the volume of digital content, offering valuable resources for initiatives like citizen journalism, raising public awareness, and supporting political campaigns. However, this freedom has also facilitated negative uses, leading to an increase in online hostility, as evidenced by the spread of content such as disinformation, hate speech, propaganda, and cyberbullying (Brooke, 2019; Joksimovic et al., 2019; Schmidt and Wiegand, 2017; Davidson et al., 2017; Da San Martino et al., 2019a; Van Hee et al., 2015).

Social media posts often combine various modalities, such as text, images, and videos. In recent years, *Internet memes* have become a prevalent form of content on these platforms. A meme is defined as "a collection of digital items that share common characteristics in content, form, or stance, which are created through association and widely circulated, imitated, or transformed over the Internet by numerous users." (Shifman, 2013) Memes generally consist of one or more images accompanied by textual content (Shifman, 2013; Suryawanshi et al., 2020). While memes are primarily aimed at humor, they can also convey persuasive narratives or content that may mislead audiences. To automatically identify such content, there have been research efforts directed towards addressing offensive content (Gandhi et al., 2020), identifying hate speech across different modalities (Gomez et al., 2020; Wu and Bhandary, 2020), and detecting propaganda techniques in memes (Dimitrov et al., 2021a).

Focusing on propaganda detection, research efforts have been specifically directed towards defining techniques and addressing the issue in news articles (Da San Martino et al., 2019), tweets (Alam et al., 2022b), memes (Dimitrov et al., 2021a), and textual content in multiple languages (Piskorski et al., 2023b). The associated shared tasks include SemEval-2020 Task 11 on news articles (Da San Martino et al., 2020), SemEval-2021 Task 6 on memes (Dimitrov et al., 2021b), WANLP-2022 and ArabicNLP-2023 focusing on Arabic

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 2009–2026

(Alam et al., 2022b; Hasanain et al., 2023), and SemEval-23 Task 3 on news articles in multiple languages (Piskorski et al., 2023b).

The SemEval-2024 shared task extends previous tasks but introduces multilinguality, covering four languages, and features the largest dataset in English, along with a new hierarchical evaluation method. It has attracted significant participation. The task consists of three subtasks and was run in two phases: *(i)* the development phase and *(ii)* the evaluation phase. In the remainder of this paper, we define the tasks, describe the datasets, and provide an overview of participating systems and their official scores.

2 Related Work

2.1 Persuasion Techniques Detection

Past research on propaganda detection focused on analyzing documents as a whole to assess whether they contained propaganda. Barrón-Cedeno et al. (2019) created a corpus categorized into *propaganda* and *non-propaganda*, exploring the writing style and readability levels. Their results indicated that using distant supervision combined with comprehensive representations could lead the model to predict the source of the article instead of accurately differentiating between propaganda and non-propaganda content. An alternative approach to research has concentrated on identifying the use of specific propaganda techniques within texts. For example, Habernal et al. (2017, 2018) constructed a corpus containing 1.3k arguments, each annotated with different fallacies directly associated with propaganda techniques.

Building on previous work, Da San Martino et al. (2019b) created a corpus of news articles annotated for eighteen fine-grained propaganda techniques, approaching the problem as a task of span detection and classification. The majority of these studies have primarily focused on English. To address this gap in multilingual settings, Piskorski et al. (2023c) developed a dataset of news articles encompassing nine languages (Piskorski et al., 2023c). This dataset has enabled research into developing multilingual models.

Focusing on multimodality, specifically on memes, Dimitrov et al. (2021a) developed a corpus consisting of 950 memes and investigated various transformer models for automatic detection.

2.2 Multimodal Content

Multimodal content has been effectively utilized for propagating information and generating positive impacts. At the same time, it has also been used to cause harm (Sharma et al., 2022) or spread mis- and dis-information (Alam et al., 2022a). Research in this area include predicting misleading information (Volkova et al., 2019), detecting deception (Glenski et al., 2019), emotions and propaganda (Abd Kadir et al., 2016), hateful memes (Kiela et al., 2020), and propaganda in images (Seo, 2014).

To address the problem, current state-of-the-art research includes fine-tuning transformer models such as ViLBERT (Lu et al., 2019), Multimodal Bitransformers (Kiela et al., 2019), and VisualBERT (Li et al., 2019). Several studies have also explored the use of prompting strategies for hateful meme classification (Cao et al., 2022), aiming for detection from both text and visual modalities by leveraging (Prakash et al., 2023). For a recent survey, please refer to the work by Hee et al. (2024), which reports on the role of multimodality and LLMs in hateful content moderation.

2.3 Related Shared Tasks

To foster community engagement, several shared tasks on propaganda detection have been organized in the past. *SemEval-2020 task 11 on Detection of Persuasion Techniques in News Articles* (Da San Martino et al., 2020) focused on news articles, and asked to detect the text spans where propaganda techniques are used, and to predict their type (14 techniques). Closely related to that is the *NLP4IF-2019 task on Fine-Grained Propaganda Detection* (Da San Martino et al., 2019), which asked to detect the spans of use in news articles of each of 18 propaganda techniques. The *SemEval-2023 task 3 Detecting the Category, the Framing, and the Persuasion Techniques in Online News in a Multi-lingual Setup* was focused on news articles covering nine languages Piskorski et al. (2023b). The WANLP'2022 and ArabicNLP'2023 shared task asked to detect the use of 20 propaganda techniques in Arabic tweets and news articles (Alam et al., 2022b; Hasanain et al., 2023).

The *SemEval-2021 Task 6 on Detection of Persuasion Techniques in Texts and Images* focused on identifying 22 persuasion techniques in memes (Dimitrov et al., 2021b). Following this prior work, we have significantly extended the size of the English dataset to 10K memes and added three sur-

prise languages. The task is divided into three subtasks and also presents the persuasion techniques in a newly formed hierarchy allowing for better system predictions in cases of low confidence when predicting persuasion.

3 Tasks and Dataset

3.1 Tasks

The objective of the shared task is to develop models capable of identifying persuasion techniques (see Table 2 for a list and Dimitrov et al. (2021b) for a detailed description). This involves one subtask focused solely on analyzing the textual content of memes and another two subtasks dedicated to a multimodal analysis, where both textual and visual content are examined together. The subtasks are defined as follows:

Subtask 1 (ST 1): Given only the "textual content" of a meme, identify which persuasion techniques, organized in a hierarchy, it uses. If the ancestor node of a technique is selected, only a partial reward is given. This is a multilingual hierarchical multilabel classification problem.

Subtask 2a (ST 2a): Given a meme, identify which persuasion techniques, organized in a hierarchy, are used both in the textual and in the visual content of the meme (multimodal task). If the ancestor node of a technique is selected, only a partial reward is given. This is a multilingual hierarchical multilabel classification problem.

Subtask 2b (ST 2b): Given a meme, identify whether it contains a persuasion technique. This is a binary classification problem.

	EN					BG	MK	AR
Subtask	Train	Val	Dev	Test	**Total**	Test	Test	Test
ST 1	7,000	500	1,000	1,500	10,000	436	259	100
ST 2a	7,000	500	1,000	1,500	10,000	436	259	120
ST 2b	1,200	150	300	600	2,250	100	100	160

Table 1: Number of memes for every language on each subtask and associated data splits. Note that **only** the test split contains all four languages. EN=English, BG=Bulgarian, MK=North Macedonian, AR=Arabic

3.2 Dataset

Collection: We collected English, Bulgarian, North Macedonian, and Arabic memes from our personal Facebook accounts by scraping public Facebook groups, which focus on politics, vaccines, COVID-19, gender equality, and the Russo-Ukrainian War. However, Facebook groups did not provide enough memes for North Macedonian and Arabic therefore we collected some of the memes for these languages from Instagram. We considered a meme to be a "*photograph style image with a short text on top of it*", and we removed examples that did not fit this definition, e.g., cartoon-style memes, memes whose textual content was strongly dominant or non-existent, memes with a single-color background image, etc.

Annotation: The list of persuasion techniques and the annotation process are as described in (Dimitrov et al., 2021b). For each meme, we first annotated its textual content, and then the entire meme. We performed each of these two annotations in two phases: in the first phase, the annotators independently annotated the memes; afterward, all annotators met together with a consolidator to discuss and select the final gold label(s). This process was applied to each language, however, for English we had an additional step in the process where an expert linguist reviewed random samples of consolidated memes and communicated his observations back to the team of annotators. This was done to ensure we maintained high-quality annotations throughout the whole annotation campaign, considering the high cognitive complexity of the task.

Statistics: Table 1 shows the number of memes for each subtask in all four languages. The data for every subtask was split into train, validation, dev, and test as shown in the table. We introduced a validation set to allow parameter optimization on a predefined set of data, making it comparable across different systems. Bulgarian, North Macedonian, and Arabic were only used for the test set as they were surprise languages.

Table 2 and Table 3 show the label distribution for all subtasks. *Transfer* and *Appeal to (Strong) Emotions* do not apply to text, i.e., to Subtask 1. For Subtasks 1 and 2a, each technique can be present at most once per example. From the persuasion technique distribution we can see that the dataset is extremely imbalanced with some labels being present in more than 50% of the memes (Smears) and others in less than 1% (Obfuscation, Intentional Vagueness, Confusion). Moreover, Figure 2 (in Appendix A) shows that most of the memes contain more than one persuasion technique.

Persuasion Techniques	Subtask 1 EN	BG	MK	AR	Subtask 2a EN	BG	MK	AR
Smears	2,838	41	25	17	5,159	320	220	63

Total	**16,629**	**737**	**401**	**130**	**23,052**	**1,254**	**778**	**245**

Table 2: Persuasion techniques distribution for subtasks 1 and 2a in every language. For each technique, we show the number of instances.

Label	EN	BG	MK	AR
propagandistic	1,500	80	90	113
non propagandistic	750	20	10	47
Total	2,250	100	100	160

Table 3: Subtask 2b label distribution

We also observe a higher number of memes with 2 or more labels in ST2a which shows that a lot of memes require not only the text but the visual content to form enough context.

4 Evaluation Framework

4.1 Hierarchy

We introduce a hierarchy to allow the assignment of high-level categories in case of high uncertainty when predicting persuasion techniques. The persuasion techniques are grouped in a hierarchy, to be more precise a directed acyclic graph, as shown in Figure 3. The leaves of the hierarchy are the 22 persuasion techniques. The internal nodes are defined according to (Sourati et al., 2023; Piskorski et al., 2023a). Starting from the ROOT, we have the first level with *Ethos*, *Pathos*, and *Logos*. On the next level under Ethos – *Ad Hominem* and under Logos – *Justification* and *Reasoning*. Finally, Reasoning branches into *Distraction* and *Simplification*.

4.2 Evaluation Measures

Considering the hierarchical setup of the task, the evaluation metrics have to take into account the possibility of label assignment different than the original 22 persuasion techniques. Additionally, the metrics need to support a multilabel setting. We use adjusted F_1, $precision$, and $recall$ for hierarchical evaluation (Kiritchenko et al., 2006). For example, given the hierarchy in Figure 1, Let G be the ground truth value and H the predicted value, then to calculate the hierarchical measures we extend G to a set of its ancestor classes $S_{gold} = \{G, E, B, C\}$ and then do the same for H – $S_{pred} = \{H, E, B, C\}$. Then hierarchical $precision$, $recall$, and F_1 (hP, hR, and hF_1) would be:

$$hP = \frac{|S_{gold} \cap S_{pred}|}{|S_{pred}|} = \frac{|\{E, B, C\}|}{|\{H, E, B, C\}|} = \frac{3}{4} \quad (1)$$

$$hR = \frac{|S_{gold} \cap S_{pred}|}{|S_{gold}|} = \frac{|\{E, B, C\}|}{|\{G, E, B, C\}|} = \frac{3}{4} \quad (2)$$

$$hF_1 = \frac{2 \cdot hP \cdot hR}{hP + hR} = \frac{2 \cdot \frac{3}{4} \cdot \frac{3}{4}}{\frac{3}{4} + \frac{3}{4}} = \frac{3}{4} \quad (3)$$

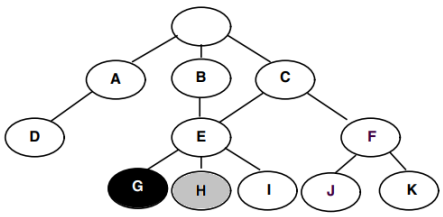

Figure 1: Example graph for hierarchical evaluation

Subtask	#team	#subm	#team	#subm
	EN Dev	EN Dev	EN Test	EN Test
ST 1	38	1159	35	130
ST 2a	11	61	14	28

Total	27	62	27	60
	AR Test	AR Test		
ST 1	17	36		
ST 2a	8	19		
ST 2b	15	24		
Total	24	79		

Table 4: Submission statistics. Note that only English has dev submissions, as the other languages were only released for test. *#team*: Number of teams that submitted results; *#subm*: Number of submissions.

Subtasks 1 and 2a are hierarchical multilabel classification problems. We used $hierarchical - F_1$ as the official evaluation measure. We also computed $hierarchical\ precision$ and $hierarchical\ recall$.

Subtask 2b is a binary classification problem. We used $macro\ F_1$ as the official evaluation measure. We also computed $micro\ F_1$.

4.3 Task Organization

The shared task was run in two phases:

Development Phase: During the development phase, we made *training* and *development* sets available for the participants. However, gold standard labels were not released for the development set. The participants submittd systems' results on the development set. They could make an unlimited number of submissions, and the best score for each team, regardless of the submission time, was shown in real time on a public leaderboard.

Test Phase: In this phase, we have released the test set and the *development* set together with the gold labels. The participants were given a week to submit their final predictions on the *test* set. It is important to note that the test data included memes in three additional languages such as Bulgarian, North Macedonian, and Arabic, which were not disclosed to the participants in advance as surprise languages. Similar to the development phase, participants could submit multiple entries; however, they have not received any feedback on their performance. Only the latest submission from each team was considered official and used to determine the final team rankings. Overall, 153 teams registered for the task, out of which 48 made official submissions. Moreover, 24 teams submitted results for all four languages. Specifically, 17 teams submitted results for all languages for ST1, 8 for ST2a, and 14 for ST2b, respectively. The total number of submissions across both phases was 2,087, with 1,677 on the development set and 410 on the test set. More details on submission statistics can be found in Table 4.

The results for the development and the test phases are available on the leaderboard page.[1] After the competition was over, we left the submission system open for the test dataset for post-shared task evaluations and to monitor the state of the art for the different subtasks across the languages.

4.4 Baseline Systems

Due to the highly imbalanced dataset, as seen in Table 2, the baseline for each subtask is the most common label or majority class baseline, i.e., for each meme, we make a prediction with the most frequent label. *Smears* is the most frequent label for Subtasks 1 and 2a, and *propagandistic* is the most frequent label for Subtask 2b. Note that the baseline is chosen according to the most common label across all languages.

5 Results

5.1 English Subtasks

The results for the three English subtasks are presented in Tables 5 and 6. All systems outperformed the baseline and the winning system is noticeably better than the second in subtasks 1 and 2a. In Subtask 2b there are three teams with top performance, two winning systems ex-aequo, and a third with a 0.001 difference in F_1.

We now briefly describe some of the top systems for each subtask. In Subtask 1 **914isthebest** (Li et al., 2024a) developed a transformer-based model

[1] https://propaganda.math.unipd.it/semeval2024task4/leaderboard.php

with in-domain pre-training. For system training, the training dataset was augmented following a Chain-of-Thought-based data augmentation approach using GPT-3.5. The main classification architecture includes four RoBERTa models and one DeBERTa model initialized using different random seeds. A soft voting approach, which averages the predicted probabilities of each label from all five models, is used to predict labels.

In Subtask 2a **HierarchyEverywhere** (Ghahroodi and Asgari, 2024) adapted the hierarchical text classification (HTC) model to the task by placing "propagandistic" and "non-propagandistic" nodes at the initial level and utilizing the "[CLS]" Token between sentences in memes enhanced model performance (Wang et al., 2022). Moreover, they employed additional datasets. Interestingly, the image component of memes was disregarded, and only the textual content was provided to the model. Furthermore, for all the sub-tasks that are non-English, Google Translation API was used to translate them into English.

In Subtask 2b, **LMEME** (Li et al., 2024b) proposed a detection system that employs a Teacher Student Fusion framework. Initially, a Large Language Model serves as the teacher, engaging in abductive reasoning on multimodal inputs to generate background knowledge on persuasion techniques, assisting in the training of a smaller downstream model. The student model adopts CLIP as an encoder for text and image features, incorporating an attention mechanism for modality alignment.

5.2 Bulgarian Subtasks

The results for the Bulgarian subtasks are reported in Tables 7 and 8. For Subtask 1, seventeen out of nineteen systems outperformed the baseline; for Subtask 2a, four out of seven systems outperformed the baseline; and for Subtask 2b, all systems outperformed the baseline.

We briefly describe some of the top systems for each subtask. The top system, **OtterlyObsessedWithSemantics** (Wunderle et al., 2024) for Subtask 1, used a custom classification head that is designed to be applied atop a large language model. For the non-English test sets, the system was used after translating all documents to English using GPT-4.

For Subtask 2a, the top system is **BCAmirs** (Abaskohi et al., 2024). It involved using GPT-4 to generate a descriptive caption of the meme. The caption is then combined

Table 6: Official results for English - Subtask 2b. Runs ranked by the official measure (Hierarchical F1).

with the meme text, before being passed to a RoBERTa model. A vision encoder utilizing a pre-trained vision transformer model (CLIP-ViT), is used to encode and analyze the meme image. Finally, a multi-layer perceptron classifier takes the combined visual and textual representations and classifies the meme. The models used were monolingual, and thus, for non-English tasks, the system was applied to test sets translated using Google Translate.

In Subtask 2b, the top system is **LMEME** (Li et al., 2024b), which was also the top system for Subtask 2b in English, and presented in Section 5.1.

5.3 North Macedonian Subtasks

The results for the North Macedonian subtasks are presented in Tables 9 and 10. Our observations for the North Macedonian subtasks closely align with those for the Bulgarian subtasks. For subtasks 1 and 2a, a few teams were unable to surpass the baseline results. However, for Subtask 2b, all teams exceeded the baseline performance.

As with the Bulgarian Subtask 1 and Subtask 2a, the top systems for North Macedonian were also **OtterlyObsessedWithSemantics** (Wunderle et al., 2024) and **BCAmirs**, respectively.

Team **BERTastic** (Mahmoud and Nakov, 2024) achieved the best performance for Subtask 2b. The system uses three representations of the input meme, including the image, associated text, and a generic description of the meme generated

by a vision-language model. A multilingual model, MPNet, was used to extract embeddings from text elements, while a multimodal multilingual model, CLIP-ViT-B-32, was used to represent both text and image. All extracted features were fused into a single feature vector, followed by logistic regression for classification.

5.4 Arabic Subtasks

In Tables 11 and 12, we report the results for Arabic subtasks. Here, we also observe similar patterns to Bulgarian and North Macedonian. The top systems for Subtask 1 and Subtask 2a are also **OtterlyObsessedWithSemantics** (Wunderle et al., 2024) and **BCAmirs**, respectively. **BCAmirs** also achieves the top performance for Subtask 2b.

Considering all non-English languages, we see that many systems struggled to surpass the baseline for Subtask 2a specifically. This can be due to the difficult nature of this subtask, as it is a hierarchical multilabel classification task that also requires considering multimodal content. Such difficulty also affected the number of participants, with a relatively smaller number of systems submitted to this

6 Conclusions and Future Work

We presented SemEval-2024 Task 4 on *Multilingual Detection of Persuasion Techniques in Memes*. The task consists of detecting persuasion techniques in memes in a multimodal setting. The task offered a significantly larger dataset for English (10K memes) than previous ones, and three surprise languages: Arabic, Bulgarian, and North Macedonian.

The task attracted a lot of attention: 153 teams registered for the task and 30 teams submitted a task description paper. Fine-tuning transformer-based architectures was the most dominant approach followed by most teams. The majority of teams participating in Subtask 2 considered both the text and image components of the data, utilizing corresponding transformer models. Finally, several teams designed hierarchical classification techniques, to tackle the hierarchy of labels in Subtask 1 and Subtask 2a. As for the surprise languages, at least a third of the submitting teams used automatic translation to translate the datasets into English.

7 Limitations

The dataset we have collected originates from various public Facebook groups, with a primary focus on politics. Consequently, the representativeness of this dataset may be limited for other domains and topics. The highly imbalanced distribution of the labels in the dataset may affect the model's performance. Therefore, it is important to develop models with this aspect in mind.

Ethics and Broader Impact

Our dataset solely comprises memes, and we have not collected any user information; therefore, the privacy risk is nonexistent.

Any biases present in the dataset are unintentional, and our intention is not to cause harm to any group or individual. It's important to acknowledge that annotating propaganda techniques involves a degree of subjectivity, making biases in our gold-labeled data or label distribution unavoidable. To mitigate these concerns, we have collected examples from a diverse range of users and groups. Furthermore, we adhere to a well-defined schema with clear definitions, which has enabled us to achieve high inter-annotator agreement. Additionally, our annotation team was diverse, consisting of six members, including both females and males.

We advise researchers of the risk that our dataset could be exploited to biasly moderate memes, potentially due to biases related to demographics or specifics in the text. To prevent this, the implementation of human moderation is crucial.

A Additional Dataset Details

Figure 2 shows statistics about the distribution of the number of persuasion techniques per meme for Subtasks 1 and 2a. The techniques hierarchy in 3 shows the details of coarse and fine-grained categories.

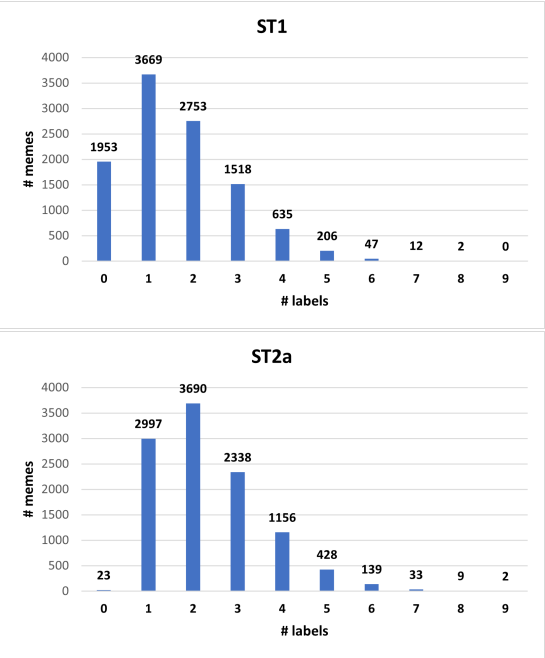

Figure 2: Subtasks 1 and 2a number of labels distributions.

B Overview of Participating Systems

In this section, we provide a summary of the approach followed by each of the participating systems.

BDA (Sherratt et al., 2024) The team participated in both Subtask 2a and Subtask 2b. For Subtask 2a, the proposed architecture is an ensemble of models operating on two modalities, text and images. For text, an ensemble of mBERT and XLM-RoBERTa is used, while CLIP and a monolingual BERT model is used to process visual entities extracted from images using Google Vision. Finally, a late fusion engine is used to merge predictions; generate additional translated task data; and modify the prediction confidence threshold based on the task hierarchy. As for Subtask 2b, the system is an ensemble of three models: 1) XLM-RoBERTa, that is trained on augmented task data, 2) VGG19 trained on task images and 3) a BERT model trained on visual entities extracted from the images using Google Vision. Late fusion is applied to join predictions from the models.

OtterlyObsessedWithSemantics (Wunderle et al., 2024) For Subtask 1, a custom classification head that is designed to be applied atop of a large language model was used. This approach includes reconstructing the hierarchy across multiple fully connected layers, allowing for incorporation of previous foundational decisions in subsequent, more fine-grained layers. For the non-English tasks, the same system was used after translating all documents to English.

BAMBAS (Vasconcelos et al., 2024) The proposed system for Subtask 1 does not consider the hierarchy of labels. First, text embeddings are extracted leveraging a multilingual tweets-based language model, Bernice. Next, those embeddings are used to train a separate binary classifier for each label, in a binary-relevance style, adopting independent oversampling strategies in each model.

nowhash (Chowdhury and Ptaszynski, 2024) In their submission to Subtask 1, the team starts from meme texts as input to the system and fine-tunes a Language-agnostic BERT sentence embedding (LaBSE) model on top of Flair's Transformer Document Embeddings. Further, those document vectors are then fed to a single-layer feed-forward linear classifier to obtain the prediction label.

For Subtask 2b, the proposed system operates on both meme images and texts. The architecture includes a vision transformer and XLMRoBERTa to extract effective contextual information from both modalities. Finally, the features are fused, to be passed to a single feed-forward linear layer. The architecture is fine-tuned given the task training data.

RDproj (Zhu, 2024) In their participation in Subtask 1, the team built an ensemble learning system employing a soft voting strategy. Propaganda techniques were grouped into ten subsets based on their representation in the training subset. Subsequently, one classifier including XLM-RoBerta$_{large}$ with a classification head is trained on each of these training sets. Finally, a classifier with the same architecture is used to learn a weighted average of the label's probability generated by the other classifiers.

BERTastic (Mahmoud and Nakov, 2024) For Subtask 2, the proposed architecture covers three

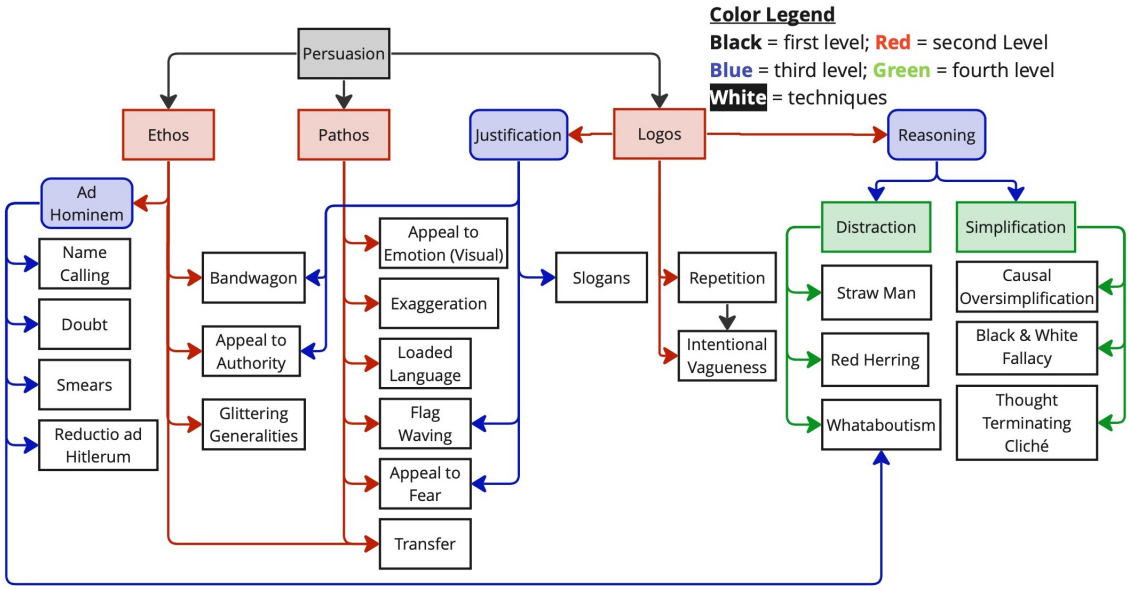

Figure 3: Persuasion techniques hierarchy.

representations of the input meme, including the image, associated text, and a generic description of the meme generated by a vision-language model. A multilingual model, MPNet, is used to extract embeddings from text elements, while a multimodal multilingual model, CLIP-ViT-B-32, is used to represent both text and image. All extracted features are fused into a single feature vector, followed by logistic regression for classification. During training, models' weights were frozen.

GreyBox (Roll and Graham, 2024) For Subtask 1, GPT 3.5 Turbo was fine-tuned in multiple stages using the training and validation datasets from all subtasks. Then, zero-shot prompting was used to generate predictions. The team also experimented with the original GPT 3.5 Turbo, Llama 2 70B Chat model, and Mistral AI's Mixtral 8x7B instruct, mixture of experts model.

SuteAlbastre (Anghelina et al., 2024) In submitting to Subtask 1, a BERT model was fine-tuned on the provided data. As for Subtask 2a: The backbone of the solutions is a BERT + ViT architecture where the BERT-based model creates embeddings from the text data while the ViT creates features from the image data. The two embeddings are concatenated and the resulting one is passed to a fully connected layer to obtain the scores for each persuasion technique. The same architecture was used for Subtask 2b, except the output of the final fully connected layer was adjusted for binary classification on whether the provided meme is propagandistic or non-propagandistic.

Pauk (Pauk and Pacheco, 2024) For Subtask 1, a student-teacher knowledge distillation approach was implemented. DeBERTa was adopted as the student model, in addition to a softened logic rule layer on top with a collection of logic rules that encode the hierarchical relationship between possible output labels. The student model then learns by both emulating the gold labels as well as the teacher's predictions that respect the hierarchy. The same knowledge distillation approach was used for Subtask 2a. However, the student model consists of DeBERTa for processing the textual content and ResNet for processing the image content with output embeddings concatenated and fed into a feed-forward network for predictions.

DUTIR938 (Yu et al., 2024) For Subtask 2b, the team developed a dual-channel model based on semi-supervised learning and model ensemble. Within the image channel, CLIP was used to extract image features from memes. Concurrently, in the text channel, diverse pre-trained language models were utilized. A concatenation and fusion process of the extracted features was applied and the resulting features were subsequently fed into a classification layer. Lastly, a two-stage soft-voting ensemble strategy was used to amalgamate the predictions of multiple models.

CLaC (Nayak and Kosseim, 2024) Similar to several other systems submitted to Subtask 1, the proposed approach was based on fine-tuning indi-

vidual language models (BERT, XLM-RoBERTa, and mBERT) and leveraging a mean-based ensemble model. Additionally, the training dataset was augmented by a relevant dataset extracted from a previous SemEval task

EURECOM (Peskine et al., 2024) The proposed system for Subtask 1 uses an ensemble of multiple models trained with different parameters. Experiments were conducted with different models (BERT, RoBERTa, DeBERTa, DistillBERT, AlBERT), different training datasets (SemEval 2024, + 2021, + PTC), different loss functions (BCE, CE, Focal, Hierarchical) and data augmentation (back translation, GPT-4-turbo augmented). The best results were obtained by leveraging the hierarchical nature of the data, by outputting ancestor classes and with a hierarchical loss. The official submission was based on the majority voting of our top-3 models for each persuasion technique.

Fralak (Laken, 2024) Different from transformer-based approaches presented so far, the system developed for Subtask 1 involved training an RNN. It was based on restructuring the labels into strings that showed the full path through the label hierarchy, and training a basic RNN that generated these strings based on the multilingual sentence embedding of the meme text. This RNN module was then incorporated into an ensemble model with 2 more models consisting of basic fully connected networks.

Snarci (Zedda et al., 2024) The system submitted to Subtask 2b involved a modular architecture that combines image and language embedding models. As image encoders, several versions of CLIP were used. Similarly, to process the textual part of memes the system resorts to several pre-trained language models (specifically TinyLlama, phi-1.5, and phi-2). The embeddings extracted from the CLIP model undergo an image embedding projection to fit a compatible size for large language models. An optional Token Merger module, inspired by the Patch Merger module proposed in vision transformers, merges tokens from image and text embeddings to focus on relevant meme aspects. This module aims to aggregate similar tokens together, regardless of their original position. To make the system more computationally efficient, freezing techniques were used to maintain the pre-trained weights of both image and language embeddings, and then Low-Rank Adaptation techniques were leveraged to fine-tune the models' weights.

SheffieldVeraAI (Grimshaw et al., 2024) For Subtask 2b, the team approached the problem by prompting and fine-tuning the large vision-language model, LLaVa. Fine-tuning was done using the multi-modal training data through LoRA training technique, however, this did not improve the model's performance. We achieved the best results prompting the baseline LLaVa model. We adapted the model to the unseen languages, by using a machine translation model, NLLB. We translated the meme transcriptions into English and used this translated text prompt with the original meme.

ShefCDTeam (Gibbons et al., 2024) The team participated in subtask 1, exploring sequence-to-sequence modeling for this task using a Flan-T5 model with sequential parameter efficient fine-tuning methods - Low-Rank Adaptation and prompt tuning.

whatdoyoumeme (Chatterjee et al., 2024) Subtask 1 was approached by fine-tuning a transformer model. The hierarchical labels for the task were integrated into the system by extending the training labels to include all ancestors. Experiments were conducted using several models like DistilBERT and mBERT but the best results were achieved with mBART. The model employed the standard classification architecture (mBART+classification head) and was trained using a BCE loss. When running the system over the non-English test sets, the documents were translated to English using the NLLB-200 model.

LomonosovMSU (Skiba et al., 2024) Two approaches were used to solve Subtask 1. 1) A generative approach involving training a generative model to generate explicit responses to questions. 2) A BERT-like approach involving training a simple fully connected network on top of a frozen pre-trained embedding model to solve the hierarchical classification task. Subtask 2 was tackled similarly to Subtask 1, but using multimodal text-to-image embedding models.

HierarchyEverywhere (Ghahroodi and Asgari, 2024) In Subtask 1, a state-of-the-art hierarchical text classification model called HPT was used. This required representing the propaganda techniques hierarchically as a directed acyclic graph. Two supplementary datasets were also added to the training. In Subtask 2a and Subtask 2b, the image

component of memes was disregarded, and only the textual content was provided to the model. Furthermore, for all the sub-tasks that are non-English, Google Translation API was used to translate them into English.

914isthebest (Li et al., 2024a) The team developed a transfer-based model for Subtask 1. For system training, the training dataset was augmented following a Chain-of-Thought-based data augmentation approach using GPT-3.5. The main classification architecture includes four RoBERTa models and one DeBERTa model initialized using different random seeds. A soft voting approach, which averages the predicted probabilities of each label from all five models, is used to predict labels. To predict non-English languages, the testing sets were translated using GPT-3.5.

LMEME (Li et al., 2024b) In Subtask 2b, the team proposed a detection system that employs a Teacher Student Fusion framework. Initially, a large language model serves as the teacher, engaging in abductive reasoning on multimodal inputs to generate background knowledge on persuasion techniques, assisting in the training of a smaller downstream model. The student model adopts CLIP as an encoder for text and image features, incorporating an attention mechanism for modality alignment.

McRock (Siino, 2024) The team approached Subtask 1 by prompting an instruction-tuned large language model called Mistral-7B-Instruct-v0.2. The prompt used included both the definitions of all 20 techniques targeted by the subtask, a short instruction on the task to perform, and the sample to predict on. The post-processed model's outputs were then submitted to the task's leaderboard.

BCAmirs (Abaskohi et al., 2024) The team participated in all subtasks but mainly focused on Subtask 2a. GPT-4 was used to generate a descriptive caption of the meme. The caption is then combined with the meme text before being passed to a RoBERTa model. A vision encoder utilizing a pre-trained vision transformer model (CLIP-ViT), is used to encode and analyze meme images. Finally, a multi-layer perceptron classifier takes the combined visual and textual representations and classifies the meme. The RoBERTa and MLP classifiers are fine-tuned, while CLIP remains frozen.

They conducted a series of experiments exploring different methods of combining the textual and visual data: *text-only* (Vicuna-1.5, BERT, RoBERTa), *image-only* (LLaVa without textual input), *text + image* (VisualBERT, ConcatRoBERTa, LLaVa-1.5), *text + caption + image* (LLaVa-1.5, Vicuna-1.5, VisualBERT, ConcatRoBERTa). Experiments were conducted using LLaVa and GPT-4 generated captions with GPT-4 captions showing consistently better results.

Puer (Dao et al., 2024) The team participated in Subtask 1 on the English test data with a detection system based on RoBERTa, using Roberta-large, which was fine-tuned on a corpus of social media posts. They conducted extensive parameter tuning over the dev set to identify an optimal threshold, epoch, etc. Finally, They compare the performances of other different deep learning model architectures, such as BERT, ALBERT, and XLM-RoBERTa, on multilingual detection of persuasion techniques in memes.

Hidetsune (Takahashi, 2024) The team approached Subtask 2b with a text-only classical NLP solution using SpacyV3 textcat_multilabel classification architecture. The model was trained on the official dataset for Subtask 2b, combined with additional data from Kaggle consisting of non-propagandistic tweets. The team participated in all languages included in Subtask2b by translating non-English text into English and applying the same model for text classification.

UMUTeam (pan et al., 2024) The team participated in all subtasks of the competition focusing only on English data. In Subtask 1 the team fine-tuned the RoBERTa-large model using an epoch-based evaluation strategy. In Subtasks 2a and 2b, they again used RoBERTa-large as their classification model but trained it by combining the textual content of a meme with image descriptions extracted using LlaVa.

MagnumJUCSE (Khurshid and Das, 2024) The team participated in Subtask 1 in all languages. They participated in the subtask with a node-level hierarchical classification system consisting of four phases: data denoising, feature generation, node-level classifier training, and finally inference. They first clean the data, then generate features using pre-trained sentence transformers, afterwards they predict whether an example belongs to a given node or not using SVM (Support Vector Machine). Finally, inference is done in a top-down fashion by selecting the most suitable depth for the prediction

results, based on the decision probabilities of the classifier at each node.

IUSTNLPLAB (Osoolian et al., 2024) The team addresses Subtask 1 on the English dataset. Their study focused on fine-tuning language models using the training dataset, including BERT, GPT-2, and RoBERTa, with GPT-2 showing the best performance for the task. Additionally, they used data on persuasion techniques from Semeval 2023 Task 3 increasing the training data with 3,445 new samples, however, this approach did not yield discernable improvements. Finally, the participants adjusted the prediction threshold which lead to a noticeable improvement in model performance.

IITK (Chikoti et al., 2024) The team participated in all three Subtasks in every language. Subtask 1: they presented an approach to meme classification based on HypEmo (pre-trained hyperbolic embeddings) and emotion prediction through a multi-task learning framework, incorporating auxiliary tasks, including masked language modeling (MLM) and class definition prediction to enhance the understanding of emotional concepts. The predictions from HypEmo and the Fine-grained class-definition-based model are merged for the final prediction. Subtask 2a: the team experiments with an ensemble of HypEmo and the class definition-based multi-task learning model for the textual content of the meme and using the CLIP model embeddings from the visual content of the meme. Subtask 2b: the team uses a fusion approach, concatenation pre-trained BERT-base model for textual features and CNN model for visual features. They use weighted binary cross entropy as a loss function due to the dataset imbalance.

NLPNCHU (Guo and Fan, 2024) The team participated in all three Subtasks in every language. They explored various finetuning techniques and classification strategies, such as data augmentation, problem transformation, and hierarchical multi-label classification strategies. In Subtasks 1 and 2a, they explored different classification strategies: Global Classifier (GC), Stacking + GC, and Stacking + Local Classifier per Level (LCL), combined with Distribution-Balanced Loss (DBL) loss to address the long-tail distribution of the data. For Subtask 1 the team compared the performance of XLM-RoBERTa and XLM-RoBERTa-Twitter to asses the impact of domain-specific pre-training. For Subtask 2a the team used XLM-RoBERTa and XLM-RoBERTa-Twitter for extracting textual features and CLIP for extracting visual features combining them through Feature-wise Linear Modulation (FIM), these two encoders encode to obtain a representation embedding vector containing both image and text For Subtask 2b the team employed the same strategy as Subtask 2a applied to a binary classification setting.

SemEval-2024 Task 5: Argument Reasoning in Civil Procedure

Abstract

This paper describes the results of SemEval-2024 Task 5: Argument Reasoning in Civil Procedure, consisting of a single task on judging and reasoning about the answers to questions in U.S. civil procedure. The dataset for this task contains question, answer and explanation pairs taken from *The Glannon Guide To Civil Procedure* (Glannon, 2018). The task was to classify in a binary manner if the answer is a correct choice for the question or not. Twenty participants submitted their solutions, with the best results achieving a remarkable 82.31% F_1-score. We summarize and analyze the results from all participating systems and provide an overview over the systems of 14 participants.

1 Introduction

"Arguing a legal case is an essential skill that aspiring lawyers must master. This skill requires not only knowledge of the relevant area of law, but also advanced reasoning abilities, such as using analogy arguments or finding implicit contradictions." – (Bongard et al., 2022)

In order to test these abilities, we organized the SemEval-2024 Task 5: Argument Reasoning in Civil Procedure. By basing our dataset on an established textbook in the domain of U.S. civil procedure (*The Glannon Guide To Civil Procedure*, (Glannon, 2018)), we ensure that we can leverage the high quality and refined content aimed at law students to create a challenging task in the competition. The book follows the philosophy, that learning about civil procedure can be achieved by reading about a given topic and answering questions afterwards. Therefore, each chapter is accompanied by a set of hard reasoning problems formulated as multiple-choice questions. As a teaching resource, the book provides a thorough analysis for each answer candidate. This enables the student to learn by example.

We frame our task in a simple manner: classifying whether the given answer is a correct solution to the question or not. With this task, we want to put the legal reasoning capabilities of various state-of-the-art models to the test and provide a reliable benchmark.

2 Related work

As the task is based upon our previous paper (Bongard et al., 2022), we refer to the detailed related work section in there. In a nutshell, legal question answering is an inherently difficult task because it requires both reasoning skills and expertise. Legal question datasets in NLP are scarce and vary in terms of the specific topics covered, such as the U.S. Multistate Bar Examination (Fawei et al., 2016), Tax Law (Holzenberger et al., 2020), and Japanese Bar Exams (Kano et al., 2019; Rabelo et al., 2022). Although existing datasets focus on finding the correct answer to the question posed, the reasoning behind a correct or incorrect answer is often ignored. More recently, LLMs have found their way into legal question answering, demonstrating their potential in this area (Katz et al., 2023) by solving complex legal questions at a level comparable to humans. But these circumstances also highlight the need for appropriate tasks to evaluate such systems (Guha et al., 2023).

3 Dataset

The dataset was collected by parsing *The Glannon Guide To Civil Procedure* (Glannon, 2018) which was done in our previous work (Bongard et al., 2022). The details of the data collection and baseline methods are also outlined there. Instead of treating the questions from the book as multiple choice queries, we decided to pair each answer with its question and attach a binary label for a correct or incorrect conclusion. Because there are usually multiple incorrect answers to a question, the dataset is highly imbalanced towards incorrect answers. A question can either be a stand-alone sentence or in cloze text form. To make the context

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 2027–2038

Question 7. A switch in time. Yasuda, from Oregon, sues Boyle, from Idaho, on a state law unfair competition claim, seeking $250,000 in damages. He sues in state court in Oregon. Ten days later (before an answer is due in state court), Boyle files a notice of removal in federal court. Five days after removing, Boyle answers the complaint, including in her answer an objection to personal jurisdiction. Boyle's objection to personal jurisdiction is

Answer not waived by removal. The court should dismiss if there is no personal jurisdiction over Boyle in Oregon, even though the case was properly removed.

Solution 1

Analysis D is the correct answer. Boyle has not waived his objection to personal jurisdiction. If the federal court lacks jurisdiction over Boyle, it should dismiss the case, even though it was properly removed.

Complete Analysis There are so many ways to go astray on this issue [...].

Introduction My students always get confused about the relationship between removal to federal court and personal jurisdiction [...].

Figure 1: Example data point

of most of the questions clear, there is an introduction text which provides background information to the question. In addition, Glannon has written further explanatory texts which justify why the answer was a correct choice or not. Each data point in the dataset consists of *question, answer candidate, solution, analysis (answer), complete analysis (all answers to the question), introduction*. An example data point is presented in Figure 1.

However, the dataset version used in the competition differs slightly from the original version. To correct errors in the initial version of the dataset, we removed a mistakenly included chapter of the book. Additionally, we corrected two instances in which the explanation text was missing. Although the dataset size changed, the partitions are still based on the paradigm used in (Bongard et al., 2022), resulting in a training partition (666), development partition (84), and testing partition (98). The *rational data split* is meant to sort questions which appear later in each chapter into the test set, assuming that these questions are harder to answer than earlier ones. To conceal the labels in the test set, we eliminated both fields *label* and *analysis* in that partition.

3.1 Potential question leakage from dev to test

When splitting the dataset partitions, we created some unwanted potential leakage. In particular, some questions that appear in the test partition may have already been part of the development partition with a different answer candidate. This occurred because each partition should contain questions from each chapter and data points were not considered as questions with multiple answer candidates, but rather as question-answer pairs. Because some dataset requests had already been answered, we chose not to readjust the partitioning. The training partition is not affected by this. About 27 of 98 data points in the test partition are affected and due to the small size of the dataset, we chose not the remove the data points either.

Instead, we take this opportunity to analyze if the behavior of the participating systems differs in regards to the leaked questions. The details of this additional analysis are presented in section 6.2. However, a future version of the dataset will contain a modified split that fixes the issue.

4 Task description

Reasoning is still one of the hardest task state-of-the-art models and techniques can face. Simply understanding language is certainly not enough to understand expert legal questions, much less answer them correctly. The task is meant to probe the capacity of methods for understanding complex legal topics and applying them in exemplary scenarios. However, to avoid over-complicating the output and evaluation, the task is formulated as a simple yes or no question. By default this approach also makes the task harder, because there is no option to find one correct answer by process of elimination. The task remains the same as introduced by Bongard et al. (2022):

Task Given a question with a possible correct answer and a short introduction to the topic of

the question, identify if the answer candidate is correct or incorrect.

Although systems may use the analysis that is provided in the training and development partitions for enhancement, they should be able to produce a prediction based on introduction, question and answer candidate alone.

4.1 Evaluation methods

Due to the simplicity of the task itself, we consider standard metrics to be best suited to evaluate the submissions. We calculate the macro F_1-score to account for the dataset imbalance between correct and incorrect answers. We evaluate the accuracy as well as an additional point of comparison. The F_1-score is the relevant evaluation metric for the competition ranking.

As a baseline, we provide a simple majority baseline which predicts each answer as incorrect and achieves an F_1-score of 42.69%.

4.2 Organization

We setup the competition on the CodaLab platform.[1] Participants needed to register first and acquire the dataset by filling out the required form as agreed with the publisher of the book[2]. We sent out the training and development partitions of the dataset first. The practice phase of the competition was officially accessible from November 28th, 2023 to allow participants to get accustomed to the submission platform and upload their scores for the development set. The test partition was sent out on January 9th, 2024 via email to those who had previously requested the dataset. Between January 10th, 2024 and February 1st, 2024 (00:00:00 UTC), participants could upload up to 5 submissions in total. After the end of the evaluation phase, participants could still upload contrastive runs in the post-evaluation phase with the same evaluation script.

5 Participant systems

During the competition period, we received 59 requests for the dataset. Of the 55 participants who registered on the CodaLab platform, 20 submitted results in the evaluation phase. We summarize and evaluate the 14 teams that submitted system papers.

Table 1: Official Leaderboard, counting the last submission made by a participant.

In addition to the descriptions, we present a brief summary of the key features of the proposed systems in Table 3.

5.1 Leaderboard results

We allowed participants to make up to 5 submissions in the evaluation phase to encourage them to try out several approaches. For the official leaderboard, which is taken from CodaLab, only the last valid submission is counted, resulting in the ranking shown in Table 1. We have also created a leaderboard that counts the best submission instead of the last one. This leaderboard variant is shown in Table 2. The differences between the leaderboard rankings are minimal. Both leaderboards are available on the competition webpage[3].

5.2 System descriptions

The systems mostly rely on established LLMs like GPT-4 (OpenAI, 2023), Llama (Touvron et al., 2023a) or Llama 2 (Touvron et al., 2023b), Mistral (Jiang et al., 2023) or Mixtral (Jiang

Table 2: Leaderboard, counting the best submission made by a participant.

et al., 2024), Zephyr (Tunstall et al., 2023) or Flan-T5 (Longpre et al., 2023). Other popular models are Legal-BERT (Chalkidis et al., 2020), RoBERTa (Liu et al., 2019), Longformer (Beltagy et al., 2020) and Big Bird (Zaheer et al., 2020). Many teams explore different strategies to prompt the LLMs, for instance using Chain-of-Thought (Wei et al., 2022).

Rank 1: HW-TSC – Self-Eval? A Confident LLM System for Auto Prediction and Evaluation for the Legal Argument Reasoning Task (Zhao et al., 2024) This team uses different GPT-4 prompt designs and strategies alongside a self evaluation approach leveraging a confidence score. Their best-performing system remodels the task into a multiple-choice question answering task and uses an ensemble of 3 runs. The authors' experiments show that prompting the LLM for a confidence score improves the performance in all tested settings. Their results also highlight that remodeling the task into a multiple-choice question answer task improves the performance significantly.

Rank 2: MAINDZ – CLUEDO - Choosing Legal oUtcome by Explaining Decision through Oversight (Benedetto et al., 2024) This team took an interesting approach by employing a two-stage decision process. In the first step, an ensemble of three models is fine-tuned with all available information (introduction, questions, answer cast as multiple-choice task) and not only generates the correct predictions, but also the explanations. In the second step, these generated candidates are evaluated by another zero-shot system (a 'detective') which chooses the final solution (given the labels and the explanations).

Rank 3: SU-FMI – From BERT Fine-Tuning to LLM Prompt Engineering - Approaches in Legal Argument Reasoning (Krumov et al., 2024) The authors experimented with a large number of approaches, starting with fine-tuning BERT-based models, adding external fine-tuning data, over to utilizing commercial LLMs with prompt engineering. The best results were achieved by utilizing GPT-4 and legal prompt engineering (prompts tailored for legal reasoning tasks). This team also provides a thorough comparison with other, partly open-source models.

Rank 5: UTSA-NLP – Prompt Ensembling for Argument Reasoning in Civil Procedures with GPT4 (Schumacher and Rios, 2024) This team uses the analysis part as a Chain-of-Thought mechanism in in-context learning. In particular, they prompt GPT-4 which, given the intro, question, and the answer candidate at test time, also generates the analysis part and the final label. The final system is an ensemble model combining several variants of the base models. The authors also provide an error analysis, showing that longer introductions tend to confuse the models.

Rank 7: NLP at UC Santa Cruz – Legal Answer Validation using Few-Shot Multi-Choice QA (Pahilajani et al., 2024) This team analyzed several fine-tuning strategies based on BERT models, or the effects of integrating additional CaseHold data, but concludes that multi-choice QA few-shot prompting on GPT-4 was the most effective method in their experiments.

Rank 9: 0x.Yuan – Enhancing Legal Argument Reasoning with Structured Prompts (Lu and Kao, 2024) The team investigates several prompting strategies on Mixtral-8x7B in a zero-shot man-

ner which make use of established legal reasoning methodologies like the IRAC (Issue, Rule, Application, Conclusion) analysis. The authors note that prompt designs tailored to legal reasoning methods outperform Chain-of-Thought strategies and direct prompting.

Rank 10: YNU-HPCC – Regularized Legal-BERT for Legal Argument Reasoning Task in Civil Procedure (Shi et al., 2024) The approach by this team employs fine-tuning of Legal-BERT and other BERT models and overcomes the input limitations by applying sliding window approaches. On top of comparing several losses (Cross-Entropy, Focal, Dice), they also compare the use of Regularized Dropout and Supervised Contrastive Learning for data augmentation and imbalances.

Rank 11: Mistral – Mistral 7B for argument reasoning in Civil Procedure (Siino, 2024) This team tested the pre-trained LLM Mistral-7B in a zero-shot prompting manner to classify a given question-answer pair.

Rank 13: Transformers – Legal Argument Reasoning Task in Civil Procedure using RoBERTa (Singhal and Bedi, 2024) The approach proposed by this team fine-tunes a pre-trained RoBERTa model with all input fields available in the training data and further uses minority sampling to counter the dataset imbalances.

Rank 14: ignore – A Legal Classification Model with Summary Generation and Contrastive Learning (Sun and Zhou, 2024) The team uses a Legal-BERT classifier with a contrastive learning approach. They additionally shorten the introduction text by summarizing it with GPT-3.5 and augment the training data by concatenating parts of the input in different ways. The authors note that generative summarization proves feasible to handle the introduction text and the contrastive loss improves the robustness of the model.

Rank 15: Archimedes-AUEB – LLM explains Civil Procedure (Chlapanis et al., 2024) This team proposes extending the training data by synthetic data generated by GPT-3, where the generated data resemble Chain-of-Thought reasoning. The authors also fine-tune a student model, an open-source Llama-2-7b, with QLoRA and provide an expert-based analysis, which reveals some shortcomings in explanations of the models.

Rank 16: SCaLAR NITK – Towards Unsupervised Question Answering system with Multi-level Summarization for Legal Text (Prabhu et al., 2024) The team tried various approaches using Word2Vec, GloVe and Legal-BERT embeddings to identify the most likely answer in a multiple-choice setup based on similarity scores. Additionally, they employ a segment-wise summarization of the introduction text with T5 and investigate the differences in similarity scores between the summarized and original input. The approach relies on open-source models and is reproducible.

Rank 17: eagerlearners – The Legal Argument Reasoning Task in Civil Procedure (Sabzevari et al., 2024) This team experimented with different designs for prompting GPT-3.5, Gemini and Copilot in a zero-shot manner. In additional experiments, the authors find that among some BERT-family models, a fine-tuned Legal-BERT exhibits the best potential, outperforming Longformer and Big Bird.

Rank 18: DUTh – A multi-task learning approach for the Legal Argument Reasoning Task in Civil Procedure (Maslaris and Arampatzis, 2024) This team compared the Legal-BERT model with a multi-task Flan-T5 model, which eventually performed on par. The authors relied mostly on fully open-source models and make their approach reproducible.

6 Analysis

6.1 Error analysis

We take a closer look how individual instances in the test set were classified. For this, we cluster the instances by the chapter they appear in and sort the chapters by the average performance (see Figure 2). With the goal of identifying the questions that were more challenging for the systems to answer, we cross-check the chapter titles and content of the best and worst-performing chapters. Chapters 6, 12, and 7 were the best-performing and cover the topics "More Personal Jurisdiction: General In Personam Jurisdiction and In Rem Jurisdiction", "Two Ways to Run a Railroad: Substance and Procedure After York, Byrd, and Hanna" and "More than an Afterthought: Long-arm Statutes as a Limit on Personal Jurisdiction". Legal expertise would be required to carefully assess why some chapters appear more difficult than others. Throughout our analysis, we could not identify a clear common

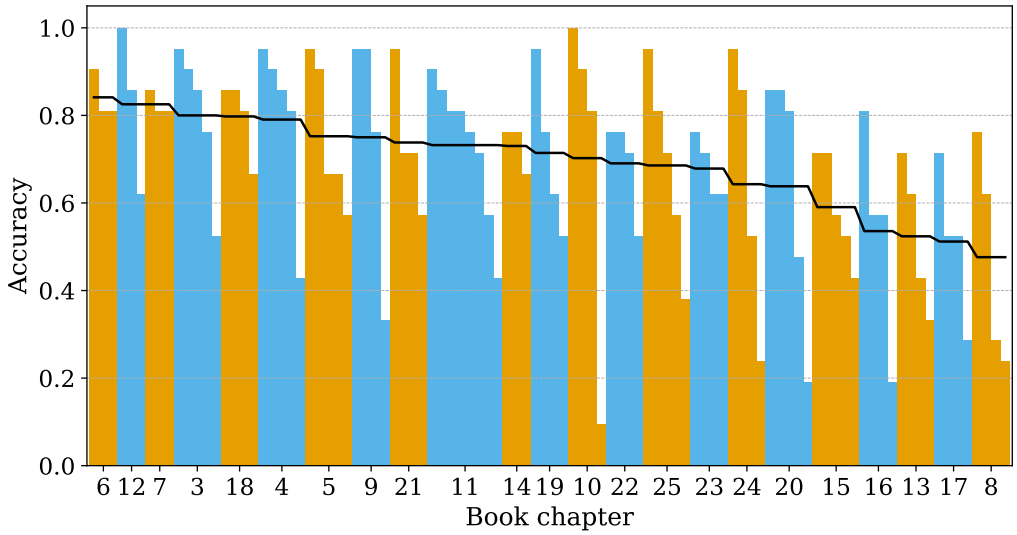

Figure 2: Prediction accuracy of all systems on all questions individually, grouped by the chapter the questions appear in *The Glannon Guide To Civil Procedure*. The line indicates the average accuracy per chapter. The alternating colors serve to delimit the individual chapters.

factor for difficult and easy instances. This can be attributed to the small sample size of the test partition and the carefully designed questions. Please refer to Table 5 for a full list of chapter titles.

Another important distinction is between question-answer pairs with a correct answer and those with an incorrect answer. As expected, because of the imbalance of the dataset, correct answers were much harder to classify correctly, as shown in Figure 3 (highlighted in green). On average, only 48.76% of these instances were classified correctly by all participants. For incorrect answers, 76.25% were classified correctly.

6.2 Potentially leaked data points

Furthermore, we want to investigate the impact of our potentially leaked data points. We compare the performance on non-leaked questions to that on potentially leaked questions in Figure 3 (indicated by a red border) and find that the performance remains almost identical for incorrect answers (76.69% for leaked vs. 76.10% for non-leaked), but shows a slight increase for correct answers (53.57% for leaked vs. 46.50% for non-leaked).

Table 4 also displays the difference in the final score that would result from removing potentially leaked data points for each participant. While the ranking may change for some teams, the gains and losses are minimal and do not follow a discernible pattern.

All in all, we could not detect a strong impact of

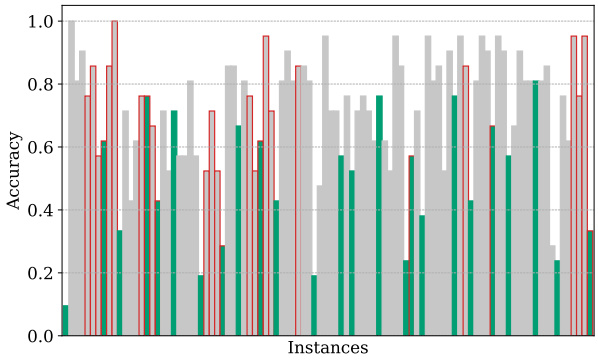

Figure 3: Prediction accuracy of all instances in the test set. Green instances mark questions-answer pairs with a true answer. Indicated by red boxes are instances that could have potential leakage of the question from the dev set.

the potentially leaked data points. This could also be due to the very limited use of fine-tunining or training with the provided data, since many models simply use zero-shot prompting or similar methods that do not require the training data at all.

6.3 Findings

The best-performing systems all use GPT-4, either with a double-checking mechanism (prompting more than once), tailoring the prompt to a legal reasoning method, or using ensembling to achieve optimal results. Domain-specific models, such as the popular Legal-BERT, which were explored in several approaches, are consistently outperformed by systems using GPT-4 and could not demonstrate

their advantages. The authors of some systems also noted that task performance improved when the task was remodeled as a multiple-choice task. Although this was not prohibited, it undermines the idea of the task and should be taken into account in a potential future iteration. Lastly, additional data was rarely used and did not contribute to the best results. Although the focus of the best submissions was on leveraging the power of LLMs, the techniques used to acquire a label from the prompts were creative, diverse and tailored to the legal domain.

7 Conclusion

In this paper we presented an overview of Task 5 of the SemEval-2024 competition, a task on argument reasoning in civil procedure. The dataset and the problems related to data leakage due to partitioning were briefly outlined. The submitted systems were described and summarized, and insights into the achieved results were provided. The submitted solutions indicate that LLMs, specifically GPT-4, are surprisingly decent in handling argument reasoning in civil procedure. Although Legal-BERT and other older domain-specific models can still solve the task to some extent, they are outperformed by a significant margin. The average performance of older or simpler techniques also suggests that this task is a suitable benchmark for evaluating legal reasoning in civil procedure. Although the top-performing systems still have room for improvement, the submitted solutions demonstrate that performance can be enhanced using various techniques. This task is far from solved. A future iteration of this competition could also utilize the mostly unused *analysis* field. This could alleviate the dataset's shortcoming of lacking traceable reasoning steps in the solution to further boost the emphasis on the reasoning aspect of the task.

Limitations

In theory, the dataset should not have leaked to a large language model yet, because the book is not freely available online. Consequently, the dataset should contain mostly new and unseen questions for the NLP community, while also having limited risk of leakage into a large language model. However, especially because of the use of closed LLMs and the lack of knowledge about the training corpora used for them, we can not be entirely sure that our dataset has not been seen by the LLMs used in the systems.

Although some of the answers to the questions can be argued about and might even be outdated in terms of applicable laws and statutes (the basis for the dataset is the 4th edition of the book), we can consider them correct, because they were answered by an expert – the author of the book.

Abstract

The ability to understand emotions is an essential component of human-like artificial intelligence, as emotions greatly influence human cognition, decision making, and social interactions. In addition to emotion recognition in conversations, the task of identifying the potential causes behind an individual's emotional state in conversations, is of great importance in many application scenarios. We organize SemEval-2024 Task 3, named Multimodal Emotion Cause Analysis in Conversations, which aims at extracting all pairs of emotions and their corresponding causes from conversations. Under different modality settings, it consists of two subtasks: Textual Emotion-Cause Pair Extraction in Conversations (TECPE) and Multimodal Emotion-Cause Pair Extraction in Conversations (MECPE). The shared task has attracted 143 registrations and 216 successful submissions. In this paper, we introduce the task, dataset and evaluation settings, summarize the systems of the top teams, and discuss the findings of the participants.

1 Introduction

Understanding emotions is crucial to achieve human-like artificial intelligence, as emotions are intrinsic to humans and significantly influence our cognition, decision-making, and social interactions. Conversation is an important form of human communication and contains a large number of emotions. Furthermore, given that conversation in its natural form is multimodal, many studies have explored multimodal emotion recognition in conversations (ERC), using language, audio and vision modalities (Poria et al., 2019b; Mittal et al., 2020; Lian et al., 2021; Zhao et al., 2022; Zheng et al., 2023).

However, emotion recognition alone is not sufficient to fully understand the intricacies of human emotions. Emotion cause analysis (ECA), the process of identifying the potential causes behind an individual's emotion state, has broad application scenarios such as human-computer interaction, commerce customer service, empathetic conversational agents, and automatic psychotherapy. For example, conversational agents equipped with emotion cause analysis can better understand the user's emotional state, offer empathetic responses, and provide more personalized services. By identifying the cause of the emotional state of a patient, a psychotherapy system can provide more accurate and customized treatments. ECA has gained increasing attention both in academic and practical fields (Ding et al., 2019; Xia et al., 2019; Xia and Ding, 2019; Ding et al., 2020a,b; Poria et al., 2021; Li et al., 2022; An et al., 2023; Wang et al., 2023b). However, to our knowledge, there has not been any evaluation competition conducted specifically for emotion cause analysis in conversations.

To promote research in this direction, we organize a shared task in SemEval-2024, named Multimodal Emotion Cause Analysis in Conversations. Our task consists of two subtasks: Subtask 1 (Textual Emotion-Cause Pair Extraction in Conversations, TECPE) focuses on extracting emotion and textual cause spans solely based on text; Subtask 2 (Multimodal Emotion-Cause Pair Extraction in Conversations, MECPE) involves extracting emotion-cause pairs at the utterance level considering three modalities.

For this shared task, we provide a multimodal emotion cause dataset ECF 2.0 sourced from the sitcom *Friends*. This dataset contains 1,715 conversations and 16,720 utterances, where 12,256 emotion-cause pairs are annotated at the utterance level, covering three modalities (language, audio, and vision). Specifically, in our preliminary work (Wang et al., 2023a), we have constructed a benchmark dataset, Emotion-Cause-in-Friends (ECF 1.0), which contains 1,374 conver-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 2039–2050

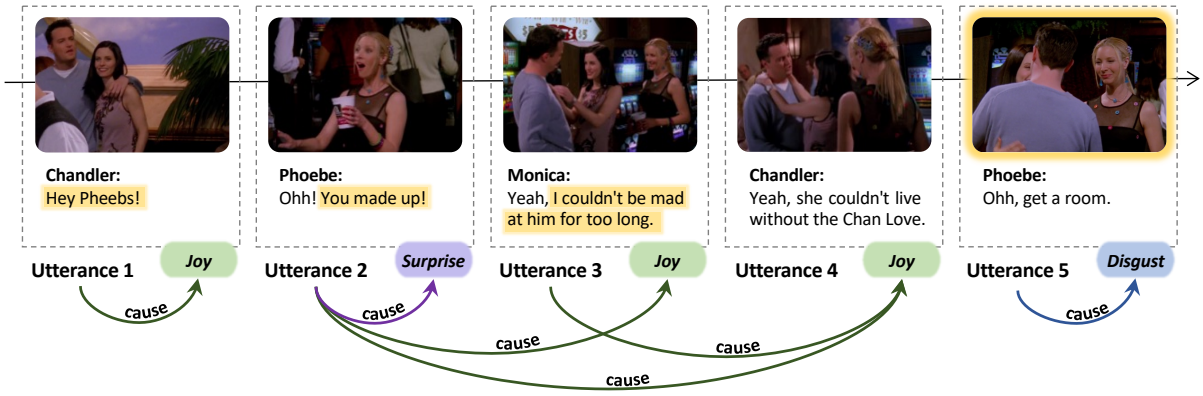

Figure 1: An example of our task and annotated dataset. Each arc points from the cause utterance to the emotion it triggers. The textual cause spans and the visual cause evidence are highlighted in yellow. Background: Chandler and his girlfriend Monica walked into the casino (they had a quarrel earlier but made up soon) and then started a conversation with Phoebe.

sations and 13,619 utterances. On this basis, we have furthermore annotated an extended test set as the evaluation data and provided the span-level annotations of emotion causes within the textual modality.

Our task has attracted 143 registrations and a total of 216 successful submissions during the 16-day evaluation phase. Participants tended to decompose our task into emotion recognition and cause prediction, proposing numerous well-designed pipeline systems. Moreover, many teams applied advanced Large Language Models (LLMs) for emotion cause analysis and achieved promising results. After the evaluation, 18 teams finally submitted system description papers.

2 Task

We clarify the definitions of emotion and cause before introducing the task and dataset. **Emotion** is a psychological state associated with thought, feeling, and behavioral response (Ekman and Davidson, 1994). In computer science, emotions are often described as discrete emotion categories, such as Ekman's six basic emotions, including *Anger*, *Disgust*, *Fear*, *Joy*, *Sadness* and *Surprise* (Ekman, 1971). In conversations, emotions were usually annotated at the utterance level (Li et al., 2017; Hsu et al., 2018; Poria et al., 2019a). **Cause** refers to the objective event or subjective argument that triggers the corresponding emotion (Lee et al., 2010; Russo et al., 2011).

The goal of our shared task, named Multimodal Emotion Cause Analysis in Conversations, is to extract potential pairs of emotions and their corresponding causes from a given conversation. Figure 1 illustrates a typical multimodal conversation scenario, which involves multiple emotions and their corresponding causes. Under different modality settings, we define the following two subtasks:

Subtask 1: Textual Emotion-Cause Pair Extraction in Conversations (TECPE). Extracting all emotion-cause pairs from the given conversation solely based on text, where each pair contains an emotion utterance along with its emotion category and the textual cause span, e.g., (*U3_Joy*, *U2_*"*You made up!*") in Figure 1.

Subtask 2: Multimodal Emotion-Cause Pair Extraction in Conversations (MECPE). It should be noted that sometimes the cause cannot be reflected only in text. As shown in Figure 1, the cause for Phoebe's *Disgust* in *U5* is that Monica and Chandler were kissing in front of her, which is reflected in the visual modality of *U5*. Therefore, we accordingly define this multimodal subtask to extract all emotion-cause pairs in consideration of three modalities (language, audio, and vision). In this subtask, the cause is defined at the utterance level, and each pair contains an emotion utterance along with its emotion category and a cause utterance, e.g., (*U5_Disgust*, *U5*).

3 Dataset

3.1 Data Source

Sitcoms come with real-world-inspired interhuman interactions and usually contain more emotions than other TV series or movies. Based on the famous American sitcom *Friends*, Poria

et al. (2019a) constructed the multimodal conversational dataset MELD by extracting audiovisual clips corresponding to the scripts of the source episodes and annotating each utterance with one of six basic emotions (*Anger*, *Disgust*, *Fear*, *Joy*, *Sadness* and *Surprise*) or *Neutral*. MELD has recently become a widely used benchmark for ERC.

In our preliminary work (Wang et al., 2023a), we chose MELD as the data source and further annotated the causes given emotion annotations, thereby constructing the ECF 1.0 dataset. For this SemEval competition, we release the entire ECF 1.0 dataset as a training set and additionally create a test set as evaluation data, which is also sourced from *Friends*.

3.2 Data Collection

To construct the extended test set, we first crawl the subtitle files of all the episodes of *Friends*, which contains the utterance text and the corresponding timestamps. The subtitles are then separated by scene (scene descriptions are written in square brackets in the subtitle files), and each scene in every episode is viewed as a conversation. If the length of a conversation exceeds 40 utterances, we further divide it into several conversations of random lengths. Conversations included in the ECF 1.0 are removed. Next, we divide the collected conversations into several parts according to their lengths, with each part falling within the length ranges [1, 5], [6, 10], [11, 15], [16, 20], [21, 25], and [26, 35], respectively. Finally, we randomly sample conversations from each part according to the distribution probability of conversation lengths in ECF 1.0, and a total of 400 conversations are sampled for annotation.

3.3 Data Annotation

We employ three graduate students involved in the annotation of the ECF 1.0 dataset to annotate the extended test set. Given a multimodal conversation, they first need to annotate the speaker and emotion category for each utterance, and then further annotate the utterances containing corresponding causes for each non-neutral emotion. If the causes are explicitly expressed in the text, they should also mark the textual cause spans. After annotation, we determine the emotion categories and cause utterances by majority voting, and take the largest boundary (i.e., the union of the spans) as the gold annotation of the textual cause span. If disagreements arise, another expert is invited for the final decision.

Dataset	Modality	Scene	# Ins
Emotion-Stimulus (Ghazi et al., 2015)	T	–	2,414 s

ECF 2.0	T,A,V	Conv	16,720 u

Table 1: Comparison of existing ECA datasets. T, A, and V refer to text, audio, and video. Blog and Conv represent microblog and conversation, and s, d, p and u denote sentence, document, post and utterance.

Items	ECF 1.0	Extended Test	ECF 2.0
Conversations	1,374	341	1,715
Utterances	13,619	3,101	16,720
Emotion (utterances)	7,690	1,821	9,511
Subtask 1 (TECPE)			
Emotion (utterances) with causes	6,761	1,626	8,387
Emotion-cause (span) pairs	9,284	2,256	11,540
Subtask 2 (MECPE)			
Emotion (utterances) with causes	7,081	1,746	8,827
Emotion-cause (utterance) pairs	9,794	2,462	12,256

Table 2: Statistics of our dataset.

Annotation Cost. The average duration of each conversation in our dataset is 31.6 seconds and it takes about 10 minutes to annotate a conversation. Each annotator would be paid CNY 300 when finishing every 50 conversations, which leads to the basic salary of CNY 36 (USD 5.2) per hour, which is higher than the current average salary in Jiangsu Province, China.

Data Post-processing. We conduct the following post-processing and cleaning of the data:

- Correct the utterance text that does not match what the speaker said in the video;
- Correct the timestamps that are not aligned with utterance text;
- Separate the utterance whose segment of timestamps covers two speakers' utterances and modify their timestamps;
- Separate the conversation which spans scenes;
- Discard conversations if there is significant disagreement in annotations and the expert also finds it difficult to determine.

After these steps, we store the text data in JSON files separately for each subtask. For Subtask 2, we use the FFmpeg[1] tool to extract video clips of

Figure 3: The distribution of emotions. The horizontal axis represents the number of utterances, and the vertical axis represents emotion categories.

each utterance from the source episodes based on the start and end timestamps.

3.4 Dataset Statistic

In our preliminary work (Wang et al., 2023a), we have already constructed the ECF 1.0 dataset that contains 1,374 conversations and 13,619 utterances. Furthermore, we have annotated an extended test set specifically for this SemEval evaluation, which together with ECF 1.0 constitutes the **ECF 2.0** dataset[2] that contains 1,715 conversations and 16,720 utterances.

In Table 1, we compare our dataset with the related datasets for ECA, in terms of modality, scene, and size. It is evident that ECF 2.0 is currently the largest available emotion cause dataset.

Table 2 presents the detailed statistics of our dataset for the two subtasks. It can be seen that, in the entire ECF 2.0 dataset, 56.88% of the utterances are labeled with one of the six basic emotions, 92.81% of the emotion utterances have corresponding cause utterances, and 88.18% of the emotion utterances are annotated with textual cause spans.

In addition, as shown in Figure 2 and Figure 3, the newly annotated test set is basically consistent with the original ECF 1.0 dataset in terms of conversation length and emotion distribution.

4 Evaluation

Our SemEval task runs on CodaLab[3]. We released the training data in September 2023, and notified participants to commence model development. The evaluation phase began on January 16, 2024, and ended on January 31, 2024. We mixed the extended test set (consisting of 341 conversations with emotion and cause annotations; the labels are not publicly available) with some noise data (containing 324 conversations, not intended for evaluation) and released them together. Each team is allowed to submit their results up to three times a day.

4.1 Evaluation Metrics

We evaluate the emotion-cause pairs of each emotion category with F_1 scores separately and further calculate a weighted average of F_1 scores across the six emotion categories, denoted as "**w-avg. F_1**". Specifically, for Subtask 1, which involves the textual cause span, we adopt two strategies to determine whether the span is extracted correctly:

- *Strict Match*: A predicted span is regarded as correct if it's the same as one of the annotated spans;

[2]Our dataset is available on Google Drive.

Table 4: The leaderboard for Subtask 2 (MECPE). "†" indicates that the team has submitted a system description paper to SemEval-2024.

- *Proportional Match*: Calculate the overlap proportion of the predicted span and the annotated one.

The evaluation metrics for the two strategies are "w-avg. S. F_1" and "w-avg. P. F_1", respectively. Taking into account the complexity of Subtask 1, we choose "**w-avg. P. F_1**" as the main metric[4] for the ranking.

4.2 Baselines

As mentioned in our previous work (Wang et al., 2023a), for Subtask 2 we also employed the BiLSTM-based ECPE-2steps model as our baseline system. Specifically, we maintain the validation set of the ECF 1.0 datset unchanged and merge the test set into the training set to train the model. The evaluation of the model predictions on the extended test set achieves a weighted average F_1 of **0.1926**.

For Subtask 1, based on the same model, we just convert the cause extraction module in Step 1 from the cause utterance prediction to the prediction of the start index and end index within the utterance, then simply match the indexes as candidate cause spans, followed by emotion-cause pairing and filtering in Step 2. The evaluation result for the weighted average proportional F_1 on the extended test set is **0.1801**.

4.3 Participating Systems and Results

Our competition was created on Codalab in November 2023, and has attracted 143 registrations and a total of 216 submissions. After the evaluation, 18 teams have submitted system de-

[4]Specific calculation details can be found on GitHub.

scription papers.

Team *Samsung Research China-Beijing* (Zhang et al., 2024) won first place in both subtasks, holding a significant lead over the second-place team. Teams *petkaz* (Kazakov et al., 2024) and *UIC NLP GRADS* (Chandakacherla et al., 2024) respectively captured the second and third places in Subtask 1. Teams *NUS-Emo* (Luo et al., 2024) and *SZTU-MIPS* (Cheng et al., 2024) attained second and third positions in Subtask 2. The official leaderboards for Subtask 1 and Subtask 2 are shown in Table 3 and Table 4, respectively.

4.3.1 System Overview

Almost all systems have implemented our task through a two-step framework, first performing the ERC task and then predicting the causes based on emotions. In the following, we briefly introduce the systems from the top teams and some other notable approaches.

Team *Samsung Research China-Beijing* (Zhang et al., 2024) achieved first place in both subtasks with a pipeline framework. They fine-tuned the LLaMA2-based InstructERC (Lei et al., 2023) to extract the emotion category of each utterance in a conversation. For further data augmentation, they added three additional auxiliary tasks based on the original training data strategy of InstructERC. Then, the MuTEC (Bhat and Modi, 2023) and TSAM (Zhang et al., 2022) models are used, respectively, to extract cause spans for Subtask 1 and cause utterances for Subtask 2. They also obtained different multimodal representations through openSMILE (Eyben et al., 2010), LLaVA (Liu et al., 2024), and a self-designed face module to explore the integration of audio-visual information. It should be noted that they used various models for ensemble learning to determine the final prediction.

Team *petkaz* (Kazakov et al., 2024) ranked second in Subtask 1. They fine-tuned GPT 3.5 (Ouyang et al., 2022) for emotion classification and then used a BiLSTM-based neural network to detect cause utterances. The cause extractor model is initialized with BERT (Devlin et al., 2019), followed by three BiLSTM layers. They treat the entire cause utterance as a cause span.

Team *NUS-Emo* (Luo et al., 2024) achieved the second highest score in Subtask 2. First, they conducted zero-shot testing experiments to evaluate multiple LLMs, including OPT-IML3 (Iyer et al., 2022), Instruct-GPT4 (Peng et al., 2023), Flan-T5 (Chung et al., 2022), and ChatGLM (Du et al., 2022). ChatGLM3-6B is ultimately selected as its backbone model based on its superior performance. They designed an emotion-cause-aware instruction-tuning mechanism to update the LLM and incorporated the visual representation from the ImageBind (Girdhar et al., 2023) encoder.

Team *UIC NLP GRADS* (Chandakacherla et al., 2024) achieved the third place in Subtask 1, and their system performed well in the strict metric, ranking second. They fine-tuned RoBERTa (Liu et al., 2019) for emotion classification, and then further fine-tuned a SpanBERT (Joshi et al., 2019) model that had been fine-tuned in SQuAD 2.0 (Rajpurkar et al., 2018), to predict cause spans in QA format.

Team *SZTU-MIPS* (Cheng et al., 2024) ranked third in Subtask 2. They integrated text, audio, and image modalities for emotion recognition and adopted the MiniGPTv2 model (Chen et al., 2023) for multimodal cause extraction. Specifically, textual features are obtained from InstructERC, while acoustic features are extracted using HuBERT (Hsu et al., 2021). For visual modality, faces are first extracted using OpenFace (Baltrusaitis et al., 2016) from video frames, followed by extraction of facial features using expMAE (Cheng et al., 2023).

Team *nicolay-r* (Rusnachenko and Liang, 2024) finetuned Flan-T5 by designing the chain of thoughts for emotion causes based on the Three-Hop Reasoning (THOR) framework (Fei et al., 2023), to predict the emotion of the current utterance and the emotion caused by the current utterance towards the target utterance. Their reasoning revision methodology and rule-based span correction technique bring further improvements.

Team *JMI* (Arefa et al., 2024) implemented two different approaches. In their best system, they used in-context learning using GPT 3.5 for emotion prediction and cause prediction, respectively. Conversation-level video descriptions were extracted via GPT-4V (Yang et al., 2023) to provide more context to GPT 3.5. In addition, they also fine-tuned two separate Llama2 (Touvron et al., 2023) models to recognize emotions and extract causes.

Team *AIMA* (Abootorabi et al., 2024) fine-tuned EmoBERTa (Kim and Vossen, 2021) for emotion classification and then obtained the emotion-cause pairs via a Transformer-based encoder. After finding the pairs, they further fine-tuned the

DeBERTa (He et al., 2021) that had been fine-tuned on SQuAD 2.0 to extract the cause spans for Subtask 1.

Team *UWBA* (Baloun et al., 2024) fused the features of three modalities at the utterance level and then used them for emotion classification and pair prediction. It is interesting that they summarized five span categories (*Whole Utterance*, *First part*, *Last part*, *Middle part*, *Other*) through observations of training data, and then trained a classifier to further predict textual cause spans in cause utterance.

Furthermore, Team *DeepPavlov* (Belikova and Kosenko, 2024) investigated the performance of Video-LLaMA (Zhang et al., 2023) in several modes and found that model fine-tuning yields notable improvements in emotion and cause classification. Team *PWEITINLP* (Levchenko et al., 2024) utilized GPT-3 for emotion classification. Some other Teams, including *UIR-ISC* (Guo et al., 2024), *LyS* (Ezquerro and Vilares, 2024), *QFNU_CS* (Wang et al., 2024) and *Hidetsune* (Takahashi, 2024), all employed BERT-based models to address our task, among which *LyS* proposed an end-to-end model comprising a BERT encoder and a graph-based decoder to identify emotion cause relations. Team *LastResort* (Mathur et al., 2024) tackled our task as sequence labeling problems and used BiLSTM followed by a CRF layer to solve it. Team *NCL* (Li et al., 2024) solely utilized pre-trained models to extract features from three modalities. Team *VerbaNexAI Lab* (Garcia et al., 2024) demonstrated the inadequacy of machine learning techniques alone for emotion cause analysis.

4.3.2 Discussion

Our task, Multimodal Emotion Cause Analysis in Conversations, involves informal real-life conversations and complex audio-visual scenes. Additionally, emotions exhibit strong subjectivity, and we have observed that even humans sometimes struggle to accurately identify emotions and their causes. This complexity underscores the intricate nature of human emotions and the nuanced contexts in which they occur, posing a substantial challenge for data annotation and subsequent model development.

Dataset Bias. Emotion category imbalance is an inherent problem in the ERC task (Li et al., 2017; Hsu et al., 2018; Poria et al., 2019a), aligning with real-world phenomena where people tend to express positive emotions like *joy* more frequently in their daily communications, while expressions of *disgust* and *fear* are less common. Our dataset is sourced from TV series that closely resemble the real world, naturally also exhibiting an imbalance in emotions, as illustrated in Figure 3. However, such an imbalance may adversely affect a model's ability to learn and generalize across different emotions, potentially leading to biases towards frequently expressed emotions (Kazakov et al., 2024; Chandakacherla et al., 2024). Moreover, emotion cause datasets often have a noticeable pattern in the location of causes and emotions. Some systems rely on this position bias, either by using a fixed window size or by direct post-processing to add the emotion utterance as the cause (Rusnachenko and Liang, 2024; Arefa et al., 2024), which overlooks the effective semantic connections between distant contexts and may lead to poor generalization capabilities for unseen data where the cause is not in proximity to the emotion. In the future, LLMs can be leveraged to assist with annotation to expand the diversity of datasets available for fine-tuning, which encompass a wider range of emotional expressions and cultural backgrounds. This can mitigate existing dataset biases and enhance the model's applicability and generalizability across various scenarios.

Utilization of LLMs. Recently, LLMs have exhibited remarkable capabilities in a wide range of tasks and are rapidly advancing the field of natural language processing. Therefore, LLMs are allowed to be used in our competition. It is evident that about a third of the teams have used LLMs for emotion cause analysis, and most of them are ranked at the top. However, some participants have observed that LLMs perform poorly in zero-shot and few-shot settings on emotion and cause recognition tasks (Kazakov et al., 2024; Arefa et al., 2024; Belikova and Kosenko, 2024), indicating a crucial need for task-specific fine-tuning. Furthermore, prompt engineering is essential, as LLMs often produce hallucinations or unstructured outputs. Due to resource and cost constraints, most researchers cannot take full advantage of the strongest capabilities of LLM. Future research is encouraged to explore ways to enhance lightweight models or to bridge the gap between pre-training and downstream tasks, thereby augmenting LLMs' ability to understand emotions.

Potential of Multimodal Information. Multimodal information is important for discovering both emotions and their causes in conversations. In our daily communications, we depend not only on the speaker's voice intonation and facial expressions to perceive his emotions, but also on some auditory and visual scenes to speculate the potential causes that trigger the emotions of speakers beyond text. However, some participants found that the introduction of audio or visual modalities results in minimal improvements or even a decrease in system performance (Zhang et al., 2024; Cheng et al., 2024; Baloun et al., 2024). This issue arises partly due to the characteristics of our dataset, which involves a large number of complex visual scenes but few visual cause clues, leading to the introduction of noise. Another limiting factor might be that multimodal feature extraction methods are not advanced enough or fusion strategies are not effective enough. The challenges that require further exploration include the effective interaction and fusion of multimodal information, as well as the perception, understanding, and utilization of audiovisual scenes. Furthermore, there is a demand for more high-quality data sets on multimodal emotion cause analysis to support research in this area.

5 Conclusions

In this paper, we describe the SemEval-2024 Task 3 named Multimodal Emotion Cause Analysis in Conversations, which aims to extract all potential pairs of emotions and their corresponding causes from a conversation. The shared task has attracted 143 registrations and 216 successful submissions. We provide detailed descriptions of task definition and data annotation, summarize participating systems, and discuss their findings.

As an important direction of affective computing, multimodal emotion cause analysis in conversation plays an important role in many real-world applications. We hope that our research and resources can contribute towards the design of future systems in this direction.

6 Ethics Statement

Our **ECF 2.0** dataset is annotated on the basis of the MELD dataset [5] which is licensed under the GNU General Public License v3.0 and is used only for scientific research. We do not share personal information and do not release sensitive content that can be harmful to any individual or community. Conducting multimodal emotion cause analysis will help us better understand emotions in human conversations, build human-machine dialogue systems, and contribute to society and human well-being.

Acknowledgements

We express our sincere gratitude to the annotators who contributed to constructing the dataset, laying a solid foundation for our research. We also extend our heartfelt gratitude to all the participants who participated in our competition, especially the teams who submitted system description papers and completed the reviewing tasks assigned to them. Furthermore, we thank the anonymous reviewers for their invaluable feedback and insightful comments.

SheffieldVeraAI at SemEval-2024 Task 4: Prompting and fine-tuning a Large Vision-Language Model for Binary Classification of Persuasion Techniques in Memes

Charlie Grimshaw, Kalina Bontcheva and **Xingyi Song**
Department of Computer Science
University of Sheffield
Sheffield, UK
{cgrimshaw1, k.bontcheva, x.song}@sheffield.ac.uk

Abstract

This paper describes our approach for SemEval-2024 Task 4: Multilingual Detection of Persuasion Techniques in Memes. Specifically, we concentrate on Subtask 2b, a binary classification challenge that entails categorizing memes as either "propagandistic" or "non-propagandistic". To address this task, we utilized the large multimodal pretrained model, LLaVa. We explored various prompting strategies and fine-tuning methods, and observed that the model, when not fine-tuned but provided with a few-shot learning examples, achieved the best performance. Additionally, we enhanced the model's multilingual capabilities by integrating a machine translation model. Our system secured the 2nd place in the Arabic language category.

1 Introduction

Research of online misinformation is growing (Chaudhari and Pawar, 2021) as fake news and propagandistic content spreads further and replaces more real news on social media, detrimentally impacting society, including loss of lives, loss of health and economic loss (Muhammed T and Mathew, 2022). A common online propaganda format is a meme, where text and image(s) are combined to share a message, often political (Guo et al., 2020). This paper describes SheffieldVeraAI's approach for SemEval 2024 Task 4 Subtask 2b, involving detecting the presence of persuasion technique(s) within memes, a binary visual/textual classification task (Dimitrov et al., 2024). The previous research on this task including (Feng et al., 2021) (Tian et al., 2021) (Li et al., 2021) used non-autoregressive encoder representation techniques, using models such as BERT (Devlin et al., 2018) or RoBERTa (Liu et al., 2019), fused with a vision representation model such as ResNet (He et al., 2015).

Unlike the previous research, we experimented with a different approach to use and train an auto-regressive vision-language model that receives image and text as input, outputting text only. Prompting the model with a meme and expecting the model to generate a classification output. Specifically, we use the LLaVa-1.5 model (Liu et al., 2023a), which directly projects an image encoding into tokens computed as text tokens by an LLM. This technique allows us to utilise the LLMs' "knowledge" of persuasion techniques they have learnt through massive pre-training and explained outputs through prompting, improving the model's interoperability and error analysis.

1.1 Contributions

- Show that a pre-trained auto-regressive large visual language model can be prompted for binary persuasion classification.
- Show that prompting with translated text is a viable method, achieving 2nd place in the Arabic leaderboard, using an English-only model.

2 Background

Previous SemEval tasks have looked at this problem of online misinformation/persuasion/propaganda:

- **SemEval 2020 Task 11 - "Detection of Propaganda Techniques in News Articles" (Martino et al., 2020).** This task involved span and technique investigation on text-only news articles.
- **SemEval 2021 Task 6 - "Detection of Persuasion Techniques in Texts and Images" (Dimitrov et al., 2021).** The first task relating to persuasion techniques involved a subtask with images, which required classifying propaganda techniques within memes.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 2051–2056

- **SemEval 2023 Task 3 - "Detecting the Genre, the Framing, and the Persuasion Techniques in Online News in a Multilingual Setup" (Piskorski et al., 2023).** This task is similar to SemEval 2020 Task 11, which contains no visual content or news articles while adding genre and framing detection.

This theme of persuasion technique detection is prominent in recent years of SemEval, with the most similar task being SemEval 2021 Task 6 Subtask 3, which involved visual and textual persuasion techniques in memes.

2.1 Task Description

In this work, our focus is on Subtask 2b, which aims to determine whether at least one persuasion technique is present in the meme or no technique is present. This task provides both the original image and the text transcriptions. The detailed data structure is outlined as follows:

- unique *id* of the sample. e.g. 12345
- The image of the meme, an example can be found in Figure 1
- A transcription of text within the image content of the meme. For example: ‘‘GIVE A THUMBS UP IF YOU\\nSTILL SUPPORT TRUMP\\n”
- A label which is either **propagandisitic** or **non-propagandistic**. A meme is propagandistic if it contains one or more of the 22 persuasion techniques defined by the task organisers.

The language of the meme and transcription is either English, Bulgarian, North Macedonian or Arabic. The language of the meme and transcription always match.

3 System Overview

Our system follows these steps:

1. Fine-tune LLaVa with LoRA (Hu et al., 2021) using pre-processed English training data. (Optional; our final system is untrained).
2. Translate Bulgarian, North Macedonian and Arabic transcriptions to English using NLLB (Team et al., 2022).

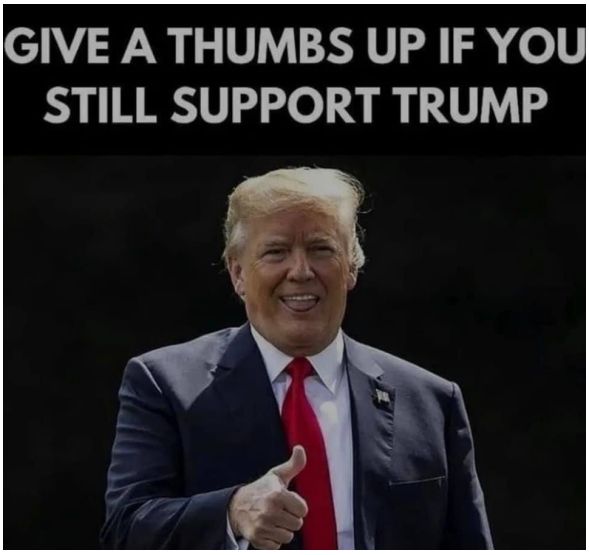

Figure 1: Example of a propagandistic image from the task

3. Prompt LLaVa for binary classification of persuasion techniques, giving a few-shot example.

3.1 LLaVa

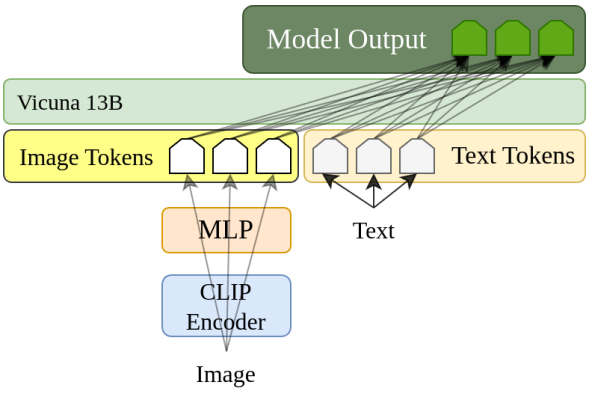

Figure 2: Diagram of LLaVa 1.5 architecture, modelled from original paper (Liu et al., 2023b).

The model we use for this task is called LLaVa (Large Language and Vision Assistant) (Liu et al., 2023b) (Liu et al., 2023a). We are using the 13B parameter version of LLaVa-1.5. We use the original author’s public code, available on GitHub[1], for training and inference. LLaVa is an English-only end-to-end fine-tuned Large Vision-Language Model (LVLM) trained on Chat-GPT4 (OpenAI, 2023) generated instruction-following data. It handles image inputs using a trained projection, a multi-layer perceptron (MLP) in LLaVa-

[1]https://github.com/haotian-liu/LLaVA

1.5, that projects image features from a CLIP encoder (Ramesh et al., 2022) into the word embedding space of an LLM, Vicuna-13B (Chiang et al., 2023). We experiment with prompting LLaVa for binary classification with a meme image and other information that could improve the models' performance and fine-tune the model using the training set for the task. We fine-tune the model using LoRA, a widely used training technique for reducing the number of trainable parameters. We use LoRA to reduce training time and required GPU memory.

3.2 Machine Translation

For the three unseen languages (Bulgarian, North Macedonian and Bulgarian), that are part of the test set, we use the machine translation model NLLB, as this model can translate English into all three unseen languages and is trained at sentence-level which matches the short form text within memes. As LLaVa is English only, we will translate all non-English transcriptions from the test set into English and use these as inputs for LLaVa, allowing LLaVa still to see the visual content of the original meme while receiving text input it understands.

4 Experimental Setup

4.1 Data processing

The dataset provided was split into 3 sets: 1200 training, 150 validation and 300 unlabeled development examples used for early testing and a leaderboard available before the test set was released. These splits were entirely in English. The final test set contained 600 memes in English, 100 in Bulgarian, 100 in North Macedonian and 160 in Arabic. We used the training set for fine-tuning our model, the validation set for finding the best prompts for our model, and the development set to get our results when the labels were released.

To preprocess the data, we removed all new lines and non-Latin characters from English and translated all non-English text from the test set into English before inputting them into the model.

4.2 Hyperparameters

The two hyperparameters we experimented with were the LoRA parameters rank (r) and α. r controls the trainable parameters for fine-tuning, and α is a scaling parameter that affects how much the LoRA adaption weights affect the base model weights. We experimented with every combination of the following values

- r - [8, 16]
- α - [4, 8, 16, 32]

We did experiment with numbers outside this range, but they only worsened the model's performance. We trained the model for 1 epoch, using a single 80GB A100 GPU. We used Python 3.10.13 and the Hugging Face models *liuhaotian/llava-v1.5-13b*[2] and *facebook/nllb-200-3.3B*[3].

4.3 Prompting

We experimented with different prompting techniques. We report the results in Table 1. We tested each technique using the development set as follows:

- **Basic Prompt:**

  USER: <image>\n
  Does this meme contain any propagandistic or persuasive techniques? Answer with "yes" or "no"\n
  ASSISTANT:

- **Meme Text Included:**

  USER: <image>\n
  This meme contains the text: <text>.
  Does this meme contain any propagandistic or persuasive techniques? Answer with "yes" or "no"\n
  ASSISTANT:

- **Persuasive/Propaganda:**
  Here, we experimented with using different words for the techniques.

  USER: <image>\n
  This meme contains the text: <text>.
  Does this meme contain any <propaganda/persuasive> techniques? Answer with "yes" or "no"\n
  ASSISTANT:

- **Examples of Persuasion techniques:**
  Here we experiment by providing an example of some persuasion techniques. We tested every combination of 1-5 persuasion techniques from subtask 2b and found the following prompt to perform the best.

[2]https://huggingface.co/liuhaotian/llava-v1.5-13b
[3]https://huggingface.co/facebook/nllb-200-3.3B

USER: <image>\n
You are tasked with detecting the presence of propaganda techniques in memes. Examples of propaganda techniques are: [Black-and-white Fallacy/Dictatorship, Doubt, Slogans, Appeal to authority, Bandwagon] This meme contains the text: <text>. Does this meme contain any propaganda techniques? Answer with just "Yes" or "No" \n
ASSISTANT:

- **Few-shot example prompt:** We experimented with providing an example of a propagandistic meme within the prompt, hoping to improve the model's classification performance. We could only give the model the transcription from a propagandistic meme, as the LLaVa model was only trained to receive one input image.

  USER: <image>\n
  You are tasked with detecting the presence of propaganda techniques in memes. Some but not all examples of propaganda techniques are: [Black-and-white Fallacy/Dictatorship, Doubt, Slogans, Appeal to authority, Bandwagon]. For example, a meme that contains the text: [American democracy and the Soviet system may peacefully exist side by side and compete with each other. But one cannot evolve into the other. (J. Stalin)] contains propaganda techniques. This meme contains the text: [<Meme Transcription>]. Does this meme contain any propaganda techniques? Answer with just "Yes" or "No".\n
  ASSISTANT:

  We use this final prompt when testing and fine-tuning our model. For fine-tuning, we pair it with a desired output of *yes* if the meme is propagandistic and *no* otherwise. Before evaluating the models, we convert *yes* and *no* back to their corresponding labels.

5 Results

Table 2 presents the results of fine-tuning our model on training data and testing it on the development set. As reported, fine-tuning using our experimental setup only worsened the model's performance, so we chose the untrained baseline LLaVa-1.5 model for submission using the test set.

Table 3 presents the final results for the leaderboard for our attempt at the task. Our worst performing result was in the English language. However, we performed better in the unseen languages, with our best result being **2nd place in Arabic.**

5.1 Error Analysis

Figure 3 shows a confusion matrix for the untrained model on the development set. We can see that by proportion, it made more errors predicting propagandistic memes as non-propagandistic than otherwise.

By prompting the model, we can "ask" the model why it made a classification for any meme, which increases the explainability and error analysis capabilities of a model like this. We provide output explanations for two examples where it predicts pro-

Technique	Macro-F1
Basic Prompt	0.42

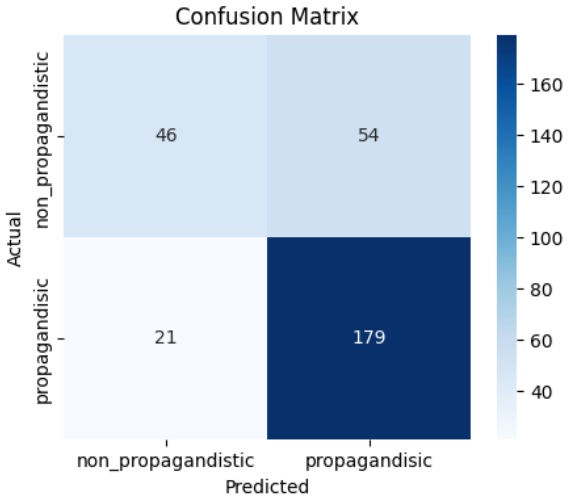

Figure 3: Confusion Matrix of untrained LLaVa on the dev set.

pagandistic (P) as propagandistic (NP) and where it predicts NP as P.

- **Classifying P as NP** - Dev Set ID 28493:

  > "The meme does not contain any of the propaganda techniques listed. It is a simple image of two men shaking hands, with a caption that is not promoting any particular ideology or using any manipulative techniques. The meme is not trying to persuade or influence the viewer's opinion, but rather it is simply presenting a visual representation of a positive interaction between two individuals."

  The original meme requires context about Russian President Vladimir Putin's relationship with intergovernmental forum G20, which the model fails to recognise. It claims the meme doesn't contain any of the propaganda techniques listed. This is likely referring to the example persuasion technique provided in the original prompt, which the model may be confusing for the **only** persuasion techniques to look for.

- **Classifying NP as P** - Dev Set ID 45439:

  > "Yes, this meme contains a propaganda technique called "Slogans." The meme is promoting a political message, specifically advocating for expanding the court. The use of the hashtag WENEEDNINE and the phrase "Expand the Court" are examples of slogans that aim to influence public opinion and support for the political cause. Slogans are often used in propaganda to create a memorable and catchy phrase that can be easily shared and repeated, thus increasing the reach and impact of the message."

  Although the meme does contain slogans in its image, they aren't part of the message and joke of the meme; the slogans are there because the meme is about a politician who happens to be photographed standing behind a slogan. However, the model fails to make this distinction.

6 Conclusion

We have presented our system for SemEval 2024 Task 4 Subtask 2b. We prompted and fine-tuned an auto-regressive large visual language model and showed that LLaVa can be used for non-English persuasion technique detection in memes through improved prompting and machine translation, with our best ranking being 2nd on the Arabic leaderboard. We experimented with different techniques for prompting to discover which produced the best-performing output. We also analysed the type of errors LLaVa can produce when classifying memes, showing how this model can easily be prompted for explainability. Further work is required to improve training LVLMs for this task, as we could not see improvements through fine-tuning.

Abstract

We present the results and the main findings of SemEval-2024 Task 8: Multigenerator, Multidomain, and Multilingual Machine-Generated Text Detection. The task featured three subtasks. Subtask A is a binary classification task determining whether a text is written by a human or generated by a machine. This subtask has two tracks: a monolingual track focused solely on English texts and a multilingual track. Subtask B is to detect the exact source of a text, discerning whether it is written by a human or generated by a specific LLM. Subtask C aims to identify the changing point within a text, at which the authorship transitions from human to machine. The task attracted a large number of participants: subtask A monolingual (126), subtask A multilingual (59), subtask B (70), and subtask C (30). In this paper, we present the task, analyze the results, and discuss the system submissions and the methods they used. For all subtasks, the best systems used LLMs.

1 Introduction

The proliferation of Large Language Models (LLMs) has led to a significant increase in the volume of machine-generated text (MGT) across a wide range of domains. This rise has sparked concerns regarding the potential for misuse in fields such as journalism, education, academia, etc (Uchendu et al., 2023; Crothers et al., 2023). Moreover, it poses challenges to maintaining information integrity and ensuring accurate information dissemination. As such, the ability to accurately distinguish between human-written content and machine-generated content has become paramount for identifying potential misuse (Jawahar et al., 2020; Stiff and Johansson, 2022; Macko et al., 2023).

In response to these challenges, we are introducing a shared task that focuses on the detection of machine-generated text across multiple generators, domains, and languages. We are providing large-scale evaluation datasets for **three subtasks** with the primary goals of fostering extensive research in MGT detection, advancing the development of automated systems for detecting MGT, and reducing instances of misuse:

Subtask A: Human vs. Machine Classification. The goal of this subtask is to accurately classify a text as either produced by a human or generated by a machine. This is the basic, but one of the most common use-cases of MGT detection systems for preventing the misuse of LLMs. This task is divided into two tracks: (i) The *monolingual track*, which focuses solely on English texts; and (ii) The *multilingual track*, which involves texts in a variety of languages, thereby expanding the diversity and complexity beyond existing benchmarks.

Subtask B: Multi-Way Generator Detection. This task aims to pinpoint the exact source of a text, i.e., determine whether it originated from a human or a specific LLM (GPT-3, GPT-3.5, GPT-4, Cohere, DALL-E, or BLOOMz). Determining a particular LLM that potentially generated the given text is important from several perspectives: it can help to narrow down the set of LLMs for more sensitive white-box detection techniques or in cases where the generated material is harmful, misleading, or illegal, it might be useful for addressing ethical concerns and legal obligations.

Subtask C: Changing Point Detection. The goal of this subtask is to precisely identify the exact boundary (changing point) within a text at which the authorship transitions from a human to machine happens. The texts begin with human-written content, which at some point is automatically continued by LLMs (GPT and LlaMA series). The percentage of the human-written section varies from 0% to 50%. This task takes into account the fact

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 2057–2079

that in many malignant use-cases of LLMs, the part of the text might be written by a human and a part might be generated by a machine. It is hard to classify a text as machine-generated if a big chunk is actually human-written. This is a way to obscure the usage of LLM, and the formulation of Subtask C addresses this challenge.

The task attracted a large number of participants: 126 teams for the Subtask A monolingual track, 59 teams for the Subtask A multilingual track, 70 teams for Subtask B, and 30 teams for Subtask C, with a total of 54 participating teams having submitted a system description paper for all subtasks.

Next, we introduce the MGT detection techniques considered in this shared task in §2; §3 describes the corpus and the evaluation metrics; §4 details the organization of the task; §5 provides an overview of the participating systems; and §6 discusses the evaluation results.

2 Background

Detecting machine-generated text is primarily formulated as a binary classification task (Zellers et al., 2019; Gehrmann et al., 2019a; Solaiman et al., 2019; Ippolito et al., 2019), naively distinguishing between human-written and machine-generated text. In general, there are two main approaches: the supervised methods (Wang et al., 2024a,b; Uchendu et al., 2021; Zellers et al., 2019; Zhong et al., 2020; Liu et al., 2022) and the unsupervised ones, such as zero-shot methods (Solaiman et al., 2019; Ippolito et al., 2019; Mitchell et al., 2023; Su et al., 2023; Hans et al., 2024). While supervised approaches yield relatively better results, they are susceptible to overfitting (Mitchell et al., 2023; Su et al., 2023). Meanwhile, unsupervised methods may require unrealistic white-box access to the generator. In the following, we provide background information on each subtask, respectively.

Subtask A: Mono-lingual and Multi-lingual Binary Classification Given the prevalence of the binary classification task, various benchmarks assess model performance in both mono-lingual and multi-lingual settings. HC3 (Guo et al., 2023) compares ChatGPT-generated text with human-written text in English and Chinese, utilizing logistic regression models trained on GLTR Test-2 features (Gehrmann et al., 2019a) and RoBERTa (Liu et al., 2019)-based classifiers for detection. Benchmark results by Wang et al. (2024b) include evaluations of several supervised detectors, such as RoBERTa (Liu et al., 2019), XLM-R (Conneau et al., 2019), logistic regression classifier with GLTR features (Gehrmann et al., 2019b), and stylistic features (e.g., stylometry (Li et al., 2014), NELA (Horne et al., 2019) features). Macko et al. (2023) create a similar resource called MULTITuDE for 11 languages in the news domain and conduct an extensive evaluation of various baselines. Our effort extends the previous works by providing evaluation setup for multiple domains, multiple languages, and for state-of-the-art LLMs, including ChatGPT and GPT-4.

Subtask B: Multi-Way Generator Detection Multi-way generator detection, attributing texts not just to their machine-generated nature but also to specific generators, resembles authorship attribution. Munir et al. (2021) find that texts from language models (LMs) have distinguishable features for source attribution. Uchendu et al. (2020) addresses three authorship attribution problems: (1) determining if two texts share the same origin, (2) discerning whether a text is machine or human-generated, and (3) identifying the language model responsible for text generation. Approaches like GPT-who by Venkatraman et al. (2023) employ UID-based features to capture unique signatures of each language model and human author, while Rivera Soto et al. (2024) leverages representations of writing styles.

Subtask C: Change Point Detection Change point detection, which is closely tied to authorship obfuscation (Macko et al., 2024), extends beyond binary/multi-class classification to an adversarial co-authorship setting involving both humans and machines (Dugan et al., 2023). Machine-generated text detection methods are vulnerable to authorship obfuscation attacks such as paraphrasing (Crothers et al., 2022; Krishna et al., 2023; Shi et al., 2023; Koike et al., 2023), back-translation, and change point detection. Related to Subtask C, (Gao et al., 2024) introduces a dataset with mixed machine and human-written texts using operations such as polish, complete (Xie et al., 2023), rewrite (Shu et al., 2023), humanize (adding natural noise (Wang et al., 2021)), and adapt (Gero et al., 2022). Kumarage et al. (2023) uses stylometric signals to quantify changes in tweets and detect when AI starts generating tweets. Different to our task, they focus on human-to-AI author changes within a given Twitter

3 Dataset and Metrics

In this section, we describe the datasets and evaluation metrics for all subtask tracks, including the size, domains, generators, and language distribution across training, development, and test splits.

3.1 Subtask A: Monolingual Track

Data: Table 1 presents statistics across generators, domains, and splits. The training set encompasses domains such as Wikipedia, WikiHow, Reddit, arXiv, and PeerRead, comprising a total of 56,400 machine-generated and 63,351 human-written texts. BLOOMz is utilized as an unseen generator in the development set, which contains 2,500 machine-generated and 2,500 human-written texts. For the test set, OUTFOX is introduced as the surprising domain, and GPT-4 serves as the surprising generator, with a dataset of 18,000 machine-generated and 16,272 human-written texts.
Metrics: Accuracy is used to evaluate detectors.

3.2 Subtask A: Multilingual Track

Data: Table 2 presents the dataset statistics. The training set encompasses texts in English, Chinese, Urdu, Bulgarian, and Indonesian, totaling 76,863 machine-generated and 80,994 human-written texts. The development set includes Arabic (sourced from Wikipedia), Russian, and German (sourced from Wikipedia), each contributing 2,000 texts from both machine-generated and human-written sources. In the test set, Italian is introduced as the unexpected language, with *OUTFOX* and *News* serving as new domains for English, Arabic, and German texts. This set comprises 22,100 machine-generated and 20,200 human-written texts.
Metrics: Accuracy is used to evaluate detectors.

	LLaMA2-70B	–	–	**1,000 (19)**	1,000 (19)
Total	all	18,245	2,525	11,123	31,893

Table 4: **Subtask C: Change Point Detection.** We use generators GPT and LLaMA-2 series over domains of academic paper review (PeerRead) and student essay (OUTFOX). The number in "()" is the number of examples purely generated by LLMs, i.e., human and machine boundary index=0. LLaMA-2-7B* and LLaMA-2-7B used different prompts. Bold data is used in shared task training, development, and test.

3.3 Subtask B

Data: In Table 3, we incorporate texts from five generators (davinci-003, ChatGPT, Cohere, Dolly-v2, and BLOOMz) alongside human-written texts. The development set features texts from the PeerRead domain, while the test set introduces OUTFOX (specifically, student essays) as the unexpected domain.
Metrics: Accuracy is used to evaluate detectors.

3.4 Subtask C

Data: The training and development sets for subtask C are PeerRead ChatGPT generations, with **5,349** and **505** examples respectively (first row of Table 4), and the test set is the combination of the *test column* of Table 4, totaling 11,123 examples.

Metrics: The Mean Absolute Error (MAE) is used to evaluate the performance of the boundary detection model. It measures the average absolute difference between the predicted position index and the actual changing point.

4 Task Organization

The shared task was run in two phases:

Development Phase. Only training and development data were provided to the participants, with no gold labels available for the development set. Participants competed against each other to achieve the best performance on the development set. A live leaderboard on CodaLab was made available to track all submissions. Teams could make an unlimited number of submissions, and the best score for each team, regardless of the submission time, was displayed in real time on CodaLab.

Test Phase. The test set was released, containing two additional languages—German and Italian for Subtask A Multilingual Track, generator GPT-4 for the Monolingual Track, and a new domain (student essays) for Subtask B. For Subtask C, both new domains and generators were introduced (GPT-4 and LLaMA-2 series based on PeerRead and OUTFOX), which were not disclosed to the participants beforehand (referred to as surprise languages, domains, and generators).

Participants were given approximately three weeks to prepare their predictions. They could submit multiple runs, but they wouldn't receive feedback on their performance. Only the latest submission from each team was considered official and used for the final team ranking.

In total, 125 teams submitted results for Subtask A Monolingual, 62 for Subtask A Multilingual, 70 for Subtask B, and 30 for Subtask C. Additionally, 54 teams submitted system description papers.

After the competition concluded, we released the gold labels for both the development and test sets. Furthermore, we kept the submission system open for the test dataset for post-shared task evaluations and to monitor the state of the art across the different subtasks.

5 Participating Systems

In this section, we first summarize common features for all teams based on the information they provided in the Google Docs. Then, we delve into the methods employed by the top 3 teams, accompanied by brief descriptions of the approaches utilized by the other top 10 teams.

The approaches of all teams are presented in Appendix A.

Table 5: **Subtask A monolingual** participants methods overview. *small PLM*: Pre-trained Language Model is used, *LLM*: LLM is used, *GPT* indicates if any GPT models are used, *fine-tuning*: applying fine-tuned models, *zero-shot* and *few-shot (k=?)* that zero or more examples are used as demonstrations in in-context learning based on LLMs, *Data augmentation* and *External Data* referes to that augmented data or other external data have been used.

5.1 Monolingual Human vs Machine

Table 5 provides a high-level overview of the methodologies employed by the top-ranking systems in Subtask A monolingual. Most systems utilized either a Pretrained Language Model (PLM) or a Large Language Model (LLM), with the majority of participants fine-tuning their models. Usage of GPT, external data, and few-shot methods was observed in only one team each.

Team Genaios$_{\text{STA_mono:1}}$ (Sarvazyan et al., 2024) achieved the highest performance in this subtask by extracting token-level probabilistic fea-

tures (log probability and entropy) using four LLaMA-2 models: LLaMA-2-7B, LLaMA-2-7B-chat, LLaMA-2-13B, and LLaMA-2-13B-chat. These features were then fed into a Transformer Encoder trained in a supervised manner.

Team USTC-BUPT$_{\text{STA_mono:2}}$ (Guo et al., 2024) secured the second position. Their model is built upon RoBERTa, with the addition of two classification heads: one for binary classification (human or machine) using MLP layers, and another for domain classification (e.g., news, essays, etc.). The latter is equipped with an MLP layer and a gradient reversal layer to enhance transferability between the training and test sets. A sum-up loss is applied, resulting in approximately 8% improvement compared to the RoBERTa baseline.

Team PetKaz$_{\text{STA_mono:12}}$ (Petukhova et al., 2024) utilized a fine-tuned RoBERTa augmented with diverse linguistic features.

In addition to the top three teams: **Team HU$_{\text{STA_mono:17}}$** (Roy Dipta and Shahriar, 2024) employed a contrastive learning-based approach, fine-tuning MPNet on an augmented dataset. **Team TrustAI$_{\text{STA_mono:20}}$** ensembles several classical ML classifiers, Naive Bayes, LightGBM and SGD. **Team L3i++$_{\text{STA\_mono:24}}$** (Tran et al., 2024) investigated various approaches including likelihood, fine-tuning small PLMs, and LLMs, with the latter, fine-tuned LLaMA-2-7B, proving to be the most effective. **Team art-nat-HHU$_{\text{STA_mono:25}}$** (Ciccarelli et al., 2024) utilized a RoBERTa-base model combined with syntactic, lexical, probabilistic, and stylistic features. **Team Unibuc - NLP$_{\text{STA_mono:28}}$** (Marchitan et al., 2024) jointly trained Subtasks A and B based on RoBERTa. Most other teams fine-tuned either RoBERTa or XLM-RoBERTa for MGT detection, enhancing the models through various techniques, ranging from a mixture of experts by **Team Werkzeug$_{\text{STA_mono:45}}$** (Wu et al., 2024) to low-rank adaptation by **Team NCL-UoR$_{\text{STA_mono:50}}$** (Xiong et al., 2024), while **Team Sharif-MGTD$_{\text{STA_mono:51}}$** (Ebrahimi et al., 2024) preferred careful fine-tuning of PLMs alone.

5.2 Multilingual Human vs Machine

Table 6 provides an overview of the methods employed by the top-performing systems for Subtask A Multilingual. Various techniques are utilized, including zero-shot learning based on LLMs, PLM-based classifiers, and ensemble models.

Team USTC-BUPT$_{\text{STA_Multi:1}}$ (Guo et al., 2024) secured the top position. They initially detect the language of the input text. For English text, they average embeddings from LLaMA-2-70B, followed by classification through a two-stage CNN. For texts in other languages, the classification problem is transformed into fine-tuning a next-token prediction task using the mT5 model, incorporating special tokens for classification. Their approach integrates both monolingual and multilingual strategies, exploiting large language models for direct embedding extraction and model fine-tuning. This enables the system to adeptly handle text classification across a diverse range of languages, especially those with fewer resources.

Table 6: **Subtask A multilingual** participants methods.

Team FI Group$_{\text{STA_Multi:2}}$ (Ben-Fares et al., 2024) implemented a hierarchical fusion strategy that adaptively combines representations from different layers of XLM-RoBERTa-large, moving beyond the conventional "[CLS]" token classification to sequence labeling for enhanced detection of stylistic nuances.

Team KInIT$_{\text{STA_Multi:3}}$ (Spiegel and Macko, 2024) combined fine-tuned LLMs with zero-shot statistical methods, employing a two-step majority voting system for predictions. Their method emphasizes language identification, per-language threshold calibration, and the integration of both fine-tuned and statistical detection methods, demonstrating the power of ensemble strategies. For the LLMs, they utilized QLoRA PEFT to fine-tune

Table 7: **Subtask B** Participants method overview.

Falcon-7B and Mistral-7B.

Other teams explored various approaches, like using LoRA-finetuned LLMs as classifiers (**Team AIpom$_{\text{STA_Multi:9}}$**) (Shirnin et al., 2024), using semantic and syntactic aspects of the texts (**RFBES$_{\text{STA_Multi:10}}$**) (Heydari Rad et al., 2024) or fusing perplexity with text and adding a classification head (**Team SINAI$_{\text{STA_Multi:21}}$**) (Gutiérrez Megías et al., 2024). Each team's method provides insights into the complexities of multilingual text detection, ranging from the use of specific LLMs and PLMs to the use of linguistic and probabilistic metrics and ensemble techniques (Wu et al., 2024; Brekhof et al., 2024; Kyriakou et al., 2024; Puspo et al., 2024; Urlana et al., 2024).

5.3 Multi-way Detection

Table 7 provides an overview of the approaches employed by the top-ranking systems for Subtask B. Similar to Subtask A, most solutions do not use GPT and zero-shot approaches. The best-performing solutions primarily exploit LLMs and data augmentation.

Team AISPACE$_{\text{STB:1}}$ (Gu and Meng, 2024) achieved the highest performance in this subtask by fine-tuning various encoder and encoder-decoder models, including RoBERTa, DeBERTa, XLNet, Longformer, and T5. They augmented the data with instances from Subtask A and explored the effects of different loss functions and learning rate values. Their method leverages a weighted Cross-Entropy loss to balance samples in different classes and uses an ensemble of fine-tuned models to improve robustness.

Team Unibuc - NLP$_{\text{STB:2}}$ (Marchitan et al., 2024) employed a Transformer-based model with a unique two-layer feed-forward network as a classification head. They also augmented the data with instances from the Subtask A monolingual dataset.

Team USTC-BUPT$_{\text{STB:3}}$ (Guo et al., 2024) leveraged LLaMA-2-70B to obtain token embeddings and applied a three-stage classification. They first distinguished human-generated from machine-generated text using LLaMA-2-70B, then categorized ChatGPT and Cohere as one class and distinguished them from davinci-003, BLOOMz, and Dolly-v2. Finally, they performed binary classification between ChatGPT and Cohere.

Team L3i++$_{\text{STB:6}}$ (Tran et al., 2024) conducted a comparative study among three groups of methods: metric-based models, fine-tuned classification language models (RoBERTa, XLM-R), and a fine-tuned LLM, LLaMA-2-7B, finding LLaMA-2 to outperform other methods. They analyzed errors and various factors in their paper.

Team MLab$_{\text{STB:7}}$ (Li et al., 2024) fine-tuned DeBERTa and analyzed the embeddings from the last layer to provide insights into the embedding space of the model.

Team Werkzeug$_{\text{STB:8}}$ (Wu et al., 2024) utilized RoBERTa-large and XLM-RoBERTa-large to encode text, addressing the problem of anisotropy in text embeddings produced by pre-trained language models (PLMs) by introducing a learnable parametric whitening (PW) transformation. They also used multiple PW transformation layers as experts under the mixture-of-experts (MoE) architecture to capture features of LLM-generated text from different perspectives.

Other teams explored various approaches, including different loss functions and sentence transformers (**Team MGTD4ADL$_{\text{STB:17}}$**) (Chen et al., 2024), RoBERTa fine-tuning (**Team UMUTeam$_{\text{STB:23}}$**) (pan et al., 2024), stacking ensemble techniques (**Team MasonTigers$_{\text{STB:38}}$**) (Puspo et al., 2024), and basic ML models with linguistic-stylistic features (**Team RUG-5$_{\text{STB:41}}$**)

Table 8: **Subtask C** Participants method overview.

(Darwinkel et al., 2024).

5.4 Boundary Identification

Table 8 presents an overview of the methods used by the top-ranking systems for Subtask C. The best performing solutions are mainly based on ensemble strategies, with some employing data augmentation.

Team TM-TREK$_{\text{STC:1}}$ (Qu and Meng, 2024) achieved the highest performance in Subtask C. They utilized an ensemble of XLNet models, each trained with a distinct seed, and used a straightforward voting mechanism on the output logits. They also explored the integration of LSTM and CRF layers on top of various PLMs, along with continued pretraining and fine-tuning of PLMs, and dice loss functions to enhance model performance.

Team AIpom$_{\text{STC:2}}$ (Shirnin et al., 2024) introduced a novel two-stage pipeline merging outputs from an instruction-tuned, decoder-only (Mistral-7B-OpenOrca) model and two encoder-only sequence taggers.

Team USTC-BUPT$_{\text{STC:3}}$ (Guo et al., 2024) fine-tuned a DeBERTa model with data augmentation and framed the task as a token classification problem.

Team RKadiyala $_{\text{STC:6}}$ (Kadiyala, 2024) fine-tuned various encoder-based models with a Conditional Random Field (CRF) layer and found Deberta-V3 to perform the best on the development set.

Team DeepPavlov $_{\text{STC:7}}$ (Voznyuk and Konovalov, 2024) fine-tuned the Deberta-v3 model using the provided dataset and developed a data preprocessing pipeline for data augmentation.

Other teams explored diverse CNN, LSTM (**Team TueCICL $_{\text{STC:22}}$**) (Stuhlinger and Winkler, 2024), (**Team Unibuc - NLP $_{\text{STC:28}}$**) (Marchitan et al., 2024), and regression-based (**Team jelarson $_{\text{STC:25}}$**) (Larson and Tyers, 2024) techniques to address this challenge, although many did not surpass the baselines due to issues related to model overfitting or inadequate word embeddings.

6 Results and Discussion

6.1 Subtask A

There were three submissions for subtask A, which were submitted in time, but had the wrong file name, which prevented us from scoring them automatically. We eventually manually fixed the names and scored them, and we also added them to the ranking but marked them with a *. They should be considered as unofficial submissions.

Monolingual Table 9 presents the performance of systems in the monolingual track of Subtask A. Out of 125 participating teams, 15 surpassed the baseline, with the top-performing team (Genaios) achieving an accuracy of 96.88. Notably, several teams demonstrated high precision and recall scores, indicating robust performance in distinguishing between human-generated and machine-generated text in a binary classification context.

Multilingual Table 10 presents the performance of systems in the multilingual track of Subtask A, where Team USTC-BUPT emerges as the top performer among 62 participating teams, achieving an accuracy of 95.99, remarkably close to the English-only result. Their methodology entails a blend of language detection and fine-tuning tasks using LLaMA-2-70B for English and the mT5 model for others, showcasing their adaptability across diverse languages.

Similarly, among the 22 teams surpassing the baseline, the majority leverage advanced LLMs such as LLaMA, Mistral, etc., while also emphasizing syntax and writing style differences between human and AI-generated texts. For example, Team FI Group implements a hierarchical fusion strategy to adaptively fuse representations from different BERT layers, prioritizing syntax over semantics for improved classification accuracy. Likewise, Team KInIT employs an ensemble approach, combining fine-tuned LLMs with zero-shot statistical methods,

Table 12: **Subtask C: Boundary Identification**.

score the importance of leveraging advanced LLMs, ensemble techniques, and comprehensive analysis to achieve superior performance in detecting machine-generated text across multilingual contexts.

6.2 Subtask B

For Subtask B (Multi-Way detection), 70 teams participated, with 20 surpassing the baseline of 74.61 accuracy. Table 11 displays the full results. In summary, the subtask results underline the effectiveness of diverse and innovative approaches, including fine-tuning advanced models (e.g., RoBERTa, DeBERTa, XLNet, Longformer, T5), data augmentation (e.g., using Subtask A instances), ensemble strategies, and the exploration of novel loss functions and learning techniques. The leading entries showcased a range of methodologies, from leveraging the power of large language models and addressing embedding anisotropy to integrating traditional and neural methods, underscoring the dynamic and evolving nature of NLP research. For instance, Team AISPACE utilized a weighted Cross-Entropy loss and an ensemble approach based on model performance per class, which led to the highest accuracy of 90.85.

6.3 Subtask C

Of the 30 systems that were submitted for Subtask C, 11 outperformed the baseline MAE of 21.54. The top system, TM-TREK, achieved the best submitted MAE of 15.68. A significant majority of the top-performing teams relied on ensembles of PLMs, indicating a consensus that combining the strengths of multiple models can lead to more robust and accurate predictions. This approach leverages the diverse representations and strengths of different models to mitigate weaknesses inherent in individual systems.

Data augmentation emerged as a critical strategy among leading teams, suggesting its effectiveness in enhancing model performance by providing a richer, more varied training dataset. This includes both the generation of new training examples and the manipulation of existing data to better capture the complexity and variability of natural language.

Despite the advanced methodologies deployed, some teams struggled with issues related to overfitting and the adequacy of word embeddings. This underscores the ongoing challenges in developing models that generalize well to unseen data and the critical role of embeddings in capturing semantic and syntactic nuances of language.

7 Conclusion and Future Work

We have described SemEval-2024 Task 8 on Multigenerator, Multidomain, and Multilingual Machine-Generated Text Detection. The task garnered significant interest from researchers, with 126, 59, 70, and 30 teams submitting entries for Subtask A Monolingual, Subtask A Multilingual, Subtask B, and Subtask C, respectively. Additionally, we received 54 system description papers before finalizing this submission.

Overall, Subtasks A and B were relatively easier, with all systems showing improvements over the baseline. However, Subtask C proved to be significantly more challenging. Fewer teams participated, and many struggled to surpass our baseline results set in (Wang et al., 2024a).

In future work, we plan to extend our focus beyond machine-generated text detection to other modalities such as image, speech, and video detection. Additionally, we intend to develop an open-source demonstration system capable of distinguishing between AI-generated content and human-produced content.

Limitations

Despite providing a comprehensive dataset that spans multiple languages, generators, and domains across three distinct tasks in machine-generated text detection, our study encounters several limitations that pave the way for future research.

Firstly, the reliance on textual data without access to white-box information, such as token-level probabilities, confines our detection methods to

black-box approaches across all tasks. These methods might exhibit reduced effectiveness and struggle to generalize across new domains, generators, and languages. Additionally, they are susceptible to language-style attacks, including paraphrasing in different tones, back-translation, and other forms of textual adversarial tactics. In contrast, methods that leverage watermarking and white-box patterns show greater promise for robust MGT detection.

Secondly, our approach to boundary identification presupposes that each text comprises an initial segment written by humans followed by machine-generated content, with only one transition point. However, real-world scenarios often present more complex challenges. It is crucial not only to ascertain the presence of mixed text but also to identify all transition points. Texts may originate from human authors and undergo refinement via machine assistance, or vice versa, encompassing machine generation followed by human revision. Addressing these nuanced scenarios will be a focus of our future research efforts.

Ethics and Broader Impact

This section outlines potential ethical considerations related to our work.

Data Collection and Licenses Our study utilizes pre-existing corpora, specifically the M4 and OUTFOX datasets, which have been publicly released for research purposes under clear licensing agreements.

Security Implications The dataset underpinning our shared task aims to foster the development of robust MGT detection systems. These systems are crucial for identifying and mitigating misuse scenarios, such as curbing the proliferation of automated misinformation campaigns and protecting individuals and institutions from potential financial losses. In fields such as journalism, academia, and legal proceedings, where the authenticity of information is of utmost importance, MGT detection plays a vital role in maintaining content integrity and trust. Furthermore, by enhancing public awareness of the capabilities and limitations of LLMs, we can cultivate a healthy skepticism towards digital content. Effective MGT detection mechanisms are essential for ensuring that users can place their trust in content generated by LLMs.

Acknowledgments

We extend our deepest gratitude to the SemEval Shared Task 2024 organizing committee for their enduring patience and support throughout our task's development, and to all participants for their innovative contributions and collaborative spirit during the task coordination phase. Our thanks also go to the anonymous reviewers and program committee chairs, whose constructive feedback has significantly contributed to the improvement of our paper.

Appendix

A Method Summary

A.1 Monolingual Human vs, Machine

Team Genaios$_{\text{STA_mono:1}}$ (Sarvazyan et al., 2024) achieves the highest accuracy on Subtask A – Monolingual by extracting token-level probabilistic features using four Llama-2 models: Llama-2-7b, Llama-2-7b-chat, Llama-2-13b, and Llama-2-13b-chat. For each token they compute the log probability of the observed token, the log probability of the token predicted by each of the language models, and the entropy of the distribution. These features are then fed to a Transformer Encoder trained in a supervised fashion to detect synthetic text.

Team USTC-BUPT$_{\text{STA_mono:2}}$ (Guo et al., 2024) incorporates domain adversarial neural networks into the task of machine-generated text detection to reach the second position in the ranking of Subtask A – Monolingual. They add a gradient reversal layer on top of the baseline, a supervised classifier based on RoBERTa. In addition, they exploit domain labels to enhance the transferability of learning between training and testing datasets. Their architecture is based on RoBERTa and adds two classification heads, one for category classification (human or synthetic) and one for domain classification (e.g. news, essays, etc.), the former uses an MLP layer and the latter is composed of an MLP together with a gradient reversal layer. Finally, the loss is also adapted by summing together the category and the domain losses. The submission evaluated an improvement of approximately 8% compared to the baseline.

Team PetKaz$_{\text{STA_mono:12}}$ (Petukhova et al., 2024) uses a PLM, RoBERTa-base, fine-tuned for synthetic text detection and enhances it with linguistic features, to train a feed-forward binary classifier (human or synthetic). Their final model uses diverse features and notably, they undersample the human data.

Team HU$_{\text{STA_mono:17}}$ (Roy Dipta and Shahriar, 2024) Adopts an architecture trained with a contrastive learning approach based on fine-tuning *sentence-transformers/all-mpnet-base-v2*. The model is trained on an augmented dataset obtained by paraphrasing sentences in the training set.

Team TrustAI$_{\text{STA_mono:20}}$ (Urlana et al., 2024) tries two approaches: (a) an ensemble approach with the combination of Multinomial Naive Bayes, LGBM Classifier (lightGBM classifier) and SGD classifier. Each is trained on the concatenation of tf-idf and spaCy embeddings obtained from the Subtask A – Monolingual dataset and (b) a synthetic text classifier based on RoBERTa fine-tuned first with the outputs of the 1.5B-parameter GPT-2 model and subsequently on the Subtask A – monolingual dataset. They show that exploring methodologies with different assumptions helps identify the best performing approach.

Team RFBES$_{\text{STA_mono:23}}$ (Heydari Rad et al., 2024) Both semantic and syntactic considerations were taken into account. For semantic analysis, emphasis was placed on smaller text segments rather than the entire document, operating under the belief that AI models could produce similarly coherent long texts as humans. To achieve this, the XLM-RoBERTa model was employed. Regarding syntactic analysis, a stacked bidirectional LSTM model was used to categorize texts based on their grammatical patterns using UPOS tags. Interestingly, no significant differences in UPOS tag distribution between AI-generated and human-written texts were revealed by the findings.

Team L3i++$_{\text{STA\_mono:24}}$ (Tran et al., 2024) Proposes a comparative study among 3 groups of methods to detect synthetic texts: 5 likelihood-based methods; 2 fine-tuned sequence-labeling language models (RoBERTa, XLM-RoBERTa); and a fine-tuned large language model, llama-2-7b. LLaMA 2 outperforms the rest and accurately detects machine-generated texts.

Team art-nat-HHU$_{\text{STA_mono:25}}$ (Ciccarelli et al., 2024) fine-tunes a RoBERTa model pre-trained for AI-detection and combines it with a set of linguistic features: syntactic, lexical, probabilistic and stylistic. To improve the classifier, they train two separate neural networks on these features, one for each class predicted by the RoBERTa-based classifier.

Team Unibuc - NLP$_{\text{STA_mono:28}}$ (Marchitan et al., 2024) fine-tunes a Transformer-based model with a MLP as a classification head. They combine the datasets of Subtask A – monolingual and Subtask B to obtain a larger training set.

NewbieML$_{\text{STA_mono:30}}$ (Tran and Tran, 2024) embeds texts with Longformer-large. Then they Ensemble SVM, LogisticRegression and XGBoost with, as a meta model, a KNN.

Team QUST$_{\text{STA_mono:31}}$ (Xu et al., 2024) experiments with multiple models on a dataset extended through data augmentation. They select the two best-performing models for ensembling: (1) a fine-tuned RoBERTa model, combined with the Multiscale Positive-Unlabeled (MPU) training and (2) a DeBERTa model. They use these two for model fusion through stacking ensemble.

Team NootNoot$_{\text{STA_mono:39}}$ (Bahad et al., 2024) carefully fine-tunes a RoBERTa-base model to classify human written and synthetic texts.

Team Mast Kalandar$_{\text{STA_mono:40}}$ (Bafna et al., 2024) trains a classifier that uses a frozen RoBERTa model with an LSTM head to classify human vs machine written texts.

Team I2C-Huelva$_{\text{STA_mono:41}}$ (rodero et al., 2024) proposes a method to use multimodal models together with text analysis to enhance synthetic text detection. To mix the two approaches they explore ensemble by testing several voting methods.

Team Werkzeug$_{\text{STA_mono:45}}$ (Wu et al., 2024) uses Roberta-large and XLM-roberta-large to encode texts. To address the anitostropic embedding space created by transformer-based language models, they employ several learnable parametric whitening (PW) transformation. They show that addressing the anisotropicity of the embedding space improves accuracy in detecting synthetic text.

Team NCL-UoR$_{\text{STA_mono:50}}$ (Xiong et al., 2024) fine-tunes several PLMs including XLM-RoBERTa, RoBERTa with Low-Rank Adaptation (LoRA) and DistilmBERT. Finally, they use majority voting ensembling with XLM-RoBERTa and LoRA-RoBERTa. To confirm that ensembling is a strong technique to boost synthetic text classification accuracy.

Team Sharif-MGTD$_{\text{STA_mono:51}}$ (Ebrahimi et al., 2024) carefully fine-tunes RoBERTa-base for synthetic text detection, show that pre-trained language models are a versatile approach.

Team BadRock$_{\text{STA_mono:*}}$ (Siino, 2024) is based on a fine-tuning of a DistilBERT trained on the SST-2 dataset.

Team Collectivized Semantics$_{\text{STA_mono:62}}$ (Datta et al., 2024) fine-tunes Roberta-base using Ada-LoRa and uses the weighted sum of all the layer hidden states' mean as features to train a classifier. They show that exploiting the knowledge at all layers of encoder language models helps when detecting synthetic texts.

Team IUCL$_{\text{STA_mono:63}}$ (Pulipaka et al., 2024) tries both classical ML classifiers, Naive Bayes and Decision Trees as well as fine-tuning transformers and they conclude that fine-tuned RoBERTa is best among the methods they try.

Team SINAI$_{\text{STA_mono:67}}$ (Gutiérrez Megías et al., 2024) compares three methods: (a) supervised classification, based on fine-tuning the XLM-RoBERTa-Large language model; (b) likelihood-based methods, using GPT-2 to compute the perplexity of each text and use this perplexity as a score; (c) a hybrid approach that merges text with its perplexity value into a classification head. The choice of a mixed approach proves effective in improving synthetic text detection accuracy.

Team MasonTigers$_{\text{STA_mono:71}}$ (Puspo et al., 2024) experiments with different transformer-based models: Roberta, DistilBERT, ELECTRA and ensembles these models. They also experiment with zero-shot prompting and finetuning FlanT5. Further confirming that ensembling is a strong methodology for detecting synthetic texts.

Team AT$_{\text{STA_mono:72}}$ (Wei, 2024) adopts three different semantic embedding algorithms, GLOVE, n-gram embeddings and SentenceBERT as well as their concatenation. The author finds that these pre-trained embeddings, while fast to compute, are not as effective as a fine-tuned RoBERTa model.

Team DUTh$_{\text{STA_mono:73}}$ (Kyriakou et al., 2024) experiments with several supervised classification models based on PLMs. Finally, they opt for a fine-tuned mBERT trained for 5 epochs. This approach shows how PLMs fine-tuning is a versatile approach that can be effective when detecting synthetic texts.

Team surbhi$_{\text{STA_mono:74}}$ (Sharma and Mansuri, 2024) creates two sets of features (a) stylometric features based on the length of text, the number of words, the average length of words, the number of short words, the proportion of digits and capital letters, individual letters and digits frequencies, hapax-legomena, a measure of text richness, and the frequency of 12 punctuation marks and (b) n-grams: frequencies of the 100 most frequent character-level bi-grams and tri-grams; (c) the output probabilities of fine-tuned Roberta model. Each set of features is used to train a classifier and finally, stylometric and n-gram features are chosen as the best-performing ones. They prove that more classical features can still be valuable when attempting the detection of synthetic text.

Team Kathlalu$_{\text{STA_mono:76}}$ (Cao et al., 2024) investigates two methods for constructing a binary classifier to distinguish between human-generated and machine-generated text. The main emphasis is on a straightforward approach based on Zipf's law, which, despite its simplicity, achieves a moderate level of performance. Additionally, they briefly discuss experimentation with the utilization of unigram word counts.

Team KInIT$_{\text{STA_mono:77}}$ (Spiegel and Macko, 2024) uses two approaches: (a) an ensemble using two-step majority voting for predictions, consisting of 2 LLMs (Falcon-7B and Mistral-7B) fine-tuned using the train set only; (b) 3 zero-shot statistical methods (Entropy, Rank, Binoculars) using Falcon-7B and Falcon-7B-Instruct for calculating the metrics. For classification they use per-language threshold calibration, showing that likelihood-based methods are a viable solution to detect machine-written texts.

Team iimasNLP$_{\text{STA_mono:78}}$ (Valdez et al., 2024) fine-tune 4 different language models to identify human and machine generated text, ERNIE, SpanBERT, ConvBERT and XLNet. They find out that RoBERTa is a stronger classifier. In general this shows how fine-tuning PLMs is an effective approach to identify synthetic text.

Team Groningen-F$_{\text{STA_mono:86}}$ (Donker et al., 2024) leverage features including tense of the sentence, the voice of the sentence, the sentiment of the sentence, and the number of pronouns vs. proper nouns on the basis of SVM and FFNN models. The hypothesis here is that traditional models may generalize better than LLMs. It is more computationally effective than LLMs.

Team RUG-D$_{\text{STA_mono:100}}$ (Brekhof et al., 2024) fine-tunes different DeBERTa models on a dataset extended with additional synthetic samples. Showing that PLMs fine-tuning is a versatile approach that can be effective in the detection of synthetic texts.

Team RUG-5$_{\text{STA_mono:101}}$ (Darwinkel et al., 2024) fine-tunes different pre-trained models for synthetic text classification, distilbert-base-cased for the monolingual tasks and distilbert-base-multilingual-cased for the multilingual ones. Moreover, they explore the use of a Random Forest classifier using frozen distilbert-base-cased embeddings concatenated with 20 linguistic and stylistic features. This approach shows how choosing the right PLMs is crucial for better performance in a given task.

Team Mashee$_{\text{STA_mono:115}}$ (Rasheed and Zarkoosh, 2024) selects high-quality and low-quality samples using a Chi-square test and adopts the selected samples for few-shot classification using the FlanT5-Large language model. This approach shows how few-shot methodologies can benefit from a careful example selection.

Team TueCICL$_{\text{STA_mono:116}}$ (Stuhlinger and Winkler, 2024) uses a Charachter-level LSTM with pre-trained word2vec embeddings as input to train synthetic text detector. Doing so, they show how one does not necessarily have to use transformers.

Team RUG-1$_{\text{STA_mono:117}}$ (Alecakir et al., 2024) combines a linear model with document-level features and token-level features that are first passed through an LSTM. Through this methodology, they leverage both local (token-level) and global (document-level) information to identify human-written and synthetic texts.

Team CUNLP$_{\text{STA_mono:unknown}}$ [1] (Aggarwal and Sachdeva, 2024) involved employing a range of machine learning techniques, including logistic regression, transformer models, attention mechanisms, and unsupervised learning methods. Through rigorous experimentation, they identified key features influencing classification accuracy, namely text length, vocabulary richness, and coherence. Notably, the highest classification accuracy was achieved by integrating transformer models with TF-IDF representation and feature engineering. However, it is essential to note that this approach demanded substantial computational resources due to the complexity of transformer models and the incorporation of TF-IDF. Additionally, their investigation encompassed a thorough exploration of various ML algorithms, extensive hyperparameter tuning, and optimization techniques. Furthermore, they conducted detailed exploratory data analysis to gain insights into the structural and lexical characteristics of the text data.

A.2 Multilingual Human vs Machine

Team USTC-BUPT$_{\text{STA_Multi:1}}$ (Guo et al., 2024) secured the top position. They initially detect the language of the input text. For English text, they average embeddings from Llama-2-70B, followed by classification through a two-stage CNN. For texts in other languages, the classification problem is transformed into fine-tuning a next-token prediction task using the mT5 model, incorporating special tokens for classification. Their approach integrates both monolingual and multilingual strategies, exploiting large language models for direct embedding extraction and model fine-tuning. This enables the system to adeptly handle text classification across a diverse range of languages, especially those with fewer resources.

Team FI Group$_{\text{STA_Multi:2}}$ (Ben-Fares et al., 2024) came in second place. Their methodology began with analyzing latent space distinctions between human and AI-generated texts using Sentence-BERT, hypothesizing that syntax and writing style differences are key. They utilized a hierarchical fusion strategy to adaptively fuse representations from different BERT layers, focusing on syntax over semantics. By classifying each token as Human or AI, their model captures detailed text structures, leveraging the XLM-RoBERTa-Large model for robust multilingual performance.

Team KInIT$_{\text{STA_Multi:3}}$ (Spiegel and Macko, 2024) placed third by employing an ensemble of two fine-tuned LLMs (Falcon-7B and Mistral-7B) and three zero-shot statistical methods, using a two-step majority voting system. This unique combination of fine-tuned and statistical methods, complemented by language identification and per-language threshold calibration, showcases their innovative approach to integrating diverse techniques for enhanced classification accuracy.

Team L3i++$_{\text{STA\_Multi:5}}$ (Tran et al., 2024) explored a comparative study among metric-based models, fine-tuned sequence-labeling language models, and a large-scale LLM, finding LLaMA-2 to outperform others in detecting machine-generated texts. Their methodological diversity and comprehensive analysis underline the strengths of fine-tuning LLMs for complex classification tasks across languages.

Team QUST$_{\text{STA_Multi:6}}$ (Xu et al., 2024) employed a fine-tuned XLM-RoBERTa model within a stacking ensemble framework, incorporating the MPU framework and DeBERTa model. Their approach emphasizes the efficacy of model fusion and fine-tuning on a multilingual dataset, highlighting the potential of ensemble strategies in enhancing model performance.

Team AIpom$_{\text{STA_Multi:9}}$ (Shirnin et al., 2024) utilized a LoRA-Finetuned LLM for classifying texts as real or fake, achieving notable results with a limited dataset. Their unique approach of using an LLM as a classifier, despite an accidental label swap during training, emphasizes the versatility and potential of LLMs in unconventional scenarios.

Team RFBES$_{\text{STA_Multi:10}}$ (Heydari Rad et al., 2024) Both semantic and syntactic considerations were taken into account. For semantic analysis, emphasis was placed on smaller text segments rather than the

[1] Team CUNLP submitted results for development set, but no submissions for the test set, resulting unknown valid rank.

entire document, operating under the belief that AI models could produce similarly coherent long texts as humans. To achieve this, the XLM-RoBERTa model was employed. Regarding syntactic analysis, a stacked bidirectional LSTM model was used to categorize texts based on their grammatical patterns using UPOS tags. Interestingly, no significant differences in UPOS tag distribution between AI-generated and human-written texts were revealed by the findings.

Team SINAI$_{\text{STA_Multi:21}}$ (Gutiérrez Megías et al., 2024) compared various systems before settling on a fusion model that integrates text with perplexity values for classification. Their comprehensive approach, blending fine-tuning with innovative use of perplexity, offers insightful perspectives on leveraging multiple data dimensions for classification.

Team Unibuc-NLP$_{\text{STA_Multi:22}}$ (Marchitan et al., 2024) focused on exploring different methods of layer selection and fine-tuning within a transformer-based architecture. Their pursuit of optimizing layer interactions for classification tasks highlights the importance of fine-tuning strategies in achieving model effectiveness.

Team Werkzeug$_{\text{STA_Multi:30}}$ (Wu et al., 2024) applied parametric whitening transformations under a mixture-of-experts architecture to address text embedding anisotropy issues. Their methodological innovation, aimed at capturing a broader range of language styles, underscores the potential of advanced architectures in improving classification accuracy.

Team RUG-5$_{\text{STA_Multi:32}}$ (Darwinkel et al., 2024) augmented DistilBERT with an additional layer for classification, exploring linguistic-stylistic features alongside Random Forest classifiers. Their approach of blending traditional ML techniques with PLMs offers a novel perspective on enhancing text classification through feature integration.

Team DUTh$_{\text{STA_Multi:33}}$ (Kyriakou et al., 2024) compared machine learning algorithms and LLMs, ultimately selecting a fine-tuned XLM-RoBERTa model. Their comparative analysis provides valuable insights into the effectiveness of different methodologies for text classification tasks.

Team RUG-D$_{\text{STA_Multi:39}}$ (Brekhof et al., 2024) used an ensemble of monolingual and multilingual models, testing the performance impact of additional training data. Their ensemble approach and data augmentation strategy highlight the importance of model and data selection in optimizing classification performance.

Team MasonTigers$_{\text{STA_Multi:49}}$ (Puspo et al., 2024) experimented with different transformer models and finetuning strategies, showcasing the effectiveness of ensembling and fine-tuning in addressing classification challenges.

Team TrustAI$_{\text{STA_Multi:55}}$ (Urlana et al., 2024) focused on fine-tuning the bert-base-multilingual-cased model, demonstrating the potential of pre-trained models in multilingual text classification tasks.

A.3 Multi-way Detection

Team AISPACE$_{\text{STB:1}}$ (Gu and Meng, 2024) achieves the highest performance in this subtask by fine-tuning various encoder and encoder-decoder models, including RoBERTa, DeBERTa, XLNet, Longformer, and T5. They augment the data with instances from Subtask A and explore the effects of different loss functions and learning rate values. Based on this analysis, they leverage a weighted Cross-Entropy loss to balance samples in different classes. Furthermore, they use an ensemble of different fine-tuned models to improve the robustness of the system. The weights of the models in the ensemble are assigned based on their performance on each class rather than their performance on the whole accuracy.

Team Unibuc - NLP$_{\text{STB:2}}$ (Marchitan et al., 2024) use a Transformer-based model with a peculiar two-layer feed-forward network as a classification head. They also augment the data with instances from Subtask A monolingual dataset.

Team USTC-BUPT$_{\text{STB:3}}$ (Guo et al., 2024) first leverage the 'Llama-2-70B' model to obtain embeddings of the tokens in the text and then average them across all tokens. Next, they employ a three-stage classification approach using the CNN classifier.

Firstly, they distinguish between human-generated and machine-generated text using the Llama-2-70B model. Secondly, they categorize ChatGPT and Cohere as a single class for a four-class classification, differentiating them from Davinci, Bloomz, and Dolly. Finally, they perform a binary classification

between ChatGPT and Cohere. Despite solid performance, their method does not require fine-tuning.

Team L3i++$_{\text{STB:6}}$ (Tran et al., 2024) conduct a comparative study among three groups of methods: metric-based models, fine-tuned classification language models (RoBERTa, XLM-R), and a fine-tuned LLM, LLaMA-2-7b. They find LLaMA-2 outperforming the methods from the other groups in MGT detection. The team reveals the analysis of errors and various factors in their paper.

Team MLab$_{\text{STB:7}}$ (Li et al., 2024) fine-tune DeBERTa and analyze the embeddings from the last layer. They provide insights into the embedding space of the model.

Team Werkzeug$_{\text{STB:8}}$ (Wu et al., 2024) utilizes RoBERTa-large and XLM-RoBERTa-large to encode the text. They tackle the problem of anisotropy in text embeddings produced by pre-trained language models (PLMs) by introducing a learnable parametric whitening (PW) transformation. Furthermore, to capture the features of LLM-generated text from different perspectives, they use multiple PW transformation layers as experts under the mixture-of-experts (MoE) architecture equipped with a gating router in their final solution.

Team TrustAI$_{\text{STB:14}}$ (Urlana et al., 2024) explore different pretrained and statistical models for detecting synthetic text, ultimately selecting the RoBERTa-base OpenAI Detector for its effectiveness. This model, originally fine-tuned with outputs from the 1.5B-parameter GPT-2 model, is further fine-tuned on the Subtask-B dataset.

Team MGTD4ADL$_{\text{STB:17}}$ (Chen et al., 2024) combine traditional Transformer models (RoBERTa-base, RoBERTa-large, GPT-2-small, XLNet, T5-small) with Sentence Transformers(all-mpnet-base-v2 and all-roberta-large-v1). They further diversify their approach by leveraging different data augmentation techniques and experimenting with various loss functions such as Cross-Entropy (CE), Supervised Contrastive Learning (SCL), and Dual Contrastive Loss (DUALCL).

Team scalar$_{\text{STB:18}}$ (M et al., 2024) employ an ensemble of three RoBERTa-base models using an individual validation set for each model.

Team UMUTeam$_{23}$ (pan et al., 2024) use fine-tuned RoBERTa model combined with syntactic features of the text such as word length, part of speech, function word frequency, stop-word ratio, and sentence length.

Team QUST$_{\text{STB:36}}$ (Xu et al., 2024) use fine-tuned RoBERTa and DeBERTa models, integrating them through a stacking ensemble technique.

Team MasonTigers$_{\text{STB:38}}$ (Puspo et al., 2024) implement an ensemble of 3 PLMs: RoBERTa, DeBERTa, and ELECTRA. Additionally, they employ zero-shot prompting and use a fine-tuned FLAN-T5 model.

Team RUG-5$_{\text{STB:41}}$ (Darwinkel et al., 2024) expands the architecture of DistilBERT models by adding an additional classification layer that incorporates 20 linguistic-stylistic features. They also explore the use of Random Forest classifier on top of embeddings from DistilBERT combined with the same set of linguistic-stylistic features.

Team RUG-D$_{\text{STB:44}}$ (Brekhof et al., 2024) focus on fine-tuning DeBERTa models.

Team Groningen-F$_{\text{STB:45}}$ (Donker et al., 2024) trained traditional machine learning models (SVM and FFNN) with features including tense of the sentence, the voice of the sentence, the sentiment of the sentence, and the number of pronouns vs. proper nouns.

Team DUTh$_{\text{STB:49}}$ (Kyriakou et al., 2024) explore traditional machine learning algorithms along with BERT for their task. Ultimately, they proceed with BERT fine-tuned for 5 epochs.

Team AT$_{\text{STB:58}}$ (Wei, 2024) adopts three different semantic embedding algorithms, GLOVE, n-gram embeddings and SentenceBERT as well as their concatenation to identify the generator in Subtask B. The author finds that these pre-trained embeddings, while fast to compute, are not as effective as a fine-tuned RoBERTa model.

Team iimasNLP$_{\text{STB:61}}$ (Valdez et al., 2024) fine-tune 4 different language models to classify text generated by different models: ERNIE, SpanBERT, ConvBERT and XLNet. They find out that RoBERTa is a stronger classifier. In general this shows how fine-tuning PLMs is an effective approach to identify the generator model.

Team CLULab-UofA$_{\text{STB:62}}$ (Rezaei et al., 2024) combine LLM fine-tuning with contrastive learning, specifically using triplet loss.

A.4 Boundary Identification

Team TM-TREK$_{\text{STC:1}}$ (Qu and Meng, 2024) achieved the highest performance in Subtask C by employing an ensemble of models including Longformer, Bigbird, and XLNet for long-text sequence labeling. A simple voting mechanism was used to aggregate the output logits. Their innovative strategy also involved integrating LSTM and CRF layers atop various pre-trained language models (PLMs), along with continuous pretraining, fine-tuning, and utilizing dice loss functions to enhance model performance.

Team AIpom$_{\text{STC:2}}$ (Shirnin et al., 2024) introduced a two-stage pipeline that combines outputs from an instruction-tuned, decoder-only model (Mistral-7B-OpenOrca) with two encoder-only sequence taggers. Initially, they trained an instruction-tuned autoregressive model to insert a [BREAK] token into input texts, delineating human-written parts from machine-generated ones. Subsequently, these annotated texts were processed by an encoder-based model for sequence tagging, differentiating human-written tokens (0) from machine-generated tokens (1). An additional encoder trained on a blend of raw and annotated texts further refined sequence tagging. The average change point positions predicted by both encoders served as the final boundary estimation.

Team USTC-BUPT$_{\text{STC:3}}$ (Guo et al., 2024) approached the task as a token classification challenge, opting to fine-tune a DeBERTa model enhanced by data augmentation techniques derived from the training set. They reported that DeBERTa-base outperformed other models, and explored the efficacy of sequence labeling (e.g., BIOS) in detecting boundaries within mixed texts. The potential of various layers, including CRF and Dropout, was also examined for their impact on system performance.

Team RKadiyala$_{\text{STC:6}}$ (Kadiyala, 2024) focused on fine-tuning various encoder-based models appended with a Conditional Random Field (CRF) layer, noting that Deberta-V3 yielded the best results on the development set.

Team DeepPavlov$_{\text{STC:7}}$ (Voznyuk and Konovalov, 2024) fine-tuned the Deberta-v3 model using a specially prepared dataset with augmented texts, created by modifying prefixes and suffixes of original texts. They emphasized the importance of augmented data quality in achieving a mean absolute error (MAE) of 15.20903.

Team RUG-5$_{\text{STC:17}}$ (Darwinkel et al., 2024) utilized an augmented Longformer model, incorporating extra features into the output state of each token to enrich them with contextual information. This approach aimed at improving token-level classification by leveraging linguistic-stylistic features beyond simple PLM optimization.

Team TueCICL$_{\text{STC:22}}$ (Stuhlinger and Winkler, 2024) experimented with character-level LSTMs and LSTMs using pretrained Word2Vec embeddings, demonstrating that smaller models could compete with transformer models in the boundary detection task.

Team jelarson$_{\text{STC:25}}$ (Larson and Tyers, 2024) explored rule-based methods and linear regression techniques, identifying specific patterns in the training data that could inform better data collection practices, such as ensuring a more randomized and unbiased dataset.

Team TueSents$_{\text{STC:26}}$ (Pickard and Do, 2024) extracted textual features at the sentence level using tools like SpaCy and trained a lightweight BiLSTM model for boundary prediction, achieving an accuracy of 0.7 and MAE of less than 0.5 on the development set.

Team MasonTigers$_{\text{STC:27}}$ (Puspo et al., 2024) combined TF-IDF, PPMI, and RoBERTa features with linear regression and Elastic Net, culminating in an ensemble approach based on a weighted development set.

Team Unibuc-NLP$_{\text{STC:28}}$ (Marchitan et al., 2024) framed the task as a token classification problem, merging character-level features (extracted via CNN) and word embeddings within a BiLSTM model, further exploring the addition of CRF for enhanced performance.
