We developed a classifier model capable of discerning prompts based on their respective dataset classes: QP, QQA, and QNLI. This classifier model serves to categorize prompts and subsequently directs them to the corresponding model tailored to handle the specific prompt class. This streamlined approach obviates the necessity for segregating the datasets, enhancing overall

efficiency and coherence in the evaluation process.This structure is shown in Figure 1.

We employed a two-step fine-tuning process. Initially, the Orca2 model underwent fine-tuning on the QP dataset. Subsequently, we further fine-tuned the model using the QNLI dataset. The sequential fine-tuning approach allowed the model to adapt to the nuances of each dataset progressively.

We use the Orca2 model as an agent to assign each task to the specific agent. To achieve this task, we used a part of the available datasets to train our agent and achieved 99.4% accuracy in assigning tasks. As a result, we reached 96.13% accuracy on QP dataset, 100% accuracy on QQA and 98.85% accuracy on QNLI.

5 Analysis

Our analysis has illuminated the intricate nature of numeral-aware language tasks, emphasizing the imperative for ongoing scrutiny and enhancement of model architectures and training methods. The insights derived from our investigation notably elucidate the performance and adaptability of the Orca2 model within the NumEval task domain.

Upon reflection, we determined that optimizing the generality of the structure entails employing expert agents for individual sub-tasks, facilitated by a supervisory agent to assign tasks effectively. This strategic adjustment yielded heightened accuracy across all sub-tasks, marking a significant advancement in our approach.

6 Conclusion

In conclusion, our analysis highlights the intricate interplay between dataset characteristics, model architectures, and training methodologies in the NumEval task. While achieving significant advancements in numeral-aware language understanding and generation, our study underscores the importance of comprehensive evaluations encompassing both quantitative metrics and qualitative assessments to unravel the complexities of numerical reasoning in natural language understanding tasks. Moving forward, further research into adaptive learning strategies and nuanced dataset annotations promises to enrich our understanding and advancement in numeral-aware language processing tasks.

A Example Appendix

A.0.1 More about data set:

In each dataset there is a column called statement-char and statement-sci-10e. statement-char has spaced between the numbers inside the text and statement-sci-10e has written the numbers inside the text in scientific form (Chen et al., 2023b).

A.0.2 Additional Experiments:

We explored the integration of human-reasoning into the AWPNLI dataset by generating human-reasoning for 190 samples using ChatGPT.

Contrary to expectations, the inclusion of human-reasoning did not yield the anticipated accuracy improvements, highlighting the complexity of the task and potential limitations of our approach.

DUTh at SemEval-2024 Task 6: Comparing Pre-trained Models on Sentence Similarity Evaluation for Detecting of Hallucinations and Related Observable Overgeneration Mistakes

Abstract

In this paper, we present our approach to SemEval-2024 Task 6: SHROOM, a Shared-task on Hallucinations and Related Observable Overgeneration Mistakes, which aims to determine weather AI generated text is semantically correct or incorrect. This work is a comparative study of Large Language Models (LLMs) in the context of the task, shedding light on their effectiveness and nuances. We present a system that leverages pre-trained LLMs, such as LaBSE, T5, and DistilUSE, for binary classification of given sentences into 'Hallucination' or 'Not Hallucination' classes by evaluating the model's output against the reference correct text. Moreover, beyond utilizing labeled datasets, our methodology integrates synthetic label creation in unlabeled datasets, followed by the prediction of test labels.

1 Introduction

Hallucinations in machine generated text are cases when the model generates output that is partially or fully unrelated to the source sentence. While being a non-frequent phenomenon, it can dramatically impact the user experience and the trust toward the system. Hallucination rates in multiple models vary from 2.8 to 16.2 percent, according to the hallucination leaderboard created by Vectara hosted on HF and GitHub. [1] While the problem of hallucinations is known, it remains challenging, and one aspect of that is the absence of proper datasets. As a result, previous studies relied on scenarios where models are encouraged to hallucinate (Lee et al., 2018; Raunak et al., 2021; Müller et al., 2019; Voita et al., 2020; Zhou et al., 2020). However, it is uncertain if these approaches are effective in more natural, undisturbed environments (Guerreiro et al., 2022).

Recent research conducted in relatively clean settings (Guerreiro et al., 2022) demonstrates that existing hallucinations detection methods fall short. The authors create a natural setting dataset, annotate it for various NMT (Neural Machine Translation) pathologies, and evaluate detection methods. They find most existing detection methods inadequate, with sequence log-probability performing best. Although they demonstrated interesting results, they were limited on detecting hallucinations on Machine Translation (MT) generated text.

SemEval-2024 task 6 (Mickus et al., 2024) goes a step further by providing a human annotated dataset of hallucinated text regarding three different scenarios. Along with Machine Translation (MT), also Definition Modeling (DM) and Paraphrase Generation (PG) cases are considered. This paper describes the system developed by the DUTh team for SemEval-2024 task 6. Our strategy is based on utilizing embeddings to evaluate the similarity between context and hypothesis sentences in order to detect hallucinated text. In our case context sentence is the 'gold' output expected from to the models for generation and hypothesis sentence is the actual model production. For generating the embeddings of the context and hypothesis we are utilizing a pretrained T5 tokenizer (Raffel et al., 2020). Then we measure their similarity by taking the dot product of their corresponding embeddings, followed by summation along axis 1. Finally, using that similarity score, we train an ensembler machine learning model to distinguish hallucinated form non-hallucinated text. We provide our code publicly [2]

2 Background

2.1 Related work

Methods for identifying hallucinations are primarily concentrated on the Machine Translation task and they generally aim to find translations of poor quality that may also satisfy additional constraints. To effectively pinpoint factual inaccuracies in LLM

[1] https://huggingface.co/spaces/vectara/leaderboard

[2] https://github.com/DataMas/ai-hallutinations-detection

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1064–1070

outputs, one straightforward strategy involves comparing the model generated output information from an external knowledge source. Relevant research, starting from traditional fact checking (Augenstein et al., 2019) tries to expand the capabilities of such systems by incorporating various web sources (Chen et al., 2023) and evaluating their truthfulness (Galitsky, 2023). Recently, there is a significant emphasis on enhancing the process of retrieving information from external sources. FACTSCORE introduced by (Min et al., 2023), is a metric specifically for long-text generation. The LLM output is decomposed into atomic facts and each one is validated by reliable external knowledge sources. Furthermore, (Huo et al., 2023), enhanced the retrieving process by augmenting the query to the external sources with the input to and the output of the LLM.

When utilizing external sources, previous research mostly focused on evaluating models output based on a pool of third party knowledge. However, implementation of such systems could be complicated. Similarity between the source and the target estimated via embeddings, has been proved to be a good indicator for hallucinations in Machine Translation scenarios (Dale et al., 2022). In this manner, we are experimenting with this strategy on detecting hallucinations on machine generated text regarding Definition Modeling and Paraphrase Generation. We hypothesize that hallucinations can have a great impact on the conceptual content of the generated text, enough to be detected through sentence similarity evaluation.

2.2 Dataset

The task provided three datasets for each track: the train and test sets comprised unlabeled datapoints, and the validation set contained labeled datapoints enriched with additional features. Each datapoint in the labeled set encompasses the following attributes. The 'model' attribute is included only in the model-aware datasets and the items without bold annotation are not featured in the test datasets.

- **"id":** The datapoint's ID
- **"task":** The model's optimization objective (DM, PG, MT).
- **"model":** The model used for text generation.
- **"tgt":** The intended reference text for model generation.
- **"src":** The input presented to the models for generation.
- **"hyp":** The actual model output.
- **"ref":** Indicates whether the 'tgt' or 'src' fields, or both, are the context that contains the requisite semantic information to discern the datapoint as a hallucination.
- "labels": A set of per-annotator labels gauging whether each annotator perceives the datapoint as a hallucination.
- "label": The majority-based gold-label derived from the per-annotator labels.
- "p(Hallucination)": The probability assigned to the datapoint being a hallucination based on the proportion of annotators considering it as such.

In the model-aware segment, we dived deeper into our data by visually representing (Figure 1) the distribution of three distinct models across data points. In both the validation and test sets, two of the three models exhibit an equal distribution, while the third one, tuner007/pegasus_paraphrase, is utilized less, accounting for roughly 33 percent. The training set shows an equal distribution of all three models.

3 System Overview

3.1 Hallucination Detection

Hallucination detection methods are a developing field in modern NLP. Given input information and parameters can vary and subsequently the methods applied for detection are subject to change. SemEval-2024 Task 6: SHROOM - a Shared-task on Hallucinations and Related Observable Overgeneration Mistakes was divided into two tracks. The first sub-task, Model-Aware, involves determining whether the model produced a hallucination, given information about which model was employed. The second sub-task, Model-Agnostic, pertains to scenarios where the model used is unknown.

3.2 System

We approached the task as a binary text classification problem, implementing our system leveraging the HuggingFace Transformer library. Concisely, our methodology aligns with the conventional approach to addressing text classification problems — training a model with a large labeled dataset and employing it to predict labels for the test set. We first opted for the labeled dataset provided by (Guerreiro et al., 2022) for the training process. Then

we tried the unlabeled training dataset supplied by the task organizers, conducting experiments to automatically generate synthetic labels for its utilization into the training process.

In summary, our system comprised distinct steps, including extraction of embeddings for 'hyp' and 'context', calculation of cosine similarity between the two, generation of synthetic labels for the training set through clustering, and prediction of the test set using ensembled classifiers.

3.2.1 Sentence Embeddings

Sentence embeddings are a potent technique utilizing deep learning models, specifically transformers, to encode words, or in our context, sentences, into vectors. These vectors capture the semantic meaning and contextual information of the input text. This encoding is valuable as vectors provide a robust representation of the semantic content embedded in sentences and are more efficiently compared or handled in any way for various NLP tasks. Our approach employed pre-trained sentence transformers sourced from the HuggingFace library (v. 2.2.2) for extracting these embeddings. From our dataset, the hypothesis ('hyp') was compared to the context sentence provided by the semantic reference ('ref'). The cosine similarity between the vectors resulting from this comparison, along with a probability measure of hallucination, was subsequently incorporated into our system. Formally, the similarity score, denoted as sims, is calculated as

$$\text{sims} = \sum_{i=1}^{n} (\text{emb\_con}_i \cdot \text{emb\_hyp}_i)$$

where emb_con_i and emb_hyp_i represent the embeddings for the i-th context and hypothesis, respectively. In this numerical measure of similarity, higher values indicate greater similarity between the encoded representations of hypotheses and contexts. The probability is computed as $1 - \text{sims}$ and is subsequently appended to the dataset.

3.2.2 Synthetic Labels Creation

Cluster analysis is a technique used in data mining and machine learning to group similar objects into clusters. k-means clustering is a popular unsupervised machine learning algorithm with vector inputs that allocates every data point to the nearest cluster. Synthetic data creation has become a widely adopted methodology within the NLP field, notably used for the purpose of label generation (Zhou et al., 2020). In our pursuit of generating synthetic labels for the unlabeled dataset, we employed the k-means algorithm with $k = 2$, signifying two centroids, to extract 'Hallucination' and 'Not Hallucination' labels. The parameters provided for clustering were the cosine similarity and the probability derived from sentence embeddings within the model-agnostic sub-task. Additionally, for the model-aware subtask, we incorporated the one-hot encoded representation of the utilized model as an additional parameter. We additionally tested the efficacy of our label extraction mechanism on the provided labeled datasets, achieving a notable accuracy rate of 75 percent.

3.2.3 Label Prediction

Following the training phase, we engaged in an ensemble approach, combining several widely recognized classification algorithms to forecast the labels of the test set and identify instances of hallucination. In text classification, each data point is allocated a label, with binary classification typically involving two labels (e.g., 0 and 1). Model ensembling aims to utilize the collective strength of various classifiers to maximize overall performance. We employed the similarity extracted from the embeddings and integrated it as a feature alongside the probability in the training of our classifiers. In our ensembling, we incorporated the following classifiers: Logistic Regression, Random Forest, Gradient Boosting, K Nearest Neighbours, XGBoost and Decision Tree. By employing this methodology, we got labeled test sets as the final outputs.

3.3 Models

Central to our system are pre-trained models from the sentence transformers library of HuggingFace (v. 2.2.2). The models we distinguished were DistilUSE (Reimers and Gurevych, 2019), LaBSE (Feng et al., 2020) and T5 (Raffel et al., 2020). The 'distiluse-base-multilingual-cased-v2' model excels at mapping sentences to a 512-dimensional dense vector space, making it ideal for tasks like clustering and semantic search. With its multilingual capabilities and nuanced representation of case information, it proves valuable across various languages for applications requiring semantic understanding and similarity assessment. LaBSE, Language-agnostic BERT sentence embedding, supports 109 languages and adopts a dual-encoder approach based on pretrained transformers. It has been fine-tuned for translation ranking with an ad-

ditive margin softmax loss. T5, or Text-To-Text Transfer Transformer, is adept at mapping sentences to a 768-dimensional dense vector space. This model particularly excels in tasks related to sentence similarity. This selection of models, ranging from BERT to LaBSE and T5, offers a diverse toolkit for our system. These pre-trained models, with their distinct architectures and capabilities, contribute to the robustness and versatility of the implemented system across a spectrum of natural language processing tasks.

4 Experimental setup

4.1 Preprocessing

Prior to any NLP problem solving , performing text preprocessing is necessary. The nature of text preprocessing varies depending on the methodology to be employed, encompassing various steps. In the context of our binary classification problem utilizing the provided dataset, we conducted thorough feature extraction and preprocessing on the raw textual data. Specifically, we opted for the English language model available in SpaCy's trained pipelines (v. 3.7.2). This choice was particularly informed by the necessity to preprocess the 'hyp' and 'context' features, being aware that the context in the Machine Translation (MT) task was in English. Across all tasks, our text preprocessing included text lowercase conversion, punctuation removal, and lemmatization, where custom lemmas were incorporated. For the Definition Modeling task, we extracted the word to define from the context. In the model-aware track of the task, we introduced one-hot encoding representation of the model used for all datapoints. Similar techniques were used for the (Guerreiro et al., 2022) dataset adapting to the corresponding feature names.

4.2 Experiments

The conducted experiments incorporated the entirety of available datasets, the training, development, and test sets. Our initial experiment, as outlined in the system section, involved the utilization of the synthetically labeled train and test sets in conjunction with the DistilUSE, LaBSE, and T5 models. In the next experiment, we only utilized T5 and skipped the synthetic labeling phase from our methodology. In this iteration, the training process was conducted by utilizing the (Guerreiro et al., 2022) dataset. This adjustment was motivated by the labeled nature of this set, making it conducive to predicting labels for the test set in both tracks of the task.

4.3 Evaluation

The evaluation measures employed in both tracks of the task were consistent. The initial metric pertained to a general accuracy score, derived from the test reference data provided by the task organizers, applied to our binary classification results. Subsequently, the evaluation for the model-agnostic track extended to include the Spearman's correlation coefficient, a statistical measure of the strength of a monotonic relationship between the output probabilities of the systems and the proportion of annotators marking an item as overgenerating. The Spearman correlation assesses the degree to which the systems' output probabilities align with the consensus among annotators, offering a nuanced evaluation of the models' performance in capturing the observed trends in overgeneration perception. Both metrics have a maximum value of 1.

5 Results

The comprehensive scores of our system across the three utilized models are presented in Tables 1 and 2, for accuracy and correlation, respectively. The highest accuracy score was T5's 0.7553 in model-aware which ranked 25th out of 38 and 0.7440 in model-agnostic which ranked 27th out of 41 while both passed the baseline scores in accuracy and correlation. There was no difference in the dataset used for the training process. The baseline score was obtained through using an instruction-finetuned Mistral model tasked with classifying the sentences as contextual or not, answering with

Algorithm	Model-Agnostic		Model-Aware	
	Score 1	Score 2	Score 1	Score 2
Logistic Regression	0.6874	0.7066	0.7086	0.7160
Random Forest	0.6873	0.7420	0.7380	0.7347
Gradient Boosting Classifier	0.6874	0.7327	0.7067	0.7393
K Nearest Neighbours	0.6867	0.6740	0.7067	0.6687
Decision Tree	0.7067	0.7447	0.7367	0.7493
XGBoost	0.7067	0.6787	0.7407	0.6887
Ensembling	**0.7440**	0.7447	**0.7553**	0.7373

Table 3: Evaluation Metrics for Seven Machine Learning Algorithms. Score 1 is using synthetic labeled train set and score 2 is using the Guerreiro set.

a yes or no. The accuracy score it achieved was 0.697 in the model-agnostic track and 0.745 in the model-aware track. If ranked by correlation, T5 scores highest with a moderate correlation of 0.5285 for the aware track using the synthetically labeled dataset and 0.5224 in the agnostic track using the Guerreiro dataset, also surpassing the baseline system which scored 0.488 and 0.403 respectively. Consequently, after careful consideration, T5 was selected for integration into our final system. For the label prediction part we tried multiple Machine Learning classification algorithms which are shown in Table 3. In both tracks using the synthetic labeled dataset, distinctions, ranging from subtle in some cases to more pronounced in others, were observed among individual algorithms. However, the ensemble strategy consistently surpassed their individual performances, scoring 0.7440 in model-agnostic and 0.7553 in model-aware. When applying the Guerreiro dataset, Decision Tree outperformed the ensemble strategy in the model-aware track, consistently staying below 0.7553. However, this did not hold in the model-agnostic track, where both Decision Tree and the ensemble of all seven algorithms achieved a score of 0.7447, closely mirroring Score 1. Based on the previously mentioned outcomes, the score obtained through the ensemble of classifiers using the synthetically labeled set was ultimately submitted to the tasks leaderboard.

6 Conclusion

Through these experiments, we found that the pretrained T5 model exhibits optimal performance in the detection of hallucinated text in the domain of artificial intelligence. Furthermore, we successfully employed an ensemble of multiple popular top-tier classifiers to augment the predictive capabilities of our system and investigated the implications of synthetically labeling unlabeled data, presenting it as a novel approach to hallucination detection.

The next step could involve an extended comparison of various language models to identify the most powerful one, as well as exploring the option of training on diverse and larger datasets. Additionally, for further exploration, we recommend fine-tuning a Language Model (LLM) to extract enhanced embeddings, thereby improving the accuracy of sentence similarity assessments and consequently bolstering the overall system performance.

Abstract

The Semantic Textual Relatedness (STR) shared task aims at detecting the degree of semantic relatedness between pairs of sentences on low-resource languages from Afroasiatic, Indoeuropean, Austronesian, Dravidian, and Nigercongo families. We use the Sentence-CROBI architecture to tackle this problem. The model is adapted from its original purpose of paraphrase detection to explore its capacities in a related task with limited resources and in multilingual and monolingual settings. Our approach combines the vector representation of cross-encoders and bi-encoders and possesses high adaptable capacity by combining several pre-trained models. Our system obtained good results on the low-resource languages of the dataset using a multilingual fine-tuning approach.

1 Introduction

Task 1 of SemEval 2024 (Ousidhoum et al., 2024b) focuses on Semantic Textual Relatedness (STR). Given two sentences, the semantic relatedness between them is defined as the degree of closeness between their meanings (Mohammad and Hirst, 2012). However, the traits that make two sentences to be understood as related entities can be of different order, such as the underlying syntactic structure, lexical affinity, or the author's style, among others.

The task organisers have chosen for this track a set of languages, among which English and Spanish stand out, two languages with numerous computational resources. The rest, are low-resourced languages from Africa (Algerian Arabic, Moroccan Arabic, Amharic, Hausa, Kinyarwanda) and Asia (Marathi, Telegu).

Three tracks were proposed in the task: supervised, unsupervised and cross-lingual. We participated in Track A, supervised. This is a regression problem since a relatedness coefficient must be given that ranges from 0 to 1 for each pair of sentences. Our solution is based on using the sentence-CROBI model, introduced in Ortiz-Barajas et al. (2022), which was designed for paraphrase detection with very good results in English. Our hypothesis is that the same methods used in paraphrase detection can be applied to the determination of the degree of relatedness.

The structure of the paper is the following. In section 2, we describe the related work on this task using pre-trained language models. Section 3 briefly describes the dataset. In section 4, we present our methodology. Finally, we present our results in the development and evaluation phases in section 5 and conclusions in section 6.

2 Related Work

The Sentence-BERT model (Reimers and Gurevych, 2019) is an approach that generates semantically meaningful sentence embeddings. By training BERT on siamese and triplet network structures, this approach is able to capture sentence similarity more effectively. It also reduces computational overhead compared to BERT (Devlin et al., 2018) and RoBERTa (Liu et al., 2019) while maintaining high accuracy in tasks such as semantic textual similarity and transfer learning.

Following this research line, there is an approach to improve BERT-based semantic embeddings for similarity tasks (Li et al., 2020). The authors propose a flow-based calibration method by transforming the original BERT embeddings into an isotropic latent space using flow. The proposed method aligns better with gold semantic similarity and reduces the influence of lexical similarity.

In this work, we use the Sentence-CROBI model, a simple architecture that combines bi-encoders and cross-encoders that was originally proposed to solve paraphrase detection. Due to its implementation facility, we adapt this model for the semantic relatedness task by only changing the task-specify

block, the loss function and the pre-trained models for the cross-encoder and bi-encoder components.

3 Corpora

We briefly describe the corpora that we use to evaluate our model in the SemEval shared task 1 in this section.

The SemRel2024 dataset (Ousidhoum et al., 2024a) is a comprehensive collection of semantic textual relatedness datasets for 14 languages, predominantly spoken in Africa and Asia. These languages cover a wide range of language families and include both high-resource and low-resource languages. Each dataset consists of sentence pairs annotated by native speakers with relatedness scores ranging from 0 (completely unrelated) to 1 (maximally related). The datasets were curated by selecting pairs from various sources such as news data, Wikipedia, and conversational data to ensure diversity in topics and formality levels. The relatedness scores were generated through Best-Worst Scaling (BWS) annotations, enhancing the reliability of the rankings. Table 1 shows the SemRel dataset statistics for all languages in the supervised learning track.

It can be noticed it is a highly unbalanced dataset. Only English has more than 2,000 training examples, followed by Hausa, Spanish, Algerian Arabic, Marathi and Telugu with more than 1,000 instances and Amharic, Moroccan Arabic and Kinyarwanda with less than 1,000 examples.

4 Methodology

In this section, we describe the proposed architecture, the experimental configuration and the training details. For pre-processing the sentence pairs, we perform the same text pre-processing steps as mentioned in (Ortiz-Barajas et al., 2022).

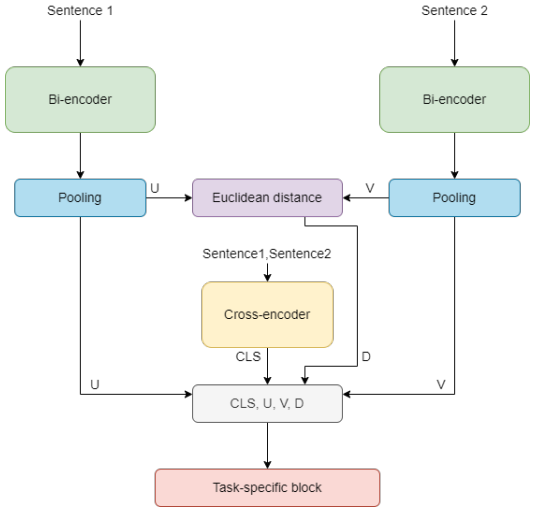

Figure 1: Diagram of the Sentence-CROBI model. U and V correspond to the individual vector representation of each text, CLS is the token classification obtained with the cross-encoder, and D is the Euclidean distance between U and V

4.1 Model

In this section, we present the Sentence-CROBI (Ortiz-Barajas et al., 2022) architecture and its implementation. The model has two main components: a bi-encoder and a cross-encoder. The bi-encoder is based on the Sentence-BERT model (Reimers and Gurevych, 2019); this is a BERT modification using a Siamese neural network that enables the model to obtain single vector representations for each text by applying a Pooling operation to the last hidden state of the bi-encoder model. We represent these vectors as u and v, respectively. The cross-encoder component receives the joint encoding of the sentence pair and is capable of capturing the relation between both texts. We use the classification token [CLS] as a final vector representation of the sequence.

We obtain a global representation of the sentence pair by concatenating the classification token [CLS] from the cross-encoder representation, the Euclidean distance D between u and v vectors, and the vectors u and v itself. This global vector is the input to a task-specific block composed of two fully connected networks with a single-neuron output. Figure 1 shows the structure of the Sentence-CROBI model.

The output of the bi-encoder component is a contextualised word embedding matrix obtained

by taking the last hidden state of the component, where each row represents a word of the input sentence. In this work, we apply a mean Pooling operation, averaging all the matrix dimensions to obtain a vector representation.

Since we are working on a regression problem, the task-specific layer of our model is composed of a fully connected network featuring two layers. Initially, it accepts the global representation of sentence pairs as input, undergoing a Dropout (Hinton et al., 2012) layer with a probability of 0.1. This regularisation technique is implemented to prevent network over-fitting by randomly zeroing some input values. Subsequently, the input proceeds through a fully connected layer of 1793 units, employing a hyperbolic tangent as the activation function. Ultimately, the output layer is composed of one neuron.

We use the Mean Squared Error (MSE) as a loss function during the training of the Sentence-CROBI model. MSE quantifies the average squared difference between the predicted values and the ground truth across a dataset, which is widely used in deep learning (Bishop, 2006; Goodfellow et al., 2016). For a dataset with N samples, MSE is defined as the mean of the squared differences between predicted $\hat{y}_i$ and actual y_i values as shown in 1.

$$MSE = \frac{1}{N}\sum_{i=1}^{N}(y_i - \hat{y}_i)^2 \quad (1)$$

Notably, our task-specific block and the loss function differ from that proposed in (Ortiz-Barajas et al., 2022) as paraphrase detection entails a binary classification task. In contrast, semantic relatedness is defined as a regression task.

One of the advantages of the Sentence-CROBI model is its implementation facility that only relies on using two pre-trained models, one as a bi-encoder and the other as a cross-encoder. The selection of these models depends on the specific task and available computational resources. The implementation facility also allows the performing of fast experimentation with minor changes. These model features enable us to build solutions for all languages in Track A following the same methodology.

4.2 Data splitting

We perform K-fold cross-validation to create training and validation subsets in the development phase of the shared task. The process entails iteratively designating one of the K folds as the validation set while the remaining $K-1$ folds collectively form the training set. This procedure is repeated K times, with each of the K folds serving as the validation set exactly once. K-fold cross-validation mitigates the impact of data partitioning on model assessment and aids in obtaining a more reliable estimate of a model's performance (James et al., 2013). We set $K = 5$ for all languages in the dataset.

4.3 Fine-Tuning

In this section, we describe our fine-tuning approaches. All approaches use a small number of epochs and a small learning rate. We train our models with a batch size of 32, a learning rate in the range $\{1 \times 10^{-5}, 2 \times 10^{-5}, 3 \times 10^{-5}\}$, and the Adam optimizer (Kingma and Ba, 2014), with a warm-up ratio of 0.06 and a linear decay to zero. We train all models for a maximum of 10 epochs and perform pseudo early stopping to use the model with the best performance on the validation data. The maximum length is 35 for individual texts and 128 for text pairs. The tokenization method differs between sentence pairs and individual texts, resulting in varying length representations. Hence, the length of each representation does not align. We use HuggingFace's Transformers library (Wolf et al., 2020) to implement the Sentence-CROBI model. Our implementation is publicly available on GitHub[1].

The first experimental setting that we use follows a monolingual approach, which means we fine-tune a model for each language of the dataset. We leveraged the HuggingFace Hub platform[2] to select bi-encoder and cross-encoder components for each model. To constrain the search space, we exclusively focused on encoder-only architectures that were either pre-trained or fine-tuned for the specific language of interest and possessed an associated paper describing the employed dataset and training details. In case there are no specific-language models, we use a multilingual model. We provide further details for the bi-encoder and cross-encoder combinations for each language in the dataset to fine-tune our model in Appendix A.

We also follow a multilingual approach to fine-tune our model. We group the languages based on their linguistic family. We consider two families.

[1] https://github.com/jgermanob/Sentence-CROBI
[2] https://huggingface.co/models

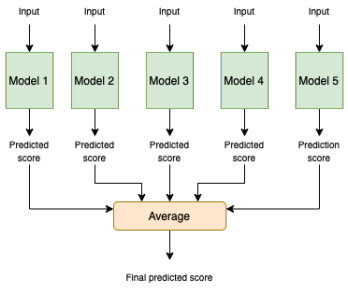

Figure 2: Bagging method diagram to obtain the final predicted score. Each model is fine-tuned using a different random seed and the final prediction is the average of all predictions.

The first one is the Semitic family, which includes Algerian and Moroccan Arabic as well as Amharic. The second one is the Indoeuropean family, which includes English, Spanish and Marathi. Telugu, Kinyarwanda and Hausa languages belong to different families; therefore, we do not include them in this approach. We concatenate each training and validation split to create each family-based split to train the models. For both families we use XLM-RoBERTa base (Conneau et al., 2020) as a cross-encoder and the multilingual uncased base version of BERT (Devlin et al., 2018) as a bi-encoder.

4.4 Ensemble Learning

In order to enhance the performance of the model in the Semantic Textual Relatedness task, we employ the Bagging method (Breiman, 1996), a strategy that mitigates generalisation errors by combining multiple models. This approach involves training different models independently and combining each output set to vote on test data and obtain the final prediction.

In the case of neural networks, differences in random initialisation or in batch generation cause independent errors in each member of the ensemble; therefore, the ensemble will perform significantly better than its members (Goodfellow et al., 2016).

We compute the final similarity score by averaging the output of each fine-tuned model with a different fold from the cross-validation splitting. Therefore, we use five distinct and independent models to obtain a final prediction. Figure 2 shows a diagram of how this method is used in this work.

5 Results

We present the results of our proposed model in the following section in the development and evaluation phases of the SemEval 2024 Task 1: Semantic Textual Relatedness.

Lang	Val ρ (avg)	Dev ρ
amh	0.4828	0.6230
arq	0.4784	0.6370
ary	0.7308	0.8030
eng	0.8709	0.8440
esp	0.5861	0.6900
hau	0.6076	0.6740
mar	0.7913	0.8470
tel	0.7290	0.8112

Table 2: Results of the proposed model in the development phase using a monolingual fine-tuning approach. We report an average of 5 runs in the validation splits used for cross-validation. We obtain the final score predictions in the development set using the bagging technique.

5.1 Development Phase

We report the average Spearman rank correlation coefficient in the validation dataset corresponding to each fold and the performance score in the development dataset reported in the Codalab page of the shared task for the development phase. We obtain the final score for each instance in the development dataset using the bagging technique and the average predictions of the five independent models for each fold.

In the case of the monolingual fine-tuning approach, we use a different model for each language in the dataset. Table 2 shows the results for each language. Half of our results in this approach achieve a performance higher than 0.80 in the performance metric, while the remaining models obtain a result above 0.60. The best performance is for the English language, with a Spearman correlation coefficient of 0.844. In contrast, the lowest performance is for the Amharic language, with a Spearman correlation coefficient of 0.623.

Due to the imbalance present in the dataset, we employed a multilingual fine-tuning approach by grouping languages into linguistic families. In this approach, we considered two groups: the Semitic (Sem) languages and the Indoeuropean (IE) languages.

Table 3 shows the results using the multilingual fine-tuning approach. There is a performance decrease in 6 of 8 considered languages. In the case of the Indoeuropean family, our model obtains a Spearman correlation coefficient of 0.8191 for En-

Lang	Fam	Val ρ (avg)	Dev ρ
eng	IE	0.8079	0.8191
esp	IE	0.8079	0.6874
mar	IE	0.8079	0.8290
amh	Sem	0.6926	0.8223
arq	Sem	0.6926	0.4727
ary	Sem	0.6926	0.8519

Table 3: Results of the proposed model in the development phase using a multilingual fine-tuning approach. We report an average of 5 runs in the validation splits used for cross-validation. We obtain the final score predictions in the development set using the bagging technique.

glish, which represents a 0.0249 decrease; in the case of Spanish and Marathi, our model decays 0.0026 and 0.018, respectively. In the case of the Semitic family, the multilingual fine-tuning approach improves the model performance in 2 of 3 considered languages: Moroccan Arabic (Moroc. A.) and Amharic. The model increases its performance from 0.803 to 0.8519 in Moroccan Arabic and from 0.623 to 0.8223 in Amharic, which represents a 0.1993 performance improvement in terms of Spearman correlation coefficient.

We must mention that we did not report any results for the Kinyarwanda language in the development phase because it was added to Track A later (December 12, 2024). Therefore, we were unable to conduct any experiments prior to the evaluation phase.

5.2 Evaluation Phase

We select the best-performing model for each language in the evaluation phase of the shared task. We use a monolingual fine-tuning approach for Algerian Arabic, English, Spanish, Hausa, Marathi, Telugu and Kinyarwanda, as well as a multilingual approach for Amharic and Moroccan Arabic. We create a new training set for each language and family by adding the development subset and its gold scores released by the shared task organisers. We train five independent models for each language and obtain the final score predictions using the bagging technique.

Table 4 shows the results of our proposed model in the evaluation test, its comparison with the baseline and the final ranking in the shared task for each language. We add a * to denote a multilingual-fine-tune-based approach. Our model outperforms the baseline in English and Moroccan Arabic with a difference from the leaders of 0.0183 and 0.0765, respectively. The lowest performance of the proposed model is in the Kinyarwanda language, with a Spearman correlation coefficient of 0.4585 and a difference from the leader of 0.3584.

Lang	Score	Baseline	Rank	Highest score
amh *	0.8398	0.85	7/18	0.8886
arq	0.5407	0.6	11/24	0.6823
ary *	0.7861	0.77	13/23	0.8625
eng	0.8316	0.83	16/36	0.8499
esp	0.6968	0.7	11/25	0.7403
hau	0.6702	0.69	9/21	0.7642
mar	0.8669	0.88	11/25	0.9108
tel	0.7847	0.82	17/25	0.8733
kin	0.4585	0.72	16/21	0.8169

Table 4: Results of the proposed model in the evaluation phase using monolingual and multilingual fine-tuning approaches compared with the baseline and the highest score. We obtain the final score predictions in the development set using the bagging technique. * Denotes a multilingual approach.

We perform an error analysis of our model's performance in the evaluation dataset for each language in Appendix B. The analysis suggests that the global vector representation of the sentence pair has a limited capacity to capture other semantic relationships between the texts apart from similarity, and future work should follow this direction. Nevertheless, it is essential to highlight that only the task-specific block should change, which illustrates the high adaptability capacity of the model.

6 Conclusions

This work presents the Sentence-CROBI model and its adaptation to the SemEval 2024 Task 1: Semantic Textual Relatedness. We evaluate the model's capacities in monolingual and multilingual fine-tuning approaches to measure its performance and adaptability across diverse linguistic families, yielding acceptable performance in low and mid-resource languages. Ensemble techniques further enhance the robustness and reliability of the model's predictions. Overall, the findings underscore the model's capacity for solving relatedness detection tasks, emphasising its versatility in accommodating linguistic variations and resource constraints.

A Monolingual approach

We use a monolingual fine-tuning approach for Track A, which means we fine-tune a model for each language in the dataset as described in section 4.3. We only consider publicily avaliable models in the HuggingFace Hub [3] that were either pre-trained or fine-tuned for the specific language and possess and associated paper describing the dataset as well as the training details.

Table 5 shows the bi-encoder and cross-encoder combinations for each language in the dataset to fine-tune our model following the monolingual approach. Following (Ortiz-Barajas et al., 2022) methodology, we choose a RoBERTa-based model for the cross-encoder and a BERT-based model for the bi-encoder. Only in the case of the Hausa language do we use a multilingual combination of bi-encoder and cross-encoder models because there are no available pre-trained or fine-tuned models that made our criteria.

B Error Analysis

We perform an error analysis of our model's performance in the evaluation dataset for each language. It is essential to mention that Spanish is excluded because the organisers do not provide the gold scores for this language.

Table 6 shows the differences between our model's predictions and the gold scores for each language in the evaluation dataset. We compute the difference by subtracting each example's predicted score from the gold score. Therefore, a negative difference means that our model predicts a higher score than the gold score, whereas a positive difference means that our model predicts a lower score than the gold score. The negative differences are higher than the positive differences in all languages. This result indicates that our model predicts a higher semantic textual relatedness score than the actual relatedness score in all cases.

Table 7 shows the top-5 negative differences predicted by the Sentence-CROBI model in the English evaluation dataset; that is, the model predicts a higher score than the gold score. It is possible to observe a high semantic similarity between the texts in the first four examples, and they can be considered paraphrases. Therefore, our model captures only one kind of semantic relatedness in these examples.

Table 8 shows the top-5 positive differences predicted by the Sentence-CROBI model in the English evaluation dataset; that is, the model predicts a lower score than the gold score. It is possible to observe different types of semantic relatedness that differ from semantic similarity between the texts. In the first example, the texts are semantic contrastive; the first text hints at excitement, while the second portrays boredom. The texts in the second example describe similar situations where a person performs some public activity. In the third example, both texts offer insights into events or situations concerning government or administration within a specific historical context. The semantic relatedness between the texts in the fourth example is their shared focus on the reading experience and the consideration of delving into further books within a series. Finally, the semantic relatedness in the fifth example lies in their depiction of situations involving young children, albeit with distinct tones and activities.

Democritus University of Thrace, Greece
{theokyri6,imaslari,avi}@ee.duth.gr

Abstract

Text-generative models evolve rapidly nowadays. Although, they are very useful tools for a lot of people, they have also raised concerns for different reasons. This paper presents our work for SemEval2024 Task-8 on 2 out of the 3 subtasks. This shared task aims at finding automatic models for making AI vs. human written text classification easier. Our team, after trying different preprocessing, several Machine Learning algorithms, and some LLMs, ended up with mBERT, XLM-RoBERTa, and BERT for the tasks we submitted. We present both positive and negative methods, so that future researchers are informed about what works and what doesn't.

1 Introduction

LLMs are becoming more and more part of our everyday lives due to their easy accessibility and their remarkably fluent responses in different fields like news, healthcare and education. This extensive usage can lead to unintended consequences. Specifically, LLMs could replace humans, provide sometimes false, incomplete or even misleading information, risk the critical thinking of students and progressively of the whole society. So, it is of high importance to find a way to identify if a text was written by a human or by a machine. Since all these complex models are trained on large datasets and have achieved generating texts that are so human like, it is difficult for a person to identify who generated a text. Here comes the importance of the automatic models, capable of differentiating between human written texts and machine generated texts, by exploiting patterns invisible to a human.

In this paper we describe the DUTh participation in *SemEval 2024 Task 8: Multigenerator, Multidomain, and Multilingual Black-Box Machine-Generated Text Detection*. The task features three directions: *Binary Human-Written vs. Machine-Generated Text Classification, Multi-Way Machine-Generated Text Classification and Human-Machine Mixed Text Detection*. The first two refer to the scenario where a system must classify input texts which are fully written by a human or a machine. One detail regarding the second scenario is that we are also provided with the specific language model which generated the input text. In the third scenario we are presented with a text which is half human and half machine written and we have to determine the boundary, where the change occurs. In all subtasks the text data are coming from different sources and different generators, and we are not allowed to use any external data except for the ones given from the organizers.

The sub-tasks can be briefly described as follows: SubtaskA monolingual: given only English texts, we need to determine whether a text is human-written or machine-generated.

SubtaskA multilingual: given texts from 8 different languages (English, Arabic, Chinese, Indonesian, Urdu, German, Bulgarian, Russian), we need to determine whether a text is human-written or machine-generated.

SubtaskB: given only English texts, we need to determine whether a text is human-written or machine-generated and which is the specific generator.

SubtaskC: given only English mixed texts, where the first part is human-written and the second part is machine-generated, we need to determine the boundary.

Our team participates by submitting on SubtaskA (both monolingual and multilingual) and SubtaskB. During the competition we examine several methods, especially on SubtaskA monolingual, like different preprocessing techniques on the text data, several Machine Learning Algorithms, some ensembling methods and LLMs. We ended up submitting LLMs to all subtasks.

The models we choose are mBERT for subtaskA monolingual, XLM-RoBERTa for subtaskA multi-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1080–1086

lingual and BERT for subtaskB, as they achieve better performance on average. All these pre-trained models have been proven to be powerful for different NLP tasks.

Our proposed system for every subtask is a classifier based on a fine-tuned Large Language Model. During the training process, our model is provided with a text as input and a label regarding whether this input is human or machine generated. Additionally, this paper provides a comparative study of different LLMs fine tuned in this task. In this context, we also provide results regarding the use of classic machine learning algorithms trained to tackle this task.

2 Background

2.1 Dataset

All datasets given from organizers are on jsonl format. For both subtaskA and subtaskB the English human-written texts are coming from the following five sources, "wikihow", "wikipedia", "peerread", "reddit" and "arxiv". The generators for machine-generated texts are "chatGPT", "cohere", "davinci", "bloomz" and "dolly".

For multilingual data, the sources and generators are the same. The languages it consists of are English, Arabic, Bulgarian, Chinese, Indonesian, Urdu, German and Russian.

More information about the datasets and tasks can be found from the organizers.(Wang et al., 2024a) (Wang et al., 2024b) (Wang et al., 2024c)

2.2 Evaluation Metrics

The evaluation metrics for this task are accuracy, micro-f1 and macro-f1. Though, the organizers ranked both on validation and test set the participants basically based on the accuracy scores.

3 System Overview

Transformers have achieved state-of-the-art(Wolf et al., 2020) performances on several natural language processing tasks such as text classification. This is why all final models submitted are LLMs. Here we present the submitted model on each subtask.

We have all the hyperparameters for tuning the models submitted in the appendix section 6.

3.1 Tokenization applied

In all three models we use the tokenizer they already have. We define a max length of 512 tokens, which means that each encoder will take the first 512 tokens of the text as an input. We use truncation and padding, so that if a text has more than 512 tokens it gets cut off on the 512th token and if it has less than 512 tokens it gets padded until it reaches 512. We want all texts to have the same length. All the encoders of the transformers can give a representation of their input tokens, in a high dimensional space (512D here), based on the meaning of each token. For example, the same word can have different representation if its meaning changes. There is no other preprocessing made on the texts except for the tokenization applied by each model.

3.2 SubtaskA models

For the monolingual part of this subtask, we select multilingualBERT (bert-base-multilingual-cased)(Devlin et al., 2018). After comparing lots of classifiers, the two most performing are BERT and multilingualBERT. Previous research finds that there is no apparent benefit in training dedicated monolingual models for single language tasks, and actually by using a multilingual model instead may yield slightly improved performance de Vargas Feijó and Moreira (2007). Our case is no different. We can see that multilingualBERT slightly outperforms BERT on Table 8. MultilingualBERT is a pretrained model on 104 languages and has 179M parameters. For the multilingual part, we select XLM-RoBERTa (xlm-roberta-base)(Conneau et al., 2019) as it demonstrates the best performance between all models we examine. We do not apply any preprocessing on the input text, so XLM-R gets used as a cased model. XLM-R is pre-trained on 2.5TB of filtered CommonCrawl data containing 100 languages and has 279M parameters.

3.3 SubtaskB model

Between ML algorithms and LLMs we select BERT (bert-base-cased) for this task as we have seen that transformers, most of the times, have better results. It is pre-trained on a large corpus of English data and it has 109M parameters.

4 Experimental Setup

4.1 Preprocessing

We apply some preprocessing only on English data, when we use Machine Learning classifiers. There is no preprocessing on English data when we use

LLMs (either for embeddings or classification) or in the multilingual subtask.

The preprocessing is done with the following order. At first, we lowercase the text data and then we can either replace unicodes or remove them, but since we see that the latter has better results, we remove them. After that, we replace the emails with the word <email> and the URLs with the word <url>. We, also, remove the digits and all punctuations. Considering both tokenization and lemmatization, we see that tokenization performs better. Moreover, we achieve better results by the removal of stop words. Finally, we create some new features from the text data. These features are the number of times some phrases, words or combinations of punctuations ("cannot", "do not", "." and more) appear in each text, the number of characters on the original texts and the number of words after tokenization.

4.2 Embeddings

For SubtaskA monolingual, we try to get the embeddings using Word2Vec(Mikolov et al., 2013), Tf-Idf(Ramos et al., 2003) and BERT encoder. On Word2Vec we try the following vector sizes 20, 40, 60, 80, 100, 150, 200 and 300. On Tf-Idf we try the following X more frequent words 500 and 1000 with Ngrams of (3,5). Finally, on BERT encoder we get embeddings from the last of the 12 layers.

After comparing all the above, we see that the best results are coming from Word2Vec with vector size 20.

On SubtaskA multilingual, we get embeddings with the multilingualBERT encoder from its last layer.

We use Word2Vec with vector size 20 as on SubtaskA monolingual, to get embeddings on SubtaskB text data too, in order to see the performance of some ML algorithms on this task.

4.3 Machine Learning Algorithms VS LLMs

The metric we use is accuracy. We have seen that micro-f1 and macro-f1 values fluctuate according to the accuracy value. We, also, standardize the embeddings before we feed them into the ML algorithms. The accuracy values are calculated based on the preprocessing mentioned above except for the part of stop words. When stop words are removed it is specified on the table. Also, when we do not standardize the input data we mention it on the table.

In this section, all models are trained and evaluated using the training set and validation set the organizers give us. All values are calculated on the validation set. ML algorithms without * or additional information presented on the tables, have the default parameters of scikit-learn and XGBClassifier libraries (versions 1.3.0 and 1.7.3 respectively).

4.3.1 SubtaskA monolingual

We start to get embeddings using Word2Vec different vector sizes and compare them based on Logistic Regression. The results are on the Table 1.

We can see that Word2Vec embeddings with vector size 20 is the best based on LR. Now, we take the best embeddings, with vector size 20, and try different ML algorithms to see what results we can take on the validation set. The results are on the Table 2.

We can see that the best result here is default AdaBoost (Freund and Schapire, 1997) with optimized RandomForest (Breiman, 2001) and removed stop words. We have also tried optimizations to other algorithms and some voting ensembling methods with some of the best results from above, but everything was worse than the best one.

Now, we try different methods on getting embeddings to see if anything can beat Word2Vec with vector size 20 based on Logistic Regression and Random Forest. The results are on Table 3.

Now, we compare the best result from the ML algorithms with miniLM and BERT. Both miniLM and BERT are trained for 5 epochs on the training set and evaluated on the validation set. We evaluate them on every 100 batches, and we take the mean of all evaluations. The results are on the Table 4.

4.3.2 SubtaskA multilingual

We take embeddings using the last layer of multilingualBERT encoder and try some ML algorithms. The results are on the Table 5.

We can see from the algorithms compared that the best here is XG Boost(Chen and Guestrin, 2016) with no standardization applied.

Now, we compare the best ML algorithm with multilingualBERT and XLMRoBERTa as classifiers. The results are on Table 6 and again for the LLMs' values, because we evaluate them on every epoch from the 5, we take the mean of them.

We can see here that XLM-RoBERTa is slightly better from default XgBoost. So, this is the best model for this task.

4.3.3 SubtaskB

On this subtask we take embeddings using the last layer of BERT and try some ML algorithms. The results of how ML algorithms perform on this multiclass task are presented on Table 7.

5 Modification on datasets

5.1 Rationale

We make some comparisons between datasets, and we decide to create new training and validation sets for subtaskA and subtaskB. We notice that subtaskA multilingual training set contains all the English data of the rest datasets and some extra, which means that it has the most English data. So, we decide to create a new monolingual dataset with all English data. We, also, notice that in the multilingual training set there are only the English, Chinese, Indonesian, Urdu and Bulgarian data and on multilingual validation set there are the three other languages. Thus, we create a new dataset with all multilingual data containing all languages. Now, from these two new datasets we create the new training and validation sets of subtaskA and subtaskB.

5.1.1 SubtaskA monolingual

Using the dataset with all the English data, we keep 131589 for training and 5000 for validation, where the 2500 texts are human-written, and the 2500 texts are machine-generated. With these new datasets we train and evaluate BERT. Because we want to train multilingualBERT, also, to see its performance on English data, we take the multilingual training set given from organizers and exclude the same as before 5000 English data for validation. By this way, this training set has the same remaining 131589 English data for training and the same 5000 English data for evaluation, with the difference now that this training set has 4 more languages (Chinese, Indonesian, Urdu, Bulgarian) and not only English data.

Both models are trained for 5 epochs and they are evaluated on all 5 epochs. The results are on Table 8 and both values are the mean of all their 5 evaluations.

5.1.2 SubtaskA multilingual

Using the dataset with all multilingual data, we create a new training set and a new validation set that contain texts from all languages. Specifically, the training set contains 133589 English, 10000 Chinese, 5000 Indonesian, 5000 Urdu, 10000 Bulgarian, 900 Arabic, 1800 Russian and 900 German data. The validation set contains 3000 English, 1934 Chinese, 995 Indonesian, 899 Urdu, 2000 Bulgarian, 100 Arabic, 200 Russian and 100 German with 50 percent human-written texts and 50 percent machine-generated texts. There is no specific technique behind the chosen percentages of each language.

We train the XLM-RoBERTa on this new training set for 5 epochs and make evaluations on each one of the 5 epochs. The result is 95.5 percent and it is the mean of all 5 evaluations.

5.1.3 SubtaskB

Using the dataset with all English data, the training and validation set for SubtaskB given from organizers, we concatenate the training and validation sets to compare them with the dataset of all English data. We can see that there are 62562 English data that are not used on this subtask. In these 62562 data there are different percentages of each class from the 6 (human, chatGPT, cohere, davinci, bloomz and dolly). We keep the same sample of

Algorithm	**W2V with 20 VS**	Tf-Idf 500 *	Tf-Idf 1000 *	Bert last layer
Logistic Regression	0.559	0.6288	0.6348	0.6618
Random Forest	**0.7552**	0.6226	0.7132	0.654

Table 3: Logistic Regression and Random Forest accuracy per different embedding methods. *With Ngram

Model	**Accuracy**
AdaBoost *	0.7584
MiniLM	0.7695
BERT	**0.783**

Table 4: Comparison of best machine learning algorithm with evaluated LLMs on monolingual task. *Adaboost with optimized Random Forest with removed stop words.

1844 texts from each class. The value is 1844, because in the 62562 texts, one of the classes has only this amount.

So, we create a new training set where we just add on the training set given from organizers these 1844 samples from each class. The validation set is the same. On this new training set we train BERT for 5 epochs, as we have seen on the other tasks that LLMs more often than not beat Machine Learning Algorithms. We evaluate BERT on every 10000 batches using the validation set organizers give us. The result is 96.81 percent and it is the mean of all evaluations.

5.2 Final Models

Finally, we combine on every subtask the new training set and validation set we created. We train the best models for 5 epochs on these datasets.

We can say that LLMs, most of the times, perform better on these tasks than Machine Learning algorithms. Nevertheless, there are some ML algorithms, combined with the right preprocessing and embeddings' method, that can give good results close to those LLMs give. As we can see, default AdaBoost with optimized Random Forest and with removed stop words achieves a quite good performance on subtaskA monolingual. The preprocessing made and the features we created on subtaskA monolingual seem to improve the performance of algorithms. Also, Default XgBoost with no standardization achieves a close enough to the best model performance on subtaskA multilingual. We believe that LLMs perform better because they are pre-trained models on a large corpus of English or multilingual data. Thus, they can better understand the meaning of a word and a whole text, and maybe this makes it easier for them to differentiate human-written from machine-generated texts.

Finally, the models submitted on the competition scored 73.243 on subtaskA monolingual, 76.45 on subtaskA multilingual and 56.683 on subtaskB. This means about 20 percent below for subtaskA and 30 percent below for subtaskB from the scores we had on the new validation sets we created from the dataset organizers give us. We think that this drop is due to the fact that the texts on the test sets are coming from different domain, generator and language. Basically, on subtaskA monolingual all texts are coming from a new domain "outfox" and there is also a new generator "gpt-4". On subtaskA multilingual, again the texts are coming from the same new domain and the languages it consists of are German, Arabic and Italian. The two first were also on the training but in a small amount and the 3rd one was not in the training set. On subtaskB, the only difference is the domain, which is the same as on every subtask, "outfox".

6 Conclusion

Based on the results we have on our new validation set and the results on the test set, we assume that this drop occurs since our model cannot generalize well. We believe that if the test sets had texts coming from the same domains and generators as the training texts, and had the same languages, then our models would have achieved better results.

Future work could focus on either training larger language models or trying to improve generalization of ours, possibly with some preprocessing like data augmentation. We look forward to further research on these tasks, hoping for better results.

Abstract

In this paper, we present our approach to the SemEval-2024 numeral reasoning task, which requires filling in a blank with a number based on a given sentence. We first attempted to predict the arithmetic operation needed to compute the correct answer and obtained some statistical insights from this process. We performed operation prediction in two ways: as a 9-class classification problem and as a set of binary classification problems for each operation. However, due to the low accuracy of this method, we switched to a zero-shot learning strategy that leverages natural language inference models to solve the task.

1 Introduction

Headline generation is the task of summarizing a full-length article into a brief, catchy, and informative line of text. A key challenge in this task is to preserve the numerical information from the article, as numerals often convey important facts and figures. However, existing encoder-decoder models, despite achieving high ROUGE scores, tend to generate inaccurate or unreasonable numerals in headlines. One of the main reasons for this problem is the scarcity of datasets that provide detailed annotations for numeral generation.

To address this gap, the authors of (Huang et al., 2023) introduce the NumHG dataset, which consists of more than 27,000 numeral-rich news articles with fine-grained annotations. These annotations indicate how the numerals in the headlines can be derived from the numerals in the articles, using various arithmetic operations and transformations. The NumHG dataset enables the evaluation of numeral accuracy, reasonableness, and readability in headline generation. Moreover, the dataset covers both English and Chinese languages, allowing for cross-lingual studies. By emphasizing the role of numerals, the NumHG dataset aims to advance the state-of-the-art in number-focused headline generation and foster further research in numeral-focused text generation.

In this paper, we present our system for the NumHG task, which is based on zero-shot learning using gpt3.5. We first apply some preprocessing steps to the dataset, such as tokenization, normalization, and masking. Then, we use gpt3.5 to generate headlines by reformulating the task as a natural language inference problem. We compare our system's performance on different types of operations, such as copy, trans, paraphrase, round, subtract, add, span, divide, multiply, and sround. We find that our system performs well on some operations, such as copy and trans, but poorly on others, such as round. Our system ranks 12th in the leaderboard with an accuracy of 74 percent.

Additionally, we have made our code openly accessible on GitHub[1] to facilitate reproducibility and further research endeavors.

2 Background

2.1 Dataset Description

There are 21157 samples in the training set and the validation set contains 2572 samples. each sample contains the fields "news", "masked headline", "calculation" and "ans". Table 1 demonstrates an example from the dataset. The objective is to ensure accurate numeral generation in headlines, and as such, detailed annotations on how to secure the correct numeral through specific operations are provided. The whole dataset is in the English language. In this task, we are asked to predict the correct numeral value that the masked headline must be filled with based on the news.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1087–1091

2.2 Related Work

The task of headline generation, a form of text summarization, endeavors to condense a lengthy source text into a succinct summary. Text summarization approaches typically fall into two categories: extractive and abstractive. Extractive approaches involve selecting fitting sentences from the source text to serve as the summary, while abstractive approaches strive to create new sentences to encapsulate the source text. The concept of headline generation aligns more closely with abstractive methodologies.

The emergence and development of large-scale pre-trained models like Lewis et al., Raffel et al. and Zhang et al., have notably advanced the capabilities of abstractive summarization models, to the extent that they now outperform extractive models. Some recent studies like Dou et al., Liu et al. and Wang et al., emphasize the significance of keyword sentences, asserting that these should be leveraged as guides for summary generation. GSum (Dou et al., 2021), for example, initially performs extractive summarization, then incorporates the extractive summaries into the input for abstractive summarization. Despite experimental evidence supporting GSum's effectiveness, Wang et al. argue that extractive summaries do not provide a reliable or flexible guide, potentially leading to information loss or noisy signals.

To tackle this issue, SEASON(Wang et al., 2022) adopts a dual approach, learning to predict the informativeness of each sentence and using this predicted information to guide abstractive summarization. Meanwhile, BRIO(Liu et al., 2022) employs pre-trained abstractive models to generate candidate summaries, assigning each a probability mass according to their quality and defining a contrastive loss across the candidates. By considering both token-level prediction accuracy and sequence-level coordination, BRIO combines cross-entropy loss and contrastive loss for abstractive summarization.

Table 1: An annotation example in NumHG.
News: At least 30 gunmen burst into a drug rehabilitation center in a Mexican border state capital and opened fire, killing 19 men and wounding four people, police said. Gunmen also killed 16 people in another drug-plagued northern city. The killings in Chihuahua city and in Ciudad Madero marked one of the bloodiest weeks ever in Mexico and came just weeks after authorities discovered 55 bodies in an abandoned silver mine, presumably victims of the country's drug violence. More than 60 people have died in mass shootings at rehab clinics in a little less than two years. Police have said two of Mexico's six major drug cartels are exploiting the centers to recruit hit men and drug smugglers, ...

Table 1: An annotation example in NumHG.

3 System Overview

3.1 Zero-Shot system

Our system is simply inferring the output by zero-shot learning. The input is given to gpt-3.5-turbo along with a prompt. The prompt is: "Act as a news expert. I have a text of news and its masked headline with a mask token specified as [MASK]. The mask should be filled with a numerical value. you should just give me the numerical value to put instead of the [MASK]. You should do some calculations to obtain the final number to put instead of [MASK] and these calculations are as follows: Copy(v): Copy v from the article Trans(e): Convert e into a number Paraphrase(v,n): Paraphrase the form of digits to other representations Round(v,c): Hold c digits after the decimal point of v Subtract(v0,v1): Subtract v1 from v0 Add(v0,v1): Add v0 and v1 Span(s): Select a span from the news Divide(v0,v1): Divide v0 by v1 Multiply(v0,v1) Multiply v0 and v1 the news is: <NEWS> the masked headline is: <MASKED HEADLINE>. your response should be in the format of JSON with the key of ans and value of the numerical answer, so do not include any of your calculation processes."

In the next step, we tried this system on a set of 100 samples from the training dataset with different prompts and the best result was an accuracy of 80 percent. Then we decided to have a set of 200 samples from the validation set but this time, the distribution of different records based on the field "calculation" was the same as the whole validation set; This time the accuracy was 77 percent.

At the end, we extract the number from the model response.

Metric	Value
Precision	0.32
Recall	0.27
F1	0.28
Accuracy	0.81

Table 2: Different metrics in operation prediction in 9-way classification using gpt2

Operation	Acc	Operation	Acc
Copy	0.9	Add	0
Trans	0.64	Span	0
Paraphrase	0.72	Divide	0
Round	0.37	Multiply	0
Subtract	0.05	Sround	0

Table 3: Accuracies for each operation in operation prediction in 9-way classification using gpt2

3.2 Operation prediction

In our investigation, we endeavored to forecast arithmetic operations using textual information extracted from news articles. To achieve this, we meticulously fine-tuned the GPT-2 language model for this specific task. The culmination of our efforts yielded the following outcomes:

Model Fine-Tuning: We conducted rigorous fine-tuning of the GPT-2 model, adapting it to the novel context of arithmetic prediction based on news content.

Performance Evaluation: Subsequently, we evaluated the model's accuracy for each arithmetic operation. The results are shown in Table 2:

The results for each operation are succinctly summarized in Table 3.

In our research endeavor, we revisited the application of the GPT-2 language model to binary classification tasks. Specifically, we aimed to predict the outcome of various arithmetic operations. Our investigation involved meticulous dataset creation, model fine-tuning, and performance evaluation. Below, we outline the key steps and findings of our study. To construct robust binary classification datasets, we adhered to a balanced approach. For each arithmetic operation (e.g., addition, subtraction, multiplication, etc.), we meticulously curated positive and negative samples.

1. Positive Samples: We collected all positive samples corresponding to each arithmetic operation.

2. Negative Samples: Achieving parity between positive and negative samples was crucial. Therefore, we ensured that the number of negative samples matched that of positive ones. However, the challenge lay in diversifying the negative samples. To address this, we introduced Distribution-Based Sampling in which each arithmetic operation in the negative sample was selected based on its distribution across all negative instances. For instance, if we were dealing with the "copy" operation and we gathered 50 positive instances from relevant data sources and the "trans" operation constituted 10% of all negative samples, we allocated 5 negative samples specifically for this operation.

$$50 * 0.1 = 5$$

The results for this method was around random classification, so we didn't continue on that.

We provide both the 9-way classification dataset and the binary classification dataset on HuggingFace[2] for public use. Researchers and practitioners can leverage these datasets for future investigations.

Our study underscores the challenges in predicting arithmetic outcomes from news content. Future research could explore alternative models, feature engineering techniques, or domain-specific adaptations to enhance classification accuracy. Additionally, investigating the impact of dataset size and quality on model performance remains an open avenue for exploration.

In summary, while our initial results did not yield groundbreaking accuracy, the datasets we present serve as valuable resources for the scientific community. As the field of natural language processing continues to evolve, we remain optimistic about refining predictive models for diverse applications.

4 Experimental Setup

4.1 Pre-processing

The news and the masked headline are pre-processed in these manners:

1. converting new line character and tab to space

2. removing the commas from comma-separated numbers, this can help the model to better understand the numbers

[2] https://huggingface.co/Sina-Alinejad-2002

3. replacing the blank in the masked headline with a new mask

4. converting some unknown characters to the closest ASCII equivalent for example uff05 to %. This makes the context easier to understand for the model

4.2 Evaluation Metrics

As this is a prediction task, we have used an accuracy metric to evaluate our model. However, there is no training stage in our system, so this metric is not used to update any parameter and it is just for us to change some hyperparameters like the prompt.

4.3 Others

We also used the tenacity library to handle some errors that may cause the cell to stop such as TimeLimit error or RateLimit error. For this, we set a retry decorator for the main function wait for 20 seconds after an error has occurred, and retry the request to API and this is for a maximum of 3 times.

```
@retry(stop=stop\_after\_attempt(3),
wait=wait\_fixed(20))
```

5 Results

5.1 Overall Performance

The overall performance of our system on the test dataset was 74 percent. We also calculated the accuracy of each of the 10 operations and the result is shown in table 4.

5.2 Error Analysis

The system performs poorly on predicting answers that require the round operation to be applied and this is probably because the model tends just to copy the exact number in the blank or round it in different ways. On copy and trans operations, the results are the best compared to others which are around 50 percent.

6 Conclusion

In this paper, we have presented a zero-shot learning system for the NumHG task, which leverages gpt3.5 to generate headlines with accurate and reasonable numerals. Our experimental results show that our system can handle simple operations, such as copy and trans, but fails to perform complex operations, such as add, subtract, and round. This indicates that current LLMs like gpt3.5 still have limitations in capturing the numerical reasoning and arithmetic skills required for the NumHG task.

Operation	Acc	Operation	Acc
Copy	0.82	Add	0.46
Trans	0.81	Span	0.5
Paraphrase	0.54	Divide	0.54
Round	0.02	Multiply	0.4
Subtract	0.5	Sround	0

Table 4: Accuracies based on the operation used to calculate the answer

For future work, we propose to explore the possibility of using multiple agents to collaborate on the task. This could involve either having different agents specialize in different operations or having a voting mechanism to select the best answer from multiple agents. We believe that this could improve the overall performance and robustness of our system, and also provide more insights into the strengths and weaknesses of different LLMs.

We suppose that it would be also useful to extend the exploration of numeral reasoning tasks by incorporating few-shot learning techniques. This approach will allow us to delve deeper into the performance enhancements across various operations, providing a more granular understanding of the model's capabilities. Furthermore, we can transcend beyond merely predicting the final answer. Inspired by the iterative prompting methodology of Chain of Thought (Wei et al., 2023), it would be possible to endeavor to refine our model's reasoning process. This will involve guiding the model to deduce the correct set of operands and the associated operation before executing it, thereby fostering a more transparent and interpretable reasoning pathway. Such advancements will not only bolster the model's accuracy but also its ability to articulate the reasoning behind its conclusions, paving the way for more robust and reliable numeral reasoning systems. The impact of dataset size and quality is also an open avenue to explore, one such experiment has been conducted by (Jain et al., 2020).

Abstract

This paper outlines our approach to SemEval-2024 Task 4: Multilingual Detection of Persuasion Techniques in Memes, specifically addressing subtask 1 in English language. The study focuses on model fine-tuning using language models, including BERT, GPT-2, and RoBERTa, with the experiment results demonstrating optimal performance with GPT-2. Our system submission achieved a competitive ranking of 17th out of 33 teams in subtask 1, showcasing the effectiveness of the employed methodology in the context of persuasive technique identification within meme texts.

1 Introduction

Propaganda is the term used when information is intentionally molded to promote a specific agenda. Memes typically involve combining an image with text. In deceptive memes, the image serves to either enhance or complement a technique employed in the text, or it independently conveys one or more persuasive techniques. In subtask 1 of SemEval-2024 Task 4 (Dimitrov et al., 2024), the challenge involves identifying which of the 20 persuasion techniques, organized hierarchically, are utilized, based on the textual content of a meme.

For this problem, GPT2 was chosen as the base model after experiments on GPT2, BERT and RoBERTa. After that, the model was fine-tuned on the given data set and after doing error analysis and comparing them with true labels, the threshold of sensitivity was changed manually to get best results. In addition, we tried to fine-tune model on SemEval-2023 Task 3 dataset which is similar to the given dataset for this task. However, the results didn't improve.

Regarding the noticeable change in scores just by changing the threshold of predicting labels, we realized the importance of error analysis and the easy tricks comes after actually understanding the behavior of model and it's problems.

We have made all the code necessary to replicate our results available in the paper's GitHub repository.[1]

2 Background

2.1 Dataset Description

The dataset consists of 7000 samples for training and 500 samples for validation. each sample contains three fields:

- id: A unique identifier assigned to each sample, facilitating the association with the corresponding meme image. It is noteworthy that, for the purposes of Subtask 1, the visual components of the memes, indicated by these IDs, are not considered in the training.
- text: this field is the textual content of the meme, as a single UTF-8 string. While the text is first extracted automatically from the meme, it has been post-processed to remove errors and formated in such a way that each sentence is on a single row and blocks of text in different areas of the image are separated by a blank row.
- label: it is a list of valid technique names used in the text. There are 22 techniques in this dataset which are leaf nodes of the hierarchy of persuasion techniques shown in Figure 1. However, only 20 of them are used for subtask 1.
- link: This field contains the social network link associated with the meme. It is imperative to acknowledge that certain samples may lack a corresponding link. In such cases, the term "null" is employed in lieu of a link.

You can see an example of training samples in Figure 2.

2.2 Related Works

Prior to the SemEval 2024 event task, researchers have endeavored to address analogous challenges, contributing to the evolution of methodologies for detecting persuasive techniques in multimodal content.

The article "Detecting Propaganda Techniques in Memes" (Dimitrov et al., 2021) establishes a novel multi-label, multimodal task of automatically detecting propaganda techniques in memes. creating a dataset of 950 annotated memes covering 22 propaganda techniques, the authors provide a crucial resource for training and evaluating future detection models. In addition, by creating a dataset of 950 annotated memes covering 22 propaganda techniques, the authors provide a crucial resource for training and evaluating future detection models.

The article "SemEval-2023 Task 3: Detecting the Category, the Framing, and the Persuasion Techniques in Online News in a Multi-lingual Setup" (Piskorski et al., 2023) provides a publicly available dataset of annotated news articles, along with code and evaluation metrics. These resources serve as a valuable starting point for future research and development in multilingual news analysis tasks.

Table 1: Class names and their IDs

2.3 Task evaluation and ranking

The hierarchical taxonomy of labels in this task necessitates a nuanced approach to evaluation. According to the task description, when predicting the ancestor node of a technique, only a partial reward is assigned, highlighting the hierarchical multilabel classification nature of the problem at hand.

To assess the performance of submissions, the chosen metric is the hierarchical F1 score (Kiritchenko et al., 2006). Hierarchical f1 score is a way of adapting the F1 score metric to be used for classification tasks with hierarchical structures. These structures involve classes having parent-child relationships, forming a kind of tree-like organization. It is crucial to note that the conventional F1 score is designed for flat classifications devoid of hierarchical relationships, making the hierarchical F1 score a pertinent choice for the evaluation of this task.

3 System overview

3.1 Model Architecture

Initially, our approach involved the utilization of three distinct models: BERT, RoBERTa, and GPT-2, all of which were subjected to fine-tuning on the training set. Subsequent evaluation based on the metrics outlined earlier revealed that the performance of the GPT-2 model surpassed that of its counterparts. (Table 2)

Given the superior performance observed with the GPT-2 model, we proceeded with this architecture for further refinement. The fine-tuning process ensued, culminating in the generation of our final results, which were subsequently submitted utilizing the GPT-2 model.

3.2 Fine tuning on extra dataset

Following the initial training on the provided dataset, our exploration extended to leveraging comparable datasets from previous studies and SemEval events. The SemEval-2023 Task 3 dataset, encompassing paragraphs extracted from diverse news articles and publications annotated with 19 distinct propaganda techniques, emerged as a pertinent source for augmenting our training data.

To ensure compatibility and coherence between the SemEval-2023 Task 3 dataset and our specific task dataset, a meticulous data cleaning process was undertaken. This involved the removal of uncommon tags, resulting in a curated dataset comprising 3,445 new samples. This augmented dataset was then incorporated into the fine-tuning phase of our model, aiming to enhance its adaptability and robustness across diverse text corpora.

3.3 Adjusting the prediction threshold

The model generates continuous probability values reflecting the likelihood of the presence of various persuasion techniques within the input text, rather than providing explicit binary predictions. A threshold is applied to discretize these probability values, where a value exceeding the threshold results in a prediction of 1, and otherwise, it is predicted as 0. The adjustment of this threshold played a pivotal role in refining the model's output, leading to noticeable improvements in performance.

In fine-tuning the threshold value, we tested a range of thresholds on the training set and assessed their performance using the F1-score. Based on the results depicted in Figure 4, we settled on a threshold value of 0.19.

Model	Accuracy	Precision Macro AVG	Recall Macro AVG	F1-Score Macro AVG
BERT	0.218	0.403	0.201	0.238
RoBERTa	0.232	0.344	0.179	0.2145
GPT2-medium	0.382	0.637	0.423	0.489

Table 2: Evaluation Metrics for GPT2, BERT and RoBERTa models on validation set

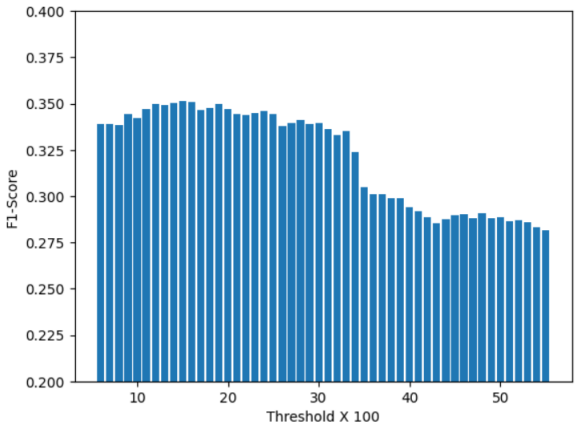

Figure 4: Adjusting the prediction threshold with F1-Score

4 Experimental setup

4.1 Dataset Split

The dataset is partitioned into distinct sets to facilitate comprehensive training, validation, and evaluation processes. The training set comprises 7,000 samples, while the validation set consists of 500 samples. The test set, used for submitting predictions, encompasses 1,500 samples.

Additionally, there exists a dev set that initially lacked labels and was subsequently annotated. This set was not incorporated into the model training process but only used to measure improvements in results and scores.

For the purpose of augmenting the training data, an extra dataset derived from SemEval-2023 Task 3 was considered. Following data cleaning, this supplementary dataset yielded 3,445 samples. However, despite this effort, training the model with the extra dataset did not yield discernible improvements. Consequently, the submitted model was not fine-tuned using this additional dataset.

4.2 Preprocessing Dataset

In the preprocessing of the main dataset, the initial step involved converting the data from JSON format to a tab-separated values (tsv) format. During this transformation, the "link" field in the samples was removed. The resulting dataset comprises columns for ID, Label, and Text.

As for the extra dataset, the samples were initially distributed across various files as paragraphs, with labels stored separately in different files. To align with the structure of the main dataset, each file was processed by splitting it into individual paragraphs. Subsequently, labels were gathered, and each paragraph was transformed into a unified sample with an assigned ID. To ensure compatibility, samples with labels not present in the main dataset were excluded, streamlining the integration of the extra dataset into the training process.

4.3 Evaluation Metrics

The system we have designed, only predicts the actual 20 classes which are the leaf nodes in the hierarchy of persuasion techniques. Therefore we have not used proposed hierarchical f1 score. The metrics we have used for our own evaluations are as follows:

- precision: Calculated individually for each class and expressed as total precision with macro averaging between classes. Precision serves to measure the accuracy of positive predictions.
- recall: Computed for each class and represented as total recall with macro averaging between classes. Recall measures the completeness of positive predictions.
- f1-score: Determined for each class and presented as the total F1 score with macro averaging. The F1-score serves as a comprehensive metric in classification tasks, considering both precision and recall.

5 Results

5.1 Overall Performance

Finally our model reached hierarchical f1-score of 0.624 and hierarchical precision of 0.631 and hierarchical recall of 0.617 in English language. In comparison, the baseline metrics for these categories were significantly lower at 0.368, 0.477, and 0.300, respectively. (Table 3)

Model	Hierarchical F1-score	Hierarchical Precision	Hierarchical Recall
First team	0.752	0.684	0.835
Our model (17th team)	0.624	0.631	0.617
Baseline	0.368	0.477	0.300

Table 3: Team ranking and model hierarchical scores

5.2 Analysis model predictions

By comparing the obtained results with the results of the first team, we see that the precision values are not much different, but the recall value for the first group is much higher than the recall of our model. This disparity indicates that our model may lack sensitivity and we can achieve better results by focusing on improving recall in the model.

6 Conclusion

In this paper, we examined different models and finally by choosing GPT2, we presented a model for the problem of identifying persuasion techniques in English memes. With the help of the presented model and adjusting the threshold for this model, we were able to reach a score of 0.624 for f1-score. Our work demonstrates the effect of choosing the appropriate model for training and the need to perform error analysis to improve the accuracy of the model.

Abstract

ECPE (emotion cause pair extraction) task was introduced to solve the shortcomings of ECE (emotion cause extraction). Models with sequential data processing abilities or complex architecture can be utilized to solve this task. Our contribution to solving **Subtask 1: Textual Emotion-Cause Pair Extraction in Conversations** defined in the **SemEval-2024 Task 3: The Competition of Multimodal Emotion Cause Analysis in Conversations** is to create a two-step solution to the ECPE task utilizing GPT-3 for emotion classification and SpanBERT for extracting the cause utterances.

1 Introduction

This paper introduces an approach for the emotion-cause extraction problem in dialogues. An emotion cause is defined and annotated in the given subtask as a textual span. Input to the model is a conversation containing the speaker and the text of each utterance. The model output should include all emotion-cause pairs, where each pair contains an emotion utterance along with its emotion category and the textual cause span in a specific cause utterance, e.g.(U3_Joy, U2_"You made up!").

Our contribution to solving **Subtask 1: Textual Emotion-Cause Pair Extraction in Conversations** defined in the **SemEval-2024 Task 3: The Competition of Multimodal Emotion Cause Analysis in Conversations** (Wang et al., 2024) is as follows: i) utilize GPT-3 for emotion classification, ii) utilize SpanBERT architecture to extract the cause utterances in dialogues as Q&A task, iii) contribute to solving the ECPE by finding its possible solutions in other NLP fields.

The task was separated into two parts - emotion classification, called subtask 1.1, and emotion-cause pair extraction, termed subtask 1.2. We have used GPT-3 and the SpanBERT model for these subtasks. In this paper, we also reflect on the results we got in the case of both subtasks, namely emotion classification and emotion-cause pair extraction. Our model, with one test entry, scored 9th in the competition.[1]

2 Related work

In recent years, many authors have suggested their approach to solving the ECPE task. Xia and Ding (2019) defined the ECPE task and proposed a two-step framework. First, independent multi-task learning (named Indep) consisting of BiLSTM modules and interactive multi-task learning (called Inter-EC for a model that uses emotion extraction to improve cause extraction and Inter-CE for a model that uses cause extraction to enhance emotion extraction) was used to extract a set of emotion cases and a set of cause clauses. Secondly, the sets were paired to yield a set of candidate emotion-cause pairs. Finally, a logistic model regression was used to filter the pairs. This two-step framework suffers from error propagation from the first step to the second step. Ding et al. (2020a) has also proposed a one-step framework that takes emotion-cause pairs as a 2D representation scheme with BiLSTM modules. These representations are forwarded into the 2D Transformer framework to capture pair interaction. Finally, binary classification is conducted to extract valid emotion-cause pairs. The new proposed framework outperforms the two-step framework by 7.6 percentage points of the F1 score. Regarding the joint framework, Ding et al. (2020b) have proposed a sliding window multi-label learning scheme named ECPE-MLL. It works on the assumption that all clauses in a document are emotion clauses, and an emotion-oriented sliding window is built centered on each emotion clause. In each window, the emotion clause extracts one or more of the corresponding cause clauses (the iterative synchronized multi-task learning (ISML) model is introduced to solve these subtasks). The results of this

[1]https://codalab.lisn.upsaclay.fr/competitions/16141#results

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1097–1105

learning can be transformed into emotion-cause pairs. This approach serves an excellent advantage over the two-step framework proposed before. Chen et al. (2022) have proposed two alignment mechanisms with a model named A^2Net. Text documents are encoded with BERT and a partition filter network (PFN) to implement the first alignment mechanism: feature-task alignment to produce emotion-specific, cause-specific, and interaction features. The features are applied for EE (emotion and interaction features), CE (cause and interaction features), and ECPE tasks (all features). The inter-task alignment reduces then the inconsistency between label spaces among all tasks. The proposed framework achieves a higher F1 score and recall in the ECPE task, a higher F1 score in the EE task, and a higher recall and F1 score in terms of the CE task when compared to ECPE-2D.

3 Methodology

The emotion extraction cause task consists of two components - emotion extraction from the conversation and emotion cause span extraction. The first one could have been considered as a baseline for the second one, as we needed to identify which emotion and utterance should be used in the process of the cause search. There are two ways of approaching this problem. We could have created one model for both subtasks or separated it into two subsequent tasks, where each could be implemented using different models.

We have decided to go with the second approach, as we concluded that those less complex parts could have better quality in the end, even though we are aware of the error propagation, which definitely will be present in such a case.

3.1 Subtask 1.1

The first subtask aims to create a classification model, which will perform emotion recognition in each utterance of the conversation.

We have focused on two different models while approaching this problem. At first, we decided to use BiLSTM, but the results were not promising (refer to Appendix A and Section 4.1.2). Then, we have focused on utilizing the GPT-3 model (Brown et al., 2020) along with AssistantAPI provided by OpenAI.

3.1.1 Dataset

The training dataset, presented by the SemEval competition organizers, contained information about conversations between groups of people and emotion-cause pairs extracted from that conversation. The conversation consisted of multiple utterances, each with defined text, speaker, and emotion expressed by the speaker and their id.

The given dataset was transformed into a set of objects, where each represents a single utterance along with information about the context (concatenated utterances within the conversation) and expressed emotion.

3.1.2 Model

For the GPT-3 model, we have decided to use a standard Assistant (by only defining its purpose) and one enriched with data retrieval (by adding properly labeled data as its knowledge base).

The purpose of both Assistants was defined using the description:

*You are a system which analyzes conversation which consists of utterances sequence (attribute "context" in the given JSON object) among with given utterance (attribute "utterance" in the given JSON object) and then predicts emotion expressed (fear, surprise, joy, disgust, sadness, anger or neutral, you cannot use any other emotion as an answer and you must detect at least one of those emotions) in that utterance adding it to the answer using "**" symbol to emphasize answer's location.*

The enrichment of the second Assistant was based on the OpenAI *Knowledge Retrieval* functionality [2]. A selected number of records described further in Section 4.1 were fed into the GPT-3 model as a knowledge base. Upon querying, the model performs either a vector search or passes the file content to the context of the model calls. For further clearance, a model with/without a knowledge base will be called *GPT-3 based Assistant with/without knowledge base*.

3.2 Subtask 1.2

The second subtask aims to find which utterances in a given context are responsible for inducing the emotion predicted in subtask 1.1 (for details please refer to Section 3.1). The main idea of the second subtask is to fine-tune the SpanBERT model (Joshi et al., 2020) and perform question-answering to find the utterances in the dialogue for predicted emotion.

Dataset	Count
train	5635
validation	1349
test	2380

Table 1: Train, validation, test dataset sizes for subtask 1.2

3.2.1 Dataset

The raw dataset that was presented in Section 3.1 and split into the 0.6-0.15-0.25 ratio was transformed to fit the question-answering task. The duplicates were removed. The original **text** field combined with the person speaking **speaker** in each **conversation** in the provided SemEval (Wang et al., 2023) dataset was converted into the **context** column. The question to be answered was formulated as follows: *What caused the [emotion]?*, where *[emotion]* refers to the predicted emotion for a given utterance combined into the context. Additionally, information was provided to indicate where the answer starts in the context, and **text** column to show the answer in the context. Table 1 shows the dataset sizes used for subtask 1.2.

A tokenizer was used with the original SpanBERT to fit the dataset into the SpanBERT input. Along the tokenization process, the following preprocessing steps were also applied:

1. For questions (column **question**) and contexts (column **contexts**), tokenization with truncation and padding on the right was applied. The max length of sequences was set to 512 (default SpanBERT value), and the stride was also used and set to 128 so that if the context is long, each of the features retrieved from the context has a context that overlaps the context from the previous feature.

2. For answers, the start position and end position were marked so that the current span's token index and the current span's end token index were put correctly even if the answer is out of span (CLS token was added in that case). If the answer was in a given span, the token start index and token end index were put to the two ends of the answer.

3.2.2 Model

The model used to finetune the data prepared for subtask 1.2 was SpanBERT[3] (Joshi et al., 2020) finetuned previously on the SQuAD v1.1 for the Q&A downstream task.

[3]HuggingFace implementation has been used.

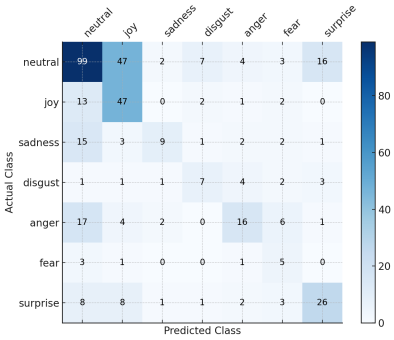

Figure 1: Confusion matrix for the GPT-3 based Assistant with knowledge base

4 Experimental Results

This section presents the experiment results (before evaluation phase) in terms of both subtasks.

4.1 Subtask 1.1

4.1.1 GPT-3 model

We have checked the accuracy of the GPT-3 model by utilizing 400 randomly selected utterances. Assistant, which was enhanced by adding a knowledge base, was using another randomly selected (but not similar to the ones in the test dataset) 500 records from the training dataset.

During the testing phase, we calculated the predicted labels' F1-score, accuracy, and recall and created a confusion matrix.

Figures 1, 2 and Tables 2, 3 refer to the confusion matrix for the Assistant with and without knowledge base accordingly.

Emotion	Precision	Recall	F1-Score
neutral	0.63	0.56	0.59
joy	0.42	0.72	0.53
sadness	0.60	0.27	0.37
disgust	0.39	0.37	0.38
anger	0.53	0.35	0.42
fear	0.22	0.50	0.30
surprise	0.55	0.53	0.54
Accuracy			0.52
Macro Avg	0.48	0.47	0.45
Weighted Avg	0.55	0.52	0.52

Table 2: Classification Report for the GPT-3 based Assistant with knowledge base

Emotion	Precision	Recall	F1-Score
neutral	0.62	0.26	0.37
joy	0.31	0.86	0.46
sadness	0.27	0.09	0.14
disgust	0.32	0.37	0.34
anger	0.43	0.48	0.45
fear	0.25	0.50	0.33
surprise	0.41	0.35	0.38
Accuracy			0.39
Macro Avg	0.37	0.42	0.35
Weighted Avg	0.47	0.39	0.37

Table 3: Classification Report for the GPT-3 based Assistant without knowledge base

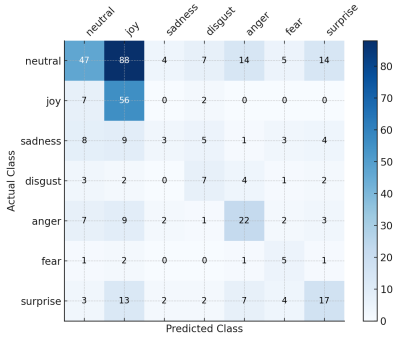

Figure 2: Confusion matrix for the GPT-3 based Assistant without knowledge base

By looking at the Tables 2, 3, one can see that average Macro and Weighted metrics are higher in all given cases: F1-score, Precision, and Recall when dealing with GPT-3 Assistant with knowledge base. Metrics for emotions such as *sadness* for GPT-3 based Assistant without knowledge are relatively low compared to much better results in terms of metrics when dealing with GPT-3 based Assistant with knowledge base. Figures 1 and 2 present the confusion matrices for two version of GPT-3 classifier. For GPT-3 based Assistant with the knowledge base, more *neutral* cases were predicted correctly. In contrast, without the knowledge base, more *neutral* cases were predicted incorrectly as *joy* class.

4.1.2 BiLSTM model

The following Figures 3, 4 and Tables 4, 5 refer to the confusion matrix for Model 1 and Model 2 accordingly used in the BiLSTM experiment (please refer to Appendix A for training and model details).

While analyzing the confusion matrix and values of the metrics for the test data, one can see that

Emotion	Precision	Recall	F1-Score
neutral	0.45	0.39	0.42
joy	0.24	0.35	0.28
sadness	0.14	0.09	0.11
disgust	0.06	0.03	0.04
anger	0.09	0.06	0.07
fear	0.05	0.04	0.04
surprise	0.20	0.32	0.25
Accuracy			0.28
Macro Avg	0.18	0.18	0.17
Weighted Avg	0.29	0.28	0.28

Table 4: Classification Report for Model 1

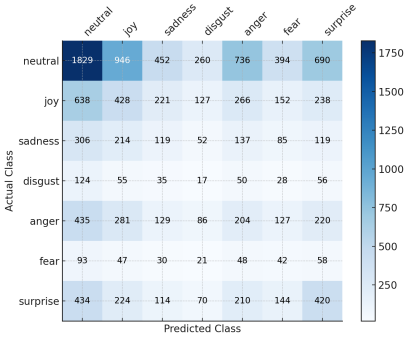

Figure 3: Confusion matrix for the Model 1

the results are not the best - weighted accuracy is around 0.3, while recall and F1-scores are approximately 0.28. Results for both Models are pretty similar, so we can only say that context was not utilized by us well enough for it to affect prediction results (Figures 3 and 4).

The performance of the model was also affected by the distribution of the labels (refer to Figure 5) - such an unbalanced dataset caused labels for neutral, joy, surprise, anger (and also sadness) were more likely to be classified in the right way than

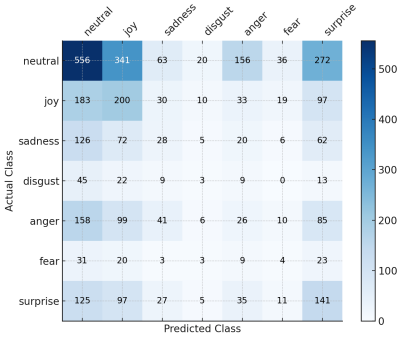

Figure 4: Confusion matrix for the Model 2

Emotion	Precision	Recall	F1-Score
neutral	0.47	0.34	0.40
joy	0.19	0.21	0.20
sadness	0.11	0.12	0.11
disgust	0.03	0.05	0.03
anger	0.12	0.14	0.13
fear	0.04	0.12	0.06
surprise	0.23	0.26	0.25
Accuracy			0.25
Macro Avg	0.17	0.18	0.17
Weighted Avg	0.30	0.25	0.27

Table 5: Classification Report for the Model 2

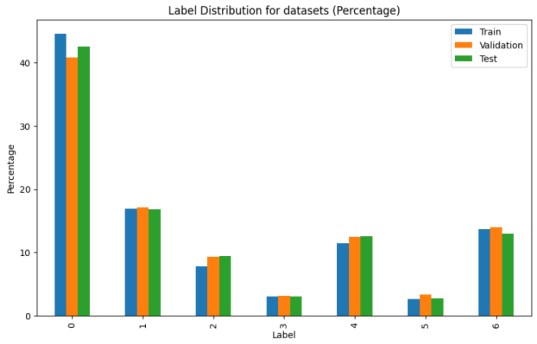

Figure 5: Label distribution in the dataset

fear and disgust ones.

When considering the best GPT-3 model with the knowledge base and all BiLSTM models, the GPT-3 overperforms the BiLSTM model in all presented metrics. It became clear that if we want to use BiLSTM models for the classification tasks where context plays an important role, there should be more complex preprocessing techniques and feature extraction for both the model input and the attention layer (both utterances and context values) that would be solved by utilizing GPT-3 model.

4.2 Subtask 1.2

Regarding fine-tuning the SpanBERT model, training and validation loss were calculated on the given dataset.

Two metrics were chosen to test the SpanBERT model. First is defined as **EM** or **exact match** and is defined as a sum of all of the individual exact match scores in the set, divided by the total number of predictions in the set. Also, the F1-score was used.

Table 6 summarizes the training configuration. The parameters were set so that the **learning rate** is minimized, **batch size** does not exceed the given

Parameter	Value
Learning rate	1e-5
Batch size	8
Training epochs	4
Weight decay	0.01

Table 6: Training config for subtask 1.2

Metric	Value
EM	21.42
F1-score	33.87

Table 7: Exact match and F1-score for Q&A task

RAM of the machine, **training epochs** was set to between 2 and 4 according to BERT's authors' (Devlin et al., 2019) and **weight decay** was set to default.

Figure 6 presents the training and validation loss. The scores obtained for the Q&A task on the test

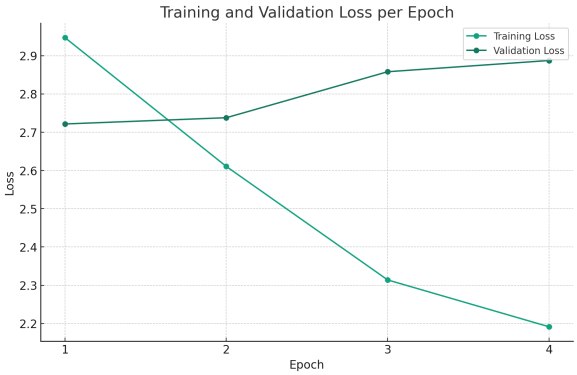

Figure 6: Training and validation in the epochs

dataset are shown in Table 7.

4.3 Results Analysis

4.3.1 Models performance

In case of subtask 1.1, the acquired metrics for both assistant models demonstrate considerable promise. The model employed in this scenario was not pretrained, relying solely on its foundational capabilities as a Large Language Model (LLM). As anticipated, the model utilizing a knowledge base yielded superior results. We achieved a weighted F1-score of 0.52, accompanied by recall and precision values of 0.52 and 0.55, respectively.

For subtask 1.2, obtained metrics presented in Table 7 are much lower than metrics obtained in the SpanBERT case, where results on the SQuAD 1.1 were EM: 85.49, F1: 91.98. Given the nature of such models, metrics on our dataset should be

close to the baseline set by SpanBERT.

4.3.2 Limitations and future work

As for subtask 1.1, textual data makes determining expressed emotion challenging due to the absence of non-verbal cues. With abundant data and resources for fine-tuning, models can predict emotions more efficiently. Despite precise instructions, models may occasionally "hallucinate" and provide unsuitable answers, interpreting emotions differently from the defined set of six instructions.

Much more attention should be paid to preprocessing and analyzing the train, val, and test dataset in subtask 1.2 to provide more meaningful and balanced questions and answers in a given context. The provided sizes of all datasets could be much higher to utilize fine-tuning training fully. The training parameters should also be applied more carefully, and hyperparameter tuning should also be used.

5 Evaluation and Conclusions

For the evaluation phase, we have used the evaluation data provided by the Organizers. The data was emotion-classified using GPT-3, and the data was suited for span extraction as in Section 3.2. We have also tried to use BiLSTM in this case, however, its capabilities were very limited when processing data with unknown words and short sentences (the probability of each occurrence of emotion was nearly identical). The results from SpanBERT were answers to questions built upon classified emotions. Obtained answers were added to the original evaluation dataset's utterances (called *main utterances* in the following text) based on the created by Author unique ID. Answers also contained spans of text that could occur in different utterances, so the utterances that did not belong to the main utterance were placed in different lists (meaning multiple cause spans) in each matched main utterance. Based on the main utterance answer and additional answers, emotion-cause pairs were created in a manner that the "emotion-cause_pairs" list contained emotion utterance along with its emotion category and a cause utterance ID followed by position indexes of predicted cause span within the utterance. The position index starts from 0, and the ending index is the index of the last token plus 1 excluding the punctuation token at the beginning and end. The evaluation phase ended for 1 entry uploaded on the CodaLab (Pavao et al., 2023) submission as follows: **w-avg. Strict F1**: 0.0449, **w-avg. Proportional F1**: 0.0723, **Strict F1**: 0.0462, **Proportional F1**: 0.0717, resulting in 9th place out of 29 teams. The results showed that each of the presented subtasks, namely emotion classification and emotion-cause pair extraction, could perform better in terms of classifying emotions and extracting spans. The changes could improve the overall score by employing GPT-4 architecture and experimenting with span extraction model architecture as well.

A BiLSTM for emotion recognition in conversations

For the emotion classification task, the BiLSTM model was tested (Schuster and Paliwal, 1997).

A.1 Preprocessing

Preprocessing for this task was separated into a few different steps:

1. Duplicates elimination, as we have discovered that sometimes data might have duplicates within;
2. Special signs and stopword removal - in this case, punctuation and digits were removed from the text, then data was converted to lowercase, split into a list of words, and cleaned from English stopwords obtained from the NLTK library;
3. Text tokenization, indexing, and text to-sequence conversion - vectorization was done on the text by turning text into a vector based on TF-IDF and by fitting it to the processed text;
4. Sequence padding, to make sure that all of the input sequences are of the same length;

A.2 Model

The training dataset, presented by the SemEval competition's creators, contained information about a conversation between some group of people and emotion-cause pairs extracted from that conversation. The conversation consisted of multiple utterances, each with defined text, speaker, and emotion expressed by the speaker and their id.

For this task, such dataset was partitioned with a ratio of 0.6-0.15-0.25 to create, train, validate, and test datasets. Such a dataset was transformed into a set of objects, where each represents a single utterance along with information about the context (concatenated utterances within the conversation) and expressed emotion.

Two configurations were checked to establish which parameters would give the best result. All of the configurations used categorical cross-entropy (Lin et al., 2017) as a loss function, Adam (Kingma and Ba, 2014) as an optimization algorithm, and f1_score, accuracy, and recall were noted during all of the training stages. The model in each configuration had seven outputs, each for every primary emotion (Ekman, 1992), including neutral.

Layer (type)	Output Shape
utterance_input (InputLayer)	[(None, 250)]
context_input (InputLayer)	[(None, 250)]
embedding_12 (Embedding)	(None, 250, 250)
embedding_13 (Embedding)	(None, 250, 250)
concatenate_6 (Concatenate)	(None, 250, 500)

dense_7 (Dense)	(None, 7)

Table 8: Second BiLSTM Model with Attention layer configuration

The first configuration (similar, but less complex than presented in Table 8) was a BiLSTM with two hidden layers and ReLU set an activation function, with an attention layer (for utterance data and without context) set with softmax as an activation function.

The second configuration shown in Table 8 was a BiLSTM with two hidden layers and ReLU set an activation function, with an attention layer for contextual data set with softmax as an activation function and an additional layer for 1D convolution operation.

A.3 Evaluation

We have trained both models using train and validation datasets and then tested them using the corresponding set.

A.3.1 Metrics

During the testing phase, loss function and accuracy were calculated for training data, and for the validation data were also calculated recall and f1 score. A confusion matrix was created for the test data.

A.3.2 Training and testing

Both models show the same tendencies for the training data, with the loss function decreasing with each epoch and accuracy getting better (Figure 7).

However, looking at the accuracy, f1 score, and recall, their values are pretty similar for the data in the same batch (Model 1 or Model 2); results for Model 2 are significantly better (Figure 8).

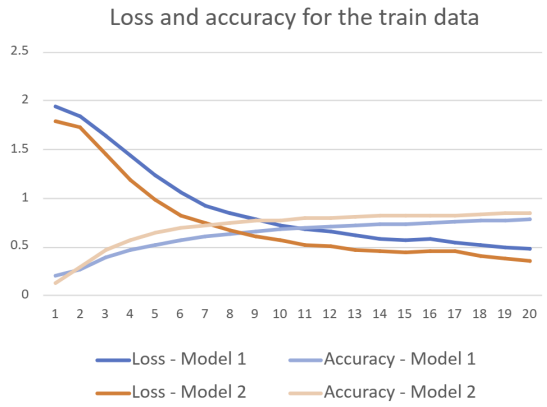

Figure 7: Metrics for test dataset in relation to the number of the epoch

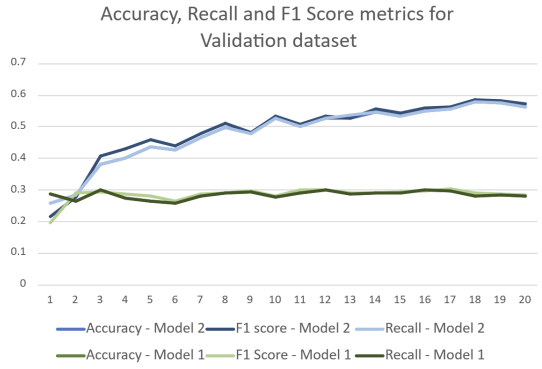

Figure 8: Metrics for validation dataset in relation to the number of the epoch

IUST-NLPLAB at SemEval-2024 Task 9: BRAINTEASER By MPNet (Sentence Puzzle)

Mohammad Hossein Abbaspour, Erfan Moosavi Monazzah, Sauleh Eetemadi
Iran University of Science and Technology
m_abbaspoor80, moosavi_m@comp.iust.ac.ir
sauleh@iust.ac.ir

Abstract

This study addresses a task encompassing two distinct subtasks: Sentence-puzzle and Word-puzzle. Our primary focus lies within the Sentence-puzzle subtask, which involves discerning the correct answer from a set of three options for a given riddle constructed from sentence fragments. We propose four distinct methodologies tailored to address this subtask effectively. Firstly, we introduce a zero-shot approach leveraging the capabilities of the GPT-3.5 model. Additionally, we present three fine-tuning methodologies utilizing MPNet as the underlying architecture, each employing a different loss function. We conduct comprehensive evaluations of these methodologies on the designated task dataset and meticulously document the obtained results. Furthermore, we conduct an in-depth analysis to ascertain the respective strengths and weaknesses of each method. Through this analysis, we aim to provide valuable insights into the challenges inherent to this task domain.

1 Introduction

The remarkable efficacy of language models in navigating complex reasoning tasks, particularly in the realm of vertical thinking, has prompted their exploration in lateral thinking problem domains (Waks, 1997). One such domain, exemplified by the BRAINTEASER task (Jiang et al., 2024), entails a multiple-choice Question Answering framework comprising two distinct subtasks: Sentence-puzzle and Word-puzzle. This paper directs its focus toward the Sentence-puzzle subtask, which hinges on unraveling the intricate nuances of common sense embedded within sentence fragments (Jiang et al., 2023).

Initially, we adopted a zero-shot approach, followed by experimentation with three distinct fine-tuning methodologies tailored for Language Model (LLM) architectures as the backbone. Additionally, we have made our code openly accessible on GitHub[1] to facilitate reproducibility and further research endeavors.

A primary challenge we encountered pertained to the constraint imposed by the dataset size, posing impediments to both fine-tuning procedures and model training from scratch. To mitigate this challenge, we employed various strategies, including the utilization of k-fold cross-validation techniques, to enhance the robustness and generalizability of our approach.

2 Background

In the implementation of the zero-shot method, we employed ChatGPT-3.5, utilizing a consistent prompt template throughout. Conversely, for the fine-tuning process, we adopted a pre-trained sentence embedding technique to map input sentences into meaningful numerical vectors, facilitating subsequent decision-making regarding the provided questions and options.

Furthermore, in our fine-tuning methodologies, we integrated two distinct types of loss functions: Binary Cross-Entropy loss and Triplet loss. The Binary Cross-Entropy loss function operates on the premise of determining whether two sentences coherently match or not. Conversely, the Triplet loss function aims to optimize the proximity between the question and the correct answer while concurrently ensuring a clear distinction between the question and unrelated options.

3 Dataset

The task dataset comprises 507 samples designated for training purposes, with an additional 120 samples allocated for the test set. Notably, the evaluation set encompasses a subset of the training samples, necessitated by data scarcity. Consequently, for two out of the three fine-tuning methods, no

[1] https://github.com/MohammadHAbbaspour/SemEval-2024_task9_BRAINTEASER

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1106–1109

data from the training set were utilized for evaluation. Conversely, the third method, employing the k-fold technique, leveraged the training samples for both the training and evaluation phases.

4 System overview

4.1 Zero Shot

For the zero-shot methodology, we leveraged the ***GPT-3.5-turbo*** model, utilizing a temperature parameter of 0.0. To elicit responses from the model, we employed a consistent prompt template outlined in Table 1. Within this template, we systematically substituted the question and available options with the corresponding tokens. Additionally, we extracted explanations from the model to facilitate a deeper analysis of its reasoning processes.

4.2 Binary Classification

In this approach, we utilized the ***all-mpnet-base-v2*** model (Song et al., 2020; Jayanthi et al., 2021) as the backbone, which was subsequently frozen. Following this, we introduced a trainable layer for inference purposes. The core principle underlying this method involves the transformation of each sample within the dataset, comprising a question and three options (excluding the 'None of the above' option), into three distinct pairs. Each pair encompasses the question alongside one of its options, with a corresponding label indicating whether the option constitutes the correct answer. Consequently, the original training dataset, comprising 507 samples, was expanded to form a new dataset comprising 1521 samples.

Moreover, during the process of feeding sentences into the model, we initially present the question and option to the backbone model. Subsequently, we concatenate the resulting vectors and forward them to the inference layer. For the final decision-making step, we apply a sigmoid function to the output of the inference layer, enabling us to ascertain the consistency between the two sentences by employing a threshold of 0.5.

During the inference stage, we determine the option with the highest score among the three available options.

4.3 Triplet loss

In this approach, our base model and backbone remain consistent with the previous section. However, the data preparation process differs. In the original dataset, each sample consists of a single question alongside three options, one of which is designated as the correct answer. Consequently, for each sample in the original dataset, we generate two samples in the new dataset. As a result, the new dataset comprises 1014 samples, with each sample comprising a question as the anchor, the correct answer as the positive, and a distractor as the negative.

As previously elucidated, the fundamental concept is to minimize the distance between the question and the correct answer while maximizing the distance between the question and unrelated options. To achieve this objective, we integrate a pre-trained sentence embedding model within the inference component.

Within our implementation, the inference component consists of two subparts: one dedicated to the anchor and the other to the positive and negative instances. The anchor component essentially functions as an identity layer, as it cannot glean meaningful insights from a single question. Conversely, the other component aims to discern the disparities between the positive and negative instances by leveraging information from the question. Hence, we concatenate the output of the sentence embedding model for the question and the correct answer to form the positive instance, and likewise for the question and the distractor to constitute the negative instance within the triplet loss framework (see Algorithm 1).

Algorithm 1 Algorithm of the triplet loss

procedure FORWARD($qemb, ansemb, disemb$)
    anchor = $qemb$
    positive = concatenate($qemb$, $ansemb$)
    negative = concatenate($qemb$, $disemb$)

    anchor = anchor_inference(anchor)
    positive = option_inference(positive)
    negative = option_inference(negative)
return anchor, positive, negative

4.4 Triplet loss (K-Fold)

As previously highlighted, the limited availability of data poses a significant challenge in this task. To address this issue, we adopt the K-Fold technique, a commonly employed strategy for mitigating data scarcity. The key components of this approach remain consistent with the previous sections, including the backbone model and the underlying algorithm. However, the distinguishing factor lies

Table 1: Constant template for prompt used in zero-shot

in the training process, wherein multiple models are trained, and the most performant one is selected as the final iteration based on its performance on the evaluation data.

Initially, we partition the training dataset into **k** folds, each serving as the basis for training a distinct model utilizing the Triplet loss. Subsequently, a subset of validation data is extracted from each fold, and the model is trained on the remaining data. Evaluation of each model is then conducted on the evaluation data corresponding to its respective fold. Upon completion of the training process, **k** models are obtained. To select the final model, we employ a sorting criterion based on the following key metric:

$$key = \frac{val\_acc}{train\_loss}$$

This metric encapsulates the trade-off between validation accuracy and training loss. The selection process involves sorting the models based on this key metric and choosing the middle model. This decision is predicated on the objective of maximizing validation accuracy while minimizing training loss. However, it is important to note that models with the highest values of **key** may exhibit signs of overfitting and possess reduced generalization capabilities. Hence, opting for the middle model mitigates the risk of overfitting and ensures enhanced generalization.

5 Experimental setup

5.1 Customized triplet loss

In methodologies utilizing the triplet loss paradigm, the loss function undergoes customization. While the original triplet loss hinges on the calculation of the **Euclidean distance** as a measure of difference, our approach diverges by customizing this metric to **cosine similarity** (see Algorithm 2).

Algorithm 2 Triplet loss, customized by cosine similarity

procedure LOSS($anchor, positive, negative$)
positive_sim = cosine_similarity($anchor$, $positive$)
negative_sim = cosine_similarity($anchor$, $negative$)
loss = $negative\_sim$ - $positive\_sim$ + $margin$
return loss

The maximum value of cosine similarity between two vectors is 1 which means two vectors are the same, and the minimum value between them is -1 which means they are different. So:

$$-2 \leq positive\_sim - negative\_sim \leq 2$$

We add the **margin=2** value to the loss for shifting it in positive numbers:

$$0 \leq positive\_sim - negative\_sim + margin \leq 4$$

Hence, if two vectors are the same it means the loss is equal to 0 and if two vectors are opposite it means the loss has its max value.

5.2 Hyperparameters

For the training of the discussed models, we scrutinized the hyperparameters outlined in Table 2.

6 Results

We conducted evaluations of the aforementioned methods on the test set, and the results are presented in Table 3. It is evident that the zero-shot method exhibits the best performance on the

	epochs	learning rate	batch size	validation size	k
Binary classification	10	0.001	4	-	-
Triplet loss	10	0.001	16	-	-
K-Fold	10	0.001	16	20	3

Table 2: Hyperparameters of models while training

	S_ori	S_sem	S_con	S_ori_sem	S_ori_sem_con	S_overall
Zero-shot	**0.7**	0.575	0.575	0.55	0.35	0.61
Binary classification	0.625	0.625	0.525	0.625	0.475	0.5916
Triplet loss(modified system)	0.65	**0.65**	**0.625**	**0.65**	**0.525**	**0.641**
K-Fold	0.6	0.6	**0.625**	0.6	0.5	0.608

Table 3: Comparison of our results

Original sentences. However, its efficacy diminishes notably when applied to other categories such as **Semantic**, showcasing a significant disparity compared to its performance on the **Original sentences**. Conversely, all of our fine-tuning methods demonstrate comparable performance across all categories.

Among our fine-tuning methodologies, the **Triplet loss** approach stands out with the most impressive performance, achieving the highest **Overall** score among all methods.

The uniformity in scores observed with the **Triplet loss** method suggests that it does not exhibit bias towards specific words or segments of the sentence; rather, it considers the entire sentence holistically. This is in contrast to the zero-shot method, where significant discrepancies exist among its scores. However, it's worth noting that the performance of our fine-tuning models could potentially improve with a larger volume of data.

7 Conclusion

In this paper, we have presented four distinct methodologies for the BRAINTEASER task, a novel challenge involving common sense reasoning and sentence puzzle solving. We have evaluated our methods on the task dataset and compared their performance across different categories. Our results show that the zero-shot approach, based on GPT-3.5-turbo, achieves the highest score on the original sentences, but fails to generalize well to other categories. On the other hand, our fine-tuning methods, based on MPNet and various loss functions, demonstrate more consistent and robust performance across all categories, with the triplet loss approach achieving the best overall score. We have also employed the K-Fold technique to mitigate the data scarcity issue and enhance the generalization capability of our models. Through our analysis, we have provided valuable insights into the strengths and weaknesses of each method, as well as the challenges inherent to this task domain. We hope that our work will inspire further research on this novel and intriguing problem of common sense reasoning and sentence puzzle solving.

Abstract

Large language models (LLMs) are artificial intelligence systems that can generate text, translate languages, and answer questions in a human-like way. While these advances are impressive, there is concern that LLMs could also be used to generate fake or misleading content. In this work, as a part of our participation in SemEval-2024 Task-8, we investigate the ability of LLMs to identify whether a given text was written by a human or by a specific AI. We believe that human and machine writing style patterns are different from each other, so integrating features at different language levels can help in this classification task. For this reason, we evaluate several LLMs that aim to extract valuable multilevel information (such as lexical, semantic, and syntactic) from the text in their training processing. Our best scores on SubtaskA (monolingual) and SubtaskB were 71.5% and 38.2% in accuracy, respectively (both using the ConvBERT LLM); for both subtasks, the baseline (RoBERTa) achieved an accuracy of 74%.

1 Introduction

Large language models (LLMs) have become widely available and easily accessible, leading to an increase in machine-generated content across diverse platforms including question-and-answer forums, social media platforms, educational resources, and academic settings.

Recent advancements in LLM technology, exemplified by models like ChatGPT and GPT-4, produce coherent responses to a vast majority of user inquiries, making them increasingly appealing for replacing human labor in various applications. However, this accessibility has raised concerns about potential misuse, such as generating fake news, financial services industry, legal domain, and disruptions in educational settings. Given the challenge humans face in distinguishing between machine-generated and human-written text, there is a pressing need to develop automated systems capable of identifying machine-generated content to mitigate the risks associated with its misuse.

Motivated by these challenges, SemEval-2024 Task-8 (Wang et al., 2024) offers three subtasks over two paradigms of text generation: (1) full text when a considered text is entirely written by a human or generated by a machine; and (2) mixed text when a machine-generated text is refined by a human or a human-written text paraphrased by a machine.

These three subtasks are composed in the following way: Subtask A is a binary classification task that focuses on identity if a given text was written by a human or a machine; it is split into monolingual (English) and multilingual (Arabic, Russian, Chinese, etc). Subtask B is a multi-class classification task that aims to identify which specific LLM generates a given text among six different known options: Human-made, ChatGPT, Cohere, DaVinci, Bloomz, and Dolly. Finally, Subtask C, given a mixed text, where the first part is human-written and the second part is machine-generated, determines the boundary, where the change occurs.

We tackled two of these three subtasks: Subtask A (monolingual) and Subtask B. We applied fine-tuning of four LLMs (described in the following section) that included structural information in their pre-training. These models have proven their efficiency in multiple Natural Language Understanding (NLU) tasks, such as question-answer entailment, paraphrasing, and textual similarity. We aim to test the efficiency in machine-text detection by comparing the results of given baselines for each subtask (A and B) with our fine-tuning LLMs with different approaches for the implementation of structural information.

Our scores show a modest performance related to the final ranking (especially in Subtask B), but, based on the analysis of the results We observe that all of these LLMs used in this research, struggle

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1110–1114

to classify human text, meanwhile, they achieve a good performance classifying machine text.

This paper is structured as follows: Section 2 summarizes related works on machine text generation. Section 3 describes the dataset used for the task. Section 4 presents the system overview and the experimental setup. Section 5 and 6 shows the results and conclusions, respectively.

2 Related Work

In recent years, many interesting shared tasks that related to the automatic detection of AI-generated text. Besides the SemEval task8, one of the most popular and challenging tasks called Autextification: Automated Text Identification (Sarvazyan et al., 2023), aims to address the detection of content created by text generation models in English and Spanish.

To mention a few interesting research works related to Autextification-2023, the system titled "I've Seen Things You Machines Wouldn't Believe: Measuring Content Predictability to Identify Automatically Generated Text" (Przybyła et al., 2023) achieves the best performance among the submissions in subtask 1 (differentiating between human- and machine-generated text), both for English and Spanish. Their model focuses on assessing the "predictability" of given text by multiple LLMs, leveraging features related to grammatical accuracy, word frequency, and linguistic patterns, along with a fine-tuned LLM representation. Another remarkable work titled "Generative AI Text Classification using Ensemble LLM Approaches" (Abburi et al., 2023), proposes an ensemble neural model that leverages probabilities generated by different pre-trained LLMs as features for a Traditional Machine Learning (TML) classifier (their model ranked in first place in subtask 2 for English and Spanish).

On the other hand, pre-training LLMs with structural information enrich the learning process with contextual and syntactic cues. These cues encompass sentence structure, paragraph organization, grammatical rules, and broader linguistic patterns. Fine-tuning LLMs with such structural knowledge enhances their ability to both comprehend and generate text that adheres to human-like writing styles and conventions.

This approach has been explored in multiple ways; so now we briefly describe the approach taken by the models we used: ERNIE model (Sun et al., 2021) implements an implicit knowledge of syntactic information through multiple levels of masking (token, phrase, and entity level). SpanBERT model (Joshi et al., 2020) masks random spans of contiguous tokens and trains to predict every token for each span instead of just masking and predicting each token. ConvBERT model (Jiang et al., 2020) substitutes attention blocks for span-based dynamic convolutions capable of storing structural information in the generated kernels. Finally, XLNet (Yang et al., 2019), this LLM does not corrupt the text with masking but rather utilizes all the multiple permutations of tokens in a given sentence during the training process.

3 Dataset

The data provided for SemEval Task 8 is an extension of the M4 dataset (Wang et al., 2023). This is a large-scale benchmark, which is a multi-generator, multi-domain, and multi-lingual corpus for machine-generated text detection. This extensive M4 corpus encompasses texts from various domains, including news articles, programming code, and fictional narratives. Additionally, the M4 corpus incorporates texts in numerous languages, such as English, Spanish, and Chinese. This diversity in both domain and language coverage contributes to the effectiveness of M4 in effectively identifying machine-generated text (see figure 1).

For machine generation, it prompts the following multilingual LLMs: GPT-4, ChatGPT, GPT3.5 (tex-davinci-003), Cohere, and Dolly-v2. The models are asked to write articles given a title (Wikipedia), abstracts given a paper title (arXiv), peer reviews based on the title and the abstract of a paper (PeerRead), news briefs based on a title (news), also to summarize Wikipedia articles (Arabic), and to answer questions (Reddit).

Figure 1: Statistics about our M4 dataset, which includes non-parallel human data and parallel human and machine-generated texts.

4 System overview

Our system evaluates different LLMs that integrate features at different language levels (such as lexical, semantic, and syntactic) with the idea of extracting human and machine writing style patterns and being able to distinguish text from each other. For this reason, We applied a fine-tuning process using the four LLMs mentioned before: ERNIE[1], SpanBERT[2], ConvBERT[3], and XLNet[4] (using the Hugging Face library) for Subtask A Monolingual and Subtask B.

Starting with the data partition process, We used the same partition proposed by the organizers in the baseline code for both tasks. The training dataset was split into the train (80%) and validation (20%) for the fine-tuning process and the development dataset was used to measure the accuracy of each model with unknown data. Finally, the test dataset was only used to rank the models and verify the results.

Afterwards, in the fine-tuned process we tried with different hyperparameters on batch size (16, 32), learning rates (2e-5, 5e-5), random seed (0, 42), epochs (3, 5), and a weight decay of 0.01. Along with these params configurations, we used the Trainer, AutoModel, and AutoTokenizer classes from the Transformers. Each sequence was padded and truncated at 512 after tokenization due to the constraints of some of the models we used (most of them had a limit in the allowed length of the input sequence). These hyperparameters were chosen based on empirical experiments and hyperparameter tuning to achieve the best performance on our validation dataset. For the evaluation we computed macro-F1, micro-F1, and accuracy scores; being the last ones used by those organized to evaluate the final ranking.

Finally, in the test process, the output predictions for the model (logits) serve as an input for a Softmax function and then apply an argmax function in order to get the final prediction class.

5 Results

After the fine-tuning process using the training dataset, we measured the performance of each LLMs on the test set (development set provided) for Subtask A (Monolingual) and Subtask B (using the respective training and test data provided).

Table 1 shows the evaluation results for Subtask A (Monolingual) using the macro-F1, micro-F1, and accuracy measures (obtained from the score scripts provided for the organizers). For the Validation set, ERNIE's model outperforms the other LLMs across all metrics achieving 79.4 % in accuracy, but, ConvBERT and SpanBERT closely follow with 77.1% and 78.8% respectively.

For subtask A (Monolingual), We submitted our two best prediction results to the Codabench platform: ERNIE and ConvBERT LLMs. Table 3 shows the final ranking for this Subtask, we ranked place 87 out of 137 with an accuracy score of 71.5% (obtained by the ConvBERT LLM). The best team (safeai) obtained an accuracy score of 96.8% and the baseline (RoBERTa LLM) achieved 88.4%. Table 1 also shows the results evaluating these models in the test set (post-submission, using gold labels released by organizers); in this case, our best model was the ConvBERT with 77.6% in accuracy.

On the other hand, Table 2 shows the performance metrics obtained for SubTask B. In the Validation set, the SpanBERT model outperforms the other LLMs across all metrics achieving 66.8% of accuracy, 66.8% of micro-F1, and 63.4% of macro-F1 score. However, the ERNIE model closely follows with 65.4% accuracy; Then, we obtained the final predictions from the validation dataset using these fine-tuned trained models and uploaded to Codabench platform one submission based on the ConvBERT LLM results. Table 2 shows the final ranking for Subtask B, where we obtained place 67 out of 77 with an accuracy score of 38.2% (obtained by the ConvBERT LLM). In this case, the best team (tmarchitan) achieved an accuracy score of 86.9% and a baseline (RoBERTa LLM) of 74.6%. Finally, as in Subtask A, We re-evaluated these models on the test set released (post-submission), and, our best model was the XLNET with 65.2% in accuracy (second part in table 2).

On the other hand, figure 2 and figure 3 show the Confusion Matrix (CM) results for Subatsk A Monolingual and Subtask B, respectively. The CM for Subtask A across all models, presents a large confusion in classifying human text (True Positive vs False Positive) compared to the performance achieved for the machine-generated text (True Negative vs False Negative). For human text classification, the ConvBERT LLM was the best model

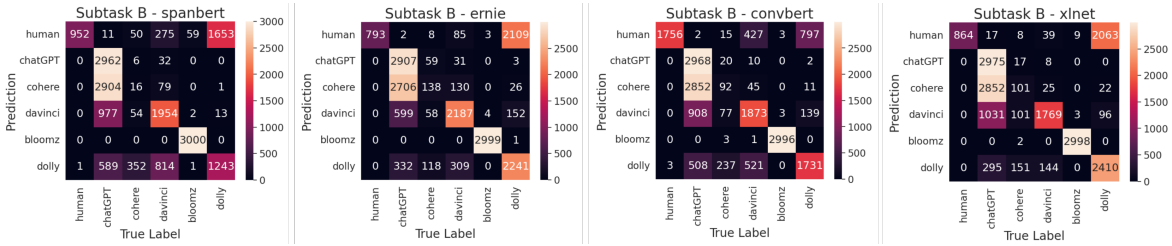

Figure 3: Subtask B. Confusion Matrix results for each LLM applied on the test set (post-submission).

getting 65% correct and 35% fail, meanwhile, the ERNIE LLM obtained a poor performance of 50% correct and 50% fail. Related to machine-generated text classification, all models performed similarly, obtaining less confusion: around 90% correct and 10% fail. Furthermore, CM for Subtask B in general struggles to classify human texts and presents a large confusion with dolly machine model across all LLM; the best performance was classifying chatGPT and bloomz text, getting around 98% correct in both, meanwhile, cohere and dolly machine obtained a poor classification performance.

Finally, We would like to mention that, due to some technical issues in our servers, We did not submit the models with the best model scores in the validation stages for both subtasks. For this reason,

77	saibewaraditya	0.153

Table 4: Final ranking per team in Subtask B

We reported different scores in the final submission compared to our scores in the Test evaluation (post-submission, with gold labels).

6 Conclusion

We applied a fine-tuning process using four LLMs: ERNIE, SpanBERT, ConvBERT, and XLNet. In general, this LLM aims to extract lexical, semantic, and syntactic information from the text. We obtained comparable results with the baselines reported (initially), but, below compared to those in the first positions.

For future work, it could be interesting to prove more LLMs that focus on multilevel language and stylistic features; also apply a more robust finetuning process to evaluate more hyperparameters; and finally try a different approach based on text graph called Graph Neural Networks.

Abstract

The Emotion Recognition in Conversation subtask aims to predict the emotions of the utterance of a conversation. In its most basic form, one can treat each utterance separately without considering that it is part of a conversation. Using this simplification, one can use any text classification algorithm to tackle this problem. This contribution follows this approach by solving the problem with different text classifiers based on Bag of Words. Nonetheless, the best approach takes advantage of the dynamics of the conversation; however, this algorithm is not statistically different than a Bag of Words with a Linear Support Vector Machine.

1 Introduction

Sentiment analysis has been very useful for emotion detection in digital text. For example, in the analysis of a customer review, a sentiment analysis system can find whether the review is positive or negative. Today, this way of finding out what the sentiment expressed in the digital text has been popular due to its potential to have a feeling over what people are writing about. Recent studies have been conducted towards sentiment analysis, not only in a one-party text (text written by one person/source) but also within a multi-party conversational text (Hazarika et al., 2018)(Majumder et al., 2018)(Poria et al., 2019), known as Emotion Recognition in Conversation (ERC). ERC refers to the emotion detection of each of the phrases/utterances within a dialogue. For instance, in a conversation between two people (speaker 1, SP1, and speaker 2, SP2) saying the following, SP1: "I had an awful day", SP2 replies "Oh no, what happened?". SP1 may have a "sad" emotion and SP2 may be also "sad". However, following the conversation SP1 answers "Somebody ate my sandwich!" and SP2 replies "I can make you a new one right now!)". This answer provokes a change in the emotion of SP1 to "joy". The aim of ERC is precisely the detection of speakers' emotional changes involved within a dialogue. ERC research has become popular due to the vast amount of conversation sources in social media such as opinion mining in chat history, social media threads, debates, and understanding consumer feedback in live conversations, among others (Majumder et al., 2018).

To date, several studies have investigated ERC using different approaches (Hazarika et al., 2018)(Majumder et al., 2018) as it is summarized by (Poria et al., 2019). (Hazarika et al., 2018) presented a framework for emotion detection in conversations using a recurrent neural network (RNN) based memory network with multi-hop attention modeling. (Majumder et al., 2018) is a method based on an RNN that maintains information of each party separately and this information is used for emotion classification. Most recent studies have been focused on more elaborated proposals about emotion detection based on the context and the common sense knowledge within the conversation (Tu et al., 2022). Recently, (Jiang et al., 2024) presented a self-supervised model to better understand the semantics within the text associated with the order of the utterances.

In this paper, we present a model given the *Task 10: Emotion Discovery and Reasoning its Flip in Conversation(subtask 1)* of the SemEval-2024 workshop (Kumar et al., 2024) which consists of applying *Emotion Recognition in Conversation (ERC)* to Hindi-English code-mixed conversations. We propose to solve the challenge as a classification problem, using a Bag of Words (BoW) for the representation. Despite the usage of BoW is not so common anymore due to the current usage of more sophisticated techniques as deep learning, our work is built on the previous work presented in (Graff

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1115–1120
June 20-21, 2024 ©2024 Association for Computational Linguistics

et al., 2023a,b), leading to a unique and customized BoW for solving this specific problem.

The rest of the paper is organized as follows: Section 2 presents the background; Section 3 introduces a description of the model; finally Section 4 shows a brief analysis of the results and Section 5 concludes the paper.

kumar2024semeval

2 Background

Emotion recognition has been a popular research field using Artificial Intelligence. According to (Saxena et al., 2020), several methods are applied for Emotion recognition including facial expression recognition, physiological signals recognition, speech signals variation, and text semantics, among others. Specifically, in this work, we focus on emotion recognition written in a digital text. Previously, emotion recognition in the text has been focused on the selection of emotional keywords (Seol et al., 2008) and the classification of their emotional state within a conversation. However, this keyword-based method presented some limitations as ambiguity and the lack of semantic and syntactic information. Emotion recognition in a conversation has shown to be a challenge due to the way emotions change over time. Other machine learning method have been applied as ICON (Hazarika et al., 2018) and DialogueRNN (Majumder et al., 2018), both using RNN. ICON (Hazarika et al., 2018) generates memories from the conversation to generate a good context for predicting emotions within a conversational video. DialogueRNN (Majumder et al., 2018) presented a model involving three aspects in a conversation: the speaker, the context of the previous phrases, and the emotion, according to them, taking into account these key aspects leads to a much better context representation. Commonsense knowledge is something difficult to pass over a machine, for that reason new approaches added external knowledge to help the machine to have a context (Speer et al., 2018)(Cambria et al., 2022) for solving new challenges as having an empathetic dialogue system (Ma et al., 2020).

3 System overview

The subtask Emotion Recognition in Conversation can be posed as a supervised learning problem. Without considering that emotions are part of a conversation, the problem can be seen as finding the mapping between an utterance and its associated emotion, i.e., it is a classification problem. In order to use the majority of classifiers, one needs to transform the utterance into a format amenable to the classifier selected. Generally, the representation acceptable for the majority of traditional classifiers is vectors.

Perhaps one of the most studied representations that transform a text into a vector is the Bag of Words (BoW); it is not so common anymore because it has been overcome by the use of deep learning techniques such as the attention mechanism (Vaswani et al., 2017). However, our participation is based solely on the use of BoW, following a similar approach used in previous competitions see (Graff et al., 2023a,b), and complementing it with an approach tailored for this specific subtask.

The realm of the BoW representation is that each token t of a text is associated with a vector $\mathbf{v_t} \in \mathbb{R}^d$. In this contribution, the i-th component of $\mathbf{v_t}$ corresponds to the token's Inverse-Document-Frequency (IDF) estimated in a collection of Hindi tweets (9.5 million), and the rest of the components of $\mathbf{v_t}$ are zero, i.e., $\forall_{j \neq i} \mathbf{v_t}_j = 0$. The set of all tokens is fixed, and these correspond to the vocabulary. The vocabulary is fixed to containing only $2^{17} = d$ elements, and this corresponds to the most frequent tokens found in the collection of tweets. Furthermore, given that only one component of each vector is different from zero, the set of all the vectors constituted a basis, and each text is represented in this vector space. Additionally, any token that is not found in the vocabulary is discarded from the representation.

Using this notation, a text x is represented by the sequence of its tokens, i.e., $(t_1, t_2, \ldots)$; the sequence can have repeated tokens, e.g., $t_j = t_k$. Then each token is associated with its respective vector $\mathbf{v}$ (keeping the repetitions), i.e., $(\mathbf{v_{t_1}}, \mathbf{v_{t_2}}, \ldots)$. Finally, the text x is represented as:

$$\mathbf{x} = \frac{\sum_t \mathbf{v_t}}{\|\sum_t \mathbf{v_t}\|}, \tag{1}$$

where the sum goes for all the elements of the sequence, $\mathbf{x} \in \mathbb{R}^d$, and $\|\mathbf{w}\|$ is the Euclidean norm of vector $\mathbf{w}$. The term frequency is implicitly computed in the sum because the process allows token repetitions.

The second representation is inspired by a self-supervised technique, particularly the procedure of masking tokens in a text and then developing an algorithm to predict the masked tokens.

The idea is pursued by creating M binary classification problems where the task is to predict the presence of a particular token; in this case, the tokens are words (defined as a string surrounded by spaces or punctuation symbols) or emojis. The words are selected based on their frequency; the most frequent words are not considered, and the words considered started when the plot of rank vs. frequency settles, i.e., it is when the flat part starts. On the other hand, all the emojis are considered. However, only the words and emojis where there are more than 1024 positive examples in the collection are kept. In total, there are 176 tweets and 2048 words.

There are 2,224 binary classification problems; each is solved using a BoW representation where the classifier is a Linear Support Vector Machine. Consequently, there are M binary text classifiers, i.e., $(c_1, c_2, \ldots, c_M)$. The utterance is represented using the decision values of the M binary classifiers; that is, the text lives in $\mathbb{R}^M$. As can be seen, each component is associated with either a word or emoji, and its value indicates the likelihood of its presence in the text. We refer to this representation as Dense. Finally, the classifier used with the dense representation is again a Linear Support Vector Machine.

After the competition ended, we decided to include in the comparison a procedure to combine (using Stacking (Graff et al., 2020)) the BoW and Dense representation, namely StackBoW. The idea is to make a convex combination of the class probabilities predicted by these two classifiers. The approach is to use the training set with k-fold cross-validation to estimate the decision function of these two classifiers on the training set. These decision functions are then transformed with softmax to obtain probabilities, and then an optimizer is used to estimate the convex combination. There are 8 emotions, so the optimizer needs to find 8 coefficients, each corresponding to a class. For example, let $\mathbf{p}_b \in \mathbb{R}^8$ be the probability given by the BoW classifier, $\mathbf{p}_d \in \mathbb{R}^8$ corresponds to the dense classifier, and $\beta \in \mathbb{R}^8$ are the estimated coefficients, then the prediction of the StackBoW is $\beta \odot \mathbf{p}_b + (1-\beta) \odot \mathbf{b}_d$ where $\odot$ is the pointwise product.

The last system, INGEOTEC, corresponds to an approach that takes advantage of the conversation dynamics. It considers the current utterance, the previous, and the next. In the extremes, either the next or the previous are empty utterances. Let $\mathbf{x}$, $\mathbf{x}_p$, and $\mathbf{x}_n$ be the dense representation, then it is computed the similarity between the current utterance ($\mathbf{x}$) and the previous and next utterance, as follows: $s_p = \rho \odot \mathbf{x} \cdot \mathbf{x}_p$, and $s_n = \rho \odot \mathbf{x} \cdot \mathbf{x}_n$. At first, ρ is a vector of ones, so s_p and s_n are the cosine similarity because the dense representations have unit length.

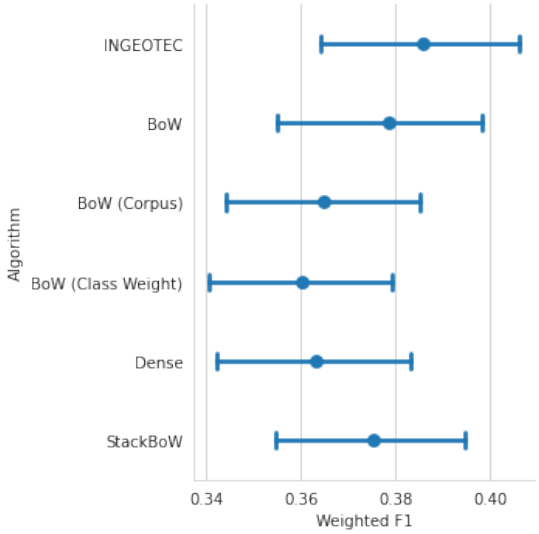
Using s_p and s_n, the contribution of each representation is computed by converting the similarity to a probability; this is done with the softmax as $\mathbf{s} = \mathsf{softmax}(1, s_p, s_n)$. Using $\mathbf{s}$ another representation is created which is the convex combination between $\mathbf{x}$, $\mathbf{x}_p$, and $\mathbf{x}_n$, i.e., $\mathbf{x}_s = \mathbf{s}_1\mathbf{x} + \mathbf{s}_2\mathbf{x}_p + \mathbf{s}_3\mathbf{x}_n$. Using $\mathbf{x}$ and $\mathbf{x}_s$, the dense representation used is the concatenation of them, i.e., $\mathbf{w} = [\mathbf{x}, \mathbf{x}_s]$. The final dense representation, $\mathbf{w}$, is used in a linear equation combined with softmax to predict the probabilities of each class. The probabilities obtained in the previous step are combined, using a convex combination, with the decision function of a BoW classifier (transformed with softmax). It is important to mention that the parameters, ρ, the coefficients to create the final convex combination, and the parameters of the linear equation of the dense representation $\mathbf{w}$ are optimized with gradient descent.

4 Results

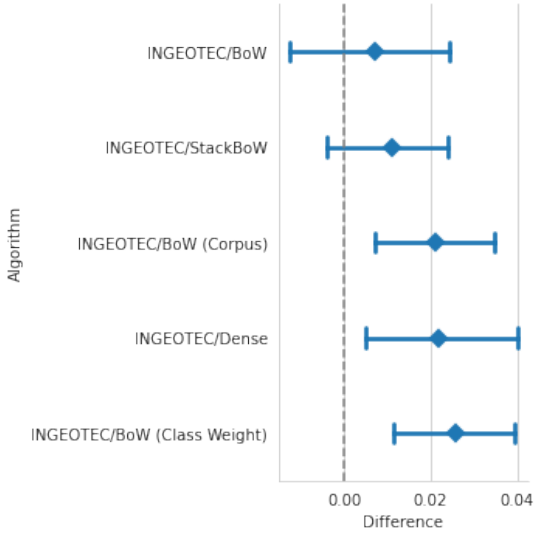
The systems' performance analysis starts with the information presented in Table 1. The table presents the performance, in terms of F1 scores per class, of the BoW (Class Weight) classifier, the Dense classifier, and their convex combination, namely StackBoW. The BoW (Class Weight) classifier is identified using the term *Class Weight* to indicate that the Linear Support Vector Machine was optimized by giving a weight inversely proportional to the class frequencies to each sample. This configuration is also used in the Dense classifier.

Table 1 is organized in three row blocks. The first one identified with the parameter β presents the coefficients used to make the convex combination of BoW and Dense. The second-row block contains the performance (F1 scores per class) estimated in k-fold cross-validation in the training set, and the third block corresponds to the performance in the test set. It can be observed from the table that the performance of StackBoW in the k-fold cross-validation is better than that of its components. This improvement is not reflected in all the cases in the test set; nonetheless, the convex combination is better than its components in the weighted

F1 score.



(a) Weighted F1 score and its estimated confidence intervals (90%) for the different systems.



(b) Difference in performance and its confidence interval (90%) between the best system (namely, INGEOTEC) and the rest.

Figure 1: Analysis of the weighted F1 score in the test set obtained by different algorithms. The dashed line corresponds to zero. An interval crossing the dashed line indicates the difference is not statistically significant with confidence of 90%.

Figure 1 complements the information presented in Table 1. Figure 1a presents the performance using the weighted F1 score on the test set for all the systems tested and its associated 90% confidence interval (the confidence intervals were estimated using the procedure described in (Nava-Muñoz et al., 2023)). The figure also includes the difference in performance (Figure 1b) between the best-performing systems, namely INGEOTEC, and the rest of the systems. The difference in performance shows the 90% confidence interval. The performance of INGEOTEC is 0.3861. The comparison figure includes a dash line that it is set in zero, consequently any confidence interval that intersect with the dash line indicates that the difference in performance is not statistical significant. Using this information, it can be observed that INGEOTEC is similar to the BoW classifier –it is worth mentioning that BoW weights all samples with 1, which makes it different and BoW (Class Weight)– and StackBoW.

5 Conclusion

We have described the algorithms tested on the Emotion Recognition in Conversation task. Most of the approaches treat this problem by looking at each utterance separately. The only system taking advantage of the dynamic of the conversation is the INGEOTEC system; this system is the one having the best performance. Nonetheless, as Figure 1b shows, it is not statistically different than a BoW classifier. The BoW classifier is the simplest model one can start experimenting with.

Appendix A: Library Usage

This appendix aims to illustrate the use of BoW, Dense, and StackBOW that are implemented using EvoMSA (`evomsa.readthedocs.io`) (Graff et al., 2020). The first step is to install the library, which can be done using the Anaconda package manager with as follows:

```
conda install -c conda-forge EvoMSA
conda install -c conda-forge IngeoML
```

Once EvoMSA is installed, one must load a few libraries.

```
from EvoMSA import BoW, DenseBoW
from EvoMSA.back_prop import StackBoW
from IngeoML.utils import soft_comp_weighted_f1,
    support
```

The BoW classifier is trained with the following instruction; it is assumed that the list D contains as elements dictionaries with two keys: text and klass; the latter is used as the emotion.

```
bow = BoW(lang='hi').fit(D)
```

Let us assume that the test set is in a list of dictionaries, G, where the utterance is in the key text. Then, the following instruction is used to predict the emotion of each utterance.

```
emotions = bow.predict(G)
```

BoW (Class Weight) is initialized with the following instructions.

```
kwargs = dict(dual='auto', class_weight='balanced')
bow = BoW(lang='hi',
          voc_size_exponent=17,
          estimator_kwargs=kwargs).fit(D)
```

On the other hand, the Dense classifier is trained using the following command.

```
kwargs = dict(dual='auto', class_weight='balanced')
dense = DenseBoW(lang='hi',
                 voc_size_exponent=17,
                 estimator_kwargs=kwargs).fit(D)
```

The StackBoW classifier is trained with the next step. Finally, all the classifiers have the method *predict* to forecast the emotions of any given utterance.

```
kwargs = dict(class_weight=support)
stack_bp = StackBoW(lang='hi',
                    deviation=soft_comp_weighted_f1,
                    voc_size_exponent=17,
                    optimizer_kwargs=kwargs).fit(D)
```

IIMAS at SemEval-2024 Task 9: A Comparative Approach for Brainteaser Solutions

Abstract

In this document, we detail our participation experience in SemEval-2024 Task 9: BRAINTEASER-A Novel Task Defying Common Sense. We tackled this challenge by applying fine-tuning techniques with pre-trained models (BERT and RoBERTa Winogrande), while also augmenting the dataset with the LLMs ChatGPT and Gemini. We achieved an accuracy of 0.93 with our best model, along with an F1 score of 0.87 for the Entailment class, 0.94 for the Contradiction class, and 0.96 for the Neutral class.

1 Introduction

The brainteasers are problems or puzzles, typically designed to be solved for amusement. To solve brainteasers is necessary the lateral and vertical think, so interpret the context itself contained in them. The SemEval 2024 BRAINTEASER: A Novel Task Defying Common Sense task poses a set of brainteasers and their answers, divided into two types: Sentence Puzzles and Word Puzzles, both in the English language and require an understanding of common sense and the ability to overwrite them through unconventional thinking that distinguishes these defaults from fixed constraints. In Sentence Puzzles, a challenge is presented that defies common sense focused on sentence fragments. In Word Puzzles, the answer challenges the predefined meaning of the word and focuses on the letter composition of the target question (Jiang et al., 2024).

Solving brainteasers requires an unconventional or out-of-the-box approach, which stimulates lateral thinking. This style of thinking is crucial for discovering ingenious solutions to complex problems and for considering situations from multiple perspectives. This type of thinking must be integrated into language models, as it enables them to provide diverse perspectives and apply them to more complex aspects of language, such as understanding metaphors, idioms, or ambiguities.

This paper documents the participation of the IIMAS team at SemEval-2024 task 9, where the resolution of brainteasers was approached using a classification framework. Our strategy relied on fine-tuning techniques applied to pre-trained models using a transformer architecture. In addition to describing our approach, we also analyze the challenges encountered during the process and discuss potential areas for improvement in future research. This paper sheds light on the application of cutting-edge techniques in natural language processing to tackle comprehension and reasoning problems, such as brainteasers, and provides valuable insight into the performance and limitations of our approach in this specific context. During the evaluation phase, the results placed us at the 33th out of 50 participants.

2 Background

We examine various methodologies for solving brain teaser challenges. In this overview, we present some of these approaches. Mitra and Baral (2015) focused on solving logic grid puzzles. Initially, they identified keywords as entities and the relationships between them. Subsequently, they constructed a pair of Answer Set Programming rules. These rules served as inputs for a logic reasoner named Logicia, equipped with a predefined set of predicates. Their model demonstrated an impressive 85.05% accuracy in classifying constituents and successfully solved 71 out of 100 test puzzles. The RIDDLESENSE challenge, introduced by Lin et al. (2021), aims to explore the task of answering riddles. This challenge presents participants with a multiple-choice question-answering scenario, where a model must select one answer from a set of five choices (one correct answer and four distractors) in response

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1121–1126

to a given riddle question. The dataset comprises 5.7k meticulously curated examples. In their experiments, researchers employed various approaches including fine-tuning pre-trained language models such as BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), and ALBERT (Lan et al., 2020), alongside fine-tuning a text-to-text QA Model (Khashabi et al., 2020). Their methodology involved concatenating the question with the answer choices. During evaluation, three native English speakers achieved an average accuracy of 91.3%, with the best-performing model achieving 68.8% accuracy.

Current language models can be evaluated in what is known as vertical or convergent thinking and perform well; however, the existence of lateral or divergent thinking in the human mind leads to considering the option of evaluating these same models in this way of thinking. This idea is taken by Huang et al. (2023) to propose a way to evaluate Large Language Models (LLMs) in Lateral Thinking Puzzles, also known as situations puzzles. This type of puzzle involves a host who knows the complete truth but gives the player a story lacking certain information. The player, through questions that are only answered with Yes or No, must deduce the whole truth. The GTP-4 model from OpenAI had the best performance in this type of puzzle according to the proposed evaluation.

Tong et al. (2023) also identified the need for non-linear thinking in LLMs, so in their work, they proposed Inferential Exclusion Prompting (IEP) inspired by the method of elimination thinking. This proposal consists of, given a problem, the IEP instructs the LLMs to plan different responses and then eliminate those options that are contradictory or irrelevant. The IEP was evaluated for various problems: parajumbles, riddles, puzzles, brain teasers, and critical reasoning queries against Chain-of-Thought (CoT) prompting.

3 System overview

The data used in this task were provided by Jiang et al. (2023), comprising a set of 507 brainteasers for sentence puzzles and 396 brainteasers for word puzzles. Each of these brainteasers includes one correct answer alongside three distractors. This dataset showcases the complexity of the posed problems, suggesting that they can be effectively addressed through a natural language understanding (NLI) approach.

In this context, the BART model (Lewis et al., 2019) serves as an option for resolving Multi-Genre Natural Language Inference (MultiNLI) problems, where a model's ability to determine which of the proposed premises is true relative to a hypothesis is evaluated using a multi-choice approach. We apply zero-shot classification to the BART model, and as result, we got a low performance as we describe in Table 1.

Table 1: Multi-choice approach accuracy.

Data	Accuracy
SP-train	0.2879
WP-train	0.2449

Given the suboptimal performance of zero-shot models in multichoice tasks, the decision was made to fine-tune a model. One initially discarded proposal was to utilize the MultiNLI dataset (Williams et al., 2018)[1] for fine-tuning, as the BART model[2] is trained on this data and yielded unsatisfactory results. Therefore, the decision was made to work with data provided by the competition or data sharing of a similar nature.

To accomplish this, data transformation was necessary to operate under a classification approach, where each question serves as a value for the premise feature, and each answer is treated as a value for the hypothesis feature, these being the indicators: distractor1, distractor2, distractor(unsure), and correct answer. Each pair of data is assigned a class label. For fine-tuning bert-base-uncased, three different classes are managed. For sentence pairs containing distractor1 and distractor2, the corresponding label is Contradiction; for distractor(unsure), it is Neutral, and for the correct answer, it is Entailment (see Fig 1). For the RoBERTa Winogrande model Sakaguchi et al. (2019), it is expected that the resulting sentence from concatenating the premise with the hypothesis will have a boolean value depending on the dependencies of the hypothesis concerning the premise. Therefore, the labels used are False and True. Both models utilize the following hyperparameter values: batch_size=32, epochs=3, learning_rate=2e-5, as well as a split of the dataset with 80% for training and 20% for evaluation purposes.

In order to enhance the performance of the models, we leveraged the unique capabilities of large language models (LLMs). We employed ChatGPT

[1]https://huggingface.co/datasets/multi_nli
[2]https://huggingface.co/facebook/bart-large-mnli

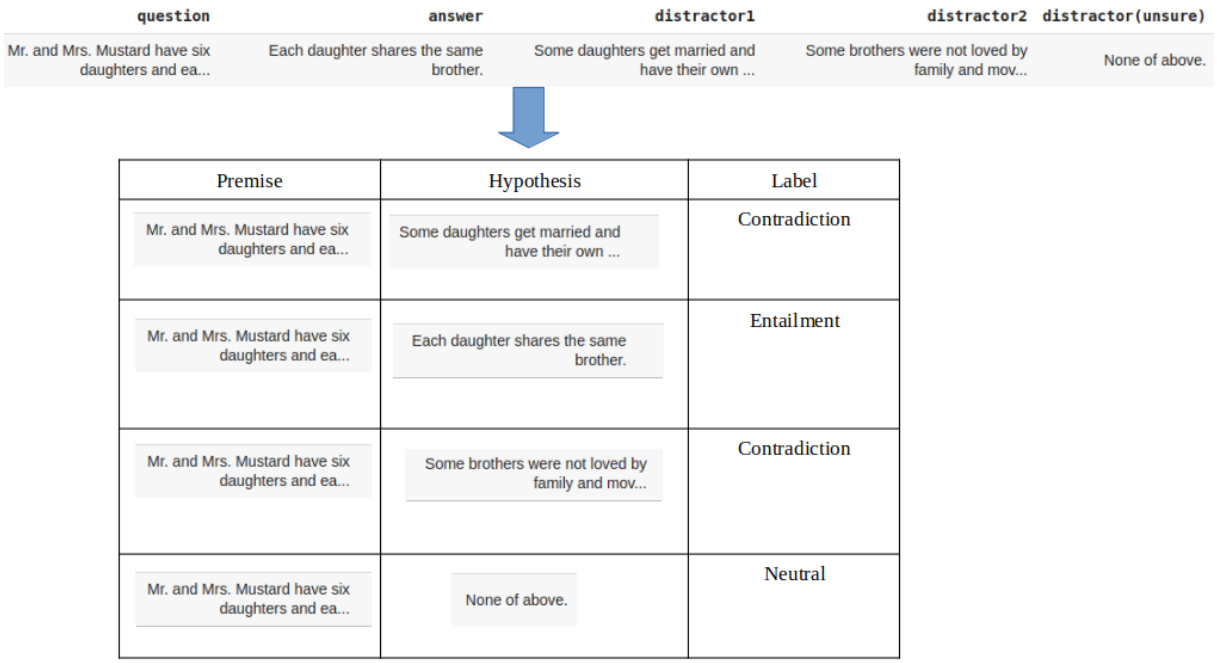

Figure 1: Data Transformation for BERT Classification Approach.

3.5[3] and Gemini[4] to generate additional brainteaser instances. These instances were then incorporated into the fine-tuning process of pre-trained models. Despite having more examples due to data transformation, additional examples were generated through language models such as ChatGPT and Gemini. The generated data underwent manual review to prevent errors regarding the correct answers to the brainteasers. With the expansion and transformation of the data, a total of 4,644 labeled pairs were obtained for fine-tuning the models with brainteasers from both tasks.

4 Experimental Setup

The evaluation results of the BERT Fine-Tuning model are presented in Table 2, revealing the model's struggle to identify the correct answer while being proficient in identifying the neutral class. Based on these findings, a decision was made to minimize the dataset size, considering the potential for model overfitting.

Consequently, the use of brainteasers generated for the Word Puzzle task was discarded, as is shown in Table 3. This decision impacted the model's performance, as evidenced in Table 4, prompting further reduction of the training dataset.

After eliminating all synthetically generated

Table 2: Evaluation Metrics of BERT Fine-Tuning Model with Original Data Train and Generated Data for Sentence Puzzle and Word Puzzle Tasks (Model 1).

Class	Precision	Recall	F1-score
Entailment	0.80	0.78	0.79
Contradiction	0.90	0.91	0.90
Neutral	**0.96**	**0.97**	**0.97**
Macro avg	0.89	0.89	0.89

Table 6 displays the results obtained during the training stage using the evaluation metrics proposed for the task. For the evaluation phase, Model 3 was selected as it exhibited the best performance.

5 Result

During the evaluation phase of SemEval-2024 Task 9, administrators provided a dataset comprising 120 sentence puzzles and 96 word puzzles. The results, depicted in Table 6, demonstrate that the majority of these results surpass the baseline established by the zero-shot models. Our average final ranking, as displayed in the posted rankings table, is 33, with a score of 0.658 for Sentence Puzzle (position 23) and 0.260 for Word Puzzle (position 22), yielding an overall average score of 0.459.

5.1 Error Analysis

The primary errors of the proposed algorithm are associated with the word puzzle task, as evidenced by the imbalance of classes. Despite efforts to mitigate this imbalance by generating additional data, addressing this task has proven challenging, as the results did not exhibit improvement. One possible contributing factor to this challenge is the necessity for a deeper contextual understanding and a more figurative sense to solve these puzzles.

6 Conclusions

This work introduced a solution for SemEval-2024 Task 9: "BRAINTEASER - A Novel Task Defying Common Sense", leveraging pre-trained lan-

guage models and fine-tuning them with the provided data (Jiang et al., 2023), along with additional data generated using LLMs as ChatGPT 3.5 and Gemini. Through experimentation with our pre-trained, fine-tuned models, we found that the BERT model yielded the best results compared to RoBERTa Winogrande. It is worth noting that a significant challenge in this process was defining the appropriate dataset, as certain records from the proposed set had to be discarded to enhance model performance. Ultimately, our results surpassed the task's baseline and secured a position of 33 out of 50 participants, indicating the effectiveness of our approach. However, there is room for improvement, particularly with the word puzzles, which proved to be challenging and require a deeper contextual understanding for resolution.

Abstract

In this paper, we present our submission to the SemEval-2023 Task 3 "The Competition of Multimodal Emotion Cause Analysis in Conversations", focusing on extracting emotion-cause pairs from dialogs. Specifically, our approach relies on combining fine-tuned `GPT-3.5` for emotion classification and a BiLSTM-based neural network to detect causes. We score 2nd in the ranking for Subtask 1, demonstrating the effectiveness of our approach through one of the highest weighted-average proportional F_1 scores recorded at 0.264. Our code is available at https://github.com/sachertort/petkaz-semeval-ecac.

1 Introduction

Developing dialog systems is a complex task that has attracted considerable attention from many technology companies and universities over the last 70 years since the introduction of Eliza in 1966 (Weizenbaum, 1966). Modern large language models (LLMs) like GPT-4 (OpenAI, 2023) are trained to avoid causing harm and often assert their lack of personal opinions on intricate matters, which is not at all natural for conversations. They do not respond in a way that is truly human, and they do not understand the range of feelings that words can cause. Recognizing the emotional implications of an utterance provides a deeper understanding of dialog, enabling the development of more human-like dialog systems. These systems could navigate conversations using a comprehensive understanding of emotional dynamics and planning responses based on this understanding rather than just predicting likely outcomes.

To bridge the gap between machine-generated dialogs and rich, complex human communication, we develop models for SemEval-2024 Task 3 "The Competition of Multimodal Emotion Cause Analysis in Conversations"[1] (ECAC) (Wang et al., 2024). This task was previously introduced in Xia and Ding (2019a) and later in Wang et al. (2023), where the authors also described a multimodal dataset called *Emotion-Cause-in-Friends* (ECF) for this task.

We focus only on Subtask 1, "Textual Emotion-Cause Pair Extraction in Conversations" (ECPE),[2] where the goal is to classify emotions and extract the corresponding textual causal spans. To accomplish this, we propose a two-stage pipeline: (1) first, emotions are classified using a fine-tuned LLM, and then (2) causes are extracted with a simple neural network consisting of BiLSTM and linear layers (see Figure 1). Our system achieved a weighted-average proportional F_1 score of 0.264, the primary metric in this competition's evaluation phase on the test set. Consequently, our team ranked 2nd out of 15 participating teams based on this metric. We provide an extensive analysis of the model's performance in Section 5.2.

2 Related Work

Recent research in the field of dialog systems and emotion-cause extraction has seen significant advancements through various innovative approaches, some of which we overview in this section. For instance, Chen et al. (2023) introduce a novel technique that uses graphs to model "causal skeletons" alongside a causal autoencoder (CAE) for refining these models by integrating both implicit and explicit causes.

Following closely, Zhang et al. (2023) present Dual Graph Attention Networks (DualGATs) that leverage discourse structure and speaker context through a combination of Discourse-aware GAT (DisGAT) and Speaker-aware GAT (SpkGAT), enriched with an interaction module for effective information exchange and context capturing.

Moving to earlier work, Kong et al. (2022) pro-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1127–1134

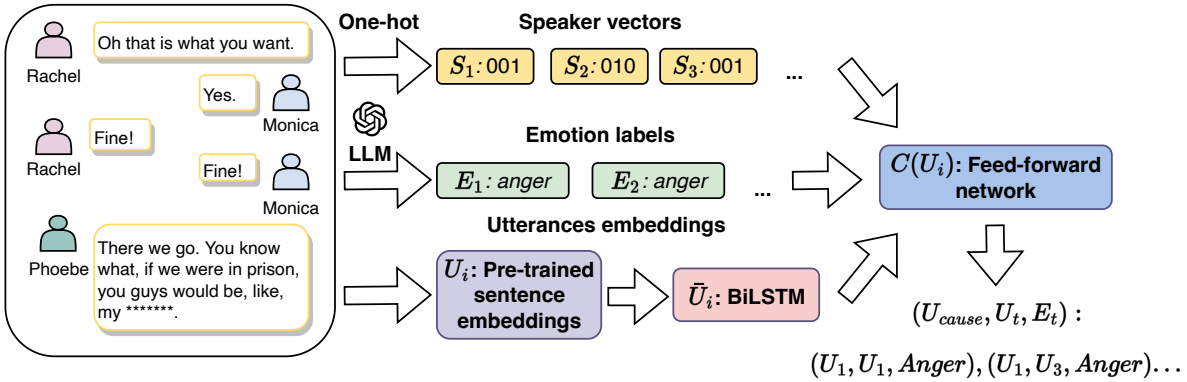

Figure 1: The pipeline for ECPE. Utterances are classified with emotion labels E_i, and speakers are represented with one-hot vectors S_i. Utterances are then encoded with pre-trained sentence embeddings U_i and enriched with context by BiLSTM $\bar{U}_i$. For each target utterance U_t, we detect whether any other utterance from the conversation history $H(U_t)$ is causal using a feed-forward network. $\bar{U}_i$, S_i (of a potential causal utterance), $\bar{U}_t$, S_t, and E_t are concatenated, and then, binary classification is performed. The pipeline outputs labelled emotion-cause pairs (U_i, U_t, E_t).

pose a discourse-aware model (DAM) that integrates emotion cause extraction with discourse parsing, using a Gated Graph Neural Network (GNN) to encode discourse structures and conversation features within a multi-task learning framework, enhancing the understanding of conversational context and structure.

Finally, Gao et al. (2021) focus on improving dialog systems' empathetic response generation by identifying emotion causes. Their framework combines an emotion reasoner for predicting emotion and its cause with a response generator that employs a gated attention mechanism to emphasize important words, exploring both hard and soft gating strategies.

3 System Overview

Our pipeline consists of two stages. Specifically, to identify emotion-cause pairs and emotion types, dialogs are passed through the following modules:

1. classification of utterances with emotion types (including *neutral* for non-emotional utterances) with a supervised fine-tuned LLM; and

2. extraction of cause utterances with a BiLSTM-based network.

The full pipeline is shown in Figure 1. Due to the limitations of the data, we perform the tasks separately, and we elaborate on each of the stages in the following sections.

3.1 Emotion classification

To categorize an utterance with an emotion label E_t, within our pipeline an LLM should consider both the target utterance U_t, which is the t^{th} utterance in a conversation, and the preceding utterance U_{t-1}. It is especially important when we deal with very short turns, such as "Instead of... ?", "No.", "Yeah, maybe...". Indeed, it would be more accurate to utilize causal utterances rather than antecedent ones; however, at the initial stage, these are unknown to us, necessitating the use of a meaningful alternative.

For this stage, we fine-tune `GPT-3.5`.[3] As a `system`'s input, we provide the prompt consisting of an instruction, U_{t-1} (`<UTT_1>`), and U_t (`<UTT_2>`) as is shown in Figure 2. This particular prompt was selected during the preliminary prompt engineering stage. The `assistant`'s output consists of one word – the emotion type.

We also note that preliminary experiments showed that the LLM performed poorly in zero-shot and few-shot settings on the emotion detection task, at least on the ECF dataset (see Section 5.1 and Table 2). Therefore, we had to fine-tune it.

3.2 Cause extraction

The second stage is concerned with the detection of the causal utterances for non-emotional utterances in a binary way. Let the whole conversational history of an utterance U_t be $H(U_t) = [U_1, U_t]$, then the set of all causal utterances is $C(U_t) \subseteq H(U_t)$.

[3] `gpt-3.5-turbo-1106`: https://platform.openai.com/docs/models/gpt-3-5-turbo

```
Take a deep breath. Your task: given two
dialog utterances, predict an emotion of
the second utterance. Select the emotion
from the following options: neutral,
anger, disgust, fear, joy, sadness,
surprise. Do not use any other
emotions!!! Respond only with the chosen
emotion, without any additional
explanation. Remember that you can only
use listed emotions!!!

Utterance 1: <UTT_1>
Utterance 2: <UTT_2>

Emotion:
```

Figure 2: The prompt used to perform emotion classification with `GPT-3.5`.

In addition, speakers are encoded with one-hot vectors $S_1 ... S_n$ within each dialog.

First, we need to enrich utterance embeddings $U_1 ... U_n$[4] obtained from a pre-trained model with the context within the conversation. Bidirectional LSTM (Hochreiter and Schmidhuber, 1997) was chosen because it can preserve context information in sequential settings using the content of the previous hidden state in encoding the current one. This way, we get new utterance representations $\bar{U}_1 ... \bar{U}_n$.

Then, for each target utterance U_t with $E_t \neq neutral$, we construct t representations:

$$\bar{U}_i \parallel S_i \parallel \bar{U}_t \parallel S_t \parallel E_t, \forall i \in [1, ..., t] \quad (1)$$

containing one of the previous utterances or the target utterance embedding itself $\bar{U}_i$ as a potential cause, its speaker vector S_i, the target utterance embedding $\bar{U}_t$, its speaker vector S_t, and the emotion label E_t. We pass them to a feed-forward neural network and obtain binary predictions $\{0, 1\}$, where 1 means that U_i is a causal utterance and 0 stands for the opposite. All U_i for which 1 is predicted make up $C(U_t)$. Thus, for each U_t with $E_t \neq neutral$ we obtain from 0 to t labelled emotion-cause pairs (U_i, U_t, E_t), where $U_i \in C(U_t)$, consisting of the causal utterance,[5] the emotion utterance, and the emotion label.

We have decided not to extract specific spans from the utterances classified as causes, following a thorough review of the dataset. This decision is based on our observation that these spans often defy straightforward explanations, even from a human annotator perspective. Here are some examples, where the rationale behind the spans remains unclear to us:

- The final punctuation marks are often not included in the cause span: e.g., while the complete utterance is *Instead of [...]?*, the identified cause span is *Instead of [...]*
- For the statement *Me, I ... I went for the watch*, the span is *I went for the watch*
- For the sentence *You know you probably did not know this, but back in high school, I had a, um, major crush on you*, the cause span is defined as *you probably did not know this, but back in high school, I had a, um, major crush on you*

We believe that this part of the task can be more accurately defined as a causal emotion entailment (Poria et al., 2021). Additionally, we note that there is an inconsistency in the dataset's annotation: specifically, the task organizers define emotion causes by identifying specific spans within an utterance, yet the emotional responses themselves are treated as consisting of entire utterances. For these reasons, we have decided that it would be methodologically more appropriate to omit the exact span detection step from our pipeline.

4 Experimental Setup

4.1 Data

The dataset proposed for the shared task contains conversations from the *Friends* series annotated with emotion-cause pairs and emotion labels, including *anger*, *disgust*, *fear*, *joy*, *sadness*, *surprise* from Ekman et al. (1987), or *neutral* for non-emotional utterances.

The shared task organizers highlight that 91% of emotions have corresponding causes and one emotion may be triggered by multiple causes in different utterances. In addition, we have noticed that 16% of them cause several different emotions.

The organizers did not provide a standalone development set, so we had to split the training set ourselves using a ratio of 9:1 relative to the dialogs. The final data splits are shown in Table 1.

[4] We use the same notation for utterances and their embeddings for simplification purposes.

[5] We did not extract causal spans and used the whole causal utterance in the evaluation.

Set	# dialogs	# utterances	# EC
Training	1,236	12,346	8,565
Development	138	1,273	799
Total	1,374	13,619	9,364

Table 1: Distribution of dialogs, utterances, and emotion-cause pairs ("EC") across the split sets.

4.2 Training and architecture details

We fine-tune `GPT-3.5` with the default hyperparameters recommended by OpenAI[6] using two epochs, which is the number automatically chosen by the platform.

The cause extractor model is initialized with mean pooling from the penultimate layer's hidden state of the pre-trained `bert-base-uncased`.[7] Our neural network consists of three BiLSTM layers, one hidden linear layer accompanied by batch normalization, and a ReLU activation function.

For training, we employ the Adam optimizer with the learning rate of $1e$-4, weight decay (L_2-norm regularization) of $1e$-5, and cross-entropy as the loss function. We train the model for 200 epochs using a batch size of 32.

As a framework for training and evaluation, we use `PyTorch`[8] (Paszke et al., 2019).

4.3 Evaulation measures

As proposed in the shared task, we apply the weighted average (w-avg.) F_1 score by emotion type for evaluation. The specific implementation of F_1 score for the ECPE task can be found in Xia and Ding (2019b). In this setting, an emotion-cause pair is considered as correctly predicted if the index of an emotion utterance, an emotion type, and the index of the cause utterance match the entry in the gold dataset. There are two strategies related to causal span detection: *strict* F_1 (the same span) and *proportional* F_1 (overlap).[9]

5 Results

Our final submission was evaluated on the test set and achieved the following results:

- w-avg. proportional F_1: 0.264;
- w-avg. strict F_1: 0.104.

[7] https://huggingface.co/bert-base-uncased

[8] https://pytorch.org

[9] For the details on the metrics, refer to https://github.com/NUSTM/SemEval-2024_ECAC/tree/main/CodaLab/evaluation.

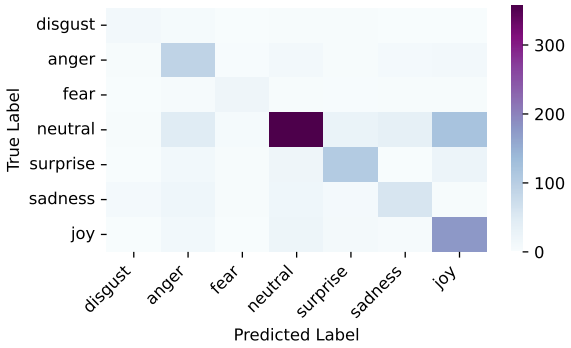

Figure 3: Performance of our emotion classifier on our development set.

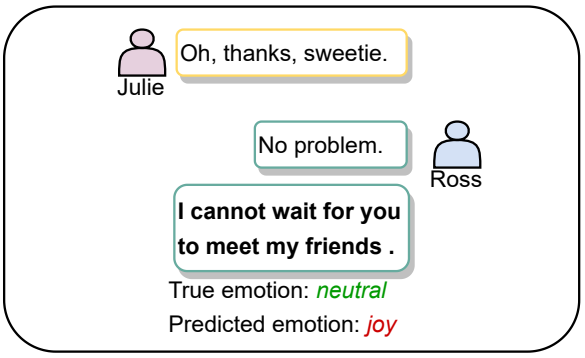

Figure 4: An example of a dialog where our model classified neutral utterance as *joy*.

As a result, we score second out of fifteen teams participating in Subtask 1 according to the main shared task metric – w-avg. proportional F_1.

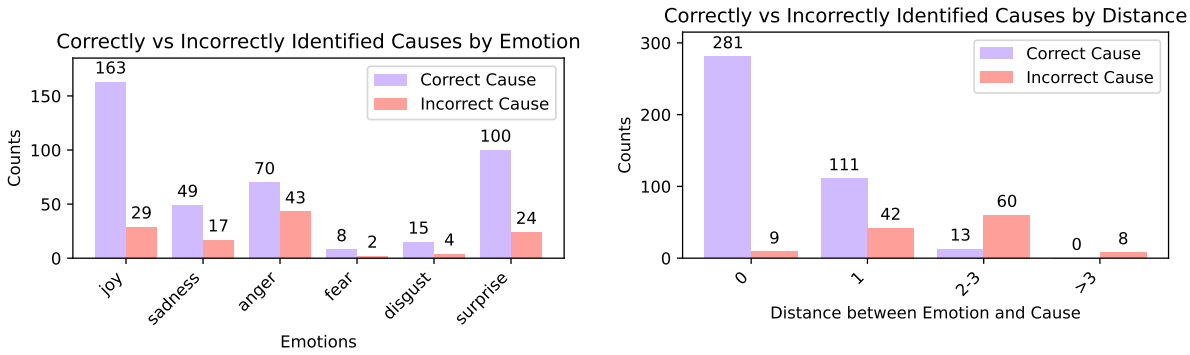
5.1 Emotion classification performance

Table 2 overviews the performance of emotion classification using `GPT-3.5` across different paradigms: zero-shot, few-shot, and fine-tuning. We note that zero- and few-shot settings use the same prompt (see Figure 2), with the few-shot setting including one handpicked example per each emotion type (see Appendix A). As expected, fine-tuning yields the best results on all emotion types and overall. Interestingly, few-shot prompting performs worse than zero-shot, which suggests that examples hamper the model's understanding of emotion types instead of improving it.

Utterances of *disgust* type turn out to be the most difficult to predict correctly: one of the possible reasons is that they are insufficiently represented in the training set (amounting to only about 6% of emotional utterances). However, the zero-shot and few-shot settings also show the poorest performance on *disgust*.

Approach	*neutral*	*anger*	*disgust*	*fear*	*joy*	*sadness*	*surprise*	macro	w-avg.
Zero-shot	0.61	0.43	0.30	0.32	0.54	0.47	0.50	0.45	0.54
Few-shot	0.57	0.49	0.31	0.34	0.54	0.37	0.41	0.43	0.51
Fine-tuning	**0.70**	**0.57**	**0.42**	**0.51**	**0.63**	**0.52**	**0.66**	**0.57**	**0.64**

Table 2: F_1 scores on emotion classification with GPT-3.5 across different approaches.



(a) Analysis across emotions on our development set (on correctly identified emotions only).

(b) Break-down of distance between emotion and cause on our development set (on correctly identified emotions only).

Figure 5: Performance of the cause extractor.

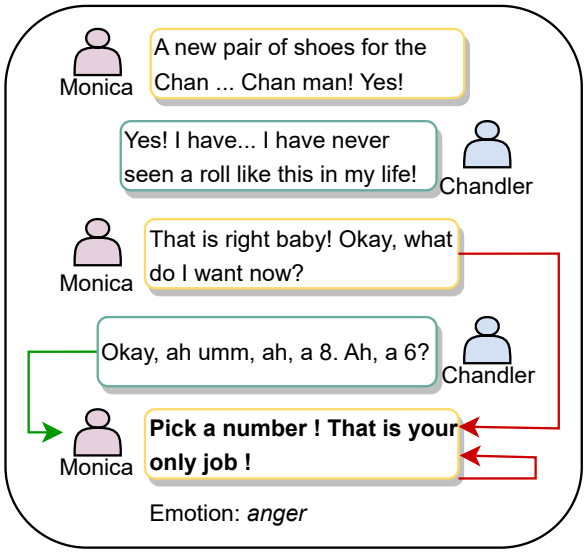


Figure 6: An example of a dialog with annotated causes for *anger* (green for causes correctly identified by our model, and red for causes that our model failed to recognize).

Our analysis of the emotion classifier's performance across different emotion types shows that the model often incorrectly classifies *neutral* utterances as indicative of *joy* (see Figure 3). After further investigation, we have found that a large number of these incorrectly categorized cases contain greetings ("*Hi!*") and expressions of gratitude ("*Thank you!*", "*You're welcome!*), which, according to our dataset, should be *neutral*, yet our classifier interprets them as *joy*. This implies that text alone may not be enough to identify an emotion, given that such utterances can express joy or remain emotionally neutral. There are other controversial cases, such as a conversation between two lovers shown in Figure 4, where the statement "*I cannot wait for you to meet my friends*" is actually more likely to express joy rather than neutrality.

5.2 Analysis

We also evaluate our model on its ability to identify the causes of utterances expressing different emotions, as shown in Figure 5a. Based on this analysis, the greatest challenge for our model is determining causes of *anger*. Similarly, manual analysis shows that this task is difficult for humans as well. As an example, Figure 6 highlights a scenario where the source of anger in Monica's utterance is not only attributed to the preceding utterance from Chandler but is also caused by the utterance that came before Chandler's, as well as the context of Monica's own statement. Intricacies like this one highlight the controversies present in the dataset.

Additionally, we have looked into how well our model performs in determining the emotion's cause based on how close it is to the emotional utterance, as we show in Figure 5b. First of all, it transpires that most emotional utterances are self-caused. Furthermore, our analysis shows that there is a clear correlation between the cause's distance from the

emotional utterance and our model's identification accuracy: the further away the cause, the lower the model's performance.

In the course of our analysis, we have discovered instances where emotions appear before their causes. This observation suggests that the organizers' definition of a cause in dialog contexts is non-trivial, as, typically, we would expect that something happens and triggers an emotion. However, in the case of the preceding emotion, the cause is fundamentally different: it is a reason in terms of linguistics and it explains the emotion, but it does not trigger it (for the difference between CAUSE and REASON, please refer to Ruppenhofer et al., 2006).

Overall, accurate identification of emotions and their causes within utterances proves to be a complex challenge, not only for models but also for humans. All issues mentioned above point to important problems in the dataset that need to be carefully thought through and fixed to enhance both the accuracy and reliability of ECPE efforts.

6 Conclusions

Our work presents a novel approach to emotion-cause pair extraction in conversations, using the capabilities of an LLM (specifically, `GPT-3.5`) for emotion classification. This methodology is further enhanced by the use of a BiLSTM-based neural network for extracting causes. Our system outperforms most of the submissions to the shared task, scoring 2nd in the overall ranking according to the main metric of weighted-average proportional F_1. For future enhancements to our pipeline, we consider the following improvements:

- Firstly, data annotation itself can be expanded and improved, potentially via the use of an LLM for annotation.
- Secondly, speaker representations can be improved to enhance the understanding and processing of the dialogs.
- Finally, more accurate methods of LLM-based cause extraction can be developed further.

Limitations

Due to OpenAI's policy, we are unable to share our fine-tuned model. Therefore, those wishing to reproduce our experiments will need to do the fine-tuning independently. Overall, the usage of an open-source solution instead of a proprietary LLM can be one of the future directions. Also, it may be applied using a more specific framework like InstructERC (Lei et al., 2024).

Furthermore, our research is limited to the emotions present in the provided task data. Consequently, adding new emotions would require further fine-tuning. Due to the shared task rules, we have to develop our system based only on the presented dataset that is limited to a single concrete domain (*Friends* series) and the English language.

A Prompt for Few-shot

```
Take a deep breath. Your task: given two dialog utterances, predict an emotion of the second
utterance. Select the emotion from the following options: neutral, anger, disgust, fear, joy,
sadness, surprise. Do not use any other emotions!!! Respond only with the chosen emotion,
without any additional explanation. Remember that you can only use listed emotions!!!

Examples:

Utterance 1: Alright , so I am back in high school , I am standing in the middle of the
cafeteria , and I realize I am totally naked .Utterance 2: Oh , yeah . Had that dream .
Emotion: neutral

Utterance 1: Do not you realise what you are ... you are doing to yourself ?
Utterance 2: Hey , you know , I have had it with you guys and your cancer and your emphysema
and your heart disease .
Emotion: anger

Utterance 1: Oh , hey , do not do that ! Cut it out !
Utterance 2: It is worse than the thumb !
Emotion: disgust

Utterance 1: I am not moving out .
Utterance 2: You would tell me if you were moving out right
Emotion: fear

Utterance 1: So , what do you think ?
Utterance 2: I think It is the most beautiful table I have ever seen .
Emotion: joy

Utterance 1: No , wait , oh , what are we sorry about ?
Utterance 2: I do not know ... right , he is the pig !
Emotion: sadness

Utterance 1: No , wait , oh , what are we sorry about ?
Utterance 2: How did I not see this ?
Emotion: surprise

Utterance 1: UTT_1
Utterance 2: UTT_2
Emotion:
```

Abstract

SemEval SubtaskB, a shared task that is concerned with the detection of text generated by one out of the 5 different models - davinci, bloomz, chatGPT, cohere and dolly. This is an important task considering the boom of generative models in the current day scenario and their ability to draft mails, formal documents, write and qualify exams and many more which keep evolving every passing day. The purpose of classifying text as generated by which pretrained model helps in analyzing how each of the training data has affected the ability of the model in performing a certain given task. In the proposed approach, data augmentation was done in order to handle lengthier sentences and also labelling them with the same parent label. Upon the augmented data three RoBERTa models were trained on different segments of data which were then ensembled using a voting classifier based on their R2 score to achieve a higher accuracy than the individual models itself. The proposed model achieved an overall validation accuracy of 97.05% and testing accuracy of 76.25%.

1 Introduction

In the current day scenario, AI has noticed a major boom due the emergence of Large Language Models (LLMs) in the field of Natural Language Processing (NLP). These LLMs are capable of generating text with any given context that they have been trained on making them versatile to a lot of applications. LLMs have also showcased their unrivaled ability to code basic to complex programs. Many Large Language Models (LLMs) depend heavily on the data used for their training. Consequently, they may occasionally provide inaccurate information, especially in contexts where precision is crucial, such as sensitive or professional advice. Hence AI-generated text classification has become increasingly important due to the surge in the use of language models for content creation. Accurately identifying the source of a text, whether human-written or generated by a specific language model, is crucial for various applications, such as combating misinformation and plagiarism detection. Subtask B - Multi-Way Machine-Generated Text Classification shared task aims to not only detect text generated by these language models, but also specifically distinguish between outputs generated by different models. This in a real life scenario helps in determining the transparency and vulnerability of a model to attacks and reasoning as to why particular models perform in certain ways. Different contributions of the paper is as follows :-

- **Data Augmentation:** Data augmentation is a crucial task of increasing the volume of available data with specific manipulations which also helps build a more robust model able to tackle edge case scenarios. We propose a novel approach to handle long texts. We initially set a specific threshold to split them into smaller segments while preserving label information, ensuring efficient model training.

- **Ensemble Learning:** Ensemble learning as name suggests weaker models are brought together to achieve a better model with enhanced performance. We employ a weighted ensemble voting classifier that combines the predictions of multiple models trained on diverse validation sets, leading to improved generalizability and robustness.

We observe how effective and relevant Language models are in tackling Natural Language Processing tasks such as the current shared task when compared to other neural network based LSTM or other sequence models. Our final submission had a test accuracy of 76.25% and our standing was 18th position in the leader-board.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1135–1139

2 Background

Our work improves model generalizability in large-scale tasks by utilising insights from (Wang et al., 2024) and building on recent studies. Previously methods proposed by authors in (Ma et al., 2023) collected 500 scientific articles from 10 domains including biology, chemistry, IT and others and used chatGPT to paraphrase texts for each article. The authors extracted certain features such as perplexity, semantic document and six others to use classifiers on these extracted features. The authors used three classifiers: XGBoost, random forest, and multi-layer perceptron, to train and test models for detecting human-generated and AI-generated texts, as well as human-generated and AI-rephrased texts. They performed a 5-fold cross-validation and evaluated the models using accuracy and F1-score which majorly motivated our approach. Another work (Mindner et al., 2023) used similar techniques to the previous one while using school topics as their dataset. In their work (Abburi et al., 2023) the authors use ensemble neural model that generates probabilities from different pre-trained LLMs which are used as features to a TML classifier following it. Author in (Huimin et al., 2018) presents his work on text classification ensemble learning method based on multi-angle perturbation heterogeneous base classifiers and validates the effectiveness of the algorithm through experiments. In a similar work (Mohammed and Kora, 2022) the authors propose a new meta-learning ensemble method that fuses baseline deep learning models using 2-tiers of meta-classifiers.

Furthermore, our method for comprehending model decision-making in short text classification—particularly in identifying AI-generated content—is influenced by methods from works on short text classification. Authors in their work (Tang et al., 2022) use a sliding window to align the sentences with the labels and preserve the edge characteristics of the long text. Another work in the same field (Shorten et al., 2021) categorizes text data augmentations into symbolic and neural methods. Symbolic methods use rules or discrete data structures to form new examples, while neural methods use auxiliary neural networks to sample new data. Our research aims to advance the development of robust and adaptable machine learning models customised to particular tasks through this synthesis of diverse viewpoints. These viewpoints are then combined back again with the help of ensembling ensuring no loss of data.

3 Methodology

Our methodology majorly focuses on exploiting Pre-trained language models such as the RoBERTa model (Liu et al., 2019) and enhancing its performance through a much simpler traditional approach of ensemble learning. We worked on the M4 based dataset with our methodology (Wang et al., 2023) The ensemble model shows better performance compared to all 3 RoBERTa-base models which were trained on different segments of augmented data. It reduces over-fitting and increases interpretability for any given task.

3.1 RoBERTaForSequenceClassification

RoBERTa which stands for Robustly Optimized BERT Approach is a variant of the famous BERT model (Devlin et al., 2018) which was developed by Google in 2018. RoBERTa was later introduced by researchers at Facebook AI in 2019. It builds upon the architecture of BERT while bringing in few major changes. It uses Dynamic masking strategies and removes the Next Sentence Prediction (NSP) in its pre-training step. It is further pre-trained with larger amounts of data with larger mini-batch size. The novelty of RoBERTa lies in its ability to achieve state-of-the-art performance on various natural language understanding benchmarks by leveraging advancements in pre-training techniques and model architectures. RoBERTa continues to employ similar tokenizing technique as BERT with WordPiece Encoder (WPE). RoBERTa as a base model in itself gives out embedding for a given sentence or a word as it is only composed of Encoder architecture.

RoBERTaForSequenceClassifcation consists of a classification head on top of the base RoBERTa model. This classification head maps the backbone outputs to logits suitable for a classification task based on the number of labels provided.

3.2 Ensemble Learning

Ensemble learning is a machine learning technique that combines multiple individual models to obtain a model with enhanced performance which is more robust as well. It involves training several individual base models which are often referred to as experts on similar data and producing an aggregation out of those models based on their individual performances. The benefits of ensembling

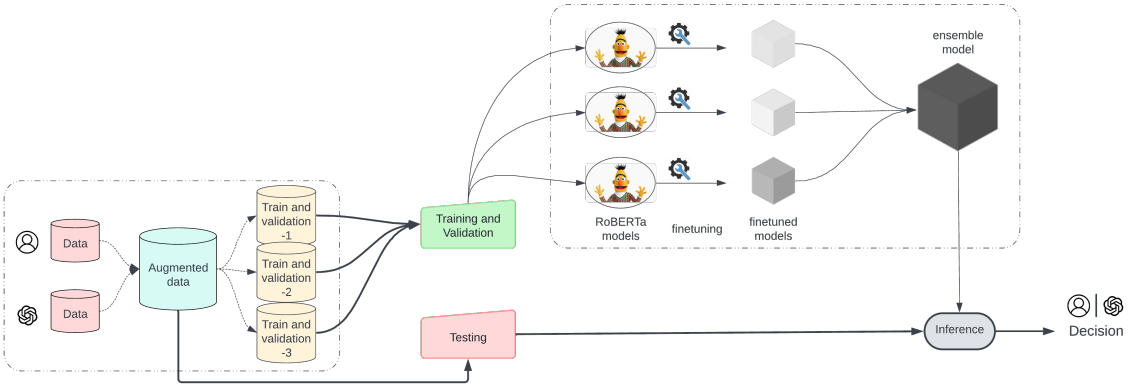

Figure 1: Proposed methodology for AI vs Human generated text Detection using weighted voting ensembling of RoBERTa classifiers

include improved generalization, more robustness compared to single models, and efficient as it compensates for the loss in performance of the poor learning algorithms. The common techniques in Ensemble learning including Bagging and Boosting. We specifically used the concept of Voting classifier which takes predictions from different models and has a specified weighting parameter based on which it gives out the final prediction. We implemented our own Voting classifier which scores the three RoBERTa models based on the R2-scores achieved by their predictions. R2-scores here are used as the weighting parameter for the prediction and thus we derive our final prediction out of the voting classifier.

4 System Overview

As mentioned, we first perform data augmentation. Before we get into the details of our experimental setup, we want to elaborate on different measures we took in order to augment our data. Data augmentation for training data was performed by carefully splitting the validation data while noting that there is no major imbalance in the class distribution. This was followed by training three different RoBERTa models on different combinations of training and validation dataset. We had 3 validation data splits namely *val1*, *val2* and *val3*. For *model1* we used *val2* and *val3* in training and *val1* for validating the *model1* and so on.

4.1 Data Augmentation

We implemented a data augmentation strategy to address instances in our dataset exceeding the token limit, ensuring no information loss while maintaining model compatibility. Given a dataset comprising 71,027 instances for training and 3,000 for validation, with some instances surpassing the 512-token limit, we devised a method to split these instances into k different segments. Utilizing the modulo operation, if an instance contains n tokens, $[n/512]$ determines the number of segments it will be divided into, while the remainder represents the number of tokens in the last augmented segment of the instance. This process yielded approximately 9985 additional instances for training and 188 for validation.

Subsequently, we merged the augmented training and validation sets to form a combined dataset of 81,012 training instances and 3188 validation instances. This validation dataset was then partitioned into three parts of which two-thirds are used for training alone with the complete training data and the remaining one-third is used for validation. Notably, each RoBERTa model was provided with a distinct subset of one-third of the validation data, thus adhering to a different k-fold validation scheme to enhance generalizability.

4.2 Implementation Details

The implementation of our method includes three vanilla RoBERTaForSequenceClassification models with 12 encoder layers with a classification head at the end were used. These models were trained on three different splits of two-thirds of validation data coupled with the training data. Each model was effectively trained on roughly 82000 samples with roughly 1060 validation instances. The voting classifier first takes in all three fine-tuned RoBERTa models and predicts on the complete validation set and analyzes the performance of each of the models based on their R2-score and constructs a weighted

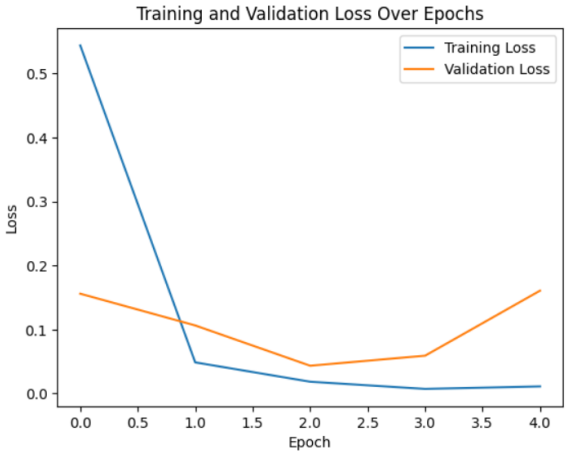

Figure 2: Training and validation loss observed over the RoBERTa model-1.

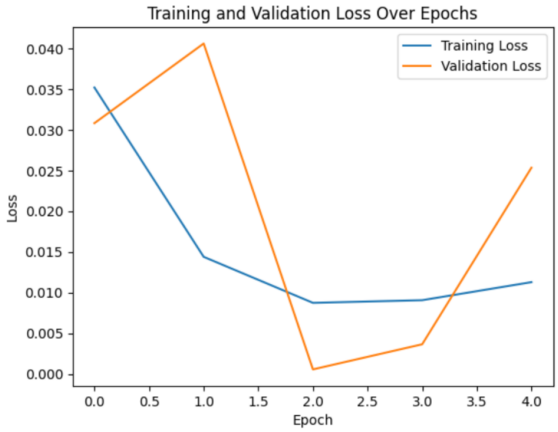

Figure 3: Training and validation loss observed over the RoBERTa model-2.

voting classifier which gives our final predictions. The R2 scores observed for each of the three models were 0.36, 0.29 and 0.35 which had roughly similar weight given to each of their predictions. The performance of each of the models were analyzed with the help of training and validation loss plots across training epochs.

5 Experimental Results

As a part of our experimental setup we used P100 GPU which is available through kaggle. Further we used the `RobertaForSequenceclassification` available through transformers library along with `RobertaTokenizerFast` for the modelling aspect. The learning rate used was a fixed one and we found it optimal at $1e-5$ along with $CrossEntropyLoss$. $AdamW$ optimizer was used with weight decay coefficient of $1e-2$ and $\beta_1 = 0.9$ and $\beta_2 = 0.999$. Batch size of 20 was

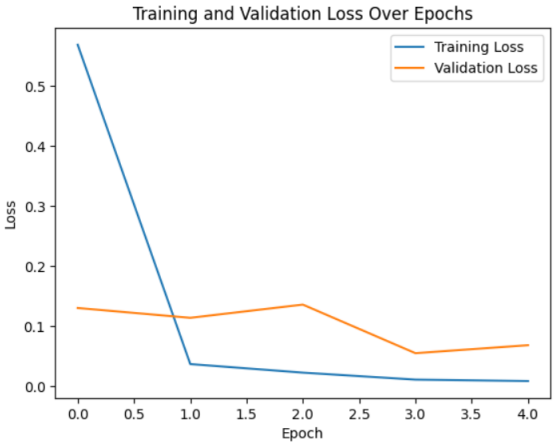

Figure 4: Training and validation loss observed over the RoBERTa model-3.

used for training and validation.

Our proposed methodology beat the baseline model which was a RoBERTa model with an average accuracy of 0.75. Our experimental results with respect to each of the RoBERTa model is displayed along with the improvement in performance with the use of R2-score based weighted voting classifier. In testing phase our model gave an accuracy of 76.25% which shows clear signs of over-fitting compared to 97.05% in validation accuracy.

Table 1: Proposed methodology performance comparison

Models	*Train Acc (%)*	*Val Acc (%)*
Baseline	75	75
RoBERTa-1	96.40	95.06
RoBERTa-2	93.64	92.10
RoBERTa-3	97.21	96.62
Voting Classifier (*proposed*)	**97.26**	**97.05**

6 Conclusion

In the proposed methodology, we beat the baseline RoBERTa model and further enhance the performance of the model using R2-score based Voting classifier. The model has performed well on the training data when compared to testing data which shows slight signs of over-fitting. In the light of ensemble learning for Pre-trained language models we see that the models are very sensitive to over-fitting hence should be used with caution. Techniques like early stopping and using data augmen-

tation. Further on embeddings from LLMs can be used to tackle this task more effectively.

Abstract

In this paper, we present our submission to the SemEval-2024 Task 8 "Multigenerator, Multidomain, and Multilingual Black-Box Machine-Generated Text Detection", focusing on the detection of machine-generated texts (MGTs) in English. Specifically, our approach relies on combining embeddings from the RoBERTa-base with diversity features and uses a resampled training set. We score 12th from 124 in the ranking for Subtask A (monolingual track), and our results show that our approach is generalizable across unseen models and domains, achieving an accuracy of 0.91. Our code is available at https://github.com/sachertort/petkaz-semeval-m4.

1 Introduction

SemEval-2024 Task 8 "Multigenerator, Multidomain, and Multilingual Black-Box Machine-Generated Text Detection" (Wang et al., 2024) has focused on the detection of machine-generated texts (MGTs). In recent years, large language models (LLMs) have achieved human-level performance across multiple tasks, showing impressive capabilities in natural language understanding and generation (Minaee et al., 2024), including their abilities to generate high-quality content in such areas as news, social media, question-answering forums, educational, and even academic contexts. Often, text generated by LLMs is almost indistinguishable from that written by humans, especially along such dimensions as text fluency (Mitchell et al., 2023). Therefore, methods of automated MGT detection, intending to mitigate potential misuse of LLMs, are quickly gaining popularity. Automated MGT detection methods can be roughly split into black-box and white-box types, with the former being restricted to API-level access to LLMs and reliant on features extracted from machine-generated and human-written text samples for classification model training, and the latter focusing on zero-shot AI text detection without any additional training (see Section 2).

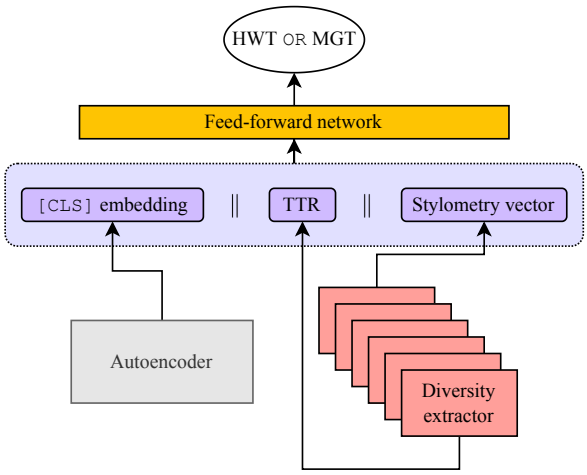

Figure 1: For each text, we get a [CLS] token embedding from an autoencoder model and extract vectors of linguistic features (e.g., lexical diversity, stylometry, etc.). Then, we pass the concatenated vector to a feed-forward network, whose output layer performs binary classification – HWT vs. MGT. The configurations of embeddings/features may vary between experiments.

For our submission to SemEval-2024 Task 8, the monolingual track of Subtask A, which focuses on MGT detection in English across a variety of domains and generative models, we have developed a system that can be categorized as a black-box detector and is based on a combination of embeddings, measures of lexical diversity, and careful selection of the training data (see Figure 1). We also present and discuss an extended set of linguistic features, including discourse and stylistic features, that we have experimented with during the development phase of the competition. The main motivation for using such a feature-based approach is that it helps us to focus on the fundamental differences between MGTs and human-written texts (HWTs) rather than capture the specifics of particular models.

Our results suggest that our best model, which uses diversity features and embeddings, outper-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1140–1147

forms a very competitive baseline introduced in this task (Wang et al., 2024), yielding an accuracy of 0.95 on the development and 0.91 on the test set. It brought us 12th place out of 124 teams participating in the shared task. Furthermore, our investigation shows that a model using no embeddings but relying on such linguistic features as entity grid and stylometry yields results that are on par with the baseline model.

The main contributions of our work are as follows: **(1)** we investigate the impact on the detection task of a variety of linguistically motivated features, ranging from widely used stylometric features to novel ones, including those based on high-level discourse analysis; and **(2)** we show how training data can be selected in an informative way to help models better distinguish between MGTs and HWTs.

2 Related Work

A comprehensive survey by Yang et al. (2023) categorizes detection methods into training-based classifiers, zero-shot detectors, and watermarking techniques, covering both black-box and white-box detection scenarios. This survey discusses a range of strategies, including mixed training, proxy models, and semantic embeddings, indicating ongoing challenges in scalability and robustness. Given the fast development of LLMs and their capabilities, of particular interest are innovations in zero-shot detection methods highlighted by Mitchell et al. (2023) and Su et al. (2023). In addition, Mitchell et al. (2023) present DetectGPT, utilizing perturbation discrepancies to discern MGTs, while Su et al. (2023) propose DetectLLM-LRR and DetectLLM-NPR, which advance zero-shot detection by harnessing log rank information.

Another relevant line of research investigates the use of linguistic and stylometric features, such as the ones overviewed in Bergsma et al. (2012), for MGT detection. For instance, Wang et al. (2023) explore the use of logistic regression with GLTR features (analyzing the distribution of token probabilities and their relative frequencies within specific probability ranges from a language model's output), stylistic characteristics, and NELA news verification features (style, complexity, bias, affect, morality, and event specifics) on the M4 dataset, and Liu et al. (2022) introduce a model exploiting text coherence, named entities and relation-aware graph convolutional networks under a low-resource setting for MGT detection.

3 Methodology

Our general pipeline, visualized in Figure 1, consists of the following components: (1) an autoencoder model fine-tuned on HWT vs. MGT classification task; (2) linguistic features extraction pipeline; and (3) embeddings and features combination passed through a feed-forward neural network. Below we describe some of these components in more detail.

3.1 Embeddings

We employ an autoencoder model. First, we fine-tune it on the HWT vs. MGT classification task, and then we use its `[CLS]` tokens' embeddings in a feed-forward model.

3.2 Features

We study the impact on the classification accuracy of several types of linguistically motivated features extracted from texts, including those based on: 1) text statistics; 2) readability; 3) stylometry; 4) lexical diversity; 5) rhetorical structure theory (RST); and 6) entity grid. Below we provide a description of the features and their relevance to the task.

Text statistics We compute the following:[1] 1) the number of difficult words (words that have more than two syllables and are not in the list of easy words[2] from Dale and Chall, 1948); 2) raw lexicon count (unique words in text); 3) raw sentence count. In Appendix A.1, we provide the values for HWTs and across models.

Readability We assess the readability of MGTs and HWTs guided by the hypothesis that HWTs are easier to read than MGTs. We calculate a range of common readability scores for both types of texts to assess their readability, including 1) Flesch Reading Ease Test (Flesch, 1979); 2) Flesch-Kincaid Grade Level Test (Kincaid et al., 1975); and 3) Linsear Write Metric (O'Hayre, 1966).

Stylometry For stylometric features, we use the approach proposed in Bergsma et al. (2012). Specifically, we collect all unigrams and bigrams from the texts and keep punctuation, stopwords, and Latin abbreviations (e.g., *i.e.*) unchanged. Then, we build two types of representations where

[1] We use Python's `textstat` library: https://pypi.org/project/textstat/.

[2] https://github.com/textstat/textstat/blob/main/textstat/resources/en/easy_words.txt

other words are replaced by their PoS tags and "spelling signatures" (forms of words; e.g., `xXX-dd` for *iOS-17*).[3] Then, log token frequencies (TFs) are computed for each text and passed to the maximum absolute scaler, and these sparse representations are used as features. For further processing, sparse matrices with stylometry features are reduced by truncated singular value decomposition to a dimensionality of 768. See Appendix A.2 for the analysis of stylometry features importance.

Lexical diversity Lexical diversity tells us how "rich" texts are in terms of vocabulary, i.e., whether they use rare words, or include a wide range of synonyms, epithets, terms, etc. There are a few measures widely used to measure lexical diversity, mostly based on the variants of the type-token ratio (TTR). We extract 10 features, such as TTR, Maas TTR, Hypergeometric distribution d (HDD; McCarthy and Jarvis, 2007), etc.[4] For an in-depth overview, see McCarthy and Jarvis's (2010) study on lexical diversity assessment.

RST features In rhetorical structure theory (RST), proposed in Mann and Thompson (1988), texts are analyzed in terms of hierarchical structures, which represent the organization of information and text flow. These structures are made up of elementary discourse units (EDUs) connected through rhetorical relations, which include "elaboration", "contrast", "cause", "result", etc. Using an open-source sentence-level RST parser (Lin et al., 2019), we count the occurrences of various relations in each text and divide them by the total number of sentences in the text.

Entity grid Finally, we use the entity grid algorithm to analyze the coherence of text by capturing patterns of entity distribution (Barzilay and Lapata, 2005). This method transforms a text into sequences of entity transitions, documenting the distribution, syntax, and reference information of discourse entities. Entities from texts are first tagged with their syntactic roles[5] and categorized into three types: subject (`s`), object (`o`), and other (`x`). The next step involves examining the transition of entities' roles across consecutive sentence pairs. This includes transitions like subject-to-object, object-to-other, subject-to-none, among others. Finally, we calculate the frequency of each transition type for all entities by dividing the total count of each transition type by the number of sentence pairs.

3.3 Feed-forward neural network

Finally, we use a concatenation of embeddings and vectors representing combinations of various features described above and pass them as input to a feed-forward neural network. Then, the output layer performs binary classification.

4 Data

Shared task organizers have used an extension of the M4 dataset (Wang et al., 2023),[6] which covers a range of domains (including *WikiHow*, *Wikipedia*, *Reddit*, *arXiv*, *PeerRead*, and *Outfox*) and texts generated by a number of LLMs (including `ChatGPT`, `Cohere`, `Davinci003`, `Dolly-v2`, `BLOOMZ`, and `GPT-4`) as well as written by humans. Overall, the training set is roughly balanced between HWTs and MGTs, with 53% being HWTs and with the number of HWTs being around 5 times higher than that of texts generated by any single LLM for each of the domains. The only exception is *PeerRead*, where the distribution of texts generated by each LLM and written by humans is about the same. At the same time, the distribution is exactly 50%:50% for HWTs:MGTs in the development set, and 47.5%:52.5% for HWTs:MGTs in the test set. In addition, while both training and development sets cover a range of domains, the test set is limited to *Outfox* only.

A curious case of WikiHow Before running the experiments, we further investigate how the training data is composed. According to Wang et al. (2023), LLMs were provided with relatively short inputs to generate texts across various domains: for example, with titles for *Wikipedia* articles and *arXiv* papers, titles and abstracts for *PeerRead* articles, etc. On the one hand, we observe a high level of parallelism in the training data across HWTs and texts generated by various models, and on the other, we note that there is little consistency in what models generate in certain domains: for example, provided with a name of a personality they generate quite different *Wikipedia* entries, which do

[3] The pre-processing was done using `spaCy`: https://spacy.io.

[4] Using Python's `lexical_diversity` library: https://github.com/kristopherkyle/lexical_diversity.

[5] Noun coreference is resolved using `spaCy` (https://spacy.io) and `neuralcoref` (https://spacy.io/universe/project/neuralcoref).

[6] https://github.com/mbzuai-nlp/M4

not only differ from the correspondent HWTs but also vary from one LLM to another (see examples in Appendix B, Table 5). In contrast, texts in the *WikiHow* domain appear to be more similar to each other across LLMs, which can be explained either by the way the data was generated (using titles and headlines as prompts to produce MGTs) or by the fact that there are fewer ways to explain *How to do X?* compared to the tasks in other domains. Moreover, our experiments with in-domain training of the MGT detection classifier suggest that the best results can be obtained when it is trained on the *WikiHow* domain. We follow up on these observations and create a customized training subset by using all MGTs from the original data and limiting HWTs to the texts from the *WikiHow* domain only. This results in a training set of 56,406 MGTs and 15,499 HWTs, with the distribution between each LLM and humans being roughly 1:1.

5 Experiments

5.1 Experimental setup

As the source of embeddings, we use `roberta-base`[7] (Liu et al., 2019) fine-tuned within the baseline framework[8] over 3 epochs with the learning rate of $2e$-5 and L_2 norm of the weights being 0.01. The feed-forward neural network with two hidden layers accompanied by a ReLU activation function is then trained with the learning rate $5e$-5, L_2 norm of the weights 0.01, and early stopping after 25 epochs. Each hidden layer has batch normalization and a dropout of 0.5. We use `PyTorch`[9] (Paszke et al., 2019) for all training and evaluation steps.

Following up on our observations on the *WikiHow* subset described in Section 4, we conduct two series of experiments and train the feed-forward network on: 1) the *full* training set; and 2) the *reduced* training set where we use MGTs from all domains and HWTs from *WikiHow* only.

5.2 Experiments on the development set

The evaluation results of our model with different feature configurations applied to the development set are presented in Table 1. Several observations are due at this point.

[9] https://pytorch.org

Configuration	Full train	Reduced train
`feat`	0.60	0.60
`sty`	0.68	0.57
`sty` ‖ `feat`	0.69	0.60
`sty` ‖ `div`	0.65	0.72
`sty` ‖ `read`	0.67	0.61
`sty` ‖ `rst`	0.64	0.57
`sty` ‖ `ent`	0.73	0.56
`emb`	0.74	0.83
`emb` ‖ `sty`	0.73	0.82
`emb` ‖ `feat`	0.76	0.90
`emb` ‖ `div`	0.73	**0.95**
`emb` ‖ `read`	0.72	0.81
`emb` ‖ `rst`	0.73	0.81
`emb` ‖ `ent`	0.73	0.82
Baseline	0.74	–

Table 1: Accuracy of different configurations and the baseline on the development set. `feat` stands for all features except stylometry, `sty` – stylometry, `div` – lexical diversity, `read` – text statistics and readability, `rst` – RST, `ent` – entity grid, `emb` – embeddings (see Section 3.2).

First of all, we note that the highest accuracy of 0.95 is achieved with the model trained on the *reduced* training set using a combination of embeddings and diversity features. This does not mean that lexical diversity is necessarily the most powerful among linguistic features, but it suggests that it complements embedding representations better than other linguistic features. Moreover, it is the only feature type that increases the accuracy obtained with embeddings only. Finally, we also note that with the linguistic features, our model can outperform a competitive baseline used by the task organizers, which sets the accuracy at 0.74.

Secondly, stylometry features turn out to be the best linguistic feature type when used on their own: the accuracy with `sty` is 0.68 vs. 0.6 with `feat`. These representations reflect some general patterns of word types used in texts. However, it seems like they alone are not enough for effective classification, at least when applied to texts generated by modern LLMs. Notably, the configuration that combines stylometry with entity grid features (`sty + ent`) demonstrates performance that is nearly identical to the baseline employing a pre-trained language model (0.73 vs. 0.74), suggesting that entity grid adds further information about text coherence. Other features like RST do not seem to help distinguish MGTs from HWTs. This finding

Configuration	Train	Accuracy	F_1
`emb` ‖ `div`	reduced	**0.91**	**0.92**
`sty` ‖ `ent`	full	0.84	0.85
Baseline	full	0.88	–

Table 2: Metrics on the test set. The first row is our main submitted configuration. The organizers do not report only the baseline's F_1 score.

suggests that the frequency or efficacy with which humans and models employ rhetorical structures is comparable.

Finally, we observe that the performance of the model using `emb` features always increases if it is trained on the *reduced* set. This determines the model configuration for our final submission.

6 Results

Table 2 presents accuracy on the test set obtained with two configurations: a model using embeddings and lexical diversity features trained on the reduced training set, and a model using stylometry and entity grid features trained on the full training set, which showed promising results on the development set. **The former one is our main configuration: our team has submitted its predictions for the test set and scored 12th in the shared task (out of 124 teams).** This model outperforms the organizers' baseline, which sets the accuracy at 0.88. However, we note that the latter model, which relies on linguistic features only and does not employ any pre-trained language model, also shows promising results, further strengthening our hypothesis that linguistic features are able to capture important properties of LLM-generated texts.

6.1 Analysis

We further analyze the performance of our best model across different LLMs on the test set, as illustrated in Figure 2. The results show that our model accurately identifies texts from `Dolly-v2`, `Cohere`, and `ChatGPT` as machine-generated, and achieves near-perfect classification precision on texts from `GPT-4` and `Davinci003`. `BLOOMZ` is the only model that presents a problem for our classifier, with an 8% misclassification rate. Additionally, we observe that 18% of HWTs are incorrectly classified as being generated by machines. This shows the remarkable generalizability of our approach compared to Wang et al. (2023), who reported that "it is

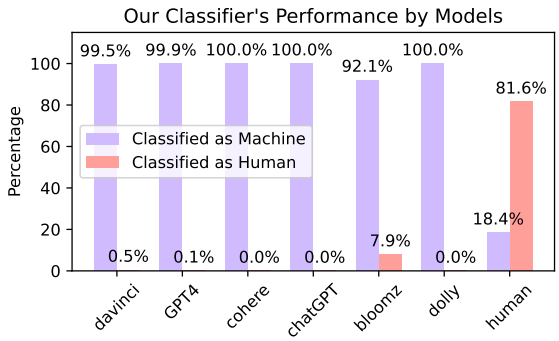

Figure 2: Performance of our classifier across models.

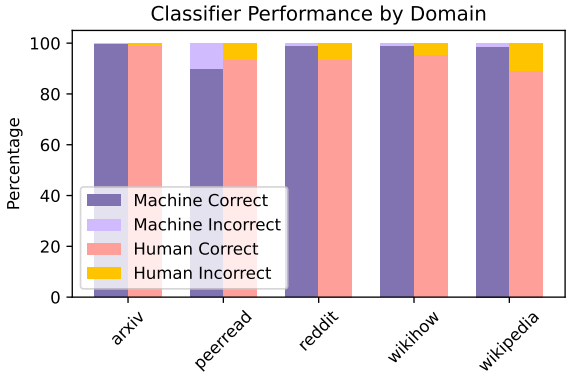

Figure 3: Performance of our classifier across domains (on the development set).

challenging for detectors to generalize well on unseen examples if they are either from different domains or are generated by different large language models. In such cases, detectors tend to misclassify machine-generated text as human-written".

Furthermore, we evaluate our model's performance across domains (Figure 3). Our analysis reveals that we can accurately identify all MGTs and nearly perfectly recognize HWTs from *arXiv*. Our classifiers face the biggest difficulties when classifying MGTs from *PeerRead* and HWTs from *Wikipedia*. These results are aligned with those reported in Wang et al. (2023), who also found that training on *Wikipedia* leads to the worst out-of-domain accuracy.

In summary, our classifier demonstrates generalizability, performing well on both previously unseen models (`GPT-4` and `BLOOMZ`) and domains (with all texts in the test set being from *Outfox*).

7 Conclusions

When developing the models for our submission to the SemEval-2024 Task 8, we have primarily focused on: (1) the contribution of linguistic features to the task, and (2) the selection of the informative training data. Our results suggest that models using

only linguistic features (specifically, those based on stylometry and entity grid) can perform competitively on this task, while careful selection of the training data helps improve the performance of the models that rely on embeddings. This shared task demonstrates that it is possible to distinguish between HWTs and MGTs, but the results also suggest promising avenues for future research, including in-depth analysis of the training data selection techniques and expansion of the linguistic features.

Limitations

Our work is limited to the English language only as we opted to participate in a single Subtask of SemEval-2024 Task 8. In addition, this work is only limited to the domains and LLMs included in the shared task data, therefore, the generalizability of our approach beyond these domains and LLMs will need to be verified in future experiments.

Acknowledgements

We would like to express our gratitude to Ted Briscoe for inspiring us with the idea that linguistics could be of help and for engaging in discussions with us. We are grateful to Mohamed bin Zayed University of Artificial Intelligence (MBZUAI) for supporting this work. We also thank the anonymous reviewers for their valuable feedback.

A Features Analysis

A.1 Text statistics across models

Table 3 shows various text statistics calculated on the training set. It can be seen that HWTs have higher values than all MGTs across all these metrics.

Model	DW	LC	SC
ChatGPT	64	350	19
Cohere	37	256	13
Davinci003	58	315	16
Dolly-v2	54	342	18
Human	91	582	30

Table 3: Text statistics on the training set. DW = difficult words (mean), LC = lexicon count (mean), SC = sentence count (mean).

A.2 Stylometry features importance

Stylometry features are passed to a linear SVM classifier[10] to extract coefficients that may be interpreted as feature importances. Table 4 presents the most important features for MGTs and HWTs in the case of binary classification: for example, we can see that proper nouns are mostly associated with HWTs. It also makes it clear how the features are ordered by importance.

MGT feature	Wt.	HWT feature	Wt.
How to	3.28	NOUN SPACE	-4.12
SPACE *How*	2.34	SPACE	-4.12
NUM VERB	2.07	xxxx	-3.93
Xxxxx *the*	2.00	SPACE ADJ	-3.10
How	1.78	SPACE PROPN	-3.10
SPACE NUM	1.77	*the* SPACE	-2.67
Well	1.57	NOUN	-2.57
Xxx *the*	1.38	NUM SPACE	-2.21
dd Xxxxx	1.37	PROPN SPACE	-2.15
NOUN *you*	1.37	_XXX_d	-2.14

Table 4: Stylometric features highly weighted by the binary SVM classifier.

B Data Statistics

Table 5 shows some examples of parallel texts extracted from three domains represented in the training set (*WikiHow*, *Wikipedia*, and *PeerRead*). As explained in Wang et al. (2023), the data for each

Table 5: Parallel HWTs and texts generated by different LLMs in the training set extracted from selected domains.

domain was generated in a different way (for instance, using an article title only in some cases, and more extended inputs in others). We observe that there is much less consistency between the outputs generated by different LLMs in such domains as *Wikipedia* and *PeerRead* than in *WikiHow*. For instance, in the case of generated *Wikipedia* articles, the models cannot even agree on what personality they are describing (which is obvious from the very first sentences of such generated articles), while in the case of generated reviews from *PeerRead*, article descriptions also exhibit high diversity in the way they are presented in the review. At the same time, we hypothesize that generating texts for the *WikiHow* domain, describing *How to do X?*, results in higher consistency in the models' outputs, which is exemplified in Table 5.

SLPL SHROOM at SemEval2024 Task 06: A comprehensive study on models ability to detect hallucination

Abstract

Language models, particularly generative models, are susceptible to hallucinations, generating outputs that contradict factual knowledge or the source text. This study explores methods for detecting hallucinations in three SemEval-2024 Task 6 tasks: Machine Translation, Definition Modeling, and Paraphrase Generation. We evaluate two methods: semantic similarity between the generated text and factual references, and an ensemble of language models that judge each other's outputs. Our results show that semantic similarity achieves moderate accuracy and correlation scores in trial data, while the ensemble method offers insights into the complexities of hallucination detection but falls short of expectations. This work highlights the challenges of hallucination detection and underscores the need for further research in this critical area.

1 Introduction

While Natural Language Generation (NLG) has empowered machines to craft increasingly sophisticated text, transforming the NLP landscape, a dark undercurrent lingers - the phenomenon of hallucinations. In NLG, hallucinations refer to fabricated or misleading content woven into a generated text, deviating sharply from reality (Laurer et al., 2023)(Varshney et al., 2023). These fictional elements, despite seeming plausible due to their learned patterns, threaten the very core of NLG's promise: **reliability** and **truthfulness** (Ji et al., 2023). Imagine summarizing news articles riddled with fictional details or translating medical instructions brimming with inaccuracies. Such scenarios underscore the profound and potentially dangerous implications of hallucinations within NLG, making their detection and mitigation an urgent priority (Huang et al., 2023).

The specter of hallucinations looms large over NLG, particularly in domains demanding unyielding accuracy and safety. Imagine a medical summary riddled with invented details or medication instructions marred by mistranslations – these scenarios, chillingly possible, could directly jeopardize patient well-being (Ji et al., 2023). Recognizing this critical threat, researchers have embarked on a mission to untangle the complexities of hallucinations, developing methods for their detection and ultimately, prevention (Huang et al., 2023).

This paper dives headfirst into the challenge of hallucination detection within NLG, leveraging recent advancements in the field. We employ diverse methodologies to unmask these fictional elements in SemEval 2024 Task 6 evaluation data. Firstly, we assess the semantic similarity between generated text (hypotheses) and the provided reference outputs, gauging their alignment in meaning. Secondly, we harness the power of cosine similarity of embeddings, allowing us to capture subtle semantic nuances and relationships within text representations. Furthermore, we integrate Natural Language Inference (NLI), analyzing whether the generated text logically implies or contradicts factual information. Additionally, we utilize Large Language Models (LLMs) to discern context similarity, leveraging their inherent language understanding to identify inconsistencies that might point toward hallucinations. But our approach goes beyond established techniques. We introduce a novel judgment LLM framework, where one LLM acts as a discerning judge, scrutinizing the outputs of other LLMs for signs of hallucination. This innovative approach leverages the collective strengths of multiple models while introducing an element of meta-reasoning to the detection process.

2 Related Work

Several approaches have been proposed for detecting hallucinations in NLG text, categorized into different access levels to the model:

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1148–1154

Knowledge-based Approaches: Fact verification compares generated text with information from a domain-specific knowledge base. This approach can be effective but requires substantial knowledge bases and may not generalize well to unseen domains.

Classification approach: (Liu et al., 2022) created a dataset specifically for hallucination detection, but it has not been very successful.

White-box and Grey-box Approaches: Hidden state analysis: (Azaria and Mitchell, 2023) use an MLP classifier on the LLM's hidden states to predict truthfulness. This requires access to internal model states and may not apply to all architectures.

Token probabilities: Grey-box methods analyze the token probabilities generated by the LLM, assuming factual sentences contain high probability tokens. However, this can be unreliable for complex or ambiguous phrases.

Black-box Approaches: Self-evaluation: (Kadavath et al., 2022) propose asking the LLM itself to assess the likelihood of its output being correct. While promising, this method relies on the LLM's self-awareness and may not be reliable for all models.

Proxy model: This approach uses a publicly available LLM to estimate the token probabilities of the black-box model's output and infer its factual consistency. However, its accuracy depends on the proxy model's similarity to the black-box model.

Selfcheckgpt (Manakul et al., 2023) introduced a black box approach. The main idea of this study is that if the LLM is trained on a concept if multiple responses are taken from it, the samples will be similar and include consistent facts. Whereas if it is hallucinating, the samples will be different and contradictory. Therefore, several samples are taken from the LLM, and by measuring the information consistency between the responses, we can understand whether they are factual or hallucinated.

Our Approach: This paper builds upon existing work by combining elements from different categories. We leverage information consistency within multiple LLM responses, inspired by Selfcheckgpt (Manakul et al., 2023), but introduce a novel "judgment LLM" framework that goes beyond self-evaluation by employing one LLM to scrutinize the outputs of others. This approach aims to address previous methods' limitations by leveraging multiple models' collective strengths and introducing meta-reasoning into the detection process.

3 Task Description

The SHROOM challenge shines a light on a crucial hurdle in natural language generation (NLG) - pinpointing seemingly correct text that holds inaccurate meaning, often referred to as "misleading outputs." We, alongside other participants, are tasked with detecting these "semantic hallucinations," even when they are flawlessly written and grammatically sound.

The challenge focuses on "fluent overgeneration," where generated text, despite being linguistically coherent, strays from the intended semantic meaning. Participants operate in a "post hoc" setting, assuming models have already been trained and their outputs generated.

This is where we step in – to identify these misleading texts amidst seemingly accurate ones. This is critical to ensure the truthfulness and reliability of NLG outputs, especially in real-world applications.

The SHROOM challenge presents a two-pronged approach to tackle fluent overgeneration hallucinations: model-aware and model-agnostic tracks. Participants can choose to leverage knowledge of the model or not, depending on their approach. This multifaceted assessment covers three key NLG domains: definition modeling, machine translation, and paraphrase generation. The challenge provides a rich dataset including:

- **Checkpoints:** Model snapshots at different training stages
- **Inputs:** Prompts or texts used for generation
- **References:** Human-written outputs that represent the intended meaning
- **Outputs:** The actual text generated by various models trained with varying accuracy

Furthermore, a dedicated development set with binary annotations by multiple annotators ensures robust evaluation. This collaborative effort results in a majority vote gold label, boosting the dataset's credibility. Ultimately, the SHROOM challenge strives to develop effective solutions for combating semantic hallucinations generated by Large Language Models.

4 Proposed Systems

In our study, we tried to do the hallucination detection task in two separate methods and tried to compare and analyze their results:

4.1 Semantic Similarity method

Detecting hallucinations based on semantic similarity involves evaluating the coherence between language model outputs and reference data. In our study, we utilized this approach due to the availability of reference outputs. By assessing the semantic alignment between the generated text and the reference data, we aimed to discern instances of hallucination where the model output diverged from the intended meaning.

LaBSE The Language-Agnostic BERT Sentence Embedding (LaBSE) model is a dual-encoder approach based on pre-trained transformers, further refined for machine translation ranking. LaBSE excels at encoding sentences into fixed-length vectors while capturing semantic information across various languages (Feng et al., 2020). We employed LaBSE, particularly due to one of our tasks being machine translation (MT). By calculating the cosine similarity between model outputs and reference data, we determined the hallucination score in our study.

LLMs We utilized Zephyr-7B-β (Tunstall et al., 2023) and Mistral-7B (Jiang et al., 2023a) language models (LLMs) to assess the semantic similarity between model outputs and reference data, assigning a score between 0 and 1.

4.2 Natural Language Inference (NLI)

Due to the insufficient data available for hallucination detection, one proposed approach is to utilize models trained for similar tasks. **Natural Language Inference (NLI)** is one such task. In NLI, a language model assesses the relationship between text fragments, namely the premise and the hypothesis. This task involves multiclass classification aimed at determining whether the hypothesis can be inferred from, contradicts, or remains neutral to the premise.

The concept here involves treating reference data as the premise and model outputs as the hypothesis, then utilizing the probability of one of the outputs as a score to determine hallucination. We employed a **DeBERTa-v3** model, fine-tuned on datasets like MNLI, FERVER, ANLI, WANLI, and LingNLI (Laurer et al., 2023), to calculate the entailment score, which serves as the inverse of the hallucination score.

Note that employing NLI models in hallucination detection is not a novel concept and has been utilized by researchers in recent years (Ji et al., 2023). Here, we employed it to compare with our proposed judgment method.

4.3 Ensemble LLMs: The Judgment Method

To improve LLMs' reasoning and decision-making abilities, we explored two approaches: intrinsic self-correction and multi-agent feedback. We acknowledge that existing LLMs struggle with self-correction, and due to our LLMs' similarities, we believe they might mislead each other in a multi-agent setup. Inspired by the (Jiang et al., 2023b)article, we designed experiments using ensemble models. We asked LLMs to generate results multiple times with confidence scores, and finally extracted the best result.

We used two "commentator" models to assess the consistency between two sentences in detail. Based on their answers (yes/no/maybe, score, and explanation), a "judge" model (Mistral 7B or Zephyr 7B) performed hallucination detection.

While Mistral 7B and Llama2 (Touvron et al., 2023) provided three responses per data point, Zephyr only gave one. The advantage of multiple responses is the potential for higher accuracy. In cases of agreement, we considered the model confident and non-hallucinating. Contradictions suggested hallucination, but instead of simply discarding opinions, we devised rules to combine the responses.

We implemented the judgment method with three configurations:

Composition 1: Mistral and Zephyr commented, with Mistral judging based on their comments (label, score, description output).

Composition 2: Same as 1, but Zephyr judged.

Composition 3: Llama2 and Mistral commented, with Zephyr choosing whose opinion was more reliable.

5 Experiments and Experimental Setup

5.1 Semantic Similarity

In semantic similarity methods, we consider the target output in MT and DM tasks, and the input in PG tasks as reference. The similarity

score between the reference and hypothesis for each data point is computed, and 1 minus this score is considered as the probability of hallucination. Probabilities below 0.5 are classified as "Not Hallucination", while others are labeled as "Hallucination".

Using the **LaBSE** model, we obtained embeddings of the reference and hypothesis, and the cosine similarity of these two embeddings was considered as the similarity score.

Using the prompt "Is the Sentence supported by the Context above?" we asked each **LLM** (Zephyr and Mistral) to provide a score between 1 and 5 determining the similarity of the reference and hypothesis. These values were then normalized to range between 0 and 1.

5.2 Natural Language Inference (NLI)

For the NLI method, we used the reference as the premise and the hypothesis of each record as the hypothesis in the NLI model. This model outputs three probabilities which determine the probability of entailment, neutral, and contradiction between the two inputs. We utilized the probability of entailment for hallucination detection as it yielded better results compared to the other two options on the validation data.

5.3 Judgement method

Commenting LLMs were prompted to check whether the sentence was supported by the context and were asked to return a label, a score between 1 and 5, and an explanation.

Prompt for commenting LLMs:

Answer the following question using this JSON format: answer: (yes, no or maybe), score: (an integer number between 1 and 5, which 1 is for not supported and 5 is for fully supported), description: (a description for your answer). question Is the Sentence supported by the Context above?

Three outputs were taken from Llama2 and Mistral for each data, and these three outputs were converted into one with rules.
In the first two compositions, Mistral and Zephyr were commenters and the judge was asked to return an output with the same label, score, and explanation format after reviewing their explanations.
To see the result of self-correction, the judge was selected from among the commentators. The first time was Mistral and the second time was Zephyr.
This was the prompt:

Two experts are asked whether the given sentence supports the given context or not. We received two responses from these two experts. According to the explanations of these two experts, what is your decision? return your response in this JSON format label: (yes/no), score: (an integer number between 1 and 5, which 1 is for not supported and 5 is for full supported), explanation: (text).

In the third combination, the commentators were Llama2 and Mistral, and Zephyr was the judge. This time, we changed the prompt to the judge so that he chose only one of the two opinions as the more correct opinion.
This was the judge's prompt:

Answer the following question.
question
I asked two experts to determine whether the Sentence is supported by the Context or not.
Above are their explanations.Now judge which one gave a better reason. Give me just the index of the best expert with no explanations using this JSON format: index: (an integer number between 0 and 1, which 0 is for the first, 1 is for the second).

6 Results and Analysis

Semantic Similarity and NLI:
Table 1 and Figure 1 showcases the results of hallucination classification on trial data for each method we employed. Based on these findings, the Semantic Similarity method, utilizing models like LaBSE and Zephyr, demonstrates moderate accuracy and correlation scores. While LaBSE holds promise due to its renowned semantic similarity capabilities, there's room for improvement.
Notably, among the two Language Learning Models (LLMs) utilized in the semantic similarity approach, Zephyr yielded considerably better results than Mistral. This was also evident in the validation data, which influenced our decision to incorporate it into all our judgmental method experiments.

The DeBERTa model or NLI method outperforms all other methods, suggesting that incorporating natural language inference strengthens our ability

	Model Aware		Model Agnostic	
	Accuracy	Correlation(ρ)	Accuracy	Correlation(ρ)
LaBSE	0.706	0.426	0.658	0.464
Zephyr	0.700	0.370	0.694	0.423
Mistral	0.630	0.213	0.568	0.183
DeBERTa-v3(NLI Model)	**0.777**	**0.661**	**0.780**	**0.689**
Mistral Judge (Zephyr & Mistral Reasons)	0.644	0.291	0.610	0.250
Zephyr Judge (Zephyr & Mistral Reasons)	0.686	0.352	0.692	0.405
Zephyr Judge (LlaMa2 & Mistral Reasons)	0.624	0.293	0.548	0.249

Table 1: Experiment Results

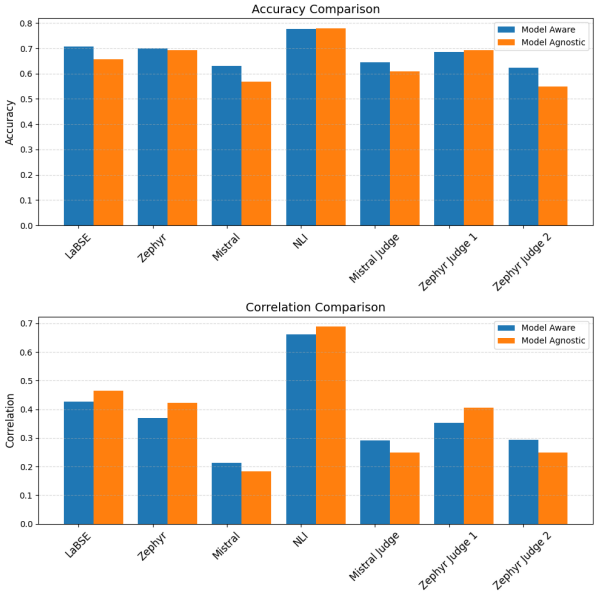

Figure 1: Comparison of accuracy and correlation scores across multiple models in model-aware and model-agnostic datasets.

to discern hallucinations by capturing semantic relationships between generated text and reference data.

Ensemble LLMs and the Judgment Method:

Furthermore, our study explored the effectiveness of Ensemble LLMs utilizing a Judgment Method. Surprisingly, the results indicate that Ensemble LLMs' performance wasn't superior to the previous method; in fact, it was even lower. Zephyr, acting as a judge, exhibited lower accuracy and correlation scores compared to Zephyr alone. While Mistral, in the role of a judge, showed improved performance compared to Mistral alone, it still falls short of methods like DeBERTa and the LaBSE model, suggesting limitations in this approach's effectiveness for hallucination detection.

7 Conclusion

This study investigated three distinct methods for hallucination detection in language models: the Semantic Similarity method, NLI and the Ensemble LLMs with Judgment method. By analyzing and comparing these approaches, we gained valuable insights into their efficacy and suitability for identifying hallucinatory content in model-generated text.

Semantic Similarity Method:
The utilization of pre-trained models such as LaBSE or large language models (LLMs) like Zephyr has demonstrated the potential for hallucination detection by assessing coherence between generated text and reference data through the Semantic Similarity method. Our findings underscore the effectiveness of employing specialized embedding models like LaBSE, which consists of approximately 500 million parameters, yielding comparable results to LLMs like Zephyr with 7 billion parameters. This highlights the efficiency of utilizing specialized embedding models for such tasks. However, while the semantic similarity method has shown moderate

success, it falls short of being deemed the optimal choice for hallucination detection. Relying solely on similarity may not adequately capture all forms of hallucination and could prove insufficient across various tasks and scenarios. It's worth noting that exploring these limitations is beyond the scope of this paper and warrants further investigation by other researchers.

NLI:
In conclusion, our findings underscore the efficacy of the NLI method as the optimal model for our study, indicating its potential utility in hallucination detection through entailment scoring. However, similar to the Semantic Similarity method, it is essential to acknowledge the inherent limitations in extrapolating the concept of entailment to the domain of hallucination detection. While NLI datasets offer valuable insights, they may not encompass the full complexity of hallucination phenomena. Therefore, while NLI tasks present promising avenues for further exploration in this area, additional research is warranted to ascertain their applicability and effectiveness in comprehensive hallucination detection frameworks.

Ensemble LLMs with Judgment Method:
This novel approach introduced multi-agent feedback and ensemble modeling for hallucination detection. LLMs acted as commentators, providing input to a "judge" model for final decision-making, aiming to enhance individual models' reasoning and decision-making. While not exceeding initial expectations, our experiments yielded valuable insights into the ensemble's effectiveness, with varying accuracy and correlation depending on composition and judging strategies.

Discussion and Future Directions:
Although the performance of the Ensemble LLMs with Judgment method wasn't as promising as envisioned, it sheds light on the complexities of hallucination detection and the limitations of current methods. One of the key challenges in these methods is finding the optimal prompt to detect hallucinations in the language model, and the utilization of prompt engineering methods can be beneficial in this regard. The potential for improved results using larger, more capable LLMs suggests avenues for future exploration.

Overall, this study contributes to addressing challenges posed by hallucinations in language models. By evaluating and comparing distinct detection methodologies, we highlight the strengths and weaknesses of each approach, paving the way for future research and development in this crucial area.

Abstract

Understanding the meaning of a written message is crucial in solving problems related to Natural Language Processing; the relatedness of two or more messages is a semantic problem tackled with supervised and unsupervised learning. This paper outlines our submissions to the Semantic Textual Relatedness (STR) challenge at SemEval 2024, which is devoted to evaluating the degree of semantic similarity and relatedness between two sentences across multiple languages. We use two main strategies in our submissions. The first approach is based on the Bag-of-Word scheme, while the second one uses pre-trained Transformers for text representation. We found some attractive results, especially in cases where different models adjust better to certain languages over others.

1 Introduction

Semantics refers to the meaning of language, including words, phrases, sentences, and overall text. Understanding semantics is essential for text comprehension and communication, as it allows us to interpret the intended meaning of a message accurately. Semantic relatedness measures how similar the meaning of two words or phrases is. It is based on the idea that words related in meaning tend to co-occur frequently in language or even have some causal relation connecting them. For example, *cat* and *dog* are semantically related because they refer to common household pets. Measuring semantic relatedness is essential for many natural language processing tasks, such as information retrieval, question answering, and machine translation.

Relatedness models play a crucial role in natural language processing (NLP). These models determine the degree of similarity or relatedness between two pieces of text. One of the critical benefits of relatedness models is that they can help improve the performance of NLP applications by providing more relevant and accurate results. For example, relatedness models can be used in information retrieval to rank search results based on their relevance to the user's query. Similarly, relatedness models can help identify the most relevant answer to a user's question while solving the question-answering problem.

A method based on corpus-based word similarity and string similarity, as well as their order, is proposed in (Islam and Inkpen, 2008). For string similarity, the authors used the longest common subsequence (LCS) in three ways to weight, i.e., the work is based on measuring the shared order of words. The word mover's distance, see (Kusner et al., 2015), reformulates the problem of comparing two sequences of words to an optimal transportation problem. It represents two sentences with its word embeddings and computes its optimal alignment using a dynamic programming solution; while it is pretty promising, it does not require sentences to be of some fixed size and works with a myriad of possible word embeddings. However, the technique was revisited by (Sato et al., 2022) and found diverse issues that limit its effectiveness.

Kenter and De Rijke (Kenter and de Rijke, 2015) have used word embeddings (word2vec) and external sources of semantic knowledge to represent text messages and meta-features. They aim to interpret proximity in the generated latent space as semantic similarity.

More recently, the Transformer deep neural networks have become a powerful alternative to both lexical and semantic approaches; the approach is based on a stack of encoders and decoders layers and the self-attention procedure (Vaswani et al., 2017). Transformers have a high computational cost, primarily for training. The first Transformer

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1155–1159
June 20-21, 2024 ©2024 Association for Computational Linguistics

that can be pre-trained and fine-tuned to match different tasks is BERT (Devlin et al., 2018a); after BERT, the high cost of training is paid once since fine-tuning needs less computational power and much less data. The interested reader should review the BERT manuscript and the seminal paper about pre-training NLP models (Howard and Ruder, 2018).

Fine-tuning BERT for classification or regression tasks is straightforward, not because it is a simple architecture but due to the myriad of literature, repositories, and examples showing how to do it [1]. However, its usage for sentence similarity needs to produce a vector that works fine for the task, and it is not trivial to produce one with its standard matrix output. The sentence transformers (Reimers and Gurevych, 2019) use siamese networks to create effective sentence vector embeddings for tasks working with pairs of sentences, for instance, similarity search and clustering.

In their research, Chandrasekaran and Mago (Chandrasekaran and Mago, 2021) have surveyed the evolution of semantic similarity methods, reviewing various NLP approaches, including traditional techniques and those found in machine learning and deep learning. They have provided a detailed study describing the strengths and weaknesses of each approach.

A binary version of the relatedness tasks is as follows: given a pair of sentences u and v, predicting true if u and v are related and false otherwise. A more elaborated task is to predict a relatedness score $\mathsf{rel}(u, v) \in [0..1]$, where values near zero mean for no relation and values near 1 mean for total relatedness. The latter definition is used in the Semantic Text Relatedness Task 1 (Ousidhoum et al., 2024b) at SemEval-2024, which asked for predicting relatedness scores for nine multilingual datasets; in particular, we tackled the problem as a supervised learning problem, i.e., we focused only on subtask 1 using the data for the nine languages(for more details about dataset see (Ousidhoum et al., 2024a)).

This document outlines the strategies we employed for the Semantic Textual Relatedness (STR) challenge in SemEval 2024, specifically the track A for the nine languages considered. To tackle this task, we utilized two distinct approaches: a transformer method for the English and Spanish languages, and an EvoMSA (Graff et al., 2020) solution for the remaining languages, which include Algerian Arabic, Amharic, Hausa, Kinyarwanda, Marathi, Moroccan Arabic, and Telugu.

The paper is organized as follows: Section 2 describes all our solutions to task 1. Section 3 shows our experimental results. Finally, Section 4 concludes our results and findings.

2 System overview

Nowadays, one of the most common approaches to dealing with natural language processing (NLP) problems is those Transformer-based language models. However, the pre-training procedure of this kind of language model needs a vast text corpus, and therefore, it may be impossible now to train them properly in many languages. In these cases, models based on counting and computing statistics may be more robust. We used Transformers for languages we know have large language models explicitly created for that language; for other datasets, we use a back-propagation optimized EvoMSA model for each one.

2.1 Out transformer-based approach

Our model was trained as a regression using the following procedure. For each pair, we extracted the sentence embedding for each sentence and evaluated the cosine similarity between pairs of embeddings. We trained a linear Support Vector Machine regressor using the cosine similarity to learn and predict the given relatedness score.

We tested several Transformer models but chose those that gave us the best performance, all of them were used directly as Hugging Face indicated. In this case, the best ones were microsoft-mpnet-base(Song et al., 2020) and multilingual BERT (Devlin et al., 2018b).

The microsoft-mpnet-base (MPNet) is a pre-training model, it tries to deal with the dependency on the predicted tokens and takes auxiliary position info into account to see a full sentence and reduce the position difference (Song et al., 2020).

The multilingual BERT is a well-known transformers model pre-trained on a large corpus of multilingual data self-supervised. In overview, it has two main tasks, MLM (Masked Language Modeling) and NSP (Next Sentence Prediction) (Devlin et al., 2018b), nevertheless, we just used the embedding representation to deal with the competition's task.

[1] For instance, one of the main sources of pre-trained Transformer models and documentation about them is the Hugging face project `huggingface.co`

2.2 Our EvoMSA approach

We use our EvoMSA framework for languages different than English and Spanish. EvoMSA models can be tailored for the dataset or pre-trained. Our pre-trained models were constructed using a small tweet corpus per language collected from the public Twitter stream. In addition, our EvoMSA models can be lexical based on bag-of-words (BoW) or semantic based on creating embeddings using numerous pre-trained classifiers in several self-supervised problems. Our BoW model produces highly sparse vectors where each component represents a token in the vocabulary. At the same time, our semantic representation (Dense) produces dense vectors created with the decision function of several binary classifiers, each one learned in a set of self-supervised tasks. The precise construction of EvoMSA models is detailed in (Graff et al., 2023).

Our approach to tackle the relatedness problem is to state it as a regression problem combining BoW and Dense representations using the following expression:

$$V = \left(S^\top \cdot S_Q, T^\top \cdot T_Q, (D \odot D_Q) \cdot \theta_1\right) \quad (1)$$

$$\hat{V} = \sigma\left(\frac{V}{\|V\|}\theta_2 + \beta\right) \quad (2)$$

where S, S_Q, T, and T_Q are sparse BoW matrices encoding pairs of sentences with statistics from pre-trained vocabularies (S) and training set-based vocabularies (T); D and D_Q are Dense matrices corresponding to pair of sentences, again computed with models pre-trained. Matrices without sub-indices mean for the first sentence in the pair, and those matrices with sub-indices Q mean for the second pair's element. The trainable parameters θ_1 and θ_2 are vectors, and β is a trainable scalar. Also, σ is the sigmoid function. We use differential programming with the JAX framework (Bradbury et al., 2018) for the Python programming language to train our models using $1 - \mathsf{pearson\_correlation}(\cdot, \cdot)$ as a loss function. In particular, we initialize θ_2 and β as the optimized parameters of a Linear Support Vector Machine parameters (solved firstly per each model with these parameters) and then θ_1 as a vector of ones instead of the typical random initialization to help on fine-tuning parameters. We call this model as One+.

We performed multiple modifications to this scheme and also found that defining V as $(T \odot T_Q) \cdot \theta_1$ results in a very competitive option. This model is called One-B. Note that this approach works only with the training set and does not require any pre-trained models.

3 Experimental results

We considered our two approaches with several expression variants for our EvoMSA-based approach and several models for our Transformer-based approach. Our model selection finds the best models using $1 - \mathsf{pearson\_correlation}$ with k-folds cross-validation along multilingual datasets. We selected the One+ and One-B model expressions since they demonstrated to be robust among many others coming from One+, also note that One-B works only with the training set.

In particular, the Transformer approach was better for Spanish and English datasets. We tested with several BERT, SBERT, and MPNet models before selecting *microsoft/mpnet-base* model for English and the multilingual BERT model, specifically the *bert-base-multilingual-cased*.[2]

Table 1 lists our best approaches for the different languages for the relatedness tasks in the third column. We can observe how transformers work fine for English and Spanish, languages with plenty of available models and data. For the rest of the languages, our EvoMSA approach performs better, but we can also observe that the simpler model One-B performs better in several datasets; this may be because of the lack of pre-trained models for that language, in particular, for languages with low available resources.

Table 1 also reports the Spearman correlation score and the global rank under the *dev* and *eval* datasets. Here, we can observe how our approach achieves different language ranks. In particular, we reached among the top ten results for Algerian and Moroccan Arabic. The English model is not among the top, but the score is not very different from the best ones. Note how One-B is competitive for Amharic, Hausa, Kinyarwanda, and Telugu, working without additional data.

It is important to say that, we did not achieve outstanding results, so, further analysis cannot be done, we saw lower results in those languages less studied, and more generalized models performed better in most common languages such as English and Spanish. Also, in the case of less-known languages, a simpler strategy was the best such as the Bag-of-Words-based proposed approach.

[2]Available on huggingface and its *Transformers* library.

Code	Language	Model	Spearman	Rank Dev Correlation (dev/eval)	Rank Eval
Arq	Algerian Arabic	One+	0.574 / 0.566	8	10
Amh	Amharic	One-B	0.676 / 0.702	19	15
Eng	English	Transformer	0.789 / 0.809	35	29
Hau	Hausa	One-B	0.547 / 0.576	20	15
Kin	Kinyarwanda	One-B	0.430 / 0.630	14	12
Mar	Marathi	One+	0.750 / 0.784	21	20
Ary	Moroccan Arabic	One+	0.820 / 0.811	12	9
Spa	Spanish	Transformer	0.701 / 0.678	7	13
Tel	Telugu	One-B	0.818 / 0.801	10	14

Table 1: Best model and results for each language dataset for the relatedness prediction problem.

4 Conclusion

This manuscript describes our participation in Task 1 of Semantic Textual Relatedness (STR) at SemEval 2024. We used two main approaches: a transformer-based approach and an EvoMSA-based one. The latter has lexical and semantic representations, with variants using pre-training and fully learned from the training data. Our transformer solution works better for Spanish and English, while our EvoMSA works better for the other languages. In particular, we support low-resource languages using our EvoMSA without pre-trained models. Our competitive results give evidence suggesting that languages with fewer resources can benefit from models that do not require an enormous corpus to be trained; this can be an alternative to large models. Nevertheless, this is a very complex task, and better efforts could be made in the future.

OctavianB at SemEval-2024 Task 6: An exploration of humanlike qualities in hallucinated LLM texts

Octavian Brodoceanu
University of Bucharest Faculty of Mathematics and Informatics
octavian.brodoceanu@gmail.com

Abstract

The objective of the SHROOM shared task (Mickus et al., 2024) is to identify sequences of text generated by Large Language Models that contain incorrect, nonfactual, or fabricated information. These sequences, referred to as 'hallucinations', are characterized by lower probabilities assigned to the outputs, as demonstrated by research (Varshney et al., 2023). This discrepancy highlights a possible contrast in the language used between hallucinated and non-hallucinated texts. The aim of this paper is to investigate whether hallucinated responses exhibit phrasing and patterns that more closely resemble those of machine-generated text rather than coherent, human-like language.

1 Introduction

The SHROOM shared task, as described by Mickus et al. (2024), has as its objective 'detecting grammatically sound output that contains incorrect semantic information (i.e. unsupported or inconsistent with the source input), with or without having access to the model that produced the output'. This type of output is encompassed by generations often referred to as "hallucinations". According to Varshney et al.,in the context of language models, hallucinations refer to the generation of text or responses that seem syntactically sound, fluent, and natural but are factually incorrect, nonsensical, or unfaithful to the provided source input. (Maynez et al., 2020; Holtzman et al., 2023; Koehn and Knowles, 2017) With the advent of mainstream Large Language Models brought upon by OpenAIs ChatGPT (Brown et al., 2020), it is a relatively new and important topic in this context. Apart from the possible spread of misinformation, being able to make this distinction is crucial for the adoption of Large Language Models in domains highly sensitive to misinformation, such as the medical, jurisdictional or financial fields. Possible repercussions include medical misdiagnosis, fictitious financial or legal advice, or exploitation by bad actors in order to deceive users.

In our approach to solving this task, we employ two methods. The first method involves utilizing models trained for detecting machine-generated text in order to distinguish between regular and hallucinated sequences. The other involves using looking at the loss of the hypothesis as scored by an LLM(Large Language Model), in the hope that generations with low probabilities can be properly tagged as hallucinations. This method was introduced by Fu et al. (2020) as GPTScore as a way to get a numerical assessment of an aspect in a given text.

When it comes to the first method, the hypothesis to be tested is that patterns which help differentiate machine generated texts will be transferable to the task at hand. The rationale is as follows: the training data of the model is human-written text, therefore deviations from the training set could be detected in this manner. From the experimental results on the model aware track, the performance of this method yielded a score of 0.483. This is below the baseline achieved using an LLM to label the generations. These results could stem from the hypothesis itself, or the fact that the model is not able to differentiate the texts of newer LLMs.

The second method was employed after the end of the competition, as a way to further explore the dataset and its characteristics. It was based on the success of Ji et al., who used a similar approach in a reprompting system meant to reduce hallucinations. On the validation data, it yielded an accuracy of 0.686 without the target reference and 0.702 when it was included in the prompt on the model aware track.

2 Background and Dataset

The objective of the SHROOM shared task is to detect hallucinations in two distinct datasets: one that is model agnostic and one that is model aware.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1160–1165

Both of the datasets consist of text pertaining to 3 tasks: DM - 'Definition Modeling' - which involves providing the definition of a word given surrounding context, PG - 'Paraphrase Generation' - in which the generated text is meant to be a paraphrase of the input, and MT - 'Machine Translation' - in which the task is to translate a given sequence. The text provided for the definition modeling and the paraphrase generation task types is in English. For the machine translation task, the prompt is provided in the native language and the hypothesis and target are both in English. The model-aware validation dataset consists of 499 datapoints, while the model-agnostic version has 501 datapoints. The test sets both have 1500 samples.

Train Model Aware		
Column Name	**Description**	**Data Type**
hyp	Generated sequence	String
tgt	Desired target sequence	String
src	Prompt sequence	String
ref	Target column	Categorical
task	Prompt task type	Categorical
model	LLM model name	Categorical

Table 1: Description of Model Aware Dataset Columns

The main difference between the datasets is that the 'model' column is not present in the model agnostic version. This distinction is not relevant to the experiments presented in this paper, as no data is used apart from the 'hyp' - generated sequence column.

The datasets are split by the organizers in train, validation and test sets respectively, with the validation and test sets containing human-annotated labels. The probability of hallucination is defined as the average of the label given by each annotator, and the final label is chosen by majority vote from said labels. The validation and test set have 5 such labels per entry.

An example datapoint consists of the input 'Resembling or characteristic of a weasel.' - corresponding to this input, the output is structured as per Table 2.

Output		
label	**p(Hallucination)**	**id**
Not Hallucination	0.470	1

Table 2: Example of Model Aware Dataset Row

3 Related Work

Due to the importance and the relative novelty of the LLM hallucination detection task, there are many recently proposed ways to alleviate the issue. Ji et al. proposed a system for preventing hallucinations via self reflection, by using GPTScore as a way to gauge aspects such as factuality and consistency. Using a community sourced body of knowledge, for example wikipedia, in order to greatly enhance context (Semnani et al., 2023). Perturbations to the input to check for model self consistency (Zhang et al., 2023). Segmenting the generations and reprompting to check for consistency also appears to have lead to good results. (Wei et al., 2023; Zhou et al., 2023; Khot et al., 2023) Looking at the log probabilities of the output words to detect low-confidence generations (Varshney et al., 2023) has also been proposed, an approach very similar to one of the two methods used.

4 Methodology

4.1 Method 1: Generated Text Detection

The first method involves using a pretrained model for distinguishing machine-generated text. The decision to use this type of model stemmed in part from the similarity of the two tasks. Considering the fact that the training set for Large Language Models is often entirely human-written, deviations from the dataset - which are a possible cause of hallucinations - should appear as machine-like generations.

The model used during inference is 'roberta-large-openai-detector' (Solaiman et al., 2019). It is a a RoBERTa-large (Liu et al., 2019) model that has been trained in order to differentiate between texts generated by the Large Language Model GPT2 (Radford et al., 2019) after its inception. As the authors explain, it is able to distinguish texts generated by the LLM with 95% accuracy. The use of this model is, however, a limitation of the experiment. As cited by the authors (Solaiman et al., 2019) 'The model developers also report finding that classifying content from larger models is more difficult, suggesting that detection with automated tools like this model will be increasingly difficult as model sizes increase.' It should also be noted

that due to the nature of the MT - Machine Translation task, hallucinations of this type are unlikely to be picked up by the model.

Input is taken as the 'hyp' hypothesis column in the dataset. Since it is under the form of simple text, it will be tokenized using the 'roberta-large-openai-detector' tokenizer with padding and truncation. No other changes were made to the text.

Outputs are represented by the logits resulting from passing the tokenized input sequences through the model. The logits are then passed through a softmax function in order to obtain probabilities attributed to each class (0 - not generated/not hallucinated, 1 - generated/hallucinated). The class with the highest probability is saved as the 'label' and the probability of the input belonging to the 'hallucinated' label is 'p(hallucination)'. In the case of the test set, the id of the sequence is added to the structure to be added to the json.

4.2 Method 2: GPTScore

The second method involves prompting a pre-trained LLM with a task and checking the loss attributed to the predefined output.

The prompt is comprised of: instruction, demos, input and output.

Instruction prompts were constructed for each of the 3 tasks in the dataset, for example: "The following is a Definition Modeling task. Please focus on capturing the correct meaning based on the surrounding context in the original text. "

For each of the 3 tasks, demos were constructed by randomly sampling 3 datapoints from a subset of the validation dataset. This subset involves rows labeled "Not hallucination" by all five human annotators, in the case of the positive examples, and "Hallucination" in the case of the negative examples.

The input is the prompt sequence provided in the dataset. The output is the response provided in the same datapoint.

As an example, a prompt with no demos would be: Give the definition for the specified words in the given context. The answer for "The sides of the casket were covered with heavy black broadcloth , with velvet caps , presenting a deep contrast to the rich surmountings . What is the meaning of surmounting ?" is "A sloping top ."

The resulting output of the method is defined as the average of the logprobs of the output sequence (i.e. "A sloping top"). Naturally, the output score is predicated on the model doing the evaluation, with more accurate models having a higher chance of giving better results.

Optionally, the target sequence can be added to the prompt. Although this increases performance, as we would expect, it changes the use of the method to that of evaluation.

The models used include a quantized version of **Mistral-7B** and **OpenHermes-13B**. After generating the scores for each of the inputs, the goal is to employ simple binary classification. Logistic regression and SVM were tested, with logistic regression consistently giving superior results.

5 Experimental Setup

The first method is fully unsupervised, and therefore does not require calibration on the training set. The second method requires us to have a subset of labeled data to determine the score threshold.

For evaluating our models, we used the metrics proposed by the organizers: accuracy, based on the labels and Spearman's Rho, based on the probabilities assigned to each entry.

6 Results

The outputs on the test set model-aware track yielded a score of 0.483. The results on the validation dataset were the following:

Validation Set Results		
Track	**Accuracy**	**Rho**
Model Agnostic	0.545	0.033
Model Aware	0.465	-0.145

Table 3: Valdiation dataset results

The results for method 2 are shown in Tables 4 and 5:

Model Aware Track Validation Set Results				
Model	**Total**	**PG**	**MT**	**DM**
Mistral-7B	0.686	**0.776**	0.696	0.638
OpenHermes-13B	0.688	**0.808**	0.691	0.643

Table 4: Validation model aware dataset accuracy results

Model Aware Track Validation Set Results				
Model	**Total**	**PG**	**MT**	**DM**
Mistral-7B	0.687	0.704	**0.812**	0.657
OpenHermes-13B	0.701	0.688	**0.802**	0.625

Table 5: Validation model agnostic dataset accuracy results

Valdiation task aware results			
Track	**DM**	**PG**	**MT**
Model Agnostic	0.540	**0.624**	0.497
Model Aware	0.489	**0.608**	0.345

Table 6: Valdiation dataset task-aware accuracy results

6.1 Track results analysis

As evident, the model agnostic accuracy surpasses that of the model-aware track by a considerable margin. This difference could be due to statistical noise, as both results seem to be within 5% of the expected value for random binary attribution i.e. 50%. One competing hypothesis would be that the hidden distribution of the agnostic track allows for the model to better differentiate between the two classes.

Inferred sample label distributions in the form of 'Hallucinated'/'Not Hallucinated' are the following: 177/322 for model agnostic and 240/261 for model aware. For comparison, the real distributions are 218/281 model-agnostic track and 206/295. The fact that the model-aware results exhibit a near 50-50 split, in contrast to the model-agnostic track, whose distribution is closer to that of the real set, leads some credence to the hypothesis that the inference model is be able to detect relevant patterns.

Spearman correlation is calculated using the 'p(hallucination)' column. In the context of the proposed model, this is the probability assigned to class 1 ('Hallucination'). From the resulting values, it is evident that the probabilities of the reference and input display little to no correlation, with both values being near 0. From this, we come to the conclusion that the proposed method is not suitable for inferring the probability of hallucination.

6.2 Task-aware results

In order to investigate if the task had any impact on the performance of the model, standard accuracy was calculated for each separate subset of sequences. This was done on both the model aware and model agnostic track. The results are as per Table 6:

6.3 Task-aware results analysis

DM - 'Definition Modeling' showcases better performance on the agnostic dataset. As stated above, this could be attributed to random noise, or a difference in the distribution of the dataset.

PG - 'Paraphrase Generation' displayed the highest accuracy out of all three tasks on both the model-agnostic and model-aware tracks. It is a consistent and large enough improvement from the random baseline to be considered significant.

MT - 'Machine Translation' task results were the lowest, with the model reaching the expected random outcome of 50% on the model agnostic track. The results for the Model Aware Track showed an unexpected and significant difference, 15.5% from the random baseline. Low performance is to be expected, as this task requires the least free generation. These results could be due to the fact that the LLM is simply translating sequences that have been written by humans, and this requires less 'creative' generation on its part.

One plausible explanation for why the method has displayed superior performance on the PG task could be attributed to its inherently free-form nature compared to the other tasks. Definition Modeling is an information retrieval adjacent task, and Machine Translation leaves little room for interpretation, apart from cases of ambiguous wording. This suggests that the proposed method may have potential applications in specific tasks given to LLMs.

As per the results showcased in 4 and 5, we notice the increased performance when using OpenHermes-13B. This is to be expected, as it is the larger model, and the efficacy of the method is predicated on the quality of the certainty attributed by each model. We notice a leap in accuracy for certain tasks, Paraphrase Generation in the case of the model aware track, and Machine Translation in the case of the model agnostic track. This may once again be due to a difference in the distributions of the two tracks.

7 Additional experiments

Post competition, in addition to method 2, we have attempted to further finetune the RoBERTa model

to see if we can improve performance. In order to do this, we have used the dataset provided by Liang et al.. It is comprised of 749 datapoints, containing text generated by GPT3 and GPT4, as well as human written text. Before any additional operations, the model has an accuracy of 0.539 on this set, further confirming the fact that more powerful models and methods of detecting machine generated text are needed for use on newer LLMs. The dataset was split in a 9-1 ratio of training-validation data. After finetuning for 3 epochs the accuracy on the evaluation dataset reached an accuracy of 0.591. From this we can conclude the model is not able to properly learn. The results of the finetuning are shown in Table 7.

Validation Set Results	
Track	**Accuracy**
Model Agnostic	0.436
Model Aware	0.411

Table 7: Validation Set Results

The reason for why the model does not seem to learn can either be due to the model itself, or the generations are too humanlike to be told apart. As for the results of the finetuning, the performance of the model has dropped significantly on both datasets.

8 Conclusions

We have proposed two methods, the first based on using models pretrained on generated text detection, and the second based on looking at the confidence displayed by the LLM under the form of logits. Reviewing the results, we can assess that the tasks of generated text detection and hallucination detection showcase too large of a divergence for the approaches to generally be used interchangeably. However, the results on the Paraphrase Generation task may warrant further investigation into the use of models pretrained for text generation detection for the hallucination detection task. Concerning the second method we have explored, it has showcased promising results on specific tasks in each track, which may warrant use in an ensemble method.

8.1 Limitations

The main limitation of this experiment was the model used for inference. As it was trained to discriminate the generations of GPT2, which is a significantly smaller model compared to the current Language Models.

8.2 Future Work

In future work, we might explore model finetuning on newer datasets used for discerning between human and machine-generated texts, as well as finetuning pretrained models on labeled hallucination related tasks.

Another simple improvement would be utilizing pretrained models able to better distinguish between generated and human written texts.

We may test the first method on other free-form generation tasks, as this seems to be a strong suit.

We may also look into newer methods for detecting machine generated text, that account for the leaps made by the recent advancements in LLMs.

We may further investigate the discrepancy in accuracy for the provided datasets when using GPTScore.

Acknowledgements

I would like to thank Ana Sabina Uban for kickstarting the idea for this work.

Abstract

In this paper, we present the description of our proposed system for Subtask A - multilingual track at SemEval-2024 Task 8, which aims to classify if text has been generated by an AI or Human. Our approach treats binary text classification as token-level prediction, with the final classification being the average of token-level predictions. Through the use of rich representations of pre-trained transformers, our model is trained to selectively aggregate information from across different layers to score individual tokens, given that each layer may contain distinct information. Notably, our model demonstrates competitive performance on the test dataset, achieving an accuracy score of 95.8%. Furthermore, it secures the 2nd position in the multilingual track of Subtask A, with a mere 0.1% behind the leading system.

1 Introduction

The evolution and widespread adoption of Generative Pre-trained Transformers, notably with the release of ChatGPT have significantly influenced the landscape of digital communication and content creation. While these advancements herald a new era of efficiency and creativity, enabling applications ranging from sophisticated writing aids to advanced conversational agents, they simultaneously introduce significant challenges and ethical concerns. In fact, the proliferation of AI-generated texts has raised alarm over issues like the dissemination of misinformation, the facilitation of academic fraud, and the potential erosion of trust in digital content. This underscores the urgent requirement for robust solutions to identify AI-generated content, safeguarding the integrity of information while embracing the benefits of AI advancements.

In this paper, we aim to develop a reliable detection system by participating in the SemEval Task 8 on Machine-Generated Text Detection. This task is notable for its complexity, as it involves Multi-generator, Multidomain, and Multilingual text, making it a highly challenging endeavor. Furthermore, the evaluation is conducted on unseen domains and languages, establishing it as a robust benchmark for evaluating AI text detectors. This requires the model to effectively generalize across different domains and languages. We focus our efforts on the binary detection, which aims to determine whether a text has been generated by an AI or not. To tackle this challenge, we propose a syntactically motivated architecture. Our approach is primarily inspired by the realization that texts generated by AI and humans are semantically similar, as they are derived from comparable topical distributions. Hence, we argue that the distinction between them lies in their syntax and writing style.

Typically, transformer-based text classification relies on information from the last layer for classification. However, our model takes a different approach by dynamically aggregating information from all layers of the transformer (a.k. *multi-layer fusion* Shi et al., 2022). This method is intentionally designed to harness the diverse linguistic information present at various levels of the transformer, as noted in previous studies (Peters et al., 2018; Jawahar et al., 2019; Tenney et al., 2019). These studies reveal the uneven distribution of linguistic features across the transformer's architecture, with syntactic details predominantly in the initial layers and complex semantic information in the deeper layers. By utilizing insights from all layers, our model aims to capture the entire range of linguistic cues, enhancing its capability to accurately differentiate between human and AI-generated content. Additionally, our model moves beyond the standard practice of using just the [CLS] token for classification in BERT-based classifiers. It applies sequence labeling to classify each token in the text as either Human or AI. We believe that

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1166–1171

this approach enables the capture of more complex phrasal structures, which helps in more effectively distinguishing the style and syntax of a text.

Our proposed model obtains competitive performance on the test leaderboard of the shared task subtask A, securing the 2nd best position on binary multilingual detection, using a much smaller model than other approaches often using finetuned LLMs.

2 Related Works

Since the introduction of large-scale pre-trained models like GPT-3, capable of generating high-quality text, the detection of machine-generated text has attracted considerable interest. The most common and straightforward strategy for addressing this task involves training models on a labeled dataset comprising both human and AI-generated text. This approach is utilized by well-known models such as the OpenAI ai text detector and commercial models such as GPTZero (Tian and Cui, 2023). While these models achieve strong in-domain results, they often require labeled datasets from a wide range of sources and domains to achieve generalization. An alternative approach involves zero-shot detectors, which do not necessitate any model training. For example, DNA-GPT (Yang et al., 2024) assesses N-Gram divergence between the continuation distribution of re-prompted text and the original text for making predictions, while Detect-GPT (Mitchell et al., 2023) employs a curvature-based criterion to determine if a passage is generated by a specific LLM.

3 Preliminary study

In this section, we detail a preliminary study that provided essential insights, guiding us towards our final model design.

Motivation Our aim was to assess the efficacy of semantic embeddings, particularly sentence-BERT, in differentiating between machine-generated and human-authored texts. Figure 1 illustrates the embeddings of texts from both humans and various language models, visualized using sentence-BERT embeddings (Reimers and Gurevych, 2019) and UMAP for dimensionality reduction (McInnes et al., 1802).

Analysis The visualization in Figure 1 reveals that texts generated by humans and various language models occupy similar positions in the latent semantic space, with data points from different sources blending together, lacking distinct separation. Given the limited utility of semantic features for discriminating human and ai-generated text, we argue that the key to distinguishing between these texts may lie at the syntactic level.

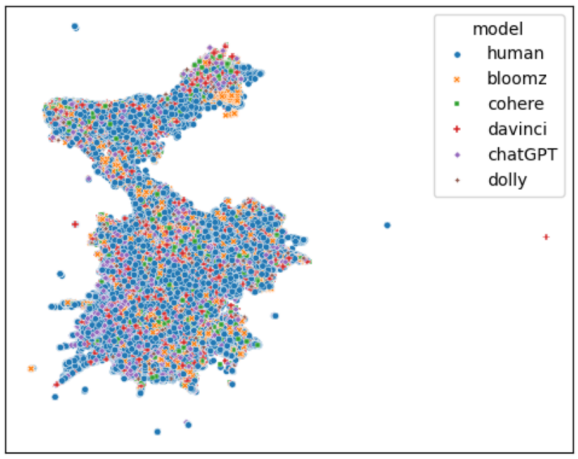

Figure 1: Visualization of UMAP-projected Sentence-BERT embedding of documents generated by human and different large language models

Model Motivated by our analysis, we propose a text classification model that take into account syntactic information. More specifically, our approach introduces two main innovations: 1) the integration of information from all layers of the transformer for classification, referred to as *layer fusion* (Shi et al., 2022). This method leverages the rich linguistic information embedded across the transformer's layers to compute classification scores (Peters et al., 2018; Tenney et al., 2019; Jawahar et al., 2019). 2) The usage of sequence labeling for text classification, which could enhance the model's ability to capture complex phrasal structures, potentially improving its ability to differentiate texts based on style and syntax.

4 Architecture

In this section, we provide a detailed overview of our proposed model's architecture illustrated in Figure 2.

4.1 Representation

Given a text input $X = \{x_1, \ldots, x_N\}$, the model first computes embeddings for each word using a multi-layer pre-trained transformer encoder such as BERT:

$$H = \texttt{transformer}(X) \in \mathbb{R}^{N \times L \times D} \quad (1)$$

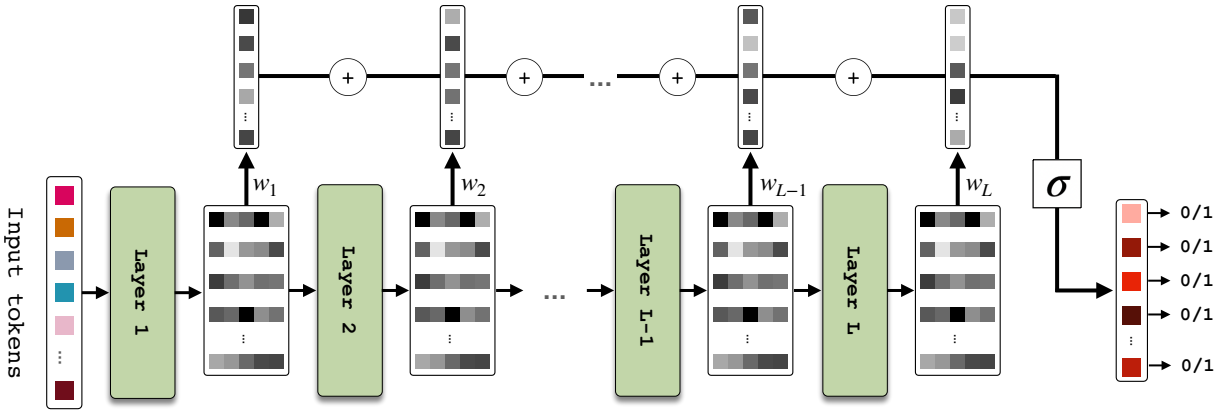

Figure 2: Architecture of Our Proposed Model. A pre-trained transformer receives a sequence of tokens as input and generates token embeddings at each layer. Token scores are computed for each layer, and the final score for each token is derived from the sum of scores across all layers. The probability of each token being AI-generated is determined by applying a sigmoid activation function to its score.

Here, N is the number of words in the input, L is the number of transformer layers, and D is the model dimension.

4.2 Scoring

The model then computes a score for each word, integrating information across all transformer layers, similar to the proposed *multi-layer fusion* by Shi et al. (2022). The score s_i for a word at position i is computed as follows:

$$s_i = \sum_{l=1}^{L} \boldsymbol{w}_l^\top \boldsymbol{h}_i^l \in \mathbb{R} \tag{2}$$

In this equation, $\boldsymbol{h}_i^l \in \mathbb{R}^D$ represents the embedding of the i-th word at the l-th layer. $\boldsymbol{w}_l \in \mathbb{R}^D$ is a learned weight vector specific to layer l. This scoring mechanism allows the model to weigh the contributions of different layers differently for each token, potentially emphasizing certain linguistic features over others.

4.3 Classification

For the classification, we employ a sequence labeling approach, where each word is classified based on its computed score. For this, a sigmoid function is applied to convert the token scores into probabilities, and a threshold is used to make a binary decision:

$$y_i = \begin{cases} 1 & \text{if } \sigma(s_i) > 0.5, \\ 0 & \text{otherwise.} \end{cases} \tag{3}$$

This step results in a binary classification for each word, indicating its belonging to the positive class. Finally, the classification of the entire sentence is determined by averaging these binary decisions:

$$y = \frac{1}{N} \sum_{i=1}^{N} y_i \tag{4}$$

This average represents the probability of the sentence belonging to the positive class, synthesizing the word-level classifications into an overall sentence-level prediction. Finally, given an input X, we consider it as being machine-generated if its computed probability is superior to 0.5, i.e $y > 0.5$.

4.4 Training

To train our model, we focus on maximizing the likelihood of the correct label for each token by minimizing the binary cross-entropy loss at the token level. The binary cross-entropy loss for an input text of length N can be formulated as follows:

$$\mathcal{L} = -\sum_{i=1}^{N} \left(y^* \log(p_i) + (1 - y^*) \log(1 - p_i)\right) \tag{5}$$

Here, y^* represents the true label of the input (1 for human-generated and 0 for AI-generated), p_i denotes the predicted probability of the i-th token being human-generated (computed by applying the sigmoid function to the score s_i).

5 Experimental setup

5.1 Data

For our experiments, we used the dataset provided at SemEval-2024 Task 8, more details can be found in the task description (Wang et al., 2024a). It is

based on the benchmark M4 dataset (Wang et al., 2024b), which is a large-scale multi-generator, Multi-domain, and Multi-lingual corpus containing human-written and machine-generated texts. The machine-generated texts were produced by prompting several LLMs, including ChatGPT, textdavinci-003, Cohere, Dolly-v2 and BLOOMz from different sources such as Wikipedia, WikiHow, Reddit, arXiv, PeerRead for English, Baike and Web question answering for Chinese, news for Urdu, RuATD for Bulgarian and news for Indonesian.

5.2 Hyperparameters

In our experiments, we utilized the `xlm-roberta-large` model as the backbone for our architecture. The model was trained with a batch size of 12 across a maximum of 2 epochs, as we found that training further harms the validation results. More specifically, we observed that while training longer always improves in-domain performance measured on a held-out subset of the training set, it harms performance on out-of-domain validation (Kumar et al., 2022). We hypothesize this is due to overfitting on in-domain data, making long training harms the generalization of the model. Due to this, we evaluated our model on the out-of-domain validation set every 500 gradient steps and kept the best-performing model for testing. We employed different learning rates for the backbone (pre-trained transformer model) parameters and the added projection parameters: the learning rate for the backbone was set to `1e-5`, and the learning rate for the projection weights (randomly initialized) was set higher at `3e-4`. This distinction allows for delicate fine-tuning of the pre-trained model (to not distort the pre-trained representation too much), while more aggressively updating the newly introduced parameters to adapt to the task-specific features. During training, we use a maximum sequence length of 128 subwords to allow faster training, but we compute test set prediction using the maximum size of 512 tokens. The experiments were conducted with a runtime limit of 2 hours and 30 minutes for each experiment, utilizing an NVIDIA V100 GPU.

5.3 Other approaches

In this section, we provide an overview of the methodologies adopted by participants based on their description[1] in the shared task (Wang et al., 2024a). The baseline approach involved fine-tuning an XLM-Roberta-base model specifically for this task. The team *USTC-BUPT* presented the top-performing system, where English texts were processed using the Llama-2-70b model to generate average embeddings. These embeddings were then classified using a two-stage CNN. For texts in languages other than English, they treated classification as a next-token prediction task utilizing the mT5 model. Another notable participant, the *KInIT* team, employed an ensemble strategy that combined fine-tuned large language models (LLMs), including Mistart and Falcon, with zero-shot statistical methods to improve performance. Lastly, the *L3i++* team opted to fine-tune a LLaMA-2–7b model for the task. In comparison to the top-performing participants, only our approach uses small-scale transformer models.

[1]Note that we do not have access to entire articles.

Rank	Team	Accuracy (%)
1	USTC-BUPT	95.9
2	FI Group (*Ours*)	95.8
3	KInIT	95.0
4	priyansk	93.8
5	L3i++	92.9
–	*Baseline*	80.9

Table 1: Test leaderboard results.

6 Results

6.1 Test leaderboard results

Table 1 shows the top 5 scores from the leaderboard obtained using the test dataset, which includes domains and languages never seen during training.

Our team achieved the second-highest score, with an accuracy of 95.8%, narrowly trailing the top system by only 0.1%. There were 69 participants in the multilingual track in subtask A, out of a total of 159 participants across all SemEval-2024 Task 8.

6.2 Ablation study

In this section, we conduct an ablation study to examine the impact of various components of our model, including the backbone, layer fusion, and sequence labeling. The outcomes of this analysis are reported in Table 2.

Results Regarding the backbone, our findings indicate that `XLM-R-large` achieves better per-

Model	Accuracy (%)	F1 (%)
Ours (`XLM-R-base`)	87.3	87.1
Ours (`XLM-R-large`)	87.6	87.5
- w/o sequence labeling	81.2	81.1
- w/o layer fusion	78.1	77.4
Baseline (`XLM-R-base`)	75.0	–

Table 2: Ablation performance on the validation set. We perform ablation of our proposed model to see the influence of sequence labeling and layer fusion.

formance than `XLM-R-base`, suggesting that our method scales effectively. Moreover, our analysis reveals that both sequence labeling and layer fusion significantly contribute to the model's performance. Specifically, omitting sequence labeling—which involves aggregating the scores of the CLS token across layers—results in a 6-point decrease in accuracy. Similarly, excluding layer fusion leads to a more pronounced decline, with over a 10-point drop in F1 score and a 9-point decrease in accuracy. These findings underscore the critical roles that token-level prediction and layer fusion play in enhancing the overall effectiveness of our model.

6.3 Learned Weight Analysis

Motivation Figure 3 visualizes the norm of the learned weight vector for each layer of our model, denoted as w_l in equation 2. We hypothesize that the magnitude of these projection weights reflects the significance of each layer in contributing to the final prediction, with higher weights suggesting a more substantial influence on the token scores.

Analysis The Figure 3 indicates that layer 0, the embedding layer, has the lowest norm value. Given that this layer does not incorporate contextual information, its minimal contribution suggests that mere word appearance is insufficient for determining whether a text is produced by a human or an AI, aligning with the findings of Gallé et al. (2021). Interestingly, layer 24, which is the final layer, also shows a relatively low norm value. This observation resonates with analyses indicating that the last layer tends to be rich in semantic content yet sparse in syntactic details. We believe this explains the lower norm value for the last layer, as semantic aspects alone are inadequate for distinguishing between human and AI writing. Conversely, the highest norm values are predominantly found in layers 3 to 6 and 20 to 22, suggesting these layers

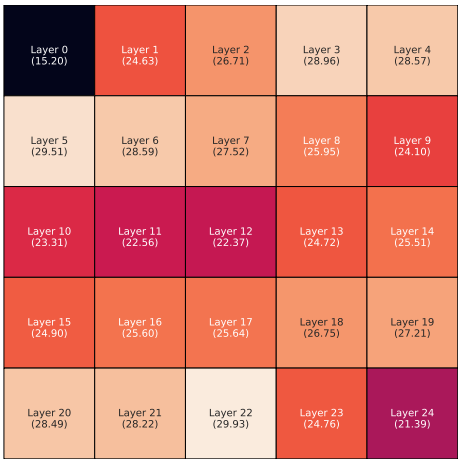

Figure 3: Norm (L1) of the weight vector w_l for each layer in our model.

play a pivotal role in the model's decision-making process.

7 Conclusion

In this paper, we presented our system submitted to SemEval-2024 Task 8 for detecting human-written and machine-generated text, achieving 2nd place for subtask A on multilingual texts. Our system relies on a hierarchical fusion strategy that adaptively fuses representations from transformer's layers, with a focus on syntactic rather than semantic information. By leveraging syntactic features, particularly through sequence labeling, we captured more phrasal structures of text, thereby enhancing our ability to distinguish text styles and syntax. Our system achieved robust performance across diverse unseen domains and languages, demonstrating its adaptability and generalization capability, notably considering that we used a smaller model compared to other proposed systems often reliant on fine-tuned LLMs.

Abstract

With the widespread adoption of large language models (LLMs), such as ChatGPT and GPT-4, in various domains, concerns regarding their potential misuse, including spreading misinformation and disrupting education, have escalated. The need to discern between human-generated and machine-generated text has become increasingly crucial. This paper addresses the challenge of automatic text classification with a focus on distinguishing between human-written and machine-generated text. Leveraging the robust capabilities of the RoBERTa model, we propose an approach for text classification, termed as RoBERTa hybrid, which involves fine-tuning the pre-trained Roberta model coupled with additional dense layers and softmax activation for authorship attribution. In this paper, we present an approach that leverages Fabien et al. (2020) Stylometric features, hybrid features, and the output probabilities of a fine-tuned RoBERTa model. Our method achieves a test accuracy of 73% and a validation accuracy of 89%, demonstrating promising advancements in the field of machine-generated text detection. These results mark significant progress in the domain of machine-generated text detection, as evidenced by our 74th position on the leaderboard for Subtask-A of SemEval-2024 Task 8.

1 Introduction

SemEval-2024 Task 8 Wang et al. (2024) is centered on the detection of machine-generated text across multiple generators, domains, and languages. This detection is crucial for mitigating the risks associated with the potential misuse of large language models (LLMs), which have advanced capabilities in generating multilingual human-like texts. In this task, the goal is to differentiate between machine-generated and human-authored texts, addressing concerns regarding the authenticity and trustworthiness of textual content in various contexts and languages.

The rapid advancement of deep learning technologies has ushered in a new era where the boundaries between human-generated and machine-generated artifacts are increasingly blurred. This evolution is epitomized by the emergence of Deepfakes, which convincingly mimic genuine human actions, and the widespread adoption of Natural Language Generation (NLG) systems, particularly those leveraging neural language models. These developments have led to the creation of neural texts that bear striking resemblances to human-authored content, posing significant challenges in distinguishing between the two.

Traditionally, Authorship Attribution Uchendu et al. (2020) within the realm of Natural Language Processing (NLP) focused on accurately attributing text to its true human author. However, with the advent of Neural Language Generation (NLG) techniques Uchendu et al. (2023) capable of producing human-quality open-ended texts, the attribution landscape has expanded to encompass authorship by humans, machines, or a combination thereof. As the quality of machine-generated texts continues to improve, the lines between human and machine-generated text become increasingly indistinct, exacerbating the challenge of differentiation.

Moreover, the potential for misuse of these technologies, including the generation of misinformation, fake reviews, and political propaganda at scale Uchendu et al. (2023), underscores the critical need for effective methods to discern neural texts from human-authored content—a problem known as Neural Text Detection (NTD) Uchendu et al. (2023), which is a sub-problem of the broader authorship attribution domain.

In this paper, we present an approach named RoBERTa hybrid, tailored to address the challenge of distinguishing between human and machine-generated texts. This method utilizes the fine-tuning of a pre-trained RoBERTa language model, enhanced with additional layers for text classifica-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1172–1176

tion, in evaluating the performance of pre-trained language models for text differentiation tasks. We specifically target the task of automated detection of machine-generated text, recognizing the growing importance of discerning between human-authored and artificially generated content in today's digital landscape.

In this paper, we present an approach named RoBERTa hybrid, tailored to address the challenge of distinguishing between human and machine-generated texts. We specifically target the task of automated detection of machine-generated text, recognizing the growing importance of discerning between human-authored and artificially generated content in today's digital landscape. We secured the rank 74 on the leaderboard for SubTasK-A

2 Related Work And Background

Subtask A of Task-8 in the SemEval challenge Wang et al. (2024) utilized a monolingual dataset, focusing on distinguishing between human-written and machine-generated text. The dataset primarily employed English as its medium. Each instance in the dataset is labeled as either 1 (indicating machine-generated text, specifically generated by Chat-GPT) or 0 (indicating human-written text).

The Subtask A dataset consists of three subsets: training, development, and testing datasets. The training dataset contains 119,757 samples, while the development dataset comprises 5,000 samples. The testing dataset includes 34,272 samples. In the training dataset, there are 63,351 samples labeled as class 0 and 56,406 samples labeled as class 1. Conversely, the development dataset consists of 2,500 samples, all of which are labeled.

Within the dataset, there are columns denoted as "model" and "source." The "model" column specifies which model generated a particular text, while the "source" column indicates the origin of the text.

Previous research has explored various approaches to authorship attribution (AA), aiming to accurately identify the authors of texts, which is crucial in fields such as forensic linguistics, plagiarism detection, and content analysis. Traditional methods have relied on Stylometric features, which capture the distinctive writing style of individual authors based on linguistic patterns and characteristics. However, recent advancements in natural language processing (NLP) have introduced transformer-based models like BERT (Bidirectional Encoder Representations from Transformers) that have demonstrated state-of-the-art performance across a range of NLP tasks. Fabien et al. (2020) showcased the effectiveness of BERT for text classification tasks, highlighting its ability to extract semantic and syntactic information from text. However, there has been a lack of systematic exploration into the performance of fine-tuned pre-trained language models, specifically for authorship attribution. The introduction of BertAA addresses this gap by fine-tuning BERT with a dense layer and softmax activation specifically for authorship attribution. The incorporation of BERT allows for the utilization of semantic and syntactic information encoded in text representations, potentially improving the accuracy of authorship attribution systems. Furthermore, BertAA integrates Stylometric features, which capture lexical and structural characteristics of text, and hybrid features, which combine character-level n-grams, enhancing the model's ability to capture both content-related and stylistic aspects of authorship.

However, Stylometric classifiers encounter challenges when tasked with accurately determining the authorship of human versus neural texts. Uchendu et al. (2023) noted that certain Stylometric classifiers were surpassed in performance by deep learning-based models. Furthermore, research findings, as cited in Schuster et al. (2020), revealing Stylometry's inability to identify neural misinformation underscore the necessity for alternative methodologies to address the Authorship Attribution (AA) task within the context of Neural Text Generation (NTD). Consequently, researchers have increasingly embraced and refined deep learning-based approaches for distinguishing between neural and human-generated text. These approaches can be further classified into three main categories: Glove-based, Energy-based, and Transformer-based Attribution models.

Language models often exhibit a lack of syntactic and lexical diversity, characterized by the repetition of the same expressions and a limited use of synonyms and references. This behavior Fröhling and Zubiaga (2021) can be approximated using named entities (NE) and properties of coreference chains, along with shifts in part-

of-speech (POS) distributions between human and machine-generated text. Features based on NE-tags, coreference chains, and POS distributions Fröhling and Zubiaga (2021) can effectively capture the differences in syntactic and lexical diversity Gehrmann et al. (2019) between human and machine-generated text.

Repetitiveness: Machine-generated text is prone to repetitiveness Holtzman et al. (2019), often overusing frequent words and exhibiting highly parallel sentence structures. Features such as the share of stop-words, unique words, and words from "top-lists" can highlight the lack of diversity in machine-generated text. Additionally, measures of n-gram overlap in consecutive sentences can reveal patterns of lexical and syntactic repetition, further distinguishing between human and machine-generated text.

Lack of Coherence: A significant challenge in machine-generated text is the lack of coherence Holtzman et al. (2019), particularly over longer sentences and paragraphs. Coherence can be assessed through the development of entities and the tracking of their appearance and grammatical roles across the text. Features based on entity grids and transition frequencies Badaskar et al. (2008) between consecutive sentences can capture the coherence or lack thereof in machine-generated text.

By incorporating these features into automated detection methods, researchers aim to develop robust and accessible tools for distinguishing between human and machine-generated text, thereby mitigating the risks associated with language model abuse.

3 System Overview

The experiments conducted encompassed Subtask A within the monolingual track. Subtask A posed a binary classification challenge, aimed at discriminating between human-generated text and text produced by the Machine (ChatGPT).

In addressing Subtask A, a Stylometric classifier was developed to exploit diverse stylistic attributes, encompassing text length, word count, average word length, count of short words, proportion of digits and capital letters, frequencies of individual characters and digits, hapax-legomena (a measure of text richness), and the frequency of 12 punctuation marks. These Stylometric features were employed in training a Logistic Regression model.

Furthermore, hybrid features, incorporating the 100 most frequent character-level bi-grams and tri-grams, were integrated. Logistic Regression was applied for classification using these hybrid features as well.

The ultimate model adopted a hybrid strategy, whereby output probabilities from the RoBERTa classifier, the Stylometric classifier, and the hybrid features classifier were concatenated. This concatenated output underwent classification using an additional Logistic Regression model. We chose RoBERTa due to its robust performance in natural language understanding tasks, its ability to handle a wide range of text data, and its pre-training on large-scale corpora, which helps capture nuanced linguistic patterns.

To refine the RoBERTa hybrid model, class probabilities derived from the Stylometric features and those obtained from fine-tuning the RoBERTa model were concatenated separately for both the training and test datasets. Additionally, the probabilities derived from training a Logistic Regression model on hybrid features were integrated into the hybrid model.

3.1 Stylometric Features Extraction

- Length of text: Count the number of characters or tokens.
- Number of words: Total word count.
- Average word length: Average length of words.
- Number of short words: Count of words below a certain threshold.
- Proportion of digits and capital letters: Ratio of digits and capitals to total characters.
- Individual letter and digit frequencies: Count of each letter and digit.
- Hapax-legomena: Words occurring only once.
- Frequency of punctuation marks: Count of specific punctuation marks.

3.2 Hybrid Features Extraction

- Character-level n-grams: Extract the 100 top frequent character-level bi-grams and tri-grams in the text.

3.3 Logistic Regression Model

- In logistic regression, the input features are linearly combined, and the result is passed through the logistic function (also known as

the sigmoid function) to obtain the probability of the positive class.

- Mathematically, the logistic regression model can be represented as:

$$P(y = 1|x) = sigmoid(w^T \cdot x + b)$$

where $P(y = 1|x)$ is the probability of the positive class given the input features x, w represents the weight vector, b is the bias term, and $sigmoid$ is the logistic function.

Hyperparameters:

- **Penalty**: This hyperparameter controls the regularization strength, with options typically including L1 (Lasso) or L2 (Ridge) regularization.
- **Tolerance**: It determines the stopping criteria for the optimization algorithm, specifying the tolerance for the change in the loss function between iterations.
- **Maximum Iterations**: This sets the maximum number of iterations allowed for the optimization algorithm to converge.
- **Intercept**: A boolean parameter indicating whether to include an intercept term in the model.

These hyperparameters are crucial for controlling the model's complexity, preventing overfitting, and optimizing performance. They are typically tuned using techniques like grid search or cross-validation to find the best combination for the given dataset and task.

Model	Parameter	Value
Hybrid feat.	Char. N-grams	(2,3)
LR	Penalty	l2
	Tolerance	0.0001
	Cost	1.0
	Max Iterations	100
	Intercept	True
RoBERTa	Max Iterations	100
	Intercept	True
	Config Epochs	1 to 5
	Input token length	512

Table 1: Parameters of the experiments.

4 Experimental Setup and Evaluation Results

Experimental Design: In our experimental setup, we fine-tuned the RoBERTa model over 5 epochs using the training dataset. To ensure model robustness and prevent overfitting, we utilized a validation dataset consisting of 80% of the training data and 20% of the testing data.

Our approach involved creating a hybrid model, which integrated class probabilities from three classifiers: Stylistic classifier, hybrid classifier, and RoBERTa classifier. These probabilities were concatenated and passed through a Logistic Regression layer for training.

To assess the efficacy of our model, we evaluated its performance using the accuracy metric.

Classifier	Accuracy (%)
Stylometric classifier	49
Hybrid Features Classifier	58
RoBERTa + Style Classifier	73
Hybrid Classifier (RoBERTa + Style + Hybrid)	73

Table 2: Accuracy Results on the Test Dataset

Evaluation of Results: The accuracy results on the test dataset are summarized in Table 2. We observe varying performance among different classifiers. The Hybrid Classifier (RoBERTa + Style + Hybrid) achieved the highest accuracy of 73%, outperforming both the Stylometriv Classifier (49%) and the Hybrid Features Classifier 58%. However, (RoBERTa + Style) based Classifier too resulted in 73% This indicates that incorporating RoBERTa-based representations along with Stylometric and hybrid features significantly improved the model's ability to classify text accurately.

The superior performance of the Hybrid Classifier can be attributed to its utilization of RoBERTa, a transformer-based model known for its ability to capture rich contextual information from text. By leveraging RoBERTa's representations along with Stylometric and hybrid features, the Hybrid Classifier achieved a more comprehensive understanding of the input text, leading to better classification accuracy.

On the other hand, the Stylometric Classifier and the Hybrid Features Classifier exhibited lower

accuracies compared to the Hybrid Classifier. This could be due to their reliance on a narrower set of features for classification, which may not capture the full complexity of the input text.

5 Conclusion

In this paper, we have presented an innovative approach, termed the RoBERTa hybrid model, for the task of detecting machine-generated text. Leveraging the robust capabilities of the Roberta model, we fine-tuned it coupled with additional dense layers and softmax activation for authorship attribution. Our method incorporates a hybrid of Stylometric features, character-level n-grams, and the output probabilities of a fine-tuned Roberta model, achieving significant advancements in machine-generated text detection.

Experimental results demonstrate the effectiveness of our approach, with a validation accuracy of 89% and a test accuracy of 73%. Although these results do not surpass the baseline methods, they highlight the potential of our approach in addressing the challenges posed by machine-generated text across diverse domains.

Moving forward, our work opens avenues for further research in enhancing the accuracy and robustness of machine-generated text detection systems. Future efforts may focus on exploring additional feature representations, optimizing model architectures, and addressing the challenges posed by monolingual machine-generated text. Our efforts in enhancing machine-generated text detection we have tried to contribute to the broader objective of safeguarding the integrity and credibility of online content.

Acknowledgements

We extend our heartfelt appreciation to all contributors to this research. Our Supervisor has provided invaluable insights and feedback, enriching the quality of our work. We extend special gratitude to the reviewers for their constructive comments and suggestions, which greatly enhanced the paper. The first author led the experimental design and paper writing process, while the second author with my guidance has contributed exclusively to proofreading and paper writing, not involved in the experimental design.

EURECOM at SemEval-2024 Task 4: Hierarchical Loss and Model Ensembling in Detecting Persuasion Techniques

Youri Peskine and **Raphael Troncy** and **Paolo Papotti**
EURECOM, France
firstname.lastname@eurecom.fr

Abstract

This paper describes the submission of team EURECOM at SemEval-2024 Task 4: Multilingual Detection of Persuasion Techniques in Memes. We only tackled the first sub-task, consisting of detecting 20 named persuasion techniques in the textual content of memes. We trained multiple BERT-based models (BERT, RoBERTa, BERT pre-trained on harmful detection) using different losses (Cross Entropy, Binary Cross Entropy, Focal Loss and a custom-made hierarchical loss). The best results were obtained by leveraging the hierarchical nature of the data, by outputting ancestor classes and with a hierarchical loss. Our final submission consist of an ensembling of our top-3 best models for each persuasion techniques. We obtain hierarchical F1 scores of 0.655 (English), 0.345 (Bulgarian), 0.442 (North Macedonian) and 0.177 (Arabic) on the test set.

1 Introduction

Online misinformation is a complex research topic. It can appear in many shape and forms (text, images, videos, etc.), within different contexts (political debates, news articles, social media posts, etc.). As memes generate high engagement on social media, they are also used for disinformation campaign by exploiting rhetoric persuasion. This year's "SemEval-Task4: Multilingual Detection of Persuasion Techniques in Memes" task aims at detecting named persuasion techniques in memes. The full overview of the task and its sub-tasks are detailed in (Dimitrov et al., 2024).

As a brief summary, SemEval-2024 Task 4 consist of detecting persuasive techniques in Memes. The task breaks down into 3 sub-tasks; sub-task 1 use the textual content of the meme to detect the persuasion techniques, sub-task 2a use the whole image and text to detect the persuasive techniques, while sub-task 2b only consist of binary detection. In sub-task 1, a total of 20 persuasion techniques are used. In this work, we only describe our solution to tackle this sub-task 1.

Our approach consists of an ensembling model of our top-3 best models for each persuasion techniques. In our experiments, we reached the best results leveraging the hierarchical nature of the data, with hierarchical loss, and outputting ancestor classes. Our method can be reproduced using the code at https://github.com/D2KLab/semeval-2024-task-4.

2 System Description

In this section, we describe the system used in our submission. We also present approaches that were considered but not kept in our final submission.

2.1 Models

We experimented with multiple transformer-based models to tackle persuasion detection in the textual content of the memes.

- **BERT** (Devlin et al., 2019): First introduced in 2018, this model is based on the bidirectional transformer encoder architecture (Vaswani et al., 2023) trained with masked language model and next sentence prediction tasks.
- **BERT-HarMe**[1]: This model is a fine-tuned version of BERT on multiple datasets[2] (Kiela et al., 2021; Suryawanshi et al., 2020) about harmful/hateful speech in memes.
- **RoBERTa** (Liu et al., 2019): This model changes the BERT pre-training approach, making it more robust.
- **AlBERT** (Lan et al., 2020): AlBERT focuses on reducing the number of parameters

of BERT to increase the training speed and lower memory requirements.

- **DistilBERT** (Sanh et al., 2020): This model uses knowledge distillation during pre-training to reduce the size of BERT.
- **DeBERTa** (He et al., 2021): DeBERTa improves on BERT and RoBERTa by introducing a disentangled attention mechanism and an enhanced mask decoder.

2.2 Datasets

In this task, we use multiple training datasets. We experimented adding the train, validation and dev sets from SemEval-2021 Task 6 (Dimitrov et al., 2021) and the PTC corpus (Da San Martino et al., 2020) to the training data. Table 1 shows the datasets and their respective sizes.

- **SemEval-2021 Task 6**: This dataset also annotates memes with regards to the same 20 persuasion techniques. The train, validation and dev sets are appended to the training set of this task without any modification.
- **PTC Corpus**: This dataset contains news articles annotated at the span level with regards to 18 propaganda techniques. We first split the articles into sentences and transfer the span-level label to sentence-level. In this dataset, some labels are the same as this year's task, and can be aligned in a straightforward manner. However, when propaganda labels are different, they often correspond to multiple persuasion techniques. To align these labels, we add all the corresponding persuasion techniques valid for the propaganda. We only appended sentences that contain a propaganda technique to the training set of this task (around 5% of the total number of sentences).

2.3 Outputting ancestor classes

In this task, the goal is to detect the 20 persuasion techniques, but they appear in a hierarchical framework. The official metrics of the challenge are hierarchical F1 (**F1H**), hierarchical precision (**PreH**) and hierarchical recall (**RecH**), which all take into consideration the hierarchical nature of the data. Since ancestor nodes are inherently outputted when detecting child nodes, we also tried to directly detect the ancestor classes. This raises the number of classes to 28 (instead of 20). Thus, the ancestor node can still be outputted even if it's child node has not been detected, resulting in better performing models.

2.4 Losses

We also experimented with different training losses, which address multiple aspects of the data. For example, balancing the classes misrepresentation in the data with class weights, or using hierarchical loss to reflect the hierarchical nature of the data.

- **Binary Cross Entropy (BCE) Loss**: This loss computes BCE losses for each class, weighted with the inverse frequency of its label, and sum them. This loss requires the output layer to have the size of number of classes.
- **Cross Entropy (CE) Loss**: We used 20 different CE losses for each class, weighted according to the inverse frequency of each label. Each loss computes the performance of the model at detecting a specific class. The final loss is the sum of the 20 losses. This loss requires the output layer to have twice the size of number of classes.
- **Focal Loss (FL)** (Lin et al., 2020): This loss addresses class imbalance by down-weighting the loss assigned to well-classified examples. We used the implementation proposed by (Edgar et al., 2020). This loss requires the output layer to have the size of number of classes.
- **Custom Hierarchical Loss (HL)**: In order to reflect the hierarchical nature of the data, we implemented a custom hierarchical loss function. This function uses max pooling on logits x^c from children classes of the same ancestor a (e.g. Name Calling, Doubt, Smears, Reductio ad Hitlerum and Whataboutism are all children of the Ad hominem ancestor). The newly created logit correspond to the output of the model on the corresponding ancestor. Thus, we can compute the BCE Loss between

this output and the true label y^a of the ancestor. We can iterate by max-pooling all the logits in the next ancestor. Note that logits can correspond to children or ancestor classes (e.g. the Logos ancestor pools the logits of Justification, Repetition, Intentional Vagueness, and Reasoning, even though the logits of Justification and Reasoning are also pooled from other child classes). We then sum all these BCE losses together, which measure how well the model performs to detect the ancestor rather than each persuasion techniques. Before summing this loss to the original classification loss of the techniques (CE, BCE or FL), we apply a normalization factor α. In practice, we found best results when α is equal to 0.5. Equations 1 and 2 describe the computation of this loss. $\mathcal{A}$ describes the ensemble of all ancestor techniques.

$$\mathcal{L}_{HL} = \mathcal{L}_{CE,BCE} + \alpha \cdot \sum_{a \in \mathcal{A}} \mathcal{L}^a_{BCE} \quad (1)$$

$$\mathcal{L}^a_{BCE} = y^a \cdot log\sigma(\max(\{x^c\}_{c \in child(a)})) + (1 - y^a) \cdot log(1 - \sigma(\max(\{x^c\}_{c \in child(a)}))) \quad (2)$$

2.5 Data augmentation

Some persuasion techniques have very little training data available in the datasets. We tried generating new samples for the bottom 5 classes with different methods.

- **Round Translation**: We translated every sample in French and translated them back to English. This can generate new sentences similar to the original ones. However, this new data is very limited and will not be varied.
- **GPT-4-Turbo Generation** (et al., 2023): We used GPT-4-Turbo to generate completely new sentences corresponding to a persuasive technique. As showed in (Peskine et al., 2023), definitions of the class label have a significant impact in the performance of GPT models. We provided the definition of the persuasive technique provided by the organizers[3] in the system prompt, along with 5 randomly selected samples. We then used few-shot prompt technique with 5 more randomly selected samples, and finally asked the model to generate a new sentence. We generated two sets of 30 and 50 examples for five classes. For reproducibility measures, the full prompt is available in Appendix A.

2.6 Training process

For training our models, we use the AdamW (Loshchilov and Hutter, 2019) optimizer with a learning rate of 2e-5, and a weight decay of 0.01. We also use a ReduceLROnPlateau Learning rate scheduler, reducing the earning rate by a factor of 0.7 if results have not improved in 4 epochs. Most experiments are done on 10 epochs, saving the best model (according to F1H) on the validation set. We also experimented with freezing the first few layers of the pre-trained BERT-based model to keep its acquired knowledge when trained on massive amount of data.

2.7 Ensembling

We trained many models according to different combinations of the previous parameters. Our final submission consists of a majority voting among the top-3 models for each persuasion technique evaluated on the dev set and according to the F1-score. These models are not necessarily the best models overall according to hierarchical F1, but demonstrate effectiveness in detecting specific persuasion technique. We also perform majority-voting on ancestor classes with models that output them (Section 2.3).

3 Results

We share our results on the dev set provided by the organisers in Table 2. These results show the performance of some single models as well as the performance of the ensembling used in the final submission. Table 4 shows the performance of each class on the dev set, using the ensembling model for classification. Table 3 shows the results of our final submission on the 4 test languages: English, Bulgarian, North Macedonian and Arabic. We translate non-English languages using `py-googletrans`[4] to English in order to run our models and obtain the predictions. We would like to note that our official submission for the Arabic language was incorrect, due to Arabic-to-English translation errors on our

end. We corrected the error and also show the performance of the model, albeit being an unofficial result.

4 Discussion

Model-wise, our best results were obtained using BERT, RoBERTa and BERT-HarMe. We ultimately did not use any of AlBERT, DeBERTa and DistilBERT models in our final submission as those were not in any top-3 best performing models of any persuasion techniques. The BERT-HarMe models were the best-performing on the detection of 'Slogans', 'Appeal to Authority', 'Flag-waving', 'Appeal to fear/prejudice', 'Black-and-white Fallacy/Dictatorship', 'Thought-terminating cliché', 'Presenting Irrelevant Data (Red Herring)', 'Glittering generalities (Virtue)', 'Doubt', 'Logos', 'Justification' and 'Distraction' classes. RoBERTa models were the best-performing for 'Repetition', 'Bandwagon', 'Ethos'.

We also noticed a slight performance increase by adding the 2021 dataset during training, which was not necessarily true when adding the PTC corpus. This is probably due to the fact that the PTC Corpus is about news articles and not memes. Our data-augmentation experiments on round-translation did not improve the results at all, while the GPT-4-Turbo augmentation experiments provided a very slight boost, but not for the augmented classes.

The hierarchical nature of the task and the evaluation metrics were reflected in the results, as most of our best performing models are outputting 28 classes by including the ancestors and/or are trained with Hierarchical Loss (**HL**). However, best models at detecting 'Causal-Oversimplification' are using BCE Loss.

We can see in Table 4 that some persuasive techniques are easier to detect than others. For example, 'Appeal to authority' seems to be the easiest class to detect, and 'Obfuscation, Intentional vagueness, Confusion' the hardest. Training data seems to lightly correlate with performance results, with some strong outliers like 'Smears' underperforming comparing to it's high number of training samples, and 'Bandwagon' over-performing. As for the ancestor classes, the highest-level 'Logos', 'Ethos' and 'Pathos' have the highest performance, while those composed of the hardest per-

Reasoning	0.552
Justification	0.727
Simplification	0.496
Distraction	0.389
Ethos	0.810
Ad Hominem	0.742
Pathos	0.704

Table 4: Results of our ensembling model on the dev set, per-class.

suasive techniques to detect like 'Simplification', 'Distraction' and 'Reasoning' have lower performance.

5 Conclusion

In this paper, we describe the system team EURECOM used for sub-task 1 at SemEval-2024 Task 4: Multilingual Detection of Persuasion Techniques in Memes. We explore multiple BERT-based models, training datasets, losses, data augmentation procedures, and training process. Our final submission consists of an ensembling model that performs majority voting between our top-3 best performing models for each persuasive technique. We find that some pre-trained models on harmful meme data are competitive, and that incorporating hierarchical information in the training process, such as outputting the whole 28 classes (including the ancestors) or using a hierarchical loss significantly improves the results. We obtain a hierarchical F1 score of 0.675 on the dev set and 0.655 (English), 0.345 (Bulgarian), 0.442 (North Macedonian), 0.177 (Arabic) on the test set.

Abstract

This paper discusses challenges in Natural Language Generation (NLG), specifically addressing neural networks producing output that is fluent but incorrect, leading to "hallucinations". The SHROOM shared task involves Large Language Models in various tasks, and our methodology employs both model-agnostic and model-aware approaches for hallucination detection. The limited availability of labeled training data is addressed through automatic label generation strategies. Model-agnostic methods include word alignment and fine-tuning a BERT-based pretrained model, while model-aware methods leverage separate classifiers trained on LLMs' internal data (layer activations and attention values). Ensemble methods combine outputs through various techniques such as regression metamodels, voting, and probability fusion. Our best-performing systems achieved an accuracy of 80.6% on the model-aware track and 81.7% on the model-agnostic track, ranking 3rd and 8th among all systems, respectively.[1]

1 Introduction

In Natural Language Generation (NLG), the trade-off of prioritising fluency over accuracy results in neural networks generating "hallucinations" – outputs fluent but factually inaccurate. The automatic identification of such errors represents a substantial challenge (Huang et al., 2023; Ji et al., 2022). The SHROOM shared task on hallucination detection (Mickus et al., 2024) highlights concerns about the practical utility of fluently generated yet inconsistent outputs. In the SHROOM shared task, Large Language Models' (LLMs) outputs for definition modeling (DM), machine translation (MT), and paraphrase generation (PG) tasks are presented with input source text and corresponding 'gold' reference text. Notably, for PG, the input source text serves as the reference 'gold' text. While the training dataset lacks labels, an issue which is addressed in Section 3, the validation dataset includes binary labels of Hallucination or Not Hallucination and hallucination probability of 0 to 1, corresponding to Hallucination and Not Hallucination, respectively, for the LLM's output. These assessments, based on five annotators' evaluations, rely on determining if the model's output is supported by the 'gold' reference, from either the 'gold' target text, source text, or both, depending on the task (DM, MT, or PG).

The SHROOM dataset is categorised into two tracks: model-agnostic and model-aware. The model-aware track, in contrast to the model-agnostic, includes the specific LLM responsible for the provided output. This paper introduces methods tailored to both tracks and since the model-agnostic techniques can be applied to both, evaluations for these methods are conducted on both test datasets to provide a comprehensive analysis. The model-agnostic methods entail employing word alignment to establish semantic similarity between the model output and the 'gold' reference as well as fine-tuning a BERT-based model for hallucination detection. On the other hand, model-aware approaches delve into the analysis of hidden states and attention flow within the model architecture. Ultimately, a diverse set of ensemble techniques, comprising logistic regression with binary labels, linear regression with raw probabilities, voting, and probability fusion, are introduced to amalgamate the proposed methods.

2 Related Work

Since the tendency of LLMs to produce incorrect output poses a serious challenge in their application, the task of hallucination detection has recently attracted a variety of research work. Model-agnostic approaches include the training of dedicated machine learn-

[1]Our code is available at https://github.com/kleines-gespenst/shroom-hackathon

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1183–1196

ing models, such as a token-level classifier for detecting hallucination in machine translation (Zhou et al., 2021) or the BERT-based Vectara `hallucination_evaluation_model`[2], the latter which we also use in our model-agnostic experiments (see Section 3.2). Recent datasets for training and evaluating such models include task-agnostic corpora such as (Li et al., 2023) and HaDeS (Liu et al., 2022) as well as datasets focusing on specific generation tasks such as text summarisation (Laban et al., 2022), fact verification (Thorne et al., 2018), question answering (Pang et al., 2022; Longpre et al., 2021), or paraphrase generation (Zhang et al., 2019; Shen et al., 2022).

Another set of approaches involves comparing a model's output to some reference using any of a variety of unsupervised similarity metrics, including standard ngram-based measures such as BLEU (Papineni et al., 2002) and ROUGE (Lin, 2004) but also distributional similarity metrics such as BERTScore (Zhang et al., 2020), BARTScore (Yuan et al., 2021), or DiscoScore (Zhao et al., 2023). A large-scale analysis of the performance of these metrics on hallucination detection have been performed in the recent TRUE survey (Honovich et al., 2022). Further model-agnostic approaches to hallucination detection include comparing multiple LLM responses to a single query (Manakul et al., 2023), prompting LLMs to evaluate the likelihood of their own output being correct (Kadavath et al., 2022) as well as the use of external knowledge bases to assess the faithfulness of model outputs (Thorne et al., 2018; Guo et al., 2022; Peng et al., 2023)

Model-aware methods for hallucination detection include classifying an LLM's hidden layer activations to determine whether the question is answerable (Slobodkin et al., 2023) or whether its output is true (Azaria and Mitchell, 2023). The latter approach is the basis of the SAPLMA system, which we have also used in our experiments for the model-aware track of the shared task (see Section 3.3).

3 Methodology

Within the scope of hallucination detection, we employed both model-agnostic and model-aware methods. Our model-agnostic approaches encompassed rule-based techniques, featuring the application of string metrics and word embeddings, alongside the fine-tuning of pretrained language models. Model-aware methods leveraged the internal data of LLMs.

3.1 Automatic Data Annotation

Beyond the primary task of hallucination detection, a significant challenge arose due to the limited availability of labeled data, with only the SHROOM validation set being provided with labels. Faced with the absence of labeled training data, we explored diverse strategies for automatic label generation. These approaches encompassed zero-shot prompting with GPT-3.5 Turbo and the utilisation of BERTScore (Zhang et al., 2020) as a quantifiable metric, capable of serving as a probability indicator for hallucination within the generated content. BERTScore, employed in our approach for automatic data labeling, entails the aggregation of pairwise cosine similarity scores between the BERT contextual embeddings of tokens in candidate and reference sentences.

3.2 Model-agnostic Methods

Word alignment for semantic similarity Based on the understanding that hallucination is defined as model output that is semantically inconsistent with the reference output, we reduce the task of hallucination detection to that of measuring semantic similarity between pairs of sentences. The probability that a hypothesis sentence generated by a model contains hallucination should then be inversely proportional to its semantic similarity to the reference. In an effort to provide measures of semantic similarity that are more explainable than modern distributional metrics such as BERTScore (see Section 3.1) we developed a set of simple methods based on word alignment and word similarity. Given a word similarity metric, we simply align each word of one sentence to the most similar word in the other and define sentence similarity as the average of these similarities. Formally, for any word similarity metric S_w that maps any pair of words w_1, w_2 to the $[0, 1]$ range we define the similarity of sentences s_1 and s_2 as

$$S = \sum_{u \in s_1} \max_{v \in s_2} \frac{S_w(u, v)}{|s_1|} \quad (1)$$

We defined several word similarity metrics and for each determined a custom threshold t for which a hypothesis sentence s_{hyp} is considered a hallucination w.r.t. the reference s_{ref} if and only if

[2] https://huggingface.co/vectara/hallucination_evaluation_model

$1 - S(s_{hyp}, s_{ref}) \geq t$ (values of t were determined empirically on the validation dataset of the model-agnostic track). For each similarity type we experimented with alternative methods for calculating overall similarity from word similarities, including the harmonic mean and the minimum of the best similarities for each word, but the plain average (Eq. 1) yielded the best performance. We also ran all experiments with stopword removal using the `nltk` library (Bird et al., 2009) but found it to cause a slight decrease in performance. In our submissions, we included outputs based on two word similarity metrics. The `levenshtein` system that uses Levenshtein distance of word pairs as the word similarity measure for Equation 1, a string similarity metric defined as the number of character-level edit operations required to transform one word into another (Levenshtein, 1966). The similarity metric S_L was defined as $1/(1 + L)$ to obtain a value between 0 and 1 that is inversely proportional to the distance measure L. The `paragram` system combines the word alignment method with distributional similarity, here word similarity is defined as the cosine similarity of two words in the static English word embedding `paragram_300_SL999` (Wieting et al., 2015), which has been fine-tuned on the task of measuring word similarity on the SimLex-999 dataset (Hill et al., 2014).

Finetuning a BERT-based Hallucination Detection Model Another approach for the model-agnostic track encompassed finetuning a pretrained hallucination detection model based on BERT (Devlin et al., 2019). An open-source model developed by Vectara was chosen for that purpose as it achieved high accuracy on a range of hallucination detection benchmarks including e.g. accuracy of 76% on the `SummaC` dataset (Laban et al., 2022). Built upon the deberta-v3-base (He et al., 2021), Vectara undergoes initial training on Natural Language Inference (NLI) data, followed by subsequent fine-tuning on summarisation datasets. The model is trained utilising a cross-encoder architecture.[3] Given the scarcity of labeled data of high quality necessary for the initial finetuning of a language model, a departure from the approach taken by Zhou et al. (2021) was considered. In their work, they utilised XLM-R (Conneau et al., 2020) for hallucination detection within the scope of a machine translation task, and RoBERTa (Zhuang et al., 2021) for hallucination detection within the scope of summarisation task. However, due to the insufficient availability of labeled data, this method was not deemed applicable in the current study.

3.3 Model-aware Methods

Hidden States Model-aware techniques are based on analysing internal data of LLM during inference. One of the possible approaches is the analysis of the outputs of the hidden layers of the transformer. Using vector values of hidden layers for hallucination detection was proposed in a method called Statement Accuracy Prediction, based on Language Model Activations (SAPLMA) (Azaria and Mitchell, 2023). SAPLMA is a probing technique that utilises a feedforward neural network trained on activation values of the hidden layers of LLM.

Attention Flow We follow the attention-based token-level importance metric proposed by DeRose et al. (2020) for sequence classification and adopt it to sequence-to-sequence. We extract and analyse the attention weights from the model predictions and trace how the model shifts its focus from the output back to the input. This is done by summing and averaging the weights in the decoder, and then mapping these influences back through cross-attention layers to the encoder. Thereby, highlighting which parts in the input text are influential for the output. As an addition, we apply exponential decay to the influence scores to account for a diminishing impact of distant tokens across layers.

Consequently, we derive an influence matrix that quantifies the influence scores for each layer and token. Under the assumption that there exists a meaningful correlation between the input and its corresponding output, and thereby, also in cases where the output is characterised by hallucinations, these identified features can be leveraged to build a classifier.

4 Experiments

4.1 Automatic Data Annotation

As described in Section 3.1, two approaches were utilised for automatic annotation of the SHROOM training set, specifically zero-shot prompting with GPT-3.5[4] and the BERTScore metrics. To generate

[3] Notably, in contrast to the SHROOM dataset, Vectara produces a probability scale from 0 to 1, where 0 represents hallucination and 1 denotes factual consistency. Implementing a threshold of 0.5 enables predictions to assess the alignment of a document with its source.

[4] gpt-3.5-turbo-1106

probabilities with GPT-3.5 in a zero-shot manner, OpenAI API was used. The prompt was crafted specifically to incorporate multiple dataset samples in one pass in order to speed up the labeling process. Specifically, there were 32 samples in the prompt. Although the latest models support larger input context length, our experiments showed that passing more samples per request results in inconsistent and poor-quality labels. The input for the model was structured as pairs, consisting of a context ('tgt' for MT and DM, and 'src' for PG) and a sentence ('hyp'). Prompt engineering was inspired by the SHROOM baseline kit combined with instructions to return structured output in a JSON format. The explicit prompt passed as an instruction to GPT-3.5 is referenced in Appendix A. The total cost associated with utilizing the GPT-3.5 API amounted to ∼3$. Performance evaluation of GPT-3.5 on the validation dataset, comprising both its model-agnostic and model-aware parts, yielded metrics of **0.68** and **0.49** for accuracy and Spearman's correlation coefficient, respectively.

Simultaneously, BERTScore calculations were conducted on identical pairs of text instances used for probability generation with GPT-3.5. The candidate sentence ('hyp') and reference sentence ('tgt' for MT and DM, and 'src' for PG) served as inputs for BERTScore computation. The resulting BERTScore values, ranging between 0 and 1, were utilised in their raw form, wherein outputs of a specific LLM featuring BERTScores closer to 1 indicate a higher probability of being non-hallucinations. We utilised BERTScore version 0.3.13 with the RoBERTa Large model (Zhuang et al., 2021). Performance evaluation of BERTScore values on the validation dataset, comprising both its model-agnostic and model-aware parts, yielded metrics of **0.67** and **0.41** for accuracy and Spearman's correlation coefficient, respectively. For these calculations, the transformation of BERTScore values into labels utilized a threshold of 0.5.

4.2 Model-agnostic Methods

Word alignment The submissions `levenshtein` and `paragram` are based on the word alignment method described in Section 3.2. Threshold values for binary classification were determined empirically using the validation set of the model-agnostic dataset and set to 0.35 for `levenshtein` and 0.3 for `paragram`. Identical parameters were used to generate the submitted outputs for both model-agnostic and model-aware tracks of the shared task.

Finetuning a BERT-based Hallucination Detection Model This section presents the finetuning of Vectara pretrained hallucination detection cross-encoder model. We conducted finetuning on 4 different data combinations, including the validation set exclusively (`vectara-val`), the training set with probabilities generated by either GPT-3.5 (`vectara-gpt`) or BERTScore (`vectara-bertscore`), and a combination of both the validation set and the training set with GPT-3.5 probabilities (`vectara-gpt-val`). Given that Vectara predicts hallucination probability independently of a specific LLM, we concatenated both model-aware and model-agnostic datasets for additional finetuning to address limitations arising from their relatively small sizes. In addition to the mentioned data combinations, we performed separate finetuning on subsets of the validation set (`vectara-val-subset`), representing model-aware and model-agnostic validation sets. These finetuned models' predictions were later used in ensemble methods (Section 4.4). Despite acknowledging potential bias associated with finetuning using automatically generated probabilities, this approach was pursued due to the necessity of labeled data. To mitigate bias from GPT-3.5 and BERTScore probabilities, approaches (`vectara-val`, `vectara-gpt-val`, `vectara-val-subset`) utilised the validation set for finetuning. The finetuning process involved creating input instances for each training pair, comprising the LLM's generated text ('hyp'), the 'gold' reference text, and the probability of hallucination obtained from annotators ('p(Hallucination)'). The 'gold' reference text corresponds to the intended reference 'gold' text ('tgt') for MT and DM tasks, while for the PG task, where 'tgt' was mostly not provided in the SHROOM dataset, the model input ('src') served as the 'gold' reference text. Consistent hyperparameters were employed for finetuning vectara across all data combinations: the model was trained for 5 epochs with a batch size of 16 and a warmup of 0.1.

4.3 Model-aware Methods

Hidden States During our experiments with SAPLMA method (see Section 3.3), we used a feedforward neural network as an activations classifier. It features three hidden layers with decreasing numbers of hidden units (256, 128, 64), all util-

ising ReLU activations. We discovered that this approach requires more data than the validation set could provide. Therefore, the classifier was trained fully on the GPT-3.5 labeled training dataset. For each task, the dataset was fed into the original task model to get outputs of each hidden layer of the decoder for a final decoded token (EOS). Hallucination classifier was trained with binary cross entropy objective where inputs were original model layer activations and outputs were GPT labeled hallucination probabilities. The exact layer number is considered a hyperparameter in this case which was selected by grid search. Further experiments were focused on selecting the exact hidden layer of the original model that may contain most of the information regarding the uncertainty of the model. Based on evaluation on a validation set the best results are different for each task: layer #10 (out of 12) for MT, layer #1 (out of 12) for DM, layer #5 (out of 16) for PG.

Attention Flow For `att-flow`, we conducted our experiments using the `scikit-learn` library (Pedregosa et al., 2011). The feature matrices that we obtained, have dimensions $L \times T$ where L denotes the number of layers and T the number of tokens, can be quite large. To address this, we employed Principal Component Analysis for dimensionality reduction, achieving six components, chosen after a structural evaluation of component ranges across tasks. This dimensionality reduction significantly enhanced the classifier's performance. A Support Vector Machine with a Radial Basis Function kernel and Platt scaling was utilised for deriving probabilities and predictions. Out of alternative kernels, none yielded comparable results. Notably, the SVM was trained independently for each task, recognising that tasks may exhibit distinct attention flows, particularly on model-aware data.

4.4 Ensemble Methods

Finally, we also created simple ensemble models by combining the outputs of the individual systems presented in previous sections. We experimented with a variety of methods including simple voting, regression metamodels, and fusion of predicted probabilities.

Logistic regression The submission `mm-logreg` involved hallucination prediction with a logistic regression model trained on a small set of binary features that correspond to the labels predicted by individual systems. For the model-agnostic track we included labels from 5 systems, `levenshtein`, `paragram`, `vectara-gpt`, `vectara-bertscore`, and `vectara-val-subset`.[5] For the model-aware track, we also included the labels predicted by the SAPLMA method (Section 4.3). For each track, the model was trained on the respective validation dataset, using default settings of the `LogisticRegression` model in the `scikit-learn` library (Pedregosa et al., 2011).

Linear Regression with Raw Probabilities Submission `mm-linreg-probs` followed a similar methodology to `mm-logreg` with the distinction being utilisation of raw probabilities predicted by individual systems instead of labels and employment of linear regression instead of logistic regression. For both the model-agnostic and model-aware tracks we included probabilities predicted by the same systems utilised in `mm-logreg`. Like `mm-logreg`, for each track the model was trained on the respective validation dataset, using default settings of the `LinearRegression` model in the `scikit-learn` library (Pedregosa et al., 2011).

Voting Simple `voting` was implemented as an additional ensemble method, using the same set of systems as for the `mm-logreg` method. For each model output, we counted the number of systems that predicted the `Hallucination` label, the threshold for the number of votes required to make a positive prediction was a parameter of the system that we optimised on the validation sets. For both tracks, the optimal strategy was to require at least 2 votes (2 out of 5 for the model-agnostic track and 2 out of 6 for the model-aware track).

Probability Fusion The `prob-fusion` method is proposed as a weighted average fusion approach for combining predictions from multiple models in hallucination detection. Confidence scores for each model are determined as the squared absolute difference between the model's predicted probability and its neutral point, serving as weights in the fusion process. The final fused probability is obtained as the weighted sum of individual model probabilities:

[5]The metamodel considered probabilities from a Vectara model fine-tuned on either the model-aware or model-agnostic validation set, depending on the track.

Table 1: Accuracy (Acc) and Spearman's rank correlation (Corr) results for each of the proposed models on detecting hallucination on the test datasets.

Model	Agnostic		Aware	
	Acc	Corr	Acc	Corr
baseline	0.697	0.403	0.745	0.488
levenshtein	0.663	0.362	0.711	0.418
paragram	0.643	0.355	0.685	0.379
vectara-val	0.809	0.723	***0.806***	0.707
SAPLMA	-	-	0.593	0.137
att-flow	-	-	0.61	0.245
mm-logreg	0.801	0.665	0.801	0.636
mm-linreg	***0.817***	***0.737***	0.801	***0.712***
prob-fusion	0.793	0.673	0.783	0.654
voting	0.735	0.597	0.756	0.587

$$P_H = \sum_{i=1}^{N} \left(\frac{|P_i - NP_i|^2}{\sum_{j=1}^{N} |P_j - NP_j|^2} \times P_i \right), \quad (2)$$

where P_H denotes the fused probability of hallucination, and P_i and NP_i denote predicted hallucination probability and neutral point of model i, respectively.

5 Results

Table 1 provides insights into the accuracy and correlation metrics for each method concerning hallucination detection, spanning both model-aware and model-agnostic tracks compared to the `baseline` results introduced by the SHROOM organisers. Compared to the organisers' baseline, which employs the Mistral model in a zero-shot manner for hallucination detection, our best-performing systems are based either on finetuning methods (`vectara-val`) or ensemble approaches (`mm-linreg`). As detailed in Table 1, our leading model in the model-agnostic track, the `mm-linreg`, achieves an accuracy of 81.7% and a Spearman's rank correlation coefficient (ρ) of 0.737 and our leading model in the model-aware track, the `vectara-val`, achieves an accuracy of 80.6% and a Spearman's rank correlation coefficient (ρ) of 0.707 for predicting labels and estimating the probability of hallucination, respectively. According to the official ranking provided by the Helsinki NLP group[6], our team's results, TU Wien team, are ranked 3rd in the model-aware track among 46 participants and 8th in the model-agnostic track among 49 participants. As reported in Table 2 in the Appendix B, the finetuning of Vectara on the validation set improves its accuracy and correlation by 5.06% and 6.48% in the model-agnostic track and 1.5% and 2.3% in the model-aware track, respectively.

6 Analysis

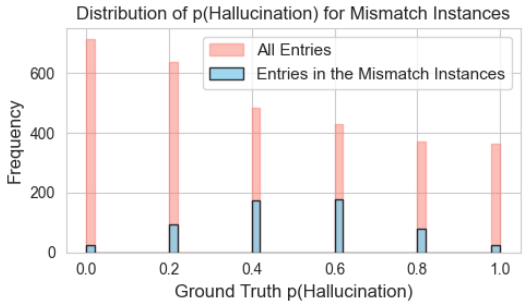

Figure 1: Distribution of hallucination probability for instances with disagreements between our top-performing `mm-linreg` predictions and the ground truth.

Figure 1 presents the distribution of ground truth p(Hallucination) entries in the entire test set encompassing both model-aware and model-agnostic test sets concatenated with those instances where the `mm-linreg` predictions mismatch the ground truth labels. The histogram highlights that the majority of p(Hallucination) entries across the entire ground truth test dataset are concentrated around 0. However, in instances where the metamodel predictions differ from the ground truth labels, there is a notable concentration around 0.4 and 0.6. This observation suggests that the model excels in predicting the correct label for non-controversial cases but encounters challenges in subjective scenarios, where the decision-making process becomes more intricate. Subsequent results, obtained by selectively filtering data based on p(Hallucination) values, reveal nuanced performance metrics: for instances where p(Hallucination) equals only 0 or 1, accuracy of 95.17% and Spearman Correlation (ρ) of 0.796 is achieved; when including p(Hallucination) values of 0, 0.2, 0.8, and 1, the accuracy remains high at 89.21% with a Spearman Correlation (ρ) of 0.731. In contrast, the analysis without filtering, yielding an accuracy of 80.87% and Spearman Correlation (ρ) of 0.724, underscores the impact of data filtering on the model's predictive perfor-

mance. This inherent subjectivity in hallucination detection, especially evident with a concentration around the controversial interval, underscores the complex nature of such judgments.

6.1 Qualitative error analysis

Building on the observations drawn from Figure 1, we conducted a more in-depth qualitative analysis of misclassifications within the entire test set. A subsequent in-depth manual analysis of misclassifications was carried out for each task independently. 46% of the misclassifications of the `mm-linreg` belong to the DM task, 33% of them belong to the MT, and 21% of them belong to the PG. For the MT task, we analysed 94 misclassified instances, covering all samples present in the test set for the Ru-En language pair[7], while for the DM and PG tasks, we analysed 20 randomly selected instances. While examining mislabeled samples, a crucial question arises about distinguishing between hallucinations and incorrect answers, such as inaccuracies in the DM task. In MT, ambiguity persists over categorising word-for-word translations, common among non-native speakers, as hallucinations or simply a translation that lacks accuracy. For instance, the model output *Her legs hurt* (MT instance with the id #826), as opposed to the 'gold' reference *Her feet ached*, was labeled by the annotators as a hallucination with a probability of 0.8. The Russian source text, У неё болели ноги, can be translated into English as both *Her feet ached* or *Her legs were hurting*, since the Russian ноги can refer to both *feet* and *legs*. Therefore, the only discrepancy in the model hypothesis lies in the incorrect grammatical form of the verb *hurt*. Analysing the aforementioned example and additional instances available in Appendix C suggests that, despite instructions for annotators to utilise either 'tgt' or 'src' as the 'gold' reference, annotators predominantly labeled the dataset using 'tgt' and 'hyp'. This discrepancy may pose a challenge. Additionally, the process of generating 'tgt' is only clarified for the DM task, with no explanation provided for the MT or PG tasks. The shared task documentation lacks explicit guidance on annotator instructions, stating only that annotators should verify if all information in the hypothesis is supported by the 'gold' reference. This formulation may lead to diverse interpretations of what constitutes a hallucination. Instances such as *If you persecute heretics or <define> discrepants </define> , they unite themselves as to a common defence [...]*[8] underscore the necessity for annotators to possess language proficiency, a requirement challenging to meet in a crowdsourced setting.

The error analysis of disagreements with 'gold' annotations highlights the subjective nature of hallucination detection, presenting a challenge for both machines and human annotators. The absence of a precise definition for hallucination further complicates the task. In NLG tasks like PG or DM, annotators require significant language proficiency or even a linguistic background. Instances with majority-based gold labels and low inter-annotator agreement (probabilities of 0.4 or 0.6) anticipate challenges for models, as these instances are ambiguous even for humans. Furthermore, qualitative analysis of the misclassifications suggests a tendency for annotators to mislabel longer texts. For instance, the model hypothesis for the MT instance with the phrase *The Beer of His Words Back*[9] corresponding to the gold reference *I stand corrected* was labeled by the annotators as a non-hallucination with a probability of 0.2. This may be attributed to the challenge of maintaining concentration when reading longer texts. This observation implies a heightened difficulty in detecting hallucinations in lengthier passages.[10] A comprehensive list of manually verified examples for all three tasks, accompanied by corresponding explanations, is extensively documented in Appendix C.

6.2 Complications with Model-aware Track

Our top-performing systems for both model-aware and model-agnostic test sets are based on model-agnostic approaches. However, the final results for our model-aware methods proved to be less promising, achieving about 60% accuracy on the test set (see Table 1). Possible reasons for the sub-optimal performance of the SAPLMA (4.3) method include the lack of reproducibility instructions for the model-aware track, poor quality of GPT-generated training labels, and the method's original design for decoder-only models, whereas all task models are encoder-decoder models. Results for the Attention Flow method (4.3) could also be enhanced through various techniques such as ad-

[7]The Ru-En language pair was selected because two authors of the paper are native Russian speakers.

[8]DM instance with the id #885 labeled by the annotators as a hallucination with a probability of 0.8

[9]Instance with the id #2251

[10]The average length of 'src' input in the SHROOM test set is 95 characters, or 17 tokens.

justing decay rates, incorporating decoder scores, and introducing feature weights.

During our experiments on model-aware datasets (train & validation set), we encountered challenges reproducing model outputs for two tasks: MT and DM. Using the provided Huggingface models with default parameters yielded different results than those shown in the dataset. Despite experimenting with numerous inference parameters from the Huggingface library, we could not obtain the same input-output pairs ('src'-'hyp') as in the dataset. This discrepancy significantly impacted label alignment, rendering samples labeled as hallucinations no longer hallucinations with newly generated results. This issue is crucial for the model-aware track, as SAPLMA and Attention Flow methods utilise internal data from forward pass for each sample but rely on labels from the dataset. We contend that this problem might substantially reduce the quality of these methods.

7 Conclusion

This paper outlines our systems for the SemEval shared task on LLM hallucination detection, covering both model-aware and model-agnostic subtasks. Our finetuned BERT-based model demonstrated strong performance, securing the 3rd rank in the model-aware track and underscoring the efficacy of our approach. Notably, our leading system in the model-agnostic track employs a metamodel that integrates predictions from diverse systems, including a finetuned BERT-based hallucination detection model, as well as rule-based methodologies and those relying on LLM hidden states.

The absence of a universally agreed-upon definition for hallucination complicates both human and machine evaluations, as evident in the error analysis of Section 6.1. Although attempts have been made to systematically define hallucination, such as by (Huang et al., 2023) and (Ji et al., 2022), the NLP community's understanding remains broad. This encompasses scenarios where a model outputs entirely false information or information close to the desired output but incomplete. Human annotators bring their world knowledge and views, influencing annotations and subsequently affecting model performance. Hallucination detection is challenging for both machines and humans, with achieving high inter-annotator agreement proving particularly difficult when the task definition is overly broad. Especially tasks like paraphrase generation or definition modeling, where numerous correct outputs are possible, are inherently subjective and tied to the annotator's real-world knowledge and beliefs (Heidegger, 2001; Honovich et al., 2022). A clearer definition of the annotation task, specifically detailing what constitutes hallucination for that task, could potentially enhance inter-annotator agreement and subsequently improve model performance. Detecting hallucinations across various NLP tasks poses a significant challenge. The SHROOM dataset encompasses three distinct tasks, whereas existing hallucination detection benchmarks often address only a single task.

C Disagreement in Annotations

During the examination of misclassifications in MT, it was observed that approximately 15% (13 out of 94) of instances pertaining to the Ru-En language pair could be subject to different labeling by the authors of this paper. Furthermore, a detailed analysis of 20 randomly selected misclassifications from the PG and DM segments of the test set, revealed notable discrepancies. Specifically, 20% for the PG task (4 out of 20) and approximately 35% (7 out of 20) in the DM task would receive distinct labels according to the authors' assessment. Tables highlighting these disagreements for each of the three tasks are provided below for reference.

The MT example below was labeled by the annotators as a non-hallucination with a probability of 0.2 (instance with the id #2251 in the model-agnostic test set)[11]:

[11]The entire sample can be found in Table 4

src: Беру свои слова обратно.
tgt: I stand corrected.
hyp: The Beer of His Words Back.

Our top-performing `mm-linreg` labeled this instance as a hallucination with a probability of 0.54.

As previously deliberated, the categorisation of a translation lacking natural fluency as a hallucination is subject to scrutiny. This contention is exemplified by the following MT example (instance with the id #826 in the model-agnostic test set):

src: У неё болели ноги.
tgt: Her feet ached.
hyp: Her legs hurt.

This instance was labeled by the annotators as a hallucination with a probability of 0.8, while our `mm-linreg` labeled it as a non-hallucination with a probability of 0.2. In Russian, ноги stands for both *feet* and *legs*. The only discrepancy in the 'hyp' lies in the incorrect grammatical form of the verb *hurt*. An English native speaker would likely formulate a sentence such as *her legs were hurting*.

Upon scrutinizing misclassified instances in machine translation, discernible patterns emerged where our model encounters challenges. Specifically, it grapples with correctly identifying the presence of a suitable pronoun in the English translation (instance with the id #1791 in the model-agnostic test set):

src: Кажется, он сломан.
tgt: I think it's broken.
hyp: Looks like he's broken.

The form сломан represents a short form of the past participle of the perfective aspect of the verb сломать. This verb form is exclusively applicable when describing an inanimate object that has been broken. Notably, due to the gender agreement of Russian pronouns with the associated noun, the sentence includes the pronoun он, corresponding to the English pronoun *he*. To express the idea of an animate object being broken, as in the English phrase *he is broken*, the Russian equivalent would be он сломлен, where сломлен represents a short form of the past participle of the perfective aspect of the verb сломить. This sample was labeled by the annotators as a hallucination with a probability of 0.8. Our best-performing model labeled it as a non-hallucination with a probability of 0.2. It is pertinent to note that the annotation of such instances lacked consistency (instance with the id #69 in the model-agnostic test set):

src: На сколько врач тебе дал освобождение?
tgt: How long did the doctor sign you off school for?
hyp: How much did the doctor give you your release?

The annotators assigned a non-hallucination label to this instance with a probability of 0.4. Conversely, our best-performing model categorised it as a hallucination with a probability of 0.8. The English 'hyp' sentence appears somewhat unconventional, and alternatives such as *How long did the doctor grant you a release?* or *For how long did the doctor excuse you?* would convey a more natural phrasing. Notably, it is essential to acknowledge that the target ('tgt') reference, referred to as the 'gold' text, does not provide a fully accurate translation of the source Russian sentence. In the original Russian sentence, освобождение (translated as *release*) does not exclusively refer to a school release authorized by a doctor. Furthermore, it is pertinent to inquire about the methodology employed by the creators of the SHROOM dataset in generating the 'gold' text for the MT and PG sections, as this information is elucidated solely for the DM part of the dataset, indicating that the gold definition is sourced from Wiktionary.

It is imperative to acknowledge that our models were exclusively trained utilising 'tgt' and 'hyp' for both MT and DM, i.e. disregarding 'src'. Consequently, this means that our models cannot possess the capability to comprehend certain grammatical nuances of the Russian language, as the models were not trained on the Russian text. The decision to employ 'tgt' as a reference was motivated by the lack of statistical data regarding the languages encompassed in an MT part of the dataset since we could not use 'src' without specifying the language for a range of our approaches including finetuning of a BERT-based hallucination detection model. Considering the potential impact on system performance, an alternative approach could involve incorporating 'src' and 'hyp', or even 'src', 'tgt', and hyp' for the automatic generation of probabilities using GPT-3.5 for at least an MT part of the dataset. However, the quality of GPT-3.5 for low-resource languages cannot guarantee promising results for the plethora of languages encapsulated in the SHROOM dataset. Despite this caveat, such an approach may empower the model trained on such sort of automatically generated probabilities to better 'learn' the linguistic idiosyncrasies of a given language, which cannot be adequately captured solely through reliance on 'tgt'.

Below you can find an example for a PG task (PG instance with the id #2907 in the model-agnostic test set):

src: Does POTUS know?
tgt: Is the president aware of this?
hyp: Does POTUS know what you're doin' with?
gold_label: Not Hallucination
gold_prob: 0.2
label_metamodel: Hallucination
prob_metamodel: 0.78

A range of instances demonstrates that the SHROOM dataset annotation requires language proficiency from the annotators that cannot be expected in a crowdsourced setting[12] (DM instance with the id #885 in the model-agnostic test set):

src: If you persecute heretics or <define> discrepants </define> , they unite themselves as to a common defence [...]
tgt: (archaic) A dissident.
hyp: (obsolete) One who disagrees; a dissenter.
gold_label: Hallucination
gold_prob: 0.8
label_metamodel: Not Hallucination
prob_metamodel: 0.35

It is noteworthy to highlight that across all three tasks encompassed in the dataset, there exists a subset of instances that were correctly labeled but received a probability very proximate to 0.5. This scenario poses a potential challenge for models trained on such data (instance with the id #2998 in the model-aware test set):

src: The war with Serbia must be the last of Europe's civil wars.
tgt: -
hyp: Europe must end with the war with Serbia.
gold_label: Hallucination
gold_prob: 0.6
label_metamodel: Non-Hallucination
prob_metamodel: 0.4

[12] Organisers of the SHROOM shared task reported that the SHROOM validation dataset was built through crowdsourcing with 200 annotators involved annotating 20 instances each. Details about the test set annotations were not provided.

silp_nlp at SemEval-2024 Task 1: Cross-lingual Knowledge Transfer for Mono-lingual Learning

Sumit Singh, Pankaj Kumar Goyal and **Uma Shanker Tiwary**
Indian Institute of Information Technology, Allahabad
{sumitrsch, pankajgoyal02003}@gmail.com
ust@iiita.ac.in

Abstract

Our team, silp_nlp, participated in all three tracks of SemEval2024 Task 1: Semantic Textual Relatedness (STR). We created systems for a total of 29 subtasks across all tracks: nine subtasks for track A, 10 subtasks for track B, and ten subtasks for track C. To make the most of our knowledge across all subtasks, we used transformer-based pre-trained models, which are known for their strong cross-lingual transferability. For track A, we trained our model in two stages. In the first stage, we focused on multi-lingual learning from all tracks. In the second stage, we fine-tuned the model for individual tracks. For track B, we used a unigram and bigram representation with suport vector regression (SVR) and eXtreme Gradient Boosting (XGBoost) regression. For track C, we again utilized cross-lingual transferability without the use of targeted subtask data. Our work highlights the fact that knowledge gained from all subtasks can be transferred to an individual subtask if the base language model has strong cross-lingual characteristics. Our system ranked first in the Indonesian subtask of Track B (C7) and in the top three for four other subtasks.

1 Introduction

The importance of semantic relatedness in language has been long recognized. Applications include sentence representation, question answering, and text summarization (Abdalla et al., 2023). Sentences can be related through either paraphrasal or entailment relations, or through broader commonalities such as shared topics, viewpoints, temporal origins, and logical connections.

This shared task (Ousidhoum et al., 2024b) aims to expand the scope of significant research in natural language processing (NLP) by incorporating 14 languages. The focus of the research is on semantic similarity and has predominantly been conducted in English. The languages included in the task are Afrikaans, Algerian Arabic, Amharic, English, Hausa, Hindi, Indonesian, Kinyarwanda, Marathi, Moroccan Arabic, Modern Standard Arabic, Punjabi, Spanish, and Telugu.

The task requires predicting the degree of semantic textual relatedness (STR) between pairs of sentences in multiple languages. The task is to rank these sentence pairs based on their level of relatedness, with scores ranging from 0 (completely unrelated) to 1 (maximally related). This task is divided into the following three tracks.

Track A: Supervised Challenge was developing a system trained on labelled datasets provided for the 11 subtasks. Publicly available related datasets could be utilized, but no additional dataset could be used in this work.

Track B: Unsupervised The challenge was developing a system without using labelled datasets to measure semantic relatedness or similarity with the text units longer than two words only. We took advantage of unigram and bigram features with SVM regression and XGBoost.

Track C: Cross-Lingual The challenge was to develop a system without labelled datasets in the target language and with the use of labelled dataset(s) in at least one other language (subtask). All datasets of track A other than the targeted subtask are utilized for similarity prediction in this work.

Our system utilizes cross-lingual learning by implementing multi-stage training methods similar to those used in (Wang et al., 2022), (He et al., 2022), and (Singh and Tiwary, 2023) for track A. In the first stage, we selected pre-trained cross-lingual language models that cover the languages used in our task and fine-tuned them on a combined dataset of all subtasks in track A for five epochs. This created a model checkpoint that had knowledge of multiple languages relevant to our task. In the second stage, we fine-tuned the model checkpoint generated in the first stage for each track individually.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1197–1203

For track C, we created a dataset by combining all the data from track A, except for the targeted subtask, and fine-tuned it with the language model in a supervised manner. We used unigram and bigram bag-of-words representation with SVM-based regression (SVR) and XGBoost for each subtask in track B.

Our team achieved the best model for the Telugu and Marathi subtasks of track A by using the MuRIL large model (Khanuja et al., 2021). In the first stage, we fine-tuned the model for all three tracks (English, Telugu, and Marathi) and then fine-tuned the model checkpoints for Telugu and Marathi.

For all track A languages, we fine-tuned XLM-R for subtasks in the 1st stage, and we fine-tuned the checkpoint generated in stage one for all monolingual tracks in the 2nd stage.

For Track B, only monogram or bigram representation is allowed for supervised training. We obtained comparable results using both unigram and bigram representations in combination with SVR and XGBoost.

In Track C, we used all training data from Track A except for the current subtask data since the use of the same language data was not allowed in Track C. We adopted a cross-lingual transfer approach, where MuRIL gave the best result for the Hindi subtask, while XLM-R predicted the best results for the other subtasks.

The results for each subtask are presented in Table 2, 3 and 4, along with the baseline results. In addition to being multilingual, the key challenges of the task were the presence of many low-resource languages that lack proper pre-trained models for learning and the limited availability of training examples for some subtasks of Track A (see Table 1). To address these challenges, we utilized language models (LMs) with cross-lingual transferability, along with a two-stage training strategy. Our code can be found here[1].

2 Related Work

The Semantic Textual Similarity (STR) task 2015 (Agirre et al., 2015) had three subtasks. The findings showed that the UMBC PairingWords system achieved the best score by semantically differentiating distributionally similar terms (Han et al., 2015). In the subsequent STR task (Cer et al., 2017), there are seven tasks that concentrate on multilingual and cross-lingual pairs. Additionally, one sub-track will delve into MT quality estimation data. The team ECNU (Tian et al., 2017) achieved the highest score using ensembles of well-performing feature-engineered models with deep learning methods. These models used random forest (RF), gradient boosting (GB), and XGBoost (XGB) regression methods. However, statistical and machine learning models were not the best, as transformer-based models gained attention after (Devlin et al., 2019). These models are pre-trained on large amounts of data and fine-tuned for various downstream tasks. Researchers have created the sentence transformer (Reimers and Gurevych, 2019) architecture for finding similar sentences. It is useful when given multiple sentences corresponding to a sentence, and we need to find the most similar one. However, fine-tuning the sentence transformer with the downstream task requires proper alignment between the dataset on which the sentence transformer is pre-trained and the dataset of the downstream task. In this task, there are multiple subtasks associated with multiple languages. Therefore, motivated by the performance of cross-lingual transformer-based models, we have used transformer-based language models that have strong cross-lingual transferability. It has been seen that cross-lingual transferability has advantages in various NLP tasks (Singh and Tiwary, 2023; Wang et al., 2022).

3 Data

This shared task provided fourteen sets of monolingual data (Ousidhoum et al., 2024a). There were nine languages for track A, each with training, validation, and testing data. For tracks B and C, only validation and testing data were provided for the Afr, Arb, Hin, Ind, and Pan languages. The training, validation, and testing data distribution for all languages is tabulated in Table 1. The English language had over 5,500 training examples, while other languages had comparatively fewer data provided.

4 Methodology

Our system has chosen robust cross-lingual transfer models such as XLM-R (Conneau et al., 2020), which is pre-trained on over 100 languages, and MuRIL (Khanuja et al., 2021), which is pre-trained on all Indic and English languages, for track A and C. We have followed a two-stage training approach

[1] https://github.com/singhsumit1/Semeval-Semantic_textual-relatedness.git

Table 1: The datasets varied in the number of instances within their training, development, and test sets. Languages such as afr, arb, hin, ind, and pan lacked training data and were exclusively utilized in unsupervised and cross-lingual contexts.

for track A. The detailed methodology for each track is explained in the following subsections.

For tracks A and C, we combined both sentences of an example data with a special token of LM (</sep> for XLM-R and Roberta, and [SEP] for MuRIL) in the preprocessing stage. Model tokenizer tokenizes the combined sentence into tokens and generates token IDs and attention masks. For other subtasks, we utilized XLM-R and MuRIL with the two-stage training approach.

4.1 Methodology for track A

4.1.1 Two-stage training

In the initial stage of our project, we conducted multi-lingual training by utilizing the training data of all subtasks of track A in a selected LM that supports them. As shown in Fig. 1, our model used the annotations of all subtasks of track A in this stage. We performed experiments using various hyperparameters across five epochs, selecting the best multilingual checkpoint based on the average validation data loss. In the second stage, we fine-tuned the multilingual checkpoint from the first stage and utilized it as an initial model for fine-tuning each monolingual subtask in track A. We trained each mono-lingual track with different hyper-parameters in the second stage and selected the final model based on the validation data loss of the corresponding subtask.

4.1.2 Model Architecture

Figure 1 shows that the model tokenizer first tokenizes the input sentence. To improve GPU utilization, the tokenizers are set to a length of 92. Next, the language model generates word embeddings for each token. The embedding of the first token (which is <s> for the XLM-R and [SEP] for MuRIL) is passed through a linear layer, which projects it into logits, a vector of size one that represents the predicted similarity. Finally, we apply the Mean Square Error (MSE) loss function to calculate the difference between the prediction and the ground truth.

4.2 Methodology for track B

For track B, the sentences were converted into unigram and bigram representation and Support Vec-

Language	A1 arq	A2 amh	A3 eng	A4 hau	A5 kin	A6 mar	A7 ary	A8 esp	A9 tel
XLM-R (one-stage)	0.49	0.49	0.78	0.68	0.23	0.86	0.63	0.58	0.78

Rank	7	8	6	5	15	13	10	17	6

Table 2: Results of all subtasks of track A has been tabulated for both the settings one-stage and two-sage with both the LMs XLM-R and MuRIL.

tor Regression[2] (SVR) (Fu et al., 2016; Liu et al., 2017).

4.2.1 Unigrams /Bigrams embeddings

Both sentences in the examples are combined and transformed into a vector. To create the vector, each sentence is indexed based on the presence of unigrams/bigrams, and the corresponding index value is filled with the count of unigrams/bigrams. The resulting vector is then fed into the SVR model along with the label values for training.

4.3 Methodology for track C

The methodology followed in track C is similar to the first stage of track A, with the difference that the combined dataset includes all subtasks except for the targeted subtask. For instance, to build a system for the English (eng) subtask, all data from the subtasks of track A, except for the eng subtask, is collected. The model architecture is also similar to that of track A but with only one stage involved.

5 Experimental setup

5.1 Track A and Track C

We achieved our best score using the MuRIL setup for the Telugu and Marathi subtasks, while the XLM-R setup worked best for the other track. During the training process, we experimented with different learning rates (5e-6, 2e-5, 5e-5, 8e-5, and 1e-4) and batch sizes (16, 32, and 64) in both stages. We selected the best model based on validation loss after five epochs of training.

For track A and track C, we used the setups outlined in Fig. 1. We implemented our task using the xxxTokenClassification class defined in (Wolf et al., 2020) for regression, where xxx refers to the selected model. We set the number of labels to one. The other hyperparameters for achieving the best results with both language models are listed in Table 5.

[2]Support Vector Regression

5.2 Track B

For subtasks which are training data available in track, we have generated monogram and bigram embedding and performed supervised learning with support vector regression (SVR) and gradient Boosting regression (XGBoost) with the Scikitlearn[3] library.

Evaluation metrics Results are Pearson correlation coefficient, which shows the similarity between two sentences.

6 Results and Analysis

The table below shows the Pearson score with official rank for Track A, Track B and Track C, along with the baseline score. Please refer to Table 2, 3 and 4 for more details. Our system performed exceptionally well in the Indonesian (ind) subtask of track B (B7), achieving 1st rank with a Pearson score of 0.53%. We secured 3rd rank in the three subtasks: B15, B10 and C10.

Track A: Two-stage MuRIL setup achieved the best scores for Telugu and Marathi subtasks, while two-stage XLM-R setup achieved the best score for all other subtasks.

Comparison between one-stage and two-stage methods with XLM-R LM. A comparison has been illustrated in Fig. 2. Based on the average performance of all subtasks in track A, it can be inferred that the two-stage strategy outperforms the one-stage strategy. The average score for all subtasks using the two-stage strategy was 0.73, while the average score for all subtasks using the one-stage strategy was 0.61.

Comparison between MuRIL and XLM-R for the Telugu and Marathi Table 2 shows that for Telugu and Marathi, MuRIL performed better than XLM-R. Two-stage MuRIL produces a 0.05 higher score for Telugu subtask than two-stage XLM-R. For Marathi, the Two-stage MuRIL produces slightly more than the Two-stage XLM-R.

Baseline_Score	0.74	0.43	0.72	0.68	0.16	0.93	0.68	0.74	0.56	0.27
Rank	5	4	5	10	3	6	1	6	6	3

Table 3: All the results for subtasks of Track B have been displayed. For subtasks B1, B7, B8, and B9, labelled data was not provided, so only the Pearson scores predicted by the Dice loss are shown. For the other subtasks, the Pearson scores are displayed for unigram SVR, bigram SVR, unigram XGBoost, bigram XGBoost, and dice loss.

Language	C1 afr	C2 arq	C3 amh	C4 eng	C5 hau	C6 hin	C7 ind	C9 arb	C10 ary	C12 esp
Cross-lingual (XLM-R)	0.7468	0.3867	0.8048	0.7372	0.6428	0.7476	0.4716	0.4267	0.6732	0.5691
Cross-lingual (MuRIL)	-	-	-	-	-	0.8008	-	-	-	-
Baseline_Score	0.79	0.46	0.84	0.8	0.64	0.76	0.47	0.61	0.4	0.62
Rank	7	6	5	6	4	5	5	6	3	9

Table 4: Table shows the results of all subtasks of track C. MuRIL LM support Hindi (C6) subtask of the track C therefore only Pearson score of C6 given for the MuRIL LM.

track B Pearson score of track B tabulated in Table 3. It is clear from Table 3 that SVR performed better than XGBoost. The performance of SVR with unigram and bigram is not straightforward. Results showed that for B4, B5, B8, and B10, bigram embeddings perform better than unigram embeddings. However for the B3 unigram performed better.

track C Pearson score of the track C also showed in Table 4. Table 4 shows that for Hindi (C6), MuRIL performed better than XLM-R. All the other subtasks of this track are only predicted by the XLM-R in cross-lingual settings.

7 Conclusion

In this paper, we utilized multi-lingual track knowledge for the STR shared task to enhance the performance of monolingual models. Our team achieved first rank in the B7 subtask and third rank in the B5, B10, and C10 subtasks. We demonstrate that two-stage fine-tuning can help the monolingual models learn from the training data of all languages, leading to better performance. The results of track C illustrate the effectiveness of cross-lingual learning in a zero-shot scenario.

Abstract

Conversation is the most natural form of human communication, where each utterance can range over a variety of possible emotions. While significant work has been done towards the detection of emotions in text, relatively little work has been done towards finding the cause of the said emotions, especially in multimodal settings. SemEval 2024 introduces the task of Multimodal Emotion Cause Analysis in Conversations, which aims to extract emotions reflected in individual utterances in a conversation involving multiple modalities (textual, audio, and visual modalities) along with the corresponding utterances that were the cause for the emotion. In this paper, we propose models that tackle this task as an utterance labeling and a sequence labeling problem and perform a comparative study of these models, involving baselines using different encoders, using BiLSTM for adding contextual information of the conversation, and finally adding a CRF layer to try to model the inter-dependencies between adjacent utterances more effectively. In the official leaderboard for the task, our architecture was ranked 8th, achieving an F1-score of 0.1759 on the leaderboard. We also release our code here[1].

1 Introduction

Emotion Analysis is one of the fundamental and earliest sub-fields of NLP that focus on identifying and categorizing emotions that are expressed in text. Earlier, research in this domain focused on Emotion Detection in news articles and headlines (Lei et al., 2014; Abdul-Mageed and Ungar, 2017). However, later Emotion Recognition in Conversation gained popularity due to the widespread availability of public conversation data (Gupta et al., 2017). Recently, the task of emotion cause analysis has gained traction, which tries to identify the causes behind certain emotions (Xia and Ding, 2019a). This has widespread application such as building chatbots that can identify the emotions of the user and even identify the cause behind the emotions to perform certain actions (Pamungkas, 2019). For instance, companies can identify causes behind dissatisfaction in customer interactions and take appropriate measures (Yun and Park, 2022), AI-driven therapeutic insights can be gained using such models (DAlfonso, 2020), social media content moderation can be better done (Sawhney et al., 2021), work management and team management by companies can be improved (Benke et al., 2020).

In the task Wang et al., 2024, we tackle the problem of Multimodal Emotion Cause Pair Extraction, where given a set of utterances in a conversation, we must identify the following:

1. Emotion of every utterance (if any). These emotions can be one of Ekman's six basic emotions (Ekman et al., 1999).

2. Cause of these emotions, which is considered as the utterance that explicitly expresses an event or argument that is highly linked to the corresponding emotion.

Our proposed system tackles the task in a 3-step fashion – (a) First, we train a model to identify the emotions that are expressed in individual utterances in a conversation. (b) Next, we train a model to identify whether an utterance can be a cause of an emotion expressed in another/same utterance (candidate causes). (c) Finally, we train a model to pair emotion-utterances with their causes among the possible candidate causes. For both the (a) and (b) models we experiment with 3 basic architectures – (i) a simple Neural Network to determine the class of emotion (N-class classifier) and another Neural Network to identify whether the utterance is a candidate cause or not (binary classification). (ii) A BiLSTM (Sak et al., 2014) architecture that accounts for the surrounding context

*Equal contribution.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1204–1211

of the conversation while doing the N-class and binary-classification. (iii) A BiLSTM CRF (Lafferty et al., 2001) architecture which accounts for the surrounding emotions as well while doing the N-class classification. We also experiment with different encoders for the three modalities.

2 Background

2.1 Dataset

The dataset used for this problem is **Emotion-Cause-in-Friends** prepared by Wang et al., 2023 specifically for this task. It has been prepared using conversations from the popular 1994 sitcom *Friends* as the source. This dataset contains 1,344 conversations made up of a total of 13,509 utterances, each conversation containing an average of 10 utterances. For each utterance, the dataset has an annotated transcript (covering text modality) and the corresponding video clip (covering visual and auditory modalities) from the show.

Each utterance is annotated with the emotion depicted by it, which is one of: `anger`, `disgust`, `fear`, `joy`, `neutral`, `sadness` and `surprise`. The dataset is highly skewed in terms of the frequency of different emotions in the dataset (see Figure 2). Further, the emotion-causes pairs for all the non-`neutral` utterances are provided in the dataset in a separate list.

The task MC-ECPE expects the model to take a list of such conversations and predict the emotion and emotion-cause pairs labels.

2.2 Related Work

A lot of work has been done in the field of emotion analysis in textual settings. Soon, work began on extracting not only the emotion but also the cause of that extracted emotion. People employed mainly two approaches for emotion cause analysis - 1. Extracting the potential causes given an emotion (Lee et al., 2010; Chen et al., 2010; Gui et al., 2016b) and 2. Extracting the emotion-cause pairs jointly (Xia and Ding, 2019b; Ding et al., 2020; Wei et al., 2020).

Poria et al., 2020 was the first to introduce the task of extracting emotion-cause in conversations but their focus was also only on the textual dialogues. However, in our natural way of conversation, we rely on things like facial expressions, voice intonations for determining the emotion of the speaker. We also rely on auditory and visual scenes to determine the cause of the speaker's emotions. Hence, it is clear that **Emotion-Cause Pair Extraction (ECPE)** is a multimodal task requiring at least three modalities: **text, audio** and **video**. Busso et al., 2008; McKeown et al., 2012; Li et al., 2022a and Poria et al., 2019 worked in the field of multimodal emotion analysis in conversations but they did not consider the emotion causes.

The task of MC-ECPE was first worked on by Wang et al., 2024.

3 System Overview

3.1 Baseline I: Utterance labeling

Our baseline model treats the problem as a simple **utterance labeling task**. We use pre-trained text, audio, and image encoders to encode the individual modalities and use these to train three models that can identify the emotions in the utterances, the candidate cause utterances, and finally identify valid emotion and cause utterance(s) pairs.

- **Text Encoding:** For encoding the transcription of each utterance, we use pre-trained BERT (Devlin et al., 2018) embeddings as the baseline embeddings. Additionally, we finetune DeBERTa-Base (He et al., 2020) on the training data for our experiments. DeBERTa makes use of a disentangled attention mechanism and an enhanced masked encoder to improve upon BERT's performance in a variety of tasks. Finally, we also tried RoBERTa-Large and (Liu et al., 2019) pre-trained EmotionRoBERTa-Base[2] which is publicly available RoBERTa-base model finetuned on the Go Emotions dataset (Demszky et al., 2020). For every text encoder, we perform mean-pooling of the word embeddings to get the textual representation of the utterance.

- **Video Encodings:** For encoding the videos, we sampled 16 equally spaced frames from the video and mean-pooled the embeddings for the 16 frames. For encoding these 16 images, we used MViTv2-small (Li et al., 2022b) encoder, which achieves state-of-the-art performance on the Kinetics video detection task (Kay et al., 2017), which makes it an obvious choice for recognizing activities happening in the conversations relevant for emotion/cause detection.

[2] https://huggingface.co/SamLowe/roberta-base-go_emotions

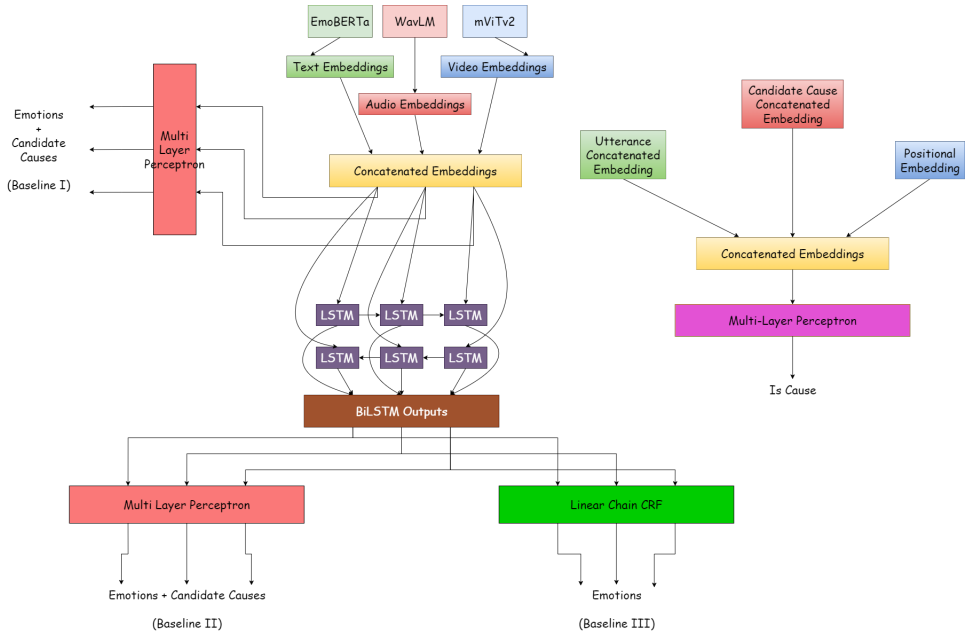

Figure 1: Model Architecture

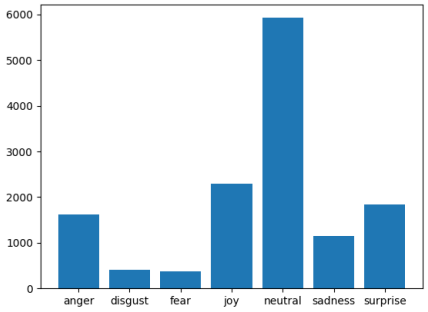

Figure 2: Emotion frequency in the dataset

- **Audio Encodings:** We used WavLM (Chen et al., 2022) for generating audio embeddings, which is trained on large audio data using masked speech representation and denoising in pre-training, making it suitable for various downstream speech tasks. We also try Wav2Vec2-Large (Baevski et al., 2020), which is trained by masking speech input in latent space and solving a contrastive task defined over a quantization of the latent representations which are jointly learned.

The model architecture is a combination of **three steps**, each of which is described below:

Step 1 – Emotion Classification

First, we concatenate the text, audio and video embeddings from the respective encoders and pass these concatenated embeddings into a dense layer, on which a Softmax function is applied to get the probability distribution over 7 classes (6 emotions and one neutral class). Due to a skewed distribution of the emotion labels in the dataset, we make use of **weighted Cross Entropy loss** to train the model, where the weights are taken as inverse of the frequency of the labels in the training dataset.

Step 2 – Candidate Cause Identification

For identifying the candidate cause, we similarly pass concatenated embeddings through a dense layer with a Sigmoid function, which predicts the probability of whether the utterance is a candidate cause or not. Binary Cross Entropy Loss is used to train the model.

Step 3 – Emotion-Cause pairing

For pairing the emotion utterances with the candidate causes, we concatenate the represenations for the emotion utterance and the cause utterance, with a distance embedding. This distance embedding is generated by giving positional embedding to each utterance, sampled from a Normal Distribution. This representation is passed through a dense layer with a Sigmoid function, which learns to predict the probability of the emotion-cause utterance pair being a valid emotion-cause pair or not for the given conversation, trained using Binary Cross Entropy Loss.

3.2 Baseline II: BiLSTM Architecture

The BiLSTM architecture is inspired by the work in Wang et al., 2024. While the Baseline I architecture treats the emotion and cause classification independently for each utterance, it is dependent on the surrounding context of the conversation too. Thus, the BiLSTM architecture models the problem as a **Sequence Labeling task**. We use the best encoders in the Baseline I architecture for generating the embeddings in this architecture.

Step 1 – Emotion Classification

Similar to the Baseline Model, we concatenate the embeddings of the three modalities, and pass them to a stacked BiLSTM. On top of the BiLSTM outputs, we apply a 7-class classifier to obtain the emotion category distribution. Similar to the Baseline I, weighted cross-entropy loss is used.

Step 2 – Candidate Cause Identification

For Candidate Cause prediction, similarly, the concatenated embeddings are passed through a BiLSTM on top of which a binary classifier is applied.

Step 3 – Emotion-Cause Pairing

The Emotion-Cause pairing model remains the same in this architecture as the Baseline I model.

In this architecture, BiLSTM provides the advantages of bidirectional and longer contexts which should help understand the emotions present in utterances better. This is because in a conversation, it is possible that the emotions are not just dependent on the current utterance, but on surrounding multimodal utterances as well.

3.3 Baseline III: BiLSTM-CRF Architecture

In the BiLSTM model, each classification decision was conditionally independent. Linear-chain CRFs are models generally used to model structured data where one output influences its neighboring outputs as it models the various transition probabilities, and have been extensively used with BiLSTMs for sequence labeling (Huang et al., 2015). This could be useful for emotion predictions because the emotion of one utterance is generally influenced by the emotions in its previous utterances. For instance, an utterance with happiness generally tends to be followed by another happiness utterance.

Step 1 – Emotion Classification

For this architecture, we add a CRF layer on top of the BiLSTM layers, and make use of the CRF-loss to train the model instead of Cross-Entropy loss as in the previous architectures. This loss models the transitions between the labels in the architecture, modelling the task as a more complex sequence labeling task. Thus, while the BiLSTM layer learns more about the language and emotions expressed through the language, the CRF layer tries to learn about the relations between the emotions.

Step 2 – Candidate Cause Identification

For Candidate Cause prediction, the architecture remains the same as in Baseline II. This is because the transitions between cause labels (being cause of an emotion in an utterance or not) does not make intuitive sense, and using BiLSTMs to capture surrounding context from other utterances is what seems more appropriate.

Step 3 – Emotion-Cause Pairing

The Emotion-Cause pairing model remains the same in this architecture as the Baseline I & II models.

4 Experimental Setup

We perform a random shuffle and use a 90-10% split for the train-validation split. The test set was provided by the authors, but its gold labels have not been made public.

The experiments involving Baseline II and III use *EmotionRoBERTa + WavLM + MViTv2* configuration. All the experiments involve applying a dropout of 0.3 on the audio, visual and textual embeddings before they are passed on to the main architectures. The BiLSTM for emotion detection consists of 4 layers while the one for candidate cause identification contains 3 layers. The dropout between the stacked layers of the BiLSTM is kept 0.3 as well. We use AdamW optimizer for all the three models, and use a linear learning rate scheduler with warmup for training the models. The Emotion Classification model is trained for 60 epochs, the Candidate Cause Identification model is trained for 40 epochs, and the Emotion-Cause Pairing Model is trained for 40 epochs as well.

In order to train the Emotion-Cause pairing model, we create positive and negative pairs during training. However, while the number of positive pairs is of the order N, the number of negative

Model Name	Emotion Detection			Candidate Cause Detection			Emotion-Cause Pairing			Emotion-Cause Pairing (Eval.)		Leaderboard

Table 1: Results for baselines on the ECAC dataset

pairs comes to the order of N^2, and thus we perform a random sampling of the negative pairs to keep the positive and negative samples in the ratio 1:5. This helps us to maintain balance between the positive and negative classes.

Evaluation Metrics

We evaluate the 3 steps separately as well apart from evaluating the performance for the final Emotion-Cause pairs:

Emotion Identification: We use Weighted Precision, Recall and F1-score for the distribution between the 7 classes (6 emotions and neutral class).

Candidate Cause Identification: We again use Weighted Precision, Recall and F1-score for evaluating the prediction between the binary classes – *is_candidate_cause* and *not_candidate_cause*.

Emotion-Cause Pairing: For evaluating this, we generate positive and negative pairs and use Weighted Precision, Recall and F1-score for evaluating the classification between the positive and negative classes.

Emotion-Cause Pairs: Weighted F1-score and Macro F1-score are the official metric used for the final evaluation for the task.

5 Results and Analysis

The performance of the three Baselines can be seen in Table 1. During the Evaluation phase, our best ranked submission of Baseline II had Wt. F1 score of 0.1836 and Macro F1 score of 0.1759, ranking 8th on the leaderboard.

Baseline I

Among the encoders in Baseline I, *BERT + WavLM + MViTv2* configuration performs the best on the validation set, including the individual steps as well as the final emotion-cause pair predictions. However, on the leaderboard, *EmotionRoBERTa + WavLM + MViTv2* gives the best performance, although the difference in the leaderboard scores is marginal among the encoders. This observation might indicate that the test data is a bit different in nature from the training data.

Better performance of EmotionRoBERTa can be attributed to the fact that the model's weights have already been finetuned towards emotion-related tasks. Further, it seems that finetuning DeBERTa on the training data caused it to overfit, leading to worse performance than vanilla BERT/RoBERTa models. RoBERTa-L performed slightly worse than BERT and EmotionRoBERTa.

Finally, WavLM being the newer architecture,

as expected performed better than Wav2Vec2. This is because WavLM is more robust than Wav2Vec2 and it is trained in a combination of supervised and self-supervised learning, making its performance much better.

Baseline II

We use the *EmotionRoBERTa + WavLM + MViTv2* configuration as encoders for the Baseline II architecture. Contrary to expectation, the wt. F1 score on the leaderboard decreased marginally, while the Macro F1 score increased marginally. This is probably because of the nature of the dataset, where the average length of a conversation is as little as 10, which causes the context of the utterance to be rather limited. In such a situation, the additional context from previous utterances doesn't prove helpful to the model, and might even prove to be noise for the model, leading to the results observed.

Baseline III

In this, we can observe a significant fall in wt. F1 and slight fall in Macro F1 score from the Baseline I and II architectures. This is in line with the observation of Baseline II that due to the nature of the dataset, sequence labeling it is not necessarily the best way to model it. Further, due to small number of utterances in the conversations, it is likely that the transition between labels needed for CRF doesn't get trained that well and leads to poorer performance.

6 Conclusion

In conclusion, we observe that the utterance labeling systems perform as good as sequence labeling systems for this specific dataset. Further, we also see that encoders which are trained on other emotion-related tasks tend to perform better on similar emotion-related tasks.

In future, it is possible to learn joint embeddings over the 3 modalities, which should provide better representations for each utterance (Girdhar et al., 2023). Further, it can be experimented to utilize the speaker information for each utterance while creating utterance representations (Liang et al., 2023).

Abstract

While significant work has been done in the field of NLP on vertical thinking, which involves primarily logical thinking, little work has been done towards lateral thinking, which involves looking at problems from an unconventional perspective and defying existing conceptions and notions. Towards this direction, SemEval 2024 introduces the task of BRAINTEASER, which involves two types of questions – Sentence Puzzles and Word Puzzles that defy conventional common-sense reasoning and constraints. In this paper, we tackle both types of questions using few-shot prompting on GPT-3.5 and gain insights regarding the difference in the nature of the two types. Our prompting strategy placed us 26th on the leaderboard for the Sentence Puzzle and 15th on the Word Puzzle task.

1 Introduction

The human brain consists of two hemispheres - left and right. Both of them are responsible for different kinds of thinking strategies. The left hemisphere is involved in vertical thinking, and the right hemisphere is involved in lateral thinking (Waks, 1997). Vertical (linear, convergent, logical) thinking is a more sequential analytical process. In contrast, in Lateral (outside the box, divergent, creative) thinking, we look at the problem from a new point of view, ignoring the expected associations with items.

In the field of NLP, much research has been done around vertical thinking and significant progress has been made. The recent work around Large Language Models (LLMs) (Devlin et al., 2018; OpenAI, 2022) has achieved great performance in solving complex reasoning tasks (Talmor et al., 2018; Bisk et al., 2020; Sap et al., 2019). This performance is consistent in both cases when no task examples have been provided to the model during inference (zero-shot) (Sanh et al., 2022) and when the model is introduced with the task during inference time (few-shot) (Chung et al., 2022).

However, lateral thinking has been overlooked when training NLP models like LLMs. When creating datasets for various models, texts that involve lateral thinking are mostly considered noise and filtered out from the data because researchers want their models to perform better at traditional reasoning tasks and not get confused by lateral thinking.

The task BRAINTEASER (Jiang et al., 2023, Jiang et al., 2024) tries to bridge this gap that exists between vertical and lateral thinking for LLMs and other NLP models. They formulated a set of Multi-choice Question Answers containing puzzles that can be solved only using lateral thinking. The benchmark dataset contains two types of lateral thinking puzzles - Sentence Puzzles and Word Puzzles. This has been constructed by designing a data collection procedure that crawled relevant puzzles from many websites that were publicly available performing semi-automatic filtering of irrelevant questions.

2 Background

2.1 Dataset

The dataset being used in this task is BRAINTEASER (Jiang et al., 2023). It was prepared by scraping puzzles from various publicly available websites and then semi-automatically filtering them out. Then *semantic reconstruction* and *context reconstruction* techniques were used to create variants of each puzzle without affecting its out-of-the-box thinking style. This helped in preventing possible memorization by LLMs and the lack of consistency of the puzzles.

The puzzles in this dataset can be divided into two categories:

- **Sentence Puzzles**: These are brain teasers where the puzzle-defying commonsense is

*Equal Contribution

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1212–1216

centered on sentence snippets.

For example, **Question**: *You are running so fast but you're not getting closer. Where are you?* **Answer**: *Treadmill.* **Explanation**: This is because while running on a treadmill, we stay put where we are. The key is understanding that running on a treadmill means you remain stationary despite the motion.

- **Word Puzzles**: These are brain teasers where the answer violates the default meaning of the word and focuses more on the letter composition.

  For example, **Question**: *How can you make "ten" out of "net"?* **Answer**: *Just flip it around.* **Explanation**: This is because if we consider the spelling of the word "ten" and we flip the letters of the word around, we get the word "net" which is what we want to make out of "ten".

The training data contains **507 Sentence Puzzles** and **396 Word Puzzles**. Each of these puzzles has 4 options to choose from and only one option is the correct answer.

2.2 Related Works

With the recent success of LLMs in various NLP tasks, researchers have also started exploring their use for Multiple Choice Question Answering (MCQA) tasks (Robinson et al., 2022; Zheng et al., 2023).

Researchers have also started employing the technique of **few-shot prompting** (Liu et al., 2023; Ma et al., 2024; Lu et al., 2021) for various tasks and it has shown improvements when compared with **zero-shot prompting**.

LLMs like GPT-3.5 have been trained on vast amounts of human-generated text. The main features around which such models are trained are **Pattern Recognition**, **Creative Reasoning** and **Wide Knowledge Range**.

Thus, we decided to employ few-shot prompting on LLMs for this task.

3 System Overview

Our architecture uses GPT-3.5 (Brown et al., 2020) (specifically *gpt-3.5-turbo*) with few-shot prompting to answer the question.

3.1 GPT-3.5

In NLP, the architecture of Generative Pre-trained Transformer (GPT) 3.5 (GPT-3.5) stands as a significant advancement, which is the culmination of iterative improvement over its predecessors. The architecture of the model is based upon the Transformer model (Vaswani et al., 2017), which uses self-attention to enhance performance over the prior sequential models. GPT-3.5 scales this Transformer architecture to over hundereds of billions of parameters, which have been trained by exposing and training the model on hundreds of billions of tokens.

In particular, due to the autoregressive nature of GPT-3.5 and due to being trained on extremely large data, it has enough knowledge about the language and the real world to perform tasks in a Zero-shot setting (Sanh et al., 2022). This Zero-shot setting allows the model to understand and execute a task it hasn't been explicitly trained for. These capabilities have been reflected in GPT-3.5 being used in Summarization (Liu and Healey, 2023), Question Answering (Bahak et al., 2023), Natural Language Inference (Ye et al., 2023), etc.

3.2 Few-shot prompting

While zero-shot prompting works well for simple tasks, tasks like BrainTeaser are a bit more complex in nature, and in such cases providing explicit instructions to the LLM about the nature of the task along with few examples of the task *(few shots)* becomes extremely helpful for the model (Chung et al., 2022). Here, the few-shot technique involves providing GPT-3.5 some examples, allowing GPT-3.5 to generalize from the few examples, drawing on its large pre-trained knowledge about the language and the real-world.

Thus, 2 different sets of prompts are created for the task, one for the Sentence Puzzle Task and another for the Word Puzzle task, since the 2 tasks are fundamentally different and need different instructions and examples.

3.3 Experimental Setup

We provide 2-shot prompts to GPT-3.5 for our leaderboard submission. We also try out 5-shot prompt in the post evaluation phase to test if providing more examples helps the model perform better.

The prompt used for the Sentence Puzzle task is shown in Listing 1. As we can see, the prompt first

```
You are given a question with multiple choices that you need to answer.
↪  The answer would only be one index of the multiple choices available.
↪  Such a question would involve  brain teaser questions where the
↪  puzzle defying commonsense is centered on sentence snippets.
IMPORTANT: It's crucial to analyze the question from an unconventional
↪  perspective, focusing on the literal or alternative meanings of the
↪  words used, rather than relying on common sense. You must not use
↪  commonsense, but look at meaning from a different perspective than
↪  what would commonly be done. For example,

Example 1:
Question: You are running so fast but you're not getting closer. Where
↪  are you?

Option 0: Country road.
Option 1: Treadmill.
Option 2: High way.
Option 3: None of above.

Answer: 1
Reason: This is because while running on a treadmill, we stay put where
↪  we are. The key is understanding that running on a treadmill means
↪  you remain stationary despite the motion. This is not valid for
↪  Country road or High way. Thus, the answer is 1 - Treadmill.

Example 2:
Question: From elementary school to collage, how many "first day of
↪  school" does the average person have in their lifetime?

Option 0: They technically only have one first day of school in their
↪  lifetime. That's the very first day they started attending school
↪  as a child.
Option 1: Average people have 4: elementary school, middle school, high
↪  school, and college.
Option 2: Average people have "first day of school" in each semester,
↪  so it will be more than 10!
Option 3: None of above.

Answer: 0
Reason: First day of school can only be one day in a person's lifetime.
↪  Here, it is important to understand that first day of middle school,
↪  high school, college won't be first day of school. Similarly, each
↪  semester's first day is not TECHNICALLY first day of school. This,
↪  the answer is 0 -  They technically only have one first day of
↪  school in their lifetime. That's the very first day they started
↪  attending school as a child. Thus, the key here is the term 'first
↪  day of school' technically refers to the very first day a person
↪  attends school, making all subsequent 'first days' at different
↪  educational levels irrelevant to the specific question.

Now, using these examples, answer the question below. It is IMPORTANT
↪  that you just provide the index of the answer in the response. DO
↪  NOT output the reason behind choosing the answer:

Question: In a small village, two farmers are working in their fields -
↪  a diligent farmer and a lazy farmer. The hardworking farmer is the
↪  son of the lazy farmer, but the lazy farmer is not the father of
↪  the hardworking farmer. Can you explain this unusual relationship?
Option 0: The lazy farmer is his mother.
Option 1: The lazy farmer is not a responsible father as he is lazy.
Option 2: The diligent farmer devoted himself to the farm and gradually
↪  forgot his father.
Option 3: None of above.

Answer:
```

Listing 1: Prompt for the Sentence Puzzle

details the task, and *IMPORTANT* keyword is used to express to GPT-3.5 that commonsense must not be used in the task, but instead it should look at meaning from an unconventional sense. Then, 2 examples are given, along with **reasoning** behind the answers too. This was important, as this gave the model more knowledge to be able to generalize the task from the examples. Further, the output format was clearly specified in the prompt so as to avoid getting extra information in the model output.

Similar prompt for Word Puzzle can be seen in Listing 2. The prompt clarifies that the structural aspect of the words should be focused on, emphasizing that unconventional meaning should be looked at. Then, 2 examples that exhibit structural aspect are given along with reasoning behind their answers as well as constraints for the output format.

```
You are given a question with multiple choices that you need to answer.
↪  The answer would only be one index of the multiple choices
↪  available. The question demands an unorthodox approach, focusing on
↪  the spellings or structural aspects of words, rather than their
↪  standard meanings. Your task is to choose the correct answer from
↪  the given multiple-choice options by analyzing the words in a
↪  literal or unconventional way.
IMPORTANT: It's crucial to analyze the question from an unconventional
↪  perspective, focusing on the spellings of certain words, rather
↪  than relying on common sense. You must not use commonsense, but
↪  look at meaning from a different perspective considering
↪  arrangement of the letters in certain words than what would
↪  commonly be done. For example,

Example 1:
Question: How can you make "ten" out of "net"?

Option 0: Just flip it around.
Option 1: Remove the letter "e".
Option 2: Move the letter "t" to the end.
Option 3: None of above.

Answer: 0
Reason: This is because if we consider the spelling of the word 'ten'
↪  and we flip the letters of the word 'ten' around, we get the word
↪  'net', which is what we want to make out of 'ten'.  The answer
↪  focuses on the literal rearrangement of the letters, disregarding
↪  the typical meanings of the words. Thus, the answer is 0 - Just
↪  flip it around.

Example 2:
Question: What is the most fast city?

Option 0: Urban city.
Option 1: Inner city.
Option 2: Velocity.
Option 3: None of above.

Answer: 2
Reason: The term 'fast' in the question prompts an unconventional
↪  interpretation. All options contain the word "city", but "velocity"
↪  stands out as it directly relates to speed or 'fastness'. The
↪  question cleverly uses the term 'city' as a red herring, while the
↪  actual focus is on the concept of speed.

Now, using these examples, answer the question below. It is IMPORTANT
↪  that you just provide the index of the answer in the response. DO
↪  NOT output the reason behind choosing the answer:

Question: What sort of cheese is made in reverse?
Option 0: Cheddar cheese..
Option 1: Edam cheese.
Option 2: Blue cheese.
Option 3: None of above.

Answer:
```

Listing 2: Prompt for the Word Puzzle

4 Results and Analysis

The results are detailed in Tab.1. For comparison, we also list the zero-shot prompting results reported in Jiang et al., 2023. As we can see, the two-shot performance on Word puzzle improved over the zero-shot setting for all the categories, while the same worsened in case of the Sentence puzzle.

This is because of the very nature of the two problems. Sentence puzzle involves deeper non-

Table 1: Results of zero-shot and few-shot prompting on GPT-3.5 for the two BRAINTEASER subtasks. Ori = Original, Sem = Semantic, Con = Context.

Model	Instance-based			Group-based		Overall
	Original	Semantic	Context	Ori & Sem	Ori & Sem & Con	
Sentence puzzle						
GPT-3.5 (zero-shot) **Baseline**	60.7	59.3	**67.9**	50.7	39.7	**62.6**
GPT-3.5 (two-shot)	57.5	55.0	42.5	50.0	30.0	51.7
GPT-3.5 (five-shot)	**62.5**	**65.0**	55.0	**62.5**	**42.5**	60.8
Word puzzle						
GPT-3.5 (zero-shot) **Baseline**	56.1	52.4	51.8	43.90	29.3	53.5
GPT-3.5 (two-shot)	71.9	71.9	62.5	59.4	46.9	68.6
GPT-3.5 (five-shot)	**78.1**	**90.6**	**84.4**	**78.1**	**68.8**	**84.4**

conventional semantic understanding of the question and the choices, which despite conveying reasoning behind the answers in the few-shot examples, cannot be generalized as easily with just 2 examples. On the other hand, the only tricky component of the Word Puzzle is that the structural aspect of certain words needs to be taken instead of the actual surface meaning of the said words. This can be much more easily generalized through just as few as two examples in the prompt. Further, adding the examples in the Sentence puzzle that don't generalize very well for other questions in the testing set might have acted as noise for the model, which led to poorer performance.

We also note that using five-shot prompt instead of two-shot prompt hugely increases the performance. This is to be expected, as providing more examples would help the model generalize even better towards solving the task. This is specially true for Word Puzzle questions, where adding more examples allows the model to generalize the task much better.

However, in Sentence Puzzle we still notice a drop in the overall performance as compared to the zero-shot model. This is because of a drop in the performance of the context reconstruction questions, and a marginal increase in comparison to zero-shot in other types of questions. However, group based accuracy increases in five-shot, which might indicate that with five examples, the model is able to handle the variations in reconstructions better, albeit with performance of Contextual Reconstruction taking a dip. These observations are in line with the drop observed in two-shot prompt in comparison to the zero-shot prompt, highlighting the difficult nature of the task of Sentence Puzzle questions and the inability of the model to generalize using few Sentence Puzzle examples. However, we do note that the performance on Sentence Puzzle also does improve with additional examples between two-shot and five-shot prompting.

5 Conclusion

In conclusion, we explored the effectiveness of few-shot prompting for LLMs for complex and unconventional tasks. Further, it demonstrates that few-shot prompting is helpful only in scenarios where the examples convey enough information that can be better generalized, as the results worsened in the Sentence Puzzle while improved in the Word Puzzle.

In future, better prompting strategies like Chain of Thought prompting (Wang et al., 2023) can be utilized to improve the performance. Additionally, finetuning the pre-trained LLMs might also help in the task further. Also, increasing the number of training examples might help in further improving the model performance, as observed in the gains of performance in the five-shot prompt in comparison to the two-shot prompt.

MorphingMinds at SemEval-2024 Task 10: Emotion Recognition in Conversation in Hindi-English Code-Mixed Conversations

MONIKA VYAS
Purdue University Fort Wayne
vyasm01@pfw.edu

Abstract

The complexity of expressing emotions in multilingual settings, particularly in Hindi-English code-mixed conversations (Bafna and Gali, 2022), presents both obstacles and prospects for natural language processing (NLP) research. This thesis ventures into the realm of emotion recognition within code-mixed text (Sasidhar et al., 2022), to enhance comprehension and technological capabilities in this domain.

The principal objective of this study is to refine NLP models tailored specifically to the intricacies of code-mixed Hindi-English conversations. By harnessing advanced deep learning architectures (Sane et al., 2019a) like BERT, RoBERTa, and BERTweet, the research systematically evaluates the efficacy of various models in capturing nuanced emotional expressions embedded within code-mixed text.

Utilizing data from the EDiReF shared task at SemEval 2024 (Kumar et al., 2024a), the dataset encompasses dialogues sourced from a popular Indian comedy television series, offering a diverse range of conversational excerpts reflecting cultural nuances and comedic elements. Through meticulous data analysis and preprocessing, insights into the distribution of emotions and linguistic patterns within the dataset are gleaned, informing subsequent model selection and training strategies.

The process of model selection adopts an iterative approach, commencing with traditional machine learning models such as Support Vector Machines (SVM) and Logistic Regression (LR) before transitioning to deep learning architectures like XLM-BERT. Techniques for model training and optimization evolve, integrating validation datasets to assess generalization capabilities and ensuring robust evaluation methodologies.

Feature extraction methods, including TF-IDF vectorization (Mikolov et al., 2023) and N-gram analysis, are employed to capture pertinent linguistic patterns and contextual information from the text data, thereby enriching the representation of textual features (Feng and Liu, 2021) crucial for emotion detection.

In summary, this thesis contributes to the advancement of emotion recognition technology in code-mixed languages (Gupta et al., 2022), shedding light on the intricate interplay of emotions within Hindi-English conversations. By addressing the unique challenges posed by code-mixed languages and harnessing state-of-the-art NLP techniques, this research lays the groundwork for applications in sentiment analysis, conversational AI, and cross-cultural communication.

1 Introduction

In this thesis, we explore the topic of Emotion Recognition in Conversation in Hindi-English Code-Mixed Conversations. The research is motivated by the challenges addressed in the SemEval 2024 Task 10: Emotion Discovery and Reasoning its Flip (Kumar et al., 2022) (Kumar et al., 2024b) in Conversation (EDiReF) (Kumar et al., 2024a).

This paper addressed the Emotion Recognition in Conversation (ERC) task one (Kumar et al., 2023), one of the three subtasks in the Emotion Discovery and Reasoning its Flip in Conversation (Kumar et al., 2022) (Kumar et al., 2024b). ERC involves assigning emotions to each utterance in a dialogue from a predefined set of possible emotions. The research specifically focuses on ERC to contribute to advancing emotion recognition and understanding in multilingual and code-mixed conversational settings.

The initial stages of the research endeavor encompassed several pivotal tasks aimed at laying the foundation for exploring emotion detection within multilingual conversational contexts. Foremost among these tasks was the meticulous preprocessing of the dataset, which involved addressing anomalies such as missing speaker information (NaN) in the JSON files. Additionally, developed a

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1217–1221

Speaker	Utterance	Emotion
Sp_1	Aaj to bhot awful day tha! *(I had an awful day today!)*	Sad
Sp_2	Oh no! Kya hua? *(Oh no! What happened?)*	Sad
Sp_1	Kisi ne mera sandwich kha liya! *(Somebody ate my sandwich!)*	Sad
Sp_2	Me abhi tumhare liye new bana deti hun! *(I can make you a new one right now!)*	Joy
Sp_1	Wo great hoga! Thanks! *(That would be great! Thanks!)*	Joy

Figure 1: ERC dataset format (Kumar et al., 2023)

common module for flattening lists and organized preprocessing code into separate modules to enhance efficiency and facilitate code reusability.

A critical aspect of the methodology involved harnessing transformer models pre-trained in Romanized Hindi for fine-tuning efforts. Particularly noteworthy was the fine-tuning of a pre-trained XLM-RoBERTa model using a custom dataset. This adaptation was necessitated by the absence of labels in a compatible format with the XLM model's training corpus. The fine-tuning process yielded promising outcomes, evidenced by the training output demonstrating a final training loss of approximately 0.3471 and robust training efficiency metrics such as runtime and samples per second.

However, challenges emerged during the subsequent phases of model evaluation and prediction. An initial attempt to predict emotions using the development dataset and the fine-tuned model yielded unexpected results, with all predictions aligning with the "neutral" label. Subsequent analysis revealed imbalances in label distribution, prompting a meticulous review of label mapping and encoding procedures to ensure the accuracy of model predictions.

In response to these challenges, alternative strategies were explored, including the augmentation of the number of epochs in model training. Despite these efforts, evaluation metrics following this adjustment showed marginal improvements, with precision, recall, and F1-scores remaining low across various emotion categories.

Further experimentation involved ensemble techniques such as bagging and boosting algorithms, implemented through classifiers like Random Forest and AdaBoost. While these approaches demonstrated some enhancement in performance metrics, challenges persisted, particularly in classes with low precision and recall. A pivotal juncture in the research journey involved the exploration of oversampling techniques, inspired by insights from the literature highlighting the limitations of undersampling in small datasets. Techniques such as Synthetic Minority Over-sampling Technique (SMOTE) [16] were considered to address the class imbalance and enhance model robustness. Additionally, attention was given to hyperparameter adjustments, including batch size, learning rate, and model architecture, to optimize model performance.

2 Related Work

Following is research on similar Emotion detection in conversations with multiple labels and multilingual language : Emotion detection and classification have been extensively explored within monolingual datasets. However, the challenge of dealing with code-mixed text, particularly in languages like Hindi combined with English, has resulted in fewer studies in this domain. Notably, Vijay et al. (Vijay et al., 2018) conducted seminal research on emotion detection in social media text characterized by Hindi-English code-mixing (Chauhan et al., 2019). They curated a corpus comprising 2866 sentences across six emotion classes and conducted experiments focusing on three classes: Happy, Sad, and Anger. Their methodology involved preprocessing the data, extracting character-n-grams and word-n-grams as primary features, employing chi-square for feature selection, and employing a Support Vector Machine (SVM) as the classifier, achieving an accuracy of 58 percent.

In a similar vein, Ghosh et al. (Ghosh et al., 2017) undertook sentiment detection tasks on code-mixed text extracted from social media platforms, utilizing English-Bengali and English-Hindi datasets. Their approach involved classifying sentences based on polarity contradictions, leveraging features such as Sentiwordnet word matches, opinion lexicons, and POS tags. They employed a Multilayer Perception model, achieving an accuracy of 68.5 percent.

Joshi et al. (Prabhu et al., 2016) explored sentiment analysis in Hindi-English code-mixed text sourced from Facebook comments, maintaining a polarity scale and forming a corpus of 3879 sentences across three classes. Their unique classification method involved sub-word level LSTM (Hochreiter and Schmidhuber, 1997), outperforming traditional algorithms like Char-LSTM, SVM-Unigram, and Naive Bayes, with an accuracy of 69.7 percent.

A survey conducted by Samar et al. (Al-Saqqa et al., 2018) categorized four different approaches to emotion classification: keyword-based, corpus-based, learning-based, and hybrid approaches. The the survey highlighted the efficacy of hybrid approaches, particularly ensemble techniques, and emphasized the promising outcomes of deep learning models.

Additionally, Shalini et al. (Shalini et al., 2019) explored stance detection in English-Kannada code-mixed data, utilizing deep learning architectures (Tripathi et al., 2013) and text representations such as Word2Vec and GloVe. Their findings showcased the effectiveness of CNN in learning new weights on top of a pre-trained model.

Further, studies by Sane et al. (Sane et al., 2019b), and Satyajit et al. (Kamble and Joshi, 2018) delved into aggression detection, humor detection, and hate speech detection in code-mixed data, respectively, employing various techniques such as text-based features, fastext embeddings, and bilingual embeddings generated using Word2Vec.

Reflecting on the reviewed literature, it becomes apparent that various machine learning models, such as Support Vector Machines (SVM), Logistic Regression, Naive Bayes, and Transformer-based models like XLM-RoBERTa (Wei, 2021), offer valuable features for model learning in emotion classification tasks. While deep neural networks, particularly those incorporating CNN as a primary layer, have exhibited superior performance in some studies, the approach focused on leveraging a diverse set of machine learning algorithms. In alignment with these findings, the study adopts different machine learning models and transformer architectures, including SVM, Logistic Regression, and XLM-Roberta, for emotion classification in code-mixed text.

3 Methodology

We initiated the data pre-processing phase to ensure the quality and relevance of the dataset. Initially, the dataset contained 3475 comments alongside unrelated information, prompting the creation of a refined dataset focusing solely on relevant information such as utterances and their corresponding emotions. In the pursuit of model development, we commenced by employing traditional machine learning (ML) models, including Logistic Regression (LR), Support Vector Machine (SVM), and Long Short-Term Memory (LSTM). Despite initial efforts, the obtained accuracy of 10 percent and F1-score were unsatisfactory 9 percent, with all predicted labels converging to neutral across the test utterances.

Subsequently, we transitioned to fine-tuning a pre-trained XLM-Roberta model tailored to handle the Romanized Hindi language. We leveraged a custom dataset due to its unique label format incompatible with the XLM model's training corpus. The training process yielded promising results, with a final training loss of approximately 0.3471. Key training metrics, including runtime, samples processed per second, and total FLOPs, underscored the efficiency and effectiveness of the training procedure.

Furthermore, we explored alternative approaches to address the neutral label prediction issue, drawing insights from external resources such as a referenced medium article and relevant research papers. Experimentation with TF-IDF feature extraction revealed discrepancies in data formatting, necessitating adjustments to ensure accurate feature extraction. By rectifying these data pre-processing issues and revisiting logistic regression, we successfully diversified predicted labels across utterances, albeit with reduced accuracy and F1-score.

To address the dataset's imbalance and size constraints, we delved into oversampling techniques, particularly the Synthetic Minority Oversampling Technique (SMOTE) and Adaptive Synthetic Sampling (ADASYN) (Maharana and Mohapatra, 2021). By oversampling the dataset and optimizing TF-IDF parameters, we observed improvements in model performance, achieving an accuracy of 33 percent and an F1 score of 35 percent.

In the adjusted formula in Equation 1 below: TP, TN, FP, and FN symbolize the counts of true positives, true negatives, false positives, and false negatives, respectively. These metrics serve as pivotal indicators in assessing the model's efficacy.

$$\frac{\text{TP}+\text{TN}}{\text{TP}+\text{TN}+\text{FP}+\text{FN}} \times \frac{\text{Precision}\times\text{Recall}}{\text{Precision}+\text{Recall}} + \sum_{i=1}^{n} \frac{\text{Synthetic Samples}_i}{\text{Original Dataset}}$$

Figure 2: Model Performance

Precision and Recall encapsulate the model's acumen in delineating emotional instances within the dataset accurately. They provide insights into the model's capability to discern and categorize

emotions effectively. The summation term of 1nOriginal Dataset- Synthetic SamplesSMOTE elucidates the influence of SMOTE oversampling on the dataset.

In this context, the Original Dataset denotes the size of the initial dataset, while Synthetic SamplesSMOTE signifies the number of synthetic samples generated through SMOTE oversampling. This component reflects SMOTE's remedial impact on rectifying class imbalances within the dataset, thereby fostering enhanced model performance.

Model			Accuracy
SVM			0.30
Logisitc Regression			0.33
XLM-Roberta			0.20
Precision	**Recall**	**F1 Score**	
0.32	0.30	0.30	
0.38	0.33	0.35	
0.25	0.20	0.28	

Table 1: Model Performance Metrices

4 Results and Discussion

The results presented in Table 1 provide valuable insights into the performance of different models in emotion recognition. Notably, the evaluation metrics—accuracy, precision, recall, and F1-Score—offer a comprehensive view of each model's effectiveness in capturing the nuances of emotional expressions within the dataset.

One striking observation is the superior performance of logistic regression (LR) compared to Support Vector Machine (SVM) and transformer-based models like XLM-Roberta. LR outperformed SVM and XLM-Roberta.

with an accuracy of 33 percent, showcasing its ability to better generalize to the dataset and make accurate predictions. This outcome is particularly noteworthy given the challenges posed by small datasets, where traditional machine learning models often excel due to their simplicity and interpretability. The utilization of SMOTE oversampling and TF-IDF feature engineering played a pivotal role in enhancing model performance. By augmenting the dataset through SMOTE and increasing the maximum number of features in TF-IDF from 5000 to 8000, effectively addressed class imbalance and enriched the feature space, leading to a notable improvement in accuracy and F1-Score. This underscores the importance of preprocessing techniques in mitigating dataset constraints and improving model robustness.

Furthermore, the decision to prioritize logistic regression over transformer-based models reflects the nuanced requirements of emotion recognition tasks in small datasets. While transformer-based models are celebrated for their ability to capture complex patterns in large datasets, their performance may be suboptimal in scenarios where data scarcity is prevalent. By leveraging logistic regression, striked a balance between model complexity and dataset size, resulting in more reliable and interpretable emotion recognition systems. Overall, these findings reaffirm the efficacy of traditional machine learning approaches in handling emotion recognition tasks, especially when confronted with limited data availability. Moving forward, exploring hybrid models that integrate the strengths of both traditional machine learning and transformer-based architectures could pave the way for even greater advancements in emotion understanding and recognition.

5 Conclusion and Future Work

In the forthcoming research endeavors, we aim to expand the scope of the emotion detection framework by integrating both word embeddings and TF-IDF features. This innovative approach seeks to create a richer representation of textual data by combining semantic embeddings with feature importance weighting.

The primary focus will be on harnessing Convolutional Neural Network (CNN) architectures to further refine the emotion detection process. Through the training and optimization of the CNN model using this blended feature space, we anticipate significant enhancements in the model's capacity to discern subtle emotional nuances within the text. To validate the effectiveness of this approach, we will employ standard performance metrics and conduct comparative analyses against baseline models.

Additionally, we envision extending the methodology to accommodate multimodal data sources, such as text paired with audio or visual inputs (Dhawan and Wadhawan, 2022). This expansion will serve to broaden the application of emotion detection, opening avenues for more comprehensive analyses and interpretations of emotional content across various media formats.

In summary, the research journey has been characterized by iterative experimentation and adap-

tation in response to emerging challenges and insights. The endeavors underscore the complexity inherent in emotion detection within multilingual conversational data and emphasize the significance of methodological rigor and innovation in overcoming these challenges. Moving forward, the focus remains on refining methodologies and exploring novel approaches to further enhance the accuracy and robustness of emotion detection systems in diverse linguistic and cultural contexts.

moshiul_240@cuet.ac.bd

Abstract

Semantic textual relatedness is crucial to Natural Language Processing (NLP). Methodologies often exhibit superior performance in high-resource languages such as English compared to low-resource ones like Marathi, Telugu, and Spanish. This study leverages various machine learning (ML) approaches, including Support Vector Regression (SVR) and Random Forest, deep learning (DL) techniques such as Siamese Neural Networks, and transformer-based models such as MiniLM-L6-v2, Marathi-sbert, Telugu-sentence-bert-nli, and Roberta-bne-sentiment-analysis-es, to assess semantic relatedness across English, Marathi, Telugu, and Spanish. The developed transformer-based methods notably outperformed other models in determining semantic textual relatedness across these languages, achieving a Spearman correlation coefficient of 0.822 (for English), 0.870 (for Marathi), 0.820 (for Telugu), and 0.677 (for Spanish). These results led to our work attaining rankings of 22th (for English), 11th (for Marathi), 11th (for Telegu) and 14th (for Spanish), respectively.

1 Introduction

Semantic textual relatedness measures the conceptual and contextual similarity of two sentences. It specifies how alike the two sentences are in terms of meaning. Determining semantic textual relatedness is crucial for various language-processing tasks, including contemporary technology, search engines, chatbots, virtual assistants, plagiarism detection, paraphrasing, question answering, text generation, and other related applications. It is possible to determine how comparable two natural language sentences are based on the quantity and quality of matched elements in each sentence. These matches offer essential insights into the relationship between and degree of semantic similarity between the two sentences and the likelihood of successful word matching in semantically equivalent text pairs.

Another critical aspect of semantic relatedness is understanding the context of sentences. Singnificant research has been done in this area, specifically in SemEval competition from 2012 to 2017 (Agirre et al., 2012, 2013, 2014, 2015, 2016; Cer et al., 2017). Most proposed methodologies perform better in high-resource languages like English and Spanish but could be better in other low-resource languages like Telegu, Marathi, and Bengali. In certain studies, translating from a low-resource language to English is conducted (Wu et al., 2017) prior to semantic analysis, contributing to suboptimal performance. Other factors include the failure of specific methods to capture the meaning of phrases and idioms within sentences effectively (Śpiewak et al., 2017), as well as a tendency for some approaches to focus excessively on individual word meanings (Śpiewak et al., 2017). This work addresses these shortcomings by proposing a transformer-based model, which gives us a good result in finding semantic textual relatedness. The main contributions of this work are:

- Investigated several ML, DL, and transformer-based models to find the semantic relatedness in various texts of four languages.
- Explored various pre-trained transformer-based methods with necessary tuning to identify semantic textual relatedness in English, Spanish, Telegu, and Marathi.

The code will be publicly available at https://github.com/ashrafulparan2/SemanticCUETSync-at-SemEval-2024-Task-1.

2 Related Work

Numerous studies have been accomplished on semantic relatedness in high-resource languages. Hasan et al., 2020 presented the process for calculating semantic similarity and proposed a feature-based metric for building semantic vectors. Their

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1222–1228

knowledge feature-based method found similarity measure of 0.82. Abdalla et al., 2021 proposed a dataset to explore questions on what makes sentences semantically related. Reimers and Gurevych, 2019 suggested using a sentence transformer model, which creates a 768-dimensional dense vector space from sentences and paragraphs. The relatedness of two sentences can be assessed using this model. Their approach achieved the best score of 0.8492 with SRoBERTa-STSb-base model. Three transformer-based clinical semantic textual similarity models intended to detect semantic relatedness in medical data were presented by Yang et al., 2020. Chen et al., 2022 proposed a semi-supervised sentence embedding technique called GenSE, which effectively uses large-scale unlabeled data. It achieved promising results on several STS datasets with an average correlation score of 0.8519. Meanwhile, Gatto et al., 2023 evaluated sentence similarity among texts using large language models (LLM). According to their research, ChatGPT and other models are proficient in recognizing textual similarity within particular areas. In addition to the transformer models, Verma and Muralikrishna, 2020 introduced a deep learning model, specifically a Recurrent Neural Network (RNN). This model utilized document embedding vectors to infer the meaning of small paragraphs comprising one, two, or three sentences.

Significant challenges arise when representing sentences with low-resource languages (LRLs), such as Telugu, Marathi, and Bengali. Furthermore, limited datasets make the process of textual similarity detection more challenging in LRLs. Joshi et al., 2023 focused on two low-resource Indian languages (Hindi and Marathi), and their proposed model was evaluated on real text classification datasets to show embeddings obtained from synthetic data, which will be an effective training strategy for low-resource languages. They achieved the highest score of 0.83 utilizing the MahaBERT and LaBSE models. A cross-lingual model for finding similarity between sentences was proposed by Deode et al., 2023a. Their system obtained an accuracy of 0.82 for finding semantic relatedness in low-resource languages like Hindi, Marathi, Kannada, Telugu, Malayalam, Tamil, Gujarati, Odia, Bengali, and Punjabi. Tang et al., 2018 proposed a multilingual framework for finding semantic textual similarity in low-resource languages utilizing rich annotation data from a high-resource language. Their shared sentence encoder approach archived score of 0.825 for Spanish language.

3 Dataset and Task Description

The dataset is developed by Ousidhoum et al. (Ousidhoum et al., 2024a) to evaluate the semantic textual similarity to perform the shard task at SemEval-2024. It includes data for Telugu, Marathi, English, and Spanish, which assess semantic relatedness between sentences. There are labeled and unlabeled data in the dataset. Labeled data is used for Track-A; each row has two sentences and a score that ranges from 0 to 1, representing the semantic relatedness of the sentences. Moreover, the dev, test, and train categories are applied to every language dataset. Table 1 shows the distribution of dev, test, and train sets for the English, Marathi, Telugu, and Spanish datasets, respectively.

Language	Dev set	Test set	Train set
English	250	2600	11000
Marathi	294	299	2400
Telegu	130	297	2340
Spanish	140	600	1562
Total	814	3796	17302

Table 1: Dataset statistics for Track-A

The task for Track-A (Ousidhoum et al., 2024b) calculates the semantic relationship and provides a score (degree of semantic relatedness) between 0 to 1. Figure 1 illustrates few examples of the task of sentence relatedness with the score.

4 System Overview

Various textual features will be extracted to employ ML and DL models. Several transformer models are exploited for the task, including MiniLM-L6-v2, Marathi-SBERT, Telugu-Sentence-BERT-NLI, and Roberta-BNE-Sentiment-Analysis-ES, to assess semantic relatedness. Figure 2 illustrates the schematic structure of the proposed approach.

Textual Feature Extraction: Feature extraction is necessary for ML and DL models to learn from text. We used TF-IDF (Takenobu, 1994) to extract the features to apply different ML algorithms. Word2Vec (Mikolov et al., 2013) and FastText (Grave et al., 2018) embeddings were used to extract features for DL models.

ML-based Approaches: This work employed traditional ML approaches, including SVR and RF. Following dataset preprocessing, we trained

Sentence #1	Sentence #2	Score

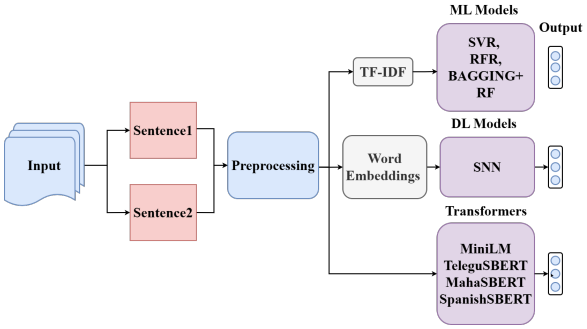

Figure 2: Schematic process of finding semantic textual relatedness

the model using the SVR for the English language. Similarly, we utilized the RF, configuring "n-estimators = 100" during training. A BaggingRegressor model is employed with the RF as the base estimator, with "n-estimators = 10" set for the base estimator.

DL-based Approaches: This work explored a Siamese Neural Network (SNN) architecture implemented in PyTorch to perform the task. The SNN model was applied exclusively to the English dataset. The text is transformed into vectors and subsequently passed through LSTM layers. The similarity between the two texts was determined using cosine embedding loss, and optimization was carried out using the 'Adam' optimizer. We set learning rate = 10, hidden-dim = 128, embedding-dim = 128 and max-length = 1000 and ran it for 10 epochs. Table 2 shows the several ML parameters and DL hyperparameters used for the models.

Classifier	Parameters	Value
SVR	kernel	rbf
	degree	3
	gamma	scale
	C	1.0
RF	n-estimator	100
Bagging+RF	n-estimator	10
SNN	epoch	10
	lr	9e-5
	hidden-dim	128
	embedding-dim	128
	max-words	10000
	max-length	1000

Table 2: Several ML parameters and DL hyperparameters of the employed models

Transformer-based Models: This work developed the task solutions in four languages: English, Marathi, Telugu, and Spanish. Thus, four different kinds of transformers were explored, including all-MiniLM-L6-v2 (Wang et al., 2020), telugu-sentence-bert-nli (Deode et al., 2023b), marathi-sentence-similarity-sbert (Joshi et al., 2023) and dccuchile-bert-base-spanish-wwm-uncased (Cañete et al., 2023). MiniLM-L6-v2 is a sentence transformer that maps sentences and paragraphs to a 384-dimensional dense vector space and can be used for tasks like clustering or semantic search. Similarly, telugu-sentence-bert-nli is a TeluguBERT model trained on a large dataset. MahaSBERT(marathi-sentence-similarity-sbert) is also fine-tuned on the STS dataset. Before applying these models, we have used other transformer models such as msmarco-distilbert-cos-v5, all-mpnet-base-v2, and all-MiniLM-L12-v2 for English. For evaluating Marathi, we also used pre-trained models like stsb-xlm-r-multilingual , marathi-roberta, and marathi-sentence-bert-nli. Similarly, we have fine-tuned transformer models like LaBSE and telugu-sentence-similarity-sbert for Tamil. Finally, for Spanish, we also used roberta-bne-sentiment-analysis-es and stsb-xlm-r-multilingual. We called all these models from `Huggingface`[1] sentence transformers library. All models were trained on the task datasets. MahaSBERT and TeluguBERT usually perform well for low-resource languages. Dataloader was used from a torch to prepare the data before passing it to the model. We

[1]https://huggingface.co/sentence-transformers

followed a similar approach to train the corresponding transformer model for all languages. Table 3 demonstrates the hyperparameters used to train transformer-based models.

Models	LR	WD	WS
all-Minilm-L6-v2	9e-5	9e-2	750
all-Minilm-L12-v2	9e-5	9e-2	750
marathi–sbert	9e-5	5e-2	500
telugu–bert-nli	9.5e-5	5e-5	750
bert-base-spanish	9e-5	9.5e-7	700

Table 3: Tuned hyperparameter for the transformer-based models, where LR, WD, and WS denotes learning rate, weight decay and warmup steps, respectively

5 Experiments

During the development, this study utilized Python 3 (3.10.12) and Python-based packages from `PyTorch`[2] framework to implement sentence transformers (MiniLM-L6, MarathiSBERT, TeluguSBERT, SpanishSBERT). To implement the models, 29GB of RAM, 16GB of VRAM, and 73.1GB of storage space were used. We utilized NVIDIA Tesla P100 GPU from `Kaggle`[3]. We used pandas (2.1.4) and numpy (1.24.3) to analyze and prepare the data. The ML models were developed with the scikit-learn (1.2.2) packages, and the DL models were trained with Keras (2.13.1) and TensorFlow (2.13.0). The PyTorch (2.0.0) packages, transformers (4.36.2), and sentence transformers (2,6,1) were used to implement transformer models.

The superiority of the models is determined based on the Spearman rank correlation coefficient (ρ) (Sennrich et al., 2015), which measures how well the system predicted rankings of test instances. This work also measures the Kendall correlation (τ) and Pearson correlation (R).

6 Results and Analysis

Table 4 exhibits the evaluation results of ML, DL, and transformer-based models for four languages: English, Marathi, Telegu, and Spanish.

The results demonstrate that the ML models perform poorly. DL models are slightly better, but they need to be better. Transformer-based models demonstrated exceptional performance across all languages. For the English language, Mpnet-v2, Distilbert, and MiniLM-L12 scored 0.821, 0.821, and 0.815, respectively. The top-performing model for English was MiniLM-L6, with a maximum score of 0.822. For the Marathi language, Stsb-xlm, Marathi-BERT-nli and MarathiRoberta received scores of 0.764, 0.866, and 0.810, respectively. The MarathiSBERT model performed best, with a Spearman correlation score of 0.870. For the Telugu language, Telugu-SBERT and LaBSE had scores of 0.761 and 0.804, respectively. The best model for this language is Telugu-BERT-nli, which has a Spearman correlation rank of 0.804. For Spanish, Roberta-bne and Stsb-xlm have scores of 0.659 and 0.677, respectively, but Spanish-BERT outperforms both by 0.677. Figure 3 illustrates the summary of the best-performed models in four languages of the task.

Transformer-based outperformed other models

Language	Models	ρ	τ	R
English	SVR	0.161	0.105	0.181
	RF	0.177	0.115	0.153
	Bagging + RF	0.178	0.114	0.156
	SNN	0.418	0.284	0.473
	MiniLM-L12	0.815	0.614	0.821
	Mpnet-v2	0.821	0.620	0.832
	Distilbert	0.821	0.619	0.829
	MiniLM-L6	**0.822**	0.620	0.832
Marathi	Stsb-xlm	0.764	0.566	0.779
	Marathi-Roberta	0.810	0.619	0.810
	Marathi-BERT-nli	0.866	0.684	0.866
	Marathi-SBERT	**0.870**	0.688	0.875
Telegu	Telugu-SBERT	0.761	0.567	0.795
	LaBSE	0.804	0.608	0.814
	Telugu-BERT-nli	**0.820**	0.617	0.827
Spanish	Roberta-bne	0.659	0.479	0.713
	Stsb-xlm	0.655	0.473	0.707
	Spanish-BERT	**0.677**	0.503	0.719

Table 4: Performance of the employed models on the test set

[3]https://www.kaggle.com/

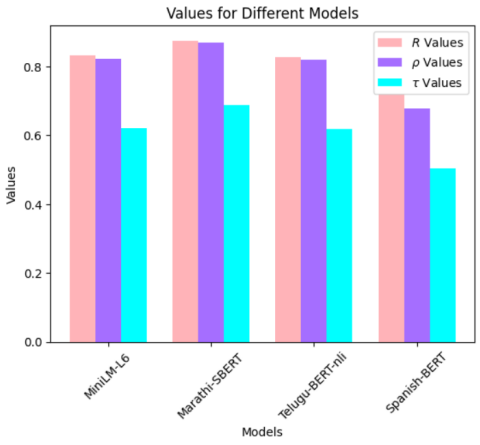

Figure 3: Performance summary of the best model in each task language

by a wide margin for four languages in the task. One explanation is its ability to capture information's bidirectional context. In addition, it produces contextual word representations that make polysemy understandable and enables capturing minute variations in meaning depending on context. Since these transformer-based model has been pre-trained on various linguistic tasks using a sizable dataset, fine-tuning these models improves results.

6.1 Error Analysis

Transformer models can recognize sentence patterns more apparently with better textual features. Thus, these models outperformed ML and DL techniques. Figure 4 depicts some example scores (actual and predicted) regarding two sentences in task languages.

Based on annotations using Best-Worst Scaling, actual scores were computed by deducting the number of times a phrase pair was selected as the least related from the fraction of times it was selected as the most related. The predicted and actual scores are incredibly close in samples 1, 2, and 4. However, the predicted score is more significant for sample 3. This may happen when a sentence is shorter than the longer sentence and contains similar terms. In this case, the model has a more challenging time figuring out the Spearman correlation between these two uneven-length sentences.

7 Conclusion

This study explores the efficacy of various machine learning (ML), deep learning (DL), and transformer-based models for analyzing semantic relatedness within texts across four languages: English, Spanish, Telugu, and Marathi. Experimental assessments reveal subpar performance of both ML and DL models across all languages. However, transformer-based models exhibit superior capabilities in discerning semantic relatedness within the given task. Specifically, the MiniLM-L6 model excels for English, MarathiSBERT for Marathi, TeluguSBERT for Telugu, and SpanishSBERT for Spanish, achieving peak ρ scores of 0.822, 0.870, 0.820, and 0.677, respectively. The study suggests that augmenting training data could enhance the performance of current models. Additionally, leveraging advanced techniques such as Large Language Models (LLM) and Generative Pre-trained Transformers (GPT) holds promise for further improvement.

Sentence #1	Sentence #2	AS	PS
Egypt's Brotherhood stands ground after killings	Egypt: Muslim Brotherhood Stands Behind Morsi	0.7	0.69

IASBS at SemEval-2024 Task 10: Delving into Emotion Discovery and Reasoning in Code-Mixed Conversations

Mehrzad Tareh and **Aydin Mohandesi** and **Ebrahim Ansari**
Institute for Advanced Studies in Basic Sciences (IASBS)
{m.tareh, mohandesi, ansari}@iasbs.ac.ir

Abstract

In this study, we introduce the SemEval 2024 Task 10, entitled "Emotion Discovery and Reasoning its Flip in Conversation (EDiReF)". Our research presents a comprehensive framework aimed at analyzing emotional dynamics within both Hindi-English mixed-language and English conversations. We extend beyond traditional emotion identification to uncover the triggers behind shifts in emotional states using advanced Natural Language Processing (NLP) techniques. Employing a systematic methodology that encompasses data preprocessing, feature engineering, and the deployment of language models such as GPT-4 and DistilBERT, we unravel the complex interplay of emotions in communication. Our approach yields significant insights, enhancing applications from social media analytics to mental health, thus marking a notable advancement in the integration of emotional intelligence into AI. Noteworthy is our system's achievement of third place on the leaderboard, demonstrating robust performance with a weighted F1-Score of 0.70. This study not only contributes to the field of emotional AI but also paves the way for future research on the nuanced understanding of emotion in mixed-language communications.

1 Introduction

In the age of global digital communication, the English language, with its pervasive influence, has led to a notable increase in bilingual or code-mixed conversations, especially on various social media and messaging platforms. Among these, Hindi-English code-mixing, or "Hinglish", has emerged as a prominent linguistic phenomenon in the Indian subcontinent, embodying the cultural and linguistic interplay of an increasingly globalized society. Despite the widespread occurrence of code-mixed communication, a gap remains in the research landscape, particularly in understanding the emotional dynamics of such interactions (Ramalingam et al., 2023; Attri et al., 2020). Studies in NLP are progressively delving into the significance of emotions in human dialogues, offering promising applications across various domains including human-computer interaction (Kulkarni and Varade, 2023), social media scrutiny (Sharma et al., 2020), and healthcare (Takale, 2024). The EDiReF plays a significant role in this area by scrutinizing emotional expression and shifts in both bilingual (Hindi-English) and monolingual (English) conversations.

Emotion recognition, a facet of affective computing, endeavors to decipher human emotions utilizing diverse technological means. Its potential implications reach far beyond traditional industries, spanning fields as diverse as transportation, finance, and entertainment, promising to revolutionize the way we interact with technology in our daily lives (Guo et al., 2024). Yet, conventional methodologies predominantly focus on analyzing monolingual, single-sentence data, while the EDiReF initiative broadens this horizon to encompass mixed-language dialogues and shifts in emotion within conversations. This acknowledgment of the intricate nature of emotional expression within diverse linguistic and cultural frameworks sets EDiReF apart.

The EDiReF (Kumar et al., 2024a) initiative consolidates three distinct subtasks: Emotion Recognition in Conversation (ERC) in Hindi-English code-mixed conversations (Kumar et al., 2023), Emotion Flip Reasoning (EFR) in Hindi-English code-mixed conversations, and EFR in English conversations (Kumar et al., 2022; Kumar et al., 2024b). Each subtask presents its own set of challenges in comprehending and interpreting emotions within conversational contexts. In the ERC subtask, we were tasked with assigning emotion labels to each utterance within a dialogue, drawing from a predefined spectrum of emotions. This demands algorithms capable of discerning and distinguishing subtle emotional cues embedded within mixed-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1229–1238

language exchanges, thereby facilitating a deeper comprehension of emotional dynamics in bilingual interactions.

The EDiReF shared task serves as a crucial avenue for researchers to delve into innovative methodologies, exchange insights, and benchmark their models using real-world conversational data. This initiative contributes significantly to the overarching objective of advancing affective computing and deepening our comprehension of human emotions within natural language interactions.

2 Related Work

The exploration of emotion in human dialogue, especially within the realm of code-mixed conversations, represents a burgeoning field of study that intersects with computational linguistics, affective computing, and cross-cultural communication. This section reviews seminal works and recent advancements that set the stage for our investigation into EDiReF.

Emotion recognition, an integral part of the expanding domain of affective computing, endeavors to decipher and interpret human emotions through technological means. This interdisciplinary field amalgamates aspects of computer science, psychology, and neuroscience to forge innovative devices capable of recognizing, understanding, and reacting to human emotional states (Montag and Davis, 2020). Such advancements hold the potential to significantly transform human-computer interactions, promising to enhance user experiences across various sectors such as retail, finance, and entertainment, thereby enabling personalized and intuitive interactions (Matin and Valles, 2020).

Historically, the focus has predominantly been on monolingual, single-sentence analyses; however, the EDiReF task expands this horizon by exploring mixed-language dialogues and the dynamics of emotion flips within conversations. This forward-looking approach acknowledges the intricacies of communication, emphasizing the significance of context, cultural differences, and linguistic diversity in the accurate interpretation of emotions. By incorporating mixed-language data, the task addresses the growing occurrence of bilingual conversations in global communications, aiming to develop more inclusive and precise emotion detection algorithms that reflect the true complexity of human interactions (Muhammadiyeva, 2022).

The availability and quality of annotated datasets for training and evaluation emerge as significant hurdles, especially for less represented languages. The quest for consistency in annotations across languages and emotions further adds to the complexity (Garg, 2020). Furthermore, the requirement for effective cross-lingual representation learning highlights the need for models to accurately capture language-specific features and emotions, necessitating sophisticated approaches in transfer learning (Ranaldi and Pucci, 2023). Additionally, identifying trigger utterances for emotion flips introduces another layer of complexity, requiring a nuanced understanding of dialogue dynamics and contextual cues (Kumar et al., 2024c). The scalability and generalization of models across different conversational contexts, languages, and domains remain formidable challenges.

In summary, while existing research provides valuable insights into emotion recognition and code-mixing, there remains a notable paucity of studies specifically addressing the dynamics of emotion in code-mixed conversations. Our work seeks to fill this gap, leveraging state-of-the-art NLP techniques to analyze emotional content and reasoning in Hindi-English mixed-language dialogues. By doing so, we contribute to the broader discourse on advancing affective computing in multilingual and multicultural contexts.

3 Task Description

This task comprises three subtasks, each addressing distinct aspects of emotional understanding and analysis in dialogues.

3.1 Emotion Recognition in Conversations (ERC)

Emotion Recognition in Conversations stands at the forefront of computational linguistics and artificial intelligence, employing advanced algorithms and methodologies to decipher emotional nuances within textual exchanges. By meticulously collecting and preprocessing data, ERC systems utilize machine learning models to classify emotional states expressed in conversations, ranging from joy to sadness and anger to fear (Dessai and Virani, 2022). Such advancements hold transformative potential across diverse sectors, from revolutionizing customer service interactions to enhancing mental health support through an early intervention based on text analysis. The applications of ERC extend beyond sentiment analysis, playing pivotal

roles in education, market research, and human-computer interaction (Loveland, 2011). Moreover, ERC serves as a potent tool for market research, enabling companies to gauge public sentiment towards products or brands by analyzing social media conversations and consumer reviews (Razouk et al., 2023).

Emotion	Proportion(%)
Neutral	45.4
Joy	19.0
Anger	9.4
Sadness	7.3
Fear	6.3
Contempt	6.1
Surprise	4.9
Disgust	1.4

Table 1: Distribution of emotions in dataset for ERC

Despite the immense potential of ERC, ethical considerations regarding privacy, biases in emotion detection algorithms, and responsible data handling are paramount. However, as ERC continues to evolve, particularly in navigating the complexities of Hindi-English code-mixed conversations, it offers promise in bridging cultural divides and enabling more nuanced sentiment analysis in multicultural settings. Nevertheless, addressing ethical concerns through responsible research and implementation is crucial to fostering a more inclusive and empathetic digital landscape (Bagora et al., 2022; Sitaram et al., 2015).

3.2 Emotion Flip Reasoning (EFR)

Dataset	0.0(%)	1.0(%)
Subtask 2	93.5	6.5
Subtask 3	84.7	15.3

Table 2: Distribution of triggers in dataset for EFR

3.3 Code-mixing in Conversations

Code-mixing in conversations occurs when speakers blend elements from two or more languages within the same discourse. This phenomenon is prevalent in multilingual communities where individuals are fluent in multiple languages and switch between them based on social context, familiarity, or communicative needs. In such conversations, speakers may switch between languages mid-sentence or incorporate phrases, expressions, or even entire sentences from one language into another. Code-mixing adds richness and depth to communication, allowing speakers to draw from a wider linguistic repertoire to express their thoughts and convey nuances that may not be readily available in a single language. Hindi-English code-mixing, commonly known as Hinglish, is a prominent example of code-mixing in conversations, especially in regions with significant bilingual populations like India (Kodali et al., 2022). In Hinglish conversations, speakers seamlessly integrate Hindi and English elements, creating a unique linguistic fusion that reflects the cultural and linguistic diversity of the Indian subcontinent. Hinglish code-mixing serves as a linguistic bridge, allowing speakers to navigate between their cultural identities and accommodate the diverse linguistic backgrounds of their interlocutors (Jawahar et al., 2021).

The use of code-mixing, whether in general conversations or specifically in Hinglish, serves several communicative functions. Firstly, it facilitates smoother communication by allowing speakers to express themselves using the most appropriate linguistic resources available to them. Additionally, code-mixing can convey social and cultural affiliations, signaling aspects of the speaker's identity such as ethnicity, education level, or social status. Moreover, code-mixing can serve pragmatic functions, such as clarifying meanings, emphasizing certain points, or creating humorous effects (Vogh, 2022).

3.4 Hindi-English Code-mixed Conversations

Code-mixed conversations, blending Hindi and English, are a common phenomenon in bilingual societies like India. This linguistic fusion reflects the cultural and social dynamics of the populace. In everyday interactions, individuals effortlessly switch between the two languages, often using Hindi for informal contexts and English for formal or technical discussions. These fluid exchanges showcase the flexibility and richness of language usage in diverse settings (Yadav et al., 2020; Mukherjee, 2019).

Code-mixing isn't just about linguistic versatility; it's also deeply ingrained in identity expression. By integrating Hindi and English, speakers navigate their cultural affiliations and social environments. This blending of languages is not only a means of communication but also a reflection of one's hybrid cultural identity (Attri et al., 2020). Furthermore, code-mixed conversations play a cru-

cial role in digital communication, especially on social media platforms and messaging apps. In the virtual realm, users often employ a mix of Hindi and English to cater to a wider audience while maintaining a sense of familiarity and belonging. This phenomenon has led to the emergence of unique online subcultures and linguistic trends. In essence, code-mixed conversations not only bridge linguistic divides but also serve as a vibrant expression of cultural fusion in a globalized world (Dabrowska, 2019).

Task	Hindi(%)	English(%)
Subtask 1	59.8	40.2
Subtask 2	39.8	60.2
Subtask 3	17.7	82.3

Table 3: Hindi vs English proportions in dataset

4 Dataset Description

The organizers have supplied and divided the datasets for participants into train, development, and test sets. The table 4 provided contains details regarding the number of instances used for training, development, and testing.

Dataset	Train	Dev	Test
Subtask 1	8,506	1,354	1,580
Subtask 2	98,777	7,462	7,690
Subtask 3	35,000	3,522	8,642

Table 4: Summary of dataset split

4.1 Introduction to MaSac Dataset

The MaSaC dataset is a carefully curated collection designed to investigate code-mixed dialogue interactions in the Indian context, drawing from the popular television series "Sarabhai v/s Sarabhai." This dataset captures the authentic dynamics of conversations in a multi-party, multimodal setting, predominantly featuring a blend of Hindi and English languages. With over 11,000 utterances dedicated to task 1 and 114,000 to task 2, it provides researchers with a rich corpus to explore various aspects of language usage and communication dynamics. Each utterance in a dialogue has been labeled by any of these eight emotions: Anger, Disgust, Sadness, Joy, Neutral, Surprise, Fear, and Contempt. Its multimodal nature, incorporating textual, auditory, and visual elements from the television show, offers a comprehensive view of dialogue interactions, while its labeling of emotions for each utterance enriches understanding of the emotional nuances within the conversations (Kumar et al., 2023).

Furthermore, the MaSaC dataset holds significant promise for diverse research endeavors. In the realm of natural language understanding, it facilitates the development and evaluation of models capable of comprehending and generating code-mixed utterances, thereby enhancing language processing capabilities in multilingual environments. Additionally, computational linguistics, enables investigations into code-switching phenomena and sociolinguistic variations, shedding light on language usage patterns and communicative strategies. Beyond academia, the dataset's exploration of socio-cultural aspects embedded within language interactions offers valuable insights for sociolinguists and cultural researchers, fostering a deeper understanding of identity expression, social dynamics, and cultural nuances depicted in televised narratives (Chakraborty, 2021).

4.2 Introduction to MELD Dataset

The Multimodal Emotion Lines Dataset (MELD) stands out as a pivotal resource for researchers delving into the intricate realm of emotion recognition, particularly within the context of multiparty conversations. Comprising over 47,000 utterances extracted from the beloved television series Friends, MELD is an extension and enhancement of EmotionLines (Chen et al., 2018), and presents an extensive collection of genuine exchanges, showcasing diverse interactions among numerous speakers engaged in dynamic dialogues. Unlike its predecessor, MELD adopts a multimodal approach by incorporating textual transcripts.

However, it is crucial to note that the dataset provided by the organizers did not include audio-visual cues, focusing instead on the textual aspect to understand emotional communication. Each conversation in the dataset is carefully annotated, presenting detailed labels for emotions expressed, making it a valuable resource for supervised learning techniques. The dataset labels each utterance with one of seven emotions: Anger, Disgust, Sadness, Joy, Neutral, Surprise, and Fear, aiming to capture the full spectrum of emotional dynamics in conversation (Kumar et al., 2024c; Kumar, 2023).

5 Experimental Setup

This section outlines the various aspects of the experimental setup, including dataset preparation, evaluation metrics, baseline systems, and training methodologies.

5.1 JSON Parsing

In our exploration of this task, we encounter datasets structured in JSON format, encapsulating dialogues among multiple speakers annotated with emotions and triggers. To effectively manage this data, we employ a detailed parsing process. Initially, we load the JSON data into memory, followed by iterative processing of each dialogue entry. We extract pertinent details such as episode ID, speaker ID, emotion label, trigger label, and utterance text, organizing them into a structured DataFrame format. Additionally, to ensure each entry's unique identification, we generate non-negative integer IDs for each dialogue instance, facilitating seamless referencing during subsequent data analysis and model development stages.

By effectively extracting essential information and generating unique IDs for dataset entries, we can navigate through the data with ease, enabling profound understanding and fostering advancements in emotion recognition and reasoning within code-mixed and multi-party conversation dialogues.

5.2 Dataset Preprocessing

We meticulously executed preprocessing steps on the dataset to guarantee uniformity of data and streamline subsequent analysis and model development. Initially organized by task organizers (refer to table 4), the dataset underwent thorough text normalization techniques including lowercase conversion and removal of redundant characters and excessive punctuation to enhance readability and consistency. Subsequent tokenization segmented the text for deeper analysis, followed by language-specific procedures such as stopword removal, lemmatization, and stemming to refine textual content. Language identification techniques were also employed to differentiate between Hindi and English segments, allowing for targeted preprocessing steps. Our collaborative efforts standardized and formatted the dataset in alignment with the prescribed framework of the shared task, laying a robust foundation for effective participation and further analysis.

5.2.1 Dataset Cleaning and Standardization

- Addressed data integrity by handling less than 5 samples with invalid values, assigning the most common value within the dataset to maintain consistency.
- Standardized speakers' names to ensure uniformity by resolving discrepancies like varying capitalization.
- Enhanced dataset structure by assigning non-negative IDs to episodes and speakers, enabling more efficient data processing.
- In the EFR task, focused solely on triggers with a value of 0.0, resulting in an emotional inversion where the trigger value shifted to 1.0.

5.3 Dataset Translation

Initially, while relying on Google Translate, our comprehensive manual verification process unveiled discrepancies and inaccuracies, compelling us to explore alternatives of greater reliability and precision. In this context, GPT-4 (OpenAI, 2022) emerged as a pivotal tool, distinguished for its contextual comprehension and translation proficiency. Our translation methodology was meticulously crafted to prioritize fidelity to the original dialogues, thereby ensuring the preservation of nuanced semantic and syntactic elements across linguistic boundaries. By harnessing the capabilities of GPT-4 in conjunction with supplementary support from Google Translate, we embarked on a systematic translation endeavor aimed at capturing the inherent complexity and subtlety of the conversations. The outcomes were noteworthy, as GPT-4 consistently exceeded expectations, exhibiting an exceptional aptitude for encapsulating the intricate nuances of emotional expression and linguistic subtleties. Armed with these carefully refined translations, we deftly integrated them into the final English datasets, confident in their accuracy and faithfulness to the original discourse. This meticulous approach not only ensured linguistic coherence but also paid homage to the rich cultural nuances embedded within the conversations (Nakayama et al., 2019).

5.3.1 Dataset Normalization

Hindi-English code-mixed conversations posed a significant challenge, especially with restrictions on available tools due to sanctions. Our initial

attempts with a robot browser yielded unsatisfactory results, prompting us to leverage the GPT-4 API in conjunction with the spaCy. This combination significantly outperformed traditional translation services, like Google Translate, in accuracy. Post-translation, we employed a pre-trained model (Kunchukuttan, 2020) to normalize utterances to standard Hindi/Romani, followed by tokenization and analysis with Morph to adapt the analyzed form.

5.3.2 Feature Engineering

For sentiment analysis, we utilized the INT8 DistilBERT model (He and Wenz, 2022) through the Cloudflare API, streamlining the process to calculate positive and negative scores for each utterance. A novel feature introduced was the calculation of polarity differences between consecutive utterances within an episode, aiding in the detection of emotion flips.

5.4 Dataset Polarity

In the Dataset Polarity section, we present the essential analysis conducted on the provided dataset. Here, we outline the methodology we employed to evaluate the polarity of utterances within the dataset. Utilizing cutting-edge natural language processing technology, specifically DistilBERT from Intel, we undertook the task of calculating polarity scores for each utterance.

Polarity scores serve as a quantitative measure of the sentiment conveyed within individual utterances. Our approach involved leveraging DistilBERT's pre-trained language understanding capabilities to discern the underlying sentiment expressed in the text. By employing this state-of-the-art model, we aimed to capture subtle emotional undertones present in the conversations, particularly in the context of Hinglish dialogues. Furthermore, to enhance our understanding of the dataset, we computed the difference in polarity scores between utterances. This differential analysis provides insights into the shifts in sentiment within conversations, a crucial aspect for tasks such as ERC and EFR. By discerning fluctuations in sentiment, we gain valuable information for identifying trigger utterances for emotion flips in multi-party dialogues.

The integration of DistilBERT from Intel in our polarity analysis underscores our commitment to leveraging state-of-the-art techniques for robust sentiment analysis. Through this punctilious approach, we aim to provide a comprehensive understanding of the emotional dynamics inherent in the dataset, thereby facilitating advancements in emotion recognition and reasoning tasks within code-mixed conversations.

6 Methodology

To explore the intricacies of ERC and EFR within Hindi-English code-mixed conversations, as well as EFR in English conversations, our methodology integrates a blend of traditional machine learning models with the cutting-edge capabilities of transformer-based architectures.

At the outset, we harness the advanced linguistic comprehension of GPT-4, a state-of-the-art language model, to ascertain the emotions embedded in each utterance of the dialogue. The prowess of GPT-4 lies in its nuanced grasp of context and the subtleties of natural language, rendering it highly effective for the preliminary prediction of emotions within conversations. Subsequently, we employ a spectrum of classical machine learning techniques, including Random Forest, Support Vector Machines (SVM), Logistic Regression, and Naive Bayes classifiers. These algorithms are foundational to the field of natural language processing and serve as a benchmark for evaluating the advanced methodologies employed later. This hybrid modeling approach aims to capitalize on the depth and context-awareness provided by transformer-based models, like GPT-4, while also valuing the interpretability and established nature of classical machine learning techniques. By leveraging this diverse array of models, our objective is to harness the strengths of both modern and traditional approaches to optimize performance across the ERC and EFR tasks in conversations conducted in both Hinglish and English.

For the task of Emotion Recognition in Conversation, we adopt the weighted F1-score as our primary evaluation metric (see Table 7 and 8). This metric is chosen for its ability to provide a balanced measure of the model's precision and recall, while also accounting for class imbalances that are common in real-world datasets. This nuanced evaluation allows us to assess the model's ability to accurately recognize emotions across a diverse set of conversations. In the case of Emotion Flip Reasoning, our focus shifts toward precision as the primary evaluation metric (see table 6). Precision is particularly relevant for EFR tasks as it measures the model's accuracy in identifying the specific in-

stances where an emotional flip occurs within the conversation. This metric enables us to refine the model's performance in pinpointing these critical junctures, thereby ensuring high reliability in the model's reasoning capabilities.

By employing this diverse range of models, we aimed to leverage both the sophistication of transformer-based architectures and the interpretability of classical machine learning algorithms. This hybrid approach allowed us to explore different facets of the data and optimize performance across the ERC and EFR tasks in both Hinglish and English conversations.

7 Results and Discussions

In our study, we present a comprehensive analysis of our findings, which is predicated on our noteworthy accomplishment of securing the third position on the Codalab leaderboard among forty participants.

Team	Subtask 1	Subtask 2	Subtask 3
MasonTigers	0.78	0.79	0.79
Knowdee	0.73	0.66	0.61
IASBS	**0.70**	**0.12**	**0.25**

Table 5: Top four participants' scores on CodaLab

This achievement underscores the efficacy of our comprehensive framework, which integrates advanced language models like GPT-4 and DistilBERT, alongside sophisticated data preprocessing and feature engineering techniques, to explore the nuanced interplay of emotions in conversations.

In our investigation, the evaluation of various classification models across the three subtasks of emotion recognition and reasoning exhibited distinct performance characteristics, as detailed in Tables 6, 7 and 8. For ERC, the models demonstrated a competitive range of F1-scores, with GaussianNB slightly outperforming others in terms of precision and recall, reflecting a balanced capacity for emotion classification within dialogues. The nuanced demands of EFR in both Hinglish and English conversations required precision as a critical metric due to the importance of accurately identifying emotional shifts. In this context, the SVM model showed notable efficacy, particularly in English conversations, as it achieved a precision of 0.79, indicating a strong ability to discern the nuanced triggers of emotion flips. Further analysis in Table 7 revealed that for EFR within Hinglish code-mixed conversations, the Logistic Regression model surfaced as a frontrunner, achieving a precision of 0.74, underscoring its capability to handle the intricacies of code-switching and the emotional dynamics inherent in bilingual discourse.

Meanwhile, Table 8 underscores the adaptability of machine learning models to the linguistic complexity and emotional subtleties in English conversations, with the Random Forest model marking a precision of 0.81, reflecting its robustness in parsing and understanding the nuanced indicators of emotional transitions.

precision of these models, especially within the intricate landscape of multilingual and multicultural communication.

8 Conclusion

Our study delves into how language and culture intertwine with emotional dynamics in bilingual conversations, revealing new insights through an examination of Emotion Recognition in Conversations and Emotion Flip Reasoning. It highlights the need for computational models to accurately interpret emotional nuances across different cultures and languages, advocating for interdisciplinary efforts to enhance AI's empathy and cultural awareness. The research aims to improve global understanding and connectivity, contributing to better human-computer interaction and societal unity. Future directions include expanding the research to more languages and cultures, integrating sociolinguistic and anthropological insights into computational models, and exploring the role of multimodal communication in emotion recognition to develop more sophisticated AI systems.

9 Future Work

Moving forward, our research trajectory entails several promising avenues for exploration. Firstly, we aim to broaden our linguistic and cultural scope by expanding our investigations to encompass a more extensive array of languages and cultural backgrounds. Additionally, we seek to enrich our computational models by integrating insights from fields such as sociolinguistics and anthropology, thereby fostering a more nuanced understanding of emotional expression within diverse societal frameworks. Moreover, we endeavor to delve into the realm of multimodal communication to unravel the intricate interplay between verbal and nonverbal cues in emotion recognition. By embracing these future directions, we aspire to cultivate more sophisticated AI systems capable of seamlessly navigating the intricate tapestry of human emotion across diverse cultural landscapes.

riyad.omf@gmail.com

Abstract

This research systematically forms an impression of the capabilities of advanced language models in addressing the BRAINTEASER task introduced at SemEval 2024, which is specifically designed to explore the models' proficiency in lateral commonsense reasoning. The task sets forth an array of Sentence and Word Puzzles, carefully crafted to challenge the models with scenarios requiring unconventional thought processes. Our methodology encompasses a holistic approach, incorporating preprocessing of data, fine-tuning of transformer-based language models, and strategic data augmentation to explore the depth and flexibility of each model's understanding. The preliminary results of our analysis are encouraging, highlighting significant potential for advancements in the models' ability to engage in lateral reasoning. Further insights gained from post-competition evaluations suggest scopes for notable enhancements in model performance, emphasizing the continuous evolution of the models in mastering complex reasoning tasks.

1 Introduction

The reasoning ability of the human brain demonstrates a dualistic problem-solving approach, which integrates both vertical and lateral methodologies (Bala, 2014). Vertical thinking places emphasis on a methodical and logical examination, executed in a sequential fashion, guided by established norms and regulations. On the contrary, lateral thinking (De Bono, 1970) promotes innovation and fosters the ability to perceive challenges from distinct, frequently unusual observation points, thereby encouraging individuals to go beyond conventional limitations.

Over the past few years, significant progress has been made in the booming domain of Natural Language Processing (NLP), as novel technologies aim to mimic the the complicated ways in which human think (Kumar et al., 2023; Koivisto and Grassini, 2023). This undertaking overcomes conventional logical reasoning and dives into the domain of creative cognition, wherein machines are engineered to creatively navigate and interpret the complex nature of human language and thought processes. Out of these efforts, the BRAINTEASER task is particularly noteworthy for its pioneering aspect (Jiang et al., 2023). The challenge, which is part of the SemEval 2024, has been carefully constructed to evaluate a model's capacity for lateral thinking and its aptitude for questioning and redefining conventional commonplace assumptions.

BRAINTEASER (Jiang et al., 2024) takes a significant progress in the direction of bridging the divide that exists between the cognitive flexibility of humans and that of machines (Boyacı et al., 2023), exceeding the bounds of study. By selecting puzzles that require perception at both the sentence and word levels, this task highlights the significant technological advancement towards machines capable of creative thinking and logical conclusions that beat the apparent. The task encourages participants overcome the limitations of natural language processing (NLP) models by evaluating their capacity to interpret and decode language in a manner that emulates the creative reasoning of humans. Motivated by the unique characteristics of the assignment and the potential it provides to advance the domain of NLP technology, our group wholeheartedly accepted the challenge presented by BRAINTEASER. Our approach was experimental, leveraging a variety of transformer models to explore their capacity for creative and lateral thinking (Hashim et al., 2023). These models, known for their effectiveness (Nassiri and Akhloufi, 2023) in understanding and generating human language, were put to the test to see if they could indeed mimic the thought processes traditionally attributed to humans. We ranked at 20th in each of the subtasks and in average the rank was 31. The experience was rich with learning opportunities, offering

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1239–1244

us valuable insights into the capabilities and limitations of current technologies when faced with tasks that require a departure from conventional reasoning.

2 Task and Data Description

The task (Jiang et al., 2024) is making a system which is evaluated on understanding sentences and words in ways that defy usual expectations. It has two main challenges:

- Sentence Puzzle: the system must interpret sentences in unexpected ways.
- Word Puzzle: the system need to find unconventional meanings of words.

The task employs specific tests to make sure the system analyzes information deeply instead of merely remembering answers. These tests involve altering the phrasing or setting of questions without changing the basic problem, known as semantic and context reconstruction. The systems are evaluated based on two primary factors: their ability to address single questions, referred to as instance-based performance, and their consistency in answering groups of related questions, known as group-based performance. The goal of this task is to advance the system's abilities in problem-solving and creative thinking

The dataset (Jiang et al., 2023) provided for the task includes two distinct types of files, one for sentence puzzles and another for word puzzles. Each file is rich with essential elements such as the posed question, the correct answer, three alternative options (distractors), labels, a list of choices, and the sequence in which these choices are presented. During the training phase, the dataset comprises 507 sentence puzzles and 396 word puzzles, demonstrating a comprehensive range of scenarios for model training. For the testing phase, the dataset narrows down to 120 sentence puzzles and 96 word puzzles, aimed at rigorously evaluating the models' understanding and reasoning capabilities in both puzzle types

3 System Description

3.1 Data Pre-processing

Our data pre-processing for the BRAINTEASER task involved meticulous steps to prepare the dataset for effective model training. Starting with the loading and merging of two numpy arrays—'SP-train.npy' for sentence puzzles and 'WP-train.npy' for word puzzles—we created a unified dataset comprising a diverse range of puzzles. Recognizing the importance of an unbiased dataset for model training, we employed a two-step randomization process. Initially, we randomized the order of the combined dataset. Subsequently, after converting the dataset into a pandas DataFrame, we applied an additional shuffle to guarantee thorough randomness. Given the difficulties of the puzzles, converting them into a binary classification format presented unique challenges. Each puzzle was transformed into a series of question-choice pairs labeled as correct or incorrect. This binary labeling was crucial for training our models to detect the subtle differences between potential answers, thereby enhancing their reasoning capabilities and language understanding. This careful preparation, including a strategic split of 90% for training and 10% for validation, ensured that our models were ready for the BRAINTEASER challenge.

3.2 Data Augmentation

To enrich the dataset and enhance model robustness, we implemented several data augmentation techniques. These included synthesizing new puzzle questions by paraphrasing existing ones and introducing variations in the dataset to simulate a wider range of linguistic structures and puzzle formats. Such augmentation not only expanded the diversity of our training set but also provided our models with a broader linguistic context to learn from, thereby improving their generalization capabilities. This strategy was particularly beneficial in taking decisions to choose the best model.

3.3 Encoding for Models

In the next step, we take a streamlined approach to improve question-answering models through a custom class, integrating seamlessly with PyTorch's Dataset framework. This class, initialized with essential components like questions, answers, labels, a tokenizer, and a max token length, ensures comprehensive preparation of question answer pairs for training. We have tried to apply encoding each pair to produce a dictionary containing merged question-answer texts, input IDs, attention masks, and labels, all conforming to a specified maximum token length. This process, emphasizing special tokens, padding, and truncation, readies each pair for model training, significantly simplifying data handling. The class is instrumental in converting

raw data into a format conducive to learning, thus enhancing the models' ability to generate insightful responses.

3.4 Model Training

For this part, we considered different transformer models to experiment the performance. The models are :

- BERT (Do and Phan, 2022) (Bidirectional Encoder Representations from Transformers) revolutionized NLP by training on a massive corpus in a bidirectional manner, enabling it to grasp context from both directions, thus providing a deep understanding of language distinction.
- XLNet (Ghavidel et al., 2020) extends upon BERT by employing a permutation-based training method, which allows it to capture the bidirectional context more effectively, making it particularly adept at handling tasks requiring a nuanced understanding of language order and structure.
- BART (Lewis et al., 2020) (Bidirectional and Auto-Regressive Transformers) combines the best of both auto-encoding and auto-regressive approaches, excelling in text generation and comprehension tasks by reconstructing text that has been corrupted, making it highly suitable for complex comprehension and synthesis tasks.
- RoBERTa (Robustly Optimized BERT Approach) (Liu et al., 2019) iterates on BERT by modifying key hyperparameters, removing the next-sentence pretraining objective and training with much larger mini-batches and learning rates. This results in improved performance across a range of benchmark tasks.
- T5 (Text-to-Text Transfer Transformer) (Raffel et al., 2020) adopts a unified approach, treating every NLP problem as a text-to-text task, simplifying the process of applying a single model to a variety of tasks, thus streamlining the training and inference process for NLP models.

However, the training phase is structured to leverage the computational prowess of PyTorch, utilizing DataLoader for batch processing, and optimizing model performance with AdamW. We track correctness across epochs to gauge improvement, employing a stopping criterion based on minimal gains in validation accuracy to prevent overfitting. The process begins by selecting the appropriate tokenizer and model architecture based on predefined criteria. Each model is trained over several epochs, with performance on the validation set carefully monitored to ensure improvement. We adopted a learning rate between 2e-5 and 3e-5, training across 4 epochs with batches of 16 to balance efficiency and accuracy. Early stopping was implemented to halt training if validation accuracy showed minimal improvement, preventing overfitting. This process ensured each model, from BERT to T5, was precisely tuned to our dataset's details, focusing on meaningful performance gains.

3.5 Model Fine Tuning

Model fine-tuning was an important aspect of our approach, tailored to make use of the full potential of pre-trained language models. By carefully adjusting learning rates, batch sizes, and epochs, we ensured that each model was optimally adapted to the specifics of the task. Our fine-tuning process also involved a careful selection of layers to unfreeze, enabling the models to learn task-specific details without overfitting.

3.6 Prediction On Validation Set

At the very first phase, we divided the training data into 90:10 manner to get a validation set for the prediction. We utilized a specific class to assess the accuracy of transformer models like XLNet, BART, BERT, RoBERTa, T5 on validation dataset. This class predicts the correct answers by tokenizing question-choice pairs and evaluating them through the model to select the most probable answer. The effectiveness of each model is quantified by comparing predicted answers against actual labels, providing a direct measure of performance. This approach allows us to take decision for the next step.

3.7 Prediction On Test Set

By doing the previous step on validation dataset, we have got the performance analysis of each model and it makes us to observe which model has done best in this set. We choose the best performing model to conduct a prediction on the given test set for the competition for both sentence and word puzzle data.

Model	Before Data Merging	After Data Merging
Bert	91%	**87%**
RoBERTa	90%	82%
XLNet	93%	**85%**
BART	88%	79%
T5	76%	70%

Table 1: Performance on validation dataset

4 Result

Our research explored how different transformer models performed when tasked with solving two types of puzzles: sentence and word puzzles. Initially, we observed encouraging results from all models on the sentence puzzles, which were more abundant in our dataset. This success highlighted the models' proficiency in contexts where narrative clues guide the solution process. However, when we combined sentence and word puzzles into a single dataset, we noticed a significant drop in accuracy across all models (as shown in Table 1). This decline suggests that the models, while effective at processing longer, context-rich sentences, struggled with the brevity and ambiguity typical of word puzzles. This challenge was particularly evident in our competitive analysis phase, where the BERT model achieved 77% accuracy, and a subsequent re-evaluation with XLNet showed an improvement to 80% accuracy on the test set.

The better performance on sentence puzzles can be attributed to the models' inherent strengths. Both BERT and XLNet are designed to excel in understanding and processing complex narrative contexts, benefiting from extensive pre-training across diverse text types. This foundation enables them to navigate the intricate language of sentence puzzles more adeptly. On the other hand, word puzzles often rely on subtle wordplay and linguistic nuances less represented in the models' training data, posing a greater challenge..

The disparity in performance between puzzle types underscores a crucial insight: transformer models, despite their advanced capabilities, exhibit varying degrees of adaptability to different linguistic tasks. The initial high accuracy rates with sentence puzzles showcase their potential, while the subsequent drop in performance upon introducing word puzzles highlights areas for improvement, particularly in enhancing the models' versatility and ability to generalize across diverse language tasks. Our findings indicate a clear path forward—further refining these models to better capture and interpret the breadth of human language, extending their applicability beyond structured narrative contexts to include the nuanced, often unpredictable areas of word puzzles.

5 Limitation and Error Analysis

Our study had some challenges and places where error analysis showed that things could be done better. One big problem with the models is that they are skewed because they were trained on datasets that might not fully show how people use words in different situations. This might make it harder for the models to generalise to new types of data, especially when they move from sentence puzzles to word puzzles (see Tables 2 and 3). The models' different results on sentence puzzles versus word puzzles also points out a need for error analysis and better training strategies or model architectures that can handle the complex nature of both types of puzzles equally. The fact that accuracy went down when datasets were combined suggests overfitting, an important problem that needs more research to make models more reliable. These new ideas help us plan future research, like looking into bigger and more varied training datasets and making models that are specifically made to deal with the problems that come up in different language tasks.

6 Conclusion

Our research into using transformer models like BERT, XLNet, and BART for question-answering tasks shows both their strengths and weaknesses when trying to understand words like humans do. The results point to a potential way to improve system's ability to interpret, but they also show that more progress needs to be made. In the future, action should be put into improving these models so that they understand context better, are more clear, and can be used in more areas. To close the gap between what we can do now and how well we can understand complex human language,

Phase	S_ori	S_sem	S_con	S_ori_sem	S_sem_con	S_overall
Competition	0.77	0.70	0.77	0.70	0.62	0.75
Post-Competition	0.80	0.75	0.77	0.75	0.65	0.77

Table 2: Performance metrics across for Sentence Puzzle

Phase	S_ori	S_sem	S_con	S_ori_sem	S_sem_con	S_overall
Competition	0.37	0.46	0.37	0.34	0.12	0.40
Post-Competition	0.56	0.53	0.40	0.50	0.25	0.50

Table 3: Performance metrics across for Word Puzzle

we will need to work together to improve model designs, training methods, and the way we combine different types of data. Not only does this project look like it will make NLP applications smarter, but it also opens up new ways for Computers to process and come up with language-based responses.

FtG-CoT at SemEval-2024 Task 9: Solving Sentence Puzzles Using Fine-Tuned Language Models and Zero-Shot CoT Prompting

Micah Zhang **Shafiuddin Rehan Ahmed** **James H. Martin**
University of Colorado, Boulder, CO, USA
micah.zhang@colorado.edu

Abstract

Recent large language models (LLMs) can solve puzzles that require creativity and lateral thinking. To advance this front of research, we tackle SemEval-2024 Task 9: BRAINTEASER: A Novel Task Defying Common Sense. We approach this task by introducing a technique that we call Fine-tuned Generated Chain-of-Thought (FtG-CoT). It is a novel few-shot prompting method that combines a fine-tuned BERT classifier encoder with zero-shot chain-of-thought generation and a fine-tuned LLM. The fine-tuned BERT classifier provides a context-rich encoding of each example question and choice list. Zero-shot chain-of-thought generation leverages the benefits of chain-of-thought prompting without requiring manual creation of the reasoning chains. We fine-tune the LLM on the generated chains-of-thought and include a set of generated reasoning chains in the final few-shot LLM prompt to maximize the relevance and correctness of the final generated response. In this paper, we show that FtG-CoT outperforms the zero-shot prompting baseline presented in the task paper and is highly effective at solving challenging sentence puzzles achieving a perfect score on the practice set and a 0.9 score on the evaluation set.

1 Introduction

The BRAINTEASER SemEval-2024 Task (Jiang et al., 2023, 2024) explores the ability of large language models (LLMs) to perform lateral thinking or "thinking outside the box", a topic that is currently under-explored by the natural language processing (NLP) community. Unlike vertical thinking tasks that rely only on "common sense", solving this task requires a creative thinking process. The goal is to force LLMs to challenge their preconceptions and consider new perspectives. The task organizers propose a way to assess the ability of LLMs to think outside the box by creating a multiple-choice question-answering task designed to defy default commons-sense associations. For this task, the task organizers created a sentence puzzle dataset that contains sentence-type brain teasers centered on sentence snippets, and a word puzzle dataset that contains word-type brain teasers centered on the letter composition of the target question. Both datasets are written in English.

Our approach, Fine-tuned Generated Chain-of-Thought (FtG-CoT), as depicted in Figure 1, is a novel few-shot prompting method that combines a fine-tuned BERT classifier encoder with zero-shot chain-of-thought (CoT) generation and a fine-tuned GPT-3.5 LLM. The BERT (Devlin et al., 2019) classifier is fine-tuned by treating the training set as a multi-class classification task. Each training set question and choice list is treated as the classification example. The index corresponding to the correct answer choice is the class label. Reasoning chains for each example in the training set are generated using a variation of the classic zero-shot chain-of-thought prompt.

For each example, in addition to the question and choice list, the LLM is provided with the correct answer and asked to generate an explanation of why that is the correct answer. The generated chains of thought are then used to fine-tune the LLM. For each example in the fine-tuning dataset, the prompt contains the question and choice list, and the response contains the generated chain-of-thought. To get the final generated response, the fine-tuned LLM is queried with a few-shot prompt that contains a set of generated reasoning chains as example demonstrations.

The set of training demonstrations provided in the few-shot prompt is chosen based on their cosine similarity to the test question. Only the top 20 most similar training demonstrations are provided, ranked in order of increasing similarity. We chose to use OpenAI's GPT-3.5 Turbo model as the pre-trained LLM due to the ability to easily query and

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1245–1251

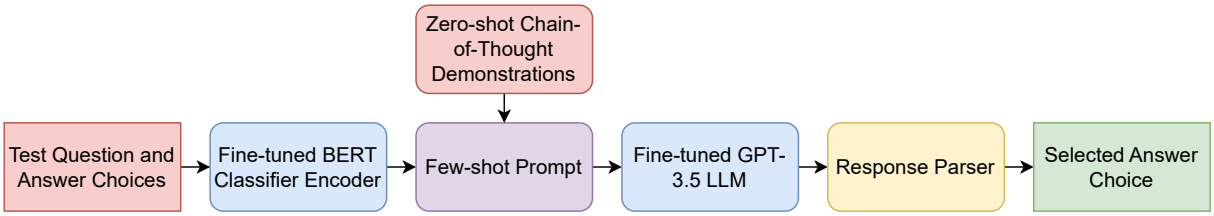

Figure 1: System diagram for FtG-CoT. To start, the test question and choice list are fed to a fine-tuned BERT classifier. The BERT classifier outputs an encoding that is used to identify the top 20 training questions that are most similar to the test question. The corresponding training demonstrations are combined in order of increasing similarity with the test question and choice list to create a few-shot prompt. The few-shot prompt is sent to a fine-tuned LLM, which outputs a generated response. A text parser matches the generated response with the most similar answer choice from the choice list.

fine-tune the model via the OpenAI API.

We provide a robust system that combines fine-tuned BERT and GPT-3.5 together with zero-shot CoT generation and ranked few-shot prompting. We found that this approach significantly improves the ability of the LLM to solve brain teaser sentence puzzles compared to the baseline zero-shot prompting approach, achieving a perfect score on the practice set and a 0.9 score on the evaluation set. Our method ranked 18th in the competition. We provide our code here: https://github.com/Micah-Zhang/SemEval-2024

2 Background

The BRAINTEASER task (Jiang et al., 2023, 2024) consists of two sub-tasks: Sentence Puzzles and Word Puzzles. Both datasets are written in English and each question is structured in a multiple-choice question format. Sentence Puzzles tend to be in a longer narrative story format. The correct answer challenges the common-sense interpretation of the question and the common-sense answer to the question. For Word Puzzles, the correct answer challenges the default meaning of a particular word and focuses on the letter composition of the question. Both types of questions provide 4 different answer choices, including 1 correct answer and 3 distractors. Figure 2 provides an example of a Sentence Puzzle and an example of a Word Puzzle for comparison.

We chose to participate in the Sentence Puzzle sub-task. For this sub-task, a training dataset consisting of 507 sentence puzzles was provided by the task organizers. The training set contained 169 original sentence puzzle examples obtained from public websites via web crawlers. Each example consisted of a question, a list of answer choices, the correct answer, and the distractors in the choice list. For each original question, a corresponding semantic reconstruction question and a context reconstruction question were generated. Semantic Reconstruction rephrases the original question without changing the correct answer and provided answer choices. Context Reconstruction changes both the question and answer to fit a new situational context, while keeping the original premise intact. The two adversarial question counterparts were created by the organizers to prevent an LLM from being able to win the competition using memorization only.

In addition to the training set, the organizers provide a practice evaluation and an official evaluation dataset for the Sentence Puzzle sub-task. Both datasets contain 120 questions. To evaluate a model, a text file containing the answer choice index for each selected answer choice is submitted to CodaLab. CodaLab then automatically calculates the corresponding accuracy scores and posts the results on the leaderboard.

Our approach is inspired by Wei et al. (2023), who introduced chain-of-thought prompting and demonstrated that providing a LLM with a series of intermediate reasoning steps improves its ability to perform complex reasoning. Our approach was also inspired by Kojima et al. (2023), who introduced zero-shot chain-of-thought prompting and demonstrated that LLMs could be made to generate their own series of intermediate reasoning steps by adding the words "Let's think step by step" to the end of the prompt. BERT (Devlin et al., 2019) is a popular transformer architecture commonly used as an sentence encoder for NLP tasks. The pre-trained BERT model can be fine-tuned by adding a classifier head to the end of the model and training it on a classification dataset. LLMs based on the GPT-3.5 architecture were popularized by Brown et al. (2020), who introduced few-shot prompting

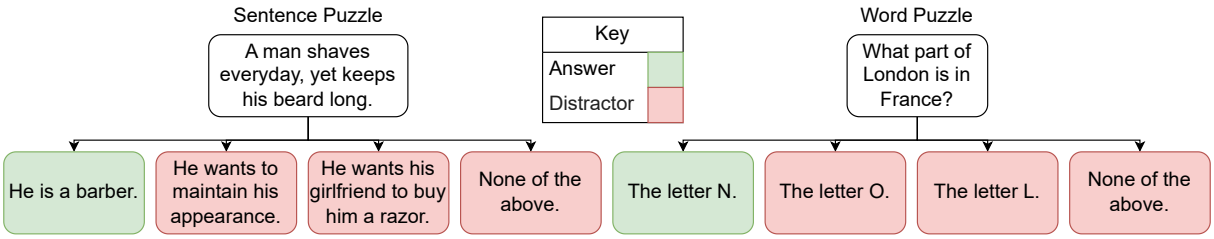

Figure 2: Diagram comparing Sentence Puzzles to Word Puzzles from the BRAINTEASER dataset. Sentence Puzzles tend to be in a longer narrative story format. The correct answer challenges the common-sense interpretation of both the question and its answer. For Word Puzzles, the correct answer challenges the default meaning of a word and focuses on the letter composition of the question.

and demonstrated that pre-trained LLMs could be made to solve new unseen tasks without needing additional training if the prompt included a set of example demonstrations.

3 System Overview

Fine-tuned Generated Chain-of-Thought Prompting (FtG-CoT) is a few-shot prompting method we developed for this competition. It consists of five steps. The first step is to fine-tune a pre-trained BERT-Small model on the training set as a multi-class classification task to use as an encoder. The second step is to use zero-shot chain-of-thought prompting (Kojima et al., 2023) to generate explanations for each demonstration in the training set. The third step is to fine-tune a large language model (LLM) on the generated chain-of-thought (Wei et al., 2023) demonstrations. The fourth step is to rank each encoded training demonstration based on its cosine similarity with the current encoded test question. The fifth step is to construct a few-shot (Brown et al., 2020) prompt by stacking the top N most similar demonstrations with the test question prompt in order of increasing similarity.

This few-shot prompt is sent to the LLM, an answer choice is extracted from the LLM's response, and the process is repeated for each question in the test set. This system is illustrated in Figure 1.

Fine-tuning BERT: We fine-tuned a pre-trained BERT model by converting it to a multi-class classifier and training it on the provided BRAINTEASER training set. This allowed us to create an encoder purpose-suited for solving sentence puzzles. During training the BERT classifier learns contextual and semantic information that is relevant to solving the sentence puzzle task. When used to encode a training or test example, this information is captured in the encoding and aids in selecting highly relevant and useful demonstrations to use for few-shot prompting.

Zero-shot prompting: Zero-shot prompting is used to generate chain-of-thought reasoning explanations for each training example. This is accomplished by prompting the LLM using a custom zero-shot prompt for each training example. The first three lines of the prompt contain the training question, answer choices, and correct answers. The fourth line is "Let's think step by step. What is the best answer? Explain in detail why this is the best answer in 5 or less sentences".

A custom fuzzy logic answer extractor parses the generated response from the LLM by isolating the sentence containing the selected answer and then using a sequence matcher to compare the generated answer against each of the answer choices in the choice list. The index of the answer choice that most closely matches the generated answer is set as the predicted label.

Fine-tuning GPT-3.5: Fine-tuning a pre-trained GPT-3.5 model on the 507 training examples and their corresponding generated reasoning chains improves the accuracy and consistency of the answers generated by the LLM. The fine-tuning dataset contains an example prompt and response for each training question. The first two lines of the prompt contain the question and answer choices. The third line is "Let's think step by step. What is the best answer?". The ground truth response is the generated response from the previous zero-shot prompting step.

Ranking Demonstrations: Cosine similarity is defined as $cos(\theta) = \frac{A \cdot B}{\|A\|\|B\|}$, where A represents the vector encoding of a test question and B represents the vector encoding of a training question, both produced using the fine-tuned BERT classifier. Providing the top N training examples that have the highest cosine similarity with test questions as few-shot demonstrations ensures that the selected

demonstrations are highly relevant to the current test question.

Few-shot Prompt: The final prompt sent to the fine-tuned LLM contains all N demonstrations ranked in increasing order of similarity, the test question and answer choices, as well as the line "Let's think step by step. What is the best answer?". The received response is parsed using the same fuzzy logic sequence-matching answer extractor.

4 Experimental Setup

Training FtG-CoT requires fine-tuning BERT and fine-tuning GPT-3.5. We use all 507 examples from the sentence puzzle training set provided for the BRAINTEASER task for fine-tuning.

To fine-tune BERT, we start with the BERT-Small pre-trained model from Google (Bhargava et al., 2021) and add a multi-class classifier head consisting of two linear hidden layers separated by a ReLU activation function to create a BERT classifier. The input to the classifier head is the [CLS] token from BERT: the first token from BERT's final hidden layer. The first hidden layer in the classifier head projects the BERT output from dimensions 512 to 256. The output of the second hidden layer is passed through a log softmax function.

To train the BERT classifier on the Sentence Puzzle training set, we first concatenate the question and choice list from each example and provide them as the input string to the classifier. The index of the correct answer from the choice list is the label for the classifier. During training the BERT classifier encodes each input string via the pre-trained BERT model and passes the encoding to the classifier head, which then assigns a class label to the input. The model calculates the negative log-likelihood loss between the predicted and true label and back-propagates the loss through the entire model, including the BERT layers. The BERT classifier was trained using an AdamW optimizer for 40 epochs with a learning rate of 0.00001. The final layer of the trained BERT classifier produces encodings that have been fine-tuned to solve sentence puzzles.

To fine-tune GPT-3.5, we start with the gpt-3.5-turbo-1106 pre-trained model from OpenAI and fine-tune the model using the OpenAI fine-tuning API. We create a fine-tuning dataset according to the format required by the OpenAI API. For each of the 507 training examples the system is set to "teacher", and the user prompt is defined as a concatenation of the question and choice list. The ground truth assistant response is defined as the generated chain of thought. The fine-tuned GPT-3.5 model was trained for 3 epochs with a batch size of 1 and a learning rate multiplier of 2. All other training hyperparameters cannot be set externally by the user and are instead defined internally by OpenAI.

The model is evaluated using the test set provided for the BRAINTEASER task. The test set consist of 120 questions, each with their own choice list. For each of the 120 questions, we use FtG-CoT to create a few-shot prompt used to query the fine-tuned GPT-3.5 model via the OpenAI API. We set the temperature to 1.0. The corresponding received response is then parsed using the custom fuzzy logic answer extractor described earlier. The predicted labels for all 120 test questions are then submitted to the BRAINTEASER CodaLab website where it is automatically graded against the ground truth labels. The resulting accuracy score is displayed on the competition leaderboard.

5 Results

The task organizers created 6 different accuracy metrics for evaluation. The first 3 metrics are instance-based accuracy scores that measure the accuracy of the model in solving the original questions, the semantic reconstruction questions, and the context reconstruction questions separately from one another. The next 2 metrics are group-based accuracy scores that consider each original puzzle and its variants as a single group. For each group, the model will score 1 accuracy point only if it successfully solves all three puzzles in the group. Otherwise, it will score 0 points. The last metric is an overall accuracy that is calculated as the average of the 3 instance-based accuracy scores.

FtG-CoT performs well at the task according to the official metrics, achieving a perfect score on the practice set and a 0.9 score on the evaluation set, ranking 18th overall in the competition. In this context, "score" refers to the accuracy score for the original practice and evaluation questions, not including the semantic and context reconstruction questions.

Table 1 compares the official leader board results for FtG-CoT evaluated on sentence puzzle evaluation dataset against the zero-shot ChatGPT baseline provided by the BRAINTEASER task organizers. FtG-CoT outperformed the zero-shot baseline for

Method	Original	Semantic	Contextual	Ori + Sem	Ori + Sem + Con	Overall
Zero-shot	0.608	0.593	0.679	0.507	0.397	0.627
FtG-CoT	0.900	0.825	0.775	0.800	0.675	0.833

Table 1: Official leader board results for sentence puzzle evaluation dataset. Compares FtG-CoT performance against the zero-shot ChatGPT baseline provided by the BRAINTEASER task organizers. The six categories correspond to the three instance-based accuracy scores, the two group-based accuracy scores, and the overall accuracy score. FtG-CoT outperforms the baseline in each of these metrics.

all 6 metrics. It performed best at answering the original question and struggled the most with the combined semantic and original group-based accuracy metric.

Method	Score (Original)
1-shot	0.8
5-shot	0.925
10-shot	0.925
10-shot w/ reversed order	0.90
20-shot	0.925
10-shot w/ fine-tuning	0.975
20-shot w/ fine-tuning	1.0
30-shot w/ fine-tuning	0.975

Table 2: Experimental results comparing the performance of FtG-CoT on the sentence puzzle practice dataset with different configurations. In general, increasing the number of demonstrations, listing them in order of increasing similarity, and fine-tuning the LLM on the training demonstrations tended to result in higher accuracy scores.

Table 2 displays practice test set scores achieved by FtG-CoT using different numbers of demonstrations, ordering, and with and without fine-tuning GPT-3.5 on the training set. By default, all demonstrations were concatenated in order of increasing similarity with the test question. In general, increasing the number of few-shot training demonstrations provided in the prompt tends to improve the performance of the LLM. However, past a certain number, in our case 10 demonstrations, adding additional demonstrations does not improve the performance of the LLM and results in decreased performance.

Furthermore, reversing the order of the demonstrations to be in order of decreasing similarity such as that the least similar demonstration is located closest in proximity to the test question in the prompt resulted in a lower score. This suggests that listing few-shot demonstrations in order of increasing similarity is the better approach.

The results also illustrate the effectiveness of fine-tuning the LLM on the training set. Whereas without fine-tuning the score peaked at around 0.925 regardless of the number of demonstrations provided, fine-tuning the LLM immediately resulted in a jump in performance to 0.975. Fine-tuning the LLM combined with increasing the number of provided demonstrations to 20 resulted in the highest achieved score of 1.0. However, increasing the number of provided demonstrations past 20 did not result in additional improved performance.

6 Error Analysis

For error analysis, we performed a 80/20 randomized train/test split on the sentence puzzle training set to create our own error analysis test set. We then fine-tuned FtG-CoT on the remaining training examples and evaluated the model against this test set.

Early analysis revealed that many of the questions that the model answered incorrectly were false negatives resulting from using exact string matching for answer extraction. This motivated the creation of the fuzzy logic answer extractor. We also found that the LLM struggled with answer consistency and repeatability. Fine-tuning the model helped to lessen this issue. However, even with the fuzzy extractor and fine-tuning, the LLM was not able to achieve perfect accuracy on the error analysis test set.

Figure 3 provides both an example of a sentence puzzle that the model answered correctly as well as an example of a sentence puzzle that the model answered incorrectly. Both questions belong to the same group of sentence puzzles. The question the model answered correctly was the original sentence puzzle. The question the model answered incorrectly was the semantically reconstructed version of the sentence puzzle. The semantically reconstructed question rephrases the original question, keeps the same correct answer, and shuffles the provided answer choices.

In this case, both questions share the same premise: a group of animals are racing to grab

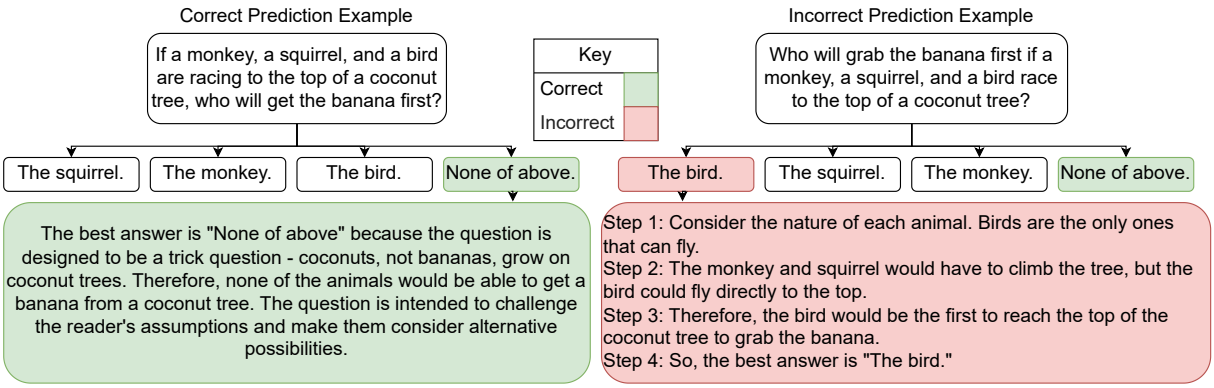

Figure 3: Example of a generated response with the correct answer for an original sentence puzzle as well as an example of a generated response with the incorrect answer for its corresponding semantically reconstructed sentence puzzle. The LLM correctly identifies the puzzle twist behind the original sentence puzzle and uses it to arrive at the correct answer, but is unable to do so for the semantically reconstructed sentence puzzle.

a fruit at the top of a tree, which animal will reach the fruit first? They also share the same puzzle twist: we are told that the animals are climbing a coconut tree yet are asked which animal will reach the banana first. Since bananas cannot grow on coconut trees, none of animals will be able to reach the banana. Therefore, the correct answer is "None of the above".

The generated response for the original sentence puzzle demonstrates that the model was able to correctly identify the puzzle twist and use it to arrive at the correct answer. However, the generated response for the semantically reconstructed question demonstrates that the model was not able to apply this same reasoning to the rephrased question. Instead, it answers the question as if it was asking about a coconut and a coconut tree and bases its answer off of the speed and movement of the animals, choosing the bird for its ability to fly.

These examples illustrate how the fine-tuned LLM model is highly sensitive to word choice and order, which helps explain why the model performs best on the original sentence puzzles and tends to struggle with the semantically and contextually reconstructed versions of the original puzzles. It is possible that the dataset OpenAI used to train GPT-3.5 contains a portion of the original sentence puzzles in the error analysis test set, allowing it to rely on memorization to improve its performance. However, since the LLM's accuracy on the reconstructed questions is only around 10% lower compared to the original questions, this suggests that the model is not relying solely on memorization to solve the sentence puzzles and may be capable of lateral thinking.

7 Conclusion

The FtG-CoT few-shot prompting method we developed for this competition combines a fine-tuned BERT classifier encoder with zero-shot chain-of-thought generation and a fine-tuned LLM. Our experiments have demonstrated that FtG-CoT is highly effective at solving sentence puzzles, achieving a perfect score on the practice set and a 0.9 score on the evaluation set, ranking 18th overall in the competition.

The key takeaways from our experiments are that FtG-CoT performs better with a larger number of demonstrations up to a certain point, few-shot demonstrations should e listed in order of increasing similarity, fine-tuning results in markedly improved performance, and that FtG-CoT significantly outperforms zero-shot prompting on the sentence puzzle evaluation set.

Regarding future work, it is possible that the performance of FtG-CoT can be further improved by using data augmentation techniques to expand the training set. For example, prompting an LLM to rephrase the existing training questions could increase the size of the training set and potentially decrease the fine-tuned model's sensitivity to word choice and order. It is also possible that the performance of FtG-CoT can be further improved by incorporating human feedback via reinforcement learning. A human could provide feedback on the quality and accuracy of the generated reasoning chains as well as manually rewrite incorrectly generated reasoning chains, improving the quality of both the fine-tuning dataset and the demonstrations.

Abstract

This paper describes our participation in SemEval 2024 Task 3, which focused on Multimodal Emotion Cause Analysis in Conversations. We developed an early prototype for an end-to-end system that uses graph-based methods from dependency parsing to identify causal emotion relations in multi-party conversations. Our model comprises a neural transformer-based encoder for contextualizing multimodal conversation data and a graph-based decoder for generating the adjacency matrix scores of the causal graph. We ranked 7th out of 15 valid and official submissions for Subtask 1, using textual inputs only. We also discuss our participation in Subtask 2 during post-evaluation using multi-modal inputs.

1 Introduction

SemEval 2024 Task 3 focused on Multimodal Emotion Cause Analysis in Conversations (Wang et al., 2024). Figure 1 shows an example provided by the organizers to illustrate the task. Two subtasks were proposed: Subtask 1, which uses only textual inputs, and Subtask 2, which allows for the consideration of video and audio processing as well.

The shared task is timely given the recent success of multimodal architectures combining computer vision (Redmon et al., 2016; Wang et al., 2023b), natural language processing (Devlin et al., 2019; Beltagy et al., 2020), and speech processing (Gong et al., 2021; Radford et al., 2022) advancements. In the particular context of multimodal emotion analysis, the task builds on top of previous work such as recognizing the triggered emotions as a classification task (Alhuzali and Ananiadou, 2021; Zheng et al., 2023) or predicting complex cause-effect relations between speakers (Wei et al., 2020; Ding et al., 2020). For the particular case of the shared task, the dataset - centered in English - relies on (Wang et al., 2023a) and provides text, image and audio inputs.

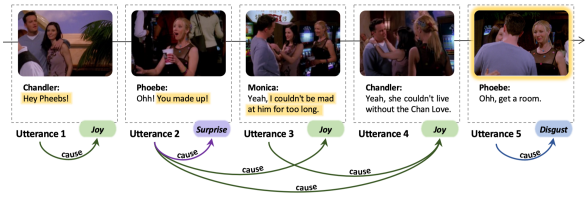

Figure 1: Example taken from the official website of the SemEval Task 3 - https://nustm.github.io/SemEval-2024_ECAC/. The goal of the task consists of predicting (i) the emotion associated to each utterance within the conversation, (ii) the cause-effect relations that trigger the emotions between utterances and (iii) the associated span in the cause utterance.

We had time and resources only to build a textual model for official participation in Subtask 1. We validated some multimodal baseline approaches using vision and audio inputs, but the computational resources required to fine-tune text and video data were beyond our range, so we participated in Subtask 2 only during post-evaluation. In what follows, we describe our approach. The implementation of our early prototype can be found at https://github.com/anaezquerro/semeval24-task3.

Contribution We propose an end-to-end multimodal prototype based on a large multimodal encoder to contextualize text, image and audio inputs with a graph-based decoder to model the cause-effect relations between triggered emotions within multi-party conversations. The large encoder joins pretrained architectures in text (Devlin et al., 2019), image (Dosovitskiy et al., 2021) and audio (Baevski et al., 2020) modalities, while the decoder is adapted from the graph-based approaches in semantic parsing (Dozat and Manning, 2018). The model is trained end-to-end.

2 Background

Multimodal Emotion Cause Analysis A number of datasets collecting multi-party conversations

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1252–1259

(Poria et al., 2019; Chatterjee et al., 2019; Firdaus et al., 2020) have been published to train and test multimodal neural architectures. Simpler configurations involve recognizing the speaker emotion at each utterance - this task is commonly known as Emotion Recognition (ER) (Poria et al., 2019) - while others require a deeper level of understanding to model interactions and causal relations between speakers - Emotion-Cause Pair Extraction (ECPE) (Xia and Ding, 2019). The most common approaches follow an encoder-decoder neural architecture where the encoder is conformed by multiple modules - one module per input modality (text, image and/or audio) - and produces an inner representation at utterance level; and the decoder accepts the encoder outputs as inputs and returns a suitable output adapted to the specifications of the targeted task. In the context of Multimodal ER, Nguyen et al. (2023) proposed a GCN-based decoder to capture temporal relations (Schlichtkrull et al., 2017), while Dutta and Ganapathy (2024) used cross-attention to fusion the input modalities and a final classification layer to predict the targeted emotions. Approaches in ECPE require an extra effort to represent and model causal information: Wei et al. (2020) scored all possible utterance tuples to predict the most probable list of emotion-cause pairs. Other authors, like Chen et al. (2020) and Fan et al. (2020), represented the emotion-cause pairs as a labeled graph between utterances and tried to predict the set of causal edges using a GCN or a transition-based system, respectively. The SemEval 2024 Task 3 joins the recognition and causal extraction tasks and challenges a system able to both model speaker emotions and elicit relations.

Graph-based decoding For structured prediction tasks, such as dependency parsing, graph-based approaches are a standard for computing output syntactic representations (McDonald, 2006; Martins et al., 2013). Particularly, Dozat and Manning (2017) introduced a classifier that computes a head and dependent representation for each token and then uses two biaffine classifiers: one computes a score for each pair of tokens to determine the most likely head, and the other determines the label for each head-dependent token pair. We will also build upon a biaffine graph-based parser: we will frame the task as predicting a dependency graph, where utterances are the nodes and emotions are dependency labels between pairs of utterances.

3 System Overview

Our system consists of two modules: a large pre-trained encoder and a graph-based decoder (see Figure 2). It can add extra input channels into the encoder without requiring any adjustments to the decoder, so the same decoder is used for both tasks, while the encoder is adapted to incorporate text-only (Subtask 1) or multimodal (Subtask 2) inputs.

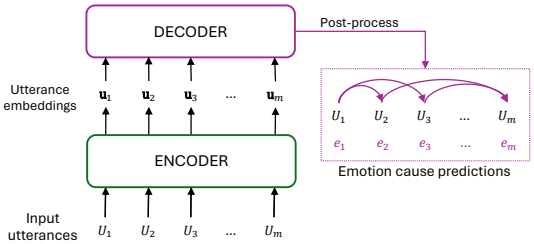

Figure 2: High-level architecture of our system. The encoder takes as input the sequence of m utterances of a given conversation and returns a unique vector representation for each utterance. The decoder uses the utterance embedding matrix to apply the affine attention product in the decoder, obtain the scores of the adjacent matrix and return the predicted sequence of emotions and the cause relations between utterances.

Let $C = (U_1, ..., U_m)$ be a conversation of m utterances, where each utterance $U_i = \{W_i, s_i, \varepsilon_i\}$ is defined by (i) a sequence of words $W_i = (w_1^{(i)}, ..., w_{\ell|w,i|}^{(i)})$[1], (ii) an active speaker s_i and (iii) a triggered emotion $\varepsilon_i \in \mathcal{E}$[2]. The set of cause-pair relations between utterances can be represented as a directed labeled graph $G = (\mathcal{U}, \mathcal{R})$ where $\mathcal{U} = (U_1, ..., U_m)$ is the sequence of utterances of the conversation assuming the role of the nodes of the graph and $\mathcal{R} = \{U_i \xrightarrow{\varepsilon_j} U_j,\ i, j \in [1, m]\}$ is the set of emotion-cause relations between an arbitrary cause utterance U_i and its corresponding effect U_j. Thus, the task can be cast as the estimation of the adjacent matrix of G, similarly to syntactic (Ji et al., 2019) and semantic dependency (Dozat and Manning, 2018) parsing. Adapting algorithms from parsing to model emotion-cause relations between utterances has also been explored by other authors, such as Fan et al. (2020), who instead explored a transition-based strategy.

[1]From now on, we denote as $\ell|\cdot, i|$ the length of the i-th in a sequence $\cdot$, so $\ell|w, i|$ denotes the length of the W_i. Table 2 summarizes the notation used in this paper.

[2]The set of emotions are described in Wang et al. (2023a).

3.1 Textual Extraction

The first subtask draws from only textual information to predict the adjacent matrix of G with a span that covers the specific words from U_i that trigger the emotion ε_j in the cause relation $U_i \xrightarrow{\varepsilon_j} U_j$.

Textual encoder Figure 3 illustrates our encoder. Given the sequence of utterances $(U_1, ..., U_m)$, we encoded with BERT the batched sequence of utterances where each word sequence was preceded by the CLS token (Devlin et al., 2019). For each U_i, we select the CLS embedding $(\mathbf{u}_i)$ from the contextualized embedding matrix $\mathbf{W}_i = (\mathbf{u}_i, \mathbf{w}_1, ..., \mathbf{w}_{\ell|w,i|})$, which is assumed to have information of the whole sentence. The CLS embedding matrix $\mathbf{U} = (\mathbf{u}_1, ..., \mathbf{u}_m)$ was passed as input to the decoder module and the word embeddings were reserved for the span attention module.

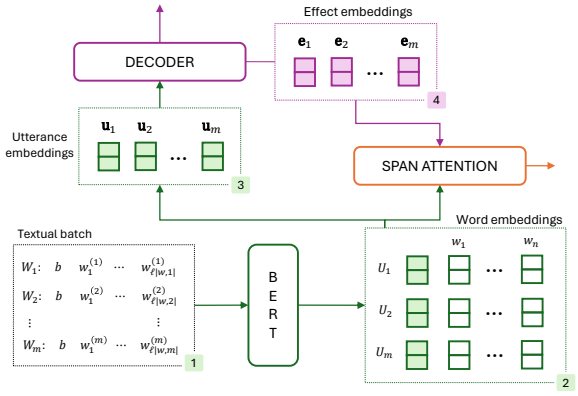

Figure 3: High level representation of the textual encoder. The input (1) is the matrix of stacked token vectors of each utterance. The last hidden states of BERT are used as word embeddings (2) and the special CLS tokens are used as utterance embeddings (3). The effect embeddings (4) - a partial representation from the decoder - are taken as input to the span module with the contextualized BERT embeddings.

Graph-based decoder Figure 4 shows the forward-pass of the graph-based decoder from the encoder output of Figure 3. To produce an adjacent matrix $\mathbf{G}$ of dimensions $m \times m$, where each position (i, j) represents the probability of a causal relation from U_i (cause) to U_j (effect), the first biaffine module uses a trainable matrix $\boldsymbol{\mathcal{W}}_{\mathrm{G}} \in \mathbb{R}^{d_{\mathrm{G}} \times d_{\mathrm{G}}}$ and maps $\mathbf{U}$ using two feed-forward networks to a cause $(\mathbf{C})$ and an effect $(\mathbf{E})$ representation. By projecting the original BERT embeddings to two different representations, $\mathbf{u}_i \sim (\mathbf{c}_i, \mathbf{e}_i)$, the decoder learns different contributions for the same utterance depending on the role. The affine product is

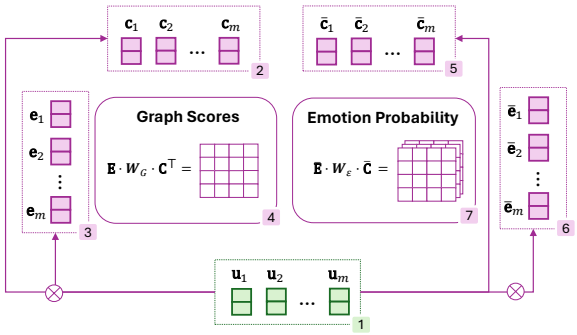

Figure 4: Graph-based decoder. The utterance embeddings (1) are projected to different representations (2 , 3 , 5 6) using four feed-forward networks to flexibly represent utterance embeddings. The scores of the adjacent matrix and the probability tensor are computed with the affine attention product.

defined as $\mathbf{G} = \mathbf{E} \cdot \boldsymbol{\mathcal{W}} \cdot \mathbf{C}^{\top}$. The second biaffine module uses a trainable tensor $\boldsymbol{\mathcal{W}}_{\varepsilon} \in \mathbb{R}^{d_{\mathrm{G}} \times |\mathcal{E}| \times d_{\mathrm{G}}}$ to predict the probabilities of triggered emotions between cause-effect utterances.

Span Attention module To maintain the end-to-end prediction while learning the span associated to each relation $U_i \rightarrow U_j$, we created a binary tensor $\mathbf{S} = (\mathbf{S}_1 \cdots \mathbf{S}_m)$ of dimensions $m \times m \times \max_{i=1,...,m}\{\ell|w,i|\}$[3] to specify if a word $w_k \in W_i$ of U_i is included in the span that triggers an emotion in U_j. To compute each $\mathbf{S}_i$, the matrix of word embeddings $(\mathbf{W}_i)$ of the utterance U_i is passed through a One-Head Attention module (see Figure 5), where $\mathbf{W}_i$ acts as the query matrix and $\mathbf{E}$ as the key and value matrices, so $\mathbf{S}_i = \Phi(\mathrm{softmax}(\mathbf{W}_i \cdot \mathbf{E}^{\top}) \cdot \mathbf{E})$, where Φ is a feed-forward network to project the embedding dimension to a unique binary value.

Encoding speaker information The dataset includes information about the active speakers in each utterance. A first approach to use this information as input would be concatenating the speaker embeddings to the sequence of utterances. However, this might lead to some issues: the model could assume that there is some inner dependency between triggered emotions and the characters in the conversation. This might be true in some cases, but it can also lead to biases, and there is still the challenge of modeling infrequent and unknown characters. To deal with this, we encoded a conversation C with speakers $s_1, ..., s_m$ using relative

[3]Note that each matrix $\mathbf{S}_i$ has dimensions $m \times \max_{i=1,...,m}\{\ell|w,i|\}$ and is associated to a *cause* utterance.

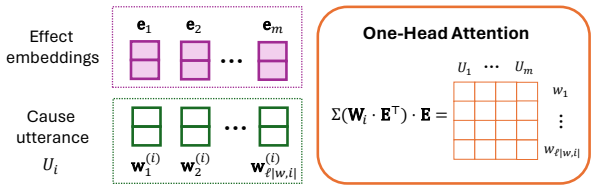

Figure 5: Span Attention module adapted from Vaswani et al. (2017). The tensor of word embeddings ($\mathbf{W}_1 \cdots \mathbf{W}_m$) from the encoder (Figure 3) and the effect contextualizations ($\mathbf{E}$) from the decoder (Figure 4) are passed to the attention product using each $\mathbf{W}_i$ as *key* and $\mathbf{E}$ as *query* and *value* matrices.

positional embeddings. For instance, the sequence (Chandler, Phoebe, Monica, Chandler, Phoebe) in Figure 1 would be encoded as $(0, 1, 2, 0, 1)$.

3.2 Multimodal Extraction

The second subtask adds a short video representation to each utterance, so U_i in a conversation $C = (U_1, ..., U_m)$ is now a tuple of five different elements $U_i = \{W_i, s_i, \varepsilon_i, \mathbf{X}_i, \mathbf{a}_i\}$. The last two added items encode the image and audio: (i) $\mathbf{X}_i = (\mathbf{x}_1^{(i)}, ..., \mathbf{x}_{\ell|x,i|}^{(i)})$ is the sequence of frames of the input video, where each frame is an image[4] tensor of dimensions $h \times w \times 3$ and (ii) $\mathbf{a}_i$ is the sampled audio signal of arbitrary length.

Image encoding We relied on a Transformer-based architecture (Ma et al., 2022; Zheng et al., 2023) to contextualize input images. While recent studies have proposed adaptations of the Vision Transformer and 3-dimensional convolutions that capture temporal correlations between sequences of frames for video classification (Arnab et al., 2021; Ni et al., 2022), our experiments were constrained by our resource limitations, preventing us from using these pretrained architectures. Hence, for our multimodal baseline we opted for the the smallest version of the Vision Transformer (ViT) model (Dosovitskiy et al., 2021) pretrained on the Facial Emotion Recognition dataset (Goodfellow et al., 2013)[5] to contextualize a small fraction of sampled frames[6], and incorporated an LSTM-based module to derive a unique image representation for each utterance. From an image batch $\mathbf{X}_i$, each image $\mathbf{x}_k^{(i)} \in \mathbb{R}^{h \times w \times 3}$ was passed to the ViT base model to recover the output of the last hidden layer and introduce it as input to the LSTM module to recover a final representation for U_i.

Audio encoding For our multimodal system we used the hidden contextualizations of the base version of wav2vec 2.0 (Baevski et al., 2020)[7]. Given a raw audio ($\mathbf{a}_i$) of an utterance U_i, the encoder of wav2vec 2.0 returns a sequence of hidden states that we summarized with an additional trainable LSTM layer to retrieve a unique vector that contents the audio information.

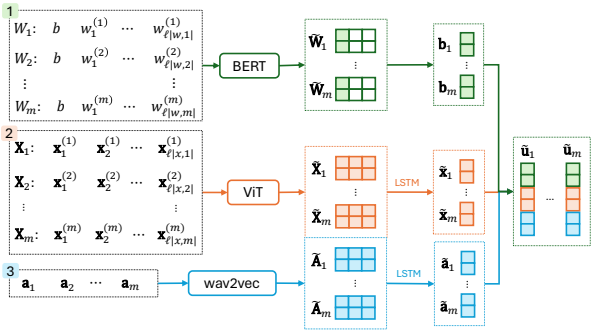

Figure 6: Multimodal encoder for Subtask 2.

Model fine-tuning The multimodal encoder (§3.2) uses three pretrained architectures to contextualize individual utterances and passes to the decoder the concatenation of the three unimodal representations (Figure 6). We chose to fine-tune only BERT during training together with the rest of the network. This was based on our empirical observation of superior results when learning from text compared to image and audio data. We entrusted the learning of audiovisual data to the LSTM learnable module within the encoder, presuming an accurate initial contextualization from wav2vec 2.0 and ViT pretrained on FER-2013.

3.3 Post-processing

Our end-to-end system directly recovers the predicted emotion-cause relations in a single post-processing step that linearly operates with the output tensors of the decoder. For the first subtask, the decoder returns (i) the adjacent matrix $\mathbf{G} \in \mathbb{R}^{m \times m}$, (ii) the labeled adjacent matrix $\overline{\mathbf{G}} \in \mathbb{R}^{m \times m \times |\mathcal{E}|}$ and (iii) the span scores $\mathbf{S} \in \mathbb{R}^{m \times m \times \ell_{\max}|w,i|}$. As Dozat and Manning (2017), each arc $U_i \rightarrow U_j$ is predicted by thresholding $\mathbf{G}$, and, once the arcs are predicted, the tensor $\overline{\mathbf{G}}$ determines the label

[4] All frames are RGB images, being the majority resolution 720×1280.

[5] https://huggingface.co/trpakov/vit-face-expression.

[6] For our experiments we used 5 interleaved frames per video, although a lower sampling rate can be considered depending on the computational capabilities.

[7] https://huggingface.co/facebook/wav2vec2-base-960h.

(emotion) associated to each arc. Since our formalization (§3.1) associates a given utterance to an unique emotion, we leveraged the scores of $\overline{\mathbf{G}}$ by the cause utterances and return the emotion with highest score. Finally, to produce a continuous span for each score vector $\mathbf{s_{ij}}$, we considered the leftmost and rightmost elements of $\mathbf{s}_{ij}$ higher than a fixed threshold.

Table 1: Evaluation of our prototype with different multimodal configurations. Precision (P), recall (R) and F-Score (F) measured the weighted average across the eight emotions of the dataset (superscript **w** denotes that the measure is weighted) and for the first subtask the span performance is considered with strict correctness (subscript **s**) or overlapping (subscript **p**). The symbol † remarks the reference metric for each subtask.

4 Experiments

Validation The annotated dataset contains 1 375 multi-party conversations with a total of 13 619 utterances (Wang et al., 2023a). Although an unbiased estimation of the performance of our system would require validating the trained architecture using all available annotated data, our time and resources limitations prevented us from conducting k-fold cross-validation. Instead, we partitioned a 15% of the annotated dataset as our development set. The specific split used will be available with the accompanying code to replicate our findings.

Evaluation We use the official metrics[8]: the weighted strict F-Score for the Subtask 1 and the weighted F-Score for the Subtask 2.

Hyperparameter configuration Our computational limitations prevented us from exhaustively searching the optimal hyperparameters for our system. We conducted some tests varying the pre-trained text encoder[9], model dimension, gradient descent algorithm and learning rate and adding or removing the speaker module. We maintained in all experiments some regularization techniques (such as dropout in the hidden layers and gradient norm clipping) to avoid over-fitting. Our final configuration uses AdamW optimizer (Loshchilov and Hutter, 2019) with learning rate of 10^{-6} and is trained during one hundred epochs with early stopping on the validation set.

5 Results

Table 1 presents the performance of our system for both subtasks. For the first subtask, we investigated various embedding sizes of the Biaffine decoder while concurrently fine-tuning the largest version of BERT[10]. For the second subtask, we conducted experiments using different types of inputs to evaluate their impact. These included: (i) using only text-based inputs, (ii) adding audio data, (iii) incorporating visual data through frames, and (iv) leveraging all available multimodal inputs together. For approaches (i), (ii) and (iii), only BERT was fine-tuned, whereas for approach (iv), all pretrained weights were frozen. These weights solely served to contextualize input information, with the learning process confined to the decoder component.

Our top-performing model for the first subtask achieved a validation score of 9.75 and ranked in the evaluation set in 7th position among 15 participants with 6.77 points. We observed a slight performance improvement by increasing the hidden dimension of the decoder. Thus, considering the expansion of decoder layers could improve the performance. It is worth noting the significant impact of span prediction on the model performance: the proportional results consistently outperform strict metrics. Removing span prediction while retaining only text inputs results in a notable increase in F-Score (20.43 points for the second subtask), indicating the crucial role of span prediction in model learning. Furthermore, we noticed that there was a consistent delay in the alignment between recall and precision metrics, with precision consistently exceeding recall by more than 5 points across all approaches. This suggests that our system tends to adopt a conservative behavior, avoiding the number

[8] https://github.com/NUSTM/SemEval-2024_ECAC/tree/main/CodaLab/evaluation.

[9] We performed some experiments using all the versions of BERT, (Devlin et al., 2019), RoBERTa (Liu et al., 2019) and XLM-RoBERTa (Conneau et al., 2020) and selected the best-performing textual encoder (BERT-large).

[10] https://huggingface.co/google-bert/bert-large-cased

of false cause emotion predictions.

The best validation performance for the second subtask is achieved through the integration of text and audio, yielding a score of 23.36 points in the weighted F-Score. Using image data also improves the text-only baseline, though unexpectedly lags behind the audio model. It is important to note that these two approaches are not directly comparable due to differences in their data inputs: the text and image model only considers a fixed number of sampled frames, suggesting that providing more image data (ideally, the full sequence of frames) could potentially yield a better performance that surpasses the audio-based approach. Unfortunately, we could not fine-tune BERT with the full multimodal encoder, so we were restricted to projecting the multimodal inputs to their respective contextualizations, and relying on the trainable weights of the decoder to optimize the full architecture. The results prove the importance of, at least, fine-tuning the text encoder: the F-Score only reaches 11.25 points, whereas the text finetuned baseline nearly doubles its performance with 20.43 points, highlighting the insufficient context of the original pretrained BERT embeddings to address this task.

Once the post-evaluation period concluded, we upload an experimental submission of our best multimodal system to the official competition. We obtained 15.32 points in the weighted F-Score, positioning our baseline in the 13th place out of 18 participants.

6 Conclusion

We proposed a graph-based prototype for the analysis emotion-cause analysis in conversations. Given the limited preparation time, we only submitted official results for Subtask 1 (text-only), but also report post-evaluation results for Subtask 2 (multimodal). The task required predicting several aspects of the conversation: (i) the emotion associated with each utterance, (ii) the cause-effect relationships triggering these emotions between utterances, and (iii) the specific span within the cause utterance responsible for the emotion. We achieved 7th place out of 15 valid submissions for Subtask 1, a promising outcome considering the time and resource constraints we had to prepare the task. Yet, our results make us optimistic about exploring future research avenues to enhance our system and study lighter approaches that can perform competitively. As future work, we aim to experiment with smaller and distilled models to encode textual, visual, and audio inputs, enabling us to fine-tune the full model cheaply.

A Appendix

Input	Description
U_i	Utterance i, defined as $U_i = (W_i, s_i, \varepsilon_i, \mathbf{X}_i, \mathbf{a}_i)$.
W_i	Word sequence of U_i as $W_i = (w_1, ..., w_{\ell\|w,i\|})$
s_i	Speaker of U_i, where $s_i \in \mathcal{S}$
ε_i	Emotion triggred in U_i, where $\varepsilon_i \in \mathcal{E}$
$\mathcal{S}$	Set of speakers in the dataset.
$\mathcal{E}$	Set of annotated emotions.
$\mathbf{X}_i$	Sequence of frames of U_i as $\mathbf{X}_i = (\mathbf{x}_1, ..., \mathbf{x}_{\ell\|x,i\|})$
$\mathbf{x}_k^{(i)}$	Specific frame of $\mathbf{X}_i$, where $\mathbf{x}_k^{(i)} \in \mathbb{R}^{h \times w \times 3}$.
$\mathbf{a}_i$	Sampled audio signal of U_i, where $\mathbf{a}_i \in \mathbb{R}^{\ell\|a,i\|}$.
$\ell\|w,i\|$	Length of the sequence W_i.
$\ell\|x,i\|$	Lenght of the sequence $\mathbf{X}_i$
Encoder	**Description**
$\mathbf{u}_i$	Encoder hidden representation of U_i from BERT, where $\mathbf{u}_i \in \mathbb{R}^{1024}$.
$\mathbf{W}_i$	BERT word embeddings of W_i as $\mathbf{W}_i = (\mathbf{u}_i, \mathbf{w}_1^{(i)}, ..., \mathbf{w}_{\ell\|w,i\|}^{(i)})$.
$\tilde{\mathbf{x}}_i$	Visual hidden representation for U_i, obtained as $\tilde{\mathbf{x}}_i = \text{LSTM}_\text{x}^{-1}(\text{ViT}(\mathbf{X}_i)) \in \mathbb{R}^{d_\text{V}}$.
$\tilde{\mathbf{a}}_i$	Audio hidden representation for U_i, obtained as $\tilde{\mathbf{a}}_i = \text{LSTM}_\text{a}^{-1}(\text{wav2vec}(\mathbf{a}_i)) \in \mathbb{R}^{d_\text{a}}$.
$\tilde{\mathbf{u}}_i$	Multimodal representation for U_i as $\tilde{\mathbf{u}}_i = (\mathbf{u}_i \| \tilde{\mathbf{x}}_i \| \tilde{\mathbf{a}}_i)$.
Decoder	**Description**
Φ	Arbitrary feed-forward network.
$\mathbf{c}_i$	Cause embedding for U_i as $\mathbf{c}_i = \Phi_c(\mathbf{u}_i) \in \mathbb{R}^{d_\text{G}}$.
$\mathbf{e}_i$	Effect embedding for U_i as $\mathbf{e}_i = \Phi_e(\mathbf{u}_i) \in \mathbb{R}^{d_\text{G}}$.
$\overline{\mathbf{c}}_i$	Emotion cause embedding for U_i as $\overline{\mathbf{c}}_i = \Phi_{c,\varepsilon}(\mathbf{u}_i) \in \mathbb{R}^{d_\text{G}}$.
$\overline{\mathbf{e}}_i$	Emotion effect embedding for U_i as $\overline{\mathbf{e}}_i = \Phi_{e,\varepsilon}(\mathbf{u}_i) \in \mathbb{R}^{d_\text{G}}$.
$\mathbf{C}$	Matrix of cause embeddings as $\mathbf{C} = (\mathbf{c}_1, ..., \mathbf{c}_m)$.
$\mathbf{E}$	Matrix of effect embeddings as $\mathbf{E} = (\mathbf{e}_1, ..., \mathbf{e}_m)$.
$\overline{\mathbf{C}}$	Matrix of emotion cause embeddings as $\overline{\mathbf{C}} = (\overline{\mathbf{c}}_1, ..., \overline{\mathbf{c}}_m)$.
$\overline{\mathbf{E}}$	Matrix of emotion cause embeddings as $\mathbf{E} = (\overline{\mathbf{e}}_1, ..., \overline{\mathbf{e}}_m)$.
$\mathcal{W}$	Trainable weights for the first biaffine module, where $\mathcal{W} \in \mathbb{R}^{d_\text{G} \times d_\text{G}}$
$\mathcal{W}_\varepsilon$	Trainable weights for the second biaffine module, where $\mathcal{W}_\varepsilon \in \mathbb{R}^{d_\text{G} \times \|\mathcal{E}\| \times d_\text{G}}$.

Abstract

In this paper we present a Chain-of-Thought enhanced solution for large language models, including flanT5 and GPT 3.5 Turbo, aimed at solving mathematical problems to fill in blanks from news headlines. Our approach builds on a data augmentation strategy that incorporates additional mathematical reasoning observations into the original dataset sourced from another mathematical corpus. Both automatic and manual annotations are applied to explicitly describe the reasoning steps required for models to reach the target answer. We employ an ensemble majority voting method to generate final predictions across our best-performing models. Our analysis reveals that while larger models trained with our enhanced dataset achieve significant gains (91% accuracy, ranking 5th on the NumEval Task 3 leaderboard), smaller models do not experience improvements and may even see a decrease in overall accuracy. We conclude that improving our automatic annotations via crowdsourcing methods can be a worthwhile endeavor to train larger models than the ones from this study to see the most accurate results.

1 Introduction

NumEval is a task first introduced in 2024 (Chen et al., 2024) building on previous work such as Cortis et al. (2017)'s fine-grained sentiment analysis (SemEval-2017 Task 5) and Jullien et al. (2023)'s clinical inference (SemEval-2023 Task 7). These prior tasks highlighted the importance of understanding numerical values in legal and medical contexts for determining outcomes. The primary objective of NumEval is to perform quantitative reasoning to generate numerical values corresponding to provided contexts.

In this project, we particularly focused on subtask 1 of task 3 (Huang et al., 2023) where our system must execute several mathematical calculations based on information from a provided passage to yield a numerical result used to fill in a headline with a blank. For instance, to complete the *CIA Cited Concerns About Snowden ____ Years Ago* headline, the model must subtract the article's publishing date by the explicitly stated date in the article (2009). Some entries involve a series of multiple mathematical operations that the model must perform.

Although numerical reasoning continues to present challenges to large language models (LLMs), advancements in larger models like DeepSeekMath (Shao et al., 2024) demonstrate promising capabilities in solving mathematical computations. DeepSeekMath is finetuned using different mathematical datasets and evaluated using Chain-of-Thought (CoT) prompting to provide intermediate reasoning steps. Inspired by CoT systems, we have developed a system pipeline that trains an encoder-decoder flanT5 (Chung et al., 2022) and an open source GPT 3.5 version[1] with additional mathematical corpora. These corpora include the Discrete Reasoning Over the Content of Paragraph (DROP) dataset (Dua et al., 2019) and another dataset which was manually and automatically annotated to include reasoning steps to reach the desired response. The core idea is that explicit intermediate reasoning, akin to chain-of-thought prompts, can enhance a model's quantitative reasoning capabilities (Wei et al., 2023).

In our revised approach, not only do we use smaller models ($\theta \leq 1$B)[2], but we also utilize multiple pipelines to determine the conditions under which our model achieves the highest accuracy. Firstly, we establish a baseline by fine-tuning with the provided dataset (Huang et al., 2023), then we incorporate additional observations from the DROP dataset into our training data. Thirdly, we adopt

a Chain-of-Thought (CoT) approach, fine-tuning both a flanT5 model and a generative open-source OpenAI model (GPT 3.5 Turbo) with more detailed inputs and outputs, including string normalizations and quantitative reasoning steps. Finally, we employ an ensemble majority voting method to select the best results from these models, resulting in a 91% accuracy and 5th place on the leaderboard of the NumEval competition [3].

2 Related Works

Through pre-training on a vast amount of text data, LLMs can develop a broad knowledge base encompassing numerical concepts, arithmetic operations, and mathematical relationships. Lewkowycz et al. (2022) propose a language model named Minerva, which demonstrates strong performance on various quantitative reasoning tasks, including undergraduate-level physics or chemistry problems.

Numerical reasoning has been extensively studied across diverse contexts, including word embedding (Wallace et al., 2019; Naik et al., 2019; Sundararaman et al., 2020) and math word problems (Wang et al., 2018; Cobbe et al., 2021). Within the domain of Question Answering, several approaches have been proposed. Xu et al. (2022) present a framework called Diagnosing Numerical Capabilities (DNC), which involves two stages: recognition of numbers in the context and question to treat them as candidate operands, followed by the correct selection of operands and operations based on understanding questions and context. Kim et al. (2022) proposes an attention-masked reasoning model that learns to leverage the number-related context to alleviate the over-reliance on parametric knowledge and enhance the numerical reasoning capabilities of the QA model. Other studies, such as those by Geva et al. (2020) and Feng et al. (2021), explore the infusion of external knowledge to augment the numerical reasoning skills of the models. Yang et al. (2021) focus on Numerical Reasoning over Text (NRoT) using T5 models, employing five training pipelines and multitasking training to progressively enhance model performance through tasks such as general reading comprehension and fine-tuning on the DROP dataset (Dua et al., 2019). Additionally, in reasoning tasks, Chain-of-Thought prompting has shown promise in improving the performance of large language models (Ling et al., 2024). While Chain-of-Thought (CoT) allows models to generate more comprehensive reasoning processes, it also introduces challenges such as hallucinations and accumulated errors. To mitigate these issues, the authors propose enabling explicit and deductive rigorous reasoning within language models. They emphasize the importance of self-verification for trustworthiness, which leads to significantly improved answer correctness in reasoning tasks. Drawing inspiration from these CoT-based methods, we incorporate them into our approach due to their superior performance in numerical reasoning tasks.

3 System Description

In our system, we defined three main pipelines that were compared against a baseline encoder-decoder model. Specifically, we used an instruction finetune model version (flan) of the Text-To-Text Transfer Transformer (T5) (Chung et al., 2022). This flanT5 model underwent fine-tuning in its small, base, and large versions, employing a learning rate of 5e-5 for 5 epochs and a batch size of 2.

3.1 DROP Dataset

To enhance performance beyond the baseline, we merged the Discrete Reasoning Over the Content of Paragraph (DROP) dataset (Dua et al., 2019) with the original numerical headline generation dataset (Huang et al., 2023). The DROP dataset consists of paragraphs with answer spans to given questions, often referencing multiple positions in the provided passage. With a total of 77400 observations in the training data split, we filtered out 46973 observations related to numerical reasoning tasks. Due to computational constraints, we merged only 20000 of these filtered observations with the original headline generation dataset. The selection of these 20,000 entries was based on a random seed of 43. Additionally, it's important to note that while the input text in the DROP dataset is structured as questions, unlike the fill-in-the-blank format used Huang et al. (2023)'s dataset, we transformed the questions into masked headlines by locating the answer in the original dataset and masking it from the passage's headline.

3.2 GPT 3.5 turbo

For this task, we utilized the GPT 3.5 Turbo model to extract numerical reasoning and explanations from the NumHG dataset (Huang et al., 2023).

[3] GitHub repository for our system

Prompt selection plays a critical role in obtaining optimal output from the GPT model. White et al. (2023) outline various prompt engineering techniques in a pattern-based catalog that have been successfully applied to improve the outputs of large language models (LLMs) in conversations. Drawing from the insights provided by White et al. (2023), we adopt three distinct patterns into our prompt design: the Persona Pattern, the Context Manager Pattern, and the Recipe Pattern. Each pattern was carefully selected to address specific challenges and enhance the interpretability of the generated responses.

Persona Pattern: It assists the GPT model in determining the types of output to generate and which details to prioritize. By incorporating persona-based prompts, we guide the model to discern the essential information to emphasize in its responses.

Context Manager Pattern: The goal of this pattern is to focus on specific topics and exclude unrelated ones from consideration. Through careful manipulation of contextual cues, we enhance the model's ability to generate contextually relevant and coherent numerical explanations.

Recipe Pattern: It introduces constraints to ultimately output a sequence of steps based on partially provided "ingredients" required to achieve a specified goal. Serving as a structured framework for our prompt design, the Recipe Pattern guides the model in constructing step-by-step sequences.

Role	Content	Matched Pattern
System	You are a helpful assistant, skilled in providing numerical reasoning.	Persona Pattern
User	context: [news] + [masked headline]	–
User	The answer to the fill-in-the-blank question is [ans]. Please provide a complete sequence of numerical reasoning steps in a paragraph format that is used to derive this answer. Begin your response by discussing the relevant sentences, and then outline the numerical reasoning steps. Conclude your response with: 'So the answer is [ans].'	Context Manager & Recipe Patterns

Table 1: Conversation prompt with matched patterns. Here, placeholder values are from the dataset.

3.3 Chain of Thought (CoT)

To further steer the capabilities of both the decoder GPT 3.5 Turbo and our trained flanT5, we incorporated chain-of-thought (CoT) prompting (Wei et al., 2023). This involved adding specific reasoning steps in the output text that the model relied on to produce the numerical response. According to Wei et al. (2023), CoT outperforms traditional prompting and finetuning approaches by providing intermediate reasoning steps that facilitate model interpretation. Moreover, in large models, even a few CoT sequences can outperform some finetuned pre-trained models in arithmetic and symbolic reasoning tasks (Wei et al., 2023).

In our CoT pipeline, our initial approach involved an automatic annotation step, which we supplemented with manual annotation to handle more complex calculations. Below, we outline this annotation process, including additional preprocessing steps implemented to normalize the input and output data.

Automated Annotation: In the original news articles, dates are written in abbreviated form and placed within brackets before the passage. Since many headline completion tasks involve subtracting a given number of years mentioned in the article from the publishing date, we extract this metadata date and transform it to prefix the overall passage with a descriptive sentence. For instance, an article with the date *(Feb 13, 2013 6:54 PM)* is transformed to *The news was published on 13th February in the year of 2013*. This approach enables our models to retrieve explicit and normalized dates for performing the corresponding mathematical operations.

Answer extraction is conducted using the *spacy* module to tokenize each passage and iterate over each resulting sentence with a custom placeholder function. If the answer is found within a sentence, it is extracted. The main answer extraction function is then applied to our main 7 placeholder functions to automate the annotation of the simpler calculations. Among these, 5 (*copy, translation, round, sround, and paraphrase* (Huang et al., 2023)) are much more straightforward, whereas *subtract* and *span* require a heuristic-based annotation, where the answer string is preprocessed to fit the appropriate format.

For instance in our span recipe, (*get_span_placeholder*), we modify the resulting string if the blank contains the following tokens.

- **No._** which we pass to the model as output with the following explanation: *No. 1 typically refers to the topmost or the best-ranked item in a list or a competition.*

- **_M** which we pass to the model as output with the following explanation: *The letter 'M' in the headline indicates that the answer refers*

to an amount that should be transformed to millions

- **_st** which we pass to the model as output with the following explanation: *The presence of 'st' in the headline gives a clue that the answer is 1*

Otherwise, we specify that the span containing the answer may refer to a person, object or event.

As previously stated, each of the simple aforementioned calculations has its own placeholder function, which we further examine in Table 6 and pass to our main algorithm in Figure 1.

One of the biggest challenges the automation system faced was inconsistent annotations from the original dataset wherein certain passages would not contain references to the answers at all or, more egregiously, wrong calculations. For the headline *Wife who got $1B in Divorce: Not Enough* where 1 corresponds to the answer, the calculation is as follows *Round(Paraphrase(995, K), 0)*. Nevertheless, the paraphrase should have an *M* instead of a K as the value is given in the millions rather than the thousands.

Furthermore, apart from the provided calculation, the passages often lack explicit numerical reasoning to justify why a model should yield the floor value of a decimal number for a headline instead of rounding it up. For example, in the article *Woman Places $615K Bet on Hillary Clinton* the value must be paraphrased and then rounded up to the nearest whole number to reach the answer of 615. However, the passage states that “"a 46-year-old woman just placed a $615,862 bet on Clinton". Mathematically, the number should be converted to thousands by dividing by 1000 and then rounded up, resulting in an answer of 616. Notwithstanding, the headline reports 615.

Manual Annotation: We employed manual annotation to address more complex operations, including addition, subtraction, multiplication, and division. In each case, we began with an automated step using GPT 3.5, as described in Table 1 and then manually cleaned up the reasoning steps, as well as, overall responses using a frontend system built with *streamlit*. Figure 2illustrates an example where we manually corrected the automated annotation to describe the steps for solving both simple and more complex calculations in a fill-in-the-blank question. In some instances, answers were incorrect, or the original logic provided by the model was overly redundant or incorrect. Consequently, we relied on 3 main human annotators[4] to review the 1K annotations completed by GPT 3.5 turbo. In Table 7, we can see some examples of patterns annotators followed to make sure the dataset would be consistent.

With both our automatic and manual annotations combined, we proceeded to fine-tune our GPT 3.5 Turbo and flanT5 models to evaluate whether the improved dataset yielded any advantages over the baseline. For this fine-tuning process, we maintained the same hyperparameters as before, except for the batch size. The batch size was increased for the small and base-sized flanT5 models to 16 and 8, respectively. This adjustment was necessary because we trained these models using a larger GPU, an A100 40GB GPU.

3.4 Ensemble

Lastly, we implemented an ensembling method using majority voting, wherein for each passage, we selected the numerical answer with the most votes as the correct one. In our ensembling pipeline, we narrowed down our majority voting to 4 models, consisting of our best-performing models: one version of large flanT5 trained for 3 epochs using only the NumHG dataset, another large flanT5 trained using NumHG for 2 epochs, a flanT5 trained for 2 epochs using the DROP dataset, and a CoT fine-tuned version of GPT 3.5 Turbo. We included versions that were trained for 2 epochs instead of 3 as they outperformed their 3-epoch counterparts, particularly the DROP-trained flanT5. However, this was only the case with the large models, as the base and small ones consistently performed better after training for 3 epochs rather than 2. During the evaluation period, we were unable to finish training the CoT models; therefore, we only used the available top 4 models for ensembling.

Since we employed an even number of models for this method, the likelihood of encountering ties is high. In instances of a tie, where a unanimous answer majority was absent, we resorted to the answer generated by our top-performing model—FlanT5 fine-tuned exclusively with NumHG.

4 Results

Based on the results presented in Tables 2 and 3, we observe that the difference in performance between the small and base flanT5 models is not par-

ticularly notable, except when employing the CoT method, where the small models significantly underperform. Additionally, as shown in Table 4, it is surprising to note that a finetuned GPT 3.5 Turbo model underperforms compared to the other flanT5 models, despite its larger size. Overall, our team ranked 5th out of 16 teams, including the baseline, on the final leaderboard, achieving 91% accuracy with our majority model.

5 Discussion

Our CoT results, as observed in Tables 2 and 3 align with the findings reported by Wei et al. (2023), indicating that smaller models do not experience significant gains when using prompting, partly due to their fewer parameters. In their study, it is explicitly mentioned that models in the range of 100 billion parameters or more exhibit the highest gains. However, all of the flanT5 models we utilized have significantly fewer parameters, failing to reach the 1 billion mark (Chung et al., 2022). We believe that conducting CoT experiments with the XL and XXL versions of these models would likely result in much more significant improvements.

5.1 Error Analysis

For our error analysis, we converted our model predictions into strings to facilitate comparison with their corresponding ground truths. It's important to note that while the competition required numerical values to be uploaded, some ground truths were formatted with commas (e.g., 1,500 instead of 1.5) or included important dates such as 9/11. In cases like the latter, where the ground truth couldn't be converted to a real number, we cast our results to string values. However, even with this adjustment, discrepancies in formatting, such as our model yielding 4.5 while the ground truth is 4.50, resulted in evaluations as incorrect. When accounting for these differences, the accuracy rate of the majority voting ensembling method reached 93%. Additionally, some answers in the test set were tagged as unanswerable.

In Table 5, we observe the error rate of our best majority voting ensembling method. Despite our best-performing model achieving a 91% accuracy rate, as noted in Table 4, we can see a high error rate for complex operations such as addition, multi-

ply, and subtraction. Additionally, the surprisingly high error rate for the round operation may stem from inconsistencies in the annotation process. As mentioned in Section 3, there are no contextual hints in the passage besides the calculation to aid the model in flooring a value instead of rounding it up. Moreover, certain calculations that instruct the model to round up a value, such as *2.8*, have a ground truth of 2 instead of 3.

Nevertheless, our models encountered several round-up errors where they failed to generalize properly, particularly when rounding up to the nearest tenth. For example, in an operation yielding 4.831 where rounding up to the nearest tenth should result in 4.83, our models rounded it up to 4.8. Similarly, in cases where 4.8 should be rounded up to the nearest whole number, our flanT5 models often failed to round it up to 5, opting instead for 4. In approximately 80% of cases where round operations were inaccurately predicted, the primary issue was the selection of an incorrect upper or lower bound for the rounding operation.Many of these mistakes involved multiple complex calculations, where a round operation had to be computed after 2 or 3 additional computations. An example of this issue can be seen in the operation: *Round(Divide(85,12),0)* where the result is supposed to be 7, but the model incorrectly yields 85 to complete the headline *Robert Durst Gets ____ Years for Gun Charges*. However, the article explicitly states “"Robert Durst, millionaire oddball and star of HBO’s true-crime documentary The Jinx, pleaded guilty to gun charges Wednesday in New Orleans, earning him 85 months in prison". While the headline requests years, the model fails to convert the value in months to years by dividing by 12, instead simply copying the number *85* from the span.

Similarly, we encountered errors with the copy operation, where either the model would copy an incorrect value or, more egregiously, round it up to another value. For instance, in the headline *Spanish Bank Offers $____B to Madoff Victims* the article states that “Spanish banking giant Banco Santander, whose clients lost nearly $3.1 billion in Bernard Madoff’s Ponzi scheme, has offered to pay back customers some $1.82 billion, reports Bloomberg.". Therefore, the correct answer should be 1.82, but our model incorrectly rounds this value to 1.8. We estimate that if we account for these errors, our majority ensembling could potentially achieve a 2% increase over our 91% result.

Finally, the divide calculation presents fewer errors in our models, with most mistakes occurring within complex operations involving multiple calculations. However, it’s worth noting that ratio conversion, specifically converting a ratio to a percentage and viceversa, poses a challenge for our models. This challenge is evident in the *Divide(1,20%)* calculation where the expected result is 5 to complete the headline *Odds of a Depression? 1 in ____*. Unfortunately, our model yields 4, indicating that it interpreted 20% as 25%. While such corner cases underscore that our models may not always accurately translate fractions to their corresponding real numbers (i.e., dividing the percentage number by 100), it’s important to consider the context. In the article, multiple percentages were mentioned in the following spans: “The bad news is that this recession is likely to be America’s worst since WWII—but the good news is there’s only a 20% chance it will become a depression (...) The lack of any major global conflicts means the chance of a depression being a major one—a decline of 25% or more—is only 2%". In other words, the model did not identify the span with the right percentage to convert to its corresponding ratio, which is 20% rather than 25%.

6 Conclusion

In this paper we observed that introducing additional observations with detailed reasoning steps can enhance a model’s ability to solve mathematical problems while also highlighting areas where its reasoning may fall short. Nevertheless, our results suggest that larger models may derive the most benefit from a CoT + finetuning approach. Because of this, we argue that leveraging larger LLMs could lead to even greater gains in quantitative reasoning tasks. Furthermore, while we have provided access to our open dataset[5], we recognize the importance of improving automatic annotations through crowdsourcing to achieve more accurate results. Given that our automatic annotations sometimes exhibit issues in reasoning steps compared to manual annotations, and certain entries in the original dataset are ambiguous or erroneous, we emphasize the necessity of data cleanup to enhance mathematical reasoning in language models.

A Error Analysis

	Percentage Error Rate	Count Error Rate
Addition	46%	42
Copy	4%	148
Divide	36%	4
Multiply	74%	20
Paraphrase	4%	16
Round	55%	101
Span	7%	1
Subtract	63%	59
Translation	2%	20

Table 5: The error rates are over the total amount of a given operation, not for the whole dataset. Note that Sround error rate is computed with the round operation.

B Data Annotation

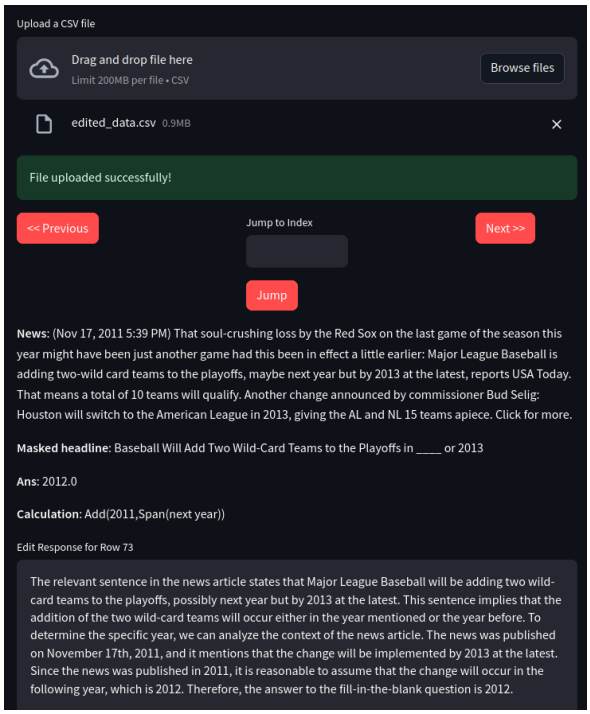

Figure 2: Example of our manual annotation system on streamlit

Recipe	Function	Example	Operation
Copy	The simplest placeholder as the model simply takes the exact response taken from a given span in the passage	A union repping 2 million health care workers has made quite a find: 39 million N95 masks	*39* → 39
Translation	Similarly to the copy placeholder, the answer is present in a given sentence. Thus, we state that the answer must be converted to its corresponding numerical value.	A University of Utah student paid his tuition bill with 2,000 one-dollar bills	*one* → 1
Paraphrase	Involves paraphrasing a value that is appended in the headline by *K*, *M*, or *B*. That is to say, if the value is to be expressed in the thousands (K), millions (M), or billions (B), the numerical value found in the passage must be transformed accordingly.	A Florida travel insurance company has awarded a Georgia high school teacher $10,000	*$10,000* → 10
Round	Akin to paraphrase, round implies rounding a value to its nearest whole number or tenth depending on the specified decimal in the calculation.	Hackers made public the email addresses, usernames, and passwords of 790,724 Brazzers members.	*$790,724* → 791
Sround	Instead of approximating to the greater value, in *sround* the model must transform the value to its nearest floor value.	Today's after-hours bad news from the credit-crunch front comes from insurer AIG, which reported a fourth-quarter loss of $5.29 billion	*$5.29* → 5
Span	It fetches the span in the given passage the headline is referring to	Brooklyn store owner Jacob Hamula could have ended up a victim of Salvatore Perrone, the suspected serial killer believed to have gunned down three other store owners before police nabbed him.	*Brooklyn store owner Jacob Hamula* → 1
Subtract	It implements a heuristic whereby the model subtracts between the published date and the date mentioned in the passage as long as these dates are present in the metadata date and the article	(Apr 1, 2014 4:03 AM CDT) Steve Jobs did it; Google founders Sergey Brin and Larry Page did, too. Now Mark Zuckerberg is joining the ranks of the $1-a-year CEOs, Bloomberg reports. That's what the Facebook boss earned in salary last year	*(Apr 1, 2014 4:03 AM CDT)* & *last year* → 2014 - 1 = 2013

Table 6: Placeholder functions used in our automatic annotation. Note that the round operation includes a paraphrase one in the given example. Additionally, the recipe for round and sround is virtually the same. Finally, the only subtract operations that were automatically annotated with this method involve dates. Otherwise, they are deemed as more "complex" operations that were manually annotated.

Recipe	Pattern Example
Paraphrase	From the presence of "M" at the end of the fill-in-the-blank, we can infer that the blank in the question is asking for the value in millions. The sentence states that the population will be 308,400,408, so we need to convert this value to millions. To do this, we divide 308,400,408 by 1,000,000 which gives us 308.400. Since the question asks for the value in millions, we round down to the nearest whole number, which is 308. So the answer is 308.
Translation (transform dates)	The presence of both the apostrophe (') and "s" surrounding the blank strongly indicates that the number is abbreviated and pertains to a decade. Taking the example of the '80s, which covers the years 1980 to 1989, when individuals refer to "the '80s," they are typically referring to the complete decade. Since 1987 is within the timeframe of the '80s, it logically follows that the appropriate response is 80. So the answer is 80.
Translation (transform to ratio)	The term "quarter" refers to one part out of four equal parts. In the context of numbers or fractions, "1 in 4" is used to express the concept of a quarter. This means that when something is divided into four equal parts, you are referring to one of those parts.

Abstract

This paper describes the inference system of FZI-WIM at the SemEval-2024 Task 2: Safe Biomedical Natural Language Inference for Clinical Trials. Our system utilizes the chain of thought (CoT) paradigm to tackle this complex reasoning problem and further improves the CoT performance with self-consistency. Instead of greedy decoding, we sample multiple reasoning chains with the same prompt and make the final verification with majority voting. The self-consistent CoT system achieves a baseline F1 score of 0.80 (1st), faithfulness score of 0.90 (3rd), and consistency score of 0.73 (12th). We release the code and data publicly[1].

1 Introduction

The Safe Biomedical Natural Language Inference for Clinical Trials (NLI4CT) task aims to investigate the consistency and faithfulness of natural language inference (NLI) models in clinical settings(Jullien et al., 2024). NLI is a typical natural language task requiring natural language reasoning (Yu et al., 2023). Fine-tuned BERT-based (Devlin et al., 2019) discriminative models have been widely applied to solve NLI problems (Liu et al., 2020; He et al., 2021). Studies show increasing reasoning capabilities of large language models (LLMs), both in proprietary (Brown et al., 2020; Achiam et al., 2023) and open-source LLMs (Touvron et al., 2023a,b; Jiang et al., 2024). However, problems of inconsistency and unfaithfulness still occur with LLMs(Golovneva et al., 2023; Turpin et al., 2023). Compared to other domains, medical applications have much higher standards regarding safety and trustfulness, so inconsistencies and unfaithfulness limit AI applications in the medical domain.

Chain of Thought (CoT) has been proposed to elicit the reasoning capabilities of LLMs (Wei et al., 2022). Based on the CoT, further concepts like Tree of Thought (Yao et al., 2023a), ReAct (Yao et al., 2023b), Self-Consistency (Wang et al., 2023), and so on have been proposed to improve the performance of CoT further. One common characteristic of the frameworks mentioned above is the explicit generation of reasoning chains. Since only verification labels are provided in the NLI4CT training dataset, we utilize GPT-4 to generate reasoning chains. With the distilled knowledge from GPT-4, we further instruction-tune an open-source LLM with low-rank adaption (LoRA) (Hu et al., 2022) for claim verification with CoT. Our system follows the self-consistency concept by generating multiple CoT reasoning chains and verifying with majority voting.

We summarize our major findings regarding this task as follows:

- LoRA instruction-tuning can bring domain-specific (biomedical) knowledge and reasoning capabilities to LLMs.
- Our instruction-tuned LLM tends to contradict the statement if the information is only contained in the statement, not in the premise, even if the information is factually correct.
- CoT reasoning gains significant performance improvement regarding faithfulness compared to the label-only prediction.
- Compared to the greedy CoT, self-consistent CoT with majority voting has a performance improvement of 1.31 (baseline F1), 0.75 (consistency score), and 0.69 (faithfulness score) percentage points. Performance improvement is limited for the binary classification problem.

2 Background

NLI4CT contains one text entailment task, namely infer the relationship between a premise and a state-

[1]https://github.com/jens5588/FZI-WIM-NLI4CT

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1269–1279

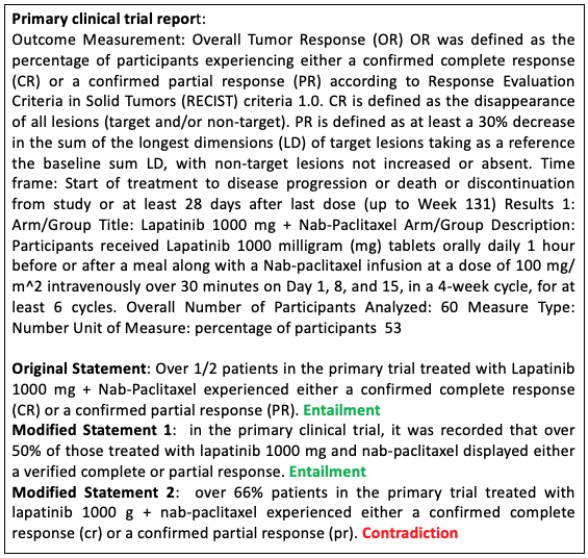

Figure 1: A data example. With the same clinical report, semantic-preserving and semantic-altering interventions on the original statement are used to evaluate the consistency and faithfulness of the verification system.

ment as either entailment or contradiction (Jullien et al., 2024). The premises in the NLI4CT dataset are collected from publicly available breast cancer clinical trial reports (CTRs), split into four sections: eligibility criteria, intervention, results, and adverse event (Jullien et al., 2023). The statements are sentences making claims about the information in the CTR premise, either about a single CTR or a comparison between 2 CTRs. The numbers of training, validation, and test examples are 1700, 200, and 5500, respectively. In the test set, 500 examples are used as anchors. The other 5000 statements are created with interventions on these first 500 examples. Figure 1 shows an example with interventions on the statements. Using the same clinical report, two statements are modified, one semantics-preserving (modified statement 1) and the other semantics-altering (modified statement 2), based on the original statement. The purpose of the interventions is to investigate the consistency and faithfulness of the inference.

For the text entailment task in the first iteration of NLI4CT (SemEval-2023 Task 7), most systems have fine-tuned discriminative transformer-based models (Jullien et al., 2023). Kanakarajan and Sankarasubbu (2023) instruction-tuned Flan-T5 model and achieved the 2nd place for the text entailment task. However, the systems mentioned above only predicted the verification labels without the reasoning process. To achieve a trustworthy verification, our system not only predicts the label but also the reasoning chains. Since the training and validation datasets have only provided verification labels. We utilize GPT-4 to verify with reasoning chains for training and validation datasets. We further instruction-tune an open-source LLM with distilled reasoning chains from GPT-4. To address the inconsistency problem in reasoning chains, we sample multiple chains and then employ a majority voting approach to determine the final verification outcome.

3 System overview

Figure 2 shows the pipelines of data creation, model training, and inference of our system. In the following, we describe each part.

3.1 Knowledge Distillation

The NLI4CT data only contains verification labels without rationales. Following the concept of knowledge distillation (Hinton et al., 2015), we leverage GPT-4 to generate rationales with CoT for the training and validation datasets. We further extract the verification labels of GPT-4 based on the CoT reasoning and filter out the examples for which the extracted labels are different from the gold labels.

3.2 LoRA Instruction-tuning

Parameter efficient fine-tuning (PEFT) gains popularity as the sizes of LLMs increase (Houlsby et al., 2019; Pfeiffer et al., 2020; Li and Liang, 2021; Hu et al., 2022). Low-rank adaption (LoRA) (Hu et al., 2022) is a PEFT approach to fine-tune LLMs. Studies show over-parametrized models reside on a low intrinsic dimension (Aghajanyan et al., 2021; Li et al., 2018; Hu et al., 2022). The key assumption of LoRA is that the updates to the weights also have a low intrinsic rank during adaptation for downstream tasks. The parameter updates of a pre-trained weight matrix $W_0 \in \mathbb{R}^{d\times k}$ can be represented as $W_0 + \Delta W = W_0 + BA$, where $B \in \mathbb{R}^{d\times r}$, $A \in \mathbb{R}^{r\times k}$ and $r \ll \min(d, k)$ (Hu et al., 2022).

Based on the concept of LoRA, given prompt x and the target output $y = (y_1, ..., y_m)$, the loss can be formulated as:

$$L = \sum_{i=1}^{m} -\log(p_\theta(\hat{y}_i = y_i|x, y_1, ..., y_{i-1})), \quad (1)$$

where θ represents W_0, B, A and only B and A are trainable.

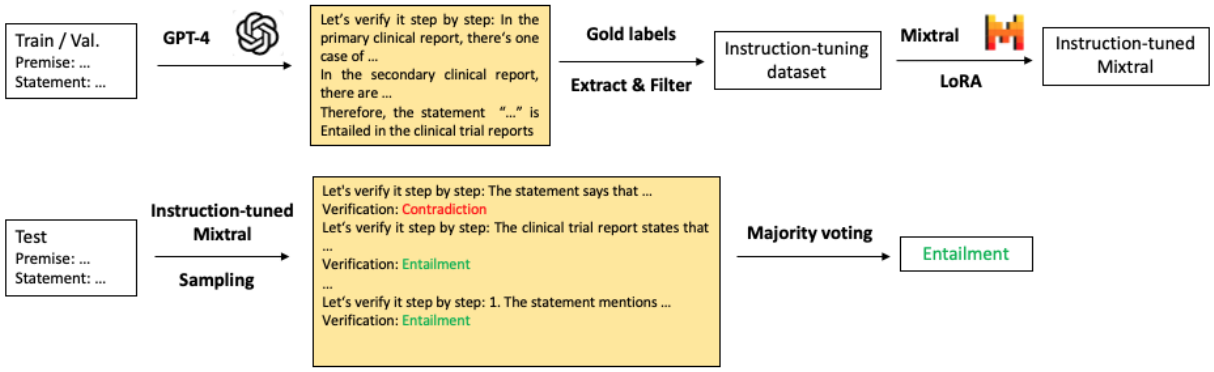

Figure 2: Training and Inference pipeline of self-consistent CoT system.

3.3 Self-Consistency

Self-consistency for LLMs was proposed by Wang et al. (2023) to replace the greedy decoding in CoT reasoning. The intuition behind self-consistency is that there are multiple ways to solve a complex problem. Another fact that supports the introduction of the self-consistency concept is that current LLMs still have difficulties with complex reasoning tasks and make mistakes in certain reasoning steps. With multiple reasoning chains, the model is less likely to make the same error and reach the same wrong answer. Wang et al. (2023) show self-consistency boosts the performance of different LLMs with different sampling strategies, including temperature sampling, top-k sampling, and nucleus sampling, on arithmetic, commonsense and symbolic reasoning tasks.

4 Experimental setup

In this section, we describe our experiment setup. We describe the CoT generation with GPT-4, the model training, and the inference setups.

4.1 LoRA Instruction-tuning

Instruction Data Creation Since GPT-4 has state-of-the-art reasoning capabilities, we instruct GPT-4 to verify the statements based on the CTR premise step-by-step for the training and validation datasets. The instruction prompt is shown in Appendix A.1. We then extract the verification labels of CoT rationales with an NLI model, namely bart-large-mnli (Lewis et al., 2020), and keyword matching. We compare the extracted labels with gold labels and filter out examples where the verification is wrong. For 1700 training and 200 validation examples, we achieve 1413 and 166 correctly verified examples with CoT, respectively, resulting in an accuracy of approximately 83%. With these selected examples, we build an instruction-tuning dataset for fine-tuning an open-source LLM. We show an example of CoT instruction-tuning data in Appendix A.2. For further comparison, we create another instruction dataset containing only verification labels without CoT for training and validation datasets. Appendix A.3 shows one label-only instruction-tuning data example.

Instruction-tuning We select Mixtral-8x7B-Instruct (Jiang et al., 2024) as our open-source LLM for instruction-tuning. The base model selection has considered reasoning capabilities and the number of model parameters. The configuration of LoRA is set as follows: r=8, alpha=32 and adaption of the attention weights of query (W_q), key (W_k), value (W_v) and output (W_o). This setup leads to 6.8M trainable parameters, which corresponds to 0.0146% of the base model size of 46.7B. We instruction-tune Mixtral-8x7-Instruct with the CoT instruction dataset and label-only instruction data separately for five epochs. Further implementation details are described in Appendix B.1.

4.2 Inference

Self-Consistent Inference To generate reasoning chains with the CoT instruction-tuned Mixtral model, we follow Wang et al. (2023) using a temperature sampling with the parameters $T = 0.7$ and $k = 50$ in top-k. For each (premise, statement) pair in the test dataset, we begin with sampling 10 reasoning chains. We then extract the verification labels and apply majority voting to decide the final label. If the result for both labels is tied, we further generate reasoning chains with different seeds. The maximal number of generated reasoning chains is 25. We show the number of generated reasoning chains in Appendix B.2.

Greedy Inference For comparison, we also apply the greedy decoding strategy to generate verification with label-only and CoT instruction-tuned models. With the greedy strategy, the models predict the next token with the highest probability without sampling[2].

4.3 Evaluation Metrics

Three evaluation metrics are used for the task: baseline F1, faithfulness score, and consistency score. The F1 score is used to evaluate the performance of the control set without intervention, consisting of 500 samples. There are 5000 samples in the test dataset, created with interventions based on the samples in the control set.

The consistency score evaluates whether the model predicts the same label when semantic-preserving interventions exist in the original statements (Jullien et al., 2024). For N statements x_i in the contrast set C, their corresponding original statements y_i and model prediction function f, the consistency score is calculated with:

$$Consistency = \frac{1}{N}\sum_{1}^{N} 1 - |f(y_i) - f(x_i)| \quad (2)$$

where $x_i \in C$: $\text{Label}(x_i) = \text{Label}(y_i)$.

The faithfulness score evaluates whether the model can change its prediction when semantic-altering interventions are present in the original statements (Jullien et al., 2024). For N statements x_i in the contrast set C, their corresponding original statements y_i and model prediction function f, the faithfulness score is calculated with:

$$Faithfulness = \frac{1}{N}\sum_{1}^{N} |f(y_i) - f(x_i)| \quad (3)$$

where $x_i \in C$: $\text{Label}(x_i) \neq \text{Label}(y_i)$, and $f(y_i) = \text{Label}(y_i)$.

5 Evaluation

In this section, we report the results of our self-consistent CoT system. For comparison, we also report the results of label-only verification and CoT-greedy. The comparison of three systems serves as an ablation study to analyze the performance improvement of extra steps, reasoning chain generation and self-consistent verification. Table 1 gives an overview of the three systems compared to the best scores in each category. Our self-consistent CoT system achieves 1st place regarding baseline F1, 3rd place regarding faithfulness, and 12th place regarding consistency. Next, we will analyze our system according to the three metrics separately.

[2] https://huggingface.co/docs/transformers/generation_strategies

Model	Base F1	Consistency	Faithfulness
Label-only Greedy	0.7867	**0.7364**	0.8102
CoT Greedy	0.7869	0.7217	0.8970
Self-Consistent CoT	**0.8000**	0.7292	**0.9039**
Best score	0.80	0.81	0.95

Table 1: Overview of three systems compared to the best scores of the task regarding each metric.

Model	Eligibility	Intervention	Adverse Events	Results
Label-only Greedy	0.7482	**0.8175**	0.8131	0.7679
CoT Greedy	0.7132	0.7794	**0.8667**	0.7961
Self-Consistent CoT	**0.7581**	0.7770	0.8305	**0.8485**

Table 2: F1 scores of three systems according to the sections in CTRs.

5.1 Baseline F1

In the test dataset, there are 500 samples without interventions on the statements, which are used as the control set. Table 2 shows the F1 scores of three systems according to the sections in the CTRs. The Eligibility section has the lowest F1 scores compared to the other sections in CTRs. Several factors have increased the difficulties for eligibility verification statements. First, the premises, i.e., criteria for inclusion and exclusion for clinical trials, are much longer than those for other sections. LLMs cannot always extract all relevant information from very long contexts. The verification of statements regarding eligibility often requires multi-step reasoning capabilities. The lack of domain-specific knowledge and common sense can also lead to verification errors. For the sections Intervention, Adverse Events, and Results, the major error type is numerical reasoning.

5.2 Consistency

Compared to the other two metrics, the consistency score of our self-consistent CoT system has the worst ranking. There are 4136 samples with semantic-preserving interventions, and they can be classified into five groups: paraphrase preserving, contradiction preserving, numerical paraphrase preserving, numerical contradiction preserving, and definitions preserving. Table 3 summarizes the consistency scores for each system according to

these categories. Compared to the other categories, self-consistent CoT and CoT greedy systems have worse performance regarding definitions and numerical paraphrase interventions. For the intervention regarding definitions, extra factual statements have been added to the original statements. A definition-intervention to the original statement in Figure 1, e.g., is:
Over 1/2 patients in the primary trial treated with Lapatinib 1000 mg + Nab-Paclitaxel experienced either a confirmed complete response (CR) or a confirmed partial response (PR). bladder solitary fibrous tumor is a solitary fibrous tumor that arises from the bladder. most tumors are benign.
Since the sentence *bladder solitary fibrous ...* is irrelevant to the clinical report, our self-consistent CoT tends to verify it as Contradiction (7 Contradictions : 3 Entailments in 10 generated reasoning chains).

For the category of numerical paraphrasing, there are 224 statements modified from 90 original statements. For the original set, we have around 81% accuracy (73 / 90), and for the modified set around 72% (162 / 224). We classify the errors, in total 34, where original statements are verified correctly and modified statements are verified wrong, into three groups: the conversion of fractional numbers, decimals, and percentages; the conversion of time, e.g., months to weeks, months to days, etc.; the conversion of units, e.g., mm to cm, mg to micrograms, etc. Among 34 misclassified statements, the system can generate at least one completely correct reasoning chain out of 10 reasoning chains for 17 statements. This indicates that the model has the knowledge for these conversions. However, our instruction-tuned model has difficulties utilizing this knowledge. The model also has difficulties understanding some paraphrased statements, e.g., from *over 1/2 patients* to *over 0.5 patients*, from *5% of patients* to *0.05 of patients*, etc. Another issue is some conversions are not quite precise, e.g., *9 months* to *36 weeks*, *6 months* to *180 days*. The model often contradicts the modified statements since they are not the same (9 months equals about 39 weeks).

5.3 Faithfulness

The contrast set for evaluating the faithfulness of the system is generated from 250 samples from the control set. All the 250 statements in the control set have the label Entailment. With contradiction intervention, 864 samples are created with the label Contradiction, 114 of which are numerically intervened. Table 4 summarizes the faithfulness scores of each system after contradiction intervention types. The scores show that both CoT greedy and self-consistent CoT have a significant performance improvement over label-only prediction. This underscores the critical role of the extra reasoning chain generation step for faithful verification.

Model	Consistency				
	para.	cont.	num. para.	num. cont.	defi.
Label-only Greedy	0.7807	0.7613	**0.7411**	0.9568	**0.6553**
CoT Greedy	0.7780	0.8427	0.7321	0.9568	0.5780
Self-consistent CoT	**0.8020**	**0.8440**	0.7232	**0.9877**	0.5720

Table 3: Consistency scores of three systems according to semantic-preserving intervention types

Model	Faithfulness	
	cont. alter.	num. cont. alter.
Label-only Greedy	0.8040	0.8509
CoT Greedy	0.8933	0.9211
Self-consistent CoT	**0.8987**	**0.9386**

Table 4: Faithfulness scores of three systems according to intervention (altering) types

5.4 Self-consistent CoT and CoT Greedy

According to Table 1, our self-consistent CoT has improved the performance of the CoT greedy system regarding all metrics, namely baseline F1 of 1.31 percentage points, consistency score of 0.75 percentage points, and faithfulness score of 0.69 percentage points. However, the improvement is insignificant compared to Wang et al. (2023). We show two examples in Appendix C. The first example shows that self-consistent CoT corrects the error in CoT greedy, and the second one shows that self-consistent CoT fails to correct the error. One possible reason for the insignificant improvement is the number of generated reasoning chains. Due to computational limitations, we have only generated 10.36 reasoning chains on average, which is much less than the 40 reasoning chains in Wang et al. (2023). Another important reason is the aggregating mechanism of majority voting. From the above-mentioned second example, we can see the late simple aggregation of the verification labels is not enough for the binary classification problem. A more finegrained verification and integration of intermediate reasoning steps of CoT is needed to tackle the inconsistency problem further.

6 Conclusion

In this paper, we have reported our self-consistent CoT system for the SemEval-2024 Task 2: Safe Biomedical Natural Language Inference for Clinical Trials. For comparison, we also reported the label-only greedy and CoT greedy inference systems. To achieve a trustworthy inference system, we utilized the CoT reasoning paradigm, not only predicting the verification labels but also rationales. We tackled CoT's inconsistency problem with self-consistent CoT. Compared to the greedy CoT system, we have improved the inference performance by generating multiple reasoning chains and verifying with majority voting. However, the performance improvement is limited. For future work, a more fine-grained evaluation of the correctness of the reasoning steps in the CoT paradigm is promising for solving complex reasoning tasks.

A Prompts

A.1 Instruction prompt for GPT-4

Figure 3 shows an instruction example for GPT-4 to verify the statements in the train and validation datasets with CoT.

<s>[INST] **Primary clinical trial report**:
Adverse Events 1: Total: 12/32 (37.50%) Anaemia 0/32 (0.00%) Neutropenia 1/32 (3.13%) Thrombocytopenia 4/32 (12.50%) Atrial fibrillation 1/32 (3.13%) Cardiac failure congestive 1/32 (3.13%) Myocardial ischaemia 1/32 (3.13%) Abdominal discomfort 0/32 (0.00%) Ascites 1/32 (3.13%) Constipation 0/32 (0.00%) Rectal haemorrhage 1/32 (3.13%) Vomiting 1/32 (3.13%) Fatigue 1/32 (3.13%) Adverse Events 2: Total: 8/20 (40.00%) Anaemia 1/20 (5.00%) Neutropenia 0/20 (0.00%) Thrombocytopenia 1/20 (5.00%) Atrial fibrillation 0/20 (0.00%) Cardiac failure congestive 0/20 (0.00%) Myocardial ischaemia 0/20 (0.00%) Abdominal discomfort 1/20 (5.00%) Ascites 0/20 (0.00%) Constipation 2/20 (10.00%) Rectal haemorrhage 0/20 (0.00%) Vomiting 0/20 (0.00%) Fatigue 0/20 (0.00%)
Statement: Most of the cases of CHF in the primary trial, were in cohort 1.
Verify whether the statement is entailed in the primary clinical trial report with Entailment or Contradiction. [/INST]
Let's verify it step by step:

Figure 3: Example prompt for GPT-4

A.2 Example for CoT instruction-tuning dataset

Figure 4 shows an example of CoT instruction-tuning dataset. The rationales in CoT are generated by GPT-4 and we add the final verification label to CoT for convenience by extracting the labels.

A.3 Example for label-only instruction-tuning dataset

Figure 5 shows an example of the label-only instruction-tuning dataset, where only the gold label is appended to the (premise, statement) pair without CoT rationales.

B Implementation Details

B.1 Instruction-Tuning

For the instruction-tuning, we have applied PyTorch Fully Sharded Data Parallel (FSDP) from Meta AI (Zhao et al., 2023). The training script is adapted based on llama-recipes[3]. We train Mixtral-8x7B-Instruct on a cluster with 16 A100-40GB GPUs with a batch size of 1 and a learning rate of 0.0001. Mixed precision and gradient checkpointing have been applied to save memory. Evaluated on the validation dataset, the model achieves the best performance with 5 epochs. Following Kanakarajan and Sankarasubbu (2023), we include the validation set as part of the training data for the final submission.

<s>[INST] **Primary clinical trial report**:
Adverse Events 1: Total: 12/32 (37.50%) Anaemia 0/32 (0.00%) Neutropenia 1/32 (3.13%) Thrombocytopenia 4/32 (12.50%) Atrial fibrillation 1/32 (3.13%) Cardiac failure congestive 1/32 (3.13%) Myocardial ischaemia 1/32 (3.13%) Abdominal discomfort 0/32 (0.00%) Ascites 1/32 (3.13%) Constipation 0/32 (0.00%) Rectal haemorrhage 1/32 (3.13%) Vomiting 1/32 (3.13%) Fatigue 1/32 (3.13%) Adverse Events 2: Total: 8/20 (40.00%) Anaemia 1/20 (5.00%) Neutropenia 0/20 (0.00%) Thrombocytopenia 1/20 (5.00%) Atrial fibrillation 0/20 (0.00%) Cardiac failure congestive 0/20 (0.00%) Myocardial ischaemia 0/20 (0.00%) Abdominal discomfort 1/20 (5.00%) Ascites 0/20 (0.00%) Constipation 2/20 (10.00%) Rectal haemorrhage 0/20 (0.00%) Vomiting 0/20 (0.00%) Fatigue 0/20 (0.00%)
Statement: Most of the cases of CHF in the primary trial, were in cohort 1.
Verify whether the statement is entailed in the primary clinical trial report with Entailment or Contradiction. [/INST]
Let's verify it step by step: The statement refers to cases of Cardiac Heart Failure (CHF) in the primary trial. Looking at the data from the primary clinical trial report, we can see that in Adverse Events 1 (cohort 1), there was 1 case of Cardiac failure congestive out of 32 participants, which is 3.13%. In Adverse Events 2 (cohort 2), there were 0 cases of Cardiac failure congestive out of 20 participants, which is 0.00%.
Therefore, the statement "Most of the cases of CHF in the primary trial, were in cohort 1" is Entailed in the primary clinical trial report.
Verification: Entailment </s>

Figure 4: An example of CoT instruction-tuning dataset

B.2 Model Inference

We use the transformers[4] library to generate responses with instruction-tuned models. There are two setups for generation, greedy decoding and temperature sampling. Under temperature sampling, we set $T = 0.7$ and $k = 50$ in top-k. For each pair, we set `num_return_sequence` as 10. Occasionally, there are duplicates in the returned sequences. If the result is tied with majority voting, we further generate reasoning chains with different seeds. The maximum number of generated chains for one pair is 25. Table 5 shows the distribution for numbers of generated distinct reasoning chains in the test dataset. On average, we generate 10.36 reasoning chains for each pair in the test dataset.

Figure 6 shows an example where CoT greedy has wrong verification while self-consistent CoT has correct verification with majority voting. Figure 7 shows an example where both CoT greedy and self-consistent CoT have wrong verification.

<s>[INST] **Primary clinical trial report**: INTERVENTION 1: Arm 1 Herceptin/navelbine INTERVENTION 2: Arm 2 Taxotere/carboplatin/herceptin
Statement: only one arm of the primary clinical trial makes use of trastuzumab as part of its intervention
Verify whether the statement is entailed in the primary clinical trial report with Entailment or Contradiction. [/INST]
Let's verify it step by step:

Gold Label: Contradiction

CoT Greedy:
The statement mentions that only one arm of the primary clinical trial makes use of trastuzumab as part of its intervention. In the clinical trial report, Herceptin is mentioned in both Intervention 1 and Intervention 2. Herceptin is a brand name for trastuzumab, a monoclonal antibody used to treat certain types of breast cancer. Therefore, the statement is Entailed in the primary clinical trial report.
Verification: Entailment

Self-consistent CoT
Generation 1:
The statement mentions that only one arm of the primary clinical trial makes use of trastuzumab as part of its intervention. Trastuzumab is a monoclonal antibody used to treat certain types of breast cancer. It is also known by its brand name, Herceptin. In the primary clinical trial report, Herceptin is mentioned in both Intervention 1 (Arm 1) and Intervention 2 (Arm 2). Therefore, both arms of the trial are using trastuzumab (Herceptin) in their interventions. So, the statement is a Contradiction to the information provided in the primary clinical trial report.
Verification: Contradiction
Generation 2:
The statement mentions that only one arm of the primary clinical trial makes use of trastuzumab as part of its intervention. Looking at the clinical trial report, we can see that Herceptin is used in both arms of the trial. Herceptin is a brand name for trastuzumab, a medication used to treat certain types of breast cancer. Therefore, the statement is a Contradiction because both arms of the trial use trastuzumab, not just one.
Verification: Contradiction
Generation 3:
The statement mentions that only one arm of the primary clinical trial makes use of trastuzumab as part of its intervention. Trastuzumab is the generic name for Herceptin. Looking at the clinical trial report, we see that Herceptin is indeed used in both interventions. In Intervention 1, Herceptin is used in combination with navelbine. In Intervention 2, Herceptin is used in combination with Taxotere and carboplatin. Therefore, the statement contradicts the information given in the primary clinical trial report. The correct answer is Contradiction.
Verification: Contradiction
Generation 4:
The statement mentions that only one arm of the primary clinical trial makes use of trastuzumab as part of its intervention. In the clinical trial report, Herceptin is mentioned in both Intervention 1 and Intervention 2. Herceptin is a brand name for trastuzumab, a monoclonal antibody used to treat certain types of breast cancer. Therefore, the statement is Entailed in the primary clinical trial report.
Verification: Entailment
Generation 5:
The clinical trial report mentions two interventions. In Intervention 1 (Arm 1), Herceptin is mentioned. Herceptin is a brand name for the drug trastuzumab. In Intervention 2 (Arm 2), there is no mention of Herceptin or trastuzumab. Therefore, the statement "only one arm of the primary clinical trial makes use of trastuzumab as part of its intervention" is Entailed in the primary clinical trial report. Verification: Entailment
.....

Figure 6: An example of self-consistent CoT successfully corrects the error in CoT greedy verification. We only show 5 generations of self-consistent CoT. The ratio of 10 self-consistent CoT generations is 8 Contradictions: 2 Entailments.

<s>[INST] **Primary clinical trial report**: Adverse Events 1: Total: 10/30 (33.33%) Hemoglobin decreased 2/30 (6.67%) Abdominal pain 1/30 (3.33%) Colitis 1/30 (3.33%) Diarrhea 7/30 (23.33%) Nausea 2/30 (6.67%) Rectal hemorrhage 1/30 (3.33%) Fatigue 1/30 (3.33%) Skin infection 1/30 (3.33%) Neutrophil count decreased 1/30 (3.33%) Platelet count decreased 3/30 (10.00%) Dehydration 1/30 (3.33%)
Secondary clinical trial report: Adverse Events 1: Total: 3/6 (50.00%) Anaemia 0/6 (0.00%) Febrile neutropenia 0/6 (0.00%) Neutropenia 0/6 (0.00%) Bradycardia 0/6 (0.00%) Diarrhoea 0/6 (0.00%) Pancreatitis 0/6 (0.00%) Vomiting 0/6 (0.00%) Disease progression 0/6 (0.00%) Fatigue 0/6 (0.00%) Pyrexia 0/6 (0.00%) Cholelithiasis 0/6 (0.00%) Hepatic pain 0/6 (0.00%) Bacteraemia 0/6 (0.00%) Adverse Events 2: Total: 3/6 (50.00%) Anaemia 0/6 (0.00%) Febrile neutropenia 0/6 (0.00%) Neutropenia 1/6 (16.67%) Bradycardia 0/6 (0.00%) Diarrhoea 0/6 (0.00%) Pancreatitis 0/6 (0.00%) Vomiting 0/6 (0.00%) Disease progression 0/6 (0.00%) Fatigue 1/6 (16.67%) Pyrexia 1/6 (16.67%) Cholelithiasis 0/6 (0.00%) Hepatic pain 1/6 (16.67%) Bacteraemia 0/6 (0.00%)
Statement: diarrhoea was uncommon among the primary trial participants compared to the secondary trial participants
Verify whether the statement is entailed in the clinical trial reports with Entailment or Contradiction. [/INST]
Let's verify it step by step:

Gold Label: Contradiction

CoT Greedy:
In the primary clinical trial report, the occurrence of diarrhea is 7/30 (23.33%). In the secondary clinical trial report, the occurrence of diarrhea is 0/6 (0.00%) in both Adverse Events 1 and Adverse Events 2. Therefore, the statement "diarrhoea was uncommon among the primary trial participants compared to the secondary trial participants" is Entailed in the clinical trial reports.
Verification: Entailment

Self-consistent CoT
Generation 1:
The statement claims that diarrhoea was uncommon among the primary trial participants compared to the secondary trial participants. Looking at the primary clinical trial report, it shows that the incidence of diarrhoea was 7 out of 30 participants, which is approximately 23.33%. In the secondary clinical trial report, the incidence of diarrhoea is 0 out of 6 participants in both Adverse Events 1 and Adverse Events 2, which is approximately 0.00%. Comparing these two reports, it is clear that diarrhoea was indeed more common in the primary trial participants than in the secondary trial participants. Therefore, the statement is a Contradiction to the information provided in the clinical trial reports.
Verification: Contradiction
Generation 2:
The statement says that diarrhoea was uncommon among the primary trial participants compared to the secondary trial participants. Looking at the primary clinical trial report, Diarrhea was reported in 7 out of 30 participants, which is approximately 23.33%. In the secondary clinical trial report, Diarrhoea was reported in 0 out of 6 participants in both Adverse Events 1 and Adverse Events 2, which is 0%. Comparing these two, it is clear that Diarrhoea was indeed more common in the primary trial participants than in the secondary trial participants. Therefore, the statement is a Contradiction to the information provided in the clinical trial reports.
Verification: Contradiction
Generation 3:
In the primary clinical trial report, the incidence of diarrhea was 7/30 (23.33%). In the secondary clinical trial report, the incidence of diarrhoea was 0/6 (0.00%) for both Adverse Events 1 and Adverse Events 2. Therefore, the statement "diarrhoea was uncommon among the primary trial participants compared to the secondary trial participants" is Entailed in the clinical trial reports.
Verification: Entailment
Generation 4:
In the primary clinical trial report, the occurrence of diarrhea is reported as 7/30 (23.33%). In the secondary clinical trial report, the occurrence of diarrhea is reported as 0/6 (0.00%) in both Adverse Events 1 and Adverse Events 2. Therefore, the statement "diarrhoea was uncommon among the primary trial participants compared to the secondary trial participants" is Entailed in the clinical trial reports.
Verification: Entailment
Generation 5:
In the primary clinical trial report, Diarrhea is reported in 7 out of 30 participants, which is approximately 23.33%. In the secondary clinical trial report, Diarrhoea is reported in 0 out of 6 participants in both Adverse Events 1 and Adverse Events 2, which is 0.00%. Therefore, the statement "diarrhoea was uncommon among the primary trial participants compared to the secondary trial participants" is Entailed in the clinical trial reports.
Verification: Entailment
.....

Figure 7: An example of self-consistent CoT fails to correct the error in CoT greedy verification. We only show 5 generations of self-consistent CoT. The ratio of 10 self-consistent CoT generations is 7 Entailments: 3 Contradictions.

Lisbon Computational Linguists at SemEval-2024 Task 2: Using A Mistral-7B Model and Data Augmentation

Abstract

This paper describes our approach to the SemEval-2024 safe biomedical Natural Language Inference for Clinical Trials (NLI4CT) task, which concerns classifying statements about Clinical Trial Reports (CTRs). We explored the capabilities of Mistral-7B, a generalist open-source Large Language Model (LLM). We developed a prompt for the NLI4CT task, and fine-tuned a quantized version of the model using an augmented version of the training dataset. The experimental results show that this approach can produce notable results in terms of the macro F1-score, while having limitations in terms of faithfulness and consistency. All the developed code is publicly available on a GitHub repository[1].

1 Introduction

Large Language Models (LLMs) currently achieve state-of-the-art performance on different Natural Language Processing (NLP) tasks, including in the assessment of textual entailment relations. However, these models are heavily susceptible to shortcut learning (Du et al., 2023), factual inconsistency (Xie et al., 2023), and performance degradation when exposed to data from specialized domains, such as in the case of medical data.

Noting the aforementioned challenges, Task 2 at SemEval-2024 addressed a safe biomedical Natural Language Inference for Clinical Trials (NLI4CT) task (Jullien et al., 2024), which concerns classifying statements about Clinical Trial Reports (CTRs). NLI4CT investigated the accuracy, faithfulness, and consistency of the reasoning performed by LLMs in this particular medical task. The goal of the task is to determine whether there is an entailment relation or a contradiction relation between CTRs and statements, making some type of claim about a single CTR or a pair of CTRs. Given the specific focus on assessing model faithfulness and consistency (i.e., the ability to make correct predictions for the correct reasons), the dataset associated to the task involved the systematic application of controlled interventions, either preserving or inverting the entailment relations originally generated by clinical domain experts. This way, the task investigated the robustness of NLI models in their representation of the semantic phenomena necessary for complex inference in clinical settings.

Our approach to the NLI4CT task involved the use of open-source LLMs, with good results in general purpose benchmarks[2] and capable of following task instructions. We opted for `Mistral-7B-Instruct-v0.2`[3] (Jiang et al., 2023), quantizing the model to 4-bits and simultaneously using Low-Rank Adaptation (LoRA) (Hu et al., 2021; Dettmers et al., 2023) to fine-tune the model to the NLI4CT task, using a slightly augmented version of the training dataset that features a mixture of manually curated and synthetic statements.

Our overall best submission to the task achieved a **macro F1-score** of 0.80 (1st place on the leaderboard), a **consistency** score of 0.72 (15th), and a **faithfulness** score of 0.83 (11th). Our method excels in classification accuracy, but fails at being robust to perturbations on the statements, i.e. predicting the same label on contradictory examples and different labels on paraphrased examples.

2 Background

The NLI4CT task concerns inferring if statements can be entailed by a given textual context, with each statement referring to one or two CTRs. These CTRs belong to a corpus consisting of 1000 different trials concerning breast cancer, extracted from

Set	# Samples	Single - Compari.	Entail. - Contr.
Training	1700	60.9% - 39.1%	50% - 50%
Development	200	70% - 30%	50% - 50%
Pratice-test	2142	71.2% - 28.8%	34.1% - 65.9%
Test	5500	46.4% - 53.6%	33.5% - 66.5%

Table 1: The NLI4CT task dataset.

Set	# Interventions	Preserving - Altering (Label)
Pratice-test	1942 (90.7%)	82.7% - 27.3%
Test	5000 (90.9%)	82.7% - 27.3%

Table 2: Interventions over statements on the test splits.

the United States National Library of Medicine[4]. These trial reports are exclusively written in the English language and average 817 words in length.

CTRs are divided into four sections: **Eligibility Criteria**, describing a set of conditions to allow or exclude patients in the trial; **Interventions**, detailing all information about the conducted treatments; **Results**, outlining outcomes and experimental results gathered through the trial; and **Adverse Events**, reporting patient observations concerning symptoms and physiological signs. An instance of the NLI4CT dataset contains either one or two CTRs (i.e., cases denoted as single or comparison, respectively), a statement, a section marker, and a ground-truth label (i.e., entailment or contradiction). An example is shown next.

Listing 1 An instance from the NLI4CT dataset.

`Primary Trial:`
INTERVENTION 1:
• Letrozole, Breast Enhancement, Safety.
• Single arm of healthy postmenopausal women to have two breast MRI (baseline and post-treatment). Letrozole of 12.5 mg/day is given for three successive days just prior to the second MRI.

`Secondary Trial:`
INTERVENTION 1:
• FFDM Mammography Exam - LIP Algorithm
• Screening or diagnostic Full Field Digital Mammography (FFDM) exam
INTERVENTION 2:
• FFDM Mammography Exam - SIP Algorithm.
• The same 130 raw data images were externally reprocessed with the Siemens processing algorithm.

`Section:` Intervention
`Statement:` The primary trial and the secondary trial both used MRI for their interventions.
`Label:` Entailment.

The dataset[5] provided by the task organizers considered training, development, practice-test, and test splits (the last two without ground-truth labels during the competition), with a general statistical characterization provided in Table 1.

The first two splits, i.e. training and development, are similar to those used in the SemEval-2023 edition of the task (Jullien et al., 2023b), based on the work by Jullien et al. (2023a). These are two balanced sets, with mostly unique CTR-statement associations (i.e., statements that are not rephrasing or contradicting other ones). On the other hand, this composition contrasts with the practice-test and test splits, that are both imbalanced and almost solely composed of statements featuring interventions (e.g., paraphrasing, contradicting, or appending text) over a small set of original statements (< 10%), as show in Table 2. This distribution favours systems that focus on robustly classifying a small set of samples.

3 System Overview

We now describe our general approach to the SemEval-2024 NLI4CT task.

3.1 Choice of LLM

When deciding on how to build our NLI4CT system, we started by testing the zero-shot and few-shot capabilities of several open-source LLMs, before settling on the use of `Mistral-7B-Instruct-v0.2`. In addition to achieving good zero-shot results, this model also allowed us to process arbitrarily long input texts, which in this task is particularly relevant, since some CTRs can exceed 3000 tokens in length.

3.2 Model Prompting

A great deal of attention is currently given to prompting techniques, as the successful use of an LLM can be severely impaired by suboptimal prompts, and also since instruction fine-tuning (Chowdhery et al., 2022; Chung et al., 2022) is dependant on the prompt quality. In order to address the task of choosing a good prompt, we started by creating a prompt template that we deemed as suitable for the task at hand, sub-dividing our prompt into distinct parts (pre-pended with "$") that can latter be replaced with different textual realizations. The overall structure is illustrated next.

[4] https://clinicaltrials.gov/
[5] https://github.com/ai-systems/Task-2-SemEval-2024/blob/main/README.md

Listing 2 Overall prompt structure.

```
$task_description
$ctr_description

Primary Trial:
$primary_evidence

Secondary Trial:
$secondary_evidence

$statement_description
$statement

$option_description
```

Four of the parts are **sample independent**: `$task_description` provides a general description for the natural language inference task between CTRs and statements; `$ctr_description` delineates the general contents of a CTR and its different sections; `$statement_description` conveys the nature of the $statement; and lastly `$option_description` outlines the answers we expect from the model (e.g., an answer of YES or NO, depending on whether the CTR supports the statement). Conversely, `$primary_evidence`, `$secondary_evidence`, and `$statement` are **sample dependent**, as these parts should be replaced by the primary CTR, the secondary CTR (if applicable), and the statement, respectively.

We created 5 base prompts (see Appendix A.1) for each of the 4 sample independent parts, yielding 625 possible combinations for the general template. We evaluated all the combinations on the development set, and chose the prompt that yielded the top **macro F1-score**, which is shown in Listing 3.

3.3 Generating Answers

With the aforementioned template, we used the Python HuggingFace Transformers library[6] to generate answers with `Mistral-7B-Instruct-v0.2`, using as parameters `do_sample=True`, `top_k=5`, and `max_new_tokens=30`. We opted not to constrain the generation process, instead looking for sets of words, associated to each label, in the sequence of generated tokens. The words "Yes", "yes", and "entailment" were used for the entailment class, while the words "No", "no" and "contradiction" were used for the contradiction class. Preference was given to the first token in the sequence that belongs to either of the sets, and if none were found we label the instance as entailment.

[6] https://huggingface.co/docs/transformers/en/index

Listing 3 The best performing prompt.

<s>[INST]The objective is to examine semantic entailment relationships between individual sections of Clinical Trial Reports (CTRs) and statements articulated by clinical domain experts. CTRs elaborate on the procedures and findings of clinical trials, scrutinizing the effectiveness and safety of novel treatments. Each trial involves cohorts or arms exposed to distinct treatments or exhibiting diverse baseline characteristics.
Comprehensive CTRs comprise four sections: (1) ELIGIBILITY CRITERIA delineating conditions for patient inclusion, (2) INTERVENTION particulars specifying type, dosage, frequency, and duration of treatments, (3) RESULTS summary encompassing participant statistics, outcome measures, units, and conclusions, and (4) ADVERSE EVENTS cataloging signs and symptoms observed. Statements posit claims regarding the information within these sections, either for a single CTR or in comparative analysis of two. To establish entailment, the statement's assertion should harmonize with clinical trial data, find substantiation in the CTR, and avoid contradiction with the provided descriptions.
The following descriptions correspond to the information in one of the Clinical Trial Report (CTR) sections.

Primary Trial:
$primary_evidence

Secondary Trial:
$secondary_evidence

Reflect upon the ensuing statement crafted by an expert in clinical trials.
$statement
Respond with either YES or NO to indicate whether it is possible to determine the statement's validity based on the Clinical Trial Report (CTR) information, with the statement being supported by the CTR data and not contradicting the provided descriptions.[/INST] **Answer:**

3.4 Data Augmentation

The NLI4CT dataset features 1700 training instances and 200 development instances, which is perhaps insufficient for fine-tuning an LLM in order to generalize to a testing split that is almost thrice as large. We decided to augment the available data, and created the 3 different training splits outlined in Table 3.

Set	# Samples	Single - Compari.	Entail. - Contr.
Train_Manual	2344	61.8% - 38.2%	50% - 50%
Train_Manual-Synthetic	3720	63.7% - 36.3%	50% - 50%
Train_Full-Synthetic	11011	60.9% - 39.1%	46.3% - 53.7%

Table 3: Results from task data augmentation.

The three new sets were constructed as follows:

- **Train_Manual:** Starting from the train split, we added queries created by using pre-existing samples with the entailment class, negating them using the Python negate li-

brary[7] (i.e., to generate corresponding contradiction examples), and also manually paraphrasing the original instance (i.e., to generate different entailment samples). All 644 additional samples that were generated through this procedure were manually curated;

- **Train_Manual-Synthetic:** starting from the **Train_Manual** dataset, we added 1376 new automatically generated instances to this set: half of the new instances were generated with the negate library, and the other half were generated by paraphrasing existing statements using the `Mistral-7B-Instruct-v0.2` model;

- **Train_Full-Synthetic:** Starting from the train split, we added 9311 new samples, using the negate library on entailment instances, and the `Mistral-7B-Instruct-v0.2` model to paraphrase each original statement 5 times.

3.5 Instruction Fine-tuning

Noting that `Mistral-7B-Instruct-v0.2` is a generalist instruction fine-tuned model, we sought to fine-tune this LLM to the NLI4CT task, using the aforementioned instructions. To improve the training efficiency and support very long sequences (i.e., up to 6000 tokens), we quantized the model to 4-bit representations of the parameters, and used LoRA (Hu et al., 2021). Model training used a supervised fine-tuning objective based on auto-regressive language modelling, completing the input instruction with the correct label for each instance (i.e., outputting either "Yes" or "No" after "Answer:" in the prompt). The implementation relied on the PEFT[8] and TRL[9] Python libraries.

4 Experimental Setup

Making official submissions to the task leaderboard required the participants to submit full runs of the test set, outputting a label for each of its instances. We obtained the labels for each instance by following the procedure described in Subsection 3.3.

The task uses the following evaluation measures: **macro F1-score**, i.e. the arithmetic mean of precision and recall, averaged over the two classes; **Faithfulness**, i.e. a measure created to assess the capacity of model to arrive at the correct prediction for the correct reason, calculated by measuring the ability of model to change its prediction label after semantically altering a statement; and **Consistency**, which completes faithfulness by measuring the ability of a model in outputting the same prediction for semantically equivalent statements[10]. We evaluated our runs using the official metrics obtained from the leaderboard.

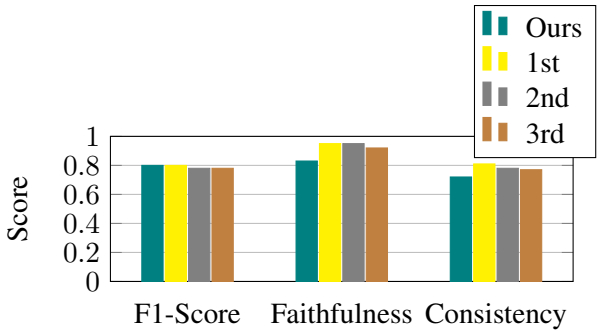

Figure 1: Comparison of top submissions against our system, according to different evaluation metrics.

Following the training procedure described in Section 3.5, we tested different combinations of training data (as described in Section 3.4). The full set of hyper-parameters associated to our best run can be found in Appendix A.2. All the different runs used Python libraries and packages that can be found in our GitHub repository[11].

5 Results and Discussion

Table 4 presents our most important results, showing the best result that we achieved with each training set. In turn, Figure 1 compares our overall best run with the top three submissions, per metric.

Trained Sets	F1-Score	Faithfulness	Consistency
None (Zero-Shot)	0.67 (3)	0.61 (8)	0.53 (8)
Train	0.81 (2)	0.72 (3)	0.69 (2)
Train_Manual	**0.82 (9)**	0.76 (9)	0.71 (9)
Train_Manual-Synthetic	0.80 (1)	**0.83 (1)**	**0.72 (2)**
Train_Full-Synthetic	0.78 (1)	0.78 (0)	0.71 (0)

Table 4: Results on different training datasets.

We tested the LLM without any training (i.e., zero-shot results), and fine-tuning with the base and augment datasets, all with our best instruction format. As expected, there is a significant difference in performance towards fine-tuned models. Overall, a mixture between manually curated sam-

[7] https://github.com/dmlls/negate
[8] https://huggingface.co/docs/peft/en/index
[9] https://huggingface.co/docs/trl/en/index
[10] https://github.com/ai-systems/Task-2-SemEval-2024/blob/main/evaluate.py
[11] https://github.com/araag2/SemEval2024-Task2/blob/main/environment.yml

ples and synthetically generated ones performed best (Train_Manual-Synthetic, as described on Section 4), outperforming the best run that did not use any data augmentation. If more instances could have been manually curated, specifically targeting adversarial re-writes of the same statements, we hypothesize that results could be improved further. Even though **Train_Full-Synthetic** corresponds to the largest training set (i.e., featuring 11011 samples), the lack of quality in the automatically generated statements potentially impaired the **F1-score** while also limiting **consistency** and **faithfulness**.

The run trained with **Train_Manual-Synthetic** corresponds to our best overall result. When compared to the top submissions, we can see that our F1-score corresponds to a tie with another system in the 1st place of the leaderboard. However, results are much worse in the other two metrics, with significant differences between the top systems (i.e., with scores of 0.95 in faithfulness and 0.81 in consistency) and our submission.

In the post-task phase of the competition, ground-truth labels for all examples were released, specifying which type of interventions were made in each instance. Therefore, we are now able to analyse our system's errors (see Table 5), to support a discussion on the main short-comings of our work.

Type of Error	# Occurrences / # Total Samples
Base Statement Errors	99 / 500 (19.8%)
Intervention Errors	1328 / 5000 (26.7%)
Total Errors	1427 / 5500 (25.9%)
Label Preserving Intervention Errors	1177 / 1328 (88.6%)
Label Altering Intervention Errors	151 / 1328 (11.4%)
Paraphrasing Errors	344 / 1500 (22.9%)
Text Appending Errors	609 / 1500 (40.6%)
Contradicting Errors	293 / 1500 (19.5%)
Numerical Paraphrasing Errors	58 / 224 (25.9%)
Numerical Contradicting Errors	24 / 276 (8.7%)

Table 5: Error analysis for our best overall run, categorizing errors by intervention types.

Comparing all errors across the different instance types, the average error rate is much higher on intervention errors (26.7%) against base statement errors (19.8%), which is to be expected as our training sets had fewer examples of this type. Specifically, we can see that label preserving interventions (88.6%) have a high percentage of errors. Our system can identify instances which suffered contradictory interventions with an error rate of 19.5% for textual changes, and 8.7% for numerical changes. Instances that were perturbed with paraphrasing cause an error rate of 22.9%, while numerical paraphrasing errors correspond to 25.9%. At the worst end we have the samples with text appended to the end, which causes an error rate of 40.6%. Note that we did did not explicitly augment the training instances by appending text to the existing statements, and the absence of examples like this was very costly in terms of the final results.

6 Conclusions

Adapting evaluation methodologies to better inform the safe deployment of LLMs in critical domains is an urgent necessity. The NLI4CT task at SemEval-2024 addressed this specific concern, and through our participation we improved our understanding on how LLMs can be fine-tuned to encompass robust results on clinical natural language inference. Overall, our results show that the simple fine-tuning of an open-source LLM to this specific task can achieve notable results in terms of the macro-averaged F1, although with limitations in terms of faithfulness and consistency. Augmenting the data with high-quality curated examples can improve result quality, although augmenting the training set with synthetic examples requires careful quality control.

For future work we would like to explore the following ideas:

- Test our general approach with different models, specifically considering models fine-tuned in the medical domain (e.g., models like `qCammel-70-x`[12] or `BioMistral`[13]);
- Refining the considered prompt through recently-proposed prompt optimization methods (Wen et al., 2023; Guo et al., 2023), instead of relying on manually curated prompts;
- Incorporating additional training data, e.g. by generating a more diverse set of instances from the CTR data made available in the context of other shared tasks (e.g., the CTR data from the Text Retrieval Conference (TREC) clinical trials track[14]);
- Carefully curating a new training set, with a focus on statement interventions rather than quantity of base statements, in order to better guide the model into understanding the nuances of textual and numerical paraphrasing/contradiction.

A Appendix

We now present additional details about the prompt considered for instructing the `Mistral-7B-Instruct-v0.2` model, and about the hyper-parameters considered for model fine-tuning.

A.1 Base Descriptions For Each Prompt Part

This section presents the five different alternatives that were considered for the different parts of the `Mistral-7B-Instruct-v0.2` prompt.

A.1.1 Task Description Part

1 : Consider the task of determining semantic entailment relations between individual sections of Clinical Trial Reports (CTRs) and statements made by clinical domain experts. Note that CTRs outline the methodology and findings of a clinical trial, which are conducted to assess the effectiveness and safety of new treatments. Each trial involves 1-2 patient groups, called cohorts or arms, and these groups may receive different treatments, or have different baseline characteristics. The complete CTRs contain 4 sections, corresponding to (1) a list of the ELIGIBILITY CRITERIA corresponding to the conditions for patients to be allowed to take part in the clinical trial, (2) a description for the INTERVENTION that specifies the type, dosage, frequency, and duration of treatments being studied, (3) a summary of the RESULTS, detailing aspects such as the number of participants in the trial, the outcome measures, the units, and the conclusions, and (4) a list of ADVERSE EVENTS corresponding to signs and symptoms observed in patients during the clinical trial. In turn, the statements are sentences that make some type of claim about the information contained in one of the aforementioned sections, either considering a single CTR or comparing two CTRs. In order for the entailment relationship to be established, the claim in the statement should be related to the clinical trial information, it should be supported by the CTR, and it must not contradict the provided descriptions.

2 : You are tasked with determining support relationships between individual sections of Clinical Trial Reports (CTRs) and clinical statements. CTRs detail the methodology and findings of clinical trials, assessing effectiveness and safety of new treatments. CTRs consist of 4 sections: (1) ELIGIBILITY CRITERIA listing conditions for patient participation, (2) INTERVENTION description specifying type, dosage, frequency, and duration of treatments, (3) RESULTS summary detailing participants, outcome measures, units, and conclusions, and (4) ADVERSE EVENTS listing signs and symptoms observed. Statements make claims about information in these sections, either for a single CTR or comparing two.

3 : Evaluate the semantic entailment between individual sections of Clinical Trial Reports (CTRs) and statements issued by clinical domain experts. CTRs expound on the methodology and outcomes of clinical trials, appraising the efficacy and safety of new treatments. The statements, on the other hand, assert claims about the information within specific sections of CTRs, for a single CTR or comparative analysis of two. For entailment validation, the statement's claim should align with clinical trial information, find support in the CTR, and refrain from contradicting provided descriptions.

4 : The objective is to examine semantic entailment relationships between individual sections of Clinical Trial Reports (CTRs) and statements articulated by clinical domain experts. CTRs elaborate on the procedures and findings of clinical trials, scrutinizing the effectiveness and safety of novel treatments. Each trial involves cohorts or arms exposed to distinct treatments or exhibiting diverse baseline characteristics. Comprehensive CTRs comprise four sections: (1) ELIGIBILITY CRITERIA delineating conditions for patient inclusion, (2) INTERVENTION particulars specifying type, dosage, frequency, and duration of treatments, (3) RESULTS summary encompassing participant statistics, outcome measures, units, and conclusions, and (4) ADVERSE EVENTS cataloging signs and symptoms observed. Statements posit claims regarding the information within these sections, either for a single CTR or in comparative analysis of two. To establish entailment, the statement's assertion should harmonize with clinical trial data, find substantiation in the CTR, and avoid contradiction with the provided descriptions.

5 : Consider the problem of assessing semantic entailment connections between distinct sections of Clinical Trial Reports (CTRs) and statements put forth by clinical domain experts. To establish entailment, the statement's assertion should be supported from the CTR, not contradicting the provided descriptions. In brief, CTRs elucidate the procedures and findings of clinical trials, evaluating the efficacy and safety of emerging treatments. Complete CTRs encompass four sections: (1) ELIGIBILITY CRITERIA specifying conditions for patient inclusion, (2) INTERVENTION details on the type, dosage, frequency, and duration of treatments, (3) RESULTS summarizing the participant statistics, outcome measures, units, and conclusions, and (4) ADVERSE EVENTS listing observed signs and symptoms. Statements advance claims about the information within these sections, either for a single CTR or in a comparative analysis of two CTRs.

A.1.2 CTR Description Part

1 : The following descriptions correspond to the information in one of the Clinical Trial Report (CTR) sections.

2 : The provided descriptions coincide with the content in a specific section of Clinical Trial Reports (CTRs), detailing relevant information to the trial.

3 : The provided descriptions correspond to the content found in one of the four standard clinical trial report sections.

4 : The provided descriptions pertain to the contents found within one of the sections of Clinical Trial Reports (CTRs).

5 : The descriptions that follow correspond to the information contained in one of the standard sections of the clinical trial reports.

A.1.3 Statement Description Part

1 : Consider also the following statement generated by a clinical domain expert, a clinical trial organizer, or a medical researcher.

2 : Contemplate the ensuing statement formulated by a clinical expert or researcher.

3 : Review the subsequent statement provided by an expert in clinical trials, attending to the medical terminology and carefully addressing any ambiguities.

4 : Deliberate upon the subsequent statement formulated by an healthcare practitioner, a coordinator of clinical trials, or a medical researcher.

5 : Reflect upon the ensuing statement crafted by an expert in clinical trials.

A.1.4 Option Description Part

1 : Answer YES or NO to the question of whether one can conclude the validity of the statement with basis on the clinical trial report information.

2 : Indicate with either YES or NO whether it is possible to determine the validity of the statement based on the Clinical Trial Report (CTR) descriptions. An answer of YES means that the statement is supported by the CTR descriptions, not contradicting the provided information.

3 : Provide a YES or NO response indicating if it's possible to assess the statement's validity based on the information presented in the clinical trial report descriptions. Do this by interpreting the medical terminology and the context in both the report and the statement, carefully addressing any ambiguities or gaps in the provided information.

4 : Respond with either YES or NO to indicate whether it is possible to determine the statement's validity based on the Clinical Trial Report (CTR) information, with the statement being supported by the CTR data and not contradicting the provided descriptions.

5 : Indicate with a YES or NO response whether it is possible to assess the statement's validity based on the clinical trial report data.

A.2 Full List of Hyper-Parameters

The full list of hyper-parameters considered for model fine-tuning can be seen in the source-code in our GitHub repository[15].

The chosen parameters concerning model quantization options are as follows.

```
load_in_4bit = True
bnb_4bit_quant_type = "nf4"
bnb_4bit_compute_dtype = torch.bfloat16
bnb_4bit_use_double_quant = False
```

The parameters concerning the use of Low-Rank Adaptation (LoRA) are as follows.

[15] https://github.com/araag2/SemEval2024-Task2/blob/main/finetune_Mistral.py

```
lora_r = 64
lora_dropout = 0.1
lora_alpha = 16
bias = "none"
```

Finally, the general model training hyper-parameters are as follows.

```
train_epochs = 5
batch_size = 2
gradient_accumulation_steps = 4
learning_rate = 2e-5
pooling = "mean"
max_sequence_length = 6000
```

GIL-IIMAS UNAM at SemEval-2024 Task 1: SAND: An In Depth Analysis of Semantic Relatedness Using Regression and Similarity Characteristics.

Abstract

The STR shared task aims at detecting the degree of semantic relatedness between sentence pairs in multiple languages. Semantic relatedness relies on elements such as topic similarity, point of view agreement, entailment, and even human intuition, making it a broader field than sentence similarity. The **GIL-IIMAS UNAM** team proposes a model based in the SAND characteristics composition (Sentence Transformers, AnglE Embeddings, N-grams, Sentence Length Difference coefficient) and classical regression algorithms. This model achieves a 0.83 Spearman Correlation score in the English test, and a 0.73 in the Spanish counterpart, finishing just above the SemEval baseline in English, and second place in Spanish.

1 Introduction

The Semantic Textual Relatedness (STR) task (Ousidhoum et al., 2024b) aims at creating systems that measure STR on pairs of sentences based on their closeness in meaning (Abdalla et al., 2023). This task is comprised of three tracks. Tracks A and B focus on monolingual models. Track A only accepts supervised models trained with the available tagged datasets, whereas track B focuses on the unsupervised approach relying on the same datasets but without the tagged score. Track C is the cross-lingual case where the target language has to follow an unsupervised approach. The datasets provided consist of sentence pairs that were sampled from various semantic similarity datasets.

This task expands upon classic sentence similarity comparisons, encouraging the use models and algorithms capable of analyzing more than meaning of a pair of sentences, focusing deeper on characteristics such as the syntactic structure of the sentences, lexicon relationships, as well as meaning and emotion. The GIL-IIMAS UNAM team participated in Track A. Although it included nine languages we have only worked with the Spanish and English dataset.

Track A is a regression problem since each dataset contains the sentence pairs as well as a corresponding sentence relatedness score that ranges from 0 to 1. The evaluation compares the ground values in the test set with the proposed model's prediction, meaning track A is evaluated using the Spearman Correlation.

This paper makes use of the SAND composition, a set of STR relevant characteristics, as well as regression algorithms trained with these characteristics in order to predict the STR score of other sentence pairs. In this paper the precise characteristics, algorithms, and parameters are presented as well as language based analysis. The final scores correspond to the best performing regression algorithm.

Our work also compares different metrics and their influence on the STR task compared to classic semantic similarity, as well as the model's varying behavior over the different languages used.

The paper is structured as follows: Section 2 explains the theories and models that are the background of our proposal. Section 3 explains the set of characteristics that have been chosen for our experiments. Section 4 explains the configuration of the data and the experimental methodology. In Section 5 we discuss the results obtained in the experiments, and compare them to the scores of other participants in the track. We close in Sec-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1288–1292

tion 6 with some conclusions and ideas for further experiments.

2 Related Work

In the field of STR, various methodologies have been proposed. One such approach, outlined by Asaadi et al. (2019), involves analyzing the relatedness between word bi-grams. They describe the construction of a dataset tailored for this purpose. To compute the STR between bi-grams, or between bi-grams and unigrams, they utilize word embeddings represented as vectors generated by GloVe, fastText, and models employing matrix factorization of word-context co-occurrence matrices. They explore various methods for composing bi-gram vectors, such as addition, multiplication, tensor product with convolution, and dilation. The relatedness between two vectors is determined by computing the cosine similarity between them.

In a study by Abdalla et al. (2023), the concept of Semantic Textual Relatedness (STR) is extended to encompass the comparison between entire sentences. The authors delineate the construction of a specialized dataset tailored for this task and show the annotation process applied to this dataset. Their investigation delves into the influence of various linguistic factors, including lexical overlap, related words, related words belonging to the same part of speech, and the relatedness of subjects or objects, on the semantic relatedness between pairs of sentences. They represent each sentence as a vector and employ cosine similarity between these vectors as a metric for predicting semantic relatedness. To facilitate this analysis, they use static word embeddings such as Word2Vec, GloVe, and fastText, as well as contextual word embeddings like BERT and RoBERTa.

3 SAND Composition

This section describes the SAND (named based on the used characteristics: **S**entence Transformers, **A**nglE Embeddings, **N**-grams, Sentence Length **D**ifference coefficient) regression system used for the task. The STR datasets are comprised of senbtence pairs and a target score, in order to train the model with task relevant information certain similarity metrics were chosen in order to create a vector of characteristics that represent each sentence pair, such vectors were used as training data for the regression algorithms. An initial approach relied on similarity metrics such as Jaccard, and Dice coefficients as well as Jaro-Winkler and Levenshtein distance, nonetheless these metrics proved to be inefficient at training the model adequately, returning poor results when evaluated with partitioned training data. After revising the dataset and the nature of the sentences in question, the initial chosen characteristics were a coefficient analyzing the length of the sentences with and without stoptwords. Consider x, y two sentences, then both coefficients are obtained from the following:

$$\text{LenCoef}(x, y) = |\frac{\text{length}(x) - \text{length}(y)}{\text{length}(x) + \text{length}(y)}| \quad (1)$$

An observation on lexical overlapping in highly related sentences led to the choice of an n-gram based coefficient. For $n \in \{1, 2, 3\}$, the n-gram coefficient is defined as:

$$\text{n-gramCoef}(x, y) = \frac{\text{n-grams}(x) \cap \text{n-grams}(y)}{\text{n-grams}(x)} \quad (2)$$

Sentence pairs in the dataset often rely on contextual similarity apart from lexical overlap when it comes to measuring relatedness, meaning the use of a pretrained model is in order. The first approach relied on the use of Sentence Transformers (ST) (Reimers and Gurevych, 2019), a siamese neural net that uses pretrained encoders in order to generate contextualized sentence embeddings. Each pair of sentences was embedded using the ST architecture and the cosine similarity of the resulting vectors was obtained as the initial pretrained characteristic. Formally speaking:

$$\text{ST}_{sim}(x, y) = \cos(\theta) = \frac{x \cdot y}{\|x\| \, \|y\|} \quad (3)$$

Nonetheless standard encoder generated embeddings have shown to be improvable, for that the final characteristic relies on similarity based on AnglE-optimized embeddings (Li and Li, 2023). These type of embeddings optimize the cosine similarity saturation zones during training using complex space embeddings so that resulting vectors achieve a higher level of similarity. Nonetheless the final comparison between AnglE vectors is done in the same manner as equation 3.

Once these characteristics are extracted from each sentence pair they are passed to various regression algorithms for training, validation and testing. For this task four regression algorithms

were used. The reported scores correspond to the best model for each language. The precise details of the implementation are presented next.

4 Experimental Setup

4.1 Data and Evaluation Methodology

We use the official dataset (Ousidhoum et al., 2024a) in English and Spanish for Task 1, track A (supervised), which is structured as follows: PairID, Text and Score. PairID is an identifier of the pair, the Text column is the sentence pair separated by a line break, and the Score column is a float number between 0 (completely unrelated) and 1 (maximally related) which indicates the degree of semantic textual relatedness between the two sentences.

The English training corpus is composed of 5500 sentence pairs meanwhile the Spanish counterpart has 1561 pairs. The score distribution comparison in figures 1 and 2 indicates that the English scores have a wider variance than the Spanish ones, nonetheless the most represented scores (scores corresponding to over 50 sentence pairs) follow roughly a Gaussian distribution. In contrast the Spanish score distribution doesn't behave as cleanly.

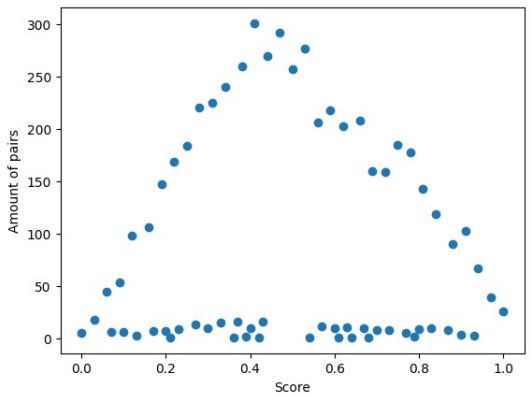

Figure 1: English score distributions.

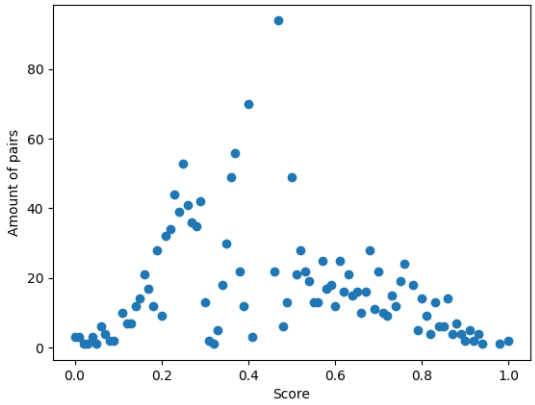

Figure 2: Spanish score distributions.

The results of the shared task are evaluated with the Spearman rank correlation coefficient which is used to discover the strength of a relationship between two sets of data, in this case two sentences.

4.2 Algorithms, parameters and pretrained models

The following regression algorithms, along with the particular parameters, were trained and validated using 7-dimensional vectors corresponding to each characteristic in the SAND Composition:

- SVM and SVM with epsilon: Both algorithms' used the default regularization parameter of 1, meanwhile the SVM ϵ variation used $\epsilon = 0.3$.
- RandomForest: Default parameters were used except for maximum depth which was set to 5, and randomness of the bootstrapping of the samples used when building trees was set at 0.
- Ridge regression: Default parameters except the constant that multiplies the L2 term α. For the English corpus α was set at 0.8, while for the Spanish corpus it was set at 0.9.

Regarding ST and AnglE Embeddings the use of a pretrained model was necessary in order to compute the embeddings and eventually the similarity score. For the English version of ST the ALL-MPNET-BASE-V2 checkpoint was used, meanwhile for the Spanish version the PARAPHRASE-MULTILINGUAL-MPNET-BASE-V2 checkpoint was chosen, both developed particularly for the ST architecture (Reimers and Gurevych, 2020). Meanwhile AnglE embeddings

used the ANGLE-BERT-BASE-UNCASEDNLI-EN-V1 checkpoint, prioritizing the BERT (Devlin et al., 2019) based model over the LLaMA (Touvron et al., 2023) based one due to computational power needed for each model.

5 Results and Analysis

The final SAND composition was the result of an ablation test performed using various combinations of different characteristics. The previously mentioned regression algorithms were trained and tested using each individual characteristic as well as different combinations of each. The SAND composition was the best performing combination for both English and Spanish, each of the four regression algorithms achieved the best result in the ablation test with SAND than with each simpler combination.

Tables 1 and 2 show the best Spearman Correlation for each characteristic combination as well as the model that achieved said score in each language when evaluating in the validation dataset.

Char	SVM	RF	SVM_ϵ	Ridge
ST	0.7891	0.7847	0.7865	0.7891
AnglE	0.7789	0.7737	0.7772	0.7789
N-grams	0.6634	0.6496	0.6620	0.6584
Distance	0.2343	0.2090	0.2839	0.2888
SAND	**0.7986**	**0.8197**	**0.7992**	**0.7921**

Table 1: English Spearman Correlation for different characteristics.

Char	SVM	RF	SVM_ϵ	Ridge
ST	0.6397	0.6058	0.6310	0.6397
AnglE	0.6140	0.5976	0.6038	0.6212
N-grams	0.6425	0.6232	0.6419	0.6431
Distance	0.5595	0.5584	0.5586	0.5594
SAND	**0.688**	**00.6783**	**0.6937**	**0.7029**

Table 2: Spanish Spearman Correlation for different characteristics.

Finally table 3 shows the results of each model with the SAND Composition. The reported results correspond to the predicted scores made by the highlighted models: Random Forest for English, and Ridge Regression for Spanish.

It is important to note that the embeddings created with pretrained models were the feature with the greatest impact on our model. Even as an isolated measure they both prove to be better metrics than their n-grams and distance counterparts. Similarly, considering that both BERT and ALL-MPNET-BASE-V2 are trained in English primarily, it is logical that the regression algorithms performed better in said language.

Model	Spanish	English
RandomForest	0.6968	**0.8197**
SVM	0.6881	0.8133
Ridge	**0.7029**	0.8117
SVM Epsilon	0.6997	0.7945

Table 3: Spearman coefficient for SAND composition.

Nonetheless the SAND Composition proves that these characteristics can be complemented and improved using relevant information such as n-grams coefficients. Since they don't rely on pretrained models and rather focus on lexical overlapping, this coefficient was able to discern certain relatedness measures.

SAND Composition was able to achieve the best results of the ablation test meaning that regression models do benefit from the mix of characteristics and still be relevant in a competition setting.

6 Conclusion

In this paper, we describe the SAND composition for the STR shared task, which is based on both semantic and lexical features, because we observe that: two sentences can share most of the words and apparently have no semantic relation but a high value of Spearman coefficient and vice versa, they can share semantics without matching words. With this in mind the SAND Composition contains half semantic features, and half lexical ones. This approach allowed achieved the 18th place in English and 2nd place in Spanish, with 0.83 and a 0.73 Spearman Correlation score respectively. In both cases the results are over the baseline and only 0.05 of the first place in English and 0.01 in Spanish, meaning SAND proves to have relevant characteristics.

For future experiments added features that consider both semantic, lexical and contextual parts simultaneously might prove to be more efficient than various unrelated metrics. Mixing word embeddings and PoST tagging might generate a relatedness score that proves to be more useful than separate similarity metrics.

Abstract

In this paper, we present our system for the SemEval Task 5, *The Legal Argument Reasoning Task in Civil Procedure* Challenge. Legal argument reasoning is an essential skill that all law students must master. Moreover, it is important to develop natural language processing solutions that can reason about a question given terse domain-specific contextual information. Our system explores a prompt-based solution using GPT4 to reason over legal arguments. We also evaluate an ensemble of prompting strategies, including chain-of-thought reasoning and in-context learning. Overall, our system results in a Macro F1 of .8095 on the validation dataset and .7315 (5th out of 21 teams) on the final test set. Code for this project is available at https://github.com/danschumac1/CivilPromptReasoningGPT4.

1 Introduction

Mastering the reasoning behind legal arguments is a fundamental skill required of all law students. In this study, we develop a novel approach for SemEval Task 5, The Legal Argument Reasoning Task in Civil Procedure Challenge (Held and Habernal, 2024). The SemEval Task released a dataset that was scraped from *The Glannon Guide To Civil Procedure*, a textbook designed for law students. Specifically, given case law, a question, and a potential answer to that question, students must be able to reason over the contextual information (case law) to determine if the question is correct or not.

There has been substantial research in developing NLP-based reasoning systems (Guha et al., 2024; Bongard et al., 2022; Chalkidis, 2023; Blair-Stanek et al., 2023; Kuppa et al., 2023; Yu et al., 2022). The methods can be categorized into two major frameworks: fine-tuning and large language model-based (LLM) solutions. For fine-tuning approaches, Bongard et al. (2022) introduced an approach that fine-tunes LegalBERT (Chalkidis et al., 2020) and developed several methods for handling long text that does not fit within the token limitations of LegalBERT. For LLM solutions, Chalkidis (2023) explored the use of ChatGPT for solving legal exams. Guha et al. (2024) introduced a more comprehensive evaluation benchmark geared to large language models consisting of 162 tasks. Many of their experiments show that GPT4 is one of the top performing approaches for legal reasoning across all language models, while Flan-T5-XXL is the best open-source option. Although showing substantial generalization is important, developing specific prompting strategies for different reasoning tasks can substantially improve performance. Hence, this paper adds to existing literature on the exploration of prompting approaches in the legal domain.

For this work, we adapt several prompting-based strategies to develop an LLM-based solution for the shared task. Specifically, we combine a retrieval system with in-context learning and chain-of-thought reasoning. There are several studies showcasing the utility of in-context learning (Liu et al., 2022a; Lu et al., 2022) and chain-of-thought reasoning (Wei et al., 2022; Sun et al., 2023; Yao et al., 2024). Moreover, there is work using both human-curated and machine-generated reasons. In this work, we focus on human-generated reasons for the training data, and machine-generated examples are only used at test times when human expert annotations are not provided. Furthermore, rather than providing a step-by-step reasoning approach, which may not make sense in this context, our approach is more similar to single-step rationales (Brinner and Zarrieß, 2023; Yasunaga et al., 2023), which simply provides a single step of reasoning for why an answer is correct or incorrect.

In summary, this paper makes the following contributions to our solution for the SemEval 2024 Task 5 shared task:

- We evaluate prompting strategies using GPT4

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1293–1301

that combine several popular ideas, including in-context learning and chain-of-thought reasoning.

- In-context learning can be sensitive to the actual choice of examples, particularly when only a few examples are provided. Hence, we also explore an ensemble of prompt-based predictions to improve overall performance.

- Finally, we provide a unique error analysis where we found limitations and common error types generated by GPT4 using our prompting strategies. For example, when a part of an answer candidate is correct, but the reasoning is wrong, GPT4 is likely to generate a false positive (i.e., predict it is correct instead of incorrect).

2 RELATED WORK

Overall, there are three major areas of legal NLP: legal question-answering (Khazaeli et al., 2021; Kien et al., 2020; Ryu et al., 2023; Martinez-Gil, 2023; Wang et al., 2023), judgment prediction (Masala et al., 2021; Valvoda et al., 2023; Juan et al., 2023), and corpus mining (e.g., summarization, text classification, information extraction, and retrieval-related research) (Poudyal et al., 2020; Li et al., 2022; Vihikan et al., 2021; Zhang et al., 2023; Limsopatham, 2021; de Andrade and Becker, 2023). There has also been some broad methodology work that is aimed at working on various legal tasks in general (e.g., LegalBERT (Chalkidis et al., 2020)).

The SemEval task is most similar to question-answering related research. In the domain of legal question-answering, recent research efforts are focused on creating new systems, developing evaluation criteria, and compiling datasets, considering the significant variation across different legal fields. Khazaeli et al. (2021) introduced a commercial question-answering system for legal inquiries, leveraging information retrieval techniques, sparse vector search, embeddings, and a BERT-based reranking system, trained on both general and legal domain data. Ryu et al. (2023) developed a novel evaluation method for LLM-generated texts that assess their validity using retrieval-augmented generation, showing improved alignment with legal experts' assessments and effectiveness in identifying factual errors. Wang et al. (2023) created the Merger Agreement Understanding Dataset (MAUD), a unique, expert-annotated dataset for legal text reading comprehension, highlighting promising model performance and the need for further improvement in understanding complex legal documents.

From a methodological point-of-view instead of a task-oriented view, recent research efforts have concentrated on the advancement of NLP-based reasoning systems, with a particular focus on applications within the legal domain (Guha et al., 2024; Bongard et al., 2022; Chalkidis, 2023; Blair-Stanek et al., 2023; Kuppa et al., 2023; Yu et al., 2022). These efforts can be broadly classified into two distinct methodologies: fine-tuning approaches and those leveraging large language models (LLMs). Within the fine-tuning paradigm, Bongard et al. (2022) have proposed modifications to LegalBERT (Chalkidis et al., 2020) aimed at enhancing its ability to process texts that exceed the model's inherent token limitations. This approach is representative of a broader trend towards tailoring pre-existing models to better suit specific textual analysis tasks in the legal sector. Kien et al. (2020) developed a retrieval-based model employing neural attentive text representation with convolutional neural networks and attention mechanisms for accurately matching legal questions to relevant articles, demonstrating superior performance on a Vietnamese legal question dataset.

Conversely, the exploration of LLMs has also been wide covering new general approaches for legal question answering and reasoning to new datasets and benchmarks. Yu et al. (2023) investigated the impact of chain-of-thought prompts and fine-tuning methods on legal reasoning tasks, specifically the COLIEE entailment task, and found that prompts based on legal reasoning techniques and few-shot learning with clustered training data significantly enhance performance. Chalkidis (2023) demonstrates the potential of utilizing models like ChatGPT for complex reasoning tasks, such as solving legal examination questions. Building on this, Guha et al. (2024) have introduced a comprehensive evaluation framework designed specifically for assessing the capabilities of LLMs across a suite of 162 tasks. This benchmark aims to provide a more nuanced understanding of the strengths and limitations of LLMs in the context of legal reasoning. Additionally, while employed within a distinct domain from legal reasoning, a comparable methodology in prompt engineering—encompassing chain of thought prompting

and in-context prompting—is illustrated in Liu et al.'s recent work (Liu et al., 2022b). Overall, compared to the prior work that developed methods and datasets for generating answers to questions, the SemEval task focuses on understanding whether a provided answer candidate is valid given a specific context.

3 METHOD

We provide a high-level overview of our approach in Figure 1. Overall, we explore three major different prompting approaches: Zero-shot prompting, few-shot prompting, and few-shot prompting with chain-of-thought-like reasoning. Moreover, we explore an ensemble of multiple approaches. The methods are described in the following subsections.

3.1 Few-Shot Retrieval Augmented Chain-of-Thought Prompting

We refer to our approach as "Few-Shot & CoT & RAG." Each example within the dataset contains an Introduction, Question, Answer Candidate, Analysis, and Label. For new examples at test time, we only have access to the Introduction, Question, and Answer Candidate. The Introduction consists of a general background about a legal case. The Question is about the case, and the Answer Candidate is an answer to the Question. It is important to note that the Question could be in question form, where the answer directly answers what is asked. However, it may function as a fill-in-the-blank exercise, where the question presents an incomplete statement that the Answer Candidate is expected to complete. The Analysis, which is only provided in the training and development datasets, is a detailed expert-defined explanation for why the Answer Candidate is or is not valid. The Label is a TRUE or FALSE value, where TRUE means that the Answer Candidate correctly addresses the question given the provided context. Likewise, FALSE means that the Answer Candidate is incorrect.

As shown in Figure 1, our prompting strategy contains three main components, a system prompt, the in-context examples, and the final test instance we will classify as TRUE or FALSE. The system prompt describes what the large language model (LLM) should do. In the Figure, it is shown that we also added explicit information to limit the model from generating non-relevant information.

The in-context examples are provided to the LLM before the final text instance. Intuitively, the goal is to provide some examples of the task we are accomplishing to better ground the LLM to make better-generated responses. This is the Retrieval Augmented aspect of our system (i.e., RAG). While any random examples could be provided, we search for the most relevant examples for each test instance. Formally, given an input instance x_i consisting of a concatenated Introduction, Question, and Answer triplet w, we retrieve the most similar examples $\{x_1, \ldots, x_{\mathcal{N}(x_i)}\}$, where $\mathcal{N}(x_i)$ are the k most similar examples to x_i. Each question-answer pair is embedded using LegalBERT. The in-context examples all come from the provided training dataset. Once retrieved, all of the relevant information for the retrieved examples are used in the prompt (i.e., the Introduction, Question, Answer Candidate, Analysis, and Label). Figure 1 shows an example with two in-context examples.

Finally, the last component of the prompt is the text example. Basically, for every example we wish to make a prediction for, we pass the Introduction, Question, and Answer Candidate. The model will first generate the Analysis for that example, then it will generate the Label.

3.2 Ensemble

Besides the method described in the previous section, we also explored prompting variants to create an ensemble. We describe each of the additional methods below (besides the Few-SHOT & CoT & RAG method described in the previous subsection).

Zero-shot. This approach does not use any in-context examples. We provide the system prompt and the test example to the model directly to get the final prediction.

Zero-shot & CoT. This method builds on the Zero-Shot approach by adding the CoT aspect to the test example. Note that this is not available at test time, so the model generates an Analysis section without previous examples.

Few-Shot. The few-shot approach will use multiple in-context examples. However, unlike our main method explained in the previous section, it uses the same in-context examples for all test cases. The examples were chosen in an ad-hoc manner with an emphasis on relatively short examples to limit the number of tokens to reduce costs.

Few-Shot & CoT. This builds on the Few-Shot method, where ad-hoc in-context examples are still

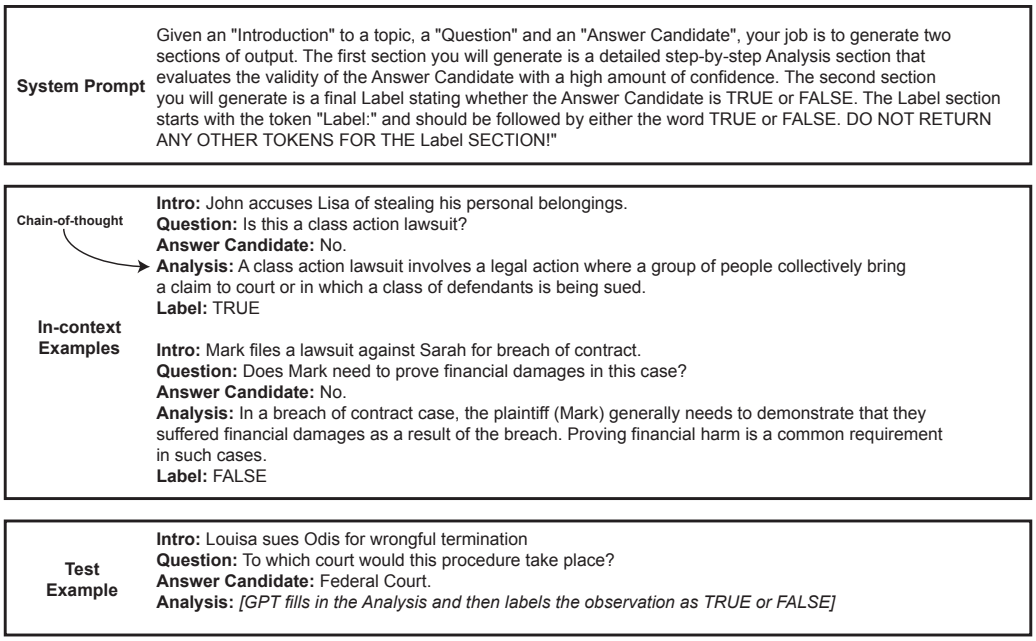

Figure 1: Overview of our prompting strategy.

used, but we also provide the CoT reasoning (Analysis) section to the in-context examples. The GPT4 model will generate the Analysis section for each test example.

Few-Shot & RAG. This also builds on the Few-Shot method, but instead of using ad-hoc examples, it uses LegalBERT and cosine similarity to find relevant in-context examples for each test case (as explained in the previous section).

Overall, there are a total of 4 models in our ensemble. Few-Shot and Few-Shot & RAG were not used, but we evaluated them. The models in the ensemble were chosen by checking combinations on the validation dataset. To make a prediction, we use voting with a threshold (i.e., where the votes are processed to generate the proportion of TRUE values).

3.3 Model Details

For all of our prompts, we use GPT-4-1106-preview with a temperature of .7. The similarity metric used for finding relevant in-context examples is cosine similarity. Moreover, we choose a total of 2 in-context examples, consisting of 1 TRUE example and 1 FALSE example. We searched for the best threshold after voting by calculating the proportion of TRUE vs. FALSE predictions, ultimately choosing .5 as the threshold.

There were many cases where GPT4 does not return a final label in an easy-to-process fashion (i.e., it does not end with a TRUE or FALSE). We explored multiple approaches to parse the answer. Our ultimate strategy involves re-submitting examples to GPT-4 that initially failed to produce a valid label, explicitly indicating the absence of the label, and prompting the model to generate the correct information.

Method	Macro F1	Acc.

RoBERTa	.5128	.2286
Legal-BERT	.5575	.2941
Zero-shot	.6681	.7857
Zero-Shot & COT	.7162	.7500
Few-shot	.6935	.7738
Few-shot & COT	.6762	.7262
Few-shot & RAG	.6898	.7500
Few-Shot & COT & RAG (Ours)	.7306	.7857
Ensemble (Ours)	.8095	.8571

Table 1: Validation dataset results

4 RESULTS

In this section, we present our own results on the validation dataset as well as the final results in the competition.

Baselines In our experiments, using the validation data, we compare our approach (Few-SHOT & CoT & RAG) with the other approaches used in the Ensemble. Moreover, we compare our system to both RoBERTa (Liu et al., 2019) and Legal-BERT. However, because both RoBERTa and Legal-BERT are limited to 512 tokens, we split the Introduction into b pieces. b is calculated by subtracting the number

of words in the question and answer from 512. We halve that result to accommodate the fact that the number of tokens typically exceeds the number of words. Next, we divide the number of words in the Introduction by the previously calculated number to obtain the total number of windows. Finally, all of the tokens in the Introduction are evenly split into the windows. Each piece of the introduction is appended to the Question and Answer pair independently to generate multiple predictions for each instance. We then use voting to make a final prediction for the entire sequence. This method is similar to what was explored in Bongard et al. (2022).

Validation Results. The validation performances are shown in Table 1. We observe that the fine-tuned methods (e.g., RoBERTa), perform less effectively compared to all methods utilizing GPT-4. Between the fine-tuned methods, we find that Legal-BERT outperforms RoBERTa, which is expected given Legal-BERT was fine-tuned on relevant corpora.

Next, between GPT4 methods (not including the ensemble), we find that performance varies substantially between .6681 and .7162 for Macro F1. All methods outperform Zero-Shot. However, Zero-Shot & COT achieved the best performance across all baseline methods for Macro-F1. When we compare the baseline approaches to our method (Few-Shot & COT & RAG), we find that the method outperforms all variations. From an ablation standpoint, removing RAG has the biggest performance drop (.7306 vs. .6762). Interestingly, we find that removing CoT has the second largest drop in performance (.7306 vs. .6935), and removing the in-context examples has the smallest drop in performance (.7306 vs. .7162). Before the study, we expected removing the in-context examples would result in the largest performance drop.

Competition Results. In Table 2, we report the final results of the competition, achieving a Macro F1 of .7315. But, why do we see such a large performance drop between the competition and validation results (.7315 vs. .8095)? We hypothesize two major reasons. First, we realized that the validation dataset contains many Introduction-Question pairs identical to the ones in the training dataset. Despite the Answer Candidates differing across the two datasets, the substantial overlap in Introduction-Question pairs may lead to an overestimation of our model's performance on the validation dataset,

rendering it potentially too optimistic when applied to entirely new data. Second, we spent time over-optimizing the ensemble on the validation dataset causing overfitting issues (e.g., checking thresholds, model combinations, and more). By generating a better validation split, we may have seen better generalization.

Error Analysis Our method resulted in twelve mistakes on the validation dataset: ten false positives and two false negatives. The confusion matrix is shown in Figure 3. In Table 4 (See Appendix), we categorize each false positive into one of four categories: "Incorrect reasoning," "Shared the same introduction and question pair," "lots of similar language", and "Other." With only two false negatives, there are few useful patterns to understand among the errors. Hence, we only have a general FN category. However, from the false positives, we make two major findings which we describe below.

The first was when the answer candidate had the correct answer but *incorrect reasoning*. Here is a toy example demonstrating this pattern:

> **Introduction**: Carlos enjoys riding his skateboard in the skate park. Unfortunately, during one of his rides, he fell and split his head open.
>
> **Question**: Should Carlos go to the hospital?
>
> **Answer Candidate**: Yes, Carlos should go to the hospital because he likes to kick-flip so much.
>
> **Analysis**: While it is correct that Carlos should go to the hospital for medical attention after splitting his head open, the reasoning provided in the answer candidate is flawed. The decision to seek medical help should be based on the severity of the injury and the need for professional medical treatment, not on Carlos's enjoyment of skateboard stunts.

Intuitively, part of the Answer Candidate is correct, i.e., Carlos *should* go to the hospital, yet the reasoning that states why he should go to the hospital is wrong.

The second point is that three of our ten false positives all *shared the same introduction and question pair.* The introduction contained more extraneous information than usual and was 128 words longer than the average. In these instances, our model would analyze the answer candidate as correct but without taking into account the particular case that was asked about. Below is a toy example:

> **Introduction**: My dog Louisa loves to learn new tricks, go for walks, eat her dinner, then sleep through the night
>
> **Question**: What does Louisa like to do *after dinner*?
>
> **Answer Candidates**:
>
> 1. Learn new tricks (*wrong*)
> 2. Go for walks (*wrong*)
> 3. Eat her dinner (*wrong*)
> 4. Sleep through the night (*correct*)

In the example, three of the answers are incorrect, while "Sleep through the night" is the correct example. When the Introduction is long, the actual context of the question may be ignored, which can be interpreted as a needle in a haystack issue. Developing better systems that provide direct "attention" to relevant information may improve performance.

Finally, a third point that we believe caused our model to predict incorrect answer candidates is *similar language* in both the introduction and question compared to the answer candidate.

> **Introduction:** While making eggplant Parmesan for the first time in a buttery dutch over Paige burned herself on the stove
>
> **Question:** How does Paige remember this incident.
>
> **Answer Candidates:** She remembers making eggplant Parmesan for the first time in a buttery dutch oven fondly.

5 CONCLUSION

In this paper, we described our approach for 2024 SemEval Task 4, The Legal Argument Reasoning Task in Civil Procedures. Specifically, we introduced a GPT4 prompting-based strategy that achieved 5th place in the competition out of 21 participants. Overall, we find that combining in-context learning, where we use a retrieval-based approach to find relevant examples, as well as in-context learning improves model performance. Based on our experiments, there are three natural areas for future research. First, the actual Analysis section used for chain-of-thought reasoning does not match traditional methods which use step-by-step reasoning. Hence, a logical next extension is to reword (potentially with GPT4) the Analysis section to provide a step-by-step explanation for an answer. Second, this work was limited to 2 in-context examples to limit API costs and allow us to test other models in our initial experiments. However, extending that to 10 or more examples can potentially improve performance. Third, the current approach relies on a closed-source model (GPT4). Exploring open-source models, particularly smaller open-source models such as T5 (Chung et al., 2022) and LLama2 (Touvron et al., 2023), is important to better understand the impact of pretraining data on performance.

A Error Analysis

Table 4 reports the basic statistics for the error types we observed in our error analysis.

Type	Frequency	Example
FP: Incorrect Reasoning	16.67% (1/12)	Carlos enjoys riding his skateboard in the skate park...
FP: Shared the same introduction and question pair.	25% (3/12)	My dog Louisa loves to learn new tricks...
FP: Lots of Similar Language	8.33% (2/12)	While making Eggplant Parmesean...
FP: Other	25% (3/12)	...
FN	25% (3/12)	...

Table 4: Manual categorization of error types. False positives are categorized as either "Incorrect Reasoning," "Shared the same introduction and question pair," "lots of similar language," or "Other." We use a single FN category because of the lack of errors to analyze.

BD-NLP at SemEval-2024 Task 2: Investigating Generative and Discriminative Models for Clinical Inference with Knowledge Augmentation

Abstract

Healthcare professionals rely on evidence from Clinical Trial Records (CTRs) to devise treatment plans. However, the increasing quantity of CTRs poses challenges in efficiently assimilating the latest evidence to provide personalized evidence-based care. In this paper, we present our solution to the SemEval- 2024 Task 2 titled "Safe Biomedical Natural Language Inference for Clinical Trials". Given a statement and one/two CTRs as inputs, the task is to determine whether or not the statement entails or contradicts the CTRs. We explore both generative and discriminative large language models (LLM) to investigate their performance for clinical inference. Moreover, we contrast the general-purpose LLMs with the ones specifically tailored for the clinical domain to study the potential advantage in mitigating distributional shifts. Furthermore, the benefit of augmenting additional knowledge within the prompt is examined in this work. Our empirical study suggests that DeBERTa-lg, a discriminative task-specific natural language inference model, obtains the highest F1 score of 0.77 and consistency score of 0.76 on the test set, securing the fourth rank on the leaderboard. Intriguingly, the augmentation of knowledge yields subpar results across most cases.

1 Introduction

Clinical trials are conducted on human subjects to test the safety and effectiveness of the medicine prior to designing a new treatment, especially in evidence-based treatments (Avis et al., 2006). Medical professionals prescribe and treat their patients based on clinical trial reports (CTR) in which the methodology and results of clinical trials are outlined. However, the increasing quantity of CTRs poses a challenge for healthcare professionals to manually assess all of them since this process is both time-consuming and labor-intensive (Bastian et al., 2010; DeYoung et al., 2020).

To tackle the aforementioned issue, recent advancements in natural language processing (NLP) encourage medical professionals to employ large language models (LLMs) to interpret and retrieve medical evidence from large quantities of CTRs (Lee et al., 2020). Employing natural language inference (NLI) and textual entailment in the clinical domain (Bowman et al., 2015), professionals can formulate a prompt or statement, for example, *"A minimum bodyweight of 55kg is required to participate in the primary trial."* and input it along with the CTRs into an LLM to determine whether the statement entails or contradicts the evidence from CTRs (Jullien et al., 2023b). Additionally, LLMs can aid in retrieving evidence from the vast amount of CTRs. This technology has the potential to ensure a higher level of precision and efficiency in delivering personalized evidence-based care.

While LLMs have demonstrated significant performance in numerous NLP tasks in recent years (Brown et al., 2020), it is still challenging for them to be deployed in the clinical domain due to their limitation in semantic and quantitative reasoning in language understanding. Moreover, the distribution shift in the clinical domain makes it even more intricate, which requires extensive research in this field (Miller et al., 2020). To address the challenges, Jullien et al. (2024) organizes the SemEval-2024 Task 2, titled "Safe Biomedical Natural Language Inference for Clinical Trials", which aims to investigate the robustness of NLI models when applied to clinical trials with cancer patients. This task seeks to develop an NLI system to connect the new evidence and infer the knowledge from CTRs to find an inferential relation, namely either entailment or contradiction, between a clinical trial document and a statement/claim.

In this study, we investigate the performance of discriminative and generative transformer-based LLMs in the realm of clinical inference. In addition, we explore the potential of clinical domain-specific

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1302–1308

LLMs and compare them with the general-purpose ones with the hypothesis that LLMs pre-trained on clinical data may exhibit superior performance. Furthermore, we study the impact of augmenting knowledge on the semantic reasoning abilities of these LLMs. Our extensive experiments demonstrate that our system, leveraging the discriminative, general-purpose DeBERTa-lg NLI model, achieves an F1 score of 0.77 and consistency score of 0.76 without employing knowledge augmentation on the test set and ranks fourth on the official leaderboard.

2 Background

2.1 Task Definition

In the textual entailment identification task, each input data contains a medical statement, a section name indicating which section the statement claims about, and one or two CTR records that serve as evidence to verify the statement. If the statement only makes claims about one certain trial defined as a primary trial, then only the primary trial will be used as input data. On the other hand, if the statement claims a comparison between a primary trial and a second trial defined as a secondary trial, both CTRs need to be considered as input text. Table 1 presents an example of CTR with four sections. The task is to determine the inferential relation between the medical statement and the associated section in the CTR(s). There are two possible inferential relations for each statement: entailment and contradiction. Models are designed to predict whether each statement entails or contradicts the associated section from the claimed CTR(s).

2.2 Dataset

The Natural Language Inference (NLI) task is designed based on breast cancer CTRs collected by clinical domain experts (Jullien et al., 2023a). Each CTR dataset consists of four sections: intervention, eligibility criteria, results, and adverse events. Each section contains multiple sentences, Formally, $S_t = s_t^1, s_t^2, ..., s_t^n$, here t denotes for the type of section. The participants are provided a text file containing a statement, 1-2 CTRs, an inference label (Entailment or Contradiction), section that is used for the statement. A statement can be made from a single CTR or a comparison between two CTRs.

3 System overview

In this section we describe about our system for this task.

3.1 Input Prompt

According to the data description, a section contains multiple sentences namely evidence. For short input, we consider only the selected sentences of the section which are annotated as related to the statement. All the sentences are concatenated by adding a space in between each sentence to consider a hypothesis. To design the input text, we consider the statement as premise followed by all the selected sentences as claims from the section of the claimed CTR. A separation token, denoted as [SEP], is used between the statement and the claims. For comparison between two claims, we concatenate the selected sentences from both primary and secondary trials, formally, $C^1 s_t^1, .., C^1 s_t^n, ..., C^2 s_t^1, .., C^2 s_t^n$.

3.2 Knowledge Augmentation

In knowledge augmentation, we consider all the sections as evidence. To design input text, we first take all sentences from the related section as a priority. Then, we concatenated the text with other sentences from the rest of the sections. During the comparison between the two trials, we consider the first 500 tokens from the primary trial and 500 tokens from the secondary trial to limit the length of the sentence to 1024 tokens.

In both cases, we design the prompt in the following way:

$$statement\ [SEP]\ primary\ trial:\ C^1 s_t n.$$
$$secondary\ trial:\ C^2 s_n$$

Secondary trials are added only for comparison between two trials.

3.3 Discriminative Models

Discriminative models, in contrast, are focused on learning the decision boundary that separates different classes within the input data. Instead of modeling the entire data distribution, they concentrate on capturing the conditional probability distribution of labels given the input data. We experiment with a collection of transformer-based discriminative pre-trained language models. We choose models that are trained on medical data, such as electronic

Section	Subsection	Sentence
Intervention	N/A	TX/Maintenance Therapy for Stage IIIB/IV Breast Cancer busulfan: Given orally tamoxifen citrate: Given orally
Eligibility	Inclusion	Hepatic function: Bilirubin =< 2 mg% Karnofsky performance status > 60 Creatinine =< 2.0 mg/dl
	Exclusion	Patient is pregnant Are > 100 days from transplant Are on steroids
Results	Outcome Measurement	Event-free Survival Time frame: 11 years
	Results 1	busulfan: Given orally Overall Number of Participants Analyzed: 50
Adverse events	N/A	Total: 2/50 (4.00%) Pulmonary Emboli [2]1/50 (2.00%)

Table 1: An example of a clinical trial record (shortened) containing four sections namely intervention, eligibility, results and adverse events.

health records, biomedical texts, and scientific articles. We used the BioLinkBERT (Yasunaga et al., 2022) model, which was trained on PubMed abstracts along with citation link information. ClinicalBERT (Wang et al., 2023) trained on a large multicenter dataset with a large corpus of 1.2B words of diverse diseases and utilized a large-scale corpus of EHRs from over 3 million patient records to fine-tune the base language model. Bio_ClinicalBERT (Wang et al., 2023), a domain-specific BERT-based model initialized with Bio-BERT model and fine-tuned with electronic health records from ICU patients, namely MIMIC (Johnson et al., 2016). We also choose a task-specific model, proposed by Laurer et al. (2024), based on DeBERTa large and trained on general domain datasets such as MultiNLI (Williams et al., 2018), Fever-NLI (Nie et al., 2019), Adversarial-NLI (ANLI) (Nie et al., 2020), LingNLI (Parrish et al., 2021) and WANLI (Liu et al., 2022) datasets, which comprise 885,242 NLI hypothesis-premise pairs. A classification layer is added on top of the pre-trained layers and fine-tuned on the training set to predict the probability of entailment or contradiction of the statement. An overall descriptions of the models are provided in table 2.

3.4 Generative Models

For comparison, we also solve this task by using generative models. These models use encoder-decoder architecture to encode input text and directly generate output label entailment/contradiction. Similar to discriminative models, we choose SciFive (Phan et al., 2021) as a domain-specific generative pre-trained model that follows The text-to-text transfer transformer (T5) model (Raffel et al., 2019) and sequence-to-sequence encoder-decoder framework. Pubmed and PMC datasets are utilized for training the models and MIMIC is employed to fine-tune for NLI task. To demonstrate the effectiveness of further fine-tuning the Clinical Trial dataset, we apply both zero-shot and few-shot learning approaches on SciFive. On the other hand, we choose Flan-T5 (Chung et al., 2022) as a general domain generative model. Similar to SciFive, Flan-T5 builds based on T5 architecture. For generative models, we slightly change the prompt. For SciFive, $mednli : sentence1 : < premise > sentence2 : < claims >$ and for FlanT5, $natural\ language; inference : premise : < premise > hypothesis : < claims >$.

Type	Model	Parameters	Variation	Task-specific	Domain-specific
Discriminative	ClinicalBERT	110M	base	No	Yes
	BioLinkBERT	340M	large	No	Yes
	BioClinicalBERT	110M	base	No	Yes
	DeBERTa-lg	304M	large	Yes	No
Generative	FlanT5	250M	base	No	No
	SciFive	770M	large	Yes	Yes

Table 2: Model specifics including the number of trainable parameters in million, variation/size, task-specificity (whether further pre-trained on NLI task or not), and domain-specificity (whether pre-trained on medical domain datasets or not) are shown.

Type	Model	W/o knowledge augmentation			With knowledge augmentation		
		Basline F1	Faithfullness	Consistency	Basline F1	Faithfullness	Consistency
Discriminative	ClinicalBERT	0.56	0.35	0.46	0.54	0.35	0.41
	BioLinkBERT	0.57	0.31	0.49	0.57	0.31	0.49
	BioClinicalBERT	0.58	0.47	0.61	0.57	0.31	0.49
	DeBERTa-lg	0.77	0.80	**0.76**	0.75	0.79	0.75
Generative	FlanT5-base	0.58	0.57	0.63	0.51	0.63	0.61
	SciFive (without FFT)	0.49	0.61	0.49	0.47	0.64	0.51
	SciFive (with FFT)	0.44	0.76	0.63	0.65	0.49	0.62

Table 3: Experiment results of the clinical NLI task on the test set for several discriminative and generative models. We report baseline F1, faithfulness, and consistency scores proposed by (Jullien et al., 2024) for each model with/without knowledge augmentation. The best performance with respect to consistency score is bold-faced. Discriminative DeBERTa-lg achieves the best performance while generative models show promise in several cases. Knowledge augmentation implies including all evidence from CTR concatenated with the prompt statement and then passed as input to the LLM. However, Knowledge augmentation shows negligible impact on model performance. FFT stands for further fine-tuning.

4 Experimental setup

We keep the original data split (1700: 200: 5500) provided by the task organizer for training, validation, and testing sets respectively. Huggingface Transformers [1] library is used for tokenization and further finetuning. Data preprocessing steps are mainly adapted from Vladika and Matthes (2023). For short text, the max sequence length for the tokenizer is set to 256 and 512 for long text for BioLinkBERT, ClinicalBERT and BioClinicalBERT. For Deberta-large, SciFive and Flan-T5 the max sequence length for the tokenizer is set to 512 and 1024 for short and long input text respectively. We train all language models for 20 epochs and an AdamW (Loshchilov and Hutter, 2019) optimizer is used for optimization with a default learning rate of 5e-6 for discriminative models and 5e-5 for generative models with weight ratio of 0.06 and weight decay of 0.01. The models are evaluated on the validation set after each epoch by using precision, recall, and F1 scores and saved best model based on least evaluation loss. We measure the performance of the models based on Faithfulness and Consistency proposed by (Jullien et al., 2024). Faithfulness measures the ability to predict the output based on the correct reason. Therefore, if semantic reason change in future, models will be able to change its prediction accordingly. On one hand, consistency measures the ability to make same prediction for the semantically equal statements which ensures the semantic preserving in a model.

5 Results and Discussion

The experimental results are presented in Table 3. All results are calculated on the standard test

[1] https://huggingface.co/docs/transformers

set provided by the shared task organizers. The outcome of the NLI model can be binary: either entailment or contradiction. We use the metrics including baseline F1-score, faithfulness, and consistency, proposed by (Jullien et al., 2024) to calculate the performance of the models.

Among discriminative and generative models, we can observe that generative models including FlanT5 and SciFive outperform the discriminative models e.g. ClinicalBERT, BioLinkBERT, and BioClinicalBERT, in terms of faithfulness and consistency. Given the moderate amount of labeled data for this clinical inference task and textual data as input to the model, which is of low-dimensionality in the latent space compared to high-dimensional vision and speech data, this enables generative models to perform well by learning the joint probability distribution of the input features and the class labels. However, the DeBERTa-lg, which is a discriminative model, achieves the highest F1 scores among all discriminative and generative models. This is likely because the task involves simple binary classification, which can be comparatively easily performed by a discriminative model by separating the data points in the data manifold through a decision boundary. Therefore, for the clinical inference task with the provided dataset, both generative and discriminative models can be useful and demand empirical evaluation.

Table 3 also demonstrates that knowledge augmentation by adding evidence from all the sections does not improve the performance of the models in almost all cases. One possible reason is that adding more information makes it more challenging for the models to extract the relevant information. Also, by increasing the input length, the model struggles with high-dimensional input space.

Among the models, only DeBERTa-lg and FlanT5 are general-purpose models while the rest are tailored for the clinical domains by pre-training the models on domain-specific data. Also, DeBERTa-lg and SciFive are the only task-specific NLI models studied in this work. This is intriguing to observe that although DeBERTa-lg is not pre-trained on clinical data, it yields the highest F1-score. Thus, a model tailored to the task but not initially trained on domain-specific data may outperform a domain-specific model that lacks task specificity, demonstrating the importance of task-oriented adaptation rather than relying solely on domain-specific pre-training. This outcome contradicts our initial hypothesis that domain-specific pre-trained LLMs are necessary for superior performance.

Finally, the number of trainable parameters of the discriminative models is not found to be linked with model performance since discriminative BioLinkBERT, containing 340M parameters, performs either on par with or subpar than ClinicalBERT and BioClinicalBERT with 110M parameters each. However, the generative SciFive model, consisting of a larger number of trainable parameters than FlanT5, exhibits better performance in certain metrics e.g. faithfulness and consistency.

6 Conclusion

In this paper, we describe our system for the SemEval-2024 Task 2, dealing with NLI for clinical trials. Leveraging DeBERTa-lg, a discriminative pre-trained model tailored to the NLI task, we achieve a consistency score of 0.76, securing the 4th position out of 31 participants. Our exploration yields intriguing insights: both discriminative and generative models exhibit promise for this clinical inference task. In addition, we find that knowledge augmentation poses challenges for the model, possibly due to the higher dimensionality of the input space. Moreover, task-specific but not domain-specific models are found to be better performing than domain-specific but not task-specific models. However, it is worthwhile to mention that all the models are fine-tuned with the same clinical data. Interestingly, while the performance of the discriminative model is not affected by the number of parameters, it appears to influence the performance of generative models.

As part of future work, we intend to explore the applicability of parameter-efficient techniques including adapter-tuning (Houlsby et al., 2019), LoRA (Hu et al., 2021), etc. by deploying them for the clinical inference task.

7 Acknowledgments

The authors would like to thank the committee of SemEval2024, the organizers of Task 2, and the reviewers. Special thanks to Md Zobaer Hossain for providing continuous support.

Abstract

This paper presents our submission to the SemEval 2024 Task 5: The Legal Argument Reasoning Task in Civil Procedure. We present two approaches to solving the task of legal answer validation, given an introduction to the case, a question and an answer candidate. Firstly, we fine-tuned pre-trained BERT-based models and found that models trained on domain knowledge perform better. Secondly, we performed few-shot prompting on GPT models and found that reformulating the answer validation task to be a multiple-choice QA task remarkably improves the performance of the model. Our best submission is a BERT-based model that achieved the 7th place out of 20.

1 Introduction

The field of Natural Language Processing (NLP) has made significant strides in understanding and generating human language. Yet, specialized fields such as legal reasoning within the sphere of civil procedure pose distinct challenges. These challenges stem from the intricate nature of legal texts and the requisite domain-specific knowledge. In this paper, we present a solution to the problem posed in Semeval 2024 Task 5, which introduces a new NLP task and dataset focused on the U.S. civil procedure. Our approach in this task aims to evaluate the ability of large language models (LLMs) in interpreting and applying legal principles and laws to specific case questions. To support this paper, we have made our codebase publicly available as a GitHub repository.* This repository contains all our code and instructions how to run it. At the request of the task organizers, we have not included the dataset splits as they are meant to be private.

The dataset for this task is curated from "The Glannon Guide to Civil Procedure" (Glannon, 2019). It comprises a series of legal cases, each with a general introduction, a specific question related to U.S. civil procedure, and a possible answer candidate. For every answer choice, a comprehensive analysis is provided, rationalizing why it is correct or incorrect. A correct answer is labeled with 1, and an incorrect answer is labeled with 0. The dataset is available in English, and its training, validation, and test splits contain 666, 84, and 98 examples respectively.

2 Related Work

The domain of legal question-answering systems has witnessed substantial progress, utilizing cutting-edge computational techniques to address the complexities of legal discourses. A prime example of innovation in this field is the LEGAL-BERT system, introduced by Chalkidis et al. (2020), illustrating the enhanced efficacy of models tailored specifically for legal content through the pretraining of BERT (Devlin et al., 2019) on legal documents (Chalkidis et al., 2020). In addition, Khazaeli et al. (2021) achieved a notable breakthrough by developing a flexible legal question-answering system that goes beyond conventional query patterns, incorporating sparse vector search with a BERT-based re-ranking process. The expansion of legal corpora, notably with the Casehold corpus by Zheng et al. (2021), marked a significant stride forward. This work employed language models for legal analysis, setting a comprehensive standard for measuring model effectiveness in legal reasoning tasks using a dataset based on U.S. court cases. Furthermore, the creation of targeted NLP tasks has played a crucial role in the assessment of models and systems in this field. An important example is the task introduced by Bongard et al. (2022), which is the focus of this paper.

These works collectively underscore the diverse methodologies and technological advancements employed in legal question answering. Each of

*Equal contribution

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1309–1314

these contributions brings unique insights and solutions, paving the way for more sophisticated and efficient legal question-answering systems in the future.

3 System Overview

Our approach at creating a system entailed utilizing few-shot prompting on OpenAI's GPT-3.5 (OpenAI, 2023a) and GPT-4 (OpenAI, 2023b). We devised a script with a prompt, two examples of the expected model input and desired output, and used an altered version of the task dataset as our input queries for this system. We experimented with a few prompts for both GPT models, trying to figure out what gave us the best results. Following the guidance outlined in Bsharat et al. (2024) and White et al. (2023), we decided to structure our prompt in the following manner:

- A system instruction that describes to the model the structure of our data, the input it will receive, and what the model should return,
- Two examples from the training dataset, one with a correct answer prediction and one with an incorrect answer prediction,
- The dataset containing our questions and answer candidates.

Additionally, we also altered the dataset from a binary classification format to a multi-choice QA format. Rather than presenting individual question-answer pairs, each question was now accompanied by the entire set of potential answer choices. Figure 1 demonstrates a visual example of this restructuring. As can be inferred from Figure 1, the binary classification format of the dataset requires the system to label each answer choice as 0 or 1, whereas the multi-choice format requires the system to return one single answer prediction for each question. We chose to convert the dataset in this way to address an issue we found in the experimental phase of our work. This issue is elaborated upon in section 4.

A small note on our multi-choice QA format, we added an additional option "None of the Above" because in some cases, the training or the validation data had all incorrect answer choices listed for a given question. This was done to make sure that the model would not be forced to pick between multiple incorrect answers.

2: <None of the Above>}
```

Figure 1: Difference between the original dataset format and our restructuring

Figure 2 shows our best performing system instructions for the binary classification format of the dataset and the multi-choice QA format of the dataset. We ran experiments on both dataset formats to compare system performance, and section 5 contains our results for evaluation metrics.

4 Experiments

4.1 Finetuning with BERT

To establish a solid baseline, we opted to fine-tune various BERT models. This process involved inputting both the question and its corresponding answer into the model, with the goal of generating an output label of either 0 or 1. We trained our model on the data for 500 epochs before having it predict. In the predictions we observed a propensity for both BERT models to disproportionately favor the 0 label, a phenomenon likely stemming from the dataset's natural imbalance due to it being formatted for binary classification. Since the source material for the dataset is in a multiple choice format, there are inherently more answers with the 0 label than answers with the 1 label, and a predic-

Multi-Choice System Instruction:

```
You are an AI legal expert with
expertise in U.S. Civil Procedure
and U.S. Civil Law, known for your
strong reasoning abilities. Your
task is to answer a Multiple
Choice Question in the legal domain.
Choose an answer only if you are
very confident, otherwise, select
"None of The Above."

You will be provided with:
1. question: A legal question
2. context: Additional context for
better understanding
3. choices: Multiple answer candidates

Your response should be a JSON with two
keys: "correct_answer" and "reasoning."
Place the correct answer exactly as
provided in the "correct_answer" key.
Provide a detailed explanation of your
reasoning in the "reasoning" key. Do
not add or remove any other text.

Your goal is to ensure accurate
answers and thorough reasoning.
```

correct answer as 1, and an
incorrect answer as 0.

Your goal is to ensure accurate
answers and thorough reasoning.
```

Figure 2: System Instructions for Both Dataset Formats

tive model would tend to prefer the majority label (Tanha et al., 2020). After noticing this issue, we tried experimenting with altering the dataset.

4.2 Data Augmentation

To address the challenge of our model's tendency to overfit on the 0 label, we explored incorporating the Casehold corpus into our dataset. Casehold (Zheng et al., 2021), a rich legal corpus derived from the Harvard case law collection and spanning from 1965 to the present, was initially formatted for multi-label use, offering a wealth of potential answers for each question. Despite our efforts to adapt this corpus into a binary format to align with the organizers' dataset format, we encountered persistent overfitting issues, leading us to believe that trying the balance the dataset would not yield any productive results.

Subsequently, we reverted to using solely the task dataset and refined our approach by integrating each question's text with its corresponding explanation to provide more context. This was done with the hope that our model would use the additional input to steer its prediction in the correct direction. However, this addition faced a technical bottleneck due to the 512-token limit inherent in the BERT models, prompting us to investigate alternative large language models (LLMs) that could handle the larger input size. We decided to explore two options. The first was finetuning Longformer because it uses windowed attention and can handle longer context lengths (Beltagy et al., 2020). The second was exploring few-shot prompting with GPT-3.5 and GPT-4 as we could run further experiments also comparing how the GPT models do with both formats of the dataset, if the overfitting issue would persist or if one dataset format would outperform the other. We also wanted to try few-shot prompting as Brown et al. (2020) found it to be a better approach for QA tasks than finetuning.

4.3 Finetuning Longformer

Finetuning Longformer helped us resolve the context length limit that we ran into with BERT, but it did not yield better results. Considering that in our experiments with BERT we found LEGAL-BERT to be the better performing model (see section 5), we decided to use a Longformer model with legal context embedded into it. This legal Longformer model is devised by Chalkidis et al. (2023) and is a derivative model of a base RoBERTa trained on the LexFiles corpus (Chalkidis et al., 2023).

Using this legal Longformer model, we were able to incorporate the explanation feature into our input. Our input was explanation, question, answer. We first ran the finetuning code for 100 epochs where we ran into the same problem of overfitting. In fact, our F1 score would not go above 44.37 on the validation set - the model would only predict 0 labels and performed worse than finetuning

the BERT models. We then increased the number of epochs to 500, but that also did not show an improvement in F1 scores on the validation set. We believe that Longformer performed worse than LEGAL-BERT due to differences in their pretraining corpora.

4.4 Few-Shot Prompting with GPT-3.5 and GPT-4

Our experimentation with GPT-3.5 and GPT-4, through few-shot prompting, offered promising directions. Notably, this method enabled us to effectively incorporate even the analysis feature of the dataset within the context limit, achieving an impressive F1 score of 90 on the validation set. Despite this success, the approach did not consistently extend to the test set, suggesting that using analysis to predict correct answers has its limitations, as the test set inputs lacked the feature.

In our final strategy to mitigate the dataset's imbalance, we shifted from binary to multi-choice classification, allowing for a more nuanced model assessment. This change meant our model now aimed to identify the correct answer from a set of options, rather than simply labeling each answer as 0 or 1. Reapplying few-shot prompting to GPT-3.5 and GPT-4, with the dataset's adjusted format, led to our most improved performance on the dataset.

For the prompting experiments, we used the OpenAI API. We ran our prompting code for 3 epochs, and did not alter any other hyperparameters.

4.5 Rule-based Algorithm Application

After successfully implementing a prediction system, we increased our F1 score and accuracy by applying a rule-based algorithm tailored to the characteristics of each dataset. Recognizing the inherent imbalance within the datasets, we devised a strategy where if all answers to a question were labeled as 0 in the training and validation sets, then the answer for said question in the test set was presumed to be labeled as 1. Conversely, if there were any correct answers in the training or validation sets, the data entries with the corresponding question were considered incorrect in the test set. This adjustment allowed us to enhance our performance metrics significantly for the baseline BERT models and the GPT-3.5 and GPT-4 predictions, giving us the metrics outlined in Table 4 and Table 5 for the test dataset. We only utilized this technique for the competition part of the task, as we wanted to see how high we could score. We did not submit our predictions with the GPT models.

5 Results

Our submission to the SemEval task ranked 7th out of 20 on the competition leaderboard. What we submitted to the task competition was our best performing finetuned BERT model after applying the rule-based algorithm. This was not our best method, as we were able to achieve higher metrics through subsequent experimentation. Our best results overall can be seen in Table 5, which stem from few-shot prompting on GPT models using the multi-choice QA format of the dataset, and then applying the rule-based algorithm to the predictions generated.

Table 1 presents our F1 score and accuracy across the two BERT models we chose to fine-tune. Our experiments not only aligned with but also surpassed the benchmarks established by the task organizers (Bongard et al., 2022), achieving a 0.2 increase in F1 score by merely utilizing the question and answer features in the input coupled with our fine-tuning approach. When comparing the baseline results from Bongard et al. (2022) with our own, we found that our question, answer input alone had a similar score to their input that also utilized the explanation feature. They achieved a 65.73 F1 score, whereas our submission to the task competition achieved a 65.99 F1 score as shown in Table 4.

Our best results without utilizing the rule based algorithm came from few-shot prompting with GPT models using the multi-choice QA format of the dataset. Table 2 shows these result metrics, while Table 3 shows the metrics of few-shot prompting using the binary classification format of the dataset for comparison.

Model	F1 Score	Accuracy
BERT	57.56	**73.47**
LegalBERT	**63.27**	72.45

mEval 2024 Task 5, has led us to several significant insights. These insights not only highlight the capabilities and limitations of current AI technologies in legal applications but also chart a course for future advancements in this intriguing intersection of technology and jurisprudence.

6.1 Best system

Our research identified that the application of multi-choice QA few-shot prompting on GPT-4 was the most effective method, achieving an F1 score of 71.70 and an accuracy of 80.61 on the test dataset. A significant insight from our experiments is the inherent limitation encountered with BERT models, notably their 512-token context length constraint. This limitation poses a unique challenge in legal reasoning tasks, where the richness and complexity of legal texts often necessitate a comprehensive contextual understanding that exceeds the input capacity of traditional models. By successfully navigating these constraints with GPT-4's advanced capabilities, our approach demonstrates the benefits of leveraging the more flexible and expansive context handling offered by newer generation models to effectively process and interpret dense legal information.

6.2 Impact of analysis feature

The inclusion of an analysis feature significantly improved LLM performance during the fine-tuning process on both the training and validation datasets. However, the anticipated benefits of this feature did not extend to the test dataset, likely due to differences in input structure between the training/validation and test phases. This suggests a potential overfitting problem, indicating that while models may become adept at recognizing patterns in training data, they may not necessarily understand the fundamental legal reasoning principles underlying the data.

6.3 Format of Dataset

The imbalance of the dataset, coupled with the fact that it was primarily sourced from a single textbook, introduced a challenge in preventing models from exploiting its predictable structure. To foster more rigorous and analytically profound datasets in this research domain, we propose diversifying the sources of dataset content. Additionally, we suggest that future datasets should challenge models to not only select the correct answer but also to generate the reasoning behind their choices. This method could provide a use case for the analysis feature, promoting a deeper understanding and application of legal principles, leveraging the full potential of Generative AI in legal reasoning.

6.4 Future Work

Exploring the integration of specific laws or precedents as a form of analysis presents an intriguing direction for enhancing the capabilities of Large Language Models (LLMs) in legal reasoning tasks. This approach deviates from the current format of analysis; explaining why an answer choice is correct or incorrect. Instead, it involves presenting the LLM with the relevant legal principles or statutes directly related to the question input. The model is then tasked with interpreting these legal documents to deduce the correct answer based on the law's stipulations.

Such a methodology could foster the model reaching a deeper level of engagement with the ma-

terial, as it not only challenges the model to grasp the nuances of legal language but also might help improve the model's ability to generalize from the principles of law to the specifics of individual cases, potentially leading to more accurate and legally sound predictions. As such, future work could involve curating or enhancing existing datasets to include these legal references, alongside developing model architectures and training methodologies that are adept at handling such complex, text-based inputs.

Acknowledgements We would like to express our gratitude to Professor Ian Lane, Professor Jeffrey Flanigan, Nilay Patel, and Jeshwanth Bheemanpally from University of California, Santa Cruz. Their comments, insights, and feedback helped us along the process of participating in this task and writing this paper.

Abstract

Memes are commonly used in online disinformation campaigns, particularly on social media platforms. They are primarily effective on social media platforms since they can easily reach many users. Semeval2024-Task4(Dimitrov et al., 2024), "Multilingual detection of persuasion techniques in memes", focuses on detecting persuasive methods across four languages: English, Bulgarian, North Macedonian and Arabic. Subtask 1 aims to identify the given text fragments of memes and which of the 20 persuasion techniques it uses, organized in a hierarchy. For the difficulty of this task and the fundamental role of text in the artificial intelligence area, we concentrate solely on this task. We develop a system using CoT-based data augmentation methods,in-domain pretraining and ensemble strategy that combines the strengths of both RoBERTa and DeBERTa models. Our solution achieved the top ranking among **33** teams in the English track during the official assessments. We also analyze the impact of architectural decisions, data construction and training strategies. We release our code at https://github.com/ldlbest/semeval2024-task4

1 Introduction

In the present digital era, persuasive communication is pivotal across diverse arenas, from political discourses to the viral spread of content on social media platforms. A nuanced comprehension of the intricacies of persuasion is indispensable in safeguarding against misinformation, upholding the integrity of information, and nurturing a constructive digital discourse.

In online communication, memes have become decisive for disseminating information and influencing opinions. The focus of this task centres on addressing the intricate task of identifying persuasive techniques within the textual content of memes. This paper addresses the "Textual Persuasion Technique Identification" task, emphasizing recognizing persuasive techniques within meme text. Our approach aims to deliver a robust multi-label classification system tailored to navigate the intricate challenges posed by this task.

We employ the Transformer (Vaswani et al., 2017) architecture. We introduce ensemble learning (Breiman, 1996), integrating one DeBERTa (He et al., 2021) model and four RoBERTa (Liu et al., 2019) models, each trained with different random seeds. In the pretraining phase of our system development, we utilize the in-domain pretraining method to improve our model's context and semantic comprehension. To bolster our dataset, we incorporate additional data from similar past tasks. Furthermore, we implemented the data augmentation technique, enhancing data diversity by employing data augmentation techniques.

Below is a summary of our contributions:

- We augment the training dataset with a Chain-of-Thought (CoT) based data augmentation method and improve our model's performance.
- Our system utilizes in-domain pretraining to enhance performance and leverages ensemble learning to combine DeBERTa and RoBERTa for further improvements.
- In task 1, we achieve first place on the English test set among **33** participants with an F1 score of **0.752**.

2 Background

2.1 Persuasion Techniques

Persuasive communication wields a critical influence across various sectors, including political rhetoric and the spread of online content. Such communication is instrumental in guiding public discourse and moulding opinions, ensuring its significance in the modern digital landscape (Yu et al.,

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1315–1321

2021). This task extends these concepts to analyzing memes, an increasingly prevalent medium on social media and internet platforms. With their distinctive blend of fun and brevity, memes deftly navigate the web to share insights, provoke conversation, and distribute knowledge.

In our task, we concentrate on identifying persuasive techniques within textual content. According to the work of Piskorski et al. (2023), this task involves categorizing textual persuasive techniques into three subtypes: ethos, pathos, and logos. This taxonomy is further amplified to include 20 subordinate precise methods, providing an extensive framework for understanding and interpreting the art of persuasion in digital content.

2.2 Data Augmentation

Data Augmentation (DA) techniques are usually initially explored in computer vision (CV), but they have been relatively slow to gain traction in NLP. Challenges arise due to the discrete nature of language, which rules out continuous noise and makes it hard to maintain diversity (Feng et al., 2021). Although challenges exist, the evolution of NLP has led to an increasing demand for exploring tasks and domains with insufficient training data. Consequently, this trend has resulted in the proliferation of research studies utilizing DA techniques. One classical DA method is back translation (Sennrich et al., 2016), which involves translating the text into another language and then back into the original language. Wei and Zou (2019) proposed EDA to improve the performance of text classification tasks and exhibit solid results on smaller datasets. These techniques are helpful for augmenting data, but they only modify the original text in fundamental ways, sometimes even changing the entire meaning of the sentence. Additionally, Chen et al. (2023) proposed knowledge-guided data augment based on the semantic relations of the knowledge graph.

Recently, Large Language Models (LLMs) can provide a unified solution for various NLP tasks and achieve competitive performance (Zhao et al., 2023). For example, GPT-3 (Brown et al., 2020) and ChatGPT (Ouyang et al., 2022) have demonstrated strong performance in various NLP tasks and benchmark tests (Qin et al., 2023). Furthermore, LLMs play a role in data augmentation, enhancing their utility in multiple applications. Dai et al. (2023) introduced a text data augmentation approach based on ChatGPT, which can be used in downstream model training. Abaskohi et al. (2023) proposed Contrastive Paraphrasing-guided Prompt-based Fine-tuning of Language Models (LM-CPPF). To enhance the capacity of LLMs for intricate reasoning tasks, Wei et al. (2022) proposed Chain-of-Thought (CoT). Inspired by the effectiveness of the CoT method, we leverage CoT prompts to generate paraphrases used for data augmentation, ensuring the preservation of semantic consistency while significantly expanding our dataset. This augmentation strategy contributed to the enhanced performance of our model.

3 Our System

As depicted in Figure 1, our system comprises the following parts: Data Model, in-domain Pretraining, RoBERTa encoder, DeBERTa encoder and Soft Voting. The final prediction is obtained as $\hat{y}$. We ignore the hierarchical structure of the labels and define it as a multi-label classification problem (Tsoumakas and Katakis, 2007) for the labels of the training dataset are all final nodes of the graph.

3.1 Dataset Construction

We construct different data augmentation datasets based on various data augmentation strategies. In practice, while efforts to balance label distribution (such as using techniques like Nlpaug and CoT) aim to increase the number of samples for less frequent labels, it is essential to note that, since the data typically involves multiple labels, they can also result in the expansion of more frequent labels.

Nlpaug: We identify labels corresponding to train data with fewer than 1000 entries. Subsequently, we employ the nlpaug (Ma, 2019) library for these data points to implement data augmentation. Specifically, we utilize the method of synonym replacement, generating new training samples by substituting words in the text with their synonyms. This approach enhances the diversity of training data, thereby enhancing the model's robustness to different text inputs. Using this method, we augment more than 5700 data entries in total.

CoT-based Paraphrasing-Guided Data Augmentation: We filter data corresponding to labels that occupy less than 0.16 of the entire label distribution and rewrote these entries using GPT-3.5, generating 10,000 entries through this method. The LLM can fully understand the context and focus on improving the targeted content by explaining the labels and tasks and providing a specific description

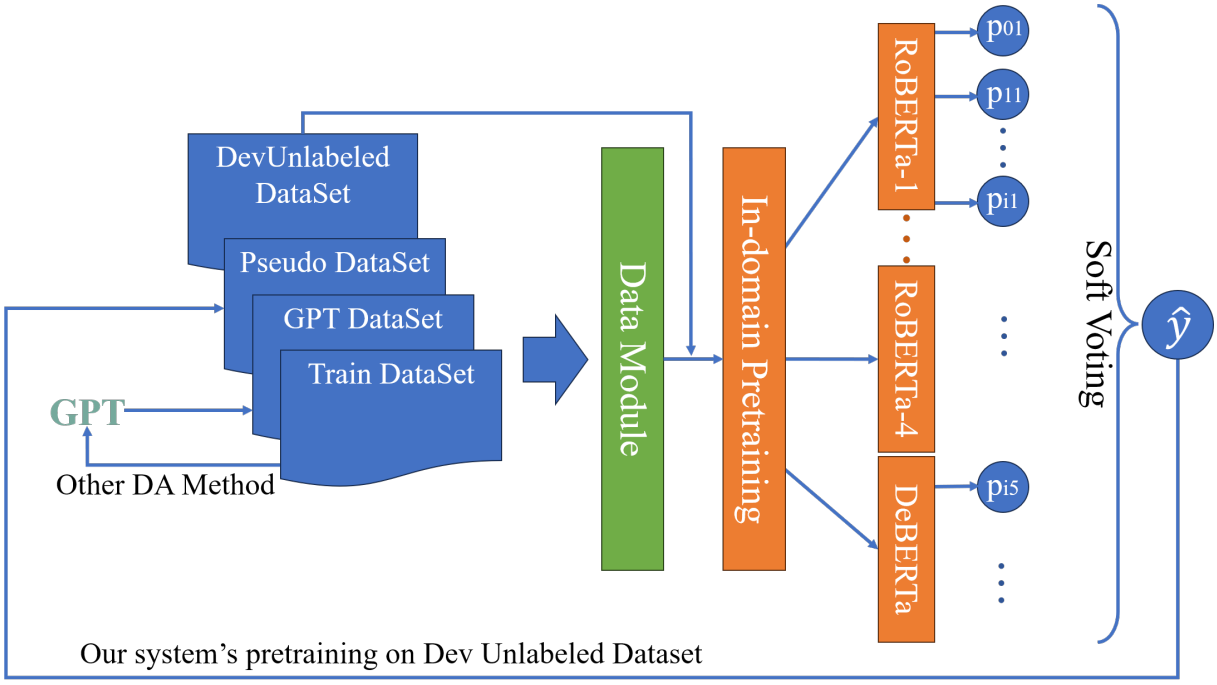

Figure 1: The overall architecture of our system.

of the problem and data that need to be rewritten. Applying the CoT technique enables the model to acquire more information and generate improved augmented data.

Input

User : Label Flag-waving means …
I will send you data with labels Flag-waving, Thought-terminating cliché at the same time, please elaborate again.
AI : Certainly! Feel free to provide the data with labels Flag-waving, Thought-terminating cliché and I'll do my best to help you analyze and elaborate on them.
User : Generate a paraphrase of the following text that uses different words and sentence structures while still conveying the same meaning. **REAL PATRIOTISM IS A WILLINGNESS TO CHALLENGE THE GOVERNMENT WHEN IT'S WRONG.**

Output

AI : True loyalty to one's country is demonstrated through a readiness to question the government's actions when they are unjust.

Figure 2: An example of using CoT for data augmentation.

We illustrate Figure 2. In the third round of our conversation with GPT-3.5, we use the instruction "Generate a paraphrase of the following text using different words and sentence structures while still conveying the same meaning" because it accurately describes the task with its instructions. Abaskohi et al. (2023) proved its effectiveness as an instruction template.

Pseudo-labeling: We use our model to classify 1000 data points on the dev dataset and 1500 on the test dataset. Pseudo-labelling (Lee, 2013) employs labelled data for training and utilizes information from unlabeled data to enhance the model's performance. The objective is to make more complete use of available data resources and improve the model's performance.

3.2 In-domain Pretraining

We utilize Masked Language Model (MLM) pertaining to all data, including data from SemEval 2023 task 3, which injects in-domain knowledge of our training datasets, thereby encouraging better learning outcomes for the model.

For a given input text x, we first tokenize it to obtain the tokenized representation $x_{tokenized}$ and truncate or pad them according to the maximum sequence length. For each text, a certain proportion of tokens are randomly masked based on the MLM probability and replaced with the masked token $[MASK]$. We use cross-entropy loss as the loss function for the masked language model. We compare the model's predicted probabilities for each token position with the actual token's one-hot encoding and calculate the cross-entropy loss.

Method	Recall	Precision	F1-score
BCAmirs	0.732	0.668	0.699
OtterlyObsessedWithSemantics	0.755	0.648	0.697
TUMnlp	0.714	0.638	0.674
GreyBox	0.688	0.652	0.670
BCAmirs	0.690	0.640	0.664

NLPNCHU	0.706	0.604	0.651
Baseline	0.300	0.477	0.369
Our System	**0.836**	**0.684**	**0.752**

Table 1: Comparison of the performance between other team's models on Task 1 English test dataset.

$$L(t, \hat{t}) = -\frac{1}{N}\sum_{i=1}^{N} t_i \log(\hat{t}_i) \quad (1)$$

where t is the encoding of the true token, and $\hat{t}$ is the probability distribution of the model's predictions.

3.3 Ensemble Learning

We train four RoBERTa models and one DeBERTa model using different random seeds. We integrate them using the soft voting approach, which averages the predicted probabilities of each label from all five models. Given predictions $p_{i1}, ..., p_{iN}$ for class i from these models, we employ the following formula to obtain the final prediction $\hat{p_i}$

$$\hat{p_i} = \frac{1}{N}\sum_{j=1}^{N} p_{ij} \quad (2)$$

We then set a threshold of 0.25, where $\hat{p_i}$ greater than the threshold is chosen as the predicted label.

3.4 Low-Resource Languages

Since our training data is limited to English, we utilize GPT-3.5 to translate Bulgarian, North Macedonian and Arabic datasets into English. Subsequently, we perform inference on the translated data. The results obtained from these experiments can be found in the A.1. For the loss of information during translation, our system gets a relatively low F1 score in these languages.

4 Experimental Setup

The completion is based on PyTorch, Transformers and Pytorch-Lighting. During training, we set the batch size as 16, the learning rate as 3e-5, and the warmup steps ratio as 0.3. Five seeds(42,3407,114514,4096,1234) are used for the label ensemble. We use the AdamW optimizer and the cosine decay scheduler with a power of 0.01. We set a maximum epoch of 7. All experiments are run on one RTX 4090 GPU.

We create three additional datasets for the experiment: GPTDataset, PseudoDataset, and GPT-PseudoDataset (GPT-PDataset). The GPTDataset contains 7,500 training data and 10,686 sentences generated by LLM. PseudoDataset contains 7500 training data and test dev dataset labelled by the Ensemble model. GPT-PDataset is a union of GPTDataset and PseudoDataset.

5 Result and Analysis

In this section, we display our results and analyze the impact of each component through ablation studies.

5.1 Results

In this competition with 33 teams, we achieve first place with a hierarchical F1 score of 0.75247. We outperform the official baseline by 0.38382. The result is shown in Table 1.

We conduct a comparative analysis between our system and other models, including LLMs on the Task 1 English dev set, revealing the superior performance of our approach.

As illustrated in Table 2, GPT-3.5 (Ouyang et al., 2022) and GPT-4 (OpenAI, 2023) utilized zero-shot learning, where only label meanings were provided in textual form without specific examples. We compare ourselves with other participating teams; the results are shown in Table 2. We achieve fourth place with a Hierarchical F1 score of 0.67833. Our performance is significantly better than the official baseline by 0.32010.

Method	Recall	Precision	F1-score
GPT-3.5	0.457	0.385	0.418
GPT-4	0.432	0.482	0.456
CLaC	**0.967**	**0.808**	**0.881**
OtterlyObsessedWithSemantics	0.754	0.636	0.690
GreyBox	0.716	0.657	0.685
EURECOM	0.702	0.650	0.675
Baseline	0.291	0.466	0.358
Our System	0.727	0.636	0.678

Table 2: Comparison of the performance between LLM and other team models on Task 1 English dev.

5.2 Ablation Study

We also conduct ablation experiments to validate our designs, including the encoder model, data modules, training strategy and ensemble.

Encoder Model We build our baseline model with BaselineDataset and BCE loss and run experiments to find out the best encoder model among RoBERTa (Liu et al., 2019), BERT (Devlin et al., 2019) , DeBERTa (He et al., 2021) , etc. As shown in Table 3, the large version of DeBERTav3 achieves the best score. Due to limited computility, we chose RoBERTa as our base model.

Method	F1-score
$BERT_{base}$	0.542
$BERT_{large}$	0.576
$RoBERTa_{base}$	0.614
$RoBERTa_{large}$	0.632
$DeBERTav3_{large}$	**0.649**

Table 3: F1 score of different Transformer-based models.

Training strategy We apply the in-domain pretraining on all encoder-based models to facilitate their performance on the downstream task. The result is shown in Table 4. For the five models, the F1 score improved by 0.2.

Method	F1-score
$BERT_{base}$	0.599
$BERT_{large}$	0.613
$RoBERTa_{base}$	0.630
$RoBERTa_{large}$	0.664
$DeBERTav3_{large}$	**0.667**

Table 4: F1 score of models after MLM training.

Data Module We use the best encoder model based on the result of dev datasets for ablation experiments on different datasets, including PseudoDataset, GPTDataSet, and GPT-PseudoDataset. The results are shown in Table 5.

Method	dataModule	F1-score
$RoBERTa_{large}$	GPTDataSet	0.685
$DeBERTav3_{large}$	GPTDataSet	0.700
$RoBERTa_{large}$	PseudoDataset	0.707
$DeBERTav3_{large}$	PseudoDataset	0.704
$RoBERTa_{large}$	GPT-PDataset	0.718
$DeBERTav3_{large}$	GPT-PDataset	**0.719**

Table 5: results on different dataset.

Ensemble Our ensemble approach can significantly improve performance. We integrate the results of different seeds and models based on their performance on the dev set. The result is shown in A.2, where we can see our ensemble approach outperforms the best single model by 0.15 F1 score over the dev set.

6 Conclusion

This paper details the architecture and performance of our multi-label classification system designed for the Persuasion Techniques Detection task. Our system achieves the highest rank for English in the leaderboard, signalling a notable accomplishment in the competitive framework. A comprehensive analysis of the data characteristics and model dynamics informs the strategic modifications we institute to the dataset construction and model training strategy. The efficacy of these refinements is corroborated by extensive empirical evaluation.

For future research, exploring methods to integrate the informational richness of hierarchical labels within the multi-label classification framework and fully exploiting LLMs to identify persuasion

techniques remain promising avenues for further exploration.

Abstract

This paper presents the Hallucination Recognition Model for New Experiment Evaluation (HaRMoNEE) team's winning (#1) and #10 submissions for SemEval-2024 Task 6: Shared-task on Hallucinations and Related Observable Overgeneration Mistakes (SHROOM)'s two subtasks. This task challenged its participants to design systems to detect hallucinations in Large Language Model (LLM) outputs. Team HaRMoNEE proposes two architectures: (1) fine-tuning an off-the-shelf transformer-based model and (2) prompt tuning large-scale Large Language Models (LLMs). One submission from the fine-tuning approach outperformed all other submissions for the model-aware subtask; one submission from the prompt-tuning approach is the 10th-best submission on the leaderboard for the model-agnostic subtask. Our systems also include pre-processing, system-specific tuning, post-processing, and evaluation.

1 Introduction

The HaRMoNEE team proposes two architectures to use on the SHROOM (Mickus et al., 2024) task: transformer model fine-tuning and large-scale LLM prompt tuning. First, we pre-process the data. We identify two fields from each example to use in our models.

For the fine-tuning models, the fields are then formatted into a single string with a separator token. We use three different training strategies with SHROOM data to improve performance on the test sets. Finally, we run the model on the test set and post-process the data to get a score. For prompt-tuning, the prompt is constructed around the two selected fields. Using the validation datasets, we experiment with two models and two prompts. We select the best of both and finally evaluate the test sets.

This paper reports our results from these experiments submitted during the SHROOM task's evaluation phase. We discuss the data, the task, our methods, and the experiments we ran. In addition, we analyze and discuss our results and make proposals for future work in hallucination recognition. We make our code and best results publicly available.[1]

2 Related Work

Several approaches have been taken to scoring faithfulness and identifying hallucinations. Laban et al. (2022a) proposed to use Natural Language Inference (NLI) to detect inconsistency in summarization tasks. They applied NLI to sentence pairs and aggregated the scores on the document level to obtain a faithfulness score. Lattimer et al. (2023) adopted a similar method by chunking the whole document into smaller pieces. However, they prompted LLMs to generate their scores. TrueTeacher (Gekhman et al., 2023) leveraged LLMs to generate synthetic data that could augment models' ability to identify factual inconsistencies in summarization tasks. AlignScore (Zha et al., 2023) is a unified evaluation metric for factual inconsistency that is based on the information alignment between two arbitrary text pieces. SelfCheckGPT (Manakul et al., 2023) proposed using LLMs, particularly GPT models, to generate multiple potential consistent/contradictory responses as a task-agnostic method for hallucination detection and fact-checking.

Several datasets for NLI and hallucination are commonly used to pre-train and fine-tune models for these tasks. SNLI (Bowman et al., 2015) is a large NLI dataset collected from image captions. It consists of sentence pairs labeled as entailment, contradiction, or neutral. PAWS (Zhang et al., 2019) proposed a new dataset for paraphrase identification that features non-paraphrase pairs with high lexical overlap. Honovich et al. (2022) stud-

ied the factual consistencies from text generation systems. They proposed TRUE, an automatic factual consistency assessment tool for tasks including summarization, dialogue generation, fact verification, and paraphrase detection. HaluEval (Li et al., 2023) proposed a dataset with human-annotated hallucinated instances specifically for evaluating the performance of LLMs in recognizing hallucinations.

Laban et al. (2022b) and Zha et al. (2023) both fine-tune pre-trained language models to obtain a score for each example indicating faithfulness between two texts or the likelihood of the presence of hallucination in one of the texts. Lattimer et al. (2023), Gekhman et al. (2023), and Manakul et al. (2023) all use LLMs in various ways to perform the same tasks.

3 Data and Task

SHROOM is split into two subtasks, model-aware and model-agnostic, with corresponding datasets. Task participants receive two sets of unlabeled training data, two sets of labeled validation data, and two unlabeled test sets. There is also a smaller labeled trial dataset.

3.1 Datasets

Table 1 shows a breakdown of each dataset. Table 2 shows a breakdown by label for the labeled datasets. The training sets are evenly split by example task. The validation and test sets are split 25:37.5:37.5. In each of the validation and test sets, there are more examples of "Not Hallucination" than "Hallucination".

Figure 1 is an example from the model-aware validation set. Every datapoint in the datasets includes the following fields: `task` (task: the task that the model is trained to perform, e.g. "DM", "MT", "PG"[2]), `src` (source: the text passed to the model), `hyp` (hypothesis: the model output), `tgt` (target: the "gold" text that the model should output), `ref` (reference: which field should serve as a reference for semantic information, e.g. "src" or "tgt").

The model-aware datasets include the additional field `model` (the name of the model used). The labeled data includes `labels` (the list of votes from all annotators), `label` ("Hallucination" or "Not Hallucination"), and `p(Hallucination)` (probability of hallucination: the likelihood that the model output contains hallucinated content).

The validation and test sets were labeled through crowdsourcing. Five annotators annotated each datapoint for the validation and test sets, and three annotators each for the trial set. The label of each datapoint is the label the majority of annotators chose. The probability of hallucination is reported as the ratio of "Hallucination" labels to all labels.

3.2 Task

This task is a binary classification task to determine whether the text generated by the LLM contains any hallucinated content. Accuracy is the main benchmark for this task. This task also uses Spearman's correlation coefficient, ρ, to measure the degree of agreement using `p(Hallucination)`.

From the example in Figure 1, we see the challenges of this task. Annotators were asked to determine whether the hypothesis, "Having an intense interest in something." contains hallucinated information. In addition, annotators know that the hypothesis was generated by the model `tg/flan-t5-definition-en-base`, a Definition Modeling model, from the input "I'm an avid reader. What is the meaning of avid?" Annotators are told to use "enthusiastic; keen; eager; showing great interest in something or desire to do something" as a semantic reference to make their

decision.

In this example from the model-aware validation dataset, four out of five annotators label this as "Not Hallucination". A simple probabilistic model may not be able to identify hallucinations. In this example, the target includes a few definitions of avid. Human annotators recognize that only matching one definition indicates no hallucination is present, while a probabilistic model will only see that very few tokens between these fields match. Here, one annotator did believe there was hallucination present, possibly because the hypothesis was not equally diverse or not semantically similar enough.

Another challenge is approximating the diversity of what humans consider a "Hallucination" to be across the three example tasks (PG, MT, DM). With all of this in mind, we formulate methods to identify hallucinations in LLM output.

4 Methods

4.1 Model Fine-Tuning

We first explore how transformer-based models would perform on this task. Due to the similarity of this task to NLI, models made for hallucination detection and NLI models are considered. For our preliminary experimentation, all models are trained and tested using only the validation datasets as they are labeled. Each of the validation datasets was split 80/20 into a train and test subset. The best-performing model is used for evaluation on the test set. Our preliminary experimentation shows that hallucination recognition models significantly and consistently outperform NLI models.

Despite the similarity of NLI to this task, the SHROOM dataset is more diverse than NLI datasets. SHROOM's three example tasks include many different forms of hallucinations that NLI models do not encounter as frequently or at all in their training. Models for hallucination recognition are usually trained on NLI datasets as well as others. This data diversity makes hallucination models especially well suited for the hallucinations and data in the SHROOM task.

After identifying the best model, we experiment with different fine-tuning approaches. We vary the number of epochs, which data the model is fine-tuned on, and the order of fine-tuning. Additionally, we inference these models before any training to serve as a baseline.

All models we fine-tune take in two texts as input. The first text is the frame of reference to determine if hallucinated material is present. The second text is the text that may or may not have a hallucination. The output of the model is a number from 0 to 1. A score of less than 0.5 indicates that a hallucination is "likely" present.

A score of 0 represents high confidence that hallucination is present; a score of 1 represents high confidence that hallucination is not present. Because this scale is inverse to the scale used by the task organizers, where `p(Hallucination)` being 1 indicates all annotators have chosen the label "Hallucination", the model output is subtracted from 1 and the difference is used as `p(Hallucination)`.

For our fine-tuning model architecture (as shown in Figure 3), we pre-process each datapoint by selecting two text fields to pass to the model and inverting the numerical scale to match the model output. After training, we post-process the output by re-inverting the numerical scale to get our `label` and `p(Hallucination)` fields.

Definition modeling is a task to generate a definition for a given word in context. In the example shown below, The source corresponds to the context; The target is the correct definition for this context; the hypothesis is the predicated definition from the model.

Example:
source: The sides of the casket were covered with heavy black broadcloth, with velvet caps, presenting a deep contrast to the rich surmountings. What is the meaning of surmounting?
target: A decorative feature that sits on top of something.
hypothesis: A sloping top.

Your task is to answer whether the hypothesis from the example contains any hallucination (e.g., incorrect semantic information unsupported or inconsistent with the source) and explain why. The target is inferred from the source without any hallucination. You should consider both the source and the target before making a judgment on the hypothesis.

The output should be formatted as a JSON instance that conforms to the JSON schema below.
As an example, for the schema {"properties": {"foo": {"title": "Foo", "description": "a list of strings", "type": "array", "items": {"type": "string"}}}, "required": ["foo"]}
the object {"foo": ["bar", "baz"]} is a well-formatted instance of the schema. The object {"properties": {"foo": ["bar", "baz"]}} is not well-formatted.

Here is the output schema:
{"properties": {"answer": {"title": "Answer", "description": "answer 'Yes' if the hypothesis contains hallucination; answer 'No' if the hypothesis does not contain hallucination", "type": "string"}, "reason": {"title": "Reason", "description": "a brief explanation to your answer", "type": "string"}}, "required": ["answer", "reason"]}

Figure 2: GPT Prompt 1 (Three Fields)

4.2 LLM Prompt-Tuning

Our team also uses LLMs as black-box hallucination detection systems. We first experiment with zero-shot classification on the validation sets. We use GPT-3.5 (Brown et al., 2020) and GPT-4 (OpenAI, 2023) with the prompt shown in Figure 2. If a model performs well on the validation sets, it would also be used to evaluate the test sets.

After choosing a model, we tune the prompt. The prompts we experiment with vary with respect to which fields are provided, the structure/order of the prompt, the inclusion of the task definition, and the overall verbosity of the prompt. One additional experiment we performed was the specific format of the model response. Asking a large-scale LLM to respond to a Yes/No question and give a reason may lead to many different responses. Although we expect the model to answer "Yes" or "No" when told to, it may ignore that part of the instruction and respond in a way that is correct but not directly interpretable by our post-processing such as "This contains a hallucination" instead of "Yes".

Asking the model to respond in JSON format increased the likelihood that the answer would be directly interpretable. Additionally, we ask our models to provide explanations for their "Yes" or "No" responses. While we do not use these to determine the `label` or `p(Hallucination)` for any datapoint, we found that asking LLMs to provide reasoning boosted performance. Shorter prompts such as those seen in Figure 5 were also used with these models. To ensure replicability, we set the hyperparameter `temperature` to 0.0. Setting this hyperparameter as such leads to increased determinism in responses.

Our post-processing assigns the `label` field "Hallucination" or "Not Hallucination" based on the value of the key `answer` found in GPT's JSON output. For these models, `p(Hallucination)` was set naively. Therefore, if the model returns `...{"answer": "Yes"}...`, `label` is "Hallucination" and `p(Hallucination)` is 1. When "Not Hallucination" is the label, `p(Hallucination)` is 0.

5 Experiments

Each datapoint contains up to three semantically relevant text fields, `hyp`, `src`, and `tgt`. In the model-agnostic subtask, these fields are always provided. In the model-aware subtask, `tgt` is left blank if the `task` is Paraphrase Generation (PG).

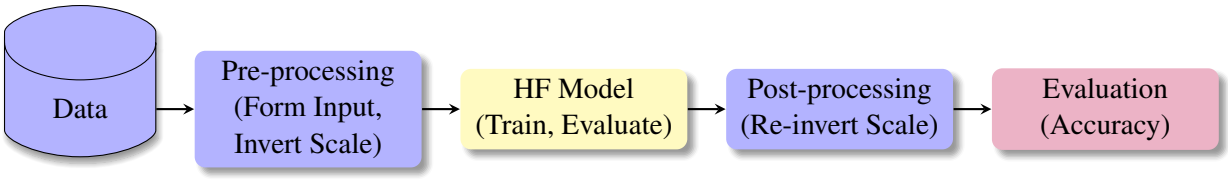

Figure 3: Fine-tuning architecture

Figure 4: Prompt-tuning architecture

Your task is to determine whether the hypothesis contains any hallucinations based on the target. (e.g., incorrect semantic information) and explain why. Only consider target and hypothesis when making the judgement. Your answer must start with 'Yes' or 'No'.

Example:
target: A decorative feature that sits on top of something .
hypothesis: A sloping top .

The output should be formatted as a JSON instance that conforms to the JSON schema below.
As an example, for the schema {"properties": {"foo": {"title": "Foo", "description": "a list of strings", "type": "array", "items": {"type": "string"}}}, "required": ["foo"]}
the object {"foo": ["bar", "baz"]} is a well-formatted instance of the schema. The object {"properties": {"foo": ["bar", "baz"]}} is not well-formatted.

Here is the output schema:
{"properties": {"answer": {"title": "Answer", "description": "answer 'Yes' if the hypothesis contains hallucination; answer 'No' if the hypothesis does not contain hallucination", "type": "string"}, "reason": {"title": "Reason", "description": "a brief explanation to your answer", "type": "string"}}, "required": ["answer", "reason"]}

Figure 5: GPT Prompt 2 (Two Fields)

We experiment by varying which of these fields get passed to our model and the structure of the model input.

We conduct a series of experiments using two approaches to detecting hallucinations. We first fine-tuned existing hallucination detection models using SHROOM validation data. Second, we experiment with a series of prompts to increase determinism and accuracy of LLMs on the same task. We show similarities of note between the best results of each architecture.

5.1 Fine-Tuning Experiments

The model that we find to perform the best on this task is a model to detect LLM-generated hallucinations. We find that the best results were obtained from this model when the input is of the form [CLS]+tgt+[SEP]+hyp for DM and MT. When tgt is not provided for the model-aware PG examples, the input [CLS]+src+[SEP]+hyp is used. This model is vectara/hallucination_evaluation_model on HuggingFace. This model took microsoft/deberta-v3-base (He et al., 2021) and trained it on two NLI datasets, SNLI (Bowman et al., 2015) and MultiNLI (Williams et al., 2018), as well as one paraphrase dataset, Paraphrase Adversaries from Word Scrambling (PAWS) (Zhang et al., 2019).

We first conducted our preliminary experiments on the split validation sets. After, we took the best-performing model, fine-tuned it on the entire validation set(s), and evaluated it on the test set(s). We experimented with varying the number of epochs, the datasets used, and the training order.

For both the model-agnostic and model-aware subtasks, we experimented with inferencing, 1-5

Dataset	Test AG		Test AW

All Data	0.785	0.652	0.808	0.713
All + Corresponding	0.783	0.683	0.810	0.671
GPT-4 (Two Fields)	**0.814**	0.626	0.783	0.614

Table 3: Best results from each approach and the baseline results. Corresponding Dataset, All Data, and All + Corresponding are fine-tuning results; GPT-4 is prompt-tuning results

epochs of training on the corresponding validation dataset, 1-5 epochs of training on all validation data, and 1, 3, or 5 epochs of training on both validation datasets before one epoch of tuning on the corresponding validation dataset.

5.2 Prompt-Tuning Experiments

In addition to fine-tuning off-the-shelf models, we experiment with GPT-3.5 and GPT-4 using several prompts. After evaluating the validation sets on GPT-3.5 and GPT-4, further prompt tuning was done on GPT-4 due to its superior performance.

The first prompt we experiment with includes `hyp`, `src`, and `tgt`, task instructions, the example task definition, and the main prompt. The second prompt we used only included two fields (`hyp` and `tgt` for DM and MT, `hyp` and `src` for PG), task instructions, and the main prompt.

6 Results

Our best results from each training architecture are shown in Table 3. One notable similarity between our best results from each system is that they required pre-processing (data pruning). We obtain our best results by only including two of the three meaningful fields for each datapoint in both fine-tuning and prompt-tuning methods. For the fine-tuning methods, converting three fields into two via concatenation underperformed ignoring one field (`src` was ignored if `tgt` was provided). Additionally, removing the definitions of DM, MT, and PG from the prompt led to improved results.

Despite not making explicit use of the `model` field for the model-aware subtask, our models' best performances earned a higher spot in the model-aware subtask than the model-agnostic one. For the model-aware subtask, we use `src` when `tgt` is not provided for the model-aware PG examples. We also believe it to be due to the differences in other fields. For instance, the DM examples for the

Dataset	Test AG	Test AW

All + Aware Data	0.794	0.808		0.810		0.795

Table 5: Table of accuracy data shown in Figure 6

model-aware and model-agnostic tasks are formatted differently. The model-aware examples ask for the definition explicitly at the end of the `src` field (e.g. "... What is the meaning of spoilage ?"). The model-agnostic examples put the word to define in tags (e.g. "The <define> sacrifice bunt </define> was fielded cleanly..."). These different tagging strategies reflect inputs different DM models take in. Based on our results in Table 4, it seems that our systems are better are recognizing hallucinations obtained via <define> tags.

Scores within .001 point of each other were obtained for each subtask using these systems, yet different systems performed the best for each. Our shorter prompt with GPT-4 produced our best results (#10) for the model-agnostic subtask, .117 points above the task organizer baseline. Training on the corresponding SHROOM validation dataset produced the best results (#1) for the model-aware subtask, .068 points above the task organizer baseline.

6.1 Fine-Tuning Results

Our team's first experiments on the test set involved varying the number of epochs, the training set(s), and the training order. These results for the model-agnostic and model-aware subtasks are shown in Figure 6 and Table 5. The 0 epoch results are from inferencing the model before training on SHROOM data. They serve as a baseline for all training strategies. This model's strong performance at inference for both test sets made it a strong contender for more fine-tuning. On the model-agnostic subtask, inferencing resulted in an accuracy of 0.756. On the model-aware subtask, it obtained a score of

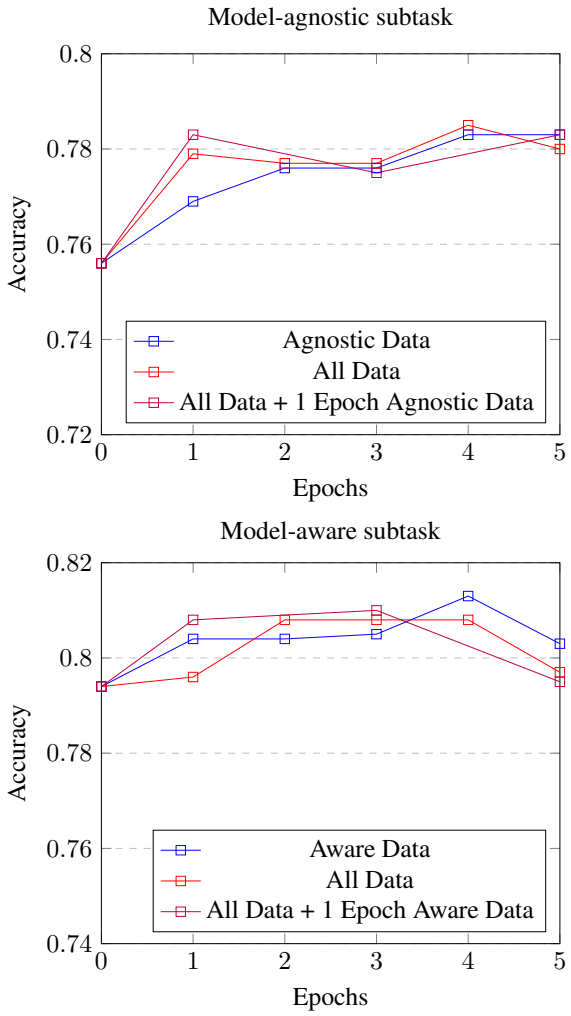

Figure 6: Line graphs showing accuracy on the test sets of both subtasks after fine-tuning

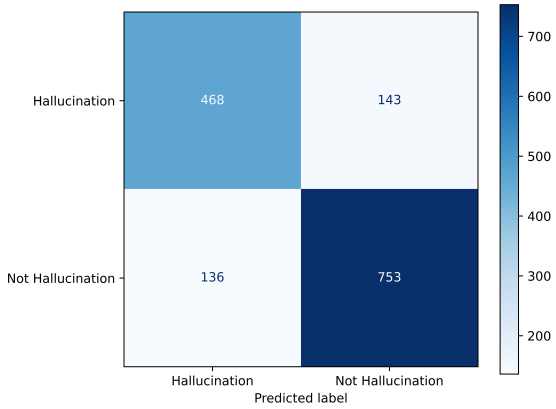

Figure 8: Confusion matrix for the #10 submission on the model-agnostic dataset (prompt-tuning approach)

Dataset	Val AG	Val AW
SHROOM Baseline	0.649	0.707
GPT-3.5	0.661	0.596
GPT-4 (Three Fields)	0.778	0.751
GPT-4 (Two Fields)	**0.782**	**0.773**

Table 6: Comparison of the baseline results to our results on the validation sets using accuracy

0.794.

Training with any SHROOM data led to better performance on the test set. For the model-agnostic subtask, our team's best result came from fine-tuning the model on the model-agnostic and model-aware datasets together for four epochs. This increased the accuracy from our inference baseline by 0.029 to 0.785. On the model-aware subtask, our team's best results were obtained after fine-tuning the model using only the model-aware data for four epochs. This increased the accuracy from the inference baseline by 0.019 to 0.813, our winning submission for the model-aware subtask.

As seen in Figure 7, this architecture performs well on the SHROOM model-aware subtask. Figure 9 and Table 4 show a breakdown by task. This model performed very well on PG and MT but much worse on DM. We believe this task has the lowest accuracy for the same reason we identified earlier in the paper. The target, source, and hypothesis fields may vary much more than in the other two tasks. The target may be much more or much less semantically rich than the hypothesis, which can be interpreted by human annotators and out models in many different ways. For the winning submission, the accuracy for the PG task was .875, MT was .837, and DM was .747.

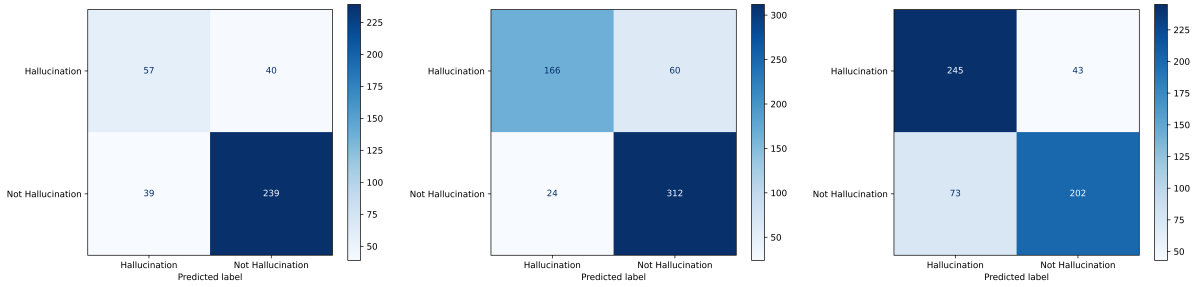

Figure 10: Confusion matrices the #10 submission on the model-agnostic dataset (prompt-tuning method) split by example task. Left to right: Paraphrase Generation, Machine Translation, Definition Modeling

6.2 LLM-Tuning Results

Our LLM experimentation results are shown in Table 6. Because we experimented with prompt-tuning on the validation sets, we were able to directly compare our results to the baselines provided by the task organizers. We found that GPT-3.5 performed worse than the baseline for one subtask and did not pursue further experiments with it. We tested two prompts on the validation sets.

Our first prompt (Figure 2) includes all meaningful fields that annotators had access to when labeling the data. For the model-agnostic subtask, this prompt outperformed the baseline by 0.129 with an accuracy of 0.778. it improved the accuracy in the model-aware subtask by 0.044 with an accuracy of 0.751.

Our second prompt (Figure 5) includes selected fields of meaningful information from each datapoint. It does not explain the example task (DM, MT, or PG) for the datapoint but still explains the shared-task instructions and output formatting instructions. This reduction in verbosity led to improved performance for both subtasks. For the model-agnostic validation set, this change resulted in a .133 point increase in accuracy above the baseline and a .004 point increase compared to the first prompt. For the model-aware validation set, this change resulted in a .066 point increase compared to the baseline and a .022 increase compared to the first prompt.

We also experimented with few-shot learning and found that both random examples and selected examples did not improve performance on either subtask. Overall, we found that a less verbose prompt outperformed a more verbose prompt indicating that GPT has difficulty making connections across large amounts of text. Additional information that GPT may not need in each prompt, such as the example task definition and the third field, adds noise to the prompt and impairs its ability to detect hallucinations.

The confusion matrices in Figures 8 and 10 show the performance of this architecture on the entire test set and on each task for the model-agnostic subtask. For this submission, the accuracy for the PG task was .789, significantly lower than the other example tasks. We believe this is because we used the `tgt` field for all tasks here as it is always provided. In the model-aware subtask, `tgt` is not provided for PG examples, so `src` is used instead. This may indicate that `tgt` is best for MT and DM, but `src` for PG even if `tgt` is provided. The accuracy for the MT task examples was .851, similar to the model-aware subtask. The accuracy for Definition Modeling was .794.

7 Discussion and Conclusion

In this paper, we present two systems for hallucination recognition, one transformer-based model fine-tuned on SHROOM data and one prompt-tuned zero-shot classification model using GPT-4. Our results show that both systems can better handle semantically complex tasks such as hallucination recognition when only semantically relevant information is provided. Pre-processing each example is essential to good performance on this task. From our results, fine-tuning using available labeled data from all tasks improves performance from the baseline. Additionally, pruning information such as over-explicit instructions, irrelevant fields, and definitions from prompts also improves performance from the baseline.

Some avenues we did not fully explore include training on pseudo-labeled training data, training on additional datasets besides SNLI, MultiNLI, and PAWS (specifically adversarial translation or word disambiguation datasets), as well as experimenting with dense paraphrasing and frame saturation methods as proposed by Tu et al. (2023). In this shared task, our team found that it is easier to harmonize by tuning fewer, clearer voices.

epuerta@utb.edu.co

Abstract

This study introduces an innovative approach to emotion recognition and reasoning about emotional shifts in code-mixed conversations, leveraging the NRC VAD Lexicon and computational models such as Transformer and GRU. Our methodology systematically identifies and categorizes emotional triggers, employing Emotion Flip Reasoning (EFR) and Emotion Recognition in Conversation (ERC). Through experiments with the MELD and MaSaC datasets, we demonstrate the model's precision in accurately identifying emotional shift triggers and classifying emotions, evidenced by a significant improvement in accuracy as shown by an increase in the F1 score when including VAD analysis. These results underscore the importance of incorporating complex emotional dimensions into conversation analysis, paving new pathways for understanding emotional dynamics in code-mixed texts.

1 Introduction

Exploring emotion recognition in textual and multimodal conversations is crucial within Natural Language Processing (NLP) and Artificial Intelligence (AI). This domain addresses the complexity of human emotional expression, particularly challenged by the interlacing of multiple languages in code-mixed texts. Such code-switching, prevalent in digital communication, necessitates innovative computational strategies to decipher the embedded emotional substrates (Wang et al., 2022), presenting unique challenges for emotion recognition and understanding.

Recent advancements have highlighted the potential of complex neural architectures, like hierarchical transformers, to dissect the nuanced interplay between linguistic codes. This approach indicates a broader NLP trend that prioritizes models capable of parsing linguistic structures and decoding emotional cues within them (Cuadrado et al., 2023a). Significantly, the dynamic nature of conversational emotion and the phenomenon of emotion flips in multi-party interactions call for adaptive models that can trace these shifts accurately (Puertas et al., 2022).

Moreover, multimodal approaches that integrate visual, textual, and auditory cues are pivotal in capturing the essence of code-mixed interactions. These strategies convey sentiment and intention, underscoring the significance of non-verbal cues (Martinez et al., 2023). Additionally, the exploration of large language models for understanding complex conversational patterns has led to an evolving AI research landscape, where the efficacy of models like GPT in nuanced tasks such as sarcasm explanation and affect understanding in dialogues is rigorously evaluated (Cuadrado et al., 2023b).

Analyzing sociolinguistic features in digital social networks further enriches the discourse on digital communication's implications for emotion recognition and conversational AI. It includes bot detection, gender profiling, and community detection through sociolinguistic cues analysis (Moreno-Sandoval et al., 2019; Puertas et al., 2021, 2019). Moreover, the precision application of NLP methodologies, such as phonetic detection techniques for identifying hate speech spreaders on Twitter, showcases the necessity for targeted approaches to specific social media phenomena (Puertas and Martinez-Santos, 2021).

Our research aims to advance the understanding of NLP's multifaceted applications in digital interactions' integrity and authenticity. Through the analysis of polarity, emotion, and user statistics for fake profile detection, alongside multimodal emotion-cause pair extraction in conversations, we seek to significantly improve the comprehension of the complex interrelations between emotional expressions and their triggers (Moreno-Sandoval and Alvarado-Valencia, 2020; Wang et al., 2022).

In evaluating the incorporation of Valence,

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1332–1338

Arousal, and Dominance (VAD) scores from the NRC VAD Lexicon into our computational models, we observed a marginal performance improvement. Specifically, the inclusion of VAD scores resulted in F1 scores of 0.34 for Emotion Flip Reasoning (EFR) and 0.23 for Emotion Recognition in Conversation (ERC), compared to models without VAD scores, which achieved F1 scores of 0.32 and 0.20 for EFR and ERC respectively. These results underscore the nuanced challenges of accurately capturing emotional shifts in code-mixed conversations, paving the way for future research to refine and enhance emotion recognition systems in complex conversational contexts. Find here the GitHub repository[1]

2 Related Work

The recognition of emotions in code-mixed text and multimodal conversations has garnered increasing attention within the natural language processing (NLP) and artificial intelligence (AI) communities. The growing prevalence of code-switching in digital communication fuels this surge in interest and the multifaceted nature of human emotional expression.

Recent advancements in understanding code-mixed language semantics have underscored the potential of hierarchical transformer models to grasp the nuanced interplay between different linguistic codes (Sengupta et al., 2022). Through their ability to capture deep semantic relationships, these models offer a promising avenue for more accurate emotion recognition in code-mixed conversations. Such approaches align with the broader trend of employing sophisticated neural architectures to tackle the complexities of multilingual text processing.

Studies focusing on multiparty interactions have specifically addressed emotion flip in conversations, where the emotional trajectory can shift dramatically due to a single utterance or interaction (Kumar et al., 2023a, 2024a,b, 2022b). These studies highlight the dynamic nature of conversational emotion and the need for models that can adaptively reason about these shifts to maintain coherence and accuracy in emotion recognition tasks.

Multimodal approaches to sarcasm detection and humor classification in code-mixed conversations further illustrate the rich potential of integrating visual, textual, and auditory cues to enhance the understanding of conversational context and emotional undertones (Bedi et al., 2021). This multimodal perspective is critical in fully capturing the essence of code-mixed interactions, where non-verbal cues significantly convey sentiment and intention.

Exploring large language models' capability in logical reasoning and understanding complex conversational patterns points towards an evolving landscape in AI. Researchers have tested models like GPT (Generative Pre-trained Transformer) for their efficacy in nuanced tasks such as sarcasm explanation and effect understanding in dialogues (Xu et al., 2023). These inquiries into the logical capabilities of large models contribute to a deeper understanding of their potential applications in conversational AI and emotion analysis.

Moreover, research on explaining sarcastic utterances to enhance affected understanding in multimodal dialogues sheds light on the importance of context and the subtleties of human communication. Such work suggests that describing a particular emotional expression's underlying intent or cause beyond detecting sarcasm or emotion is crucial for advanced AI systems for naturalistic human-computer interaction (Kumar et al., 2023b).

The development of comprehensive datasets like MELD, which provides a multimodal multiparty dataset for emotion recognition in conversations, has been instrumental in advancing research in this area (Poria et al., 2018). These datasets not only facilitate the training and testing of sophisticated models but also enable the exploration of new methodologies for emotion recognition across diverse conversational settings.

As we move forward, the integration of insights from masked memory networks, transformer models, and intent-conditioned counter speech generation into the realm of emotion recognition and conversational AI promises to open new avenues for research and application (Poria et al., 2018; Kumar et al., 2022c; Christ et al., 2023). The collective efforts in these areas underscore the ongoing pursuit of more empathetic, contextually aware, and linguistically versatile AI systems capable of navigating the complexities of human emotion and communication.

3 Methodology

This section details the methodology adopted for analyzing emotion causes in multimodal conversations. Our approach, grounded in integrating

[1]https://github.com/VerbaNexAI/EmoVAD.git

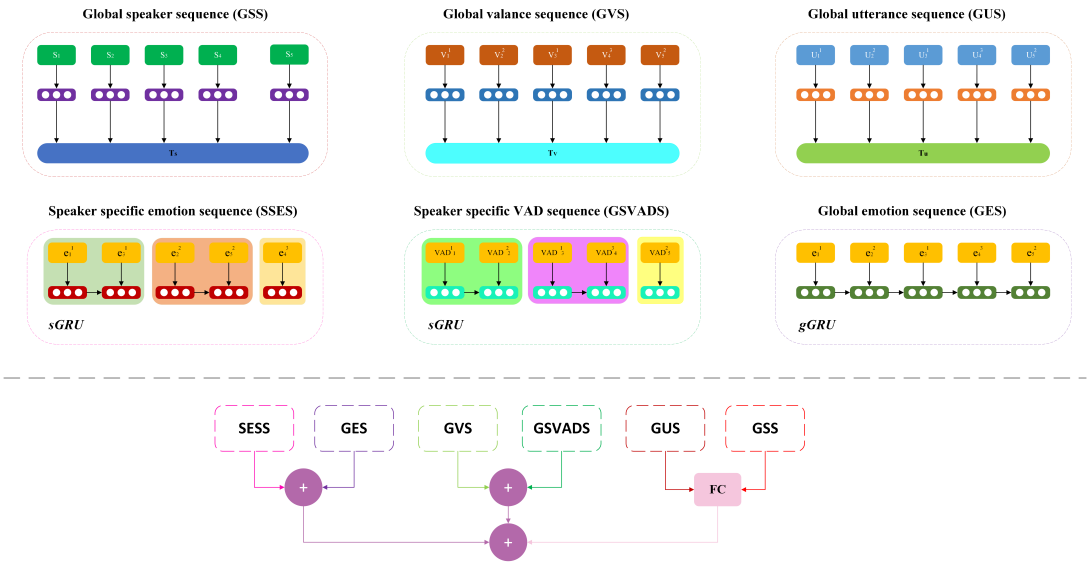

Figure 1: System General Pipeline

the NRC VAD Lexicon and computational models, aims to systematically identify and categorize emotion triggers. The methodology encompasses Emotion Flip Reasoning (EFR) for detecting shifts in conversation emotions and Emotion Recognition in Conversation (ERC), focusing on classifying these emotions accurately. By employing a combination of Transformer and GRU models, we enhance the analysis of valence, arousal, and dominance (VAD) scores, contributing to a nuanced understanding of emotional dynamics in conversations. All scripts and data related to this study are available at SemEval 2024 VerbaNex AI Repository.

3.1 Emotion Flip Reasoning

This section shows the proposed model and how this can identify the trigger for the corresponding emotional flip in the conversation; the way to identify it is by analyzing each utterance in the sequence; that is, the task is essential for a binary classification because we're trying to categorize each utterance responsible or not for the emotion flip. (Kumar et al., 2023a) propose the TGIF model, which contains the context of utterances, speakers, and emotions. This model explains how to process these three inputs through the pipeline. They propose four modules:

- **Global Utterance Sequence:** They use a Transformer (Vaswani et al., 2017) encoder architecture to push the $U = u_2, u_1, ..., u_i$ utterance distribution into a latent space, capture the global context of the dialogue
- **Global Emotion Sequence:** In this approach, we use GRU for the emotions processing, due to there are just a few (Ekman, 1992) emotions {*disgust, joy, surprise, anger, fear, sadness*} encoded in one hot.
- **Speaker-Specific Emotion Sequence:** This time, they also process the emotions, but concerning the speakers, each speaker has their own GRU for the speaker's emotions
- **Global Speaker Sequence:** For the speakers processing, they also use a Transformer approach encoded in one hot.

The original task in (Kumar et al., 2023a) was to predict the instigator(s) label(s) for each emotion flip; for example, they assign 'nervousness' and 'adoration' instigators to the trigger utterances u_2 and u_3, the instigator is the reason why the emotion flip occurs. We worked on a simple task: identify the trigger in the conversation and which utterance was the cause of the emotion flip.

We propose a new serial of data input to contribute to the model performance; this data is (Mohammad, 2018) NRC VAD Lexicon. This Lexicon contains the {*valence, arousal, dominance*}, with the valence the positive/negative or pleasure/displeasure dimension, arousal is the excited/calm or active/passive dimension. Dominance is the powerful/weak or 'have full control'/' have no control' dimension. We compare the words between the NRC VAD Lexicon dictionary and the words in each utterance and build a personal-

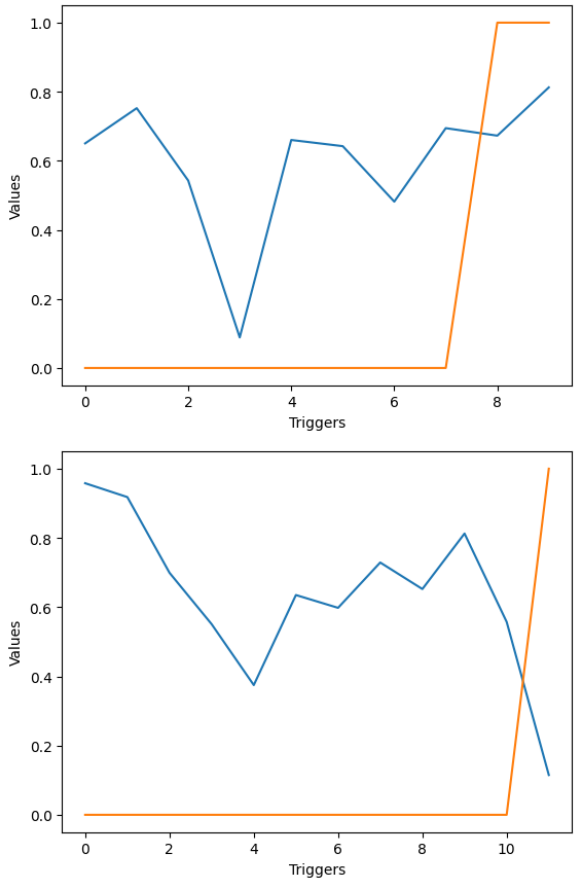

Figure 2: These two graphics describe the relationship between the valence behavior and triggers

ized dictionary for our dataset. We get the following distributions, $u_i = w_0, w_1, ..., w_l$, l begin the number of words in a given utterance, and each word has this distribution $w_l = v_l, a_l, d_l$ (or in the case of the articles, pronouns, etc., the value will be 0), the aim here is to calculate the values of valence, arousal, and dominance that represent the whole utterance, then we apply $1/l \sum_{i=1}^{l} v_i$, $1/l \sum_{i=1}^{l} a_i$, $1/l \sum_{i=1}^{l} d_i$, so the final shape is $u_i = v_{avg}, a_{avg}, d_{avg}$, the VAD values will be lower so we scale it into [0,1]

We took all these features to help the model in the classification task; we found a relationship between the VAD values peak and the trigger sequence location in several samples. see Figure 2

To contribute to the model, we added a new Transformers Encoder for the valence, arousal, and dominance values and a GRU for VAD speaker-specific values. Like the Speaker-Specific Emotion Sequence, we compute a particular speaker's VAD sequence and go through lineal classification layers, see Figure 1.

3.2 Emotion Recognition in Conversation

The architecture for emotion recognition parallels EFR's, with modifications to accommodate emotion as the primary label. This adjustment allows for a direct correlation between VAD scores and emotion classification, eliminating the need for separate emotion modules. The methodological choice to employ GRU models for processing speaker-specific emotional sequences facilitates a refined analysis, enabling the identification of diverse emotional expressions within the conversational context.

4 Experiments

This section presents the experimental setup, including dataset description, data preprocessing techniques, and model evaluation. Utilizing the MELD dataset, we describe our approach to representing conversational utterances through advanced embedding methods. The experiments aim to validate the effectiveness of our methodology in identifying and classifying emotional causes within conversations. Our findings, evaluated against established metrics, indicate a promising direction for future research in multimodal emotion analysis.

4.1 Dataset

MELD. (Poria et al., 2019) is an extension and enhancement of (Chen et al., 2018) EmotionLines. MELD contains dialogues from the TV series Friends. Each utterance is annotated with emotion and sentiment labels and encompasses audio, visual, and textual modalities. The SemEval 2024 Task 10 Subtask 1 presents a variation of MELD, providing *speakers, utterance, emotion* as only textual features and *triggers* as labels.

(Kumar et al., 2023a) identify a set of trigger utterances that cause the emotion to flip at the target. They mark each utterance that acts as a trigger as 'Yes' and the ones not contributing as 'No'.

MaSaC. (Bedi et al., 2023) develop a Hindi-English code-mixed dataset for the multi-modal sarcasm detection and humor classification in conversational dialog. Like MELD, SemEval modifies the dataset for two tasks (ERC and EFR) and only textual data(Kumar et al., 2023c). ERC uses *emotions* as labels, and EFR uses *triggers*

NRC-VAD Lexicon. The National Research Council Canada Valence, Arousal, and Dominance (NRC-VAD) Lexicon (Mohammad, 2018) includes a list of more than 20,000 English words and their valence, arousal, and dominance scores. For a given word and a dimension (V/A/D), the scores range from 0 (lowest V/A/D) to 1 (highest V/A/D). The lexicon with its fine-grained real-valued scores was created by manual annotation using Best-Worst Scaling. The lexicon is markedly more significant than any of the existing VAD lexicons.

4.2 Data Preprocessing

Utterances. To represent the sentences in a dense numerical vector, we use Sentence Embedding pre-trained models. Specifically (Song et al., 2020) the model MPNet, due we handle a sequence of sentences and not a sequence of words is necessary to put all the utterance meaning in just one vector that the Transformer Encoder could process. In the case of Hindi-English code-mixed, we use paraphrase-multilingual-mpnet-base-v2 - Multilingual version of MPNet, trained on parallel data for 50+ languages.

Emotions and Speakers. We use One-Hot Encoder in both cases; the speaker's sequence has a tensor shape of max sequence length and max number of unique speakers in a dialogue in the whole dataset. We assign a one-hot vector for each emotion.

One of the other steps is padding the dataset for every sequence by the maximum sequence length.

5 Results

In our experimental investigations, we meticulously evaluated various configurations of our model and adjusted hyperparameters, alternating between Transformer and GRU modules. For the Emotion Flip Reasoning (EFR) task, we utilized sigmoid neurons with binary cross-entropy loss for binary classification. For Emotion Recognition in Conversation (ERC), we employed softmax neurons with cross-entropy loss for multi-class classification. The F1 score was chosen as the primary metric for evaluation, reflecting the balanced consideration of precision and recall in our assessments.

The integration of Valence, Arousal, and Dominance (VAD) values, crucial emotional dimensions discussed in Section 3, was meticulously analyzed to optimize the model configuration. Drawing on the methodology proposed by (Kumar et al., 2022a), we processed the VAD values with a Transformer Encoder and amalgamated them with other Transformer modules via a linear layer. Similar to processing emotion-specific data, we treated VAD values in a speaker-specific manner using several GRUs, subsequently integrating them with emotion modules through straightforward concatenation.

As depicted in Table 1, the results underscore the significance of including VAD in the model. With VAD integration, the model achieved F1 scores of 0.34 for EFR and 0.23 for ERC, demonstrating improvements of approximately 13% and 5%, respectively, over the configurations without VAD. These findings were consistent across both MELD and MaSaC datasets, highlighting VAD's contribution to enhancing model performance in identifying emotion flips and recognizing emotions in code-mixed conversations.

Our analysis revealed a notable observation regarding the model's distribution loss function. The model's propensity to predict triggers at the beginning of sequences was identified, with ROC and AUC analyses suggesting an optimal threshold of 0.3. For the ERC task, a tendency to predict the 'neutral' category was observed, possibly due to the low deviation of most VAD values from the mean. However, considering the broadly spaced combinations of valence, arousal, and dominance led to slight but discernible improvements in model performance.

Comparatively, while showing promise, our model's performance indicates room for further refinement, especially when juxtaposed with other participants in the shared task. It underlines the necessity for ongoing enhancements and reevaluating the methodological approach to emotion recognition in complex, code-mixed conversational contexts.

Limitations of our current work, including potential dataset biases and the model's generalizability across varied types of code-mixed text, warrant further investigation. Future research directions could encompass exploring additional linguistic features and incorporating other dimensions of emotional reasoning, aiming to build on the foundational insights gained from this study.

6 Conclusion

This study ventured into the complex domain of emotion recognition and reasoning in code-mixed

Model	F1 Score	
	MELD	MaSaC
With VAD	0.34	0.23
Without VAD	0.32	0.20

Table 1: Model Results

conversations, with a particular focus on the tasks of Emotion Flip Reasoning (EFR) and Emotion Recognition in Conversation (ERC). Our primary contribution has been the integration of Valence, Arousal, and Dominance (VAD) values into computational models, aiming to enrich the models' understanding of emotional shifts within dialogues. Despite the modest improvements observed in our experimental results, our work underscores the nuanced challenge of effectively identifying emotion flips and recognizing emotions in code-mixed texts. The incremental advancements achieved, particularly the slight enhancements in F1 scores with VAD values, highlight the potential of incorporating emotional dimensions into NLP models for a deeper understanding of conversational dynamics.

7 Future Work

The pathway forward from this investigation is twofold. Firstly, there is a pressing need to explore additional linguistic and emotional features that could enhance the accuracy and robustness of emotion recognition models. It includes delving deeper into the complexities of code-mixing phenomena and how they influence emotional expression and perception. Secondly, our findings advocate for developing more sophisticated model architectures capable of handling the intricacies of multimodal data and the multifaceted nature of human emotions. Future research should also consider the implications of dataset biases and the challenge of generalizing models across diverse code-mixed contexts. By addressing these areas, subsequent work can build upon the foundational insights provided by this study, contributing to the advancement of NLP and AI's capability to navigate the rich tapestry of human emotions in digital communications.

Abstract

This study delineates our participation in the SemEval-2024 Task 3: Multimodal Emotion Cause Analysis in Conversations, focusing on developing and applying an innovative methodology for emotion detection and cause analysis in conversational contexts. Leveraging logistic regression, we analyzed conversational utterances to identify emotions per utterance. Subsequently, we employed a dependency analysis pipeline, utilizing SpaCy to extract significant chunk features, including object, subject, adjectival modifiers, and adverbial clause modifiers. These features were analyzed within a graph-like framework, conceptualizing the dependency relationships as edges connecting emotional causes (tails) to their corresponding emotions (heads). Despite the novelty of our approach, the preliminary results were unexpectedly humbling, with a consistent score of 0.0 across all evaluated metrics. This paper presents our methodology, the challenges encountered, and an analysis of the potential factors contributing to these outcomes, offering insights into the complexities of emotion-cause analysis in multimodal conversational data.

1 Introduction

The automatic detection and analysis of emotions in the text have gained substantial traction within the realm of computational linguistics and affective computing, particularly given their profound implications for understanding human-computer interaction (Moreno-Sandoval et al., 2019; Puertas et al., 2021), mental health, and the dynamics of social communication (Cuadrado et al., 2023a; Puertas et al., 2022). Integrating emotion analysis technologies into interactive systems can revolutionize user experience, providing applications that can adapt to users' emotional states in real-time, thus creating more engaging and personalized interactions (Moreno-Sandoval et al., 2020). SemEval-2024 Task 3 introduces a compelling challenge in this arena: the Multimodal Emotion Cause Analysis in Conversations (Wang et al., 2024). This task necessitates the identification of emotions within conversational utterances and elucidating the underlying causes behind these emotional expressions, a nuanced inquiry that extends beyond the textual modality to encompass a multimodal understanding.

In mental health, the automated text analysis for emotional content has shown promise as a tool for early detection of disorders such as depression and anxiety, using data from social media platforms as a rich source of behavioral indicators (Martinez et al., 2023). Similarly, in the domain of social communication, understanding the interplay of emotions and their causes in conversations can enhance the development of systems designed for conflict resolution, educational purposes, and even in the entertainment industry to create more compelling narratives and interactive experiences (Cuadrado et al., 2023b; Moreno-Sandoval et al., 2020; Marrugo-Tobón et al., 2023; Puertas and Martinez-Santos, 2021; Puertas et al., 2019).

Motivated by this task's complexity and innovative potential, our study endeavors to bridge the gap between emotion detection and cause analysis through a methodological approach. By integrating logistic regression models for emotion identification with advanced dependency analysis techniques for cause extraction, we aimed to uncover the intricate patterns of emotional causality in conversations. Our approach is distinguished by its reliance on linguistic features extracted from dependency graphs, facilitating a deeper understanding of the relational structures that underpin emotional discourse.

However, the journey from conceptualization to realization was fraught with challenges. Initial results, marked by a uniform score of 0.0 across evaluation metrics, starkly underscored the task's difficulty and highlighted our methodology's limita-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1339–1343

tions. This outcome reflects the complexities inherent in the nuanced analysis of emotional causality. It emphasizes the need for continuous innovation in the field. The exploration of multimodal data sources, including text, audio, and visual cues, represents a frontier in affective computing, promising to enrich our understanding of emotions in human interactions.

2 Related Work

The task of emotion-cause analysis in conversations has been extensively explored, with recent advancements highlighting the integration of multimodal data and sophisticated natural language processing techniques. This section synthesizes contributions from several seminal works that are directly relevant to the challenges and objectives of SemEval-2024 Task 3 (Wang et al., 2024, 2023; Xia and Ding, 2019).

The MELD dataset introduced by Poria et al. presents a comprehensive multimodal multi-party dataset for emotion recognition in conversations, underscoring the significance of leveraging verbal and non-verbal cues for accurate emotion detection (Poria et al., 2018). This work emphasizes the complexity of emotion and sarcasm recognition in dynamic conversational contexts. It sets a foundational benchmark for subsequent research.

Kumar et al.'s exploration of emotion and its flip in multi-party conversations through a masked memory network and transformer model offers profound insights into the transitional dynamics of emotional states within dialogue (Kumar et al., 2022). Their methodology provides a robust framework for understanding emotional shifts, contributing valuable perspectives to conversational emotion analysis.

Research on multimodal sarcasm detection and humor classification in code-mixed conversations by (Christ et al., 2023) illustrates the challenges and opportunities in identifying nuanced affective states through a combination of textual and visual information. This study highlights the intricate relationship between language use and non-verbal indicators in conveying sarcasm and humor.

The work by (Gupta et al., 2023) on explaining sarcastic utterances to enhance affect understanding in multimodal dialogues further delves into the importance of context and explicit presentation of utterances for sarcasm detection. Their approach underscores the necessity of comprehensive analysis to grasp the underlying affective dimensions in conversations.

The investigation into the reasoning capabilities of large language models by (Xu et al., 2023) questions their efficacy in logical deduction and emotional understanding within conversational settings. This critique prompts a reevaluation of the applications of such models in affective computing, suggesting a need for more nuanced and context-aware methodologies.

Recent studies introduce novel problems and solutions, such as sarcasm explanation in multimodal multi-party dialogues (Yadav et al., 2021), targeted sentiment analysis in the financial domain using transformer-based models and phonestheme embeddings (Vasanth et al., 2022), and automated depression detection leveraging lexical features and RoBERTa transformer models (Naseem et al., 2020). These contributions highlight the expanding scope of affective computing research, including advancements in hate speech detection (Sisi and Jing, 2023) and the nuanced analysis of economic sentiment (Vasanth et al., 2022), underscoring the versatility and complexity of emotion analysis in diverse contexts.

3 Methodology

We designed our methodology to address the challenge of emotion-cause analysis in Conversations, as outlined in SemEval-2024 Task 3, focusing exclusively on textual analysis before considering other modalities. This decision stemmed from our initial goal to establish a solid foundation in text analysis, which, if successful, would have been extended to a multimodal approach. Unfortunately, our endeavors in the textual dimension did not yield the expected results, leading us to concentrate on addressing these challenges without extending our analysis to include audio or video data. We made accessible all scripts and data related to this study at SemEval 2024 VerbaNex AI Repository.

3.1 Data Acquisition and Preprocessing

Our initial phase involved collecting a dataset of conversational utterances provided by the SemEval-2024 Task 3 organizers. Despite the task's multimodal nature, we primarily focused on the textual component. We aimed to extract and analyze linguistic features indicative of emotional expression and causality using standard NLP techniques such as tokenization, lemmatization, and part-of-speech

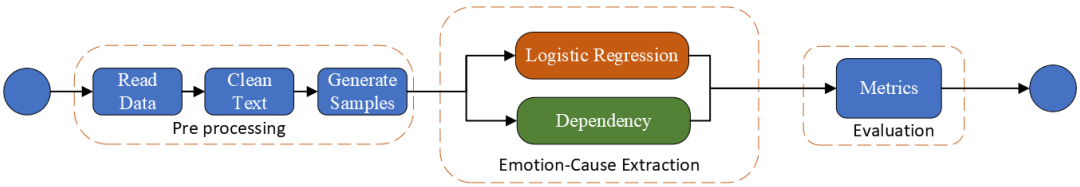

Figure 1: System General Pipeline

tagging facilitated by the SpaCy NLP library.

3.2 Emotion Detection Using Logistic Regression

We implemented a logistic regression model for emotion detection, chosen for its simplicity and effectiveness in binary classification tasks. We trained this model on a dataset subset labeled with emotional annotations. We based the features selected for the model on their potential relevance to emotional expression, including word embeddings derived from pre-trained models and syntactic features extracted during preprocessing. Additionally, we utilized 'CountVectorizer' from scikit-learn to transform text documents into a numerical matrix of word or token counts, which aided in the feature extraction process.

3.3 Dependency Analysis and Feature Extraction

Our core methodology involved analyzing dependency structures within conversational utterances. Utilizing SpaCy's dependency parser and basing our approach on Universal Dependency Relations and the concepts outlined in the "Universal Stanford Dependencies: A cross-linguistic typology," we identified and analyzed noun chunks and their syntactic relationships. We focused on dependencies indicative of emotional causality, such as objects, subjects, adjectival modifiers, and adverbial clause modifiers. These dependency relationships were conceptualized as edges in a graph-like structure, aiding in analyzing the connection between emotional expressions and their causes within the conversation.

3.4 Analysis for Emotion Cause Identification

The culmination of our methodology involved applying a graph-based analysis to map the extracted dependency features onto a framework modeling the conversational flow and interconnections between utterances. This analysis aimed to identify patterns signifying the causality of emotions by tracing the path from an emotional expression to its trigger within the graph. Despite the theoretical soundness of this approach, it encountered challenges in accurately capturing the nuances of emotional causality.

3.5 Task Formulation and Model Inputs

The task was formulated to detect emotion-cause pairs within a complete conversation, with each conversation serving as a single input to our model. We designed this approach to capture the intricacies of conversational dynamics and the contextual interplay of emotional expressions and their causes.

4 Partial Results and Failure Analysis

The logistic regression model achieved a score of 0.52 in emotion detection. However, the final results for emotion-cause pairing were disappointingly at 0.0. The initial low precision of the emotion detector contributed to these results. Further complicating our analysis, handling punctuation and syntactic ambiguities in dependency analysis introduced additional challenges, underscoring the complexity of accurately analyzing emotional causality in text.

5 Conclusions

Using logistic regression and dependency analysis techniques, our exploration into Emotion Cause Analysis in Conversations encountered unexpected hurdles, culminating in a consistent score of 0.0 across all evaluation metrics. This outcome reflects the inherent challenges in interpreting emotional cues from text alone. It highlights a fundamental mismatch between our initial methodological choices and the task's complexity. Our experience underlines the intricacies of detecting and analyzing emotional expressions and their causes within conversational dynamics. Our chosen tools did not capture the nuanced interplay of emotions in a multimodal context.

6 Future Directions

Our research will pivot towards employing more sophisticated models, focusing on transformer-based approaches. These models are renowned for their ability to grasp deeper contextual nuances and hold promise for significantly improving our analysis. Recognizing the pivotal role of multimodal data in enriching emotion analysis, we aim to extend our methodology to incorporate audio and visual cues alongside textual information. This expansion might offer a more holistic understanding of emotional causality in conversations. By refining our evaluation framework and integrating these diverse data types, we aspire to contribute meaningfully to the fields of affective computing and computational linguistics, paving the way for a more nuanced and comprehensive exploration of emotional interactions in conversational settings.

VerbaNexAI Lab at SemEval-2024 Task 1: A Multilayer Artificial Intelligence Model for Semantic Relationship Detection

Anderson Morillo and **Daniel Peña**
Juan Carlos Martinez-Santos and **Edwin Puertas**
Universidad Tecnologica de Bolivar, Cartagena Colombia
epuerta@utb.edu.co

Abstract

This paper presents an artificial intelligence model designed to detect semantic relationships in natural language, addressing the challenges of SemEval 2024 Task 1. Our goal is to advance machine understanding of the subtleties of human language through semantic analysis. Using a novel combination of convolutional neural networks (CNNs), long short-term memory (LSTM) networks, and an attention mechanism, our model is trained on the STR-2022 dataset. This approach enhances its ability to detect semantic nuances in different texts. The model achieved an 81.92% effectiveness rate and ranked 24th in SemEval 2024 Task 1. These results demonstrate its robustness and adaptability in detecting semantic relationships and validate its performance in diverse linguistic contexts. Our work contributes to natural language processing by providing insights into semantic textual relatedness. It sets a benchmark for future research and promises to inspire innovations that could transform digital language processing and interaction.

1 Introduction

The analysis of semantic relationships in natural language is considered an essential pillar for understanding the inherent complexity of textual communication Wolfe et al. (2005). With the increasing application of artificial intelligence (AI) models in natural language processing, the ability to discern semantic similarity between text fragments has become a fundamental challenge due to the complexity of natural language and the diversity of meanings that words and phrases can have in different contexts Zunino (2023). In this context, Semantic Textual Relatedness (STR) is a crucial element in natural language understanding, gaining increasing significance with integrating artificial intelligence (AI) models in language processing.

This article aligns with the objectives set by SemEval 2024 Task 1, a pivotal challenge centered on predicting semantic textual relationships between sentence pairs in the English language. The task's importance lies in its profound impact on advancing contextual language understanding, a cornerstone for AI applications across diverse domains.

Our approach to tackle this challenge involves a four-layer feature extraction process. The first layer focuses on extracting lexical similarity, providing a foundation for understanding semantic connections based on word usage. Subsequently, the second layer delves into capturing knowledge-oriented similarity and incorporating domain-specific insights into the model. The third layer concentrates on Corpus-oriented features, considering the contextual influence of larger text corpora. Finally, in the fourth layer, we employ an Embedding approach. Here, we train a Long Short-Term Memory (LSTM) model, extracting sentence features from phoneme embeddings and a sentence transformer model, thereby capturing nuanced semantic nuances.

Throughout the SemEval 2024 Task 1 competition (Ousidhoum et al., 2024b), our system secured the 24th position out of 36 teams, achieving a competitive score of 0.8192. Notably, our system was designed and optimized for the English language. To foster transparency and collaboration, we have released our code, accessible at https://github.com/VerbaNexAI/SemEval2024.

2 Related Work

The analysis of semantic relations is considered fundamental for understanding the connection of meanings between words, phrases, and sentences in a text. Various relationships, such as synonymy, antonymy, hyperonymy, meronymy, and cohyponymy, can manifest in this context. Two main approaches have addressed this field: rule-based and machine learning-based approaches.

Rule-based approaches use ontologies, struc-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1344–1350

tures that define concepts and their relationships, and semantic networks, which are graphical representations of these relationships. Lexical patterns, which are rules that describe semantic relationships based on the structure of words, have also been used. On the other hand, approaches based on machine learning have gained relevance, utilizing technologies such as convolutional neural networks (CNN), recurrent neural networks (RNN), attention models, and word embeddings.

In the literature, we can find several methods for semantic relation detection. In "Learning short-text semantic similarity with word embeddings and external knowledge sources" Nguyen et al. (2019), authors propose an approach that uses word embeddings and external knowledge to measure semantic similarity between short texts, managing to outperform traditional methods on diverse datasets.

Another significant work is "A multi-layer system for semantic relatedness evaluation" Gomaa (2019), which presents a multi-layer system for semantic relatedness evaluation between sentences, combining various similarity features and achieving promising accuracy on the SICK dataset.

In addition, "A New Methodology for Computing Semantic Relatedness: Modified Latent Semantic Analysis by Fuzzy Formal Concept Analysis" Jain et al. (2020) proposes a hybrid methodology that combines latent semantic analysis and fuzzy formal concept analysis to compute the semantic relatedness between words and sentences, obtaining improved results compared to other baseline measures on a specific corpus.

In the field of language-specific semantic relatedness detection, "Sentence Embedding and Convolutional Neural Network for Semantic Textual Similarity Detection in Arabic Language" Mahmoud and Zrigui (2019a) proposes a deep learning-based approach to detect paraphrases in Arabic, using word2vec and a convolutional neural network to overcome traditional methods and other stylometric feature-based approaches.

Finally, "Attention-based model for predicting question relatedness on Stack Overflow" Pei et al. (2021) introduces a deep learning model called ASIM, which uses the attention mechanism to predict the semantic relationship between questions in programming question and answer websites. This model outperforms previous models in terms of performance and generalization in detecting duplicate questions and predicting the relationship between knowledge units.

Despite these advances, knowledge gaps persist. Most models focus on semantic relationships at the word or phrase level. However, we need more research in sentence- and paragraph-level relationship detection. In addition, we require more robust models to adapt to different domains and text types, ensuring a more complete and accurate understanding of semantic relations in natural language processing.

3 System Overview

This section outlines our proposed model for tackling the task presented in SemEval 2024, Track A, which involves assessing the semantic relationship between pairs of sentences. Initially, the text data undergoes preprocessing, including separating sentence pairs, followed by training a Long Short-Term Memory (LSTM) model on the training dataset. Subsequently, we extract text features based on a four-layer architecture proposed by Gomaa (2019), as illustrated in Figure 1. These layers include word embedding, syntactic relationships, corpus topics, and contextual information.

Additionally, we incorporate novel features to enhance our model's performance. These include:

Senticnet: Utilized to extract the polarity of sentences in the knowledge-oriented layer. Latent Semantic Indexing (LSI) is employed for the corpus-oriented layer to gain insights into the underlying structure of the text corpus.

Phoneme Extraction: A novel approach to capture phonetic information from the sentences.

Furthermore, we integrate an attention mechanism inspired by Vaswani et al. (2017) to effectively capture intricate dependencies within sequences. Leveraging insights from recent advancements, our model incorporates a Part-of-Speech (POS)-aware and layer ensemble transformer, further enhancing its ability to discern semantic relationships.

By drawing from diverse studies on data augmentation, ensemble learning, and transformer-based profiling, our model aims to provide a robust solution for semantic relationship detection. It showcases a comprehensive understanding of attention mechanisms and their integration with state-of-the-art techniques.

3.1 Data Description

We used the dataset STR-2022 proposed by Abdalla et al. (2021) and collected by (Ousidhoum et al., 2024a) for training the system. This dataset

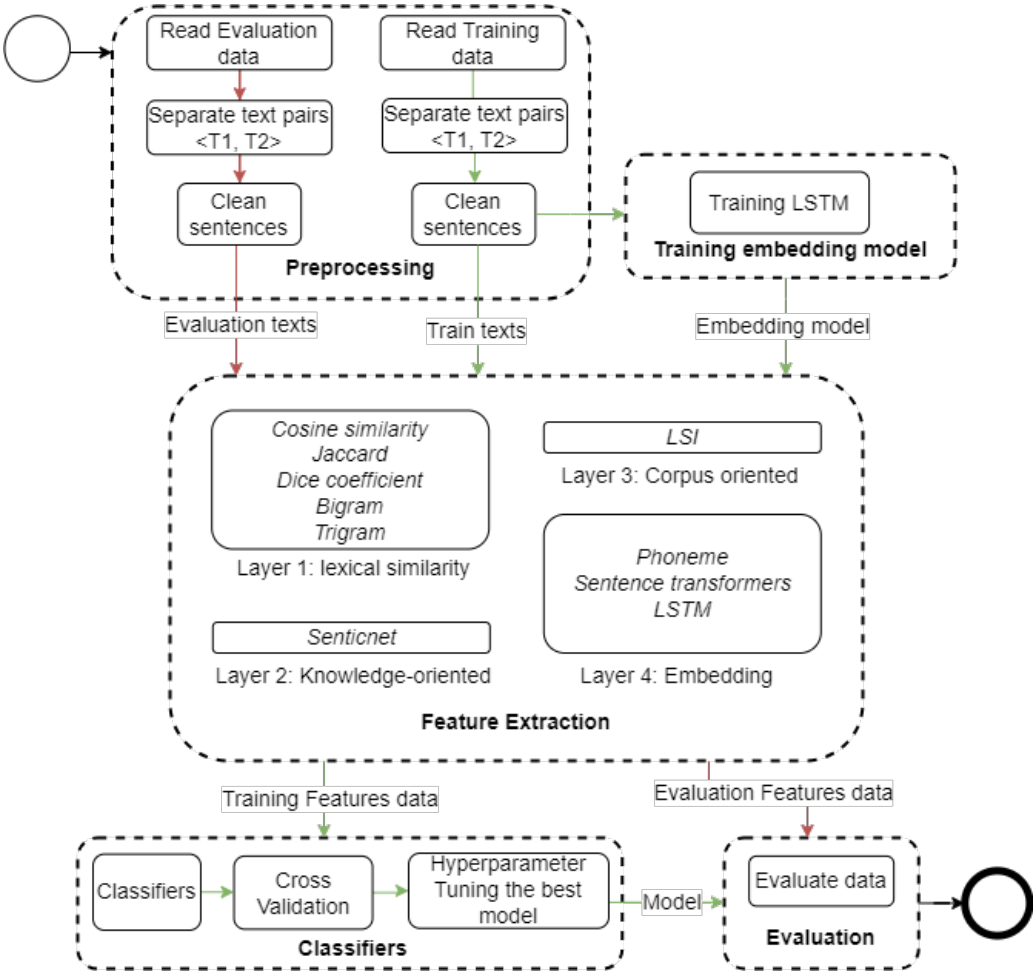

Figure 1: System General Pipeline

comprises 5,500 pairs of sentences in English. This dataset underwent meticulous curation procedures, sampling sentences from various sources, such as social media tweets, book reviews, and paraphrases, to encompass diverse linguistic characteristics and styles. Each pair is labeled with their relatedness score and distribution as shown in Table 1.

Table 1: Frequency distribution of scores intervals

Score intervals	Frequencies
0 - 0.2	502
0.2 - 0.4	1376
0.4 - 0.6	1861
0.6 - 0.8	1149
0.8 - 1	612

3.2 Data Preprocessing

During preprocessing, we separated sentences, and verb and subject decontraction were applied. Subsequently, the model was evaluated with and without lemmatization, as well as with and without stopwords, to assess differences in performance. We removed capitalization, special characters, and numbers as part of the preprocessing process. Data preprocessing is a fundamental step that significantly influences the validity and performance of text classification models, both modern transformers and traditional classifiers Siino et al. (2024). Several preprocessing decisions, such as the treatment of negation, conversion of text to lowercase, application of hyphenation, and consideration of corpus size and document length, are critical to ensure the capture of the true textual meaning and improve the reliability Hickman et al. (2022).

3.3 Training Embedding Models

This part details the training process of a Long Short-Term Memory (LSTM) neural network model for relatedness identification. It begins with data splitting into training and validation sets, followed by message tokenization and constructing a unique vocabulary. We indexed words and applied padding to standardize sequences. We converted

the data into PyTorch tensors and defined a custom dataset and data loaders to handle training batches efficiently.

We defined the model with an embedding layer, an LSTM layer, and a linear output layer. During training, the Adam optimizer and Mean Squared Error (MSE) loss function are utilized, with a loop updating model weights over multiple epochs. For monitoring, we evaluated model performance on the validation set after each epoch.

Finally, upon completion of training, the model and its parameters are saved to a file for future use, enabling its application without the need to retrain it from scratch.

3.4 Feature Extraction

In this section, we explain how the new features are built and used within the text extraction; we try to create a system that could receive the pairs of sentences and return values with consistent output shapes that can feed the model.

3.4.1 Layer 1: String-Oriented Similarity

We based this feature on text extraction, either the characters or the words. It comprises the best features evaluated by Gomaa (2019), Cosine Similarity, Jaccard Similarity, Dice's Coefficient, Bigram, and Trigram.

This layer computes string-oriented similarity features using the following equations:

$$\text{Cosine Similarity} = \frac{A \cdot B}{\|A\|\|B\|} \tag{1}$$

$$\text{Jaccard Similarity} = \frac{|A \cap B|}{|A \cup B|} \tag{2}$$

$$\text{Dice's Coefficient} = \frac{2|A \cap B|}{|A| + |B|} \tag{3}$$

where A and B represent the sets of words in both sentences.

3.4.2 Layer 2: Corpus-Oriented Similarity

The system extracts general information using Latent Semantic Indexing (LSI) with the framework Gensim described by Řehůřek and Sojka (2010) to capture the overall thematic similarity between two sentences.

We extract the representation of the average LSI values for the primary five topics, aiming to capture the thematic similarity between the sentences.

3.4.3 Layer 3: Knowledge-Oriented Similarity

This layer is oriented to extract semantic information related to sentiment within the sentences. We used SenticNet proposed by Cambria et al. (2022), a commonsense-based Neurosymbolic framework that extracts the polarity of words. LSI was extracted by averaging the polarities of each sentence and creating a vector with it.

3.4.4 Layer 4: Sentence Embedding

We proposed three forms of word embedding, taking advantage of the good behavior of this layer to evaluate the semantic relationships within two sentences. We used the pre-trained model of sentence transformer Ni et al. (2021), LSTM, and the phonemes embedding. The phoneme embedding works by taking each letter within the sentences, extracting its representation to a phoneme, and returning its representation as a vector.

3.5 Classifiers

We compared the performance of various machine learning models proposed in (Gomaa, 2019) and evaluated the combination of different characteristic types represented by vector inputs.

Random Forest, Gradient Boosting, Multi-layer Perceptron, AdaBoost, and Support Vector Regression (SVR) were employed using the framework Sklearn proposed by Pedregosa et al. (2011), alongside an ensemble voting system combining them. This research aimed to identify the most suitable model(s) for analyzing diverse feature vector inputs.

3.6 Evaluation

The evaluating part of the code serves as a fundamental component within an empirical study focused on assessing the performance of machine learning classifiers. Its primary purpose is to automate the evaluation process, enabling the systematic comparison of various classifiers in a supervised learning context. By implementing k-fold cross-validation, the code ensures robustness and reliability in the evaluation by mitigating potential biases associated with a single train-test split.

Within the evaluating part, we compute a comprehensive suite of performance metrics for each classifier, including Spearman correlation, Mean Squared Error (MSE), R-squared (R^2), Mean Absolute Error (MAE), Root Mean Squared Error (RMSE), and Mean Absolute Percentage Error

(MAPE). These metrics provide a multifaceted assessment of the classifiers' predictive capabilities, accuracy, and robustness.

4 Experimental Setup

The system model utilized sentences without lemmatization and stopword removal, preserving the original form of the sentences to capture a broader range of semantic nuances. Phoneme extraction, as proposed by Del Castillo, was incorporated into the system, utilizing specific components of the provided code. This inclusion aims to enhance the model's sensitivity to phonetic features, contributing to a more comprehensive understanding of textual relationships.

We employ the ShuffleSplit method for cross-validation to assess the model's training. The dataset was split into training and validation sets using a test size 25%, and we utilized ten pairs (n_splits = 10) to ensure robust evaluation. We set the random state to 42 (random_state = 42) for reproducibility. The details of the library versions used in the implementation are provided in Table 2.

Table 2: Python Libraries and Versions

Library	Version
nltk	3.8.1
gensim	4.3.2
spacy	3.7.2
scikit-learn	1.3.2
sentence-transformers	2.2.2
senticnet	1.6
numpy	1.23.4
scipy	1.10.1
matplotlib	3.7.4
seaborn	0.13.0
torch	1.6.0
pandas	2.0.3
epitran	1.24

5 Results

We evaluated the semantic relation detection model using the training and test datasets, and the results are in Table 3. Our model secured the 24th position in the competition ranking, achieving a Spearman correlation coefficient of 0.8192 on the English language dataset. It is relevant to note that this is slightly below the baseline value of 0.83 set as baseline.

Table 3: Ranking of results in framing detection classification

Lang	Spearman Correlation
EN	0.8192

In addition, Table 4 summarizes the performance of the voting system's configuration, and we also present its performance compared to the best individual model.

While the results obtained are below the established baseline, we recognize opportunities for improvement. Abstraction analysis could reveal the specific contributions of each system component to this performance and guide future improvements. It is also crucial to consider the nature of the baseline and the inherent complexity of the task at hand.

6 Limitations

While presenting our approach for evaluating semantic relations between sentences, it's crucial to acknowledge certain limitations that may impact the interpretation and applicability of our proposed model. We outline these limitations below:

- Dataset Representativeness: The STR-2022 dataset, comprising 5,500 English sentence pairs, may not fully capture linguistic diversity and semantic nuances across different languages, limiting the model's generalization to diverse linguistic contexts.
- Preprocessing Impact: Decisions done during preprocessing (such as removing capital letters, special characters, and numbers) could significantly affect semantic representations. When modifying these preprocessing steps, careful consideration is needed to avoid potential bias or information loss.
- Hyperparameter Sensitivity: The model's performance is sensitive to hyperparameter choices, like the number of LSTM layers or the learning rate of the Adam optimizer. Fine-tuning is crucial for optimizing the model's ability to capture semantic relationships effectively.

7 Ethical Considerations

We linked the text similarity field to the detection of paraphrasing (Mahmoud and Zrigui, 2019b), which

Table 4: Correlation of Spearman's Rank between Various Text Preprocessing Methods and Machine Learning Models

Preprocessing	Machine Learning Model	Spearman's Correlation Coefficient
No lemmatized, no stopwords	AdaBoost	0.82
Lemmatized, no stopwords	AdaBoost	0.82
No lemmatized, no stopwords	Gradient Boosting	0.82
Lemmatized, no stopwords	Gradient Boosting	0.82
No lemmatized, no stopwords	Multi-layer Perceptron	0.82
Lemmatized, no stopwords	Multi-layer Perceptron	0.82
No lemmatized, no stopwords	Voting	0.81
Lemmatized, no stopwords	Voting	0.81
No lemmatized, stopwords	Multi-layer Perceptron	0.77
Lemmatized, stopwords	AdaBoost	0.76

can pose an ethical problem when using an author's work without proper citation. Our solution addresses the bias by extracting various text features, from word information to context and vector representation. This way, we can avoid some limitations from training the model with insufficient features.

8 Conclusions

This paper presented a comprehensive approach to evaluating semantic relations between sentences, addressing the challenges posed by SemEval 2024 Task 1. Our model employs a sophisticated four-layered feature extraction technique, encompassing lexical similarity, knowledge orientation, corpus orientation, and embedding layers.

Despite achieving a notable 24th place in the competition, we acknowledge certain limitations, including concerns about dataset representativeness, preprocessing decisions, and hyperparameter sensitivity. These insights serve as valuable lessons for future enhancements in our approach.

While the Spearman correlation of 0.8192 places our model slightly below the established baseline of 0.83, this outcome provides an invaluable learning experience. Moving forward, we plan to conduct ablation studies to dissect the impact of individual components, explore alternative models and preprocessing strategies, and conduct a detailed error analysis to address specific shortcomings.

Ultimately, this work contributes to a deeper understanding of semantic relations and provides a competitive model for SemEval 2024. We are committed to advancing semantic understanding and improving AI systems for natural language processing. The journey from this competition is a stepping stone toward more refined and practical solutions in semantic relationship detection.

Abstract

The aim of SemEval-2024 Task 1, "Semantic Textual Relatedness for African and Asian Languages" is to develop models for identifying semantic textual relatedness (STR) between two sentences using multiple languages (14 African and Asian languages) and settings (supervised, unsupervised, and cross-lingual). Large language models (LLMs) have shown impressive performance on several natural language understanding tasks such as multilingual machine translation (MMT), semantic similarity (STS), and encoding sentence embeddings. Using a combination of LLMs that perform well on these tasks, we developed two STR models, *TranSem* and *FineSem*, for the supervised and cross-lingual settings. We explore the effectiveness of several training methods and the usefulness of machine translation. We find that direct fine-tuning on the task is comparable to using sentence embeddings and translating to English leads to better performance for some languages. In the supervised setting, our model performance is better than the official baseline for 3 languages with the remaining 4 performing on par. In the cross-lingual setting, our model performance is better than the baseline for 3 languages (leading to 1^{st} place for Africaans and 2^{nd} place for Indonesian), is on par for 2 languages and performs poorly on the remaining 7 languages.

1 Introduction

The objective of the SemEval 2024 Task 1 is to build and evaluate models capable of identifying relatedness between a sentence pair. Sentence pairs from 14 African and Asian languages belonging to 5 language groups are annotated for relatedness and released for model development. The task is divided into 3 tracks targeting different types of model training: supervised (Track A), unsupervised (Track B), and cross-lingual (Track C). Each track targets a different subset of languages. Extensive details about the languages, language groups, and the data collection process are provided in the task description paper (Ousidhoum et al., 2024a). A detailed description of the shared task, tracks, and datasets are provided in the shared task description paper (Ousidhoum et al., 2024b).

Semantic relatedness helps with understanding language meaning (Jarmasz and Szpakowicz, 2012; Miller, 1995; Antony et al., 2022; Osgood, 1949) and is useful in many areas of natural language processing such as word-sense disambiguation (Banerjee and Pedersen, 2003), machine translation (Bracken et al., 2017) and sentence representation (Reimers et al., 2019; Wang et al., 2022) which have numerous applications. Until recently, semantic relatedness has been mostly restricted to finding word relatedness (Feng et al., 2017; Budanitsky and Hirst, 2006), leading to a lack of sentence-relatedness datasets. At the sentence level, relatedness has been limited to similarity, providing a restricted view of STR (Abdalla et al., 2021). The current shared task aims to broaden the scope of sentence relatedness and extend it to several languages with the goal of encouraging model and resource development in these languages (Ousidhoum et al., 2024b).

Recent advancements in multi-lingual translation and the availability of models for obtaining high-quality sentence embeddings allowed us to explore the effectiveness of machine translated data. Using various sentence embedding models to encode data translated into English, we trained a model, *TranSem*, to find the relatedness score between sentence pairs. Although the task requires the sentence pair to be from the same language, our model can handle sentences from two different languages. Our second model, *FineSem* directly fine-tunes a T5 model (T5 is already fine-tuned on the STS benchmark) on the STR task using both untranslated and translated data to explore the

[†]These authors contributed equally to this work

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1351–1357

usefulness of translation. We use both these models to evaluate languages in Track A. For Track C languages, we use a T5 model fine-tuned only on the english STR data. For evaluating the English dataset in the cross-lingual track, we use a T5 model fine-tuned on the Spanish dataset.

Our contributions to the STR task are as follows: We 1) develop unified models for STR to work with all languages. 2) participate in supervised and cross-lingual tracks. 3) explore the usefulness of machine translation. 4) explore data augmentation using machine translation. Our code is publicly available at https://github.com/dipta007/SemEval24-Task8

2 System Overview

After exploring models and datasets available in the languages we understand[1], we realized the dearth of resources available in these languages. To leverage resources available in English, we translated the 13 non-English languages into English. Assuming the translated data accurately reflects the semantic meaning of the source language, the derived relatedness value from our model for a translated sentence pair should reflect the STR between the sentence pair in the source language. This section describes our machine translation process and models, *TranSem* and *FineSem*. Besides using different training strategies, these models can use both translated and untranslated data.

2.1 Translation to English & Data Augmentation

We use Meta's "No Language Left Behind (NLLB) open-source models" that provide direct high-quality translations for 200 languages with many low-resource languages (Costa-jussà et al., 2022). We use four of the translation models[2] ranging from 600 million to 3.3 billion parameters. Using each of the 4 models, we translated the training data for all languages in track A, except Amharic and Algerian Arabic, and obtained 4 translated datasets for each language. None of the 4 models we used supported Amharic, Algerian Arabic or Punjabi. We decided against translating track C languages with 3 of 12 unsupported languages. Using 4 different model translations gave us a 4-fold augmentation of the training data. We translated the test data using only the largest model (*facebook/all-200-3.3 B*) to obtain the best translation features.

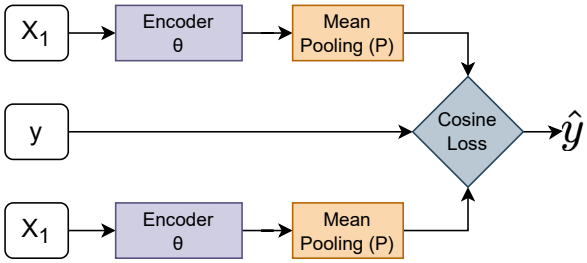

Figure 1: Overview of TranSem model architecture (Inspired by Reimers et al. (2019)). The encoder (θ) is shared, and the diamond box represents the loss function. The encoded sentence pairs (x_1, x_2) and the label (y) are the input to the cosine similarity loss.

2.2 *TranSem* Model

Inspired by Reimers et al. (2019), we used the Siamese model architecture (shown in Fig. 1). For a given pair of sentences (x_1, x_2) and their semantic relatedness score (y), we encode each sentence with a sentence encoder (θ). The embeddings for the sentences go through a pooling operation (P) to produce sentence embeddings (s_1, s_2). The cosine similarity of the encoded embeddings is trained to match the semantic relatedness score using the mean-squared error loss:

$$\mathcal{L} = MSE(\text{cos-sim}(P\theta(x_1), P\theta(x_2)), y) \quad (1)$$

We experimented with several sentence encoding models for encoding our translated and augmented training dataset. We chose DistilRoberta[3] to submit results for the competition leaderboard based on our primary validation (details on §4.1.1, §4.1.2, and §4.1.3). This is a distilled version of RoBERTa (Liu et al., 2019) fine-tuned on sentence-level datasets and suitable for clustering and semantic searches, which we further fine-tuned on our translated and augmented dataset. The sentence-t5-xl embedding model was chosen to compare the effectiveness of sentence embeddings as opposed to the direct fine-tuning used in the *FineSem* model. After experimenting with different pooling mechanisms of mean, max, and CLS tokens, we found that mean pooling works well for our setting. This aligns with earlier findings, which show that mean pooling produced encodings lead to better performance on downstream tasks.

[1] Of the 14 languages, the authors are proficient in English, Hindi & Telugu languages.

2.3 *FineSem* Model

T5 (Raffel et al., 2020) is a transformer model that uses transfer learning; the model trained on "Colossal Clean Crawled Corpus" is fine-tuned on a mixture of 8 downstream unsupervised and supervised tasks converting them into a unified text-to-text task setting. The T5 model is available in several sizes, of which we use the base, large, and XL models ranging from (660 million to 3 billion parameters). One of the supervised tasks used in the T5 model training is the semantic textual similarity benchmark (STS-B) dataset trained as a regression classification problem. We use the STS task setting to train on the track A STR training datasets using 3 different options: separate T5 models trained on individual languages, a single model trained on all 14 languages (without translation), and a single model trained on the translated and augmented dataset (for 12 languages). These settings allow us to contrast the effectiveness of direct fine-tuning with the sentence embedding-based *transem* model and the usefulness of machine translation.

From the T5 models fine-tuned on the individual languages, we use the English and Spanish fine-tuned models (we refer to these models as the English and Spanish models) for evaluating the cross-lingual Track C languages. We use the English model to evaluate development and test data from all languages except English and the Spanish model to evaluate the English data.

3 Experimental Setup

3.1 HyperParameters

We train our models using AdamW (Loshchilov and Hutter, 2017) optimizer with a learning rate of 1e-5 and weight decay of 0.01. We use an effective batch size of 32 (batch size 16 with 2 steps of gradient accumulation) (for TransSem) and a batch size of 16 (for FineSem).

We train our *transem* model infinitely with an early stopping patience of 10 on the validation Spearman Correlation score. We train the *finesem* model for 10 epochs (2 epochs for the model trained on the translated and augmented model) and checkpoint the models at the end of every epoch. We evaluate the dev sets for each language against these 10 checkpoints. We evaluate the corresponding test data using the checkpoint which provides the best performance on the dev data for a language.

3.2 Infrastructure

All experiments were conducted on an NVIDIA Quadro RTX 8000 with 48GB of VRAM and A100 80GB. We utilize the PyTorch Lightning library [4] for conducting the experiments and Weight & Biases [5] for logging purposes (for the *TransSem* Model) and HuggingFace Transformers (for the *FineSem* Model).

4 Results

We first report our results and analysis on Track A languages (§4.1), and then on Track C (§4.2). We use the official baseline (Ousidhoum et al. (2024b)) that used LaBSE (Feng et al., 2020) fine-tuned on the provided training dataset and refer to this model as $baseline$.

4.1 Track A Languages

This section discusses our findings using various model settings with the *TranSem* model.

4.1.1 Effect of Batch Size

Comparing performance with various batch sizes (results are shown in Table 1), we show that our batch size selections are fairly good (32 for task *TranSem* and 8 for *FineSem*).

	Batch Size	A3 eng	A4 hau	A5 kin	A6 mar	A7 ary	A8 esp	A9 tel	avg
TranSem+	2	.8102	**.6857**	.6886	**.8515**	.7376	**.6519**	**.8342**	**.7514**
TranSem+	4	.5415	.1355	.0643	.5394	.3038	.5998	.4231	.3725
TranSem+	8	.8132	.6519	.6642	.8348	.7340	.6355	.8187	.7360
TranSem+	16	.8093	.6377	**.6997**	.8429	**.7500**	.6462	.8257	.7445
TranSem+	64	.8092	.6589	.6456	.8271	.7247	.6234	.8131	.7289
TranSem+	128	.8129	.6787	.6659	.8417	.7411	.6396	.8324	.7446
TranSem+	256	**.8152**	.6716	.6589	.8357	.7197	.6353	.8189	.7365

Table 1: The effect of batch size on $TranSem$ for different batch sizes $\{2, 4, 8, 16, 64, 128, 256\}$

4.1.2 Effect of Encoder Pooling

In Table 2, we compare performance using 3 different pooling operations. We used mean pooling for the official results we submitted, as it showed good performance in most languages.

	Pooling	A3 eng	A4 hau	A5 kin	A6 mar	A7 ary	A8 esp	A9 tel	avg
TranSem+	CLS	**.8133**	**.6737**	.6655	.8339	.7376	.6363	**.8309**	.7416
TranSem	Mean	.8125	.6403	**.6807**	**.8406**	**.7448**	**.7211**	.8255	**.7522**
TranSem+	Max	.7960	.6157	.5809	.8227	.6643	.6075	.7997	.6981

Table 2: The effect of pooling on $TranSem$ using different pooling mechanisms (CLS Token, Mean, Max)

[4] https://lightning.ai/
[5] https://wandb.ai/

4.1.3 Effect of Sentence Embedding Models

In Table 3, we provide contrastive results with several sentence embedding models used in *TranSem*. For official results, we submitted results from the distilroberta-v1 sentence embedding model (results for some of the languages are from the *FineSem* model fine-tuned on individual STR training datasets).

4.1.4 Usefulness of Machine Translation and Direct Fine-tuning

We compare the performance of the *FineSem* models fine-tuned using the 3 data options (results are shown in Table 3). FineSem-Individual shows the performance of T5-XL models fine-tuned on the individual datasets. Unified and Translated models show the performance of the two T5-XL models fine-tuned on the untranslated data and translated+augmented data. The model trained on untranslated data performs poorly on the Marathi dataset, but performs on par with the other models indicating that we may not need to translate all languages to English. We find that direct fine-tuning with the translated and augmented data is comparable with the *TranSem* model using various sentence embeddings.

4.2 Track C Languages

In Table 4, we compare the performance of various T5 models on the track C languages. We submitted official results using our T5-XL based FineSem model (FineSem-LB) where the results are obtained using the checkpoint after the third epoch. With the same model we also report with the approach where we use the checkpoint which results in the best performance on the development data for a given language. These results are shown as FineSem-XL. We compare these results with the T5-base and T5-large based FineSem models. We bold the best scores for easy readability but underline scores that are better than the baseline. Among our models the overall performance of the XL model is better and this model improves upon the baseline for Afrikaans, Indonesian and Spanish.

5 Related Work

In this section, we present previous research conducted in the fields of Machine Translation (see §5.1), Sentence Embedding (see §5.2) and Semantic Similarity (see §5.3).

5.1 Machine Translation

Machine translation has evolved in the last 75 years from rule-based systems to statistical-based systems to the current neural machine translation (NMT) systems. In the 10 years since the first sequence-to-sequence NMT model (Bahdanau et al., 2014), machine translation reached a point where translations from models for high-resource languages rival human translators (Läubli et al., 2018; Popel et al., 2020). This was possible due to the amount of bilingual data pairs available for training in these languages (Haddow et al., 2022). Translation systems for medium and low resource languages that lacked the scale of these resources either developed cross-lingual models (Nguyen and Chiang, 2017; Zoph et al., 2016) or developed datasets (Bañón et al., 2020; Schwenk et al., 2019). Current state-of-the-art translation models use a many-to-many approach to handle a large number of medium to low-resource languages (Costa-jussà et al., 2022).

5.2 Sentence Embedding

Generating a sentence-level embedding is useful for semantic searches and clustering. Since the first transformer model (Vaswani et al., 2017), several encoder-only models such as BERT (Devlin et al., 2018), RoBERTa (Liu et al., 2019), XLNet (Yang et al., 2018) were used to learn effective sentence embeddings that also performed well on downstream NLP tasks (Cer et al., 2018; Roy Dipta et al., 2023). Reimers et al. (2019) developed a Siamese-like network architecture with two BERT sentence embedding models that improved semantic search systems. Using T5 (Raffel et al., 2020) models in a similar architecture, sentence embeddings produced by T5 were shown to be superior to the encoder-only model embeddings with performance gains in downstream tasks (Ni et al., 2021). A more recent work (Reimers and Gurevych, 2020) showed that a teacher-student model can be efficiently used to develop a sentence embedding system for many low-resource languages.

5.3 Semantic Similarity

Semantic textual similarity captures a type of semantic relatedness requiring similarity on all aspects between a sentence pair. SemEval tasks on semantic textual similarity from 2012 to 2017 resulted in the STS benchmark (Cer et al., 2017). Recently, Deshpande et al. (2023) proposed condi-

tional semantic textual similarity to explore semantic relatedness.

6 Conclusion & Future Work

We developed two different models and showed how the models performed in supervised and cross-domain training tasks in 14 languages. We explored using machine translation, sentence encoders, and SST-B style training with T5 models. Our models improved over the official baseline for some of the languages. For computational purposes, we have excluded using more recent models like mistral-7b (Jiang et al., 2023), which have outperformed most of the open-source and close-source models in various benchmarks (Zheng et al., 2024). For future work, we intend to explore prompting for STR and prompt-based LLMs [6] for translation.

7 Disclaimer

We did not use AI assistants to write any part of our paper or code. All writing is original and produced by the authors.

[6] https://chat.openai.com/

8 Limitations

We acknowledge our work has the following limitations. We use several pre-trained LLMs in our experiments. It is well known that these models can echo biases and misinformation either implicitly or explicitly. We did not control for any of these when training them on the STR datasets. In addition, the STR datasets may also echo several biases related to social groups, cultural groups, race, gender, behavioral, and perceptual differences of annotators. We did not explore or control for any of these biases in our work. As a result, our work carries the limitations of both the models and the datasets we used.

mraihan2@gmu.edu

Abstract

This paper presents the *MasonTigers*' submission to the SemEval-2024 Task 9 which provides a dataset of puzzles for testing natural language understanding. We employ large language models (LLMs) to solve this task through several prompting techniques. We show that zero-shot and few-shot prompting with proprietary LLMs outperform open-source models. Results are further improved with chain-of-thought prompting. We obtain our best results by utilizing an ensemble of chain-of thought prompts, ranking 2^{nd} in the word puzzle subtask and 13^{th} in the sentence puzzle sub-task.

1 Introduction

In recent years, LLMs have achieved impressive performance on several question answering and language understanding tasks when provided with appropriate prompting (Brown et al., 2020). However, complex reasoning abilities often present a challenge for these models. SemEval-2024 Task 9 (Jiang et al., 2024b) introduces a novel dataset called *BrainTeaser* (Jiang et al., 2023) which includes a set of complex puzzles and brainteasers. Such tasks involve solving word and sentence puzzles, which require multi-step inference and deduction. The dataset covers a diverse range of puzzle types including sequences, analogies, classification, mathematical reasoning, inferences about implicit relationships, and more. Solutions frequently demand a chained application of knowledge and logic across multiple steps to uncover insights or concepts not directly stated in the problem description.

Solving these elaborate reasoning problems is a challenging scenario for NLP systems. We explore whether and how LLMs can succeed on this task. We employ proprietary models such as GPT-4 (OpenAI, 2023) and Claude 2.1 (Anthropic, 2023) through APIs. These models have shown promising few-shot reasoning ability. We also use Mixtral (Jiang et al., 2024a), an open-source LLM that shows state-of-the-results in several language reasoning tasks. The prompting paradigm involves providing models with natural language descriptions that encode the reasoning process step-by-step (Liu et al., 2021). We implement various prompting approaches for mapping puzzles to conditional text and systematically transforming reasoning into explanation chains. Our core method, chain-of-thought prompting (Wei et al., 2022), iteratively breaks down the deduction into simplified logical steps.

Experiments reveal that while zero-shot performance lags due to a lack of grounding, multi-step prompts can unlock substantial reasoning ability in models. Performance improves with more steps and more specificity in the prompt. While introducing few-shot prompting generates good results, we observed that models do significantly better with chain-of-thought prompting. We experiment with several chains of thought and achieve mostly similar results with each attempt. To make a more empirically confident guess towards solving the puzzles we adopt an ensemble of these chains based on majority voting. Our approach achieves competitive performance, ranking *2nd* on the word puzzle subtask and *13th* on sentence puzzles.

2 Related Work

LLMs have been widely used for complex and challenging language processing tasks recently (Raihan et al., 2023a,b; Goswami et al., 2023). They have shown good reasoning abilities in several tasks. The task of solving puzzles and the BrainTeaser dataset (Jiang et al., 2023) represent both a novel task and a novel dataset respectively. Similarly to their multiple choice questions (MCQs) approach, a few datasets like MathQA (Austin et al., 2021), have been compiled. However, these are intended for specific tasks in which domain knowledge is usually enough thus they not requiring deep reason-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1358–1363

ing. A similar work is done by Saeedi et al. (2020) where they investigate a task that combines natural language understanding and commonsense reasoning. They present deep learning architectures for distinguishing between sensible and nonsensical statements.

Pun detection by (Zou and Lu, 2019) is a puzzle-like activity that is similar to BrainTeaser. It presents a method for joint pun detection and localization utilizing a sequence labeling perspective. This highlights the complexity of language comprehension, especially in detecting subtle wordplay. Another dataset, LatEval is curated by Huang et al. (2023) that delves further into lateral thinking and commonsense reasoning, highlighting the challenges faced by language models in tasks requiring unconventional thinking and creativity. Zhou et al. (2023) presents ROME, a dataset designed to assess vision-language models' capacity to reason beyond intuitive understanding, highlighting the shortcomings of existing models in understanding events that defy common sense.

In the field of reasoning task, a *chain-of-thought* (Wei et al., 2022) implies a logical sequence of connected ideas, fostering coherence and depth in responses. On the other hand, a *tree-of-thought* suggests branching out into various related ideas, offering a more comprehensive exploration of a topic. While few-shot prompting is effective for some tasks by providing examples to guide the model, it may have limitations in capturing the complexity of nuanced conversations. The optimal choice may involve a hybrid approach, where a few-shot prompt sets the initial (Yao et al., 2023) context, and the model subsequently follows a chain or tree of thought to generate more contextually rich and coherent responses useful for reasoning tasks.

Tan (2023) shows the performance of LLM's on the reasoning of arithmetic word problems. It states that higher degrees of realization are associated with better overall accuracy on arithmetic problems. And chain-of-thought is really helpful in this aspect as it covers a variety of prompts to strengthen the reasoning. Similarly, Mo and Xin (2023) presents a new reasoning framework for large language models by addressing a gap in prior tree-based reasoning methods which overlooked inherent uncertainties in intermediate decision points made by models. Overall, the key innovation is leveraging uncertainty estimation locally within the models during tree reasoning to enable more precise problem-solving and reasoning.

3 The BrainTeaser Dataset

The BrainTeaser dataset (Jiang et al., 2023), introduced with the task (Jiang et al., 2024b) is a question-answering benchmark designed to evaluate models' ability for lateral thinking, i.e., to defy default commonsense associations and reason creatively. The dataset contains 1,100 multiple-choice questions divided into two sub-tasks - 627 sentence-based puzzles relying on narrative context and common phrases and 492 puzzles focused on the literal form and letters of words.

For a fair comparison with human performance, the dataset also provides a separate human evaluation set with 102 randomly sampled questions. Each question in BrainTeaser has one correct answer and three distractor choices, including the option "none of the above". To prevent memorization of training data, the dataset also contains semantically and contextually reconstructed variants for every question while preserving the original reasoning process and answers. The key statistics of the dataset are shown in Table 1.

	Sentence	**Word**
Number of puzzles	627	492
Avg. tokens (prompt)	34.88	10.65
Avg. tokens (choices)	9.11	3.0

Table 1: Key statistics of the BrainTeaser dataset in the sentence and word puzzle sub-task.

During the SemEval-2024 Task 9 development phase, a total of 240 prompts (120 for both sentence and word puzzles) are provided. During the test phase, a total of 216 prompts (120 for sentence and 96 for word puzzles) are provided.

4 Experiments

In our experiments, we focus on several prompting strategies by employing three state-of-the-art models including proprietary models like GPT-4 (OpenAI, 2023) and Claude 2.1 (Anthropic, 2023) (accessed via API key) and one open-source model - Mixtral (Jiang et al., 2024a).

4.1 Zero-Shot Prompting

We start with zero-shot prompting by assigning the AI a role, describing the task, and giving it one puzzle at a time, as shown in Figure 1.

Role:
You are a helpful AI assistant. You are given the task of solving a sentence/word puzzle.

+

Definition:
It's a Multiple Choice Question paired with 4 potential answers. Choose the most suitable one.

+

Question: What part of London is in France?
Choices:
1. The letter N.
2. The letter O.
3. The letter L.
4. None of the above.

Choose the most suitable answer. Thanks.

Figure 1: Sample structure for Zero-Shot Prompting.

4.2 Few-Shot Prompting

In order to give the LLMs more context we integrate more examples and design prompts for few-shot prompting. We include 4 solved puzzles from the train set and then attach one puzzle from the test set each time we prompt the models. We also use some tags for better extracting the generated answers, as shown in Figure 2.

4.3 Chain-of-Thought

To guide the models toward better reasoning - we experiment with chain-of-thought prompting. We give the model the puzzle, and the potential answers and work with every example one-by-one in order to choose the most reasonable one. Like the original CoT approach (Wei et al., 2022), we do not assign any role or explain the task - just pose the question, the CoT, and the answer (see Figure 3). We do this as 2-shot, 4-shot, and 8-shot for all three models.

4.4 Ensemble of Chain-of-Thought Prompts

To assess model performance, an ensemble approach is utilized with chain-of-thought prompting to make more confident guesses regarding the correct answers. Specifically, majority voting is done across an ensemble of models prompted by different question groups. For each prompt, 8 different random questions are selected from the BrainTeaser training set - repeated 5 times in total. Finally, the predictions are aggregated through voting to output the overall ensemble prediction.

This ensemble methodology with chain-of-thought prompting helps improve robustness to outlier examples and noise compared to using a single model. By prompting the ensemble components on different random question subsets, diversity is promoted to capture a more holistic representation of the overall data distribution. The voting also helps cancel out issues with single models latching onto spurious patterns. Overall, the ensemble approach with multiple chain-of-thought prompt sets provides a robust assessment strategy suited for the open-ended nature and diversity of the BrainTeaser puzzles.

Role:
You are a helpful AI assistant. You are given the task of solving a sentence/word puzzle.

+

Definition:
It's a Multiple Choice Question paired with 4 potential answers. Choose the most suitable one.

+

Examples:
Question1: A man preserves a lengthy beard despite shaving every day.
1. He is a barber.
2. He wants to maintain his appearance.
3. He wants his girlfriend to buy him a razor.
4. None of the above.
Correct Answer: <ans1> 1 **</ans1>**
.....
Question4: Tom attends class every day but doesn't do any homework.
1. He is a teacher.
2. He is a lazy person.
3. His teacher will not let him fail.
4. None of the above.
Correct Answer: <ans4> 1 **</ans4>**

+

Question5: The brother of a beggar passed away, but the deceased had no brothers. How is that possible?
Choices:
1. The beggar was the man's sister.
2. The man is angry for his brother being a beggar and cut ties with him.
3. The bagger's brother is a murderer.
4. None of the above.
Correct Answer: <ans5> ? **</ans5>**
Choose the most suitable answer. Thanks.

Figure 2: Sample structure for Few-Shot Prompting.

5 Results

We analyze the performance of the three models - including GPT4 Turbo, Claude 2.1, and Mixtral.

Question 1: How do you spell COW in thirteen letters?

–

Choices 1:

1. SEE OH DEREFORD.
2. SEE O DOUBLE YOU.
3. COWCOWCOWCOWW.
4. None of above.

–

Chain-of-Thought 1:

1. SEE OH DEREFORD: Doesn't seem to spell out "COW" in any conventional or playful manner.
2. SEE O DOUBLE YOU: Spells out "COW" in a creative way, matching the letter count required.
3. COWCOWCOWCOWW: Simply repeats the word "COW" without cleverly meeting the thirteen-letter criteria.
4. None of the above: Not applicable since there is a viable option.

–

Decision 1: The answer "SEE O DOUBLE YOU" creatively spells "COW" using thirteen letters, making it the correct choice.

–

Answer 1: 2.

.....

.....

.....

.....

Question 8: –

Choices 8: –

Chain-of-Thought 8: –

Decision 8: –

Answer 8: –

———

———

Question 9: How do you spell COB in seven letters?

–

Choices 9:

1. COBCOBB
2. COBBLER
3. SEE O BEE.
4. None of the above.

–

Figure 3: Sample structure for Chain-of-Thought Prompting (8-shot).

These models are tested with different types of prompts - regular and chain-of-thought, and with a varying number of examples, known as shots, ranging from zero to eight. Additionally, an ensemble method is applied to the eight-shot chain-of-thought prompting to see if it can further improve the models' performance. The results, shown in Table 2, reveal how the models performed under each condition. A human baseline with scores of 0.91 for both Sentence and Word puzzles in the test set is provided by the task organizers for comparison purposes.

GPT4 Turbo shows the best performance, especially with chain-of-thought prompting and an increasing number of shots. The model performs best with the eight-shot chain-of-thought prompting combined with the ensemble method ([E]), reaching the highest Sentence and Word scores of 0.93 and 0.95 in the test set, respectively. This shows that chain-of-thought prompting and the ensemble method significantly improve the model's understanding and output. Claude 2.1 also improves with chain-of-thought prompting and more shots. Its best scores were with the eight-shot chain-of-thought with the ensemble, achieving Sentence and Word scores of 0.86 and 0.95 in the test set, respectively. The asterisk (*) mark in Table 2 denotes our submission during the test phase. Even though Mixtral's performance is inferior to the performance of the other two models, it consistently gets better with more shots and chain-of-thought prompting. Mixtral delivered best results with the eight-shot chain-of-thought and the ensemble technique, with Sentence and Word scores of 0.88 and 0.82 in the test set, respectively.

Finally, the results highlight the effectiveness of chain-of-thought prompting in boosting the performance of LLMs. This approach, especially when combined with more examples and the ensemble method, greatly improves models' abilities to process and generate more accurate responses. GPT4 Turbo's top performance is likely due to its advanced design, which makes the most of these strategies. On the other hand, Claude 2.1's results point to the importance of model-specific adjustments.

6 Conclusion and Future Work

In this paper, we presented MasonTigers' approach to SemEval-2024 Task 9 on solving puzzles using LLMs. We explored various prompting strategies to guide the models, including zero-shot, few-shot, and chain-of-thought prompting. Our key method involved iteratively breaking down reasoning into simplified logical steps to decompose the complex

Model	Prompting	# of Shot	Sen_Dev	Sen_Test	Word_Dev	Word_Test
Human Baseline	–	–	–	0.91	–	0.91
GPT4 Turbo	Regular	Zero Shot	0.79	0.76	0.81	0.79
GPT4 Turbo	Regular	4 Shot	0.90	0.91	0.87	0.86
GPT4 Turbo	CoT	2 Shot	0.87	0.88	0.85	0.89
GPT4 Turbo	CoT	4 Shot	0.89	0.90	0.92	0.91
GPT4 Turbo	CoT	8 Shot	0.93	0.92	0.94	0.94
GPT4 Turbo	CoT **[E]**	8 Shot	**0.94**	**0.93**	**0.96**	**0.95**
Claude 2.1	Regular	Zero Shot	0.76	0.77	0.71	0.62
Claude 2.1	Regular	4 Shot	0.87	0.84	0.87	0.85
Claude 2.1	CoT	2 Shot	0.84	0.81	0.83	0.84
Claude 2.1	CoT	4 Shot	0.91	0.84	0.90	0.94
Claude 2.1	CoT	8 Shot	0.90	0.84	0.90	0.94
Claude 2.1	CoT **[E] [*]**	8 Shot	***0.91***	***0.86***	***0.91***	***0.95***
Mixtral	Regular	Zero Shot	0.71	0.66	0.45	0.51
Mixtral	Regular	4 Shot	0.81	0.82	0.79	0.75
Mixtral	CoT	2 Shot	0.79	0.75	0.63	0.70
Mixtral	CoT	4 Shot	0.84	0.86	0.77	0.76
Mixtral	CoT	8 Shot	0.89	0.86	0.80	0.81
Mixtral	CoT **[E]**	8 Shot	0.89	0.88	0.81	0.82

Table 2: Comparing the results generated by the models with different prompting strategies. **[CoT]** - denotes chain-of-thought. **[E]** - denotes Ensemble (as described in 4.4). **[*]** - denotes submission during the test phase on the Leaderboard.

deduction process.

Our experiments revealed promising results. While zero-shot performance was limited, providing explanatory prompts substantially improved the models' reasoning abilities. Performance increased with more prompt specificity and steps. Our best results came from an ensemble approach applying majority voting across multiple chain-of-thought prompts.

Ultimately, our system achieved competitive rankings on the leaderboard, placing 2^{nd} in the word puzzle sub-task and 13^{th} on sentence puzzles. The strong capability unlocked through guided prompting highlights these models' latent reasoning potential when given a structured thought process. Our work sheds light on how explanatory chains can elicit more of the knowledge within large language model parameters.

A few key limitations remain to be addressed in future work. First, constructing effective prompts requires extensive human effort and insight - automating this prompting process could improve scalability. Additionally, performance still lags behind human levels, indicating that there is room for advancement. Architectural constraints related to long-term memory and reasoning likely need to be overcome. Finally, our approach focused narrowly on the given puzzles rather than teaching broader inferential skills - developing more generalizable reasoning through prompts is an open challenge.

Acknowledgments

We would like to thank the shared task organizers for proposing this interesting competition and for providing participants with the BrainTeaser dataset.

Abstract

This paper presents the *MasonTigers'* entry to the SemEval-2024 Task 8 - Multigenerator, Multidomain, and Multilingual Black-Box Machine-Generated Text Detection. The task encompasses Binary Human-Written vs. Machine-Generated Text Classification (Track A), Multi-Way Machine-Generated Text Classification (Track B), and Human-Machine Mixed Text Detection (Track C). Our best performing approaches utilize mainly the ensemble of discriminator transformer models along with sentence transformer and statistical machine learning approaches in specific cases. Moreover, zero-shot prompting and fine-tuning of FLAN-T5 are used for Track A and B.

1 Introduction

In academia and beyond, machine-generated content is proliferating across news platforms, social media, forums, educational materials, and scholarly works. Breakthroughs in large language models (LLMs), like GPT-3.5 and GPT-4, facilitate the creation of fluent responses to diverse user queries. While this capability raises prospects of replacing human labor in various tasks, concerns arise about potential misuse, including the generation of deceptive misinformation (Chen and Shu, 2023) and completing student assignments, which hinders the development of essential writing skills (Jungherr, 2023).This highlights the importance of developing automated systems to detect and mitigate the potential abuse of machine-generated content, as well as distinguishing between machine-written and human-generated text. Additionally, Prior studies (ZeroGPT [1]; Mitchell et al., 2023; Bao et al., 2023) predominantly adopted a binary classification approach for machine-generated text (MGT), with a primary focus on English. However, there has been limited research addressing the amalgamation of human-written and MGT texts (Wang et al., 2024d).

In response to these limitations, SemEval-2024 introduces a shared task: Multigenerator, Multidomain, and Multilingual Black-Box Machine-Generated Text Detection (Wang et al., 2024c). This task comprises three subtasks, each targeting different aspects of machine-generated text complexity.Subtask A focuses on Binary Human-Written vs. MGT Classification, involving two tracks: monolingual and multilingual. Subtask B tackles Multi-Way Machine-Generated Text Classification to identify the source of a given text. Subtask C involves detecting the transition point within a mixed text, determining where it shifts from human-written to machine-generated. The data provided for this task is an expansion of the M4 dataset (Wang et al., 2024d) and benchmark evaluation of (Wang et al., 2024b). .

In conducting these tasks, we conduct a range of experiments and observe that ensemble methods outperform individual models significantly in classification tasks, e.g., Goswami et al. (2023) Emran et al. (2024), Ganguly et al. (2024). Our weighted ensemble approaches achieve accuracies of 74%, 60% and 65% in subtask A monolingual; multilingual tracks and subtask B respectively, given that we have used different models for both tasks. In subtask C, we explore different setups, ensembling which results in Mean Absolute Error (MAE) of 60.78. For the classifications, we utilize zero-shot prompting and fine-tuning of FlanT5[2], while adhering to the restriction of no data augmentation in this task.

trustworthy methods for evaluation are highlighted by recent research (e.g. Chaka 2024, Elkhatat et al. 2023). In terms of human evaluation of MGT, Guo et al. (2023) indicates that generated texts from large language models tend to exhibit less emotional and objective content compared to human-written texts. Tang et al. (2023) suggests that distinct signals left in the machine-generated text may facilitate the identification of suitable features to differentiate between MGT and human-written texts. Whereas, Sadasivan et al. (2023) observes that detection techniques become less effective as language models improve. Moreover, Ippolito et al. (2019) advocates for the importance of using both human and automatic detectors to assess the humanness of text generation systems.

Previous work in determining MGT from human-written ones include higher order n-grams (Gallé et al., 2021), utilizing linguistic patterns (Muñoz-Ortiz et al., 2023), curvature-based criterion (Mitchell et al., 2023), tweaking with multiple variables (Dugan et al., 2023), fine-tuning transformer-based models e.g., Capobianco; Chen and Liu (2023). Very recently, Wang et al. (2024a) puts forward LLM-Detector, offering a fresh method for identifying text at both document and sentence levels by employing Instruction Tuning of LLMs. To tackle challenges of this field, several datasets have been released, e.g., MULTITuDE (Macko et al., 2023), M4 (Wang et al., 2024d). Additionally, there have been multiple shared tasks organized related to this topic (Shamardina et al., 2022a; Molla et al., Molla et al.; Kashnitsky et al., 2022. Despite several collective findings and techniques, as argued by Sadasivan et al. (2023), there remains a critical need for the creation of reliable detection methods capable of accurately distinguishing between human and machine-generated text, a requirement essential across both English and other languages.

3 Datasets

Wang et al. (2024d) collects datasets from a variety of sources, including Wikipedia (the March 2022 version), WikiHow (Koupaee and Wang, 2018), Reddit (ELI5), arXiv, PeerRead (Kang et al., 2018)(for English), and Baike (for Chinese). They employ web question answering for Chinese, news content for Urdu, Indonesian, and RuATD (Shamardina et al., 2022b) for Russian language. The method of prompting machine-generated text (MGT) has been extensively outlined in Wang et al. (2024d).

Subtask A, Binary Human-Written vs. Machine-Generated Text Classification, in the monolingual track involves a same-domain cross-generator experiment, where instances are exclusively in English and gathered from five distinct sources with two labels: 0 and 1. Human-generated texts receive a label of 0, while machine-generated texts from four different LLMs (chatGPT, Cohere, *davinci-003*, and Dolly-v2) are labeled as 1. The distribution of Train and Validation datasets, both in terms of labels and sources, along with the number of test instances, is detailed in Tables 1. During the test phase, there are 16,272 instances labeled as 0 and 18,000 instances labeled as 1.

On the other hand, Subtask A in the multilingual track entails a cross-domain same-generator experiment. Instances are sourced from nine different sources during the training phase, including four different languages, while the validation dataset comprises three different languages as indicated in Table 2. Similar to the monolingual task, human-generated texts are labeled as 0, and machine-generated texts from five different LLMs (Bloomz (Muennighoff et al., 2022), chatGPT, Cohere, *davinci-003*, and Dolly-v2) are labeled as 1. In the test phase, there are 20,238 instances labeled as 0 and 22,140 instances labeled as 1.

Table 4: Label Distribution of Test Data for Multi-Way Machine-Generated Text Classification (Subtask B)

Subtask B, Multi-Way Machine-Generated Text Classification, represents another cross-domain same-generator experiment. In contrast to Subtask A, Subtask C involves six labels: 0 for human, 1 for chatGPT, 2 for Cohere, 3 for *davinci-003*, 4 for Bloomz, and 5 for Dolly. These labels correspond to instances sourced from five different sources. However, it's noteworthy that the sources for the training and validation data differ, and this distinction is outlined in Tables 3 and 4.

Subtask C, involving Human-Machine Mixed Text Detection, provides a composite text with a human-written first part followed by a machine-generated second part. The task is to discern the boundary, and labels are provided as word indices to distinguish it. The label distribution of data is shown in Table 5.

Table 5: Number of Instances for Human-Machine Mixed Text Detection (Subtask C)

4 Experimental Setup

4.1 Data Preprocessing

In the monolingual track of subtask A, we received approximately 160K instances for training and development. To preserve the text's integrity, we eliminate special characters, extra new lines, unnecessary whitespace, and hyperlinks from the data, ensuring that only the essential text remains in sub-

tassk A (monolingual), B & C. However, in the multilingual track of subtask A, since none of our team members are familiar with the languages present in the instances, we only remove hyperlinks. We ensure that punctuation marks such as full stops, commas, and exclamation signs are retained in all instances, as they play a crucial role in this task (Tang et al., 2023).

4.2 Hyperparameters

In our experimental setup, we configure several key parameters to train our model effectively. We utilize a batch size of 16, controlling the number of training samples processed in each iteration, learning being set to 1e-5, and incorporating dropout with a rate of 0.25 to prevent overfitting by randomly dropping a fraction of units during training. Maintaining a fixed sequence length of 512 tokens ensured consistency in input data processing. For optimization, we employ the AdamW optimizer (Loshchilov and Hutter, 2017), known for its efficacy in training deep neural networks with added weight decay regularization. These experiments are conducted on a 80GB NVIDIA A100 GPU machine over the period of 24 hours, leveraging its computational power and memory capacity. By systematically adjusting these parameters, we aim to understand their influence on the model's performance, ultimately optimizing our approach for the task at hand. The adjustment of these parameters is carried out in both subtask A & B.

4.3 Models: SubTask A

In monolingual track, we employ Roberta (Liu et al., 2019), DistilBERT (Sanh et al., 2019), and ELECTRA (Clark et al., 2020). Subsequently, we apply a weighted ensemble method, incorporating RoBERTa, DistilBERT, and ELECTRA, employing a voting strategy due to their closely comparable individual accuracies. The weights are their corresponding accuracy.

Similarly, in the multilingual track, we utilize LASER (Li and Mak, 2020), mBERT (Devlin et al., 2018), and XLMR (Goyal et al., 2021). Following that, we deploy a weighted ensembled strategy involving these models, utilizing the voting method.

4.4 Models: SubTask B

Subtask B, poses a considerable challenge, as opposed to the first two tracks where the model distinguishes between human and machine-generated text. Here, the model must differentiate among human-generated text and five distinct LLMs. For this, we leverage Roberta, ELECTRA, Deberta (He et al., 2020), and subsequently create a weighted (weights are set as acauracy) ensemble approach of these models using voting technique.

4.5 Models: SubTask C

In subtask C, we find the embedding of the training data using Term Frequency - Inverse Document Frequency (TF-IDF) (Aizawa, 2003), Positive Point-wise Mutual Information (PPMI) (Church and Hanks, 1990), and the embedding using language model RoBERTa (Liu et al., 2019). Then for each training embedding generated by these approaches, we apply Linear Regression (Groß, 2003) and ElasticNet (Zou and Hastie, 2005) separately on these embeddings and predict the first word or index of from where the machine-generated text started in a specific data instance. We selected the word that is the starting word of the closest neighboring paragraph as the predicted word index. Then we clip the predicted values to ensure the predictions range from 0 to the length of the specific data instance (rounded if necessary). In the development phase, we find the Mean Absolute Error (Chai and Draxler, 2014) of these six predictions (three each by Linear Regression and ElasticNet). Then we perform a weighted ensemble depending on the Mean Absolute Error of the six predicted results and get our ensembled MAE in the development phase. We also perform this approach on the test data and find our smallest MAE in the evaluation phase.

4.6 Prompting and Fine-Tuning LLM

> **Prompt:** <*Text*> If this piece of text is Human Generated, answer 0 or If Machine Generated, answer 1.

Figure 1: Sample FlanT5 prompt.

For subtasks A & B, we experiment with FlanT5 zero-shot prompting, utilizing the Hugging Face Transformers[3] library, specifically the T5ForConditionalGeneration class and T5Tokenizer. Training is conducted on an NVIDIA A100 GPU with 80GB memory over 24 hours. The prompting sample for subtask A is shown in Figure 1. In subtask B, we maintain consistency in prompting by keeping the question the same as

Ensemble (Wt. accuracy)	0.79	0.74	**Ensemble (Wt. accuracy)**	0.63	0.60

Table 6: Accuracy of Binary Human-Written vs. Machine-Generated Text Classification (Subtask A)

labeling the human-generated text as "1", while prompting the machine-generated texts from various Language Model Models (LLMs) as categories "2" through "6."

We also finetune a t5-small model over 2 epochs, setting the learning rate to 0.001 and the batch size to 4. We employ a full finetuning (FFT) approach without the utilization of any quantization method like LoRa (Hu et al., 2021) or QLoRA (Dettmers et al., 2023). Due to the adoption of an FFT approach and the sheer size of the dataset, we do not experiment with a wide set of hyper-parameters. We empirically choose a few combinations and report the best results.

5 Results

Subtask A and B are evaluated based on Accuracy, as specified by (Wang et al., 2024c), while Subtask C employs Mean Absolute Error (MAE) as the evaluation metric [4].

In the monolingual track of Subtask A, ELECTRA demonstrates superior accuracy (0.78) compared to RoBERTa (0.70) and DistilBERT (0.69) during the development phase. Consequently, the weighted ensemble of these three models achieves an accuracy of 0.79 in our development submission, surpassing the baseline RoBERTa model. Upon publishing test labels, a comparison with the test label results reveals accuracies detailed in Table 6, with the ensemble model achieving an accuracy of 0.74, while the baseline accuracy increases to 0.88, differing by 0.14 compared to the development phase. In the multilingual track, XLM-R outperforms LASER and mBERT with an accuracy of 0.61. Ensembling these models achieves accuracies of 0.63 in the development phase and 0.60 in the test phase, whereas the baseline accuracies are 0.72 and 0.81, respectively. Both zero-shot prompting and fine-tuning FlanT5 demonstrate less than satisfactory performance, yielding accuracies of 0.53 and 0.43 in the monolingual and multilingual tracks, respectively.

Model	**Dev**	**Test**
Baseline (RoBERTa)	0.75	0.75
FLAN-T5 Prompting	0.54	0.48
FLAN-T5 Fine-tuning	0.57	0.54
RoBERTa	0.72	0.56
ELECTRA	0.73	0.59
DeBERTa	0.77	0.64
Ensemble (Wt. accuracy)	0.79	0.65

Table 7: Accuracy of Multi-Way Machine-Generated Text Classification (Subtask B)

Within subtask B, DeBERTa outperforms RoBERTa and ELECTRA, achieving superior performance with an accuracy of 0.77. Ensembling these models yields accuracies of 0.79 and 0.65 in both the development and test phases, whereas baseline RoBERTa gives 0.75 in both phases. Similar to subtask A, fine-tuning and prompting FLAN T5 exhibit suboptimal results in both phases shown in Table 7.

In subtask C, various methods are considered, and it is found that RoBERTa with Elastic Net achieved the minimum Mean Absolute Error (33.28). Table 8 highlights that Elastic Net outperforms Linear Regression in terms of lower MAE during both the development and test phases. To enhance predictive performance, we employ a weighted ensemble of development phase MAE of six combinations, resulting in MAE values of 31.71 and 60.78 during the development and test phases, respectively. However, the baseline (longformer) model gives MAE of 3.53 ± 0.21 and 21.54.

[4] https://github.com/mbzuai-nlp/SemEval2024-task8

Model	Dev	Test
Baseline (Longformer)	$\simeq 3.53$	21.54
TF-IDF + LR	44.15	71.23
PPMI + LR	41.93	68.41
RoBERTa + LR	37.52	65.82
TF-IDF + EN	38.36	67.09
PPMI + EN	35.67	63.36
RoBERTa + EN	33.28	62.34
Wt. (dev. MAE) Ensemble	31.71	60.78

Table 8: Mean Absolute Error(MAE) value of Human-Machine Mixed Text Detection (Subtask C) (LR = Linear Regression, EN = ElasticNet)

6 Error Analysis

In the monolingual track of Subtask A, the final model demonstrates proficiency in accurately identifying machine-generated text. Nonetheless, there is a notable presence of false positives, indicating instances where the model incorrectly identifies human-written texts as machine-generated. Despite this, the model effectively detects machine-generated text without omission. Similarly, in the multilingual track of Subtask A, the ultimate model excels in accurately distinguishing machine-generated text. However, false positives are prevalent, indicating numerous cases where human-written texts are inaccurately classified as machine-generated. Additionally, the model encounters instances where it fails to predict machine-generated texts.

In Subtask B, the model excels in accurately predicting chatGPT-generated texts. However, its performance declines notably for davinci-generated text, often misclassifying it as chatGPT generated. Additionally, the model's accuracy is lower for Dolly-generated and human-written texts, indicating a discrepancy in handling machine-generated versus human-written content.

For subtask C, MAE is higher due to the presence of outliers because the dev MAE was significantly lower than the test MAE. To handle this issue, it is essential to address the preprocessing of data, handling outliers, selecting appropriate features, optimizing model complexity, improving data quality, and ensuring model stability through proper tuning and evaluation procedures. This can be the future scope of research in this specific domain.

For a clearer understanding, refer to the visual evaluations in Figure 2, 3, 4 of Appendix.

7 Conclusion

In our investigation of SemEval-2024 Task 8, we applied a diverse set of methodologies, encompassing statistical machine learning techniques, transformer-based models, sentence transformers, and FLAN T5. Subtask A involved binary classification, where the monolingual track focused on cross-generator scenarios within the same domain, and the multilingual track addressed cross-domain scenarios within the same generators. Subtask B dealt with multi-label classification, requiring the discrimination of human-generated text from five distinct language models. Subtask C centered on Human-Machine Mixed Text Detection, employing TF-IDF, PPMI, and RoBERTa with Linear Regression and ElasticNet for prediction. The outcomes of three subtasks highlighted the efficacy of ensemble methods, showcasing specific models excelling in each subtask. Additionally, we explored the applicability of zero-shot prompting and fine-tuning FLAN-T5 for Tracks A and B.

In summary, our approach harnessed a blend of transformer models, machine learning methodologies, and ensemble strategies to tackle the complexities presented by SemEval-2024 Task 8. The paper underscores the imperative need for robust detection methods to effectively navigate the growing prevalence of machine-generated content.

Limitations

The task involved extensive datasets in each phase of all subtasks, leading to prolonged execution times and increased GPU usage. Additionally, the texts themselves were lengthy. Moreover, the prohibition of additional data augmentation added to the complexity of the task. The nuanced distinction between human-written and machine-generated text, which can sometimes be challenging for humans to discern, poses an even greater difficulty for models attempting to learn this differentiation.

Acknowledgements

We express our gratitude to the organizers for orchestrating this task and to the individuals who diligently annotated datasets across various languages. Your dedication has played a crucial role in the triumph of this undertaking.

Abstract

Disentangling underlying factors contributing to the expression of emotion in multimodal data is challenging but may accelerate progress toward many real-world applications. In this paper we describe our approach for solving SemEval-2024 Task #3, Sub-Task #1, focused on identifying utterance-level emotions and their causes using the text available from the multimodal *F.R.I.E.N.D.S.* television series dataset. We propose to disjointly model emotion detection and causal span detection, borrowing a paradigm popular in question answering (QA) to train our model. Through our experiments we find that (a) contextual utterances before and after the target utterance play a crucial role in emotion classification; and (b) once the emotion is established, detecting the causal spans resulting in that emotion using our QA-based technique yields promising results.

1 Introduction

The task of **e**motion **c**ause **a**nalysis in **c**onversations (Wang et al., 2023, ECAC) aims to decipher the expression of human emotion in conversational data, either through unimodal (text-only) or multimodal (e.g., with the addition of video and/or audio) information. On a fundamental level, this is a complex two-part problem: emotion must be identified for a given utterance, and the span of dialogue causing that emotion must subsequently be recognized.[1] SemEval-2024 Task #3 (Wang et al., 2024) was organized around solving this problem, broken into two subtasks varying in the data allowed to build the solution; in Sub-Task #1, identification of emotion cause was limited to the use of only text information. We address Sub-Task #1 in this paper.

We pursued two strategies in our approach toward solving the task. First, we trained a question answering (QA) model (Rajpurkar et al., 2018) to extract causal spans given the reference emotions for non-neutral utterances within the training set. In doing so, we achieved comparable results to those reported by Wang et al. (2023) and Poria et al. (2021), the latter of which is a popular benchmark for this task. Next, we devised a two-step disjoint model that separately learns to classify emotion and extract causal spans during training. During inference we (1) run the emotion classifier, enriching the test set with emotion labels; and (2) run inference on the QA model to extract the causal spans. Our approach achieved third place according to the primary task metric (a weighted-average proportional F_1) and 2nd place on the secondary metric (weighted-average strict F_1; see §A.2 for results on all relevant task metrics). We elaborate on our findings in the remainder of this paper.[2]

2 Background

2.1 Task Description

Given a conversation with a sequence of n emotional utterances $u \in \{u_1, ..., u_n\}$, the twin goals in SemEval Task #3 are to identify (a) the emotion label $e_i \in \{$HAPPINESS, SADNESS, DISGUST, FEAR, SURPRISE, ANGER, NEUTRAL$\}$; and (b) for emotions other than those identified as NEUTRAL, the corresponding span of text c_i that caused u_i to be assigned label e_i.

Input and Output. Each input u_i is a sequence of text. This text is matched with video and audio in the dataset, although for Sub-Task #1 only the text is used for learning and inference. Output for each u_i is a categorical label e_i in the label space defined previously, and a sequence of text c_i signifying the reason why e_i was assigned to u_i.

*Authors contributed equally.

[1] *Neutral* utterances have no corresponding causal spans.

Attribute	Frequency
# Conversations	1374
# Utterances	13619
anger	11.85%
disgust	3.03%
fear	2.74%
joy	16.90%
sadness	8.42%
surprise	13.51%
neutral	43.53%

Table 1: Dataset statistics. *# Conversations* and *# Utterances* are raw frequency counts, whereas all emotion categories are percentages of total utterances.

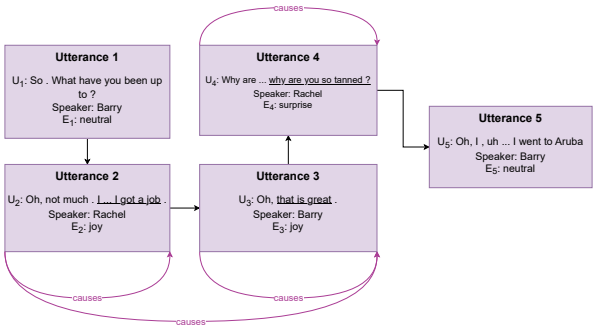

Figure 1: An example conversation from the dataset.

Dataset. All Task #3 entries were trained and evaluated using Wang et al. (2023)'s multi-modal conversational emotion cause dataset (ECF). ECF is an English-language dataset sourced from transcripts, audio, and video clips from the popular television sitcom *F.R.I.E.N.D.S*; the series comprises daily informal conversations involving a cast of six friends living in New York City. Conversations are segmented into individual speaker utterances, referred to as "emotional utterances." Causal spans are linked to emotional utterances in the dataset, and annotators could source them from any utterance in the given conversation. Dataset statistics, including the distribution of emotion labels across utterances in ECF, are presented in Table 1. Sample inputs to the emotion classification model and the causal span extractor are shown in Figure 1.

2.2 Related Work

ECAC has been studied previously to some extent in both disjoint and joint training settings. ECE (Gui et al., 2016) introduced a dataset with emotion causes extracted from a Chinese news article corpus; the language in this dataset is formal and in passive voice. Instances place focus on both clause-level (to capture emotion) and phrase-level (to capture boundaries) annotations. Building on this, ECPE (Xia and Ding, 2019) proposed a joint training model to extract emotion and corresponding causal spans, using word2vec embeddings (Mikolov et al., 2013) pre-trained on a corpus extracted from a Chinese micro-blogging website. They used a two-step process to address the emotion-cause pair extraction task, performing emotion extraction and cause extraction first, followed by emotion-cause pairing and filtering using a hierarchical Bi-LSTM model.

Poria et al. (2019) introduced a novel multimodal, multi-party conversational dataset for emotion recognition in conversations (MELD). Wang et al. (2023) makes use of MELD, and created another corpus of emotional utterances paired with their causes; this corpus also serves as the dataset for our task. Wang et al. (2023) establish baselines for the Multimodal Emotion-Cause Pair Extraction in Conversations (MC-ECPE) task using the same guidelines described in ECPE. The authors of RECCON (Poria et al., 2021) solve the task of recognizing emotion cause in conversations using causal span extraction and causal emotion entailment with transformer-based models. However, they employ their methods on IEMOCAP (Busso et al., 2008) which is a dyadic dataset and DailyDialog (Li et al., 2017) which consists of manually written dialogues focusing on physically-situated topics. Other prior work has used formal conversation datasets or reported speech where emotions are often expressed explicitly (Gui et al., 2016). Performing emotion classification and causal span extraction using a QA-based paradigm for an informal conversational setting is a novel approach to link emotion causes to implicitly expressed emotion.

3 System Overview

We model the task to maximize the probability of finding emotion-cause pairs, (e_i, c_i), for the given conversation context x. We disjointly train models with parameters θ and ϕ to estimate the emotion e_i from x and the causal span c_i from (e_i, x), respectively. We approximate x to the prompts x_e and x_c to provide the appropriate contextual information to our models, as shown in Equation 1.

$$\begin{aligned} P_{\theta,\phi}(e_i, c_i|x) &= P_\theta(e_i|x)P_\phi(c_i|e_i, x) \\ &\approx P_\theta(e_i|x_e)P_\phi(c_i|e_i, x_c) \end{aligned} \quad (1)$$

Our approach is a two-step process, by which we first identify e_i for the given utterance u_i in a

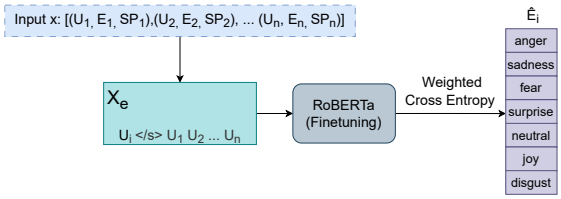

Figure 2: Training the *emotion classifier*.

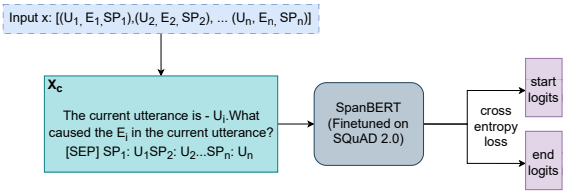

Figure 3: Training the *emotion causal classifier*.

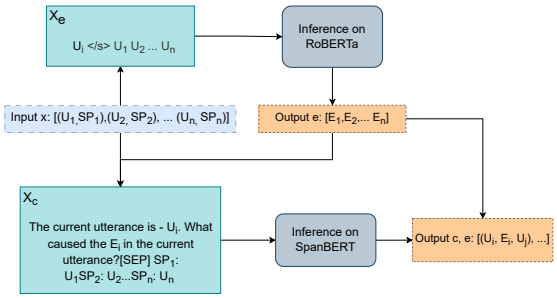

Figure 4: Performing inference at test time.

conversation from x_e, and then identify the causal span c_i for u_i in all cases when $e_i \neq$ NEUTRAL. We fine-tune separate pre-trained language models (PLMs) for these two steps. While fine-tuning for emotion cause spans, we use the emotion labels provided as part of the training set to construct x_c.

Emotion Classifier. We use a RoBERTa base model (Zhuang et al., 2021) as the backbone of our emotion classification model, with a weighted cross entropy loss to penalize emotion label predictions. We use class weights from our training set as weighing terms for the loss function, and fine-tune for 20 epochs using the AdamW optimizer (Loshchilov and Hutter, 2019) with linear rate scheduler with 500 warm-up steps. We use the learning rate 5×10^{-5} with 0.01 weight decay rate, and select the best epoch based on weighted F_1. The input prompt to this model is a space-separated concatenation of u_i, the separator token proposed by Zhuang et al. (2021), and all utterances in the conversation ($U_{\text{all}} = \{u_1, ..., u_n\}$) space-separated in sequential order, as shown in Figure 2.

Emotion Cause Classifier. We frame emotion cause classification as a QA task. To avoid asking our model to answer impossible questions, we skip utterances where the predicted label is NEUTRAL. We use a SpanBERT base model (Joshi et al., 2020) fine-tuned on SQuAD2.0 (Rajpurkar et al., 2018).[3] We then further fine-tune this model on our task. The input prompt to this model is:

> `The current utterance is - [`u_i`]. What caused the` e_i `in the current utterance? <SEP>` U_{all}

This is shown in Figure 3. For fine-tuning SpanBERT, we change the batch size from 32 to 12 and the maximum sequence length from 512 to 400. We set the learning rate to 2×10^{-5} and train the model for five epochs. Figure 4 shows inference using our proposed system. We first perform inference on our *emotion classifier* for the test dataset to augment test x_c with emotion labels e_i, and then perform inference on our *emotion cause classifier*.

4 Experimental Setup

ECF is already split into *train* and *test* sets. We separate a *dev* set from *train* by holding out the last 20% of the training data. We make use of pre-trained RoBERTa (Liu et al., 2019) and SpanBERT (Joshi et al., 2020) models from HuggingFace. Other details regarding our hardware and software libraries can be found in §A.3.

For training the *emotion classifier* we make use of weighted F_1 score, choosing the best performing model based on this metric. While training the *emotion cause classifier*, we select models based on metrics defined by Joshi et al. (2020) for span-based learning with PLMs: unweighted exact match, and F_1 score.

5 Results

5.1 Main Quantitative Findings

Our proposed system achieves 3rd place in SemEval Task #3, Sub-Task #1, based on the primary task metric of weighted average proportional F_1 (Wang et al., 2023). We achieve 2nd place overall based on the auxiliary metric of weighted average strict F_1,[4] which accounts for exact span matching. We show

[3] We observe that this additional fine-tuning boosts our model's performance (Appendix A.1).

[4] https://github.com/NUSTM/SemEval-2024_ECAC/tree/main/CodaLab/evaluation

Metric	Score	Ranking
w-avg. Strict F_1	0.1839	2
w-avg. Proportional F_1	**0.2442**	**3**
Strict F_1	0.1851	2
Proportional F_1	0.2397	4

Table 2: Official task scores, shown alongside final leaderboard rankings for Sub-Task #1.

Model	Metric	Score
Our Model	**w-avg. Strict F_1**	**0.2741**
Wang et al.	w-avg. Strict F_1	0.2625

Table 3: Comparing our model's performance on the *dev* set to Wang et al. (2023)'s text-only baseline.

our *test* scores for all official task metrics in Table 2. In Table 3 we compare to Wang et al. (2023)'s baseline for this task, showing that our model improves upon this baseline. Results reported in Table 3 are based on *dev* performance, since *test* was held private by the task organizers.

5.2 Quantitative Analysis

To investigate the performance of our approach, we used the *dev* dataset to perform an ablation study regarding prompt context length and fine-tuning data for the *emotion cause classifier*. We also experimented with varied scaling factors and input context for *emotion classification*.

5.2.1 Emotion Classification

Scaling Factors. We experimented with the use of class size as a scaling factor to improve performance for less-represented classes (e.g., *disgust* or *fear*). In Table 4, models post-fixed with *(w)* are scaled versions of the emotion classification model trained with a weighted cross-entropy loss. We observe large performance differences for under-represented classes under this condition; however, we also observe a slightly reduced F_1 overall. This is a positive observation for our disjoint training regime, as the causal span extractor model isn't trained on neutral cases during training, and it confirms the utility of class weight scaling for this task.

Input Context. We also experimented with varied input context, adjusting the context of the input by passing only `u_i` compared to the longer `u_i <SEP> U_all` used in our final model.

	u_i	u_i (w)	u_i </s> U_{all}	u_i </s> $U_{\text{all}}(w)$
Anger	0.46	0.45	**0.48**	**0.48**
Disgust	0.10	0.23	**0.24**	0.20
Fear	0.17	0.26	0.20	**0.27**
Joy	0.55	0.53	0.59	**0.60**
Sadness	**0.76**	0.74	0.73	0.72
Surprise	0.38	0.35	0.39	**0.40**
Neutral	0.63	0.53	**0.64**	0.58
F_1	0.60	0.58	0.60	0.59

Table 4: Ablation study on different prompts for the *emotion classifier*. </s> is the special token and (w) represents models trained with a weighted cross-entropy loss. F_1 is weighted average strict F_1.

5.2.2 Emotion Cause Classification

We experimented with two QA configurations examining prompt context length and fine-tuning data, shown in Table 5. In the former, we tweaked the model's maximum sequence length for models using the complete set of utterances in a conversation, U_{all}. We compared our results to a model trained only on prior context, i.e., $u \in \{u_1, ..., u_i\}$ where u_i is the current utterance. Interestingly, such models exhibited slightly higher F_1 scores; this is comparable to causal span extraction scores in (Poria et al., 2021). In the latter, we compared versions of our approach using (a) the pretrained SpanBERT directly, and (b) a version that was fine-tuned using SQuAD 2.0 data. We observed that additional training on a model previously trained on the SQuAD 2.0 dataset yields better performance than the pretrained SpanBERT model.

Sequence Length	EM	F_1
400	**0.4466**	**0.6133**
512	0.4397	0.6095
Model		
SpanBERT & SQuAD 2.0	**0.5147**	**0.6810**
SpanBERT	0.4428	0.6494

Table 5: Ablation study on sequence length (full context) and model for the *emotion causal classifier*. *EM* is exact match, and *F_1* is weighted average strict F_1. The base model of SpanBERT used is `spanbert-base-cased`. We prompt the model with only past and current context.

5.3 Error Analysis

We analyzed mispredicted examples from the *dev* set to identify commonly occurring errors that

might not be readily apparent by the w-avg proportional F1-score, and we observed that some of these conversations had neutral utterances with no corresponding emotion-cause pairs. From the 275 conversations, there were 23 such instances of which 12 were composed of only neutral utterances. In such cases, our span extractor model's output is accurate as it simply skips such utterances by design, and when neutral utterances are predicted correctly, this is the correct action. Conversely, in the cases where there are emotional utterances yet no causal pairs provided, the span model is unpredictable as it is not trained to predict empty causal spans, reinforcing our hypotheses grounded in Equation 1, i.e., that results of span extraction are dependent on the emotion classification model.

We also observed errors where incorrect spans were predicted for correctly identified emotions. In many instances, this involved the prediction of causal spans from *future* utterances. Given the nature of the data (informal conversations), it is possible for future utterances to overlap temporally with the current utterance. In other cases, it might seem to a third-person viewer that the cause of an emotion expressed at a timestep *t* becomes apparent after an utterance from a later timestep. Our model was not able to handle such cases predictably. Following manual review of all 32 predictions made for causal spans appearing in future utterances, we found that only 7 predictions were correct, mostly for the numerous emotion classes. This supports our rationale behind fine-tuning both our models in a full-context setting as explained earlier (§3), but suggests that there is still room for improvement. We suspect that the autoregressive context studied in follow-up analyses (§A.1) may result in better performance by skipping such examples, or perhaps a jointly-trained or multimodal model would help bridge the shortcomings.

Finally, we present a sample of correct predictions and mispredictions in Table 6. We observe that emotion classification for the most representative classes works as hypothesized, i.e., the emotions *joy* and *surprise* are predicted better than *fear*. For the span extraction task, we observe that rows 3 and 4 with non-neutral emotion predictions have "N/A" as their span prediction as, in these instances, the best prediction for an utterance with multiple causes returned identical spans as rows 2 and 5, respectively. One way to avoid such cases could be to pair all utterances u_i and u_j along with u_{all} ($u_i, u_j \in \{u_1, ..., u_n\}$), resulting in a quadratic increase in resource requirements and clipped inputs due to the model's limited token length. However, as this behavior was not consistent across all cases, we opted for the simpler solution described in §3. This also helped with resource constraints.

Utterance	Gold Emo.	Pred. Emo.	Gold Cause	Pred. Cause

Ooh! Ah! Okay!	fear	surprise	It is got a tail!	It is moving.

Table 6: Correct and incorrect predictions from *dev*.

6 Conclusion

We introduce a disjoint model comprising an emotion classifier and an emotion-cause classifier. Our system addresses emotion cause extraction competitively based on the official leaderboard and on follow-up analyses (§5). We set out with the objectives of developing a disjoint model making use of

the entire conversation to identify emotions in utterances and using a well-known QA paradigm to extract the causes of the emotions, and we achieve this with varying degrees of success. We observe that emotion classification is harder than emotion cause extraction when emotion annotations are present (Tables 4 and 5), and that when the model assigns emotions correctly, it also has a greater chance of extracting causal spans correctly (Table 6). This is more evident when only prior contexts are present, yielding higher scores.

Acknowledgments

We thank the anonymous reviewers for their helpful feedback, and the SemEval-2024 Task 3 organizers for introducing us to this challenging and intriguing research problem.

A Appendix

A.1 SQuAD 2.0 Fine-Tuning Affects Emotion Cause Classification

We observe a strong increase in performance of the *emotion cause classifier* if additional fine-tuning is performed using SQuAD 2.0 (Rajpurkar et al., 2018). In this case, the model is prompted with The

current utterance is u_i What caused the e_i in current utterance?. We did not consider utterances $u \in \{u_{i+1}, ..., u_n\}$. The unweighted exact match and F_1 increases, as shown in Table 5.

A.2 Other Metrics for the Model

Metric	Value
Weighted strict precision	0.339
Weighted strict recall	0.235
Weighted strict F-1	0.274
Weighted Proportional precision	0.425
Weighted Proportional recall	0.288
Weighted Proportional F-1	**0.339**
Strict precision	0.348
Strict recall	0.235
Strict F-1	0.280
Proportional precision	0.431
Proportional recall	0.280
Proportional F-1	0.339

Table 7: Additional results for our model on the *dev* set as defined by Wang et al. (2023). Weighted Proportional F_1 was the primary metric used for SemEval Task #3.

We provide additional results for other metrics defined by Wang et al. (2023) in Table 7.

A.3 Hardware and Hyperparameters

We make use of PyTorch 2.2.0,[5] HuggingFace transformers 4.37.2 for the RoBERTa-base implementation,[6] FAIR's[7] spanbert-base-cased, FAIR's SpanBERT fine-tuned on SQuAD2.0 and sklearn 1.3.2[8] to fine-tune our models. We train our models using an Nvidia RTX 3090Ti GPU.

MasonTigers at SemEval-2024 Task 1: An Ensemble Approach for Semantic Textual Relatedness

Dhiman Goswami, Sadiya Sayara Chowdhury Puspo, Md Nishat Raihan, Al Nahian Bin Emran, Amrita Ganguly, Marcos Zampieri
George Mason University, USA
dgoswam@gmu.edu

Abstract

This paper presents the *MasonTigers*' entry to the SemEval-2024 Task 1 - Semantic Textual Relatedness. The task encompasses supervised (Track A), unsupervised (Track B), and cross-lingual (Track C) approaches to semantic textual relatedness across 14 languages. *MasonTigers* stands out as one of the two teams who participated in all languages across the three tracks. Our approaches achieved rankings ranging from 11^{th} to 21^{st} in Track A, from 1^{st} to 8^{th} in Track B, and from 5^{th} to 12^{th} in Track C. Adhering to the task-specific constraints, our best performing approaches utilize an ensemble of statistical machine learning approaches combined with language-specific BERT based models and sentence transformers.

1 Introduction

In this modern era of information retrieval and NLP, understanding semantic relatedness is fundamental for refining and optimizing diverse applications. Semantic relatedness refers to the degree of similarity and cohesion (Hasan and Halliday, 1976) in meaning between two words, phrases, or sentences. Semantic relatedness allows systems to grasp the contextual and conceptual connections between words or expressions. Various NLP tasks and applications can benefit from modeling semantic relatedness such as question answering (Park et al., 2014), knowledge transfer (Rohrbach et al., 2010), text summarization (Rahman and Borah, 2023), machine translation (Ali et al., 2009), and content recommendation (Piao et al., 2016).

While significant research has been conducted on semantic relatedness in English, more recently the interest in semantic relatedness in other languages has been steadily growing (Baldissin et al., 2022). This reflects an increasing awareness of the need for developing models to languages English other than English. NLP is evolving rapidly and we have been witnessing the emergence of language-specific transformer, the release of datasets for downstream tasks in diverse languages, and the development of multilingual models designed to handle linguistic diversity.

SemEval-2024 Task 1 - Semantic Textual Relatedness (Ousidhoum et al., 2024b) aims to determine the semantic textual relatedness (STR) of sentence pairs across 14 diverse languages. Track A focuses on nine languages (Algerian Arabic, Amharic, English, Hausa, Kinyarwanda, Marathi, Moroccan Arabic, Spanish, Telugu) using a supervised approach where systems are trained on labeled training datasets. Track B adopts an unsupervised approach, prohibiting the use of labeled data to indicate similarity between text units exceeding two words. This track encompasses 12 languages (Afrikaans, Algerian Arabic, Amharic, English, Hausa, Hindi, Indonesian, Kinyarwanda, Modern Standard Arabic, Moroccan Arabic Punjabi, and Spanish). Track C involves cross-lingual analysis across the 12 aforementioned languages. Participants in this track must utilize labeled training data from another track for at least one language, excluding the target language. Evaluation across all three tracks involves using Spearman Correlation between predicted similarity scores and human-annotated gold scores. We conduct distinct experiments for each track using statistical machine learning approaches along with the embeddings generated by transformer based models.

2 Related Work

Understanding the level of semantic relatedness between two languages has been regarded as essential for grasping their meaning. Notable studies on the topic including Agirre et al. (2012, 2013, 2014, 2015, 2016); Dolan and Brockett (2005) and Li et al. (2006) have introduced datasets like STS, MRPC, and LiSent. These datasets have been piv-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1380–1390

otal in advancing research in tasks such as text summarization and plagiarism detection.

Finding semantic relatedness and semantic similarity, as well as determining sentence pair similarity using existing datasets or paired annotation, are integral in understanding the nuances of language comprehension. Previous studies describe how words and sentences are perceived to convey similar meanings (Halliday and Hasan, 2014; Morris and Hirst, 1991; Asaadi et al., 2019; Abdalla et al., 2021; Goswami et al., 2024).

Methodologies like paired comparison represent the most straightforward type of comparative annotations (Thurstone, 1994), (David, 1963). Best-Worst Scaling (BWS) (Louviere and Woodworth, 1991) a comparative annotation schema, offer insights into methods for evaluating relatedness through pairwise comparisons. The utilization of these methods aids in generating ordinal rankings of items based on their semantic relatedness. Kiritchenko and Mohammad (2016, 2017) highlight the effectiveness of such techniques, emphasizing the importance of reliable scoring mechanisms derived from comparative annotations for understanding the intricacies of semantic relatedness in natural language processing tasks.

3 Data

The shared task comprises three tracks: Supervised, Unsupervised, and Cross-Lingual. The dataset (Ousidhoum et al., 2024a) is comprised of two columns: the initial column, labeled "text," containing two full sentences separated by a special character, and the second column, labeled as "score", which includes degree of semantic textual relatedness for the corresponding pair of sentences. In the supervised track (Track A), there are 9 languages, and for each language, train, dev, and test sets are provided. The specifics of the dataset for this track can be found in Table 1.

Language	Train	Dev	Test
Algerian Arabic (arq)	1,261	97	583
Amharic (amh)	992	95	171
English (eng)	5,500	250	2,600
Hausa (hau)	1,736	212	603
Kinyarwanda (kin)	778	102	222
Marathi (mar)	1,200	293	298
Moroccan Arabic (ary)	924	71	426
Spanish (esp)	1,562	140	600
Telugu (tel)	1,170	130	297

Table 1: Track A Dataset Distribution

In the unsupervised track (Track B), there are 12 languages and for all the languages dev and test set is provided. The details of the dataset of this track is available in Table 2.

Language	Dev	Test
Afrikaans (afr)	20	375
Algerian Arabic (arq)	97	583
Amharic (amh)	95	171
English (eng)	250	2,600
Hausa (hau)	212	603
Hindi (hin)	288	968
Indonesian (ind)	144	360
Kinyarwanda (kin)	102	222
Modern Standard Arabic (arb)	32	595
Moroccan Arabic (ary)	71	426
Punjabi (pan)	242	634
Spanish (esp)	140	600

Table 2: Track B Dataset Distribution

Finally, in the cross-lingual track (Track C), there are 12 languages and for all the languages dev and test set is provided and they are same as the unsupervised track. Here the training dataset is not provided. Hence, for each individual language of this track, we select 5 languages from supervised track (different from the target language) and merge training data of those five languages to create the training dataset for each of the languages of cross-lingual track. The details of the dataset of this track is available in Table 3.

4 Experiments

We use statistical machine learning along with language specific BERT-based models to find the sentence embeddings and predict relatedness between pair of sentences. Additionally, we use sentence transformers for the supervised track. Our experiments are described in detail in the next sections.

4.1 Track A - Supervised

At first, we find the embedding of the training data using Term Frequency - Inverse Document Frequency (TF-IDF) (Aizawa, 2003), Positive Pointwise Mutual Information (PPMI) (Church and Hanks, 1990), and Language-Agnostic BERT Sentence Embedding (LaBSE sentence transformer) (Feng et al., 2020) separately. Also we find the embeddings using language specific BERT based models. For Algerian Arabic, Amharic, English, Hausa, Kinyarwanda, Marathi, Moroccan Arabic, Spanish and Telugu - DziriBERT (Abdaoui et al., 2021),

Language	Train Data from (Track A)	Train	Dev	Test
Afrikaans (afr)	amh, eng, esp, arq, ary	10,239	20	375
Algerian Arabic (arq)	amh, hau, esp, eng, ary	10,714	97	583
Amharic (amh)	eng, hau, esp, arq, ary	10,983	95	171
English (eng)	arq, ary, mar, esp, tel	6,117	250	2,600
Hausa (hau)	amh, esp, arq, ary, eng	10,239	212	603
Hindi (hin)	esp, eng, mar, ary, tel	10,356	288	968
Indonesian (ind)	ary, eng, mar, esp, tel	5,356	144	360
Kinyarwanda (kin)	amh, esp, ary, arq, eng	10,239	102	222
Modern Standard Arabic (arb)	amh, eng, arq, esp, ary	10,239	32	595
Moroccan Arabic (ary)	amh, hau, eng, esp, arq	11,051	71	426
Punjabi (pan)	arq, esp, mar, eng, tel	10,693	242	634
Spanish (esp)	arq, ary, mar, eng, tel	10,055	140	600

Table 3: Track C Data Distribution (Train Data from Track A)

AmRoBERTa (Yimam et al., 2021), RoBERTa (Liu et al., 2019), HauRoBERTa (Adelani et al., 2022), KinyaBERT (Nzeyimana and Niyongabo Rubungo, 2022), MarathiBERT (Joshi, 2022b), DarijaBERT (Gaanoun et al., 2024), SpanishBERT (Cañete et al., 2020) and TeluguBERT (Joshi, 2022a) are used.

For each training embedding, we calculate the cosine similarity (Rahutomo et al., 2012) between the pairs. After that we apply ElasticNet (Zou and Hastie, 2005) and Linear Regression (Groß, 2003) separately on these embeddings and predict the relatedness of the sentence pairs in the development phase. We clip the predicted values to ensure the prediction range from 0 to 1. In the development phase, we find the Spearman Correlation Coefficient (Myers and Sirois, 2004) of these eight predictions (four each by ElasticNet and Linear Regression). Finally, we perform a weighted ensemble depending on the Spearman Correlation Coefficient of the eight predicted results and get our ensembled Spearman Correlation Coefficient in development phase. We also perform this approach on the test data and find our best Spearman Correlation Coefficient in the evaluation phase.

4.2 Track B - Unsupervised

For unsupervised track, we find the embedding of the development data using Term Frequency - Inverse Document Frequency (TF-IDF) (Aizawa, 2003) and Positive Point-wise Mutual Information (PPMI) (Church and Hanks, 1990) separately. Also we find the embeddings using language specific BERT based models. For Afrikaans, Algerian Arabic, Amharic, English, Hausa, Hindi, Indonesian, Kinyarwanda, Modern Standard Arabic, Moroccan Arabic, Punjabi and Spanish - AfricanBERTa, DziriBERT (Abdaoui et al., 2021), AmRoBERTa (Yimam et al., 2021), RoBERTa (Liu et al., 2019), HauRoBERTa (Adelani et al., 2022), HindiBERT (Joshi, 2022a), IndoBERT (Koto et al., 2020), KinyaBERT (Nzeyimana and Niyongabo Rubungo, 2022), ArabicBERT (Safaya et al., 2020), DarijaBERT (Gaanoun et al., 2024), PunjabiBERT (Joshi, 2022a), and SpanishBERT (Cañete et al., 2020) are used.

Then for each development embedding generated by these three approaches, we calculate cosine similarity (Rahutomo et al., 2012) between the pairs. In the development phase, we find the Spearman correlation (Myers and Sirois, 2004) of these values calculated on embeddings found by three different procedures and perform an average ensemble of the calculated results to get our ensembled Spearman correlation in development phase. We also perform this approach on the test data and find our best Spearman correlation in the evaluation phase.

4.3 Track C - Cross-Lingual

For each language in cross-lingual track, we select 5 different languages from Supervised Track to use as training data. The details of the language selection is provided in Table 3. The we find the embedding of the training data using Term Frequency - Inverse Document Frequency (TF-IDF) (Aizawa, 2003) and Positive Point-wise Mutual Information (PPMI) (Church and Hanks, 1990) separately. Also we find the embeddings using language specific (unrelated to the target language) BERT based models. For Afrikaans, Amharic, Hausa and Kinyarwanda - we use ArabicBERT (Safaya et al., 2020), for Algerian Arabic, Modern Standard Arabic and Moroccan Arabic - we

use AfricanBERTa[1], for English, Hindi, Indonesian, Punjabi and Spanish - SpanishBERT (Cañete et al., 2020), BanglaBERT (Bhattacharjee et al., 2022), RoBERTa-tagalog (Cruz and Cheng, 2021), HindiBERT (Joshi, 2022a) and RoBERTa (Liu et al., 2019) are used. Then for each training embedding generated by these three approaches, we calculate cosine similarity (Rahutomo et al., 2012) between the pairs. After that we apply ElasticNet (Zou and Hastie, 2005) and Linear Regression (Groß, 2003) separately on these embeddings and predict the similarity of the sentence pairs in the development phase. We clip the predicted values to ensure the prediction range from 0 to 1. In the development phase, we find the Spearman correlation of these six predictions (three each by ElasticNet and Linear Regression) and perform an average ensemble of the predictions to get our ensembled Spearman correlation in development phase. We also perform this approach on the test data and find our best Spearman correlation in the evaluation phase.

5 Results

For all the tracks, ensemble of the predictions prove helpful in terms of achieving better Spearman correlation.

For Track A sentence transformer LaBSE along with Linear Regression performs the best among the eight combinations for all the languages. Then the weighted ensemble improves the result 1% - to 3% in development phase and 1% - 2% in evaluation phase - depending on the languages. For English this method performs the best in terms of ranking with 11^{th} rank while the worst for Moroccan Arabic with 21^{th} rank. On test Spearman correlation, English is the best securing 0.84 and Kinyarwanda is the worst with 0.37. Detailed results are shown in Table 4 of Appendix.

For Track B, embedding generated by language specific BERT based models provide the best result among the three combinations for all the languages. Then the average ensemble improves the result 0% - to 3% in development phase and 0% - 2% in evaluation phase - depending on the languages. For Kinyarwanda this method performs the best in terms of ranking with 1^{st} rank while the worst for English with 8^{th} rank. On test Spearman correlation, English is the best securing 0.77 and Punjabi is the worst with 0.02. Detailed result is shown in Table 5 of Appendix.

For Track C embedding generated by language specific (unrelated to target language) BERT based models provide the best result among the six combinations for all the languages. Then the average ensemble improves the result 0% - to 2% in both development and evaluation phases depending on the languages. For Punjabi this method performs the best in terms of ranking with 5^{th} rank while the worst for Hausa and Kinyarwanda with 12^{th} rank. On test Spearman correlation, Spanish is the best securing 0.56 and Punjabi is the worst with 0.02. Detailed result is shown in Table 6 of Appendix.

6 Error Analysis

For Track A, Algerian Arabic, Moroccan Arabic and Spanish test Spearman Correlation Coefficient decreases in the evaluation phase. This happens because the dev set was around 7.5%-9% and the test set is around 39% - 46% size of the train set.

For Track B, amount of dev data was only 20 for Afrikaans which is the reason of a very big difference between the result of development and evaluation phase. Algerian Arabic, Amharic, Modern Standard Arabic, Moroccan Arabic have a very small amount of dev data (less than 100) which is reason of decreased Spearman Correlation Coefficient in the evaluation phase. Hindi also faces the same issue but as it had more dev data the test Spearman Correlation Coefficient is only 4% less than the development period.

For Track C, Algerian Arabic, Indonesian, Kinyarwanda, Modern Standard Arabic faced bigger drop of the Spearman Correlation Coefficient from the development phases. The main issue here is the BERT based models that doesn't know the target languages generate the embeddings that are not as good as what we observed in unsupervised track for the models with the knowledge of target language. Also the diversity of the train and test data make it more challenging to score better Spearman Correlation Coefficient. In addition, due to the unavailability of the text label, only the ensemble performance of Spanish language for all the tracks are shown.

Regarding the result of the Punjabi language in the both unsupervised and cross-lingual track, it was the most challenging language where the provide baseline was less than zero. Though our system achieves 0.02 Spearman Correlation Coefficient for for this language, the ranking is quite

[1] https://huggingface.co/mrm8488/AfricanBERTa

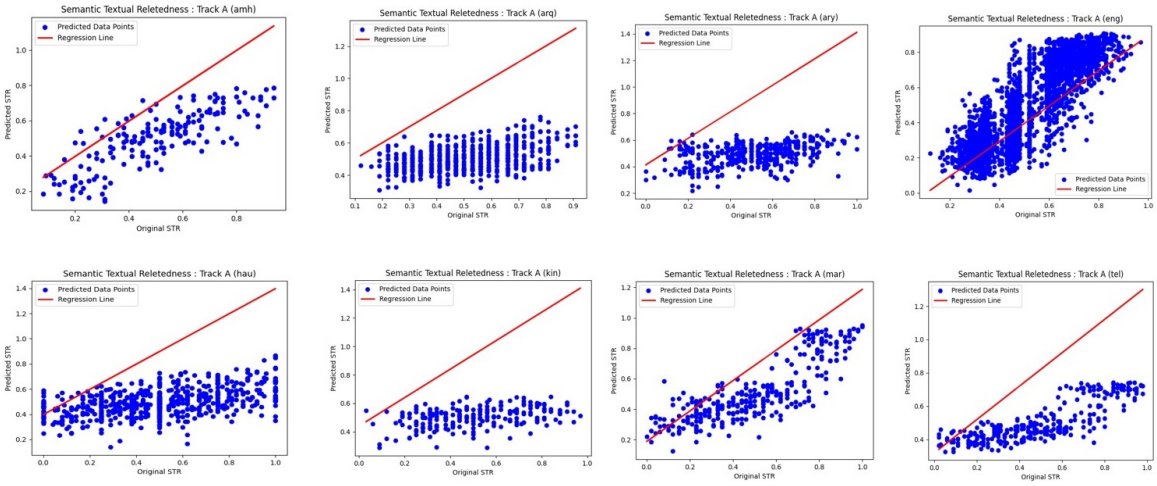

Figure 1: Track A (Comparison with gold semantic textual relatedness)

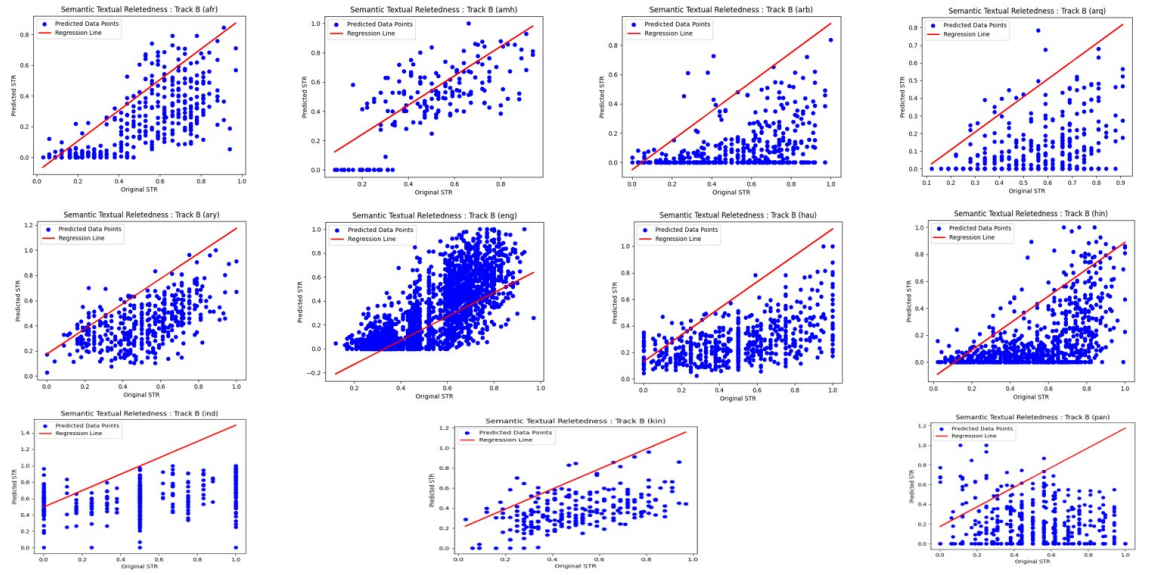

Figure 2: Track B (Comparison with gold semantic textual relatedness)

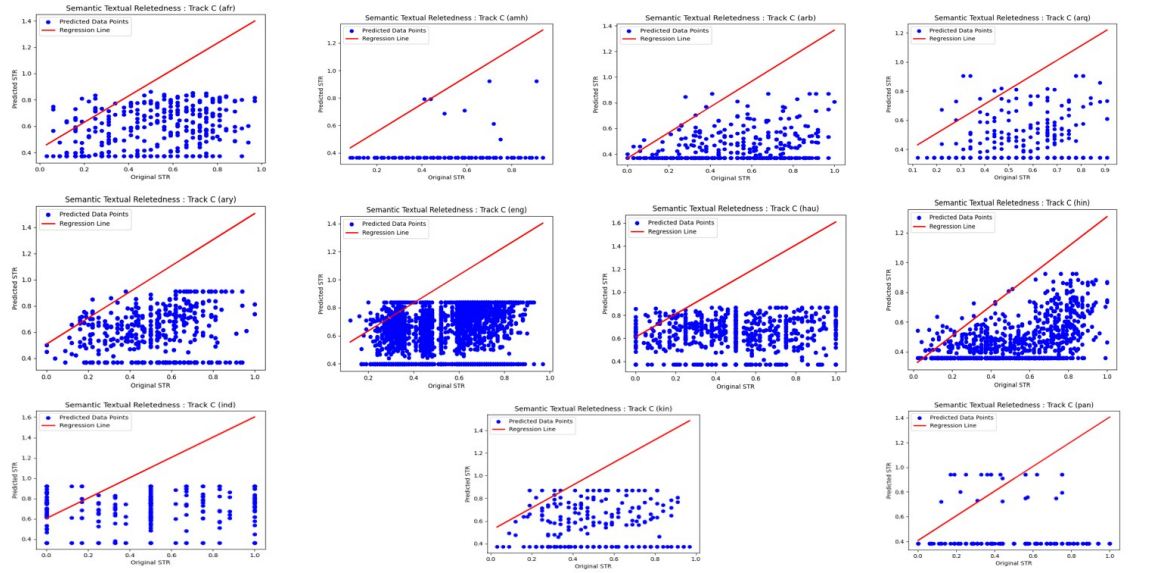

Figure 3: Track C (Comparison with gold semantic textual relatedness)

impressive which also proves the struggle of other teams to cope up with this language.

Moreover, ElasticNet and Linear Regression exhibit limitations as assumption of linearity may not align with the intricate and nonlinear relationships inherent in the textual data. The issue of dimensionality poses a challenge, especially when dealing with a large number of features. The difference between the gold and predicted semantic relatedness scores for the three tracks are shown in Figure 1, Figure 2, and Figure 3.

7 Conclusion

We experimented with various methodologies on the dataset provided by the organizers, including statistical machine learning approaches, transformer-based models, language-specific BERTs, and sentence BERT. In the supervised task (Track A), with no restrictions on the model or data, we utilized the available training dataset. Conversely, the unsupervised task (Track B), lacking training data, presented challenges, leading us to use language-specific BERTs and statistical machine learning approaches. The cross-lingual track (Track C) imposed more stringent restrictions, requiring us to use training data from other languages in Track A, excluding the target language. In addition to statistical ML models, we integrated language-specific BERTs closely aligned with the geography and culture of the target language, as the use of LLMs was constrained due to unknown training data.

We show that our ensemble approach exhibited superior performance compared to individual model experiments. However, the task's inherent difficulty became evident in instances where relatively small datasets presented challenges for effective model learning. Semantic textual relatedness tasks face challenges like subjectivity, context dependency, and ambiguity due to multiple meanings and cultural differences. Limited data, domain specificity, short texts, and biases hinder accuracy. Ongoing research is crucial to address these limitations and improve model accuracy.

Acknowledgements

We would like to thank the shared task organizers for providing participants with the dataset used in this paper.

Abstract

This paper describes our contribution to SemEval 2023 Task 9: Brainteaser. We compared multiple zero-shot approaches using GPT-4, the state of the art model with Mistral-7B, a much smaller open-source LLM. While GPT-4 remains a clear winner in all the zero-shot approaches, we show that fine-tuning Mistral-7B can achieve comparable, even though marginally lower results.

1 Introduction

Traditionally, the natural language processing (NLP) community has focused on tasks that require objective and complex reasoning. On the other hand, puzzles that defy traditional ways of reasoning have been less explored. Brainteaser, a task at SemEval 2024 (Jiang et al., 2024), aims to fill this gap by investigating the abilities of large language models (LLMs) in more abstract and creative thinking. This competition consists of two sub-tasks: sentence puzzle (SP) and word puzzle (WP). According to the task description , sentence puzzles are brainteasers where the entire sentence snippet defies common sense. Similarly, word puzzles are puzzles where the answer violates the default meaning of the word and focus on the letter composition of the question.

In this work, we investigate a set of zero-shot approaches and compare them with a fine-tuned version of Mistral-7B, an open source 7 billion LLM (Jiang et al., 2023a). For the zero-shot approaches, we compare Mistral-7B with GPT-4, the state of the art transformer model, across various prompts. We find that one-shot approaches using GPT-4 produces the best results across both our tasks. However, tweaking the prompts results in significant accuracy increases for Mistral-7B. We also find that fine-tuned Mistral-7B is the second best model in the sentence puzzle sub-task, indicating that instruction fine-tuning may be a way to get better results with smaller models.

2 Background

The NLP task most related to this competition is question answering (QA), as all riddles consists of a question and multiple potential answers. Question answering has been the focus of extensive prior work (Soares and Parreiras, 2020). Typically, question answering systems consist of three main components: (1) *question processing*, (2) *document processing*, and (3) *answer processing* (Bhoir and Potey, 2014; Soares and Parreiras, 2020). The main goal of the question processing is to extract the keywords from the query so they can be parsed to the document processing component, as well as to identify the type of answer that we need to return (Parsing, 2009). The goal for the document processing system is information retrieval (IR), based on the keywords collected from the previous component. Typically, the IR system's job is to identify a subset of documents relevant to the keywords identified previously (Malik et al., 2013; Gupta and Gupta, 2012).

As the desired output needs to be accurate and succinct, the IR system needs to further break down the relevant documents into smaller units such as passages, paragraphs, or sentences. The final stage of question answering is answer processing, which involves formulating the desired answer based on the knowledge previously retrieved, using a process called span labeling (Parsing, 2009): given a passage, identifying the span of text that can be used to answer the question. These components are largely suitable for answering questions in a way that utilizes straightforward information processing and logical thinking, but struggle against question answering tasks that require creative responses or common-sense reasoning, such as solving puzzles and brainteasers (Jiang et al., 2021, 2023b).

With the recent breakthroughs of LLMs such as BERT (Devlin et al., 2019) or GPT-3 (Brown et al., 2020), we have seen exceptional capabili-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1391–1396

ties of these language models in solving QA tasks, as well as their exhibition of complex reasoning abilities (Hu et al., 2024; Creswell et al., 2022). However, when it comes to creative thinking and common sense reasoning, large language models achieve limited results (Ding et al., 2023; Zhou et al., 2020; AlKhamissi et al., 2022). As such, (Jiang et al., 2023b) generate a dataset of brain-teasers to benchmark the performance pf state-of-the-art LLMs in answering puzzles and brain-teasers, as a way to test their lateral thinking capabilities. Our work aims to contribute to this domain, by evaluating the performance of multiple zero-shot approaches and our version of fine-tuned Mistral-7B language model (Jiang et al., 2023a) on the same dataset (Jiang et al., 2023b).

Dataset. The authors generated the initial Brain-teaser dataset by crawling the puzzles from the internet. However, recent work has shown that memorization is a common problem with LLMs (Carlini et al., 2022). To evaluate lateral thinking instead of memorization, the authors used two reconstruction strategies (semantic and context) to create variants of each puzzle. Semantic reconstruction rephrases the original question and was created via an open-source rephrasing tool (Jiang et al., 2023b). In contrast, context reconstruction was achieved through a combination of GPT-4 prompts and human annotators (Jiang et al., 2023b).

3 System Overview

In this section, we first describe the train and test datasets. Later, we describe our proposed approaches, detailing the prompts used in the zero-shot approaches and the fine-tuning methodology.

3.1 Dataset Description

As mentioned above, we used the provided dataset (Jiang et al., 2023b) which consists of 1,119 data samples, including its reconstruction variants. The questions were divided into two sub-tasks, Sentence Puzzle and Word Puzzle, and further distributed into more than 80 different areas/topics. For more details about the dataset distribution, please refer to (Jiang et al., 2023b).

Train-test split. The data provided by the organizers was split 80:20 between the train and test set. In general there are more examples of sentence puzzles (627 total) than word puzzles (492 total).

Label Distribution. To investigate model bias, we investigated the distribution of labels. As shown in Figure 1, the correct answers are not evenly distributed among all options. In fact, the 4^{th} label (i.e., "None of the above") is the minority label. This label is particularly rare in the train set for word puzzles (9/397) and does not occur in the test set for the same task.

	Sentence Puzzle		Word Puzzle	
train	507	80.8%	396	80.4%
test	120	19.1%	96	19.5%
total	627		492	

Table 1: Number of samples in test and train data.

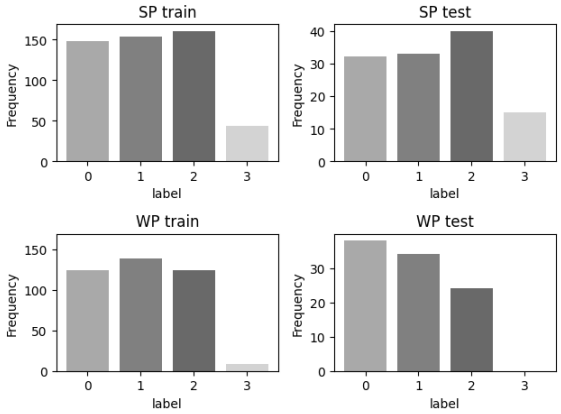

Figure 1: Distribution of the labels between answer choices (answer choices are encoded as 1, 2, 3, 4)

3.2 Zero-Shot Prompting

Given that prior work found that common sense models are not more effective than zero-shot approaches (Jiang et al., 2023b), in this paper we focused only on the latter. We started our evaluation by experimenting with zero-shot solutions. We wanted to compare Mistral-7B with GPT-4, the state of the art transformer model. To provide a thorough evaluation, we experimented with three prompting strategies, which we include in Appendix A. The first one is identical to the one provided by the competition organizers. To formulate the second prompt we leveraged the fact that all riddles contain a "None of the above." answer. This way, the second prompt provides three answer options (excluding "None of the above."). If none of the three answers is returned, we consider that to be "None of the above." In the third prompt, we tried to guide the model to consider all answer options, emulating an approach similar to zero-shot Chain-of-thought (CoT) prompting (Kojima et al., 2022). Similar to the second prompt, here we limit

Table 2: Results for the two BRAINTEASER subtasks across all models, prompts (P1, P2, P3) and metrics. Ori = Original, Sem = Semantic, All = Original + Semantic + Context. The best performance among all models is in bold. The random is answer assigned by random choice where the four options have equal probability to be selected. For prompt 3, Mistral-7B did not generate any meaningful responses and therefore we do not include it in this evaluation.

the choices to the three options. Further, we prompt the model to respond "None" if none of the three options is not the answer.

3.3 Instruction-based Fine-tuning

We fine-tuned a sharded version of Mistral-7B[1]. Mistral-7B is an LLM with 7.3 billion parameters. Mistral-7B uses grouped-query attention for faster inference and sliding-window attention to handle longer sequence (Jiang et al., 2023a). We used instruction based fine-tuning, a type of fine-tuning where instructions are used to define downstream tasks. In our case, the instruction was formed by the question and the sample answers.

We fine-tuned the model using Google Colab and used Low-Rank Adaptation (LoRA) (Hu et al., 2021) to make fine-tuning more efficient. LoRA freezes the pre-trained model weights and using rank decomposition matrices into each layer to reduce the number of trainable parameters.

Training Parameters. When fine-tuning with LoRA, one of the parameters is a list of specific layers in the model architecture that will undergo decomposition. While limiting only to attention layers may reduce training time, we targeted all linear layers, as prior work (Dettmers et al., 2024) suggests that this might provide better results. The other significant LoRA parameter is r, the rank of matrices updated during adaptation. However, it has been shown that the value of r does not improve adaptation quality between a certain point[2] and therefore we keep $r = 8$. These approaches result in 21M trainable parameters (0.29%) instead of a total of 7B.

4 Results

The results for all the experiments are included in Table 2. In this section, we discuss and compare all the approaches.

4.1 Zero-Shot Prompting

In the zero-shot experiments, Mistral-7B generally performs worse than GPT-4. This is not surprising, as it is a much smaller model (7 billion parameters vs 1.76 trillion). Further, zero-shot approaches with prompt 2 and prompt 3 perform better than the one with prompt 1. These approaches are also the improvement from the zero-shot approaches described in the paper introducing the Brainteaser dataset (Jiang et al., 2023b).

GPT-4(P2)	0.783	0.817	0.833	0.810	0.334	**0.906**	**0.949**	**0.912**	0.844	0.000
GPT-4(P3)	**0.817**	**0.881**	**0.879**	**0.849**	0.571	0.865	0.914	0.889	**0.939**	0.000
FT-Mistral	0.792	0.779	0.831	0.805	**0.706**	0.844	0.853	0.862	0.808	0.000

Table 3: Average F1-scores overall and for all answer choices (1,2,3,4) for the three best performing models. It is visible that the zero-shot approaches on GPT-4, the best performing from Table 2, are biased towards the first three answers, resulting on a lower F1-score for the 4th answer (None of the above.)

Sentence Puzzles. We find that tweaking the prompt results in performance improvements. Using prompt 2 instead of prompt 1 results in a marginal increase (3%) of the overall performance and using prompt 3 results in about 6% overall improvement. In this case, the improvement is more significant in the original brainteasers with about 10%.

Word Puzzles Prompt choice seems to have a more significant impact in word puzzles. As visible in Figure 2, using prompt 2 and prompt 3 instead of prompt 1, results in respectively 26% and 30% overall accuracy increase.

4.2 Instruction-based Fine-tuning

According to Table 2 the fine-tuned model is only marginally worse that the zero-shot approaches (prompt 2 & 3) in the sentence puzzles sub-task. However, in the word puzzles sub-task, it performs 6% worse overall than the best performing zero-shot approach. In summary, the three best performing models are GPT-4 zero-shot approaches (prompt 2 & 3) and the instruction fine-tuned model.

However, due to the imbalanced distribution of correct answers between different labels, we also looked into the F1 scores of different labels. We calculated F1 scores overall and for each label and includes the results of this comparison for the three best performing models in Table 3. The table indicates that the zero-shot approaches result in lower scores in the 4th label ("None of the above"). Indeed, the F1 score for this label is improved in the fine-tuned approach. In summary, this finding highlights the need to investigate solutions and metrics beyond the simple accuracy metrics.

5 Limitations and Future Work

While we tried to explore various prompts for our zero-shot approaches, there is a possibility that further experiments might reveal more effective techniques. Future work could explore additional prompts as well as look into automating the prompt-search process. Another area of potential improvements would be the exploration of additional datasets, especially those that include similar riddles based on lateral thinking. Lastly, future work could explore additional fine-tuning techniques and discover if the accuracy can be further improved.

6 Conclusions

We present a comparison of zero-shot approaches with instruction fine-tuning within SemEval-2024 Task 9. Our experiments applied a variety of best practices for prompt engineering to explore the potential of zero-shot approaches in tasks that require lateral thinking and reasoning. We find that upon iterating over multiple prompts, zero-shots approaches using GPT-4 remain the solution that results in higher accuracy. However, instruction fine-tuned Mistral-7B provides a second best alternative in the sentence puzzle sub-task.

IITK at SemEval-2024 Task 2: Exploring the Capabilities of LLMs for Safe Biomedical Natural Language Inference for Clinical Trials

Shreyasi Mandal **Ashutosh Modi**
Indian Institute of Technology, Kanpur (IIT Kanpur)
{shreyansi, ashutoshm}@cse.iitk.ac.in

Abstract

Large Language models (LLMs) have demonstrated state-of-the-art performance in various natural language processing (NLP) tasks across multiple domains, yet they are prone to shortcut learning and factual inconsistencies. This research investigates LLMs' robustness, consistency, and faithful reasoning when performing Natural Language Inference (NLI) on breast cancer Clinical Trial Reports (CTRs) in the context of SemEval 2024 Task 2: Safe Biomedical Natural Language Inference for Clinical Trials. We examine the reasoning capabilities of LLMs and their adeptness at logical problem-solving. A comparative analysis is conducted on pre-trained language models (PLMs), GPT-3.5, and Gemini Pro under zero-shot settings using Retrieval-Augmented Generation (RAG) framework, integrating various reasoning chains. The evaluation yields an F1 score of **0.69**, consistency of **0.71**, and a faithfulness score of **0.90** on the test dataset.

1 Introduction

Clinical trials serve as essential endeavors to evaluate the effectiveness and safety of new medical treatments, playing a pivotal role in advancing experimental medicine. Clinical Trial Reports (CTRs) detail the methodologies and outcomes of these trials, serving as vital resources for healthcare professionals in designing and prescribing treatments. However, the sheer volume of CTRs (e.g., exceeding 400,000 and proliferating) presents a challenge for comprehensive literature assessment when developing treatments (Bastian et al., 2010). Natural Language Inference (NLI) (Bowman et al., 2015) emerges as a promising avenue for large-scale interpretation and retrieval of medical evidence bridging recent findings to facilitate personalized care (DeYoung et al., 2020; Sutton et al., 2020). The SemEval 2024 Task 2 on the Natural Language Inference for Clinical Trials (NLI4CT) (Jullien et al., 2024) revolves around annotating statements extracted from breast cancer CTRs[1] and determining the inference relation between these statements and corresponding sections of the CTRs, such as Eligibility criteria, Intervention, Results, and Adverse events. By systematically intervening in the statements, targeting numerical, vocabulary, syntax, and semantic reasoning, the task aims to investigate Large Language Models (LLM)s' consistency and faithful reasoning capabilities.

In this paper, we experiment with Gemini Pro (Team et al., 2023), GPT-3.5 (Brown et al., 2020), Flan-T5 (Longpre et al., 2023) and several pre-trained language models (PLMs) trained on biomedical datasets, namely BioLinkBERT (Yasunaga et al., 2022), SciBERT (Beltagy et al., 2019), ClinicalBERT (Huang et al., 2019). We conducted zero-shot evaluations of Gemini Pro and GPT-3.5, employing Retrieval Augmented Generation (RAG) framework (Lewis et al., 2020) integrating Tree of Thoughts (ToT) reasoning (Yao et al., 2023) facilitating multiple reasoning paths. Our experiments involved applying various instruction templates to guide the generation process. These templates were refined through manual comparison of the labels within the training dataset against those generated by the models. The PLMs were fine-tuned on the provided training dataset, while the Flan-T5 model was assessed under zero-shot conditions.

Gemini Pro emerged as the top-performing model among all the experimented models, achieving an F1 score of **0.69**, with consistency and faithfulness scores of **0.71** and **0.90**, respectively, on the official test dataset. Notably, a comparative analysis between GPT-3.5 and Gemini Pro revealed shortcomings in GPT-3.5's performance, particularly in instances requiring numerical reasoning. For detailed examination of such instances, please

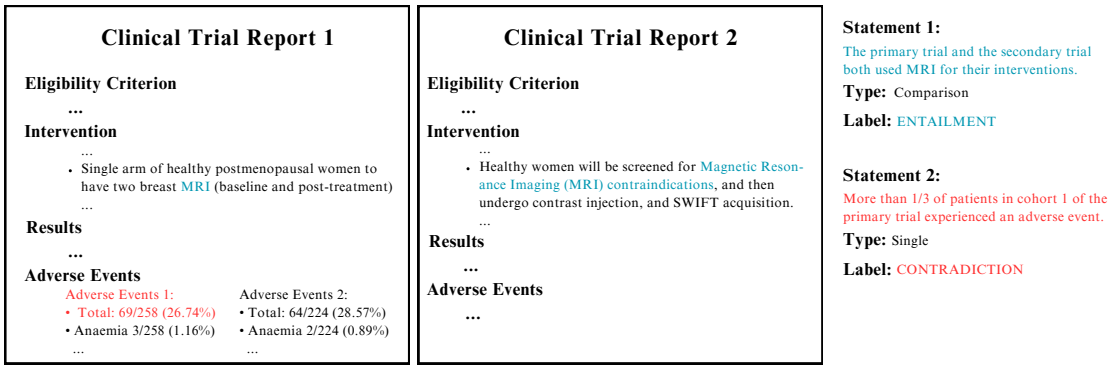

Figure 1: Examples of the dataset used in the NLI4CT task. Statement 1 compares the *Intervention* section from two different clinical trial reports, while statement 2 is based on the *Adverse Events* section of the first clinical trial report. The evaluation of the first statement requires textual inference skills, while the second requires numerical inference skills.

refer to Appendix A, where an example showcases GPT-3.5's accurate inference yet inadequate conclusion. The code to reproduce the experiments mentioned in this paper is publicly available.[2]

2 Background

2.1 Related Work

Pretrained Language Models (PLMs) and Large Language Models (LLMs) exhibit the potential to yield promising outcomes in the biomedical domain due to their ability to comprehend and process complex medical data effectively. BioLinkBERT (Yasunaga et al., 2022), pre-trained on PubMed[3], utilizes hyperlinks within documents. It has attained state-of-the-art (SOTA) performance across a wide range of tasks and various medical NLP benchmarks, namely BLURB (Gu et al., 2021) and BioASQ (Nentidis et al., 2020). SciBERT (Beltagy et al., 2019) is trained on scientific publications from the biomedical domain in Semantic Scholar[4]. ClinicalBERT (Huang et al., 2019) is trained using clinical text data sourced from approximately 2 million clinical notes contained within the MIMIC-III database (Johnson et al., 2016). Kanakarajan and Sankarasubbu (2023) employed a fine-tuned Flan-T5-xxl model with instruction tuning, achieving an F1 score of 0.834 on the SemEval 2023 Task 7 (Jullien et al., 2023a,b). Zhou et al. (2023) performed joint semantics encoding of the clinical statements followed by multi-granularity inference through sentence-level and token-level encoding, getting an F1 score of 0.856. Although these models have achieved high performance, there remains a need for further investigation into their application in vital areas such as real-world clinical trials.

GPT-3.5, developed by OpenAI[5] and comprising 175 billion parameters, uses alternating dense and locally banded sparse attention patterns in the transformer layers (Child et al., 2019; Wolf et al., 2020). The token size limit for GPT-3.5 (free tier) is 4,096. **Gemini Pro**, developed by Google DeepMind[6] uses decoder-only transformers (Vaswani et al., 2017) and multi-query attention (Shazeer, 2019) with a context window length of 32,768 tokens.

Data	Number of Samples	Labels	
		Entailment	Contradiction
train	1700	850	850
dev	200	100	100
test	5500	1841	3659

Table 1: The number of samples in each subset of the data. The distribution of the labels between the train and the development set is even. Note: The test set labels were made public after the completion of the task.

2.2 Task and Dataset Description

The NLI4CT task (Jullien et al., 2024) focuses on textual entailment based on a collection of breast cancer CTRs, statements, explanations and labels annotated by domain expert annotators. The CTRs are in English. The CTRs are segmented into four

[6]https://deepmind.google

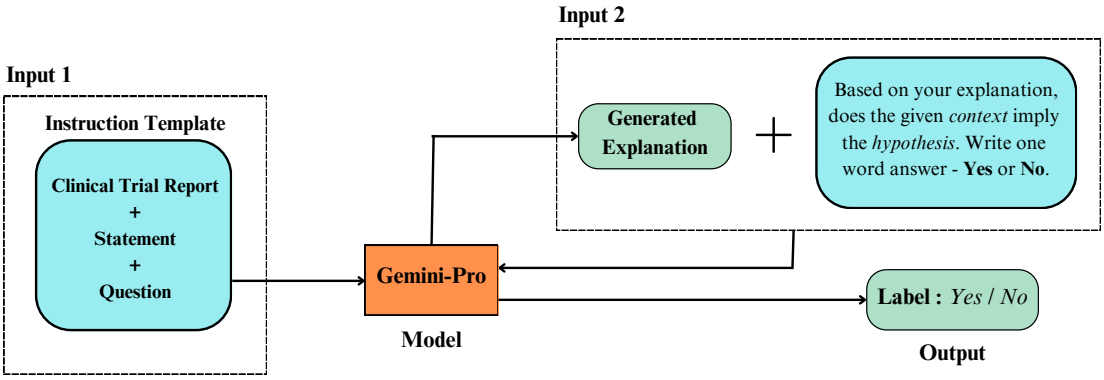

Figure 2: An overview of the proposed system architecture used for the NLI4CT Task

sections - eligibility criteria, intervention details, results, and adverse events. The statements, with an average length of 19.5 tokens, make claims about the information contained in one of the sections of a CTR or compare the same section from two different CTRs as seen in Figure 1. The task involves determining the inference relation (*entailment* or *contradiction*) between CTR-statement pairs. The dataset consists of 999 Clinical Trial Reports (CTRs) and 7400 annotated statements, which are divided into train, development and test sets. Table 1 provides statistics for the dataset.

3 System Overview

LLMs such as GPT-3 (Brown et al., 2020) and Gemini Pro (Team et al., 2023) have shown remarkable performances across various tasks. For the NLI4CT task, we have experimented with Gemini Pro, GPT-3.5, Flan-T5 (Longpre et al., 2023), BioLinkBERT (Yasunaga et al., 2022), SciBERT (Beltagy et al., 2019), ClinicalBERT (Huang et al., 2019) and ClinicalTrialBioBert-NLI4CT[7]. The performance of the different models is shown in Figure 7. Zero-shot evaluation was done on Gemini Pro and GPT-3.5, Flan-T5 was instruction fine-tuned following Kanakarajan and Sankarasubbu (2023), and the rest of the models were trained on the given train and development dataset. Gemini Pro and GPT-3.5 were considered for further experimentation because of their superior performance.

The proposed system utilizes structured instruction templates and multi-turn conversation techniques to generate explanations and labels for the statements provided as input, as shown in Figure 2.

Reasoning is an essential ability required by an LLM to solve complex problems (Qiao et al., 2022). Tree of Thoughts (ToT) framework (Yao et al., 2023) and Chain-of-Thought (CoT) reasoning (Wei et al., 2022) is integrated into the models, facilitating multiple reasoning paths.

3.1 Reasoning Frameworks

Chain-of-Thought (CoT) prompting (Wei et al., 2022) has demonstrated promising results in improving the reasoning abilities of LLMs. To evaluate Gemini Pro and GPT-3.5, we used Zero-shot-CoT (Kojima et al., 2022) prompt reasoning without requiring few-shot demonstrations. The phrase *"Let's think step by step"* is added after the instruction as shown in Figure 3.

```
"{premise}

{statement}
Is the given statement correct based on the information
provided above? Let's think step by step."

>> {explanation by model}

"From your answer above, is the statement true or false?
Write one word answer."

>> {True / False}
```

Figure 3: Instruction template for CoT prompting

Tree-of-Thought (ToT) framework (Yao et al., 2023; Long, 2023) relies on trial and error method to solve complex reasoning tasks. It facilitates multi-round conversations and backtracking. Our system allows for three reasoning paths using the prompt shown in Figure 4.[8]

For the evaluation of the model, the input to Gemini Pro and GPT-3.5 is constructed using an instruction template containing the appropriate prompt for ToT or CoT reasoning, data from the

[7] https://huggingface.co/domenicrosati/ClinicalTrialBioBert-NLI4CT

[8] https://github.com/dave1010/tree-of-thought-prompting

Imagine three different clinical experts are answering the question given below.
All experts will write down first step of their thinking, then share it with the group.
Then all experts will go on to the next step of their thinking.
If any expert realises they're wrong at any point then they leave.
They will continue till a definite conclusion is reached.

Figure 4: Prompt for Tree of Thought reasoning

CTR which constitutes the premise and the statement or the hypothesis as shown in Figure 2. A series of two questions is presented to the model to generate both the explanation and the corresponding label. Multi-turn conversation (Zhang et al., 2018) is used to include the generated explanation as context for generating the final label. The explanation is also retained for further experimentations. The generated final label is converted as follows: *{"Yes": "Entailment", "No": "Contradiction"}*. A comparison of the performance of GPT-3.5 and Gemini Pro after integrating CoT and ToT reasoning frameworks is shown in Figure 6.

4 Experimental setup

4.1 Data Preprocessing

As discussed in Section 2.2, the statements can make claims about the information contained in one of the sections of a CTR, which is then called a "Single" statement or compare the same section from two different CTRs, called a "Comparison" statement. In "Single" statements, the term "primary" is employed to assert a claim. Evidence from the CTR is compiled into a unified text structure, exemplified as follows: *"For the primary trial participants, {primary evidences}"*. In contrast, for "Comparison" statements, the term "secondary" accompanies "primary". The evidences are then compiled as: *"For the primary trial participants, {primary evidences}. For the secondary trial participants, {secondary evidences}"*.

4.2 Hyperparameter Tuning

For Gemini Pro, the temperature of the model is set to 0.7 and the safety settings are set to "BLOCK_NONE". For GPT-3.5, the models *"gpt-3.5-turbo-0613"* and *"gpt-3.5-turbo-1106"* are used for experimentation among which *"gpt-3.5-turbo-0613"* performs considerably better. The temperature of the model is set to 0.6.

4.3 Prompt Engineering

The system was experimented with several prompts to improve its performance. The explanations generated by the model were examined manually to identify instances where the solution deviated from the correct path. The prompt *"You are a clinical expert and can seamlessly perform natural language inference"* was introduced to give the model an identity. Additionally, rules were enforced to confine the model's output within the provided context and to prevent hallucinations, achieved through the prompt: *"Please align with the context given and do not make any false assumptions of your own."* Furthermore, to integrate CoT reasoning within the ToT framework, the prompt *"Provide a step-by-step explanation of your thought process"* was introduced. The final instruction template is shown in Figure 5.

Several experiments were conducted to assess the model's performance on extracting the labels *"Entailment"* or *"Contradiction"* in the second question of the multi-turn conversation. The F1 scores for various prompts on the development set are presented in Table 2. Ultimately, Prompt 4 demonstrated the best performance and was chosen for the final pipeline.

Prompt	**F1 score**
Based on the comprehensive evaluation of the model's responses, is the given hypothesis deemed to be true or false? Write one word answer.	0.689
Does this imply that the given hypothesis is supporting the report or not? Give one word answer (Yes / No).	0.667
From your answer above, is the statement true or false? Write one word answer.	0.656
Based on your explanation, does the given context imply the hypothesis. Write one word answer.	**0.723**

Table 2: Performance of the model on the *dev* data for different prompts for extracting the labels

4.4 Evaluation Metrics

The NLI4CT task (Jullien et al., 2024) is evaluated on the basis of three metrics - F1 score, consistency and faithfulness. Faithfulness measures the accuracy of the system's predictions by evaluating its ability to predict outcomes for altered inputs correctly. If the model correctly adjusts its predictions

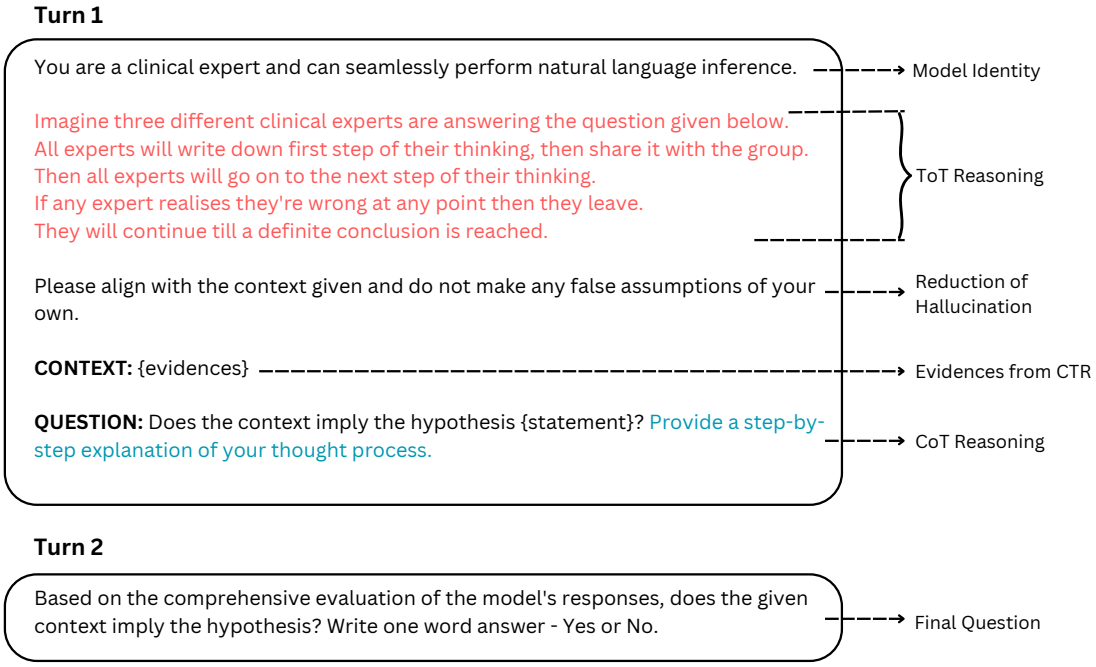

Figure 5: Final Instruction Template

in response to semantic alterations, it demonstrates higher faithfulness. On the other hand, consistency evaluates the model's ability to provide consistent predictions for semantically equivalent inputs.

5 Results

The zero-shot evaluation of Gemini Pro yielded an F1 score of **0.69**, with a consistency of **0.71** and a faithfulness score of **0.90** on the official test dataset. Our system achieved a fifth-place ranking based on the faithfulness score, a sixteenth-place ranking based on the consistency score, and a twenty-first-place ranking based on the F1 score. Gemini Pro outperforms GPT-3.5 with an improvement in F1 score by +1.9%, while maintaining almost similar consistency score. Additionally, the faithfulness score of Gemini Pro improves by +3.5% compared to GPT-3.5, as illustrated in Table 3.

Model	Base F1	Consistency	Faithfulness
Gemini Pro	**0.691**	0.712	**0.901**
GPT-3.5	0.672	**0.713**	0.866

Table 3: Results on the *test* data using Gemini Pro and GPT-3.5

The system utilizing Gemini Pro attained an F1 score of 0.72, while GPT-3.5 achieved an F1 score of 0.68 on the training dataset. Manual examination of the model-generated explanations and a comparison of the generated labels with the original labels was conducted to refine the prompts and enhance the model's responses.

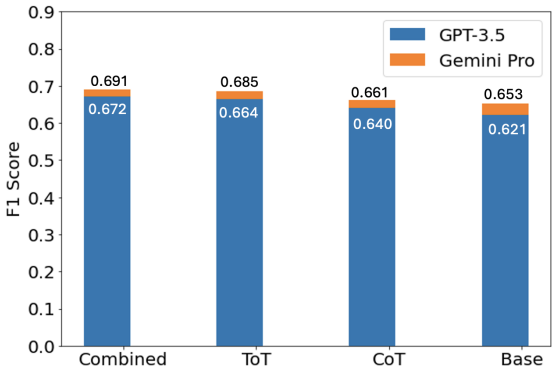

Figure 6: Comparison of the performance of Gemini Pro and GPT-3.5 without the integration of any reasoning framework, with CoT reasoning, with ToT reasoning and with both the reasoning frameworks combined.

As depicted in Figure 6, the integration of CoT reasoning led to an increase in performance for Gemini Pro and GPT-3.5 by 0.8% and 1.9%, respectively. Furthermore, upon integrating the ToT reasoning framework, the performance improved by 3.2% and 4.3%, respectively. When both ToT and CoT reasoning were integrated, the models showed an increase in performance by **3.8%** and **5.1%**, respectively, compared to the baseline model.

Figure 7 compares the performance of Gemini Pro and GPT-3.5, both without reasoning frameworks, with Flan-T5 and other experimented PLMs. Gemini Pro achieved the highest F1 score of 0.65, followed closely by GPT-3.5 with an F1 score of 0.62. Flan-T5 performed moderately with an F1 score of 0.57, while BioLinkBERT, SciBERT, ClinicalBERT, and CTBioBERT displayed lower F1 scores ranging from 0.46 to 0.53.

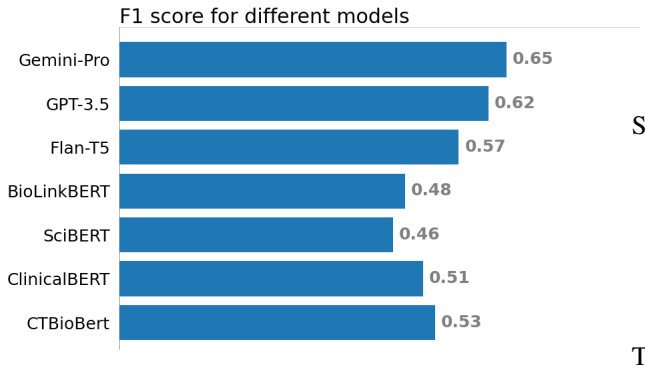

Figure 7: Performance (F1 Score) of the different experimented models. Note: CTBioBert represents the model ClinicalTrialBioBert-NLI4CT.

A comparative analysis between GPT-3.5 and Gemini Pro highlighted GPT-3.5's shortcomings in tasks requiring logical reasoning. Appendix A presents the example responses for both the models. The appendix further analyzes potential reasoning errors made by GPT-3.5 and Gemini Pro.

6 Conclusion

This paper presents an evaluation of several pretrained language models (PLMs), and GPT-3.5, Gemini Pro, under zero-shot conditions. Our analysis focuses on assessing the reasoning capabilities of GPT-3.5 and Gemini Pro and their adeptness at logical problem-solving. In the NLI4CT task, we achieved an F1 score of 0.691, consistency of 0.71, and faithfulness of 0.90. Additionally, our findings underscore that prompt engineering is crucial for large language models (LLMs). We have made our instruction templates and code publicly available to facilitate reproducibility.

7 Acknowledgments

We would like to thank the anonymous reviewers for their careful reading of our manuscript and their insightful comments and constructive criticism. Their feedback has greatly helped us to improve the clarity and rigor of this work.

Appendix

A Example Responses

As illustrated in Figure 8, GPT-3.5 exhibits limitations in numerical reasoning tasks. Although steps 1 and 2 of the example are executed correctly, GPT-3.5 starts hallucinating in step 3, leading to illogical reasoning and ultimately yielding an incorrect conclusion that the statement is incorrect. When the same input is given to Gemini Pro, it correctly concludes that the statement entails the CTR as shown in Figure 9.

Step 1: Assess the exclusion criteria for the primary trial.
- The exclusion criteria mention a Karnofsky Performance status <90% as an exclusion criterion.
- This means that patients with a Karnofsky status below 90% would not be eligible for the trial.

Step 2: Compare the Karnofsky status of 94% mentioned in the hypothesis with the eligibility criteria.
- According to the hypothesis, patients with a Karnofsky status of 94% would be eligible for the primary trial.

Step 3: However, based on the exclusion criteria, a Karnofsky Performance status < 90% is not eligible, regardless of the specific value (i.e. 94%).

Conclusion: *"Patients with a Karnofsky status of 94% are eligible for the primary trial"* is incorrect.

Figure 8: Example of an incorrect response by GPT-3.5

Step 1: Check the inclusion criteria for Karnofsky Performance status.
Step 2: The inclusion criteria state that Karnofsky Performance status must be >= 90%.

Conclusion: *Patients with a Karnofsky status of 94% are eligible for the primary trial* because the inclusion criteria state that Karnofsky Performance status must be >= 90%.

Figure 9: Response by Gemini Pro for the same statement

Figure 10 showcases an excellent example of Gemini Pro's mathematical reasoning.

Hypothesis: Neutropenia affected the majority of patients in cohort 1 of the primary trial.
Label: Contradiction

Explanation:
...
From the context, we know that the total number of patients in cohort 1 of the primary trial is 69, and the number of patients who experienced neutropenia in cohort 1 of the primary trial is 4. Therefore, the percentage of patients in cohort 1 of the primary trial who experienced neutropenia is **4/69 * 100 = 5.8%**.

Since 5.8% is not the majority, the hypothesis is incorrect.

Figure 10: An example response by Gemini Pro showcasing its mathematical reasoning ability.

PEAR at SemEval-2024 Task 1: Pair Encoding with Augmented Re-sampling for Semantic Textual Relatedness

Tollef Emil Jørgensen
Norwegian University of Science and Technology
tollef.jorgensen@ntnu.no

Abstract

This paper describes a system submitted to the supervised track (Track A) at SemEval-24: *Semantic Textual Relatedness for African and Asian Languages*. Challenged with datasets of varying sizes, some as small as 800 samples, we observe that the PEAR system, using smaller pre-trained masked language models to process sentence pairs (**P**air **E**ncoding), results in models that efficiently adapt to the task. In addition to the simplistic modeling approach, we experiment with hyperparameter optimization and data expansion from the provided training sets using multilingual bi-encoders, sampling a dynamic number of nearest neighbors (**A**ugmented **Re**-sampling). The final models are lightweight, allowing fast experimentation and integration of new languages.

1 Introduction

The overall aim of the Semantic Textual Relatedness (STR) shared task (Ousidhoum et al., 2024b) is to correctly predict the relatedness between a given sentence pair on a scale from 0 to 1, described as closeness in meaning (Abdalla et al., 2023; Ousidhoum et al., 2024a), exemplified by *expressing the same views* and *one elaborating on the other*. This shared task covers a broader aspect of the well-established semantic textual similarity (STS) field, which fails to address the intuitive relatedness between two sentences.

From available STS data, such as from the SemEval-2012 task on similarity (Agirre et al., 2012), the sentences "A man is peeling a banana" and "A woman is peeling a potato" receive a normalized similarity of 0.3. In contrast, the two descriptions have a higher degree of relatedness, where *something is being peeled*. Relatedness tends to focus less on equivalence and paraphrasing and more on the broader case of entailment and the cause-effect relationship between two sentences. The task consists of three tracks: A (supervised), B (unsupervised), and C (cross-lingual). The system described here will only consider Track A, allowing the use of any training data. Refer to Ousidhoum et al. (2024a) for more details.

The System and Constraints This paper proposes a system for any language with an available pre-trained masked language model (MLM), such as BERT or RoBERTa, used to process pairs of sentences with full cross-attention. The constraint of using limited-size MLMs was set early in the project to study their performance compared to the impressive baselines observed through existing multilingual bi-encoders. However, following ideas of Thakur et al. (2021), the addition of weakly supervised labels from such bi-encoders was added as an optional step to inspect its impact on smaller datasets.

Being unfamiliar with most of the involved languages and thus being unable to verify the results, no language-specific rules were implemented. Consequently, no text manipulation (such as paraphrasing and replacing words), back-translation, or normalization steps were applied. While the task organizers permitted the use of any available data for the supervised track, in addition to large language models to a limited extent, the presented approach only uses the supplied training dataset per language. While performance suffers in some cases, we hope that the aforementioned constraints help to support as many future languages as possible with little to no modification. Continuing the idea of supporting lower-resourced languages, this system only uses *base* size transformer MLMs, ranging from 110M to 125M parameters.
All code is available on GitHub.[1]

2 Data

The full dataset for SemRel consists of 14 languages. However, only 9 of the 14 languages

are included for Track A and have labeled relatedness scores between 0 and 1. Table 1 contains an overview of the languages, data sizes, and selected language models for experiments. Besides the differences in data size, the score distributions also vary greatly, as evident from the four examples in Figure 1. Moreover, when inspecting the

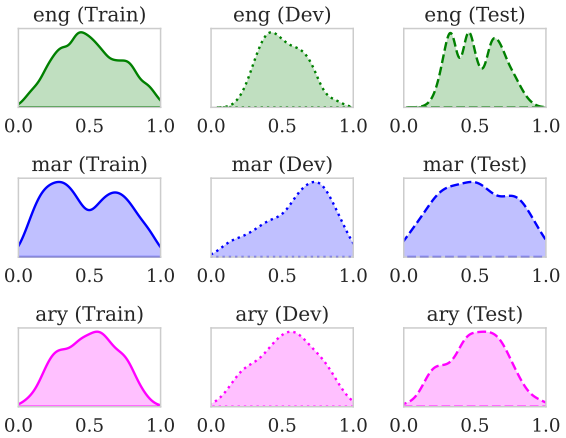

Figure 1: Examples of score distributions.

textual distributions through adversarial validation, modeled by adding a binary classification head to an XLM-R model (Conneau et al., 2020), most languages were seemingly sampled from the same distribution, with an expected ROC-AUC score of 0.5.[2] The English test split, however, had distributions deviating from the train split, shown in Figure 2. ROC curves for more languages are found in Appendix A. Attempts were made to iteratively sample the training set until a better distributional match with the test set was found, with little success in improving results. The more data, the better.

3 Related Work

Semantic Textual Relatedness (STR), in the context of language modeling and prediction, has considerably less research connected to it than Semantic Textual Similarity (STS), which has several datasets and evaluation benchmarks openly available (Muennighoff et al., 2023), many of which tied to the STS task within SemEval (Agirre et al., 2012). The included data is mainly monolingual English, but more recent additions added limited multilingual and cross-lingual tasks (Cer et al., 2017; Chen et al., 2022). The first STR dataset was introduced by (Abdalla et al., 2023), including a monolingual dataset of 5,500 English sentence pairs. New for this task is the inclusion of several low-resource languages not yet studied at the sentence level.

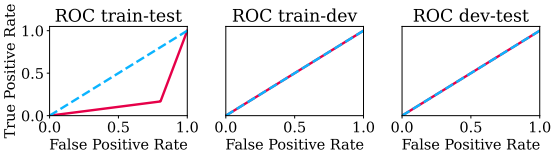

Figure 2: ROC curves for train/dev/test splits on the English data.

The field of natural language processing has drastically changed since the release of the majority of the datasets and shared tasks for semantic textual similarity, where the top-scoring methods typically included a significant amount of feature engineering based on methods like n-gram overlaps, edit distance, and longest common substrings, word alignments, and more, applied to both regression and deep learning models (Tian et al., 2017; Maharjan et al., 2017). Additionally, knowledge-informed systems included semantic information with WordNet and word frequency corpora (Wu et al., 2017). Applying the same efforts to new languages would require significant work, such as collecting new corpora.

Sentence Embeddings Modeling similarity between sentences is commonly associated with *sentence embedding* models, some of which include

[2] An ROC-AUC score of 0.5 indicates that a model cannot differ between samples in the provided data sources.

more than a billion gathered training pairs (Reimers and Gurevych, 2019; Wang et al., 2024). While applicable across many languages and domains, with models initialized from the XLM-Roberta models (Conneau et al., 2020), the included languages do not cover many of which are part of SemRel 2024.

Encoding Sentence Pairs This paper focuses on sentence-pair modeling, encoding the sentences with existing pre-trained language models to create a simpler model that allows fast and easy implementation for any language. This modeling scheme, referred to as cross-encoders, indicating full (cross) self-attention over the entire context, is well explained in previous work by (Wolf et al., 2019; Vig and Ramea, 2019; Humeau et al., 2020). Furthermore, cross-encoders have succeeded in supervised and unsupervised applications (Thakur et al., 2021; Liu et al., 2022). In addition to the sentence scoring, we follow the work by Thakur et al. (2021) to augment data with a bi-encoder, although on much smaller datasets, where the original work was carried out on data up to millions of samples. For details on bi-encoders and sentence embedding models, refer to the excellent implementations by (Reimers and Gurevych, 2019; Humeau et al., 2020; Liu et al., 2022). The baseline provided by the task organizers is LaBSE, a dual-encoder BERT-based sentence embedding model (Feng et al., 2022).

4 System Overview

After restructuring the provided datasets into sentence pairs with their respective labels, they are passed to a MLM with an added regression head; using a sigmoid layer on top of the pooled output, the model is trained using a single-class binary cross-entropy loss, with mean reduction:

$$\ell(x, y) = \frac{1}{n}\sum_{i=1}^{n}\{l_1, \ldots, l_N\}^\top$$
$$l_n = -w_n \left[y_n \log \sigma(x_n) + (1 - y_n) \log(1 - \sigma(x_n))\right]$$

The models (Table 1) were chosen based on searches for existing models in the tasks' languages and closely related language families. In the development phase, scoring was based on 5-fold validation, benchmarked with language-specific and merged data. Experiments, including those presented in Section 6, are on the final release of labeled test datasets.

Augmented Re-sampling In a separate module, a bi-encoder (*multilingual-e5-base*) is employed to find the closest non-existing sentence pairs in the data by creating sentence embeddings and searching for nearest k neighbors with cosine similarity. Before initializing the bi-encoder, the cross-encoder is trained for $\mathcal{E}_{weak}$ epochs before predicting weak labels for the augmented pairs $(s_i, s_j, pred_{i,j})$, which are added to the training data. k determines the number of nearest neighbors to retrieve for each source sentence. A Figure outlining the weak supervision pipeline is found in Figure 3.

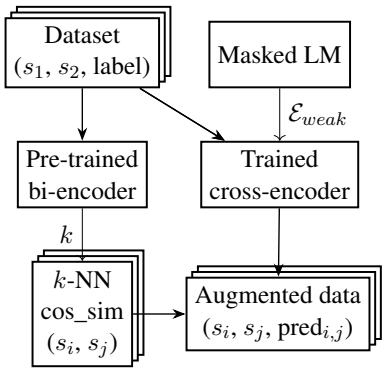

Figure 3: The weak supervision pipeline

Modularity A big focus in the development was to keep it as modular as possible. Models, parameters, data selection, and more are easily controlled through passed arguments. Furthermore, the cross-encoder is provided as a standalone module with varying levels of abstraction, e.g., calling *fit* directly or through a provided training pipeline, including optional weak supervision labeling.

5 Experimental Setup

All experiments and evaluations use the official train/dev/test data splits where applicable, and scores are presented by the Spearman rank correlation coefficient multiplied by 100. In the development phase, we studied the effect of combining or using only per-language data, working as an initial baseline before dev- and test labels were released. This was done by 5-fold validation. As stated in Section 1, no text manipulation or preprocessing was done to keep evaluations fair across languages. Moreover, upon manual inspection, the data seemed sufficiently preprocessed. The following definitions will be used to differ between model configurations:

- **`init`**: no training, only initial weights
- **`all`**: trained on all languages combined
- **`lang`**: trained on one language

Experiments were conducted in three parts:

1. Multilingual sentence embeddings with multilingual-e5-base (Wang et al., 2024)
2. Multi+monolingual MLMs as cross-encoders with XLM-R (Conneau et al., 2020) and models from Table 1.
3. Augmented data from bi-encoders

Augmentation and optimization As the data sizes and model configurations vary, Optuna (Akiba et al., 2019) is set up to search for parameter values for learning rates, k, epochs ($\mathcal{E}$), weak training epochs ($\mathcal{E}_{weak}$), and max gradient norm ($\mathcal{G}$) for clipping. With the augmentation being highly experimental for smaller datasets, we refrain from modifying the bi-encoder and use only its initial weights. Thus, this part of the system can easily be swapped with future models. While limiting the search, the learning rate, gradient clipping, and the k nearest neighbors for augmentation proved to be the most crucial parameters. Table 2 lists the parameters and ranges.

Hparam	Type	Search Space
lr	float	10^{-6} to 10^{-4} (log)
k	int	0 to 3
$\mathcal{E}$	int	1 to 5
$\mathcal{E}_{weak}$	int	0 to 2
$\mathcal{G}$	float	0.1 to 1.0

Table 2: Hyperparameter search space.

No External Data Given the readily available sentence similarity data, such as the STS-Benchmark dataset (Cer et al., 2017), experiments were done to include it in the training pipelines. However, we observed no benefits from this, likely affected by the diverging definitions and annotation styles of relatedness and similarity. Figure 4 shows scores with and without adding the STS-Benchmark dataset (Cer et al., 2017).

6 Results

Results from k-fold validation to quantify the differences between combining training sets vs. training per language show that combining data has a clear benefit. See table 3. However, important factors to consider are data size (e.g., 12,000 vs. 600 samples) and that we are validating in-domain. However,

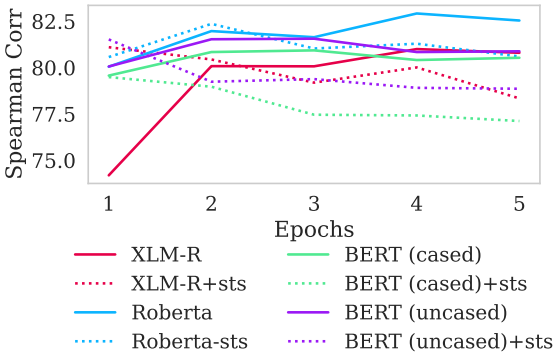

Figure 4: Scores on English-dev with and without STS data (dotted lines)

similar results on the development set show diminishing effects for merging data when predicting out-of-domain data. Development set scores are found in Appendix B. Furthermore, the results indicate how powerful MLMs are once trained, outscoring the *e5* model for most languages. Although the system performed well on the smaller dev sets, ranking in the top 2-4 in most languages in the competition, it struggled on the test sets. This is likely attributed to data distribution, overfitting, and thus failure to generalize relatedness. From the results with augmentation in Table 5, the observed change from default parameters is marginal for most languages. Increasing k without parameter optimization resulted in strictly negative results. Scores on the test set, including top scores and the LaBSE baseline, are shown in Table 4. Despite the lackluster improvement from augmentation and data expansion, the modeling scheme is still promising, outperforming the baseline (in official submissions) for 6/9 languages and 8/9 for the rerun without any changes to optimization configurations.

7 Conclusion

After testing the capabilities of commonly used models for masked language modeling and sentence embeddings, we find MLMs efficient at distinguishing relatedness with little training data. Although attempts at optimizing parameters for in-distribution data resulted in little to no performance gains, there are likely better-suited augmentation strategies for further improving performance with as little source data as possible. As a closing remark, we hope that the provided system may serve as a valuable tool for future developments in semantic textual relatedness.

8 Limitations

Few models were tested per language for the competition. Alternative multi- and monolingual models could provide much better results, especially for Algerian Arabic. This limitation is also influenced by the lack of understanding of most involved languages, e.g., to inspect the source datasets used for pretraining. Finally, grouping specific languages for training, such as merging Indo-European and Afro-Asiatic languages, was not explored.

9 Ethical Considerations

The final system performs predictions of input texts. Predictions may impose ethical concerns, e.g., when used for public-facing applications. Furthermore, automating *relatedness* has possible side effects in bias and fairness towards specific nationalities. For further details about the data and annotation, refer to Ousidhoum et al. (2024a).

A Adversarial Validation

Figures 5 and 6 show the ROC curve for a selection of languages where the AUC value deviated from the norm. English was an outlier here, where the test set is seemingly out-of-distribution. An XLM-Roberta base model set up as a cross-encoder was used for classification. 5 epochs, learning rate 2×10^{-5}. All languages not shown in the figures have an expected ROC-AUC close to 0.5.

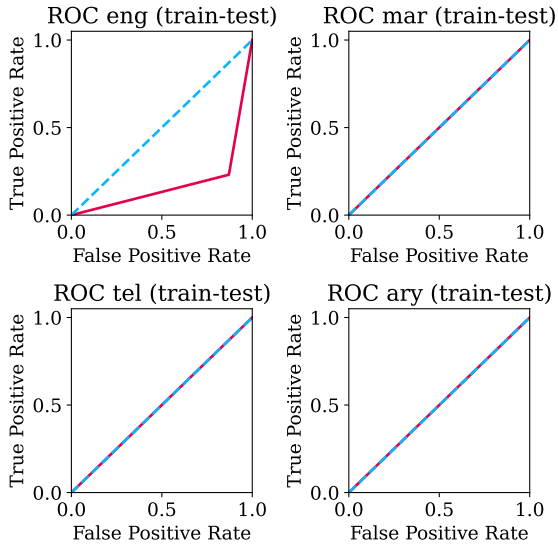

Figure 5: Adversarial validation for Train vs Test. English (eng), Marathi (mar), Telugu (tel) and Moroccan Arabic (ary).

B Development Set Results

Table 6 shows the results on dev sets for *multilingual-e5-base*, *XLM-Roberta-base*, and language-specific masked language models (as defined in Table 1). Modeling configurations are the same as listed in Section 5 – repeated below:

Abstract

Memes, combining text and images, frequently use metaphors to convey persuasive messages, shaping public opinion. Motivated by this, our team engaged in SemEval-2024 Task 4, a hierarchical multi-label classification task designed to identify rhetorical and psychological persuasion techniques embedded within memes. To tackle this problem, we introduced a caption generation step to assess the modality gap and the impact of additional semantic information from images, which improved our result. Our best model utilizes GPT-4 generated captions alongside meme text to fine-tune RoBERTa as the text encoder and CLIP as the image encoder. It outperforms the baseline by a large margin in all 12 subtasks. In particular, it ranked in top-3 across all languages in Subtask 2a, and top-4 in Subtask 2b, demonstrating quantitatively strong performance. The improvement achieved by the introduced intermediate step is likely attributable to the metaphorical essence of images that challenges visual encoders. This highlights the potential for improving abstract visual semantics encoding.[1]

1 Introduction

In this digital age, the influence of persuasive techniques, particularly in memes, is a key focus. Propaganda, using various psychological techniques, shapes information for specific agendas. Research on political memes, such as Kulkarni (2017)'s work, emphasizes their role in communication and satire. Another study on COVID-19 memes (Wasike, 2022) underscores the importance of expert-sourced, objective memes in influencing public opinion and aiding public health campaigns. As a result, understanding persuasive techniques in memes within disinformation campaigns is crucial for grasping their impact on public perception and discourse. These campaigns usually succeed in influencing users by employing various rhetorical and psychological strategies in memes, including but not limited to *causal oversimplification*, *thought-terminating cliché*, and *smear* techniques.

To address this concern, we participated in the SemEval-2024 shared task 4, as outlined by (Dimitrov et al., 2024). The primary objective of this shared task is to develop models specifically designed to detect rhetorical and psychological techniques within memes. In summary, this task involves three subtasks. In Subtask 1 the input is the textual content of a meme only. This could include any written information present within the meme, and the goal is to identify one of the 20 persuasion techniques present in the meme's textual content. The identification is based on a hierarchical structure, and the techniques are organized in a tree-like fashion. Subtask 2a involves both textual and visual content analysis of memes, and information present in both the written content and the visual elements of the meme are considered. The task is to identify the presence of 22 persuasion techniques, utilizing a hierarchical structure similar to Subtask 1. Subtask 2b is a binary classification version of Subtask 2a. The training set released for all subtasks contains only English memes. However, alongside the English language, the test datasets contain memes in three low-resource languages (Arabic, Bulgarian, and North Macedonian) that aim to evaluate the zero-shot capability of the proposed models.

Although we participated in all subtasks, we specifically focused on Subtask 2 which uses both the textual and visual modality of memes to do a multi-label classification. To achieve better results, we introduced an intermediate step, the meme captioning step. Subsequently, we employed these generated captions to compare the performance of different models like LLaVA-1.5 (Liu et al., 2023), Vicuna-1.5 (Chiang et al., 2023), BERT (Devlin

Table 1: Results of our best model (at the time of submitting evaluation results) on the test dataset of different subtasks. In the table the ranking and the values are based on hierarchical F1.

et al., 2018), and RoBERTa (Liu et al., 2019). This comparative analysis aimed to elucidate the role of the memes' text, the generated captions, and the memes' images in understanding persuasion techniques used in memes. The results of our best model (at the time of submitting evaluation results) that uses RoBERTa and our ranking relative to other teams in different subtasks are summarized in Table 1. It can be seen that our method performed well in the Subtask 2 (our main focus) for all four languages, and also the English subset of the first subtask. Our model struggled with non-English subsets of Subtask 1 since (I) we did not have access to the image of the meme and therefore no caption was available, and (II) our models only understood English, so we relied on a translation (using Google Translate[2]) of the memes' text.

Prior approaches have tried to narrow the gap between visual and textual realms to enhance image captioning. However, these methods primarily emphasized captioning visual details through textually enriched image features, rather than delving into the metaphorical significance inherent in images, particularly in the context of memes. To the best of our knowledge, this is the first work that focuses on the metaphorical semantic gap in multimodal language models to examine the gap between image and text modalities. Our ultimate goal was to gain insight into discrepancies between visual and textual metaphors in these systems. In summary, our contributions are twofold: (I) Addressing the classification problem of persuasion techniques in memes using multimodal models, and (II) Investigating the modality gap between textual and image components in multimodal models.

[2] https://translate.google.com

This paper is organized as follows: In Section 2, we review prior research on hierarchical classification, persuasion techniques classification from memes, and the gap between textual and visual modalities. Section 3 introduces the datasets, discusses models, and outlines our approach for hierarchical persuasion technique classification. Section 4 presents and discusses our experiments and findings. Finally, in Section 5, we conclude our work, summarizing key contributions and suggesting directions for future research.

2 Background

Modality Gap. In researching the modality gap between modalities, Zhao et al. (2023) presents ChatBridge, a novel multimodal large language model (MLLM) that employs language as a catalyst to bridge the gap between various modalities, such as text, image, video, and audio. By leveraging the expressive capabilities of language, ChatBridge connects different modalities using only language-paired bimodal data, showcasing strong quantitative and qualitative results on zero-shot multimodal tasks. Furthermore, Chen et al. (2023) addresses the limitations of existing MLLMs in effectively extracting and reasoning visual knowledge. The proposed model, LION, injects dual-level visual knowledge, incorporating fine-grained spatial-aware visual knowledge and high-level semantic visual evidence. LION outperforms existing models in vision-language tasks, including image captioning, visual question answering, and visual grounding, through a two-stage training process. By extending these insights to the unique realm of memes, our work not only adds to the growing body of research on multimodal models but also sheds light on the gap between visual and textual modalities, especially in the metaphorical landscape.

Persuasion Technique Classification. In exploring persuasion techniques in texts and images, Dimitrov et al. (2021) present a comprehensive framework for meme analysis. The study defines 22 techniques and provides an annotated dataset for conducting nuanced examinations of textual and multimodal memes. The incorporation of historical and mythological references adds depth to understanding the challenges in this domain. Moreover, in the work by Messina et al. (2021), the authors introduce transformer-based (Vaswani et al., 2017) models, VTTE and DVTT, for processing textual and visual content in memes. These models effec-

tively identify persuasion techniques, with DVTT showing superior performance, particularly in fine-tuning feature extractors. Given the prevalence of Large Language Models (LLMs) employing similar architectures as DVTT, our experiments include utilizing LLMs and MLLMs, which we explain in Section 3, to further investigate and advance the detection of persuasion techniques in memes.

3 Methodology

Building upon prior research on MLLMs, the prevailing method involves tokenizing image concepts and conveying these tokens alongside textual tokens to a language model. While these models possess the ability to impart more semantic information from the image, their focus typically centers on identifying objects and their relationships within the image (Park and Paik, 2023). Consequently, this study explores the impact of initially prompting the model to generate descriptive information aimed at conveying semantic context. We utilize this information for data classification, comparing it to the conventional approach of fine-tuning an end-to-end model. In this section, we outline our approach for generating meme captions and subsequently discuss our classifiers.

3.1 Caption Generation

In this paper we used three different models for generating meme captions: BLIP-2 (Li et al., 2023), LLaVA-1.5-7B (Liu et al., 2023), and GPT-4 (OpenAI et al., 2023). We fine-tuned BLIP-2 and LLaVA-1.5 for generating captions and used GPT-4 in zero-shot settings. Based on our results which are explained in Appendix C, we found out that LLaVA-1.5 outperforms BLIP-2 in the quality of generated captions. In order to fine-tune our meme captioning model, we used MemeCap (Hwang and Shwartz, 2023) dataset. Figure 1 illustrates the fine-tuning loop for LLaVA. This involved generating descriptions of memes capturing the conveyed message to uncover deeper layers of semantic understanding. Subsequently, we utilized this fine-tuned LLaVA to generate captions for the persuasion technique datasets. The generated captions provided supplementary data, offering further insights into the memes and enabling us to examine the effects of additional semantic information. Additionally, these captions were utilized to evaluate the modality gap within MLLMs. As elaborated in the subsequent section, we studied the distinctions between incorporating both the meme and its caption during the classification phase.

Considering our results in meme caption generation, discussed in Appendix C, we identified two potential issues with the captions generated by our fine-tuned models. The first issue concerns the domain disparity between the MemeCap and persuasion datasets. The memes in the task's dataset often contain toxic content and usually require a deep understanding of background knowledge and events. The second issue relates to the brevity of captions in the MemeCap dataset, which typically only mentions the meme's final goal. This brevity may not provide sufficient information for detecting persuasion approaches. Consequently, we opted to generate captions using GPT-4 in zero-shot settings. GPT-4, the latest MLLM from OpenAI, was employed in our study utilizing the recently released API known as **gpt-4-vision-preview**. This model exhibits remarkable proficiency across diverse tasks such as visual question answering and image captioning. See Appendix D for details in caption generation with GPT-4.

3.2 Persuasion Technique Classification

After generating captions for the memes, except for Subtask 1 where only the text written in the meme is provided, for classifying persuasion techniques we have three features available: meme, the text written in it, and our generated caption. In order to investigate the effect of our proposed model and assess the modality gap in MLLMs, we evaluate the effect of different combinations of these features. This will be explained further in Section 4. As our classifier model, whether in a multi-label setting like subtasks 1 and 2a, or 2b which is binary classification, we used different families of models from LLMs, MLLMs, and Language Representation Models (LRMs). These models are as follows:

LLMs. Given the promising results of LLMs in semantic classification tasks (Sun et al., 2023; Abaskohi et al., 2023), we opted to use them as our classifiers. To ensure a fair comparison and analyze the modality gap, we utilized the same LLM used in LLaVA, namely Vicuna. We initially fine-tuned the LLM solely with the text written in the meme, followed by fine-tuning with both the text in the meme and the meme's caption.

MLLMs. To assess the impact of employing our intermediate step of generating meme captions and

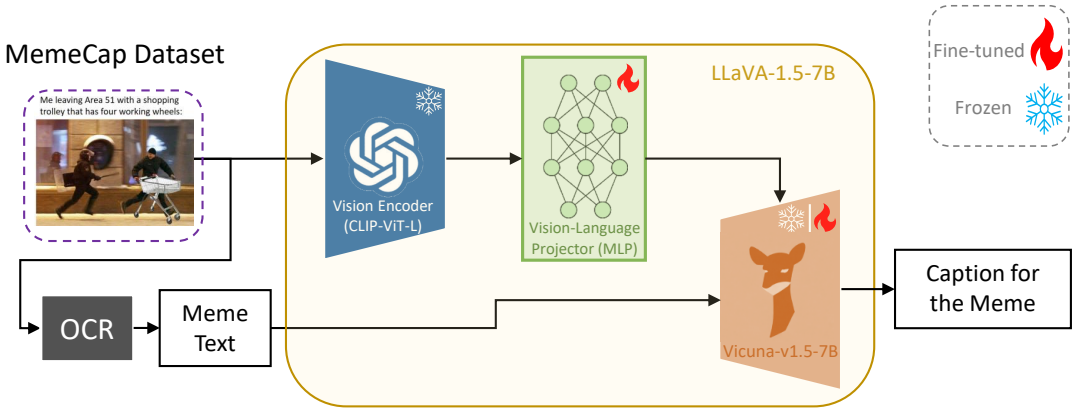

Figure 1: The figure depicts the supervised fine-tuning loop of the LLaVA-1.5-7B model on the MemeCap dataset for caption generation. The OCR module extracts text from the meme images. The vision encoder (CLIP), a frozen component of LLaVA-1.5-7B, processes the meme images. The vision-language projector bridges the gap between CLIP's representation and the embedding space of Vicuna. While CLIP remains frozen, the vision-language projector is fine-tuned. Vicuna component experimented with both frozen and fine-tuned setups to generate captions.

using them alongside the memes, we required training an end-to-end model. To accomplish this, we fine-tuned LLaVA by incorporating the meme's image, the text written within memes with or without the captions associated with them. This augmentation aimed to leverage the additional information conveyed by the captions and potentially enhance the model's performance.

LRMs. In several of our experiments, we employed BERT and RoBERTa as our classifiers. These models utilize only the encoder component of the transformer architecture. Despite the growing dominance of LLMs in various benchmarks, these models remain highly potent, particularly in semantic-related tasks. We fine-tuned the large versions of these models as our classifiers, first solely with the text written in the meme and then with both the text in the meme and the meme's caption.

Multimodal LRMs. After exploring the impact of MLMMs alongside LLMs, we delved into a BERT variant with visual understanding capabilities. Initially, we fine-tuned VisualBERT (Li et al.) on both memes and their accompanying text, with and without captions. However, given the unavailability of a pre-trained large version of VisualBERT we devised a concatenated model comprising RoBERTa-large and a vision encoder, inspired by an example from (Singh et al., 2020). We experimented with CLIP-ViT-large (Radford et al., 2021) as the component for the vision encoder. Subsequently, we concatenated the encoded features from CLIP with encoded features from RoBERTa and employed a linear classifier to determine the class based on the encoded information. We call this model *ConcatRoBERTa* (see Figure 2). To maintain consistency with previous MLLM-based methods, CLIP were frozen during the training phase.

4 Experiments

In this section, we outline our conducted experiments and provide a concise overview of the results obtained. Readers are referred to Appendix A for the details of our experimental settings.

For evaluation of the performance of the models for hierarchical classifications, we use hierarchical-precision, -recall, and -F1 introduced by Kiritchenko et al. (2006). For more information about hierarchical evaluation metrics, see Appendix E.

In the initial set of experiments, we perform hierarchical multilabel classification using the textual content of memes to fine-tune unimodal models (Vicuna, BERT, and RoBERTa) directly for identifying specific persuasion techniques. We compare this approach to multimodal models (LLaVA, VisualBERT, and ConcatRoBERTa) where both textual and visual contents of the meme are provided. Additionally, we conduct a similar experiment with LLaVA model, feeding only the image of the meme without textual data. This comparison aims to assess the information derived from each modality. The motivation behind our decision to compare encoder-only LRMs such as RoBERTa or VisualBERT to larger generative models like Vicuna or LLaVA, is their promising results in classification tasks compared to generative models (Sarrouti et al., 2022; Jiang et al., 2023). During the second stage of our experiments, we proposed to

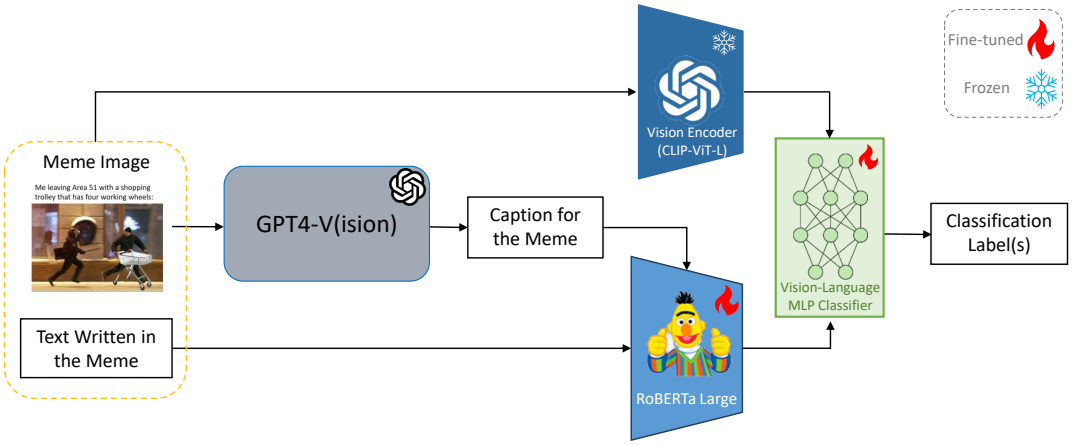

Figure 2: The figure illustrates the architecture of ConcatRoBERTa, our best-performing model. The GPT4-V(ision) component generates a descriptive caption of the meme image. The caption is then combined with the text written in the meme, which is processed by the RoBERTa. The Vision encoder utilizes a pre-trained vision transformer model (CLIP-ViT), to encode and analyze the visual elements of the meme. The MLP Classifier takes the combined visual and textual representations and classifies the meme. RoBERTa and the MLP classifiers are fine-tuned, while CLIP remains frozen.

Model	**H-F1**	**H-Precision**	**H-Recall**
LLaVA-1.5 (image)	58.21	62.74	54.31

Baseline	44.706	68.778	33.116

Table 2: Comparison of results of different methods on dev set of Subtask 2a. H-F1, H-Precision, and H-Recall, are hierarchical-F1, -precision, and -recall respectively. As expected, models prefer to receive more information about the image, and models incorporating all features (e.g., text, caption, and image) tend to perform better. However, captions appear to be more informative. This suggests that although some information from the image may not be fully conveyed through text, utilizing models to initially analyze the image, particularly in meme tasks like this, and then prompting them to make decisions based on that analysis, yields superior performance compared to making decisions without leveraging their full capabilities.

create captions for the memes, and subsequently augment the original data with these generated captions. This additional step aims to capture more information from the meme image and adopt this

additional data to improve the results of the hierarchical classification of the memes. In this phase, we mainly focused on subtask 2a. The results of our different methods on the dev set of subtask 2a are presented in Table 2.

From Table 2, we can see the best performing model is ConcatRoBERTa, which has both the image and the text written on the meme as well as the caption generated by GPT-4 as its inputs (Figure 2) with hierarchical F1 score of 71.115 on the dev set of subtask2a. It is worth mentioning that due to time constraints, we could not evaluate test datasets using ConcatRoBERTa by the evaluation deadline, therefore, the submitted results for the test dataset in Table 1 are from RoBERTa model (our second best model). It might be unexpected that MLLMs like LLaVA with text and image of the meme as their input do not perform as well as LLMs like Vicuna with text and caption of the meme in this particular task. This discrepancy could be attributed to the metaphorical nature of memes. Vision encoders, such as CLIP, are primarily trained to comprehend the visual aspects of an image, lacking a focus on the metaphorical meanings embedded in those visual elements. In contrast, language models are more adept at understanding metaphors, given their greater exposure to such linguistic nuances in textual data which has been shown previously (Hwang and Shwartz, 2023). Note the improvement in the results when employing GPT-4 for caption generation instead of LLaVA. As mentioned earlier, it is due to the domain disparity between MemeCap and this task's dataset. Regarding the superiority of the results of fine-tuned LRMs such as RoBERTa compared to LLMs like Vicuna, we argue that LLMs in general tasks are better but often for certain tasks a well-implemented LRM can outperform LLMs. In other words, the performance of LLMs fluctuates significantly based on the limitations of the data and the specific application context. This observation can be attributed to the use of a relatively small generative language model (with only 7B parameters) for a challenging task. Finally, it is not surprising that VisualBERT's results are not as good as other larger models since we only had access to the base version of pre-trained VisualBERT.

Another observation is that by adding an intermediate step of caption generation, results are improved when it is used in a supervised learning manner. In contrast, for the in-context learning scheme (Appendix B), we note that the additional information extracted from memes, specifically captions, did not improve but rather worsened the results. The diverse nature of meme captions, including more details compared to the text within the memes, may misguide the model in focusing on relevant features. In such a setting, the models' in-context learning ability is limited, and giving more information only confuses the model without any gain. Even we tried to use GPT-4 (in a zero-shot setting) for subtask 2b, and its results on the dev set were comparable but worse than using our proposed method (RoBERTa with generated caption from GPT-4), i.e., 73.242 and 79.667 versus 78.434 and 81.333 for macro- and micro-F1, respectively.

5 Conclusion and Future Work

This paper explores the persuasive communication within memes, emphasizing their role in shaping public perception. Through participation in the SemEval-2024 shared task 4, our study delves into the detection of rhetorical and psychological techniques within memes. By employing multimodal models and introducing an intermediate step of meme captioning using LLaVA and GPT-4, we aimed to bridge the gap between textual and visual modalities, thereby enhancing the classification of persuasion techniques. Our experiments demonstrate the effectiveness of this approach, with our best model, ConcatRoBERTa, achieving notable performance improvements. However, we observed that the performance gains varied based on the dataset's nature and the models' sophistication. Nevertheless, our findings contribute to advancing understanding in this domain and pave the way for future research endeavors aimed at combating online disinformation campaigns.

Regarding future work, a deeper analysis into why the model struggles to utilize its image analysis capabilities for classification, despite its proficiency in generating captions (even in zero-shot settings with GPT-4), could be explored through the implementation of chain-of-thought approaches. Additionally, exploring how well the proposed method withstands adversarial attacks is another interesting direction. Adversarial examples, as shown by different studies (Moosavi-Dezfooli et al., 2016; Sadrizadeh et al., 2023; Zhao et al., 2024), have uncovered vulnerabilities in neural models across various tasks. Studying how adding the caption generation step affects the adversarial robustness of our approach compared to end-to-end methods for this task holds promise for future research.

A Experimental Settings

All of the experiments were conducted on a Core i9 system with 64GB of RAM and Nvidia RTX3090 GPU with 24GB VRAM.

In all combinations of the experiments in Section 4 involving generative models, the temperature and number of beams for text generation were set to 0.7, and 1, and we limited the maximum number of newly generated tokens to 100. Moreover, we employed the Adam (Kingma and Ba, 2014) optimizer, and the learning rates for Vicuna-1.5 and LLaVA-1.5 were set to 2e-4, and 2e-5 respectively with cosine scheduling. For LRMs (BERT and RoBERTa) and Multimodal LRMs (ConcatRoBERTa and VisualBERT), we used a maximum length of 512 tokens, with the learning rate set to 1e-5 with Adam optimizer. We trained them for 20 epochs and chose the best model evaluated on the dev set for evaluation of the test datasets.

Similarly, in all cases of the Appendix C, the temperature and number of beams for text generation were set to 0.7, and 1, and we limited the maximum number of newly generated tokens to 100. Also, we utilized the Adam optimizer, and the learning rates for BLIP-2 and LLaVA-1.5 were 5e-4, and 2e-4 respectively with cosine scheduling.

We employed the Parameter-Efficient Fine-Tuning (PEFT) (Mangrulkar et al., 2022) and Low-Rank Adaptation of Large Language Models (LoRA) (Hu et al., 2021) techniques for fine-tuning of large models, i.e., Vicuna, LLaVA, and BLIP-2.

B In-Context Learning: Results & Discussion

In this section, the results of zero- and few-shot experiments are illustrated in Table B.1. One thing worth mentioning about this section is that for the LLaVA-1.5 few-shot experiments, for the examples (shots), we only had the text written on the memes and the captions (with no images). This was due to a limitation in the implementation of LLaVA-1.5 that only accepted one image as the input. We defer exploration of the examples with more than one image for in-context learning of the LLaVA-1.5 model to future work.

C Meme Captioning Results

To generate captions for memes, first, we compared two state-of-the-art models, namely BLIP-2 and LLaVA-1.5-7B. We fine-tuned the Q-Former part of BLIP-2 for meme captioning. The vision encoder (CLIP-ViT (Radford et al., 2021)) and the LLM (OPT-6.7B (Zhang et al., 2022)) components of BLIP-2 are frozen by design. Regarding fine-tuning LLaVA, we have a few variations. First, we only fine-tuned the projector MLP that bridges between two modalities. As the second approach, we fine-tuned both the projector and the LLM (i.e., Vicuna-1.5-7B) together. In both variations, the vision encoder is frozen.

We fine-tuned each model for 1 epoch on the MemeCap dataset. Our results show the superiority of LLaVA-1.5-7B over BLIP-2, therefore, we chose to use fine-tuned LLaVA-1.5-7B for the meme captioning. To further optimize our pipeline, we tried another variation. We tested the case where in addition to the meme caption included in the MemeCap dataset, what would happen if we also used Optical Character Recognition (OCR), utilizing EasyOCR[3],

[3] https://github.com/JaidedAI/EasyOCR

Model	Shot(s)	H-F1	H-Precision	H-Recall
Vicuna-1.5 (text)	0	15.37	31.13	10.21
Vicuna-1.5 (text+caption from LLaVA-1.5)	0	17.60	30.28	12.40
LLaVA-1.5 (image)	0	17.74	27.10	13.18
LLaVA-1.5 (image+text)	0	20.39	30.27	15.38
LLaVA-1.5 (image+text+caption from LLaVA-1.5)	0	19.30	25.91	15.38
Vicuna-1.5 (text)	3	38.26	**34.73**	42.58
Vicuna-1.5 (text+caption from LLaVA-1.5)	3	35.89	33.98	38.02
LLaVA-1.5 (image+text)	3	24.78	27.87	22.31
Vicuna-1.5 (text)	5	**40.70**	33.39	**52.11**
Vicuna-1.5 (text+caption from LLaVA-1.5)	5	36.5	31.97	42.51
LLaVA-1.5 (image+text)	5	25.80	27.86	24.03

Table B.1: Comparison of results proposed methods in an in-context learning (zero- and few-shot learning). H-F1, H-Precision, and H-Recall are hierarchical F1, hierarchical precision, and hierarchical recall respectively. In LLaVA-1.5 few-shot experiments, due to the implementation limitation allowing only one image input, examples consisted solely of text from memes and their captions, lacking images. With an increase in the number of in-context examples, it appears that the model tends to perform better. However, due to LLaVA's restriction to only one image, the improvement is marginal compared to the enhancement achieved with text alone.

as illustrated in Figure 1, to extract the text written on the meme and feed that to the model as well since in the Persuasion dataset we have this data for each meme. We also tried both BLIP-2 and LLaVA in a zero-shot setting to assess their ability for image captioning without fine-tuning as well.

As discussed in Section 4, we used MemeCap dataset to fine-tune MLLMs for meme caption generations. Table C.1 shows the performance of the various models. From these results, initially, we chose to use LLaVA-1.5-7B with both the projector and LLM fine-tuned with OCR data for caption generation, as it outperformed other methods. However, as discussed earlier, we observed that even the caption generated by LLaVA-1.5-7B had some issues potentially leading to degraded performance on the Persuasion dataset. Therefore, we chose to create captions utilizing GPT-4 in a zero-shot configuration for our final results. In Section 4, the positive effect of this change is discussed in more detail with empirical evidence.

To compare different models for caption generation, we used Bertscore (Zhang et al., 2019) (using *microsoft/deberta-xlarge-mnli* model (He et al., 2021)), BLEU score (Post, 2018), and ROUGE-L (Lin, 2004) as evaluation metrics for the quality of generated captions. Bertscore assesses semantic similarities between the generated captions and the corresponding references using cosine similarity. In contrast, ROUGE-L and BLEU score rely on evaluating n-gram overlap between the generated captions and reference captions.

D Prompts for Caption Generation with GPT-4

As mentioned in Section 3, in addition to LLaVA-1.5, we used GPT-4 to generate captions for memes. LLaVA-1.5 provided a strong foundation for understanding the content and sentiment of the memes, while GPT-4's creative text generation capabilities helped us generate more informative captions. This allowed us to explore the potential of GPT-4 for generating captions that are not only relevant to the meme content but also capture the humor and cultural references often associated with memes. However, because of some of the meme's contents, it sometimes prevented generating captions to not generate toxic information. Table D.1 illustrates our prompts for obtaining captions using GPT-4. Given the sensitivity of GPT-4 to the content of this dataset, if the first prompt failed, we utilized the second prompt. In instances where there was another failure—constituting less than 10 samples in every 1000 examples—we employed our fine-tuned LLaVA model to generate captions for those samples.

E Hierarchical Evaluation Metrics

Hierarchical classification involves organizing classes in a hierarchy, where each class has a parent

Model	F1-Bertscore	ROUGE-L	BLEU-4
BLIP-2 (fine-tuned)	58.00	26.39	47.93
LLaVA-1.5 (projector fine-tuned)	59.01	27.41	**57.78**
LLaVA-1.5 (LLM & projector fine-tuned)	59.23	27.40	45.53
LLaVA-1.5 (projector fine-tuned + OCR data)	<u>59.80</u>	**28.08**	53.33
LLaVA-1.5 (LLM & projector fine-tuned + OCR data)	**59.90**	<u>27.86</u>	<u>53.86</u>
BLIP-2 (zero-shot)	50.30	12.88	31.81
LLaVA-1.5 (zero-shot)	55.11	19.31	40.15

Table C.1: Performance comparison of meme captioning models on MemeCap test set. In this table "+ *OCR data*" means for the training data we also appended the extracted text from the meme to help with the task of captioning the memes. The fine-tuned versions of the models yield superior captions, with all LLaVA iterations outperforming BLIP. The most effective model is LLaVA when both the language model and projector are tuned, particularly when incorporating text within the image generated by the OCR model.

Prompt
`Memes are one of the most popular types of content used in an online disinformation campaign. They are mostly effective on social media platforms since there they can easily reach a large number of users. This is a meme with the following text written inside the meme: "{meme_text}". In no more than 200 words, write a caption for this meme and say what is the meme poster trying to convey?`
`Memes are one of the most popular types of content used in an online disinformation campaign. They are mostly effective on social media platforms since there they can easily reach a large number of users. Memes in a disinformation campaign achieve their goal of influencing the users through a number of rhetorical and psychological techniques, such as causal oversimplification, name calling, smear. Identifying these memes are very useful and it can help to remove them from the internet and have a better and more calm place. To do so I want your help. I want to create a caption and find what this meme is trying to convey in order to train a model to find these memes. I provided a meme to you. In no more than 200 words, write a caption for this meme and say what is the meme poster trying to convey?`

Table D.1: These prompts were utilized to generate captions using GPT-4. Due to the sensitivity of GPT-4 to this dataset, if the first prompt failed to produce satisfactory results, we resorted to the second prompt.

or child relationship with other classes. In hierarchical classification tasks, Kiritchenko et al. (2006) introduced several key definitions to form a foundation for evaluating performance metrics which will be discussed in this section.

E.1 Partial Ordering and Hierarchy

A *partially ordered set (poset)* is denoted as $H = \langle C, \leq \rangle$, where C is a finite set and $\leq \subseteq C \times C$ is a reflexive, anti-symmetric, transitive binary relation on C. The hierarchy is defined by parent-child relationships between categories.

E.2 Hierarchical Categorization Task

A *hierarchical categorization task* involves assigning a boolean value to pairs $\langle d_j, c_i \rangle \in D \times C$, where D is a domain of instances, and $C = \{c_1, \ldots, c_{|C|}\}$ is a set of predefined categories with a given poset structure $H = \langle C, \leq \rangle$.

E.3 Hierarchical Consistency

A label set $C_i \subseteq C$ assigned to an instance $d_i \in D$ is considered *consistent* with a given hierarchy if C_i includes complete ancestor sets for every label $c_k \in C_i$. Hierarchical consistency ensures that assigned labels indicate the instance's position in the category hierarchy.

E.4 Hierarchical Precision, Recall, and F1 Score

For hierarchical evaluation, we introduce *hierarchical precision (HP)* and *hierarchical recall (HR)*. Each example belongs not only to its class but also to all ancestors of the class, except the root. The combined *hierarchical F1 score* is calculated using precision and recall with equal weights. Here are the formulas:

$$HP = \frac{\sum_i |\hat{C}_i \cap \hat{C}'_i|}{\sum_i |\hat{C}'_i|}$$

$$HR = \frac{\sum_i |\hat{C}_i \cap \hat{C}'_i|}{\sum_i |\hat{C}_i|}$$

$$Hierarchical\ F_\beta = \frac{(\beta^2 + 1) \cdot HP \cdot HR}{\beta^2 \cdot HP + HR}$$

Here, $\hat{C}_i$ and $\hat{C}'_i$ represent the extended sets of real and predicted classes, respectively, including their ancestor labels. Also $\beta \in [0, +\infty)$ and by using $\beta = 1$ we will have hierarchical F1. In the context of hierarchical classification, data is organized into a hierarchy of classes or categories, with each class having a parent-child relationship. The Hierarchical F1 score takes into account both precision and recall at different levels of the hierarchy, providing a comprehensive measure of a model's ability to correctly classify instances at various levels while considering the hierarchical structure of the classes. It balances the trade-off between false positives and false negatives within the hierarchy, offering a more nuanced assessment of classification performance in hierarchical data structures.

These hierarchical metrics provide a comprehensive evaluation of classification performance in the context of hierarchical categorization tasks.

Pauk at SemEval-2024 Task 4: A Neuro-Symbolic Method for Consistent Classification of Propaganda Techniques in Memes

Matt Pauk

matt.pauk@colorado.edu

Maria Leonor Pacheco
University of Colorado Boulder
maria.pacheco@colorado.edu

Abstract

Memes play a key role in most modern information campaigns, particularly propaganda campaigns. Identifying the persuasive techniques present in memes is an important step in developing systems to recognize and curtail propaganda. This work presents a framework to identify the persuasive techniques present in memes for the SemEval 2024 Task 4, according to a hierarchical taxonomy of propaganda techniques. The framework involves a knowledge distillation method, where the base model is a combination of DeBERTa and ResNET used to classify the text and image, and the teacher model consists of a group of weakly enforced logic rules that promote the hierarchy of persuasion techniques. The addition of the logic rule layer for knowledge distillation shows improvement in respecting the hierarchy of the taxonomy with a slight boost in performance.

1 Introduction

Propaganda has long been used in media as a communication technique to influence people to subscribe to a particular idea or ideology. Identifying the presence of propaganda in media is an important subtask in building systems that can curtail the effect of propaganda campaigns. In modern times, a common way for propaganda to be spread is via memes. A meme is a either a short video or image, often overlayed with text, that is widely circulated over the internet. Identifying the presence and type of persuasion techniques used in memes is an important problem to be solved. The organizers of SemEval 2024 Task 4 propose a shared task for this very problem (Dimitrov et al., 2024). The shared task involves three sub-tasks: sub-task 1, identifying the persuasion technique(s) involved in the textual content of the meme; sub-task 2a, identifying which persuasion techniques are involved in both the visual and textual content of the meme; and sub-task 2b, identifying whether or not any persuasion technique is present in the visual and textual content of the meme. While the training data for all sub-tasks is in English, the evaluation phase includes different test sets for English, Arabic, Bulgarian, and North Macedonian. The proposed framework will focus only on the English version of the first two sub-tasks. Both 1 and 2a are hierarchical multi-label classification problems, where the goal is to classify the correct persuasion techniques used in the meme. The hierarchical nature of the persuasion techniques adds an extra element to this classification. All of the possible persuasion techniques are organized in a Directed Acyclic Graph (DAG), and full credit for a prediction is only given when the correct leaf node is predicted. Partial credit is given when any of its ancestors are given as a prediction.

There is a lot of previous work in the area of propaganda and persuasion identification. Much of this work has been based on previous SemEval shared tasks. The SemEval 2021 Task 6 is almost identical to the task explored here, without the hierarchical label structure (Dimitrov et al., 2021). The best-performing approaches on this task consisted of the use of a fine-tuned, text-based transformer for the textual content of the meme, some CNN or transformer based vision model to extract features from the image, and then a consolidation of the resulting embeddings via simple aggregation such as concatenation or average (Tian et al., 2021; Feng et al., 2021). Another SemEval task in 2023 focused on the identification of propaganda techniques in the text of news articles (Piskorski et al., 2023). In this case the best models used fine-tuned BERT based transformers (Wu et al., 2023; Hromadka et al., 2023).

The approach presented in this paper will also leverage a combination of a text-based transformer and a visual neural model. The key addition will be the incorporation of logic rules that encode the relationship between the possible hierarchical output classes. These relationships can be modeled by

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1424–1434

simple rules where the presence of a particular persuasion technique implies that its parent technique in the hierarchy is also present. For example, the rule `Straw Man` $\implies$ `Distraction` suggests that examples with the *Straw Man* persuasive technique also have it's parent technique *Distraction*. These rules will be used to promote predictions of persuasive techniques that respect the hierarchy. To test hierarchical consistency, we measure the number of hierarchy violations in predictions, where the model predicts a persuasive technique but not one of its ancestors in the hierarchy.

To incorporate logic rules, we take inspiration from the teacher-student logic rule framework proposed by Hu et al. (2016) that distills the information encoded in logic rules into the neural network parameters. The focus of this work is to explore if the incorporation of logic rules can improve on the results of neural based modes, while also producing more consistent results. The intuition is that distilling these hierarchical relationships into the weights of the network will allow the network to better recognize patterns that correspond to types of persuasive techniques, and ultimately make better predictions. We show that the addition of these logic rules does result in much more consistent predictions with a slight improvement in F1 scores.

2 Background and Related Work

Propaganda and Persuasion There is ample existing work in the identification of propaganda techniques. A similar SemEval task was proposed in 2021 to classify memes without including the hierarchy requirement (Dimitrov et al., 2021). Feng et al. (2021) proposed a framework for this task involving a text-based transformer built on RoBERTa, a visual feature extractor, and then a final transformer which takes as input the output of RoBERTa and the visual feature extractor. The authors consider two methods for this final encoder, a text pretrained transformer and a multi-modal transformer. The multi-modal transformer approach works the best, and they slightly improve on this score by combining several models together in an ensemble, which gives them state of the art results for the task. Tian et al. (2021) take a slightly different approach with this task. They similarly decompose the problem into a BERT based transformer and a visual feature extractor, but use a simpler method for combining the output embeddings by simply concatenating the output features before using a final classifier. They also experiment with a few different types of image feature extractors: a model specifically tuned to recognize faces, an Optical Character Recognition (OCR) model tuned to recognize text in an image, and the best performing extractor, which is a region based image feature extraction model that feeds into a multi-modal model.

Other previous SemEval tasks have focused just on the identification of propaganda techniques in text by leveraging multilingual datasets of news articles (Piskorski et al., 2023). Wu et al. (2023) and Hromadka et al. (2023) presented the two top performing systems for this task. Both use very similar approaches, leveraging a fine tuned version of RoBERTa for classification. Wu et al. (2023) had an interesting additional class weighting mechanism to try to improve performance on the under represented classes in the dataset. The approach proposed will leverage a lot of the same ideas regarding the usage of BERT based transformers for textual content, as well as visual feature extractors. Where this approach differs is in the incorporation of logic rules representing the relationship between propaganda techniques.

Hierarchical Classification Hierarchical multi label classification problems are split into two types: local methods, where an independent classifier is used for each node or for each level of the hierarchy; and global methods, which consider the entire hierarchy all at once (Levatić et al., 2014). In this paper, the interest is in exploring a global method that leverages logic rules to represent the relationship between classes in the hierarchy. Similar work has already been done in this area. Giunchiglia and Lukasiewicz (2021) propose a Coherent Hierarchical Multi-Label Classification Network (C-HMCNN) which uses a constraint layer on top of the regular network, as well as a specialized loss function to require the hierarchical constraints be satisfied. The constraint used is a simple one: the output probability of a subclass of a particular class in the hierarchy must be less than or equal to the output probability of its super-class. The approach for this project will be similar, but will follow more closely to the general logic rule integration method proposed by Hu et al. (2016). This framework consists of a teacher-student network, where the teacher network encodes logic rules as soft logic and distills that knowledge into the student network. This framework allows for more flexibility in the kinds of logic rules inte-

grated into a network. Additionally, it is less strict when enforcing the rules on the outputs of the neural network, allowing for a better balance between the signal coming from the direct supervision and the hierarchical knowledge.

3 System Overview

The proposed model architecture is based on a student-teacher knowledge distillation approach consisting of several components, which vary depending on the sub-task, but share a common structure. Regardless of task, base classifiers are used to encode raw textual and/or visual content. These resulting embeddings are then concatenated and used for predictions by the student network. The teacher network consists of a logic rule layer on top of the base student model that encodes the hierarchical information of the propaganda techniques. This logic layer is based on the teacher-student framework proposed by Hu et al. (2016). The framework distills the knowledge from the teacher network into the student network by training the student network to simultaneously emulate the gold labels and the teacher predictions.

3.1 Base Classifiers

Textual Model The textual model used will be the transformer-based model DeBERTa. DeBERTa was chosen based on its state of the art performance on short text datasets (Karl and Scherp, 2023). Additionally, this model was shown to do well on previous approaches for a very similar SemEval task (Feng et al., 2021; Tian et al., 2021). The version used is pre-trained version of DeBERTa proposed by He et al. (2021). This model is then fine-tuned on the textual meme content supplied by the SemEval 2024 task 6 organizers (Dimitrov et al., 2024).

Visual Model A ResNet-50 architecture is used for the vision component of sub-task 2a (He et al., 2016). This CNN based model is a medium sized model that achieved impressive results on the ImageNet classification task (Deng et al., 2009).

Combining the Textual and Visual Models The outputs of both textual and visual models need to be considered when making a prediction and therefore need to be combined in some way. A simple concatenation will be used and then inputted into a final feed forward network with sigmoid activations for each label.

3.2 Hierarchical Constraints

To introduce hierarchical constraints, we use a logical constraint layer on top of the base classifiers. The role of this layer is to distill knowledge coming from a set of logic rules into the weights of the classifiers. The implementation of this layer is based on the framework originally proposed by Hu et al. (2016) for the tasks of sentiment analysis and named entity recognition. The logic layer takes as input the sigmoid output for each label type from the base model and applies softened logic rules as regularization terms to obtain new predictions. The base network then learns weights based not only on the gold labels, but also based on the outputs of this logic rule regularized layer. This joint learning task is described by the following weight update equation which is a slightly modified version of the original formulation by Hu et al. (2016).

$$\theta^{t+1} = arg\min_{\theta \in \Theta} \frac{1}{N} \sum_{n=1}^{N} l_1(y_n, \sigma_\theta(x_n)) + l_2(s_n^t, \sigma_\theta(x_n)) \quad (1)$$

where θ represents the network parameters, N is the number of samples, l_1 is the loss function for the student network and gold labels, l_2 is the loss function for the student network predictions and teacher network predictions, y_n are the gold labels, $\sigma_\theta(x_n)$ is a vector of label probabilities outputted by the base network, and s_n^t is the output of the logic rule layer.

The output of the logic-rule based layer s_n^t is obtained by evaluating the following equation, also originally formulated by Hu et al. (2016).

$$q^*(Y|X) = p_\theta(Y|X) \exp\left\{ -\sum_{l,g_l} \lambda_l (1 - r_{l,g_l}(X,Y)) \right\} \quad (2)$$

Where $p_\theta(Y|X)$ is the output of the base model, λ is a weighting parameter used to determine how strictly to follow a particular rule, and r_{l,g_l} is a softened first order logic rule. The strategy for softening as well as the rules used for this particular application are described in the next section.

Representing Logic Rules This framework supports any FOL rules that can be grounded in the inputs, the output probabilities of the base network, and/or the gold labels. The rules can be softened using the following t-norms as found in the work done by Bach et al. (2017) regarding probabilistic

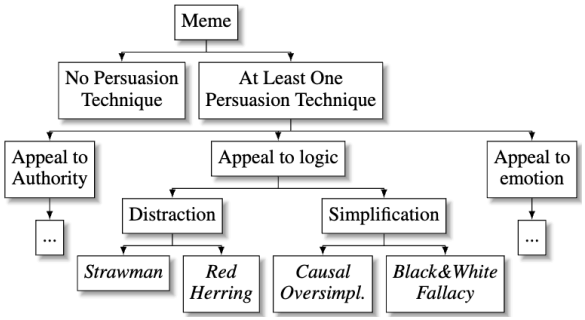

Figure 1: A subset of the hierarchy of propaganda techniques, provided by Dimitrov et al. (2024)

soft logic.

$$A \wedge B = \max(A + B - 1, 0)$$
$$A \vee B = \min(A + B, 1)$$
$$\neg A = 1 - A$$

After the rules have been converted to continuous representations they can be incorporated into the network via Equation (2). The following section describes the constraints that will be used for this specific classification task.

Hierarchical Logic Rules The rules for this application will focus on the hierarchical relationship between propaganda technique labels. The hierarchy of these labels is provided by the SemEval 2024 task 4 organizers, a sub-section of the hierarchy is shown in Figure 1 (Dimitrov et al., 2024). The full hierarchy includes 22 different persuasion techniques.

Given that the dataset is not balanced between all possible labels, we hypothesize that incorporating some of this hierarchical information into the model should allow for better prediction on lower coverage labels based on their relationship in the hierarchy to higher coverage labels. This hierarchical information will be encoded via logic rules that can be represented in the constraint layer via Equation (2), and will be distilled into the base model parameters via Equation (1) to help improve predictions.

The entire hierarchy can be represented via a sequence of rules:

$$\forall l \in L \text{ s.t. } l \neq root,\ l \implies par(l) \tag{3}$$

where L is the set of all possible labels and $par(l)$ represents the parent node of l in the hierarchy. Restructuring this rule slightly and grounding it in the outputs of the base model gives the following result:

$$\forall x \in X, \forall l \in L \text{ s.t. } l \neq root,\ \neg\sigma_l(x) \vee \sigma_{par(l)}(x) \tag{4}$$

where $\sigma_l(x)$ represents the probability that example x contains label l. Softening this logic gives the following expression for each rule:

$$\min(1 - \sigma_l(x) + \sigma_{par(l)}(x), 1) \tag{5}$$

Intuitively, these rules will enforce the hierarchy by penalizing predictions where the probability of a particular label is high, but the probability of its parent label is low.

4 Experimental Setup and Results

The method outlined above is evaluated on two separate but related tasks provided by the organizers of the SemEval 2024 Task 4 (Dimitrov et al., 2024). The details of these tasks and results are described below. Model implementations for both sub-tasks leverage Tensorflow for modeling and Hugging Face for the DeBERTa and ResNet models (Abadi et al., 2015; Wolf et al., 2019). [1]

4.1 SubTask 1

Experimental Setup The goal of subtask 1 is to identify which of the 20 persuasion techniques are present in the textual content of a meme. The dataset contains 7,000 labeled examples in the train set, 500 examples in the validation set, 1,000 in the dev set, and 1,500 in the test set. Hyper-parameter tuning is done on the validation set, with the final evaluation done on the dev and test sets.

Hierarchical F1, precision, and recall are used as the main evaluation metrics as defined by the SemEval Task organizers. However, micro F1, macro F1, and a count of the number of hierarchical violations are used as supplementary evaluation metrics. The hierarchical F1 score was originally formulated by Kiritchenko et al. (2006). This metric is the micro F1 of the label predictions, including both the actual persuasive techniques and their ancestor node categories in the hierarchy. The hierarchical violation metric is a count of the number of final true predictions which have an ancestor incorrectly marked as false. This metric is specifically used to evaluate whether the hierarchical logic rules are having an effect. The models presented will be compared against other approaches on the same

Table 3: Subtask 2a validation set results, comparing versions of NeuroSym with varying rule confidences against a baseline model leveraging only the classifiers and no logic layer.

task, as well as against themselves to measure the impact of the logical constraints.

The final hyper-parameters selected after tuning and used for evaluation on the dev/test sets are a learning rate of 3e-5, batch size of 4, and dropout of 0.1 after the BERT layer. Additionally, the teacher network rule confidences, represented by λ in Equation (2), are set to 100 for all rules. For dev set and validation set evaluations, the model is trained for 2 epochs on the training set. The model used to for the test set evaluation is trained for 3 epochs on the combined train and dev sets. Binary cross entropy is used as the loss function between the gold labels and student predictions, while KL Divergence is used between the student and teacher predictions.

Results The evaluation results for sub-task 1 on the English test set are shown in Table 1a. Dev set results can be found in Appendix A.1. Our system ranks 15th out of 33 submissions against the test set, as evaluated on the metric of hierarchical F1. The hierarchical F1 metric is a measure of micro F1 over all possible classes in the hierarchy after performing a post hoc operation to add the ancestors of predicted techniques to the list of predicted techniques for a particular example. Due to our systems focus on consistency of predictions with respect to the hierarchy, we also evaluate our system on micro F1 over all possible techniques without this post-hoc operation. Table 2 compares the average results of 3 runs against the validation set for our neuro-symbolic model with varying rule confidences of 10, 100, and Python's `sys.maxint`. In addition, a baseline version of the model without the hierarchical logic rule layer on top is added for comparison. The results for the individual runs can be found in Appendix A.2. Along with the F1 metrics, we present a measure of hierarchical violations over all predictions made.

The results show that regardless of the rule confidence used, the logic rule layer makes a noticeable improvement with regard to violations in the hierarchy of outputted predictions, with stronger rule confidences leading to less violations. This suggests that the rules are having their intended effect of making predictions consistent with the hierarchy. The results also show that very strong rule confidences seem to have a negative effect on F1 scores without much improvement in violations. The rule confidence of 100 seems to have the best compromise between consistent predictions and F1 scores, with even a slight improvement in F1 over the baseline model.

4.2 Sub-Task 2a

Experimental Setup The goal of sub-task 2a is to identify which of the 22 persuasion techniques are present in the textual and image content of a

(b) Subtask 2a leaf node evaluation against the validation set.

Table 4: Leaf node evaluation to measure the effectiveness of the hierarchy usage in performance on leaf node propaganda technique predictions.

meme. The dataset distribution into train, validation, dev, and test is the same as task 1. The same hyper-parameter tuning method, final selected hyper-parameters, and evaluation metrics as used in sub-task 1 are also used here.

Results The results for sub-task 2a on the test set are displayed in Table 1b, with dev set results in Appendix A.1. Similar to sub-task 1, our model is in the middle of the pack, ranking 7th out of 14 for submissions on the test set. Table 3 is similar to Table 2 for sub-task 1, showing the results of experimenting on the validation set with varying rule confidences and a comparison to a baseline with no logic rule layer. Once again, we observe that the logic layer is leading to more hierarchically consistent predictions and a slight improvement in F1 scores. Additional results showing the model performance for each persuasive technique can be found in Appendix A.4.

Outside of consistency, one of the goals of using this logic rule student-teacher framework is to get the teacher model to distill information about the hierarchical relationship between the persuasive techniques into the student model and improve predictions on the actual leaf nodes representing specific persuasive techniques. In order to evaluate if this is actually the case, we perform an experiment evaluating just the predictions on the leaf nodes. For this experiment, the baseline model is trained and evaluated on only the leaf nodes of the hierarchy; Baseline(H) is trained on the full hierarchical data, but evaluated only on the leaf nodes; and NeuroSym includes the logic rule layer taking advantage of the hierarchical training data but also evaluated only on the leaf nodes. The results of the experiment averaged over three runs are shown in tables 4a and 4b. As shown in the results, the NeuroSym model has the lowest F1 scores when evaluated on both sub-task 1 and 2a. This indicates that the consistency enforced by the logic rule layer is actually negatively affecting leaf node predictions. The Baseline(H) model outperforms the baseline on sub-task 1 but performs worse on sub-task 2a, leaving inconclusive results as to whether the hierarchical data is helpful in leaf node prediction. The results of the individual runs, can be found in Appendix A.3.

5 Conclusion and Future Work

The framework presented attempts to solve the task of identification of persuasive techniques in memes. The key innovation involved in this framework compared to previous work done in this space is the integration of a logic rule knowledge distillation layer that weakly applies rules encoding the hierarchy of persuasion techniques. This layer is applied on top of a base model using a transformer based DeBERTa model for the textual component and a ResNet for the image component. We find that the logic rule network has some positive effect, consistently resulting in fewer hierarchical violations and a slight improvement in micro F1 scores. However, these logic rules do not lead to better predictions on the leaf node techniques themselves.

There were some difficulties in integrating these logic rules. The way the framework is set up, violations of the rules result in low probabilities for predictions by the teacher model. The part of the loss function that involves the KL divergence between these student and teacher predictions can cause the network to learn one of two aspects to minimize this loss. The first option is to raise the prediction probability of the rule violating ancestor label in the student network which will result in no rule violation and therefore no addition to the loss. Alternatively, the student network predictions can be lowered even further which also minimizes the KL divergence. The goal is for the former result to be learned, but it seems that often the latter is learned especially when the rule confidences are very high. Further work can be done to explore alternative logic rule interactions or loss function formulations to ensure the latter is always learned by the network.

In addition to improvements in the hierarchical logic rule integrations themselves, more work can be done to improve the base model by exploring other image processing methods outside of using a basic ResNet. Additionally, more intelligent ways of combining the textual hidden states and image hidden states can be explored, such as the use of a basic attention mechanism. Finally, the exploration of additional logic rules that promote parts of the textual content of an example that may indicate a particular persuasion technique could be experimented with. This may be especially useful for persuasion techniques with low coverage in the dataset.

A Appendix

A.1 Dev Results

Tables 5a and 5b show the results of our model on the dev set for both subtask 1 and subtask 2a respectively. Our model performs in the middle of the pack for both subtasks, finishing 16th out of 33 for subtask 1 and 7th out of 11th on subtask 2a.

A.2 Validation Result Individual Runs

Tables 6 and 7 show the individual runs on the validation set measuring the effectiveness of the logic rule layer for both subtasks. The baseline model uses the classifiers with no logic rule layer, while the NeuroSym models use the classifiers and the logic rule layer with varying levels of confidence in the logic rules.

Model	Micro F1	Macro F1	Violations

A.3 Leaf Node Evaluation Individual Runs

Tables 8 and 9 show the results of the individual runs for the leaf node experiment for both subtask 1 and 2a. The Baseline model uses just the base classifiers trained and evaluated only on the leaf nodes of the hierarchy. The Baseline(H) model also uses only the base classifiers and is evaluated on only the leaf nodes of the hierarchy, but is trained on the full hierarchical data. Finally, the NeuroSym model is also evaluated on the leaf nodes but leverages the logic rule layer and the full hierarchical data.

Table 9: Individual runs on the validation set for subtask 2a evaluating only the performance of predictions on the leaf node propaganda techniques.

A.4 Results By Propaganda Technique

Tables 10 and 11 show the results of the dev set predictions on a per class basis. For both subtasks, we see the best performance for those classes higher up in the hierarchy due to the presence of the logic rules in the network as well as a larger number of training examples. Unsurpisingly, we see very poor performance for those techniques with very few training examples, ex: Obfuscation, Reductio ad hitlerum, Straw Man, and Red Herring. Unexpectedly, we see the F1 scores decrease for many of the leaf node propaganda techniques for subtask 2a despite having access to much more training data and getting overall higher F1 scores in aggregate. It appears this lift in F1 is due to the increase in F1 for the higher up nodes in the hierarchy such as Ethos, Pathos, and Ad Hominem as well as a drastic increase in a few leaf node techniques such as Smears and Loaded Language. Additionally, we see several more techniques with a F1 score of 0. This suggests that the images are helpful for classifying high level propaganda techniques and certain leaf techniques but actually confuse the model and lead to worse predictions than the textual model for many of the leaf node techniques.

Class	F1	Precision	Recall	Examples

Response to the reviewer comments for SemEval 2024 Submission #215

Paper title:
Saama Technologies at SemEval-2024 Task 2: Three-module System for NLI4CT Enhanced by LLM-generated Intermediate Labels

Reviewer 1:
There is no specific comment to work out.

Reviewer 2:

- Comment 1: It would be advantageous for the authors to include a more comprehensive review of literature relevant to their system. Specifically, an exploration of the foundational principles behind their approach, comparisons with analogous systems, and their applications across various fields and tasks in preceding studies would enrich the paper's context and depth.

  Response: Following this comment, we added more detailed literature search in the section 2.

- Comment 2: Enhancing the manuscript with highlighted examples of the system in action could significantly improve its readability. Currently, the dense text can obscure key points, making it challenging for readers to identify the central contributions and insights.

  Response: Following this comment, we added working example case as the texts in italic fonts in Figure 1.

- Comment 3: The length of the appendix is notably extensive, which is unprecedented in my experience. A more concise appendix, focused on essential information, would be more accessible and less daunting for readers.

  Response: While we fully understand the concern of the reviewer on the readability of the appendix, we also worry that anyone trying to reproduce our work would be troubled if we exclude any example we used in our prompts. So we added more subsections and explanations in Appendix C to make it more readable.

AmazUtah_NLP at SemEval-2024 Task 9: A MultiChoice Question Answering System for Commonsense Defying Reasoning

Abstract

The SemEval 2024 BRAINTEASER task represents a pioneering venture in Natural Language Processing (NLP) by focusing on lateral thinking, a dimension of cognitive reasoning that is often overlooked in traditional linguistic analyses. This challenge comprises of Sentence Puzzle and Word Puzzle subtasks and aims to test language models' capacity for divergent thinking.

In this paper, we present our approach to the BRAINTEASER task. We employ a holistic strategy by leveraging cutting-edge pre-trained models in multiple choice architecture, and diversify the training data with Sentence and Word Puzzle datasets. To gain further improvement, we fine-tuned the model with synthetic humor/jokes dataset and the RiddleSense dataset which helped augmenting the model's lateral thinking abilities. Empirical results show that our approach achieve 92.5% accuracy in Sentence Puzzle subtask and 80.2% accuracy in Word Puzzle subtask.

1 Introduction

The success of language models has inspired the Natural Language Processing community to attend to tasks that require implicit and complex reasoning. Human reasoning encompasses two types of reasoning: lateral and vertical thinking approaches. Lateral thinking demand out-of-the-box thinking. It is a form of creative reasoning that deviates from traditional, logical processes and has received little attention from NLP community. Vertical thinking on the other hand, relies on logical reasoning, and have been relatively popular in the past few years.

The BRAINTEASER dataset by (Jiang et al., 2023) stands as a crucial benchmark for evaluating question-answering systems. It particularly assesses these systems on their ability for lateral thinking — pushing them to transcend conventional commonsense reasoning towards more innovative and creative approaches to problem-solving. Additionally, as part of this effort to test language models' lateral thinking capabilities, the SemEval 2024 BRAINTEASER task (Jiang et al., 2024), offers a focused challenge derived from the broader dataset, further probing the creative reasoning abilities of these models. This task is crucial because it addresses a gap in Natural Language Processing (NLP) where most tasks focus on linear, logical (vertical) thinking, neglecting the complex, divergent aspects of human cognition represented by lateral thinking. By encompassing two subtasks — Sentence Puzzle and Word Puzzle — BRAINTEASER aims to test a model's ability to go beyond conventional commonsense associations, requiring an understanding of both standard meanings and the ability to reinterpret them in novel ways. This is vital for advancing the field of NLP, as it pushes the boundaries of what artificial intelligence can achieve in terms of mimicking the nuanced and creative aspects of human thought.

Our system adopts a multifaceted strategy for this challenge, centering on the use of advanced pre-trained models like BERT (Devlin et al., 2019) and DeBERTaV3 (He et al., 2023) through HuggingFace's (Wolf et al., 2020) AutoModelForMultipleChoice and AutoModelForSequenceClassification. This approach is enhanced by a diverse training regimen that mixes Sentence and Word Puzzle datasets, ensuring a broad exposure to different types of lateral thinking challenges. Additionally, the model is fine-tuned with a humor/jokes dataset generated by GPT-4 (OpenAI et al., 2024) and the RiddleSense (Lin et al., 2021) dataset, which introduces elements of creativity, unconventional thinking, and complex puzzle-solving. This comprehensive strategy aims to equip the model with enhanced lateral thinking abilities, crucial for tackling the creative and nuanced demands of the BRAINTEASER task in SemEval 2024.

*Both authors contributed equally to this work.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1436–1442

In our participation in the BRAINTEASER task, we discovered that our system, particularly when finetuned with AutoModelForMultipleChoice, outperformed the baseline instruction-tuned systems mentioned in the original paper. This approach demonstrated a significant advantage in handling multiple-choice tasks. However, we faced challenges with AutoModelForSequenceClassification, suggesting an area for improvement. The incorporation of additional synthetic data and open-source dataset like RiddleSense positively influenced our performance. Quantitatively, our system achieved a commendable 6th place in the Sentence Puzzle and 10th in the Word Puzzle, indicating stronger proficiency in sentence-based challenges and room for growth in word-based puzzles.

Our code and data will be available at https://github.com/soumyasmruti/semeval-2024-brainteaser after cleaning and de-anonimization.

2 Background

The task involves two types of brain teasers: Sentence Puzzle and Word Puzzle. In Sentence Puzzle, the input is a sentence-based question that defies commonsense, with multiple-choice answers. For instance, "A man shaves everyday, yet keeps his beard long." The choices include "He is a barber," "He wants to maintain his appearance," and so on. The Word Puzzle involves a word-based teaser, like "What part of London is in France?" with choices focusing on letters in the words (e.g., "The letter N"). The output in both cases is the selection of the correct choice that represents lateral thinking.

In order to counter the potential for Large Language Models (LLMs) memorizing solutions, BRAINTEASER (Jiang et al., 2023) incorporates two novel methods of puzzle generation: semantic and context reconstruction. These techniques generate variations of puzzles that preserve the core challenge of overturning conventional commonsense reasoning without altering the fundamental nature of the puzzles. This approach is aimed at enhancing the robustness of the puzzles against the memorization capabilities of LLMs, ensuring that the puzzles continue to effectively test the models' ability to engage in lateral thinking by challenging ingrained commonsense assumptions. This is to ensure the model is evaluating reasoning ability rather than memorization.

Systems are evaluated based on two accuracy metrics: Instance-based Accuracy, considering each question (original and adversarial) as a separate instance, and Group-based Accuracy, where a system must correctly solve all questions in a group (original and its adversarial versions) to score.

3 Related Work

We can broadly categorize the reasoning landscape of language models into two groups. The first, is 'commonsense reasoning', also known as 'vertical reasoning'. This refers to the ability to make deductions based on everyday knowledge. The second category is 'lateral reasoning'; i.e. a creative problem-solving approach that involves looking at situations from unconventional perspectives.

Researchers have explored various approaches to endow LLMs with commonsense reasoning abilities (Rae et al., 2021). One prominent approach is the use of knowledge graphs, which represent structured knowledge in the form of entities and their relationships (Ilievski et al., 2021). Authors in (Wang et al., 2021) proposed a method for incorporating commonsense knowledge from ConceptNet (Speer et al., 2018) into language models, leading to improved performance on commonsense reasoning tasks.

Another approach involves fine-tuning pretrained LLMs on commonsense reasoning datasets. Authors in this paper (Huang et al., 2019) introduced the COSMOS QA dataset, which consists of multiple-choice questions that require commonsense reasoning. They showed that fine-tuning pretrained LLMs on this dataset can significantly improve their commonsense reasoning capabilities.

Researchers have also investigated the use of prompting techniques to elicit commonsense reasoning from LLMs without explicit fine-tuning. (Zhou et al., 2022) proposed a method called "Conditional Prompt-Tuning" that enables LLMs to perform commonsense reasoning by conditioning on carefully designed prompts. In another work (Wei et al., 2022), chain-of-thought prompting showed how to unlock LLM's reasoning ability via effective prompting techniques.

There hasn't been extensive research on 'lateral thinking' of LLMs. Very recenlty, OlaGPT (Xie et al., 2023) proposed a cognitive architecture framework in which they summarize various methods of human reasoning into Chain-of-Thought (CoT) templates, to maximize the LLMs' reasoning effect.

Overall, while LLMs have shown flashes of non-linear, exploratory thinking on some benchmarks, lateral thinking as a holistic cognitive process remains an open challenge.

4 Methodology

In this section, we describe different methods and approaches we employed in solving the BrainTeaser puzzle.

4.1 Sequence Classification with BERT

In this approach, we enhanced the performance of a sequence classification model through the instruction fine-tuning process. We leveraged the powerful contextual embeddings provided by BERT (Devlin et al., 2019). Our methodology involved initializing the model with pre-trained BERT weights and employing the streamlined 'AutoModelForSequenceClassification' class from the Hugging Face Transformers library, which linearly projects the embedding from the language model encoder to each document into the class logits for that document. We instructed the model with selecting the most appropriate answer from a set of four choices provided alongside a given question. Despite the meticulous fine-tuning process our experimental results revealed sub-optimal performance.

4.2 MultipleChoice QA with BERT and DeBERTa

We leveraged the versatile 'AutoModelForMultipleChoice' architecture from Hugging Face's library, which integrates a pre-trained transformer model with a specialized classification head. This architecture was pivotal in adapting the model for our multiple-choice task, which involved combining both Word Puzzle and Sentence Puzzle datasets to diversify our training data.

To ensure optimal performance, we split our training data into separate training and validation sets. Throughout the training process, we utilized the validation set to fine-tune hyperparameters, ensuring the model's efficacy.

The AutoModelForMultipleChoice architecture comprises a pre-trained base transformer augmented with a classification head. This head, typically consisting of neural network components such as linear layers and activation functions, enables the model to make informed multiple-choice predictions.

Our model initialization involved embedding pre-trained DeBERTa representations, followed by further training on the designated training dataset. This approach facilitated the model's adaptation to our specific task requirements, ultimately enhancing its performance.

4.2.1 Augmenting with RiddleSence and Humor Data

Next, we decided to use two additional data sources to augment our training data. This was with the aim of expanding the diversity of our dataset, enriching it with a wide range of humor styles, scenarios, and perspectives. This augmentation not only increases the robustness and variety of our model but also enhances its adaptability to different contexts. We utilized the public Riddlesense dataset as well as creating humor style data by prompting GPT 4.

The Ridlesense dataset consists of Riddles which are a form of puzzle where a question, often presented in a cryptic or metaphorical manner, challenges the reader to find a clever or unexpected answer.

To create the humor style QA, we prompted GPT 4. Crafting jokes content often requires a touch of ingenuity, an out-of-the-box approach, and a healthy dose of lateral thinking, and GPT-4 allowed us to explore unconventional and amusing angles to questions and answers. It's like having a comedy writer who never runs out of fresh and unexpected punchlines. The details about how the dataset was generate is provided in Appendix A.

We then used the same AutoModelForMultipleChoice architecture and trained the model on augmented training data.

5 Experimental setup

5.1 Datasets Description

The task dataset and additional datasets used in our approaches are detailed in Table 1, with all datasets being in the English language. We did not perform any extra pre-processing on the original training or test data. To generate humor data, we used GPT-4 (OpenAI et al., 2024) using prompt engineering. Regarding the RiddleSense (Lin et al., 2021) dataset, which originally had five labels, we adapted it to a four-label format. This was achieved by reassigning questions with the fifth label as the correct answer to the fourth choice. Consequently, all fifth-choice answers across questions were remapped to their corresponding fourth choices, and all original fifth choices were discarded. Riddlesense and humor datasets, were

	Sentence Puzzle			Word Puzzle		
Dataset	**Train**	**Validation**	**Test**	**Train**	**Validation**	**Test**
Provided	405	102	120	316	80	96
Humor Data GPT4	211	-	-	211	-	-
Riddlesense	4531	-	-	-	-	-

Table 1: Dataset Statistics, '-' means the data was not used for the stage of the task.

selected for their similarity to the original training data, offering commonsense-defying puzzles. For details on the train-validation-test split, please refer to Table 1. We also experimented by adding SWAG (Zellers et al., 2018) and CODAH (Chen et al., 2019) datasets, but found that they reduced overall performance.

5.2 Implementation Details

The raw text was tokenized using a byte-level Byte-Pair Encoding (BPE) vocabulary with 50,257 merge rules, and inputs longer than 1024 tokens were truncated.

Our models were based on the BERT-base and DeBERTaV3 base architectures. The BERT model comprises 12 layers, 768-dimensional embeddings, and 12 attention heads, totaling 117M parameters. The DeBERTaV3 base model features 12 layers and a hidden size of 768, with 110M backbone parameters and a 128K token vocabulary introducing an additional 98M parameters in the embedding layer.

Both models were initialized with pre-trained weights in the AutoModelForMultipleChoice architecture. We conducted a random hyperparameter search, exploring batch sizes of [4, 16, 32] and learning rates of [5e-5, 1e-4, 2e-4]. The configurations yielding the highest validation accuracy were selected for each model size.

We utilized Amazon SageMaker for training, opting for the ml.p3.8xlarge instance for BERT-based approaches and the ml.p3.16xlarge instance for training our DeBERTaV3-based approaches. The training time for the BERT models with the original data was under 20 minutes, while the DeBERTa-based approaches were trained in under one hour. This efficient use of resources enabled us to achieve significant performance improvements with minimal cost and time.

6 Results

In Table 2, we demonstrate the performance of our model, where the provided numbers represent the accuracy for various groups. "Original," "Semantic," and "Context" denote the original question, its semantic reconstruction, and context reconstruction, respectively. These three categories are based on instance-based accuracy, where each question is treated as a separate instance. The score reports the accuracy for both the original question and its adversarial counterparts. "Orig. + Sem." represents group-based accuracy, where the original question and its semantic reconstruction are considered and calculated together. Similarly, "Orig. + Sem. + Con." includes the previous group along with the contextual reconstruction of the original question.

In the table, "AMSC" represents AutoModelForSequenceClassification, and "AMMC" represents AutoModelForMultipleChoice. The models used are bert-base-uncased and microsoft/deberta-v3-base. The notation "train-data-wp+sp" indicates that the training data for this approach includes both sentence puzzle and word puzzle training data provided by the organizers of the task. "Humor" represents the synthetic dataset generated by prompting GPT-4, and "RiddleSense" refers to the open-source RiddleSense dataset (Lin et al., 2021). The scores of human performance and the baseline system, as provided in the original paper (Jiang et al., 2023), are depicted in gray. Scores obtained by our system are shown in black, with the best performances for each task highlighted in bold.

6.1 Subtask A : Sentence Puzzle

Initially, we trained our models only on the provided sentence puzzle dataset but soon realized that combining both the sentence puzzle and word puzzle datasets yielded better validation scores. Consequently, we used the bert-base model with AutoModelForSequenceClassification, achieving an overall accuracy of 50.8%. Given that the dataset is in a multiple-choice format, we experimented

Table 2: SemEval2024 Task 9: BRAINTEASER results table, which shows the performance of different approaches on the test set. Orig. = Original, Sem. = Semantic, Con. = Context, AMSC = AutoModelForSequenceClassification, AMMC = AutoModelForMultipleChoice

with AutoModelForMultipleChoice using the same bert model. This change significantly improved performance, increasing accuracy by 10 points to 60%. Encouraged by this, we opted for the larger DeBERTaV3 model under the AutoModelForMultipleChoice configuration. This model, combined with the original dataset, significantly boosted performance, raising overall accuracy to 83.3%. After incorporating additional datasets containing humor-style questions and the RiddleSense dataset, our best accuracy score reached 92.5%. Our approach ranked 6th among the 31 teams that participated in the task and outperformed the baseline zero shot ChatGPT by almost 50 percentage points.

6.2 Subtask B : Word Puzzle

The word puzzle setup followed almost the same approach as sentence puzzle but during validation process we found the best model was the one which was trained with only original training data from word puzzle dataset and adding humor dataset. Adding RiddleSense data and sentence pzzle data didn't improve the score of the word puzzle in validation process, therefore we didn't submit that output. Our approach for this subtask didn't perform that well when compared to other teams, we ranked 10th among the 23 teams that participated in this task, but outperformed the baseline zero shot ChatGPT by almost 40 percentage points.

7 Conclusion

In this work, we present our novel system designed for the SemEval 2024 BRAINTEASER task, which notably achieved 6th place in the Sentence Puzzle and 10th in the Word Puzzle categories. Our approach leverages advanced pre-trained models like BERT and DeBERTa, optimized through HuggingFace's AutoModelForMultipleChoice and AutoModelForSequenceClassification. This strategy was further enhanced by incorporating a diverse training regimen, blending Sentence and Word Puzzle datasets with a unique humor/jokes dataset and

the RiddleSense dataset. This mix has been instrumental in equipping our model with the lateral thinking capabilities essential for this task. While our system excelled in the Sentence Puzzle, reflecting a stronger grasp in sentence-based lateral thinking, the performance in the Word Puzzle highlighted areas for improvement, particularly in word-based lateral reasoning. The additional challenge posed by adversarial versions of puzzles, involving both Semantic and Context Reconstruction, underscores the complexity of this task. Our system's performance underscores the efficacy of our training approach in enhancing lateral thinking in language models, a significant step forward in NLP. Future work will focus on refining our approach for word-based puzzles and further enhancing the model's ability to navigate complex, creative reasoning paths, thereby advancing the field's understanding of AI's potential in mimicking nuanced aspects of human cognition.

A Humor Dataset Details

We used the following prompts to generate Jokes or Humor style dataset. We experimented with multiple prompts and gather all the output in a json file and analyzed them manually.

PROMPT 1 - Could you create a dataset for me that includes humor-styled questions, each with multiple choices and an answer? The dataset should be in JSON format.

PROMPT 2 - Could you create a dataset of 40 jokes for me in JSON format? Each joke should include four options and the correct answer.

PROMPT 3 - Could you generate an additional 20 jokes with multiple choices and an answer? Please ensure there are no duplicates and that none of them are the same as those previously generated.

We initially prompted GPT 4 to generate 200 questions at once but that didn't go well. The output contained duplicate questions after 15 / 16 unique ones. Basically, the model kept repeating itself. So we mostly used PROMPT 3 multiple times to generate high quality data. Before adding each we checked for duplicates again manually. Provided below are some of the jokes generated by the prompt.

> "joke": "Why did the bicycle fall over?", "options": ["A. Because it was two-tired.", "B. It had a flat.", "C. It was unbalanced.", "D. It slipped."], "answer": "A"
>
> "joke": "What's orange and sounds like a parrot?", "options": ["A. A carrot", "B. An orange bird", "C. A tangerine", "D. A flamingo"], "answer": "A" ,

IITK at SemEval-2024 Task 1: Contrastive Learning and Autoencoders for Semantic Textual Relatedness in Multilingual Texts

ashutoshm@cse.iitk.ac.in

Abstract

This paper describes our system developed for the SemEval-2024 Task 1: Semantic Textual Relatedness. The challenge is focused on automatically detecting the degree of relatedness between pairs of sentences for 14 languages including both high and low-resource Asian and African languages. Our team participated in two subtasks consisting of Track A: supervised and Track B: unsupervised. This paper focuses on a BERT-based contrastive learning and similarity metric based approach primarily for the supervised track while exploring autoencoders for the unsupervised track. It also aims on the creation of a bigram relatedness corpus using negative sampling strategy, thereby producing refined word embeddings.

1 Introduction

The semantic relatedness between texts in a language is fundamental to understanding meaning (Halliday and Hasan, 2014). Automatically detecting relatedness plays an essential role in evaluating sentence representations, question answering, and summarization (Abdalla et al., 2023). The fundamental difference between semantic similarity and relatedness is that semantic similarity only considers paraphrase or entailment relationships. In contrast, relatedness accounts for all commonalities between two sentences, e.g., topical, temporal, thematic, contextual, syntactic, etc. (Abdalla et al., 2023). As highlighted in Table 1, Sentences 1 and 2 are semantically similar, but sentences 2 and 3 would have low semantic similarity but high semantic relatedness.

In Track A (Task 1) of the Semantic Textual Relatedness (STR) task (Ousidhoum et al., 2024b), we are expected to calculate the degree of semantic relatedness between pairs of sentences in 14 different languages covering both African and Asian languages. Each pair of sentences is assigned a relatedness score in the range of 0 and 1. The major challenge lies in the efficient development of a metric to facilitate the calculation of the relatedness score between the sentence pairs and harnessing the structure of multiple languages to create an efficient model (Ousidhoum et al., 2024b). Our system is based on a contrastive learning approach, utilizing a composite lexical similarity-based measure for relatedness score calculation in the supervised task. Additionally, it involved the use of transformer autoencoders for the unsupervised task. We employed Distill-RoBERTa (Sanh et al., 2020) as the model for this purpose. Several other strategies were also tested within this framework, such as employing a Siamese architecture and retraining BERT with vocabulary expansion to incorporate tokens from additional low-resource languages. For the unsupervised task, the base model used to construct the denoising autoencoder was BERT-uncased (Devlin et al., 2019). The major challenge in this task was the devising and implementing data pre-processing schemes for diverse languages and various training methodologies. A number of experiments were conducted to come up with a unified metric for semantic relatedness calculations, which resulted in relatively better performances in various low-resource languages.[1]

#	Sentence
1	The mouse was chased by the cat in the yard.
2	The cat chased the mouse around the garden.
3	The dog barked loudly as the mouse scurried away.

Table 1: Difference between Similarity and Relatedness

2 Background

There have been several attempts to define and distinguish semantic relatedness from semantic simi-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1443–1448

larity. The basic metric used in these experiments is Spearman Rank Correlation. The correlation coefficient is calculated between the correctly annotated scores for the set of pairs of sentences and the scores returned by the models. Essentially, this removes the absolute values of the scores and focuses on the relative values and, hence, the relative relatedness between the pairs of sentences.

Initial experiments explored frequency measures such as lexical overlap (Shirude et al., 2021), related words, and related subjects and objects, leading to high Spearman correlations of 0.82 and 0.83 for BERTbase (mean) and RoBERTa-base (mean) on the CompLex dataset (Shardlow et al., 2020). Despite marginal improvements over a lexical overlap baseline, unsupervised models offer limited enhancement.

Normalized Google Distance(NGD) has been used as a novel metric for measuring semantic relatedness between words or concepts (Lopes and Moura, 2019), utilizing Google search result counts to quantify relatedness. NGD (Cilibrasi and Vitanyi, 2007) normalized counts considering the overall corpus size and the co-occurrence of terms in web pages.

Various approaches have been proposed for the Arabic language (Al Sulaiman et al., 2022) like automatic machine translation to translate English Semantic Textual Similarity (STS) data into Arabic, interleaving English STS data with Arabic BERT models, and employing knowledge distillation-based models to fine-tune them using a translated dataset. Multilingual knowledge distillation (Reimers and Gurevych, 2019) techniques have been proposed where a student model, $\hat{M}$, learns from a teacher model, M, on source language sentences and their translations by minimizing the mean-squared loss function. Focusing on low-resource Indian languages, a range of SBERT models has been introduced for ten popular Indian languages. IndicSBERT (Deode et al., 2023) utilized a two-step training method, fine-tuning models using the NLI dataset followed by Semantic Textual Similarity benchmarking (STSb), resulting in substantial improvements in embedding similarity scores and cross-lingual performance.

3 Dataset Description

The dataset (Ousidhoum et al., 2024a) consists of a total of 14 languages, namely Afrikaans, Algerian Arabic, Amharic, English, Hausa, Indonesian, Hindi, Kinyarwanda, Marathi, Modern Standard Arabic, Moroccan Arabic, Punjabi, Spanish, and Telugu. Every language consists of pairs of sentences with scores representing the degree of semantic textual relatedness between 0 and 1. The scores have been assigned to sentence pairs through a comparative annotation process (Ousidhoum et al., 2024a).

At the preliminary level, dataset length is the only non-semantic variable in these datasets. To assess semantic relatedness, it is crucial to mitigate these biases. Correlation coefficients between sentence lengths and scores fall in the range $-0.13 < \rho < 0.15$; hence, there is no discernible correlation between sentence lengths and scores, suggesting a well-distributed dataset suitable for training.

4 System Overview

Our baseline system of scoring a pair of sentences uses Jaccard Similarity, a lexical metric that calculates the number of token intersections over total tokens in both sentences. Our approach involves using Contrastive learning for the supervised part and auto-encoders for the unsupervised part. All these methods are discussed below, and our model supervised architecture is shown in Figure 1.

4.1 SimCSE

SimCSE (Gao et al., 2022), or Simple Contrastive Learning, is helpful in supervised and unsupervised learning, particularly in information retrieval, text clustering, and semantic tasks. This approach primarily uses Natural Language Inference (NLI) to create positive and negative sentence samples. It works by inducing slight variation in its representations through dropouts. The following step lies in aligning related sentences close in the embedding space and maximizing distances to unrelated sentences in each batch of data. For a supervised setting, it classifies positive samples as entailment pairs, while negative samples are derived from contradiction pairs. The training proceeds via minimizing the loss function: $-\log\left(\frac{e^{\frac{sim(h,h^+)}{\tau}}}{e^{\frac{sim(h,h^+)}{\tau}}+e^{\frac{sim(h,h^-)}{\tau}}}\right)$, where, h represents the current sentence and h^+ and h^- denotes the positive and negative samples respectively with τ being the temperature hyperparameter which controls the sensitivity and learning dynamics. The τ is mainly adjusted based on validation set perfor-

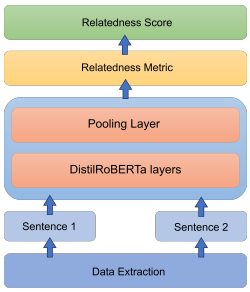

Figure 1: SIMCSE based approach for Track A

mance.

4.2 TSDAE

TSDAE (Wang et al., 2021) or Transformer Denoising through Auto Encoders is an elegant approach aimed at improving the quality of sentence embeddings through self-supervised learning. This method mainly uses sentence embeddings without labels, relying solely on the data structure to initiate learning. The first step lies in corrupting the existing tokens via methods like deleting random tokens, masking tokens, etc., and passing these modified representations through an encoder layer. The encoder layer outputs a dense latent representation, capturing the essence of the data in high-dimensional space. The encoded representations are then passed to a decoder, which attempts to reconstruct the original, uncorrupted sentences from the encoded representations. The decoder is typically another transformer model that has been trained to generate text based on the encoded embeddings. The main objective lies in minimizing the distance between the corrupted and reconstructed sentence representations through cross-entropy loss.

4.3 Training Scheme

For the supervised track, we used Distil-RoBERTa (Sanh et al., 2020) as the base model, which produced a vector representation for every word in the input sentence, resulting in a matrix of token embeddings. The embeddings were then fed to a pooling layer for the production of sentence-level embeddings, which finally proved to be useful for semantics-relatedness tasks. We used mean pooling because there were no dedicated [CLS] token representations for sequence classification tasks. As for the metrics, our approach was involved in designing a custom relatedness metric by combining standard distance-based metrics like cosine similarity, Mahalanobis distance, Euclidean and Manhattan distances, and lexical overlap-based metrics like Jaccard and Dice coefficients. For each pair of sentence embeddings in the dataset, we calculated these metrics. Not only did we calculate these metrics using the original embeddings, but we also calculated them after transforming the embeddings by raising them to higher powers (e.g., squaring them). These calculated metrics were then collected into a dataset, with each column named according to the metric and the power applied to the embeddings. For example, the column "Cosine Distance: 2" depicted the cosine distances between pairs of sentence embeddings after both embeddings in each pair have been squared. The dataset, therefore, finally had rows where each row was a 42-element vector. This vector encompassed the calculated metrics across different powers for the sentence embeddings. These enhanced sentence embeddings, with metrics covering higher orders, were then used to train the RoBERTa model. The goal was to produce scores that indicate how related different sentences are across various languages. The libraries used are in Table 5.

5 Experiments

5.1 Supervised Task

Static Approaches: The baseline models, Jaccard Coefficient, Dice Coefficient, and similar coefficients after removing stopwords were calculated to arrive at reliable baseline metrics to build upon.
Multilingual BERT: Since the best-performing model for English involved BERT, an attempt was made to train multilingual BERT: mBERT (Pires et al., 2019), by extending the vocabulary to allocate the tokens of various low-resource languages like Amharic, Hausa, Algerian Arabic, Afrikaans, Indonesian etc. The approach included generation of the vocabulary of each of the languages from the training data and then calling the pre-trained mBERT model and tokenizer. The trained tokenizer was extended to include the new tokens generated from the vocab of the corresponding low resource languages. A trainable feed-forward network was added with the corresponding dropout. The loss metric used was mean squared error loss on both the training validation data and the Spearman rank correlation were calculated at the end of each validation epoch. Finally, finetuning multilingual BERT yielded considerably good results and this avenue was found suitable for exploration, especially for the cross-lingual task.

The relatedness metric was approximated using a

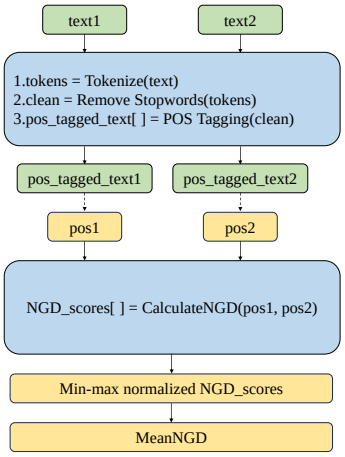

Figure 2: NGD Calculation flowchart

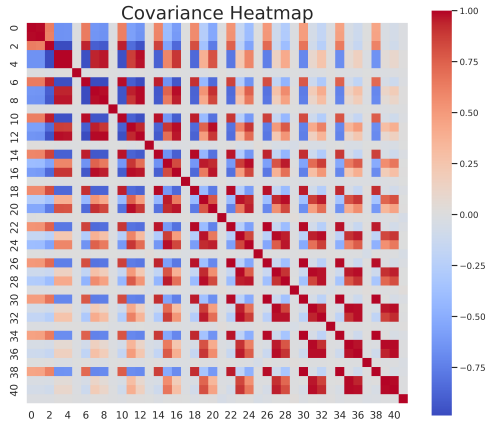

Figure 3: Covariance Matrix between all 42 metrics

trainable feed forward layer by experimenting with the number of hidden layers and activations. It was observed that having 3 hidden layers resulted in fairly good relatedness scores between pairs of sentences in almost all the languages. It was observed that GeLU performed better than ReLU activation primarily due to its steep curve around 0 which helps to model complex functions better. The combination of learning rate and weight decay also resulted in a stable training curve, avoiding sub-optimal loss convergence. Thus these specific hyperparameters were optimal for mBERT retraining in terms of resource constraints and performance. The corresponding hyperparameters of the best performing model is presented in App. Table 4.

Contrastive Learning: The details of the system are described in §4.1. Experiments were run on the number of epochs during training.

Combined Similarity Metric: Normalized Google Distance (Cilibrasi and Vitanyi, 2007) calculates a relatedness metric for two input sentences. It was proposed as a strong metric for relatedness by Lopes and Moura (2019). It starts by tokenizing and removing stop words from both sentences, followed by part-of-speech tagging. Then, it calculates NGD values for pairs of words with the same part of speech in both sentences. The NGD scores are normalized and averaged to compute the overall NGD score, representing the degree of relatedness between the two sentences. The flowchart for the process is shown in Figure 2. Cosine similarity is the standard metric used to find similarity between two sentence embeddings, which gives a 0.81-0.82 baseline score for this problem.However, similar or better results can be seen when other distance metrics like Mahalanobis Distance(0.82) and Euclidean Distance(0.83) are observed between the embeddings. Further, augmenting this with more direct relatedness metrics like NGD is promising for better results. A simple supervised deterministic regression model can be implemented to combine these metrics. Furthermore, to explore the importance of each of these metrics, a simple covariance matrix (Figure 3) can show how the vector metrics on higher element-wise-powered vectors hold information not caught directly at the lower powers of the vectors.

To implement this supervised regression model, a simple 3-layered feed-forward neural network (with neurons **[25]+[50]+[25]**) is trained with. The layers are chosen to construct a lightweight network. Each data feature $\mathbf{x}$ was composed as:

$$\mathbf{x_i} = \{S(v_{i,1}, v_{i,2}), S(v_{i,1}^2, v_{i,2}^2), \ldots, S(v_{i,1}^{10}, v_{i,2}^{10}), J(v_{i,1}, v_{i,2}), D(v_{i,1}, v_{i,2})\}$$

where $v^i = (v_1^i, v_2^i, \ldots v_n^i)$

$S(a,b) = \{C(a,b), E(a,b), M_1(a,b), M_2(a,b)\}$

$C(a,b) =$ Cosine Similarity between a and b

$E(a,b) =$ Euclidean Distance between a and b

$M_1(a,b) =$ Manhattan Distance between a and b

$M_2(a,b) =$ Mahalanobis Distance between a and b

$J(a,b) =$ Jaccard similarity between a and b

$D(a,b) =$ Dice similarity between a and b

Even though this metric did not show promise in English, this was helpful in some low-resource languages, and hence was part of our system design for some languages.

5.2 Unsupervised Task

Bigram Corpus Creation and Training Process: We developed a pipeline to generate a bigram dataset from any language corpus. A three-part tuple was created for every bigram found to note how

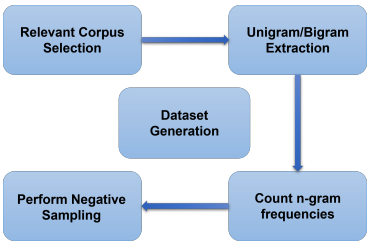

Figure 4: Bigram Corpus Creation Flowchart

often it appeared within the same sentence, paragraph, and entire document. This process aimed to quantify the connections between words by tracking their repeated sentence occurrences. Our main objective was to use these co-occurrence frequencies to produce word embeddings. We planned to enhance our method by applying hierarchical clustering, which helps identify word similarities and relationships. Moreover, we decided to use a 1:1 **negative sampling strategy** to refine the embeddings further. These embeddings were intended for computing relatedness scores, leveraging bigrams derived from sentence pairs and their lexical overlaps. Figure 4 presents a diagram illustrating this process.

TSDAE: A pipeline was developed to implement TSDAE (refer §4.2) on the languages. The number of epochs was changed and experimented on for various languages. Overall, around 20-25 epochs resulted in good results. No weight decay was implemented, and a learning rate of 3e-5 was used.

6 Results

The results for the supervised and unsupervised are mentioned in Table 2 and Table 3. The leaderboard highlights that the chosen contrastive learning approach did not perform well, especially for some languages where it fell significantly below the baseline scores provided by their system, such as Hausa, Moroccan Arabic, Telugu, etc. Some possible shortcomings of this approach might be that the negative samples were not distinguishable enough from the positive samples, which might also be attributed to the poor performance of the transformer models on languages, especially with complex lexical structures. The other issue might be the traditional loss function, which might not be good enough to capture the degree of semantic relationships between sentences. For the unsupervised track, our approach is performing reasonably well for most languages, which is indicated by the correlation score being more significant than the baseline provided.

Language	Rank	Score	Baseline Score
Amharic	17	0.55	0.85
Hausa	21	0.22	0.69
Kinyarwanda	21	0.14	0.72
Moroccan Arabic	22	0.36	0.77
Spanish	23	0.59	0.7
Algerian Arabic	23	0.34	0.6
Marathi	24	0.67	0.88
Telugu	25	0.28	0.82
English	31	0.81	0.83

Table 2: Evaluation Phase Results in Codalab Leaderboard for Track A

Language	Rank	Score	Baseline Score
Algerian Arabic	2	0.49	0.43
English	4	0.81	0.68
Amharic	6	0.07	0.72
Hausa	6	0.38	0.16
Moroccan Arabic	6	0.36	0.27

Table 3: Evaluation Phase Results in Codalab Leaderboard for Track B

7 Error Analysis

After the evaluation phase, we were provided with the labels for the evaluation data. On experimenting with the semantic relatedness scores for some languages, mainly **Hausa** and **Kinyarwanda**, we found out that our system was not performing well enough on these languages even after subsequent training and hyperparameter optimizations. The issue would be primarily attributed to the complex lexical variations and grammar rules of these languages. As for the unsupervised track, generating a bigram corpus for the case of **Amharic** seemed difficult due to its language structure.

8 Conclusion

By utilizing various approaches like contrastive learning, autoencoders, a custom relatedness metric incorporating all of the available lexical similarity metrics, we have developed a system capable of evaluating the degree of semantic relatedness between pairs of sentences in diverse high and low resource languages. In future, we will study the properties of each low resource language to find out where the models are performing poorly than relying too much on pre-trained models. This would give much clearer insights into semantics of each language thus improving the overall efficiency and performance of our system.

Compos Mentis at SemEval2024 Task6: A Multi-Faceted Role-based Large Language Model Ensemble to Detect Hallucination

Souvik Das , Rohini K. Srihari
{souvikda, rohini}@buffalo.edu
Department of Computer Science and Engineering, University at Buffalo, NY.

Abstract

Hallucinations in large language models (LLMs), where they generate fluent but factually incorrect outputs, pose challenges for applications requiring strict truthfulness. This work proposes a multi-faceted approach to detect such hallucinations across various language tasks. We leverage automatic data annotation using a proprietary LLM, fine-tuning of the Mistral-7B-instruct-v0.2 model on annotated and benchmark data, role-based and rationale-based prompting strategies, and an ensemble method combining different model outputs through majority voting. This comprehensive framework aims to improve the robustness and reliability of hallucination detection for LLM generations. Code and data[1]

1 Introduction

The modern natural language generation (NLG) (OpenAI et al., 2023; Touvron et al., 2023) landscape faces two interconnected challenges: firstly, current neural models have a tendency to produce fluent yet inaccurate outputs, and secondly, our evaluation metrics are better suited for assessing fluency rather than correctness(Bang et al., 2023; Guerreiro et al., 2023). This phenomenon, known as "hallucination," (Ji et al., 2023) where neural networks generate plausible-sounding but factually incorrect outputs, is a significant hurdle, especially for NLG applications that require strict adherence to correctness. For instance, in machine translation(Lee et al., 2019), producing a fluent translation that deviates from the source text's meaning renders the entire translation pipeline unreliable. This issue may arise as LLMs are trained on vast amounts of data from the internet, which can contain inaccuracies, biases, and false information. Also, it may arise due improper representations learned during training even if good quality data is used. As a result, LLMs can sometimes hallucinate or fabricate details, especially when prompted to discuss topics outside their training data or make inferences beyond their capabilities.

Hallucination detection (Liu et al., 2022), also known as factual verification or truthfulness evaluation, identifies and mitigates these hallucinations in the outputs of LLMs. This is an active area of research and development, as it is crucial for ensuring the reliability and trustworthiness of LLM-generated content, particularly in high-stakes domains such as healthcare, finance, and legal applications. In this task, the primary focus will be to classify whether a generation is hallucinated.

This work proposes a multi-faceted approach to detecting hallucinations in large language models' outputs. We employ automatic data annotation using a proprietary LLM (Claude 2.1[2]) to label examples from the provided training set as hallucinated or not. Then we fine-tune the Mistral-7B-instruct-v0.2[3] model on this annotated data as well as the HaluEval benchmark (Li et al., 2023) to create two fine-tuned models. To improve performance, we use role-based prompting that casts the task in specific contexts like fact-checking. We also leverage rationale-based prompting, asking the LLM to justify its hallucination label. Finally, an ensemble method combines outputs from the fine-tuned Mistral models, Claude 2.1, and different prompting strategies via majority voting. This comprehensive approach aims to enhance the robustness and reliability of hallucination detection across various language tasks.

2 Task Details

This shared task (Mickus et al., 2024) aims to foster the growing interest within the community in ad-

[2] https://www.anthropic.com/news/claude-2

[3] https://huggingface.co/mistralai/Mistral-7B-Instruct-v0.2

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1449–1454
June 20-21, 2024

dressing this issue. Participants are tasked with performing binary classification to identify instances of fluent overgeneration hallucinations in two different setups: a model-aware track and a model-agnostic track. Essentially, participants must detect grammatically sound outputs that contain incorrect or unsupported semantic information, inconsistent with the source input, with or without having access to the model that produced the output.

To facilitate this task, participants are provided with a collection of checkpoints, inputs, references, and outputs from systems covering three different NLG tasks: definition modeling (DM), machine translation (MT), and paraphrase generation (PG). These systems will be trained with varying degrees of accuracy. The validation and test sets will include binary annotations from at least five annotators, with a majority vote determining the gold label.

2.1 Data

The data split is shown in Table 1.

Task	Validation	Test
model agnostic	500	1500
model aware	500	1500

Table 1: Data-split statistics.

Each data split file is formatted as a JSON list. Each element in this list corresponds to a data point as shown:

```
{
        "hyp": "(uncountable) The study of trees.",
        "ref": "tgt",
        "src": "It is now generally supposed that the
forbidden fruit was a kind of citrus , but certain facts
connected with  arborolatry  seem to me to disprove this
opinion .",
        "tgt": "The worship of trees.",
        "model": "",
        "task": "DM",
        "labels": [
            "Hallucination",
            "Hallucination",
            "Hallucination"
        ],
        "label": "Hallucination",
        "p(Hallucination)": 1.0
}
```

Each data instance contains the following key elements: a task (task) indicating the language model's objective; a source (src) input; a target reference (tgt); a hypothesis (hyp) which is the model's actual output; a set of per annotator hallucination labels (labels); a majority-based gold hallucination label (label); and a probability score (p(Hallucination)) representing the proportion of annotators who labeled the instance as hallucinated.

2.2 Evaluation Protocol

Submissions are evaluated using two criteria:

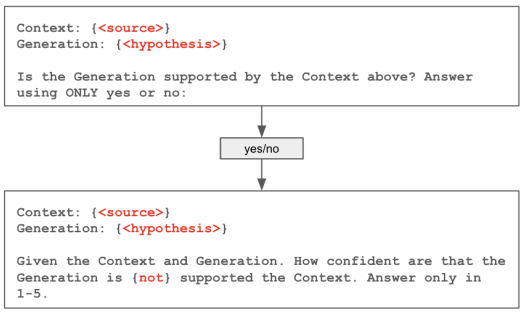
1. **Accuracy**: the system accuracy reached on the binary classification.

2. ρ: the Spearman correlation of the systems' output probabilities with the proportion of the annotators marking the item as overgenerating.

3 System Description

3.1 Automatic Data Annotation

We automatically annotate the unlabeled training data provided by the organizers. We use a strong proprietary Large Language Model(LLM) Claude 2.1 to annotate the data automatically. Since, annotations from Claude 2.1 might not be fully reliable we use a confidence-based measure to select only those training examples where the LLM is confident enough. We use the following prompts:



First, we prompt the LLM to get the hallucination label. Then we again prompt the LLM to do a retrospect on the decision it has made by asking it how confident it is with the decision. We filter out all the examples with a score less than 5.

3.2 Fine-tuning Mistral-7B-instruct-v0.2

We train two fine-tuned versions of Mistral-7B-instruct-v0.2 for this task:
Fine-tuned on our data: We split our automatically annotated dataset in 8:1:1 split for training, validation and testing. We adopt a generative approach for classification where the instruction was fed in this fashion: `[INST]`*prompt*`[/INST]`, where the *prompt* is the same as it is used during annotation phase. The goal is to generate the hallucination label. The test F1-score was 82.03%. We name this model as Mistral-7B-instruct-v0.2-halu-internal.
Fine-tuned on HaluEval dataset: Hallucination Evaluation benchmark for Large Language Models (HaluEval), a large collection of generated and

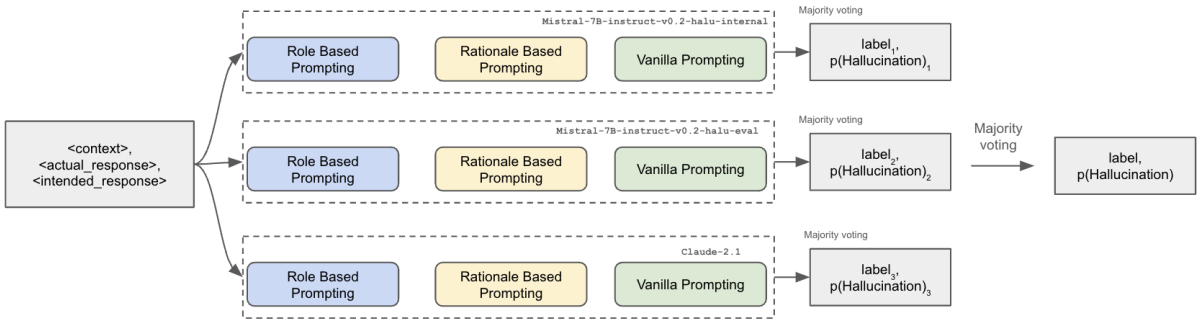


Figure 1: Our overall ensemble-based inference pipeline. We use majority voting at the model level and overall pipeline level to determine the final hallucination label.

human-annotated hallucinated samples for evaluating the performance of LLMs in recognizing hallucination HaluEval dataset contains $30,000$ hallucinated samples with $10,000$ examples for each task of QA, dialogue, and summarization. Here also, we adopt a generative approach for classification with the same instruction sequence as used during fine-tuning using our data. The test F1-score was 77.95%. We name this model as Mistral-7B-instruct-v0.2-halu-eval.

Hyperparameters: We use the original weights of Mistral-7B-instruct-v0.2 released by Mistral AI. We use QLoRA(Dettmers et al., 2023) for parameter-efficient fine-tuning. We set the maximum length of the input sequence to 512 and the rank k and α in QLoRA to 16 and 8, respectively. We use the `bitsandbytes` library to initialize the QLoRA parameters. We use an 8-bit Paged Adam optimizer to update QLoRA parameters with a batch size of 64 and learning rates of 1e-7. The trainable QLoRA parameters ($\sim$ 19.5M) are fine-tuned on 2 NVIDIA A5000-24GB GPUs. All the hyperparameter are tuned using the provided trial data, k and α were varied in the range of [4,16] with a step of 4, batch size was varied in the range of [32,72] with a step of 16, and the learning rate was varied from 1e-8 to 1e-7, the best performing hyperparameters are reported.

3.3 Role Based Prompting

Since we are dealing with multiple tasks, the same prompt might not be suitable for all the tasks during inference. We create task-specific role-based prompt for each task using the following prompt template:

```
Given the <intended_response>, <context> and
<actual_response> :

<intended_response>: {tgt}.
<context>: {src}.
<actual_response>: {hyp}.

{ROLE}

State whether the <actual_response> supports <context> and
<intended_response>. Answer using ONLY yes or no:
```

`<intended_response>` is the golden response, `<actual_response>` is the actually generated response. Here the inference-time roles will be based on the following Table:

	Role
Definition Modelling	Imagine yourself as a fact-checker; your job is to check whether <actual_response>is the definition of <context>.
Paraphrase Generation	Imagine yourself as a paraphrase-checker; your job is to check whether <actual_response> is an actual paraphrase of <context>. That means the meaning of <actual_response> should be the same as <context>, however <actual_response> will contain lesser words than <context>.
Machine Translation	Imagine yourself as a translation-checker; your job is to check whether <actual_response> is an actual translation of <context>.

Table 2: Role Definitions.

3.4 Rationale Based Prompting

We notice that when LLMs are prompted to produce rationale for its decision it often elicits more truthful response. Due to this observation we prompt the LLM to generate the explanation classifying the generation is hallucinated or not. The prompt is as follows:

```
Given the <intended_response>, <context> and
<actual_response> :

<intended_response>: {tgt}.
<context>: {src}.
<actual_response>: {hyp}.

{ROLE}

Come up with an explanation of whether the <actual_response>
supports <context> and <intended_response>.
Using the explanation, choose a final answer between yes or
no.
The final answer should be in this format:
{"explanation":<explanation>, "final_answer":<yes or no>}
```

3.5 Inference Ensemble

We combine all our prompting strategies to simulate an annotator for each sample. Also, we create an ensemble of three models: (1) Mistral-7B-instruct-v0.2-halu-internal (2) Mistral-7B-instruct-v0.2-halu-eval (3) Claude 2.1. Along with the role-based and rationale-based prompting we also incorporate a vanilla prompting where we just ask the LLM to come up with the hallucination label without assuming any role or generating a rationale, like this:

```
Given the <intended_response>, <context> and
<actual_response> :

<intended_response>: {tgt}.
<context>: {src}.
<actual_response>: {hyp}.

State whether the <actual_response> supports <context> and
<intended_response>. Answer using ONLY yes or no:
```

For each model pipeline, we get 3 hallucination labels; the pipeline label is the most common label out of 3. The hallucination probability score is determined by this equation: $p(\text{Hallucination}) = \frac{\#\text{halluciation\_labels}}{3}$. We get the hallucination label and $p(\text{Hallucination})$ for the three pipelines, and again we do a majority voting to get the final hallucination label. The final $p(\text{Hallucination})$ is set to the maximum probability of the selected hallucination label across the pipeline. We use greedy decoding for the Mistral-based models with a temperature of 0.8. Average cost of running Claude APIs for each is about 7$ for validation set and 16$ for test set. For Claude inference we use a temperature of 0.9.

4 Results

Table 3 and 4 show the results for model-aware and model-agnostic hallucination detection tasks for validation split. For both cases, we notice increased performance with rationale-based prompts for all the models. Subsequently, our ensemble-based pipeline boosts the performance even more. On the other hand, the performance of the HaluEval fine-tuned dataset is superior to our annotated dataset because there is a large possibility of noise getting introduced during our annotation process. Our annotation process uses verbalized model confidence as a proxy for data filtration; if the model is not calibrated correctly, this might lead to a faulty filtration process.

Task	Configuration	Accuracy	Rho
model agnostic	3-model-ensemble	0.738	0.595
model aware	3-model-ensemble	0.756	0.566

Table 5: Evaluation results.

During evaluation, we ran our best-performing pipeline i.e., the ensemble of 3 models. A performance similar to the validation set is observed here. Our team ranked 33 out of 48 for model agnostic sub-task and 29 out of 45 for model aware sub-task.

5 Conclusion

This work proposes a multi-faceted approach for detecting hallucinations in large language model outputs across various natural language tasks. It employs automatic data annotation, fine-tuning state-of-the-art models on annotated data and benchmarks, role-based and rationale-based prompting strategies, and an ensemble method combining multiple model outputs. The ensemble pipeline achieves promising results on model-agnostic and model-aware evaluation settings for hallucination detection. While challenges remain, this comprehensive framework highlights the potential of carefully designed prompting, model fine-tuning, and ensembling techniques to enhance the robustness and reliability of factual verification in language model generations, paving the way for developing more trustworthy natural language generation systems.

Abstract

This study describes the model design of the NYCU-NLP system for the SemEval-2024 Task 2 that focuses on natural language inference for clinical trials. We aggregate several large language models to determine the inference relation (i.e., entailment or contradiction) between clinical trial reports and statements that may be manipulated with designed interventions to investigate the faithfulness and consistency of the developed models. First, we use ChatGPT v3.5 to augment original statements in training data and then fine-tune the SOLAR model with all augmented data. During the testing inference phase, we fine-tune the OpenChat model to reduce the influence of interventions and fed a cleaned statement into the fine-tuned SOLAR model for label prediction. Our submission produced a faithfulness score of 0.9236, ranking second of 32 participating teams, and ranked first for consistency with a score of 0.8092.

1 Introduction

Biomedical Natural Language Inference (NLI) seeks to determine whether a proposed statement is entailment, contradiction, or neutral according to a given clinical trial. The MEDIQA-2019 shared task (Ben Abacha et al., 2019) covered an NLI subtask in the medical domain, including clinical sentences from the MIMIC-III database (Romanov and Shivade, 2018). In this shared task, most systems were built on the BERT model (Devlin et al., 2019) and MT-DNN (Liu et al., 2019). The BERT-BiLSTM-Attention model (Lee et al., 2019) was proposed for medical text inference. The DoubleTransfer model (Xu et al., 2019) was presented to use a multi-source transfer learning approach to acquire knowledge from MT-DNN and Sci-BERT (Beltagy et al., 2019). In addition, since the evaluation data is sourced from the clinical domain, variations of BERT such as BioBERT (Lee et al., 2020) and ClinicalBERT (Huang et al., 2020) were used frequently.

SemEval-2023 Task 7 (Jullien et al., 2023b) (called NLI4CT) focused on multi-evidence natural language inference for Clinical Trial Reports (CTR) (Jullien et al., 2023a). Participants should determine the inference relation (i.e., entailment or contradiction) between CTR-statements in the NLI subtask. The sentence-level and token-level encodings were exploited in a multi-granularity inference network (MGNet) (Zhou et al., 2023). The DeBERTa-v3 model (He et al., 2023) was fine-tuned on the prompted input sentences to discriminate the inference relation between the statement and clinical trials (Wang et al., 2023b). The BioLinkBERT transformer (Yasunaga et al., 2022) was used with a soft voting ensemble mechanism to enhance the NLI performance (Chen et al., 2023). The Flan-T5 model (Chung et al., 2022) was fine-tuned with instructions to explore its capabilities for multi-evidence NLI (Kanakarajan and Sankarasubbu, 2023).

Following the success of the NLI4CT-2023 task, SemEval-2024 Task 2 (Jullien et al., 2024) re-grounds this task in interventional and causal analyses of NLI models (Yu et al., 2022), with a contrast set containing the designed interventions and expected labels to investigate the faithfulness and consistency of the developed models. This task is based on the same collection of breast cancer CTRs (Jullien et al., 2023a). The statements in the training set are identical to those in the previous task, but perform a variety of interventions to statements on the development and test sets, making claims about a single CTR or comparing

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1455–1462

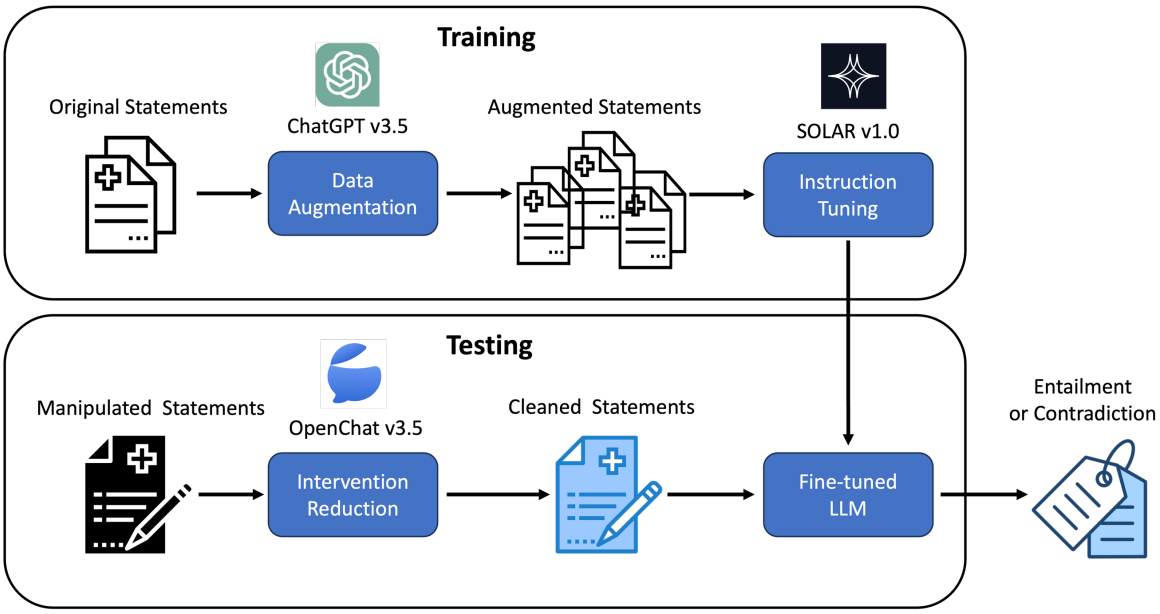

Figure 1: Our NYCU-NLP system architecture for the NLI4CT-2024 task.

two CTRs while either preserving or inversing the entailment relations. For the NLI4CT-2024 task, given a statement with/without interventions, the participating system should determine the inference relation as either entailment or contradiction.

This paper describes the **NYCU-NLP** (**N**ational **Y**ang Ming **C**hiao Tung **U**niversity, **N**atural **L**anguage **P**rocessing Lab) system for the NLI4CT-2024 task. Given the promising results obtained by Large Language Models (LLM) for various NLP tasks, we aggregate several LLMs in biomedical NLI for clinical trials. We use ChatGPT (OpenAI, 2023) to augment original statements and then fine-tune the SOLAR model (Kim et al., 2023) with instructions designed for the NLI task. Since a statement may be manipulated during testing inference phase, we first fine-tune the OpenChat model (Wang et al., 2023a) to reduce the influence of interventions. Finally, a cleaned statement along with CTRs is fed into the fine-tuned SOLAR model for label prediction (i.e., entailment or contradiction). Evaluation results show that our proposed NYCU-NLP system had a faithfulness score of 0.9236, ranking second among 32 participating teams, and ranked first for consistency with a score of 0.8092.

The rest of this paper is organized as follows. Section 2 describes the NYCU-NLP system for the NLI4CT-2024 task. Section 3 presents the results and performance comparisons. Conclusions are finally drawn in Section 4.

2 The NYCU-NLP System

Fig. 1 shows our NYCU-NLP system architecture for the NLI4CT-2024 task. Our system is composed of four main parts: 1) ChatGPT (OpenAI, 2023) for data augmentation; 2) Instruction tuning on SOLAR (Kim et al., 2023); 3) OpenChat (Wang et al., 2023a) for intervention reduction; and 4) Fine-tuned LLM for label prediction.

2.1 Data Augmentation

We use ChatGPT (OpenAI, 2023) to augment the training data for intervention adaptation. Fig. 2 shows the prompts inputted to the ChatGPT API (gpt-3.5-turbo-1106) and example outputs. We provide a system prompt to set up ChatGPT as a writer, skilled in rewriting sentences. For the first prompt, we obtain three rewritten statements without any restrictions. For the second prompt, we ask the LLM to rephrase four statements, each independently fulfilling the following requirements: 1) change as many words as possible except the existing words in primary and secondary trials; 2) change the order of existing words in the statement; 3) change percentage numbers to decimals and vice versa; and 4) change the numbers in terms of percentages and decimals to a

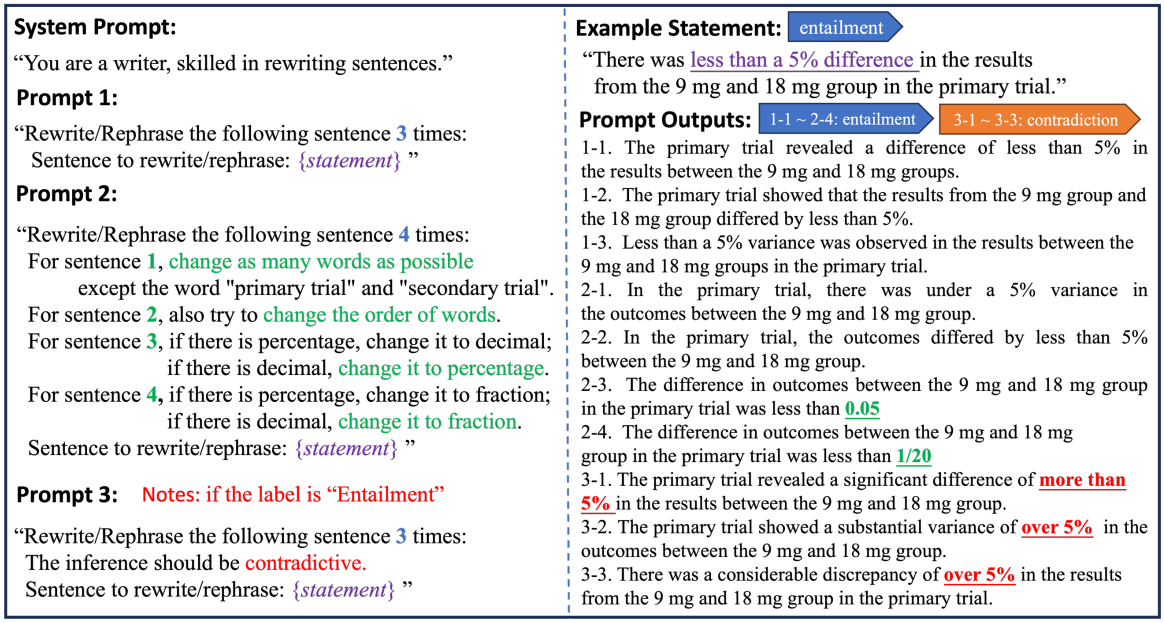

Figure 2: Prompts designed for data augmentation in ChatGPT v3.5.

fraction form. The above prompts are used for both entailment and contradiction labels. However, the third prompt is designed for the entailment label only, rewriting the original statements with contrary meanings to obtain contradictive inferences.

We also clean augmented statements to remove potentially inappropriate statements. For prompts 2-3 and 2-4, if the original statements do not contain numbers, but augmented statements contain numbers in any forms, we remove those augmented statements because these numbers are mostly hallucinations.

2.2 Instruction Tuning

We use original and augmented statements with the corresponding labels to fine-tune the SOLAR model (Kim et al., 2023). SOLAR-10.7B presents a depth up-scaling (DUS) technique to integrate Mistral 7B (Jiang et al., 2023) weights into the upscaled layers, and performs continued pre-training for the entire model. Supervised fine-tuning (SFT) and direct preference optimization (DPO) (Rafailov et al., 2023) were then used to fine-tune the model with designed instructions.

We continually fine-tune the SOLAR-10.7B-Instruct-v1.0 LLM. We use instruction tuning (Wei et al., 2022) and LoRA (Hu et al., 2021) techniques with prompts shown in Fig. 3 to optimize the SOLAR model for this NLI task. Flash attention

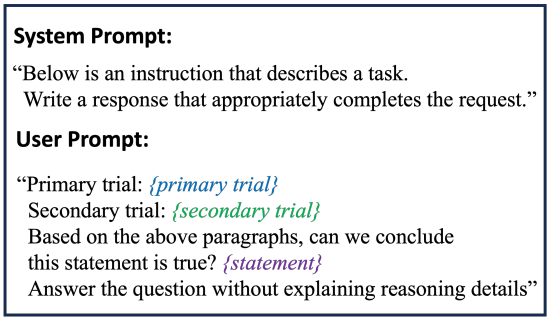

Figure 3: Prompts used for instruction tuning

(Dao et al., 2022) is also used to reduce the GPU requirements and accelerate the model fine-tuning process.

2.3 Intervention Reduction

A testing statement may be manipulated with some interventions, including numerical reasoning, vocabulary and syntax, and semantics, to investigate the consistency and faithfulness of the developed models. Technical details used to perform the interventions were not disclosed during the evaluation phase.

Therefore, we fine-tuned OpenChat v3.5 (Wang et al., 2023a) to reduce the influence of interventions. OpenChat is a framework used to advance open-source language models with mixed-quality data. As shown in Fig. 4, we used two exemplars for two-shot prompt learning. First, we

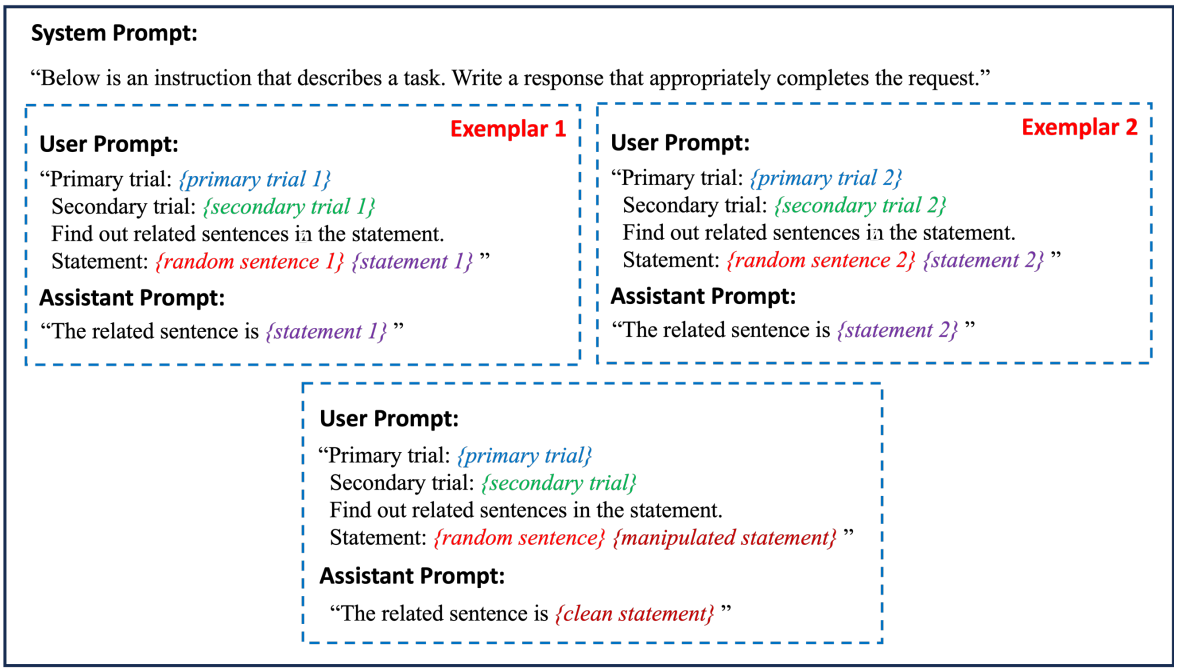

Figure 4: Prompts designed for intervention reduction in OpenChat v3.5.

randomly collected 10,000 abstracts published from Jan. 1st to Jan. 10th, 2024 from the arXiv preprint server. These were segmented into a total of 21,135 sentences. Finally, we randomly selected one sentence as an intervention sentence for both exemplars. The statements were selected from the training set, in which the first statement contains only one sentence and the second statement contains at least two sentences.

During the evaluation phase, an original statement is regarded as a manipulated statement and the fine-tuned LLM is expected to identify a cleaned statement. In most cases, a cleaned statement is a part of an original statement for intervention reduction. If an output statement contains sentences that don't belong to the original statement, the cleaned statement will be discarded and the original statement is used as the input for inference testing.

2.4 Fine-tuned LLMs for Label Prediction

Following the instruction shown in Fig. 3, the fine-tuned LLM processes a given statement based on the CTRs and answers the question without explaining its reasoning in detail. In the LLM response, if the first token is Yes or True, the predicted label is entailment, and otherwise contradiction. If the first token belongs to neither of these characteristics, we will check the vocabulary table to determine the corresponding probabilities of Entailment and Contradiction tokens. If the former exceeds the latter, the predicted label is returned as entailment, and otherwise contradiction.

3 Experiments and Results

3.1 Data

The datasets were mainly provided by task organizers (Jullien et al., 2024). A total of 1000 collected breast cancer CTRs were used as known premises. The training set used 1,700 statements to make claims about a single CTR or to compare two CTRs labelled as either entailment or contradiction. We used these statements for data augmentation, producing a total of 13,484 generated statements for LLM fine-tuning.

During the system development and evaluation phases, task organizers performed a variety of interventions on the statements in the development and test sets, either preserving or inversing the entailment relations. A total of 2,142 statements were used to develop the system and obtain the optimized parameters. Finally, the test set containing 5,500 statements was used to evaluate the system performance.

3.2 Settings

In addition to our fine-tuned SOLAR model (Kim et al., 2023), we used Mistral (Jiang et al., 2023),

Model (#para)	Development			Test		
	F1	Faithfulness	Consistency	F1	Faithfulness	Consistency
Orca2 (13B)	0.8223	0.8899	0.7914	0.7747	0.8692	0.7643
Qwen (14B)	0.8367	0.8542	0.8076	0.7657	0.8681	0.7730
Mistral (7B)	0.8500	0.9196	0.8213	0.7623	0.8611	0.7805
SOLAR (10.7B)	**0.8842**	**0.9554**	**0.8506**	**0.7790**	**0.9236**	**0.8092**

Table 1: Fine-tuned LLM results for the development and test sets.

Orca2 (Mitra et al., 2023) and Qwen (Bai et al., 2023) LLMs for performance comparison. All models were downloaded from HuggingFace[1]. We continuously fine-tuned these models using the augmented training set. All models were configured to obtain the highest average faithfulness and consistency scores on the development set. The hyperparameter values of our used SOLAR LLM were finally optimized as follows: epochs 20; batch size 8; optimizer Adafactor; learning rate schedule used a cosine decay with optional warmup; warmup ratio 0.05; max learning rate 7.5e-5; LoRA r 16; LoRA alpha 16; LoRA drop 0.05; max token length 2048 and original statement sample ratio 0.3.

3.3 Metrics

The *control F1* measures fundamental model performance of those testing instances without interventions, identical to the previous NLI4CT-2023 task and thus facilitating a direct performance comparison.

Faithfulness is estimated to measure the model's ability to correctly change its predictions when exposed to a semantic-altering intervention. The better system is expected to make the correct prediction for the correct reason.

Consistency measures the model's ability to predict the same label for original statements and contrast statements for semantic-preserving interventions. The better system is expected to produce the same outputs for semantically equivalent problems.

3.4 Results

Table 1 shows our submissions obtained consistent results for the development and test sets. The SOLAR model (Kim et al., 2023) outperformed Orca2 (Mitra et al., 2023), Quwen (Bai et al., 2023) and Mistral (Jiang et al., 2023) LLMs for all metrics.

Our SOLAR LLM achieved a control F1 score of 0.7790, significantly outperforming our submission for the NLI4CT-2023 task (F1 of 0.7091) based on ensemble BioLinkBERT transformers (Chen et al., 2023). This confirms that using LLMs properly can outperform pre-trained language models for the same task. In addition, the number of parameters in the LLM doesn't directly influence performance, indicating that model architecture is more important rather than scale.

In our proposed system workflow, regardless of which LLM model was used as the main framework for the NLI task, a higher faithfulness score was achieved when compared with the consistency score. This indicates that an LLM usually makes correct predictions with correct reasons.

In summary, in the NLI4CT-2024 task, our system based on the SOLAR model produced a promising faithfulness score of 0.9236, ranking second place among 32 participating systems, and ranked first for consistency with a score of 0.8092.

4 Conclusions

This study describes the NYCU-NLP submission for the SemEval-2024 NLI4CT task, including system design, implementation and evaluation. We aggregated several LLMs to determine the inference relation between CTRs and statements that may be manipulated with designed interventions to investigate the faithfulness and consistency of the developed models. Our system obtained a faithfulness score of 0.9236, ranking second among all 32 participating teams, and ranked first for consistency with a score of 0.8092.

Abstract

This paper explores solutions to the challenges posed by the widespread use of LLMs, particularly in the context of identifying human-written versus machine-generated text. Focusing on Subtask B of SemEval 2024 Task 8, we compare the performance of RoBERTa and DeBERTa models. Subtask B involved identifying not only human or machine text but also the specific LLM responsible for generating text, where our DeBERTa model outperformed the RoBERTa baseline by over 10% in leaderboard accuracy. The results highlight the rapidly growing capabilities of LLMs and importance of keeping up with the latest advancements. Additionally, our paper presents visualizations using PCA and t-SNE that showcase the DeBERTa model's ability to cluster different LLM outputs effectively. These findings contribute to understanding and improving AI methods for detecting machine-generated text, allowing us to build more robust and traceable AI systems in the language ecosystem.

1 Introduction

We live in a society that currently relies heavily on the use of LLMs (Large Language Models), which has followed from the explosive popularity of ChatGPT when it was released in late 2022. Now, with the introduction of GPT-4 and other more powerful LLMs, it has become increasingly important for us to have the ability to distinguish human-written text from machine-generated text. The fluency of recent models, paired with their tendency to hallucinate, has given rise to a very natural concern that there could be both accidental and intentional "bad actors" seeking to spread false information. Research has indicated that about one in every five jobs has over half of its tasks incorporated into LLMs, and that statistic is positively correlated with the barrier to entry (Eloundou et al., 2023). Consequently, these models have the necessary training data to spit out an immense number of plausibly correct but actually incorrect texts, which would be extremely detrimental because humans historically have been unable to distinguish between them beyond the level of random guessing. Such results are supported with recent work aiming to distinguish human-written sentences from AI-generated ones, with the AuTexTification study additionally demonstrating that cross-domain AI-generated text detection from Bloomz or GPT is more difficult in non-English languages (Sarvazyan et al., 2023). Furthermore, in efforts to facilitate unbiased dataset generation for related studies, the framework of TextMachina was created, and it contains crucial post-processing abilities like removing disclosure patterns and truncation (Sarvazyan et al., 2024). SemEval-2024's Task 8 (Wang et al., 2024) attempts to provide a working solution

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1463–1467

to the above problems by using standalone, self-operational means to classify whether a given text was authentically written by a human or artificially generated by a machine, in hopes of eventually building toward a foolproof method of detecting misinformation.

In subtask A, we were tasked with creating a binary classification model to determine if a given text was human-written or machine-generated. Within this subtask, there are two different tracks: one for monolingual (only English) and another for multilingual sources (something about which track we did or if we ended up doing both). Out of curiosity, we used base DeBERTa with default hyperparameters as our submission for this subtask, but it only performed 5% worse than the RoBERTa baseline. This specific subtask is important because LLMs are becoming more powerful and easily accessible, so there is a larger potential for misuse. This classification task would help catch the people who are misusing this technology to harm society.

In Subtask B, we trained a neural network to identify not only whether a given text was human-written or machine-written, but also to identify which large language model was responsible for generating that text. These language models include ChatGPT, Cohere, Dolly, and more. This task is important for many of the same reasons as subtask A; as LLMs are becoming more capable and accessible, being able to distinguish between human and model is crucial. Furthermore, being able to distinguish between different models allows for better enforcement of AI-safety laws and accountability.

2 Methods

2.1 RoBERTa

The baseline performances provided for both subtasks A and B revolved around HuggingFace's RoBERTa model. RoBERTA was developed to enhance the usability of post-BERT models, and incorporated a variety of techniques including longer training times, larger batches, more data, the elimination of the next sentence prediction objective, longer training sequences, and dynamic modification of the masking pattern (Liu et al., 2019). For the monolingual component of subtask A, roberta-base was used for a baseline of about 0.88, and for the multilingual component, xlm-roberta was used (to account for the various other languages) for a baseline of about 0.81. For subtask B, roberta-base was used again for a baseline of about 0.75.

2.2 DeBERTa

DeBERTa was designed as an upgrade to BERT and RoBERTa with the addition of disentangled attention and an enhanced mask decoder, and furthermore, its fine-tuning included adversarial training (He et al., 2021). As a result, we used the deberta-base model from HuggingFace with the assumption that it would outperform RoBERTa, and our best model did. Regarding hyperparameter tuning, we wanted to fine-tune the deberta-base model on the given dataset, so we looped through learning rates of 1e-5, 5e-5, and 1e-4, batch sizes of 4 and 8, epoch counts of 2 and 3, and weight decay constants of 1e-3, 5e-3, and 1e-2. By truncating the input length to a constant 1024 tokens, we established that the optimal hyperparameters (at least from what we tested) that yielded the highest accuracy were a learning rate of 1e-5, a batch size of 4, an epoch count of 3, and a weight decay constant of 1e-2.

2.3 Model interpretibility

To further analyze the inner working of the DeBERTa model, we analyzed our trained model's pooled outputs that encode the input sentence as whole prior to the logits. We used two dimensionality reductions algorithms, namely PCA and t-SNE for 2-D projection. PCA operates by finding orthogonal directions with the highest variance and projecting to the subspace spanned by the orthogonal directions. The t-SNE algorithm (van der Maaten and Hinton, 2008) works by preserving pairwise similarities in the data to generate related clusters. Our t-SNE projections were computed with a perplexity of 35 and iteration count of 300. Both algorithms were run on the 18,000 sentences in the test data for subtask B.

3 Results

The final DeBERTa model had the following results on the validation set, with a weighted average of 0.98633 precision, 0.98599 recall, and 0.98599 F1-score.

In comparison, our RoBERTa model performed worse, with each F1-score being lower than the corresponding F1-score for the DeBERTa model.

This model had weighted scores of 0.97979 precision, 0.97909 recall, and 0.97909 F1-score. Although these were high, they were each still a

Label	Source	Precision	Recall	F1-Score
0	Human	0.99916	0.99375	0.99645
1	ChatGPT	0.94944	0.99417	0.97129
2	Cohere	0.98735	0.99824	0.99276
3	Davinci	0.98912	0.94708	0.96765
4	Bloomz	1.0	0.99833	0.99917
5	Dolly	0.99311	0.98610	0.98606

Table 1: DeBERTa results on the Subtask B validation set

Label	Source	Precision	Recall	F1-Score
0	Human	0.99916	0.98792	0.99351
1	ChatGPT	0.93008	0.99250	0.96027
2	Cohere	0.97631	1.0	0.98801
3	Davinci	0.98367	0.92875	0.95542
4	Bloomz	0.99791	0.99667	0.99729
5	Dolly	0.99170	0.96966	0.98055

Table 2: RoBERTa results on the Subtask B validation set

bit lower than the corresponding metrics for the DeBERTa model.

We compared our model's predictions for the test set with the labels provided. The total accuracy was 0.8266666667. Below is the confusion matrix in table form for the predicted labels versus actual labels, with the labels corresponding to their respective sources. For example, the 439 entry has predicted label 2 and actual label 3, meaning that there were 439 predictions for the Cohere source that were actually from the Davinci source.

	Actual					
Pred	0	1	2	3	4	5
0	2050	3	9	237	541	151
1	0	2823	6	171	0	0
2	11	208	2342	439	0	11
3	27	624	3	2334	12	27
4	0	1	0	1	2997	1
5	77	187	34	626	541	4612

Table 3: Confusion matrix for Subtask B labels

The results on the test set are summarized in the table below.

Additionally, we analyzed the pooled outputs of the trained DeBERTa model on subtask B's data. To visualize the outputs in 2-D, PCA and t-SNE projection techniques were applied on the 768-D pooled outputs. The data points were colored by their corresponding text source (either human or LLM model) in Figures 1 and 2 on the test set.

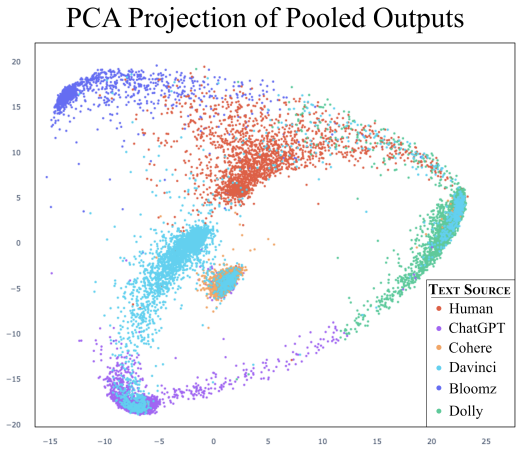

Figure 1: PCA projection of pooled outputs on the subtask B test data

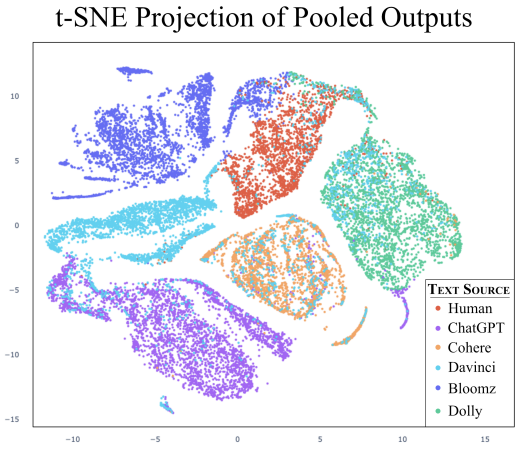

Figure 2: t-SNE projection of pooled outputs on the subtask B test data

Label	Source	Precision	Recall	F1-Score
0	Human	0.95	0.69	0.80
1	ChatGPT	0.73	0.94	0.82
2	Cohere	0.98	0.78	0.87
3	Davinci	0.65	0.78	0.71
4	Bloomz	0.84	1.00	0.91
5	Dolly	0.93	0.78	0.85

Table 4: DeBERTa test results on Subtask B

4 Discussion

4.1 Validation and Test Set Results

For both the RoBERTa statistics and the DeBERTa statistics in their validation results, the top two entries for precision and F1-score were Bloomz and Human in some order, which indicates a greater degree of identifiability from these sources. Bloomz was trained on multilingual tasks and fine-tuned on English prompts (Muennighoff et al., 2023), and many online texts are written by humans who are at least bilingual, so there could be a mannerism of text generation tied to multilingualism that makes it easier to pinpoint and distinguish these sources from the others.

Another observation is that Davinci performed reasonably well across the board for the validation sets, but had abysmal scores for the DeBERTa test set. Considering that DeBERTa is a more recent model, it is entirely possible that it has more difficulty with older data, which may explain why Davinci did as poorly as it did. However, besides Davinci and Bloomz being outliers on either end of the spectrum for F1-score, the rest of the values fell within a generally stable range, indicating that DeBERTa had a balanced evaluation of texts.

Additionally, interestingly enough, ChatGPT ranks last or near last in precision and F1-score in all the tables, but makes up for that with its high recall values. This could mean that the text was detected to be AI-generated with relative ease, but was then often misclassified as being from another AI source. Given that GPT-4 has greatly enhanced abilities compared to its predecessor, swapping out ChatGPT for GPT-4 could yield radically different results (for a potential future direction).

4.2 Visualizations of Pooled Outputs

It is clear from both the PCA and t-SNE visualizations that the DeBERTa model is successfully able to distinguish between different LLMs and human output in distinct clusters. Of note, however, are the blue points corresponding to Davinci text located in clusters of different colors. This phenomenon follows from recent research and shows that human writing tasks can still be quite susceptible to LLM influence due to their positive association with exposure (Eloundou et al., 2023). We speculate that Davinci being one of the earliest models influenced the training data of the other models that came on later, causing them to write similarly to Davinci. This supports our earlier hypothesis from the raw results, but seemingly contradicts findings that Davinci exhibits fewer confusions and is thus easily distinguishable from other models (Sarvazyan et al., 2023). One possible explanation for this is that our visualizations used parameters that clearly confined the other sources to their regions; it is entirely possible that a different configuration of parameters would yield a graph that displays an obvious Davinci scatter area while having a jumble of colors elsewhere for the other models.

5 Conclusion

For SemEval 2024 Task 8, Multigenerator, Multidomain, and Multilingual Black-Box Machine-Generated Text Detection, Team MLab submitted models for subtasks A and B. Specifically for subtask B, we used a base DeBERTa model and significantly outperformed the provided baseline set by a base RoBERTa model, with our model's final accuracy coming out to 0.827. In analyzing the precision, recall, and F1-score statistics, we discovered trends in the recorded values that seem to indicate that the method of training models, as well as the timeline of their training, have profound effects on the detectability of machine-generated text. Finally, by creating and interpreting PCA and t-SNE graphs, we present visual evidence that DeBERTa's internal reasoning groups various LLM results in separate clusters, even though Davinci acted as an exception with its colored points scattered in the general vicinity of other models. Therefore, visualizing AI thought processes can provide us with useful insights regarding how we can understand and improve the language ecosystem that they share with us.

Calc-CMU at SemEval-2024 Task 7: *Pre-Calc* - Learning to Use the Calculator Improves Numeracy in Language Models

Vishruth Veerendranath and **Vishwa Shah** and **Kshitish Ghate**
Carnegie Mellon University
{vveerend, vishwavs, kghate}@andrew.cmu.edu

Abstract

Quantitative and numerical comprehension in language is an important task in many fields like education and finance, but still remains a challenging task for language models. While tool and calculator usage has shown to be helpful to improve mathematical reasoning in large pretrained decoder-only language models, this remains unexplored for smaller language models with encoders. In this paper, we propose **Pre-Calc**, a simple pre-finetuning objective of learning to use the calculator for both encoder-only and encoder-decoder architectures, formulated as a discriminative and generative task respectively. We pre-train BERT and RoBERTa for discriminative calculator use and Flan-T5 for generative calculator use on the MAWPS, SVAMP, and AsDiv-A datasets, which improves performance on downstream tasks that require numerical understanding. Our code and data are available at https://github.com/calc-cmu/pre-calc.

1 Introduction

The advancement of language modeling in natural language processing has significantly impacted various computational tasks. However, the intricacy of numerical and quantitative comprehension in text remains a challenging frontier. Numerals, unlike words, possess unique characteristics that necessitate specialized handling by language models either in tokenization or processing. This necessity becomes particularly evident in tasks involving quantitative reasoning, where the ability to interpret and manipulate numerical information is crucial.

Numeracy involves majorly 2 properties. The first is *semantic reasoning* which focuses more on the understanding of relations in text and the second is *computational abilility* which focuses on performing explicit mathematical operations. Hence, the aim is to develop systems that can perform explicit mathematical operations while retaining or improving its quantitative reasoning.

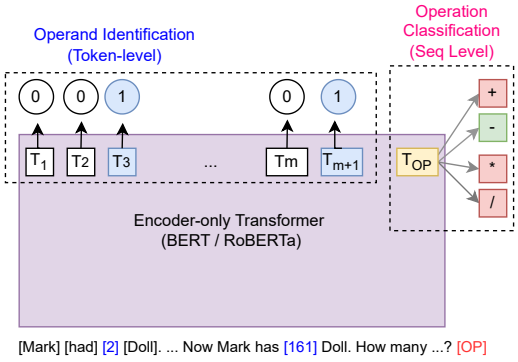

Figure 1: Pre-Calc for Encoder-Only models

We present **Pre-Calc**, a pre-finetuning objective of learning to use the calculator, to improve numerical abilities in language models. We propose Pre-Calc objectives for both the encoder-only and encoder-decoder classes of language models, and use a combination of the MAWPS (Koncel-Kedziorski et al., 2016), SVAMP (Patel et al., 2021), AsDiv-A (Miao et al., 2020) datasets to pre-finetune the models.

Our encoder-only objective, used to pre-finetune BERT and RoBERTa models, offers quick and efficient processing suitable for tasks where speed is paramount. The Pre-Calc versions of the models show competent performance on all quantitative downstream tasks from NumEval (Chen et al., 2023) and substantial improvements on 4 out of 6 sub-tasks with an improvement greater than 10 points for RedditNLI and AWPNLI specifically.

Similarly, our encoder-decoder approach, used to pre-finetune Flan-T5, demonstrates an improved ability to perform explicit computations in computation-intensive tasks like AWPNLI. Although there is a noted trade-off, with a slight decrease in performance on text-focused and semantic tasks, the objective showcases strengths in processing mathematically intensive language.

Our study underscores the potential of tailored

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1468–1475

language models to significantly enhance numeracy in NLP, providing an avenue for more efficient and effective processing of numerical data in language.

2 Task and Data

2.1 Downstream Tasks

We focus on the QNLI and QQA tasks of NumEval Task 1 (Chen et al., 2023) as our downstream tasks.

QNLI is the task of making *natural language inferences* based on quantitative clues. This dataset is adopted from the EQUATE(Ravichander et al., 2019) and is composed of NewsNLI, RedditNLI, AWPNLI and RTE-Quant. StressTest involves numerical reasoning instances from Naik et al. (2018), used as a synthetic sanity check.

QQA involves the task of *multiple-choice question answering* involving commonsense as well as quantitative comparisons. The dataset for this is adopted from Task 3 of NumGLUE (Mishra et al., 2022) and the Quarel dataset (Tafjord et al., 2019), which includes questions from quantitative domains such as physics and economics.

2.2 Pre-Finetuning Data

We use the MAWPS dataset (Koncel-Kedziorski et al., 2016), SVAMP (Patel et al., 2021) and AsDiv-A (Miao et al., 2020) as the numerical domain datasets for pre-finetuning. These consist of simple arithmetic word problems, along with their numerical solutions. The three datasets create a dataset with **4,225** total examples which are challenging and require understanding the context of numbers, represented either as digits or in words.

We construct this dataset from the Calc-X collection (Kadlčík et al., 2023) that has been annotated with equations for each problem, as well as `<gadget>` annotations in the answer to train a model to use a calculator when the `<gadget>` token is produced. We use the annotations of the equations particularly in our methodology.

3 Pre-Calc Methodology

We posit that learning to use a calculator requires understanding of numbers and ways in which numbers can be combined. This is used to formulate the **Pre-Calc** objectives described below.

3.1 Encoder-Only

3.1.1 Data Preprocessing

We preprocess Calc-MAWPS, Calc-SVAMP and Calc-AsDiv-A (from the Calc-X collection) (Kadlčík et al., 2023) and add 2 new features required for Pre-Calc. First is the *operand tag sequence*, which is a sequence of binary tags that is 1 if the original token it corresponds to is an *operand* and 0 if it isn't. Secondly we extract the *Operation*, which is the operation among {+ (add), - (subtract), * (multiply), / (divide)} that is required for the question. We extract the operation either directly from the equation or the reasoning chain in Calc-X and generate the operand tag sequence, by first extracting the operands and then tagging the occurances of the operands in the binary sequence with a 1. As part of this process we also filter out instances where there are more than one distinct operations as part of the equation.

3.1.2 Pre-Calc Method

An illustration of the Pre-Calc method for Encoder-only model can be seen in Fig 1. This is decomposed into two tasks as a dual-objective.

Firstly, we use the pretrained Encoder-only language model for the task of *Operand Identification*, which is a token-level classification task. The tags possible for each token are 1 and 0.

Secondly, we perform the task of *Operation Classficiation* by adding a special `[OP]` token at the end of each sequence and using this `[OP]` token's final layer representation to classify the operation required in this sequence (+, -, *, /). Hence, this is essentially a sequence-level classification task similar to classifying from the representation of a `[CLS]` token. However, we do not use the `[CLS]` token at the start of the sequence, to enable this objective even in non-bidirectional models with an autoregressive attention mask (like decoder-only models).

In essence, we use two heads — one token classification head for Operand Identification, and one sequence classification head for Operation Classification — to train it with the dual objective as per Equation 1

$$\mathcal{L} = \mathcal{L}_{operation} + \lambda \mathcal{L}_{operand} \quad (1)$$

where $\mathcal{L}_{operation}$ is the cross-entropy loss for the sequence classification (`[OP]`) head and $\mathcal{L}_{operand}$ is the binary cross entropy (BCE) loss for the token classification head. Here we empirically set $\lambda = 1$.

3.1.3 Downstream Task Inference

For most downstream tasks, we do not explicitly perform calculator computations using operands and operations predicted by the model and instead

use Pre-Calc only as a learning objective before finetuning it for specific downstream tasks. However, as AWPNLI task requires the model to be able to perform calculations explicitly, we utilize an alternative strategy for its inference adapted from our pre-finetuning strategy shown in Fig 1. We first extract the operand labels for each token from the premise T_i and operation using the T_{op} token. This gives us the operands and operation, after which we automate the calculation of the final answer comparing it with the hypothesis. This helps the model focus on the semantic extraction of operation and offload explicit computation to the calculator.

3.2 Encoder-Decoder

Encoder-Decoder or Decoder based models provide the abilities of long-form unbounded generations. This is advantageous for numerical problems, where multiple intermediate operations might be required for computation or reasoning(Wei et al., 2022). By reframing our task to output expressions, we distil the task to output the set of operations, leaving the computation part to the tool.

3.2.1 Data Preprocessing

As mentioned earlier, we use the MAWPS dataset for training our model to output expressions. As each instance in MAWPS consists of a question and a single numerical answer, to obtain closer resemblance to NLI format tasks, we reframe the question-numerical answer instance to a pair of complete sentences using prompting with LLaMa-7B (Touvron et al., 2023) as this is a simple text generation task. To obtain contradiction pairs, we perturb the true numerical answer by a small value (ranging from -5 to +5) before passing to the LLaMa-7B model as these will create harder instances for the model to learn from. We additionally also use the Multi-NLI(Williams et al., 2018) dataset to retain and improve textual inferential abilities of the model. We train on this combined data as Seq2Seq generation task. Combining these tasks should allow the model to infer both semantic and computational capabilities.

3.2.2 Pre-Calc Method

We utilize this ability of Seq2Seq modeling by finetuning Flan-T5 on our NLI-based tasks for pre-finetuning mentioned in 2.2. As shown in Figure 2, we use a **`math-nli`** prefix tag for tasks that require mathematical computation eg: MAWPS reformatted as above and use a **`text-nli`** tag for text-based

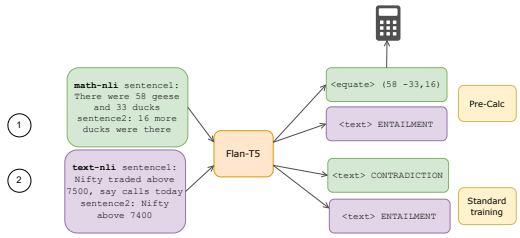

Figure 2: Our Encoder-Decoder based approach

tasks eg: Multi-NLI. This lets the model decipher whether the task requires explicit calculation - in which case it should output an expression for tool use, or use its inherent text-capabilities to reason over text numeracy.

Similar to Kadlčík et al. (2023), we make the model output token **`<equate>`** with the corresponding expression for computational tasks as essentially the task involves equating expressions in sentence 1 and sentence 2 and **`<text>`** for more textual-numeracy tasks with the final answer. This helps at inference to verify if the final computation requires to go through the calculator or not. We also hope to expand to **`<compare>,<compute>`** tokens as we extend this method in future to more down-stream tasks. We denote this as our Pre-Calc method for Encoder-Decoder models which performs tool-based pre-finetuning. As our baseline we also evaluate the performance of doing only text-based fine-tuning which we call our Standard Training approach.

4 Experiments

4.1 Baselines

We compare the performance of our method against several baseline models on tasks that require numeracy. Following Chen et al. (2023), the baseline methods involve reframing techniques, namely *Original*, *Digit-based*, and *Scientific* Notation methods, and are pre-finetuned on the *Comparing Numbers Dataset (CND)*. Each of these methods are applied to both BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) to create two versions of each baseline method.

4.2 Encoder-Only

We use the pretrained BERT and RoBERTa base models and pre-finetune as per Section 3.1.2. We use the 4-class cross-entropy loss for training the *Operation Classification* head, and a 2-class cross-entropy (equivalent to binary cross entropy) loss for the *Operand Identification* head. The models

Model	Notation	QNLI					QQA
		RTE-QUANT	News	Reddit	AWPNLI	Streess Test	
BERT	Org	66.73	74.22	62.40	59.20	99.46	**56.79**

	Pre-Calc (ours)	**73.90**	**82.21**	**78.00**	58.17	**100.00**	**61.05**

Table 1: Micro-F1-Scores (in %) of Pre-Calc trained models as compared to CN (Comparing Numbers) trained and reframing (Digit, Sci) baselines

are trained with the Adam optimizer for 20 epochs, a batch size of 8, and a learning rate of 5e-4. The checkpoint after this pre-finetuning is named Pre-Calc-BERT[1] or Pre-Calc-RoBERTa[1].

We then finetune Pre-Calc-BERT and Pre-Calc-RoBERTa on the downstream tasks of QNLI and QQA using the same hyperparameters used by the CN-BERT baselines (Chen et al., 2023) — AdamW optimizer with a learning rate of 5e-5, batch size of 8 for 5 epochs. We use 10-fold cross validation to report our results for the tasks where an explicit test split is not available.

4.3 Encoder-Decoder

We use Flan-T5 as our base model, For pre-finetuning, we collect a balanced sample consisting about 4200 instances created from MAWPS for `math-nli` task and 3900 instances extracted from Multi-NLI for `text-nli` task.[1]

As this is a sequence generation task, the objective is same as that in CausalLM modeling for next-word prediction. We use AdamW optimizer with a learning rate of 5e-5, batch size of 8 for 5 epochs. We do not perform any fine-tuning on our downstream tasks, and show results for prompt based few-shot evaluations on each task. We call our model FlanT5-Pre-Calc[1] and use 2 baselines, Flan-T5 few-shot and Flan-T5-ST only with standard text training[1].

5 Results and Discussion

5.1 Encoder-Only

Our evaluation on the QNLI and QQA tasks, as outlined in Table 1, demonstrates the efficacy of our Pre-Calc approach. For BERT, our Pre-Calc method significantly outperforms all other reframing techniques for RedditNLI, AWPNLI and RTE-Quant. These results highlight the effectiveness of our method in dealing with diverse numerical information in natural language. In the case of RoBERTa, the Pre-Calc approach consistently outperformed other methods across all three tasks - RTE-Quant, NewsNLI and RedditNLI. This performance is markedly superior compared to the original RoBERTa and other variants that use the reframing techniques, with lower scores in all categories.

For AWPNLI we report results for baselines from Chen et al. (2023), and for our results we compute F1-score on the complete dataset using our methodology described in section 4.2. We see a substantial improvement in Pre-Calc compared to the earlier baselines which can be attributed to our training and inference strategy which can precisely attend and compute an expression which is essential for the AWPNLI task.

In QQA as well, Pre-Calc-RoBERTa improves performance over its counterpart. This indicates that Pre-Calc improves commonsense reasoning abilities and this effect is more pronounced in RoBERTa which is a stronger base model.

Overall, the results validate our hypothesis that

Model \Task	AWP NLI	News NLI	RTE Quant
Few-shot	41.56	77.47	**85.74**
ST (ours)	37.55	**76.75**	73.43
Pre-Calc (ours)	**80.29**	75.20	71.26

Table 2: Micro F1-score of Flan-T5-large when using our Encoder-Decoder based approach

the Pre-Calc approach, which integrates calculator-like capabilities into the model, significantly enhances performance in tasks requiring numeral-aware semantic and computational capabilities .

5.2 Encoder-Decoder

We present the results for our Encoder-Decoder based approach in Table 2. We see that for AWPNLI which requires explicit computation, FlanT5(Pre-Calc) achives almost double performance compared to FlanT5-few shot and FlanT5-ST, showing that Flan-T5 originally did not have this capability to evaluate expressions and compare values and this property cannot be instilled only via text finetuning as can be seen from the performance of FlanT5-ST. Further compared to prior works (Chen et al., 2023), this achieves state-of-the art results on AWPNLI.

However, we see that the performance slightly decreases on NewsNLI and RTEQuant which are more text-focused tasks. We see that original pre-trained FlanT5 does better at this as it already has inherent properties to handle semantic numeracy. This is likely because training with specific tasks discussed above causes forgetting/over-fitting in the model. This can also be attributed to the language-modeling MLE loss which focuses more on generating outputs specific to the format discussed in Fig 2 rather than its original properties of in-context learning and reasoning. To combat this, in the future we hope to regularize learning better so that a diversity of tasks can be included avoiding overfitting in the model.

6 Analysis

6.1 Dual-Objective in Encoder-Only Pre-Calc

We inspect the characteristics of the two objectives during pre-finetuning. Fig. 3 shows the F1-score across epochs for the operand identification objective on the validation data. While this seems to fluctuate, it consistently stays above 90% (the accuracy for this task also consistently remains at about 99%), indicating that the operand identification task is not very challenging and that there is very little loss signal from this task beyond the first few epochs. Regardless of having the second objective, the F-1 for this task is still maintained at a high number.

In Fig. 4 we see the accuracy plot on validation data for the operation classification objective across epochs. Here we see that the accuracy consistently increases but still remains under 75% which tells us that this objective is a lot more challenging, which is also explained by the fact that it has to be inferred from text. Together, the two aid different abilities — picking numbers out with operand identification and combining numbers with operation classification — which are both important for any downstream quantitative task

6.2 Operation wise difficulty for FlanT5

We sample 500 instances from the MAWPS reframed dataset, to observe operation-wise accuracy for the model. We observe in Figure 5 that about 60% errors are for instances that entail a divide operation. This could be because understanding division requires the model to develop an understanding of what operand should be the numerator and which should be the denominator. There are also rare instances where the model is required to understand the idea of ratio-proportion which requires more complex understanding compared to other operations.

7 Related Work

Numeracy in LMs Numeracy, or the ability to understand and work with numbers, is a critical aspect that has been relatively underexplored compared to other linguistic competencies in NLP models. Spithourakis and Riedel (2018) emphasized the need for LMs to better understand numbers, setting a precedent for subsequent research.

Chen et al. (2019) introduced Numeracy-600K, a large-scale dataset designed to improve the ability of models to detect exaggerated information in financial texts. Concurrently, Wallace et al. (2019) explored the embedding properties of numbers, shedding light on how numeracy can be integrated into LMs. Zhang et al. (2020) analyzed the representation of numerals in scientific notation, addressing the challenge of scale understanding in LMs. Chen et al. (2021) furthered this exploration by suggesting a digit-based encoder for numeral encoding, providing a novel perspective on numeral representation.

Pre-Finetuning In addition to these studies focused on numeral representation, other researchers have investigated the potential of pre-finetuning tasks to enhance LM capabilities. Aghajanyan et al. (2021) introduced a massive multi-task representation with pre-finetuning, demonstrating the efficacy of pre-finetuning in improving model performance across a range of tasks.

Geva et al. (2020) proposed GENBERT, which is trained on automatically-generated synthetic data in a multi-task setup. This training significantly improves performance on numerical reasoning tasks such as DROP and math word problems, while maintaining high performance on standard reading comprehension tasks. Wang et al. (2017) presented a deep neural solver, a hybrid model combining the RNN with a similarity-based retrieval to translate math word problems into equation templates.

Tool-Use Gou et al. (2023) presented a series of Tool-integrated Reasoning Agents (ToRA) designed to solve complex mathematical problems by augmenting the model with external computational tools. The training process involves collecting interactive tool-use trajectories and applying imitation learning and output space shaping, showcasing the efficacy of combining natural language reasoning with program-based tool use. Kadlčík et al. (2023) introduced Calc-X, a collection of datasets designed to integrate calculator usage into language model reasoning chains. Calc-X consolidates 300,000 samples from several chain-of-thought tasks requiring arithmetic reasoning. The study demonstrates how Calcformers, models trained on Calc-X, significantly enhance the accuracy of generating correct results by offloading computations to symbolic systems.

8 Conclusion and Future Work

In this work, we improve the numeracy in language models on the QNLI and QQA tasks which involve textual and computational quantitative reasoning. We do so by proposing calculator usage as a pre-finetuning task in a discriminative and generative fashion for encoder-only and encoder-decoder models respectively. This improves encoder-only models across various downstream tasks and improves encoder-decoder models on tasks that require explicit computation.

Future work can address the balance between textual understanding and numerical reasoning, by refining regularization strategies to maintain the language model's core strengths while enhancing its computational abilities. Tool-use in encoder-only models could also be extended to more complex tools similar to decoder-only models.

Acknowledgments

We thank Robert Lo for the helpful discussions.

AISPACE at SemEval-2024 task 8: A Class-balanced Soft-voting System for Detecting Multi-generator Machine-generated Text

Renhua Gu, Xiangfeng Meng
Samsung R&D Institute China-Beijing
{renhua.gu, xf.meng}@samsung.com

Abstract

SemEval-2024 Task 8 provides a challenge to detect human-written and machine-generated text. There are 3 subtasks for different detection scenarios. This paper proposes a system that mainly deals with Subtask B. It aims to detect if given full text is written by human or is generated by a specific Large Language Model (LLM), which is actually a multi-class text classification task. Our team AISPACE conducted a systematic study of fine-tuning transformer-based models, including encoder-only, decoder-only and encoder-decoder models. We compared their performance on this task and identified that encoder-only models performed exceptionally well. We also applied a weighted Cross Entropy loss function to address the issue of data imbalance of different class samples. Additionally, we employed soft-voting strategy over multi-models ensemble to enhance the reliability of our predictions. Our system ranked top 1 in Subtask B, which sets a state-of-the-art benchmark for this new challenge.

1 Introduction

Large Language Models (LLMs) have emerged as a foundational element for artificial intelligence (AI) applications. Their text generation capabilities are impressive and have almost reached the human-level performance. However, their widespread use also poses risks. The use of LLM-generated text can lead to the spread of inaccurate information, academic dishonesty, and privacy breaches. Additionally, the machine-generated text may become trapped in a loop during the process of LLMs' own development, gradually replacing human-written training data and reducing the quality and diversity of subsequent models(Wu et al., 2023). To prevent the misuse of LLMs and improve the iterative refinement of AI tools, it is crucial to distinguish between machine-generated and human-written text. SemEval-2024 Task 8: Multigenerator, Multidomain and MultiLingual Black-Box Machine-Generated Text Detection(Wang et al., 2024) introduces the task of detecting machine-generated text across various generators, domains and languages. Our system focuses on Subtask B, which is a multi-class classification task. It involves detecting text from multi-generators over multi-domains in English only. Given a text, the system tells whether the text is written by a human or generated by a particular LLM. It emphasizes not only the accuracy of detecting the in-domain texts, but also the generalization to identify other out-of-domain text sources.

Current research on LLMs text detection primarily focuses on ChatGPT or a specific model in a limited domain. Gao et al., 2023 compares scientific writing between humans and ChatGPT exclusively. Wang et al., 2023b detects AI-generated news by ChatGPT. However, there are many other emerging LLMs that generate various domain texts that needed to be distinguished from those written by humans. Wang et al., 2023a presents a large-scale corpus generated by popular LLMs, including ChatGPT, Cohere, Davinci, Bloomz, and Dolly, across various domains such as Wikihow, Wikipedia, Arxiv, PeerRead, and Reddit. To address this complex scenario, we fine-tune transformer-based encoder-only, decoder-only, and encoder-decoder models.We then ensemble the model that performs best for a specific class and mitigate sample imbalance using a weighted loss function.

Our contributions can be summarized as follows:

1) We conducted a systematic research of fine-tuning language models to detect multi-class machine-generated text.

2) We developed class-balanced loss function and soft voting model ensemble to keep model robustness and generalization.

3) Our system formulated a SOTA benchmark

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1476–1481

on the task.

2 Related Work

Researchers have explored automatic detection methods for distinguishing machine-generated text from human-written text. These methods can be categorized into two distinct groups, i.e., metric-based methods and model-based methods (He et al., 2023).

2.1 Metric-based Methods

Metric-based methods utilize metrics such as log-likelihood, word rank, and predicted distribution entropy. For example, GLTR (Gehrmann et al., 2019) is developed as a visualization tool to facilitate the labeling process of whether a text is machine-generated. DetectGPT (Mitchell et al., 2023) define a new curvature-based criterion for distinguish machine-generated text under the assumption that text sampled from an LLM tends to occupy negative curvature regions of the model's log probability function. GPT-who (Venkatraman et al., 2023) is a system that computes interpretable Uniform Information Density (UID) features based on the statistical distribution of a given text. Additionally, it autonomously learns the threshold between different authors using Logistic Regression.

2.2 Model-based Methods

On the other hand, model-based methods involve training classification models using both machine-generated text and human-written text. COCO (Liu et al., 2022) incorporates coherence information into text representations through the use of a graph-based encoding method. This approach is combined with a contrastive learning framework, and an enhanced contrastive loss function is proposed to mitigate potential performance degradation resulting from simple samples.

3 System Overview

Based on the analysis of the task situation, we have carried out preliminary studies of several methods and integrated pre-trained language models fine-tuning, class-balanced weight loss function, and soft-voting model ensemble into our system.

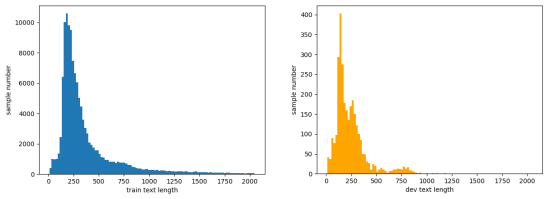
3.1 Data Process

Subtask B shares same generators, same domains and same language with subtask A. The statistical analysis reveals that subtask B lacks training data from PeerRead Source while subtask A can provide necessary data to fill the gap. To strengthen data source for training, we merged A and B train data into a unified dataset, removing any duplicated items and those present in the dev set. We then re-labeled all the texts based on task B labels. The resulting training data consists of 127,755 items. For each class, the number of sample is shown in Table 1. However, it is important to note that the training data does not include any PeerRead texts generated by BLOOMZ, unlike the dev data. We can still assess the model's generalization ability using this data.

Table 1: Sample Number of each class. C_0: human, C_1: ChatGPT, C_2: Cohere, C_3: Davinci, C_4: BLOOMZ, C_5: Dolly

C_0	C_1	C_2	C_3	C_4	C_5
63,351	13,839	13,178	13,843	9,998	13,546

Furthermore, after the merging of data, we analysed the token length of the dataset. As illustrated in Figure 1, the majority of the token length in the training text falls within the range of 0-1000, whereas the length of the development text is mostly between 0-500. So our system tested input size of 512 and 1024 tokens in Longformer model.



(a) train (b) dev

Figure 1: Token length of data

3.2 Fine-tuning Transformer-based Models

Fine-tuning pre-trained models is typically effective approach for downstream tasks(Kalyan et al., 2021). Our system utilize a series of Transformer-based models, including encoder-based, decoder-based and encoder-decoder models, to develop a multi-class classifier through fine-tuning. One purpose is to determine which architecture is better suited in such tasks. Another purpose is to construct more bases that excel in different generators, which will benefit the overall ensemble results.

3.2.1 Encoder-only

Roberta (Liu et al., 2019) is based on the architecture of BERT (Devlin et al., 2018) and incorporates several modifications and enhancements to improve its performance. One key difference with Roberta-large is its training process, which involves training on more data for a longer period of time compared to BERT. Additionally, Roberta-large uses dynamic masking during training, where the masking pattern changes from epoch to epoch, leading to better generalization. Roberta-large has demonstrated state-of-the-art performance on various NLP benchmarks and tasks, showcasing its effectiveness in understanding and processing human language. It has been widely adopted in academic research and industry applications due to its impressive results. The model was adopted as the baseline model to explore the effectiveness of our proposed methods.

Deberta (He et al., 2020) improved its performance from BERT by disentangled attention mechanism, which allows the model to focus on different aspects of the input independently, enabling better understanding of long-range dependencies and capturing complex linguistic structures more effectively. In addition, Deberta incorporates a novel masking scheme and dynamic upsampling during training, leading to improved model learning and generalization capability.

Longformer Traditional NLP models like BERT are designed to handle sequences of up to 512 tokens, limiting their applicability to longer documents such as scientific papers, legal contracts, or lengthy news articles. Longformer (Beltagy et al., 2020) includes a combination of global attention and sparse attention patterns. Global attention allows the model to capture relationships between distant tokens in the input sequence, while sparse attention reduces the computational complexity of processing long sequences. This balance enables Longformer to efficiently handle lengthy documents while maintaining strong performance. According to the analysis of token length, we fine-tuned 2 versions of this model with the input sizes as 512 and 1024 to asses the impact of input size.

3.2.2 Decoder-only

XLNet (Yang et al., 2019) builds upon the Transformer-XL (Dai et al., 2019) architecture, which includes techniques for handling long-range dependencies in sequences more effectively than standard transformer architectures. This architecture enhances XLNet's ability to capture complex relationships within text data. XLNet introduces permutation language modeling, which enables the model to capture bidirectional context without relying on the autoregressive property found in traditional models like GPT-2. This approach allows XLNet to consider all permutations of the input sequence during training, leading to a more comprehensive understanding of the contextual information.

3.2.3 Encoder-decoder

T5 (Raffel et al., 2020) belongs to the family of transformers using "text-to-text" framework, which means that it can perform a wide range of NLP tasks by converting both the input and output into text strings. This flexibility allows T5 to handle various tasks such as translation, summarization, question-answering, and more, all within a unified framework. Besides, T5 is pre-trained using a large-scale dataset and fine-tuned for specific NLP tasks, making it a highly adaptable and efficient model for a wide range of applications.

3.3 Class Balanced Weighted Loss

As shown in Table 1, each class has a different number of samples. The number of human-written samples number is even 5-6 times greater than others. To address the sample imbalance of different classes, we employed a weighted loss function during training to balance the contribution of each class sample to the loss.

For multi-class classification, the commonly used loss function is ordinary cross-entropy (CE). However when there is an imbalance-sample problem, the class-balanced weighted cross-entropy (WCE) will significantly improve the performance (Cui et al., 2019).

The weight of each class is calculated as the inverse number of samples. Denote that the number of classes is C, total number of all samples is N_{total} the number of text samples in $Class_i$ is N_i, the weight factor of each class is calculated as:

$$\{w_0, w_1, ..., w_C\} = \left\{ \frac{N_{total}}{N_0 * C}, \frac{N_{total}}{N_1 * C}, ..., \frac{N_{total}}{N_C * C} \right\}$$

3.4 Soft Voting

To enhance robustness and stability across generators and domains, we employ an ensemble approach by using the soft voting method with multiple base models.

Firstly, we obtain the confusion matrix of each base classifier. Secondly, we select the model that outperforms in a specific class. Finally, we integrate all the soft-max probability distribution matrix of all outperformed models to obtain the average probability distribution, and make the final decision based on it. The probability of the text

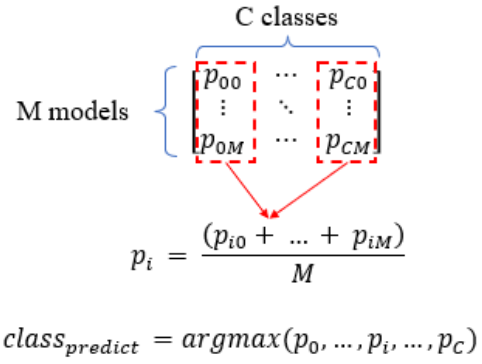


Figure 2: Soft voting over M models

belonging to $Class_i$ as predicted by $Model_j$ is denoted by p_{ij}. The final probability of $Class_i$ is calculated as the average probabilities from M models, as illustrated in Figure 2. The prediction result of the model ensemble is determined by identifying the highest probability.

4 Experimental setup

4.1 Dataset and Evaluation Metrics

For the baseline experiments on Roberta-large, we utilized the official subtaskB dataset and the merged data for separate training to determine the effectiveness of the merged data. For fine-tuning other models, we only used the merged data, which has been proven effective in the baseline experiment. The original subtaskB training data consists of 71027 items, while merging data results in a total of 127,755 items. We divided the data into train and val sets in an 8:2 ratio, and the original subtaskB dev set was kept as the dev set, which contains 3,000 items. No additional data was used for either training or evaluation. The official evaluation metric for the SubtaskB is accuracy. The experiments result in this paper is based on accuracy of dev set.

4.2 Base models

Roberta-large serves as the baseline in our system to verify the contribution of our proposed methods. We explored different datasets, loss functions, learning rates and epochs on Roberta-large to identify which are suitable for this task. Once identified, we applied them to fine-tune other models further.

There are groups of experiments on Roberta-large, settings are as follows:

- Dataset contribution: The model was fine-tuned with the original data and merged data for 3 epochs using a learning rate of 3e-5.
- Loss function contribution: The model was fine-tuned with merged data for 3 epochs with learning rate of 3e-5, applying ordinary CE and weighted CE loss in the process of training.
- Epoch contribution: The model was fine-tuned with the merged data for 3 and 5 epochs with a learning rate of 2e-5.
- Learning rate contribution: The model was fine-tuned with merged data for 5 epochs with learning rates of 1e-5, 1.5e-5, 2e-5 and 3e-5.

Deberta-large and XLNet-large applied the merged data and weighted CE as they have been shown to be effective in previous experiments. We explored various learning rates (including 1e-5, 2e-5, and 3e-5) and epochs (including 2epochs, 3 epochs, and 5 epochs), and selected the best setting as a learning rate of 1e-5 and 3 epochs as the performance comparison to other models.

Longformer is good at handling long documents, breaking the limits of 512 tokens of Bert-family models. Since we have part of long documents whose tokens numbers are greater than 512 tokens, so we tried 1024 tokens input as well as 512 tokens. Further more, to keep the pre-trained ability on semantic understanding, we fixed the top 18 layers and only fine-tuned the remained ones. Then we fine-tuned it with merged data for 5 epochs with a learning rate of 3e-5.

T5 is pre-trained on a large set of corpus and has strong adaption. We fine-tuned it with our merged data over its default parameter setting for 3 epochs with learning rates at 2e-5. Referring to the appendix of T5, a prefix (M4 sentence:) was added to each input text, then the model was trained to generate "human" or "machine".

Table 2: The performance Comparison of multiple methods on Roberta-large

Method	Epochs/LR	Accuracy
baseline	3/3e-5	0.7390
+ merged data	3/3e-5	0.9050
+ merged data + WCE	3/3e-5	0.9150
+ merged data + WCE	5/3e-5	0.9733
+ merged data + WCE	5/2e-5	**0.9800**
+ merged data + WCE	5/1.5e-5	0.9626
+ merged data + WCE	5/1e-5	0.9433

Table 3: The performance comparison of different base models

Arch	Model	Accuracy
Encoder	Roberta-large	**0.9800**

5 Results and Analysis

To assess the efficacy of our proposed methods, we carried out multiple sets of experiments.

On the baseline Roberta-large, an ablation study was conducted. The performance comparison is shown in Table 2. The results of experiments indicate that supplementing the data source significantly improves performance. Therefore, the supervised fine-tuning is crucial in such cases. Additionally, a weighted loss function can mitigate sample imbalance issue.

Further, we fine-tuned a series of transformer-based models to select the most suitable base model. The results in Table 3 shows that the encoder or decoder can achieve top performance while the Encoder-Decoder is poor for this task. For input size, 512 tokens exceed 1024 tokens. To include longer input has no contribution to the result.

At last, we conducted a model ensemble by soft voting method to ensure robustness and generalization and reduce the effect of noise. The selected single base fine-tuned model is chosen based on its performance in the specific class. We tested various combinations, and the results are shown in Table 4. We attempted to combine various single base models, including 2, 3, and 4 types. Compared to the best single model, the ensembled model showed significant improvement, even with the least number of ensemble types. Furthermore, as the differences in ensemble models increased, the results improved even further. Additionally, if the ensemble base models perform well individually in every class, the overall result is also improved.

6 Conclusion

This paper presents a systematic study on detecting machine-generated text from multi-generators and multi-domains. We fine-tuned a series of transformer-based models and found that the encoder architecture is better suited for the task. We employed a weighted Cross Entropy loss function to address the sample imbalance. To improve robustness and generalization, various base models were ensembled by soft-voting method, and resulting in 99.46% accuracy on the dev set. In the final test, our system ranked 1st. Moving forward, we plan to explore more widely used LLMs and work towards enhancing our capabilities in few-shot learning and transfer-learning for similar tasks.

Abstract

Numbers are frequently utilized in both our daily narratives and professional documents, such as clinical notes, scientific papers, financial documents, and legal court orders. The ability to understand and generate numbers is thus one of the essential aspects of evaluating large language models. In this vein, we propose a collection of datasets in SemEval-2024 Task 7 - NumEval. This collection encompasses several tasks focused on numeral-aware instances, including number prediction, natural language inference, question answering, reading comprehension, reasoning, and headline generation. This paper offers an overview of the dataset and presents the results of all subtasks in NumEval. Additionally, we contribute by summarizing participants' methods and conducting an error analysis. To the best of our knowledge, NumEval represents one of the early tasks that perform peer evaluation in SemEval's history. We will further share observations from this aspect and provide suggestions for future SemEval tasks.

1 Introduction

In the past, SemEval has predominantly focused on discussions surrounding words in text, with limited exploration of numbers in text. Recognizing the significance of understanding numbers can enhance performance in certain tasks. For instance, there is a notable difference in the sentiment degree between "expecting the stock price to increase by 30%" and "expecting the stock price to increase by 3%" in fine-grained sentiment analysis, as the former suggests a higher sentiment degree than the latter (SemEval-2017 Task 5 (Cortis et al., 2017)). Similarly, "Stealing $10" versus "Stealing $100,000" could result in differing court judgments (SemEval-2023 Task 6 (Modi et al., 2023)), and contrasting systolic blood pressure readings of 119 versus 121 offer different clinical inferences (SemEval-2023 Task 7 (Jullien et al., 2023)). These examples underscore the importance of numerical understanding in text, suggesting it as a potential research direction for enhancing the performance of downstream tasks.

Recent interest has surged in the numeracy of textual data and models within the NLP community, marking an opportune moment to evaluate current models' performance in numeral-aware language understanding and generation. To this end, we propose a collection of five published datasets encompassing three tasks: quantitative understanding, reading comprehension of numerals in text, and numeral-aware headline generation. For quantitative understanding tasks, we utilize the Quantitative 101 dataset (Chen et al., 2023). The NQuAD dataset (Chen et al., 2021) serves to explore reading comprehension with numerically rich documents, and Num-HG (Huang et al., 2024), annotated for numerical reasoning, facilitates the investigation of numeral-aware headline generation. In summary, while these are foundational NLP tasks, our focus is on discussing instances that require numeracy and the capacity to understand numbers for resolution.

In this paper, we first provide an overview of the dataset and subsequently summarize the methods and performances of participants. The comparison of models and error analysis will be included. Additionally, we employ peer evaluation to annotate and evaluate the generated outputs of participants' systems. Our analysis and observations, based on the annotations from participants, will be shared. We hope this pilot trial can offer insights and share experiences for future studies planning to conduct human evaluations among different teams.

2 Tasks and Datasets

We list the dataset for each task, the size, and the corresponding license in Table 1. Quantitative 101, which is a collection of Numeracy-600K (Chen

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1482–1491

News Article: Major banks take the lead in self-discipline. The five major banks' newly-imposed mortgage interest rates climbed to **1.986%** in May. ... Also approaching **2%** integer alert ... Up to **2.5%** ... Also increased by **0.04** percentage points from the previous month ... Prevent the housing market bubble from fully starting.
Question Stem: Driven by self-discipline, the five major banks' new mortgage interest rates are approaching nearly _____%.
Answer Options: (A) 0.04 (B) 1.986 (C) 2 (D) 2.5
Answer: (C)

Table 3: An example question in NQuAD.

et al., 2019), EQUATE (Ravichander et al., 2019), and NumGLUE Task 3 (Mishra et al., 2022). Some examples selected from these datasets are shown in Tables 2 and 3.[1] QP subtask aims to predict the magnitude of the masked number, and it is the coarse-grained setting for examining numeracy. QNLI and QQA subtasks require models to compare numbers to answer the question. RC task in NQuAD asks models to select a proper number for the question stem based on the given news article. The average of the micro-F1 score is used to evaluate the performance in Quantitative 101, and accuracy is used to evaluate the performance in NQuAD.

To go one step further, Num-HG extends the RC task in NQuAD. It provides numerical reasoning annotations to 27,746 news, and offers two subtasks, numerical reasoning and headline generation. The major goal of this task is to generate a headline that contains key numerical information in the news article. Table 4 shows an example of the Num-HG. In the numerical reasoning subtask, models need

[1]Examples in Tables 2, 3, and 4 are from the original papers.

News: At least **30** gunmen burst into a drug rehabilitation center in a Mexican border state capital and opened fire, killing **19** men and wounding **four** people, police said. Gunmen also killed **16** people in another drug-plagued northern city. The killings in Chihuahua city and in Ciudad Madero marked one of the bloodiest weeks ever in Mexico and came just weeks after authorities discovered **55** bodies in an abandoned silver mine, presumably victims of the country's drug violence. More than **60** people have died in mass shootings at rehab clinics in a little less than **two** years. Police have said **two** of Mexico's **six** major drug cartels are exploiting the centers to recruit hit men and drug smugglers, ...
Headline (Question): Mexico Gunmen Kill ____
Answer: 35
Annotation: Add(19,16)

Table 4: An annotation example in Num-HG.

to calculate the correct number of the blank part in the news headline. In the headline generation subtask, models must generate a headline based on the given news. Because each headline in the proposed Num-HG contains one number, models are expected to generate the same number as journalists. Our rationale is that the number selected by the journalists should be the most informative for summarizing the news article. Therefore, we will evaluate whether the generated number is correct or not. Additionally, we will further evaluate the generated headline by automatical metrics, such as ROUGE and BERTScore, and manual evaluation. Specifically, participants manually evaluate the system outputs from other teams.

3 Participants and Automatic Evaluation

There are 124 teams registered for NumEval, with 20 teams submitting their system description papers. This section provides an overview of the major methods employed in each paper, with detailed explorations available in the respective papers. As participants can select specific subtasks, results are reported in a fine-grained manner to encompass partial outcomes.

Table 5 presents the Quantitative 101 results. Chen et al. (2024) utilize Flan-T5 (Chung et al., 2022) with an instructional prompt across all tasks,

outperforming direct applications of pre-trained models such as BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), and LinkBERT (Yasunaga et al., 2022). Sengupta et al. (2024) emphasize the significance of number representation in character format. Kalantari et al. (2024) employ Orca2 (Mitra et al., 2023) with fine-tuning and Chain-of-Thought (CoT) prompting (Wei et al., 2022), achieving high performance across most tasks. Veerendranath et al. (2024) introduce the Pre-Calc approach, which incorporates operation classification tasks during RoBERTa training and utilizes this knowledge to decide on calculator usage for results, highlighting the value of tool utilization. Saha (2024) experiment with BERT, while Liang et al. (2024) leverage the Abe-7B model enhanced by human feedback during training, surpassing several large language models (LLMs). In summary, findings from Quantitative 101 suggest that learning calculator usage and character-format number representation can aid in quantitative tasks. Additionally, employing tailored language models like Orca2 or integrating human feedback can further enhance performance.

Table 6 presents the results on the NQuAD dataset. Chen et al. (2024) achieved the highest performance using Randeng-T5-77M (Zhang et al., 2022). Liu et al. (2024), supporting previous research (Chen et al., 2023), demonstrated that pre-finetuning with a comparing numbers task could enhance performance. Lau and Wu (2024) introduced a numeral augmentation method to improve performance. In conclusion, a well-trained language model, such as Randeng-T5-77M, can achieve superior performance in reading comprehension tasks.

Table 7 presents the outcomes of the numerical reasoning task. Due to a few teams either missing the submission deadline or reporting their results in different formats, these are included in the unofficial evaluation section. For comprehensive details on their methodologies and results, their respective papers should be consulted. LLMs demonstrated commendable performance in this task, with the methodologies of the participants detailed subsequently. Fan et al. (2024) secured the highest performance with Qwen-72B-Chat (Bai et al., 2023), employing a strategy that distinguishes the input question as either a calculation or an application problem, alongside utilizing a data augmentation technique to enhance performance. Their approach incorporated two additional datasets: GSM8K (Cobbe et al., 2021) and MetaMathQA (Yu et al., 2023). Qian et al. (2024) disclosed the results of fine-tuning GPT-3.5, whereas Chen et al. (2024) applied Flan-T5 with Chain of Thought (CoT), complemented by the use of a calculator for accuracy improvement, which yielded superior results compared to direct arithmetic computations by models. Zhao et al. (2024) fine-tuned Mistral-7B (Jiang et al., 2023), achieving performance comparable to that of fine-tuned GPT-3.5. Gonzalez et al. (2024) combined the outputs of Flan T5 and GPT-3.5, whereas He et al. (2024) implemented Llama 2-7B (Touvron et al., 2023) with CoT. Additionally, Crum and Bethard (2024) utilized Flan-T5-Lamini, and Rajpoot and Chukamphaeng (2024) fine-tuned Mistral-7B. Bahad et al. (2024) reported the performance derived from prompting GPT-3.5. In conclusion, fine-tuning LLMs and a clear understanding of the task, particularly the decision on whether to employ an external calculator, are crucial for achieving enhanced performance in numerical reasoning tasks.

Table 8 displays the outcomes of headline generation tasks. Rajpoot and Chukamphaeng (2024) enhanced Mistral-7B, yielding headlines with numerals closely matching those chosen by journalists. In the reasoning subset, this approach also secures high accuracy. Chuang and Zhunis (2024) employed BART (Lewis et al., 2020) alongside a contractive learning approach, achieving superior performance in the copying subset. Compared to these

Table 8: Automatic Evaluation — Headline Generation.

teams, several groups have utilized LLMs, obtaining improved scores in ROUGE, BERTScore, and MoverScore metrics, albeit with reduced numeral precision. Chen et al. (2024) implemented Flan-T5 with an instruction tuning strategy and enhanced it by retrieving similar cases for model referencing, leading to top results across ROUGE, BERTScore, and MoverScore evaluations. He et al. (2024) applied Llama-2-7B with retrieval augmented generation (RAG), while Crum and Bethard (2024) developed a T5-based title generator.[2] Zhao et al. (2024) fine-tuned Mistral-7B using CoT, and Bahad et al. (2024) engaged GPT-3.5 through prompting. Singh et al. (2024) examined the efficacy of Llama under a few-shot learning framework. Overall, these findings suggest that while fine-tuning can enhance numeral selection accuracy, it might decrease the similarity between the generated headlines and the actual headlines.

4 Human Evaluation

4.1 Guidelines

To enhance the evaluation of generated headlines, we implement peer evaluation for the outputs from participants' systems. Participants are required to assess the models of other teams. The evaluation comprises two metrics:

- **Numerical Accuracy**: This metric evaluates the precision of numbers within the generated headlines. It aims to verify the correctness of numerical data presented in each headline. Systems are ranked based on their average scores, adhering to the following criteria:
  - Assign 2 points for fully accurate numerical data.
  - Allocate 1 point for partially accurate numbers.
  - Give 0 points for completely inaccurate or missing numbers.
- **Optimal Headline**: This assessment involves selecting the most appropriate headline from a set of nine options. Given that nine teams have submitted their outcomes for review, we substitute the outputs from the evaluating team with journalists' headlines, serving as the ground truth. The "best headline" is identified as the one that the evaluator considers most suitable for the journalist of the corresponding news article. The system receiving the highest number of votes will be awarded one point, with points accumulated for ranking purposes. If multiple systems tie with the

Trans	9.91%
Paraphrase	11.71%
Round	21.62%
Subtract	7.21%
Add	11.71%
Span	4.50%
Divide	4.50%
Multiply	5.41%

Table 10: Statistics of the operators present in the error sets of the top four systems for numerical reasoning.

same number of votes for first place on a given instance, each will receive one point.

4.2 Evaluation Results

Table 9 presents the outcomes of the human evaluation process. Numerical accuracy is derived from evaluating 50 instances, with each instance receiving three annotations. The determination of the optimal headline originates from the analysis of 100 instances. According to the results, He et al. (2024) secures the highest marks in terms of numerical accuracy, despite their fourth position in automatic evaluation. Furthermore, while Rajpoot and Chukamphaeng (2024) achieves the top rank in automatic evaluation, their performance is observed to be the least favorable in human assessment among all systems evaluated. An additional noteworthy observation is that Zhao et al. (2024), utilizing the same language model as Rajpoot and Chukamphaeng (2024), attains higher scores in human evaluation.

In the context of optimal headline generation, Singh et al. (2024) receives the highest score, even though it is placed at the lower end in automatic evaluation and does not exhibit exceptional performance in numerical accuracy. He et al. (2024) is ranked second in this regard, outperforming other teams. These findings suggest that Llama (2) excels in tasks related to headline generation, considering both numerical accuracy and optimal headline aspects. Given that the ground truth was also evaluated as a candidate, its score is disclosed in Table 9, where it achieves 28 points. This score is superior to most systems and marginally lower than that of Singh et al. (2024).

5 Discussion

5.1 Error Analysis

Through the examination of participant contributions, it is observed that simple numerical questions are on the verge of being effectively addressed with the selection of an optimal language model for specific tasks. In quantitative tasks, Kalantari et al. (2024) reports achieving over 96% in micro-F1 across all subtasks through the application of Qrca2. Within the NQuAD framework, Chen et al. (2024) employs Randeng-T5-77M to secure approximately 90% accuracy, while Fan et al. (2024) attains a 95% accuracy rate utilizing Qwen-72B-Chat. For the task of headline generation, numerous teams have recorded impressive scores in human evaluations, matching or surpassing the ground truth benchmarks. These findings suggest that the era may be approaching a point where traditional tasks requiring numerical understanding and generation are nearly resolved.

However, there remain several challenges for current language models. In Table 10, we provide statistics of the operators present in the error sets of the top four systems for numerical reasoning. For instance, when presented with the masked headline "Mother of 3 Gives Huge Gift to Dying Friend" based on the news:

> "When Beth Laitkep's breast cancer spread to her brain and spine, doctors realized she had limited time left. The concern arose about the future of her six children. 'If a miracle doesn't occur and I do not survive, could you take my children as your own?' she inquired of her friend Stephanie Culley, as recounted to People magazine. Culley agreed without hesitation. Consequently, Ace (aged 2), Lily (5), Dallas (10), Jaxson (11), Selena (14), and Will (15) moved in with Culley, her husband Donnie, and their three children following Laitkep's demise in May at 39. Fortuitously, Donnie, a construction worker, had constructed their home in Alton, Virginia, with ample bedrooms

Table 11: Human Preference.

to accommodate everyone. 'She is exceedingly humble and refrains from seeking assistance,' a friend of Stephanie's informed WSET. 'She's an angel.' (This family adopts children who are facing terminal conditions.)"

Three out of four models filled the blank with 6, while one model suggested 7. This instance illustrates the difficulty models face with numerical reasoning in complex narrative contexts.

Another intricate scenario involves a report that "A 66-year-old woman, pregnant and poised to become Britain's oldest mother, remains unrepentant about her choice, asserting her feeling akin to a 39-year-old on certain days," as detailed by the Mirror. Despite the varied daily feelings of being 39 or 56, Munro, who is 8 months pregnant, disregards the media attention, emphasizing the personal nature of her pregnancy decision. However, all models incorrectly predicted 39 instead of 66 for the headline "Brit Mum-to-Be 'Younger at Heart' Than 66, She Tells Critics".

Moreover, there are instances where models simply replicate rather than approximate numbers. For example, the correct answer for the headline "Car Auctions Off for Record-Breaking $____M" is 34.7, yet model predictions included 34.6, 34.65, and 38.0, with 34.65 being directly taken from the article text. In this case, some generated results may still be correct but just not the same as ground truth.

5.2 Human Preference

Given that most models, particularly LLMs, are adept at producing fluent headlines, the pertinent discussion revolves around the selection criteria among multiple headline candidates. This section delves into analyzing optimal headline annotations based on participant feedback. Table 11 presents statistics from different teams' annotations, highlighting the diversity in human preferences towards

Aspect	Statistics
Average Length of Best Headlines	9.47 Words
Average Length of Other Selected Headlines	9.54 Words
ROUGE 1 between Best and Other	0.4373
ROUGE 2 between Best and Other	0.1951
ROUGE L between Best and Other	0.3791

Table 12: Statistics of the best headline (Best) and other selected headlines (Other).

headline recommendations. Notably, most systems were primarily favored by a single team, with the exception of Bahad et al. (2024), which garnered the highest votes from three teams. Singh et al. (2024)'s pronounced preference for Bahad et al. (2024)'s system outputs stands out. Apart from this unique instance, determining the superior system is challenging, as preferences may vary across users. Another key observation is the ground truth achieving scores comparable to those of headlines generated by various systems, suggesting that striving for verbatim replication of the ground truth may be becoming obsolete in the context of LLMs. The emphasis may shift towards assessing the quality of generated text through more subjective and nuanced measures. Furthermore, the human evaluation results depicted in Table 11 underscore the difficulty in appraising generated headlines through manual voting, given the variance in team preferences. This inquiry constitutes the inaugural research question posited by NumEval, paving the way for subsequent investigations aimed at enhancing headline generation methodologies.

To further elucidate, we present statistics in Table 12, computed based on headlines chosen by at least one annotator. Initially, it is observed that the length of the optimal headline closely mirrors that of other selected headlines. Additionally, we compute the ROUGE scores to compare the optimal headlines against others selected. We use the following two instances to illustrate our observations.

Consider the following headlines that garnered the most votes:

- Dow Falls 64 Points, Comes Within Half a Point of 20K
- Dow Stocks Soar but Fail to Reach 20,000 Mark

Headlines receiving one vote include:

- Dow Nears 20K, But Loses Momentum
- Dow Comes Within Half a Point of 20K
- Dow Closes Below 20K
- Dow Falls Short of 20K

This analysis reveals that while all headlines convey accurate information, their level of informativeness varies. For instance, the first headline specifies a 64-point decline, a detail absent in other titles.

Another noteworthy example is the headline "NBA Season Cancellations Likely to Extend Through November 28 Due to Salary," compared with:

- NBA Season in Jeopardy as Owners Push for 50-50 Revenue Split
- NBA Season Could Be Canceled Through Nov. 28
- NBA May Cancel 2 More Weeks of Season
- NBA to Cancel 2 More Weeks of Season
- NBA Canceling 2 More Weeks of Games? 102 More Games Gone
- NBA Planned to Ax 102 More Games

In this scenario, the optimal headline succinctly conveys the cause (salary), consequence (game cancellations), and timeframe (through Nov. 28), whereas others mention only one or two of these elements. These examples, alongside our statistics, illustrate that brevity does not necessarily equate to superiority. A headline that encapsulates the most crucial information is often more valuable. Consequently, a further proposed open research question for future studies concerns the estimation of the informativeness of the generated headline.

6 Conclusion

In this paper, we explored the complexities of numerical understanding and generation in text, an area that has garnered increasing interest within the NLP community. By introducing and evaluating a set of tasks across diverse datasets, our work highlighted significant progress towards enhancing models' numerical comprehension and their application in practical scenarios, including quantitative analysis and numeral-aware headline generation. Our comprehensive evaluation, encompassing both automatic and human assessments, demonstrated the capabilities and limitations of current methodologies, emphasizing the sophisticated understanding necessary to effectively manipulate and interpret numerical information in textual formats. As we approach the mastery of simple numerical questions with the appropriate selection of language models, our research indicates a shift towards more intricate and nuanced challenges in numerical NLP. The advancements facilitated by NumEval set the stage for future investigations into the deeper integration of numeracy and language, aiming not only for models that comprehend numbers but also for those capable of reasoning, inferring, and generating text that accurately reflects the quantitative dimensions of the world.

Limitation

Although we strive to provide a comprehensive analysis, several limitations exist in NumEval and this paper. First, for the automatic evaluation, the metrics for Quantitative 101, NQuAD, and Numerical Reasoning tasks are overly simplistic, failing to verify whether models truly engage the correct reasoning steps. Second, the numerical accuracy component of human evaluation was not annotated by a consistent group of annotators, potentially subjecting the results to variability due to the subjective nature of the task. Moreover, the selection of optimal headline candidates varies across teams since we exclude headlines generated by the annotator team's system, which may further introduce inaccuracies in human evaluation. Third, although our findings suggest the tasks appear almost solved, this perception may stem from the simplistic settings of the datasets. Our error analysis reveals ongoing challenges in complex contexts, and the discussion of NumEval omits more complex reasoning steps.

UCSC NLP at SemEval-2024 Task 10: Emotion Discovery and Reasoning its Flip in Conversation (EDiReF)

Steven Au, Decker Krogh, Esha Ubale, and Neng Wan
University of California, Santa Cruz
Baskin School of Engineering, Natural Language Processing
{sttau, dkrogh, eubale, newan}@ucsc.edu

Abstract

We describe SemEval-2024 Task 10: EDiReF consisting of three sub-tasks involving emotion in conversation across Hinglish code-mixed and English datasets. Subtasks include classification of speaker emotion in multiparty conversations (Emotion Recognition in Conversation) and reasoning around shifts in speaker emotion state (Emotion Flip Reasoning). We deployed a BERT model for emotion recognition and two GRU-based models for emotion flip reasoning[1]. Our model achieved F1 scores of 0.45, 0.79, and 0.68 for subtasks 1, 2, and 3, respectively.

1 Introduction

Emotion recognition in natural language provides quantifiable insights into the traditionally qualitative realm of emotive language, bridging fields such as psychology, cognition, and linguistics. The explosion of textual data in recent years from social media platforms like Twitter and the introduction of highly cable text-processing models has provided researchers the opportunity to perform analyses on conversations that are highly complex. Despite these developments, the inherent subjectivity of emotion continues to present a challenge to the field.

Without visual information and speech audio, NLP systems must decipher rapid changes in emotional states solely through text, missing out on the nuanced non-verbal cues that often signal these shifts during spoken interactions. The absence of these cues can lead to model inaccuracies during conversational transitions such as from joy to sarcasm, or from calmness to anger.

Understanding the dynamics of emotion in the context of conversations is vital for building better conversational agents. While classifying changes in the emotion of a speaker is an important first step in this goal, it comes up short of being able to explain why the change occurred. Emotion flip reasoning is a task which has been proposed which seeks to identify the specific cause of speaker emotion flips in the context of a conversation (Kumar et al., 2022) (Kumar et al., 2024b). For example if a speaker's emotion in one utterance is joy but in their next utterance it is sad, we would like to pinpoint which utterances in the conversation caused it whether it be another speaker's or their own.

1.1 Hinglish

Hinglish, a blend of Hindi and English written in the Roman alphabet, incorporates English words into traditional Hindi contexts. This code-mixing phenomenon is becoming increasingly prevalent as English extends its influence into non-English speaking societies. Hinglish provides a challenge to models that have only been trained on English and Hindi because the model struggles to distinguish between English and Hindi words (Solorio et al., 2014). Recent work has sought to improve model performance on code-mixed dialog and new datasets have been constructed to enable these developments (Kumar et al., 2023). One goal of this research is to contribute to this work of producing models that can better understand the emotion of speakers in Hinglish.

Commonsense discernment between languages plays a pivotal role in emotion recognition within code-mixed languages, as it aids in navigating the nuanced linguistic landscapes that arise when languages intertwine (Kumar et al., 2023). Historically, individual words and phrases have been identified as significant emotional triggers, serving as fundamental elements in the computational understanding of emotions (Mohammad and Turney, 2010). This is especially pertinent in code-mixed contexts where the semantic layers are compounded by the interplay of distinct linguistic systems.

A large number research on emotion recognition

[1] https://github.com/deckerkrogh/semeval-2024-10

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1492–1497

to date has focused on extracting and interpreting common emotion-laden lexicon from Twitter corpora. While beneficial, this approach predominantly captures public, social media-expressed sentiments, which may not fully encapsulate the subtleties found in personal or private conversational contexts. This is particularly true for code-mixed interactions, where cultural contexts and language mixing patterns can greatly affect emotional expression. Datasets produced from television shows allow for insight into these more these private conversational contexts.

2 Task Description

The **EDiReF shared task at SemEval 2024** is an amalgamation of three subtasks tasks-

(i) Emotion Recognition in Conversation (ERC) in Hindi-English code-mixed conversations,

(ii) Emotion Flip Reasoning (EFR) in Hindi-English code-mixed conversations, and

(iii) EFR in English conversations.

ERC Definition: Given a dialogue, ERC aims to assign an emotion to each utterance from a predefined set of possible emotions.

EFR Definition: Given a dialogue, EFR aims to identify the trigger utterance(s) for an emotion flip in a multi-party conversation dialogue.

Speaker	Utterance	Emotion	Trigger
Sp1	Aaj to bhot awful day tha!		
	(I had an awful day today!)	Sad	0
Sp2	Oh no! Kya hua?		
	(Oh no! What happened?)	Sad	0
Sp1	Kisi ne mera sandwich kha liya!		
	(Somebody ate my sandwich!)	Sad	0
Sp2	Me abhi tumhare liye new bana deti hun!		
	(I can make you a new one right now!)	Joy	1
Sp1	Wo great hoga! Thanks!		
	(That would be great! Thanks!)	Joy	0

Table 1: Example of a dialogue from the MaSaC dataset.

We are one of 84 teams which submitted an entry to the task 10 code submission, and one of 21 which submitted papers for the task 10 workshop. (Kumar et al., 2024a).

2.1 Datasets

Two datasets were used in this task.

MELD is a dataset released in 2017 made from dialog from the TV show *Friends*. This dataset contains a list of conversations, each with multiple utterances that have been tagged with an emotion label. It has seen extensive use in research related to emotion recognition and its use in the finetuning of transformers has produced models with major improvements in tasks such as emotion recognition. For this task the task organizers produced a modified MELD dataset which has been labeled with emotion triggers (Kumar et al., 2024b). This was used for task three.

MaSaC is a Hinglish dataset produced in 2021 containing conversations with emotion-labelled utterances which were extracted from the television show *Sarabhai vs. Sarabhai*. (Bedi et al., 2021). MaSaC was used for tasks one and two. The task organizers tagged emotion triggers for the dataset used in task two.

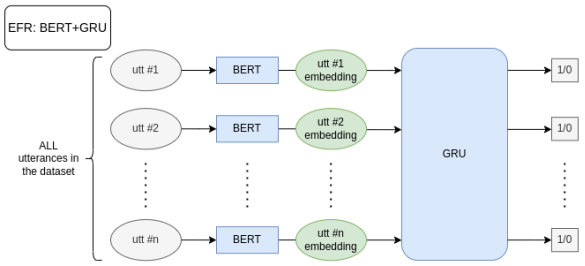

Figure 1: Illustration of the BERT+GRU architecture for the Emotion Flip Reasoning task

3 System Overview

In this study, we introduce an integrated framework that combines Bidirectional Encoder Representations from Transformers (BERT) with Gated Recurrent Unit (GRU) networks.

3.1 BERT for Emotion Recognition in Conversation

BERT was used to perform emotion recognition for the ERC task. Unlike traditional models that process text sequentially, BERT examines text bidirectionally, allowing for a comprehensive understanding of word semantics in context. Additionally, BERT's pre-training on extensive language corpora equips it with a broad understanding of language nuances, idioms, and the varied syntax used to express emotions, providing a robust starting point for fine-tuning emotion-specific datasets.

3.2 BERT+GRU for Emotion Flip Reasoning

Upon extracting contextual embeddings from BERT, we employ a GRU layer to analyze the sequence of conversational utterances. GRUs are a type of recurrent neural network optimized for

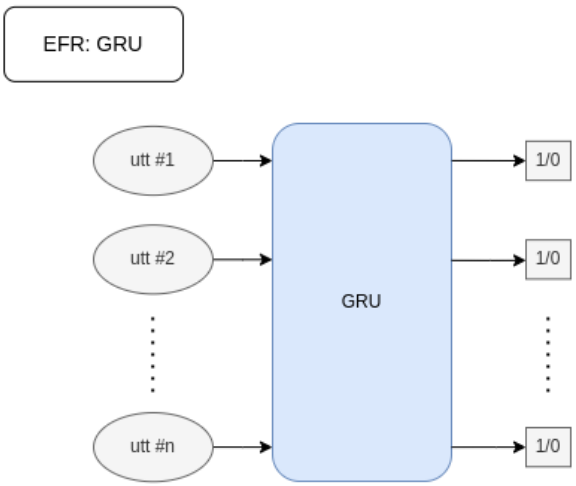

Figure 2: Simple GRU model for Emotion Flip Reasoning.

handling sequential information while mitigating issues related to long-term dependency recognition. The intent is that GRUs will be able to track the evolution of emotional states across a dialogue. Understanding the temporal sequence and the transition between emotional states is necessary in the context of emotion flip detection.

3.3 Rationale for Architectural Integration

The decision to integrate BERT with GRU stems from a strategic consideration of their respective strengths in handling different aspects of emotion analysis. BERT's contextual embeddings provide a snapshot of the emotional landscape within each utterance. While BERT excels at static context understanding, it cannot provide the sequence-to-sequence operation necessary to perform trigger classification. The purpose of the GRU is to use these static BERT embeddings to interpret the flow and dynamics of emotions through time so in order to perform trigger classification.

3.4 GRU

In addition to the BERT+GRU architecture, we also created a simpler GRU model which takes the utterances directly as input.

4 Experimental Setup

4.1 Emotion Recognition Model: BERT

We employ the pretrained BertForSequenceClassification model from the Hugging Face Transformers library. We added a fully connected linear layer with an output that matches the number of emotions. There are 7 emotions for MELD and 8 for MaSaC. The model was finetuned for 4 epochs with the AdamW optimizer set to a learning rate of 5^{-4} and an epsilon of 1^{-5}.

4.2 EFR: BERT+GRU

We constructed a deep learning model utilizing the Keras framework tailored for binary classification tasks.

BERT Embeddings: We first generate embeddings for each utterance in a conversation which will then be fed into the GRU. These embeddings were generated with the same pretrained BERT model used in the ERC task. The goal is that these embeddings can capture and provide emotion-specific information for the GRU in trigger classification.

GRU: The model consists of two bidirectional GRU layers with 32 units. We did not perform any separation between the conversations. Conversational structure is collapsed into a long sequence of utterances and passed into the GRU.

Classifier Layer: The final layer is a dense classifier with a single output unit which performs binary trigger classification for each utterance.

4.3 EFR: GRU

This model is the same as the GRU+BERT model, however instead of using BERT embeddings we use a default Keras embedding layer and pass utterances in directly.

5 Results

Table 2: F1 Scores and Task Placement

Task 1	Task 2	Task 3
0.45 (8)	0.79 (2)	0.68 (8)

5.1 Sub Task-1: ERC in Hindi-English Code-mixed Conversations

The model obtained an F1 score of 0.45 on emotion recognition in Hindi-English code-mixed conversations. The model showed a mediocre ability to capture emotional expressions.

5.2 Sub Task-2: EFR in Hindi-English Code-mixed Conversations

The GRU-only model demonstrated strong performance, achieving an F1 score of 0.76 on the validation Set and 0.79 on the test Set. This was significantly higher than the BERT+GRU model which achieved an F1 score of 0.66. These results suggest that the BERT embeddings were not able provide useful context for the GRU. It also suggests that the GRU is capable of effectively capturing the dynamic nature of emotional transitions. Despite our more novel model performing worse than the simpler one, the simple GRU achieved second place in the CodaLab competition.

5.3 Sub Task-3: EFR in English Conversations

The GRU-only model achieves F1 scores of 0.68 for the validation and 0.67 on the test set on the EFR task, outperforming the BERT+GRU model.

5.4 Further Testing

We tested additional inputs where we passed the speaker information to see if emotion recognition improved in subtasks 2 and 3 for the task. No improvements were seen in F1 but might influence the embeddings. We didn't test the EFR pipeline unless we saw improvement in ERC. We also double-checked the abnormally high emotion recognition F1 score for subtask 2 as we stripped the conversation structure and passed in duplicate utterances with shuffling. We redid the test with unique utterances and achieved .87 F1 in the test set. Surprisingly this did not affect our score for subtasks one or three. We also increased the dataset size by combining datasets 1 and 2 for Hinglish and using the whole dyadic conversations from MELD with dataset 3. The scores for ERC show no changes.

Further testing is necessary to investigate why the GRU-only model outperformed BERT+GRU. We hypothesize that it may be that the GRU simply wasn't large enough to be capable of using the the large BERT embeddings.

Another change to the model that may improve performance is to create some sort of separator embedding between the conversations. This extra information may improve performance by allowing the model to learn where triggers are placed relative to the start and end of a conversation.

6 Conclusion

The baseline approach, which employs basic embeddings of utterances and emotions, proved adequate for capturing emotion flip reasoning in large datasets, despite cultural differences and code-mixing ambiguities. The need to pass conversational information is not a substantial indicator of the prediction EFR triggers nor does passing the emotion labels into the embeddings.

In the future, we plan to explore multitask classification with BERT to determine if combined training enhances the transformer's ability to learn emotional sequence information or integrate additional conversational context to account for speaker dependencies, similar to EmoBERTa's approach. We may attempt to replicate EmoBerta's methodology to see how much emotion labels increase EFR accuracy.

Addressing the challenges of code-mixing in Hinglish and enhancing cross-cultural emotion comprehension remain critical for improving the recognition of emotional transitions.

Abstract

Detecting machine-generated text is a critical task in the era of large language models. In this paper, we present our systems for SemEval-2024 Task 8, which focuses on multi-class classification to discern between human-written and maching-generated texts by five state-of-the-art large language models. We propose three different systems: unsupervised text similarity, triplet-loss-trained text similarity, and text classification. We show that the triplet-loss-trained text similarity system outperforms the other systems, achieving 80% accuracy on the test set and surpassing the baseline model for this subtask. Additionally, our text classification system, which takes into account sentence paraphrases generated by the candidate models, also outperforms the unsupervised text similarity system, achieving 74% accuracy.

1 Introduction

The rapid evolution of large language models (LLMs) has significantly impacted the dynamics of information exchange, blurring the lines between human and machine-generated text. State-of-the-art LLMs are available to the public on a large scale, allowing users to generate human-like text with minimal effort. This advancement poses a dual-edged sword: while offering unprecedented capabilities in generating human-like text, it also raises critical concerns about privacy(Huang et al., 2022), ethics (Smiley et al., 2017; Kamocki and Witt, 2022), and misinformation (Pan et al., 2023; Goldstein et al., 2023; Stiff and Johansson, 2022) —especially given the LLMs' tendency to produce plausible yet factually baseless content, known as hallucinations (Dziri et al., 2022; Das et al., 2022). Distinguishing between human and machine authorship has thus emerged as a major challenge, bearing implications for content credibility and ethical standards in digital communication. As a response to the need for effective detection methods that can discern the origin of text in this new landscape, the SemEval-2024 Task 8 (Wang et al., 2024) presents an exciting challenge of AI-generated text detection over three different subtasks: Subtask A: Binary Human-Written vs. Machine-Generated Text Classification, Subtask B: Multi-Way Machine-Generated Text Classification, and Subtask C: Human-Machine Mixed Text Detection.

In this paper, we work on Subtask B, which focuses on multi-class classification to distinguish between human-written and machine-generated text by five state-of-the-art LLMs. These models are ChatGPT, `text-davinci-003`, LLaMa (Touvron et al., 2023), Cohere, Dolly-v2 (Conover et al., 2023), and BLOOMz (Muennighoff et al., 2023).

We propose three different systems to address this task: unsupervised text similarity, triplet-loss-trained text similarity, and text classification.

We show that the triplet-loss-trained text similarity system outperforms the other systems, achieving 80% accuracy on the test set and surpassing the baseline model for this subtask. Additionally, our text classification system, which takes into account sentence paraphrases generated by the candidate models, also outperforms the unsupervised text similarity system, achieving 74% accuracy. However, the unsupervised text similarity system performs poorly, achieving only 29% accuracy on the test set. We note that the latter is the only system that we submitted to the task, and the other systems are post-evaluation improvements. The main contributions of this paper are:

- An unsupervised text similarity system that computes cosine similarity to measure text similarity, which assesses the angle between vector representations of texts.
- A sentence transformer trained with triplet loss to learn the distinctions between the given texts.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1498–1504

- A RoBERTa classifier that makes decisions based on the given paragraph.
- A RoBERTa classifier which takes into account sentence paraphrases generated by the candidate models.

2 Background and Related Work

Recent research has resulted in significant advancements in Natural language generation (NLG) models (Vaswani et al., 2017) and generative pre-trained transformer (GPT) models (Devlin et al., 2019; Qiu et al., 2020) However, with potential threats posed by these models, research on identifying machine-generated text has also surged (Jawahar et al., 2020; Valiaiev, 2024). Initially, methods employing traditional machine learning models such as logistic regression were proposed (Ippolito et al., 2020). Nevertheless, the limitation of the machine learning model, which requires extensive re-training (Valiaiev, 2024), and the rise of the pre-trained transformer models, have prompted researchers to adopt the large models. Relatively smaller language models such as RoBERTa (Liu et al., 2020) have achieved state-of-the-art performance across various domains including social media, news articles, and online reviews (Uchendu et al., 2020; Adelani et al., 2020; Fagni et al., 2021). In addition to this, other approaches based on contrastive learning and similarity metrics (Boenninghoff et al., 2019) have also emerged. Such research efforts continue with the ongoing evolution and adoption of text-generative models.

3 Dataset

We work with M4 (Wang et al., 2023), a dataset for SemEval-2024 Task 8, which consists of 71,027 data samples for the training set, 3,000 data samples for the development set, and 18,000 data samples for the test set. Each sample is labeled with one of the six labels: Human, ChatGPT, Davinci, Cohere, BLOOMz, or Dolly. Figure 1 shows an example of the given dataset, which consists of id, text, model, label, and source.

Wang et al. (2023) prompted these models to write a passage given some information from the source. The sources of the texts are diverse, including Wikipedia, WikiHow (Koupaee and Wang, 2018), Reddit, arXiv, and Peer-Read (Kang et al., 2018).

4 System Overview

In this section, we provide a comprehensive overview of the three approaches we explored: unsupervised text similarity, triplet-loss-trained text similarity, and text classification.

4.1 Approach 1: Unsupervised Text Similarity

The first strategy we submitted is based on computing cosine similarity to measure text similarity, which assesses the angle between vector representations of texts. A label for multi-class classification is assigned based on the highest cosine similarity score.

4.1.1 Model Architecture

The text data is encoded using a pre-trained sentence transformer model (Reimers and Gurevych, 2019) without any additional training, followed by computing the averaged pooling embedding across all the training instances of each class. Subsequently, we calculated the cosine similarity between the text and the average-pooled embedding for each class, assigning the text to the class with the highest cosine similarity. This approach effectively categorizes the semantic similarity of texts based on topics and classifies texts with divergent writing styles (Ibrahim et al., 2023).

4.2 Approach 2: Triplet-Loss-Trained Text Similarity

Text similarity models can also be trained on the provided training data.[1] For this approach, we train a sentence transformer model with a triplet loss, which requires three inputs during training: anchor, positive, and negative samples $(x_i, {x_i}^+, {x_j}^-)$. This loss function aims to minimize the distance between the anchor and positive data $(x_i, {x_i}^+)$ while simultaneously maximizing the distance between the anchor and negative data$(x_i, {x_j}^-)$ (Ren and Xue, 2020). We conduct this training to enhance the vector representations of texts for multi-class classification.

4.2.1 Constructing Triplets

To construct the dataset with three inputs, we adopt the concept of hard positive ${x_i}^+$ and hard negative ${x_j}^-$ sampling. Hard positive involves selecting a text with the lowest similarity within the same class i, whereas hard negative involves choosing a text with the highest similarity from different

[1]This approach is a post-evaluation improvement and was not submitted to the task.

Id	Text	Model	Label	Source
557	Have you ever wanted to surprise someone with a unique and personalized cake? Look no further than an iPhone cake! With a few simple steps and some creativity, you can make a one-of-a-kind dessert that will impress anyone who sees it. Follow these steps to make your own iPhone cake: 1. Prepare 2 rectangular package cakes that can be easily form-fitted to fit with round corners. If you can't find rectangular cakes, you can simply cut and shape the cakes after baking to create the desired size and shape. . . . 10. Use several colors of fondant to create some of the apps all devices have. Work with these small pieces of colored fondants. You can use a toothpick to stick these apps into the cake, or use water and a brush to brush them onto the cake. In conclusion, making an iPhone cake is not as difficult as it may seem. This cake will be a hit with anyone, from your kids to your coworkers, and will impress them with your creativity. Just follow these simple steps and enjoy the final result!	ChatGPT	1	wikihow

classes. This concept maximizes the distinction between various classes (Robinson et al., 2021; Xu and Bethard, 2021). As the metric for similarity, we employ cosine similarity to select hard positive x_i^+ and hard negative samples x_j^- within a mini-batch. An example of the triple dataset is shown in Table 1.

4.2.2 Model Architecture

We first fine-tuned the same pre-trained sentence transformer model as in approach 1 (Reimers and Gurevych, 2019) using the triplet data and TripletMarginLoss. Then we attached a six-way classification head to the transformer using a linear layer and CrossEntropy loss. Figure 2 illustrates the overall framework, including triplet learning and classification.

4.3 Approach 3: Text Classification

We also explored a simple text classification approach where a classifier takes the given passage as the input and predicts one of the six possible labels (human or one of five LLMs) as output.[2]

We explored a variant of this text classification approach where we augment the input by asking each of the five LLMs to generate a short text. We mask a random sentence in the input paragraph and

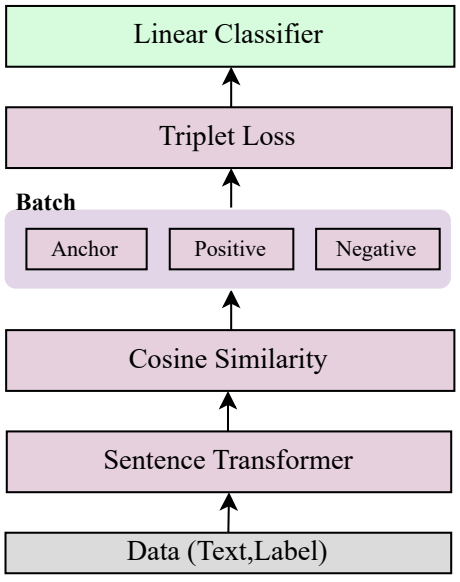

Figure 2: The overall framework of our triplet learning system proposed for Semeval-2024 Task 8.

[2]This approach is a post-evaluation improvement and was not submitted to the task.

then prompt the models to fill in the mask with a sentence that has a meaning similar to the original sentence in their own style. Due to computational limitations, we were unable to run Dolly due to its memory requirements and did not have enough resources to generate sentence paraphrases for all the over 70,000 instances in the training set. Therefore, we randomly chose 4,000 instances of each class for training, and generated paraphrases for all models other than Dolly.

4.3.1 Model Architecture

For both text classification models, we train a transformer that takes text as input and produces one of the six possible labels (human or one of five LLMs) as output. Due to the limitation of the number of input tokens for the transformer model we use (RoBERTa), we had to truncate the inputs to keep 512 tokens of the given paragraph and, for the input-augmented model, 128 tokens from each sentence paraphrase.

5 Experiments

5.1 Experimental Setup

For the unsupervised text similarity approach, we used the `paraphrase-distilroberta-base-v1` sentence transformers model from the HuggingFace library (Wolf et al., 2020). This model is based on the DistilRoBERTa architecture for clustering or semantic search. We computed the cosine similarity between the text embeddings using the PyNNDescent library[3] to facilitate an approximate nearest neighbor search in a huge dataset.

For the triplet-trained text similarity approach, we used the same sentence transformers model but trained it on the training data. We explored different hyper-parameter combinations, varying two learning rates (1-e5 and 3e-5) and two batch sizes (16 and 32) across 5 epochs and 10 epochs. Our final embedding model was trained using a learning rate of 1e-5 and a batch size of 16 for 10 epochs. For the six-way multi-class classification learning, we experimented with several classification head formulations: ReLU activation functions, dropout layers, and linear layers. The final classifier was trained with a linear layer and CrossEntropy loss. For this multi-class classification, we utilized a learning rate of 1e-5 and a batch size of 32 for 10 epochs.

Split	Metrics	UnSim	TripSim	TextCls	ParaCls
Test	A	0.29	0.80	0.72	0.74
Test	P	0.37	0.82	0.79	0.81
Test	R	0.29	0.80	0.72	0.74
Test	F1	0.24	0.79	0.71	0.73

Table 2: Accuracy (A), precision (P), recall (R), and F1 score of unsupervised text similarity (UnSim), triplet-trained text similarity (TripSim), text classification (TextCls), and paraphrase-augmented text classification (ParaCls).

For the text classification approach, we used the `roberta-large` model (Liu et al., 2020) from the HuggingFace library (Wolf et al., 2020). We used a learning rate of 1e-6 and 5e-7 respectively with a batch size of 8, and early stopping set to 3.

5.2 Results

Table 2 shows the performance of our different approaches – unsupervised text similarity (UnSim), triplet-trained text similarity (TripSim), text classification (TextCls), and paraphrase-augmented text classification (ParaCls) – in terms of accuracy (A), Precision (P), Recall (R), and F1 score. The submitted approach, UnSim, shows low metrics scores: 29% accuracy for the test dataset. Both the simple text classifier and the paraphrase-augmented text classifier performed better, achieving 72% and 74% accuracy on the test set, respectively. The paraphrase augmentation provided some additional information to the model, with a statistically significant improvement (McNemar's test (McNemar, 1947), $p < 0.05$) over not using sentence paraphrases. The best model was the text similarity model trained with triplet loss, which achieved 80% accuracy and 82% precision on the test dataset, surpassing the baseline model for this subtask. This improved performance underscores that the embedding obtained from triplet loss effectively learned the text distinctions by maximizing the differences between positive and negative samples.

We provide a breakdown by label for the text classification models, as shown in Table 3.

6 Conclusion

In this paper, we presented several different systems for SemEval 2024 Task 8's text classification between human and five distinct machines. Our submitted model, which relied on unsupervised embeddings coupled with cosine similarity, was poor at handling the diverse writing styles over the

Model	Label	P	R	F-1

ParaCls	Dolly	0.67	0.80	0.73

Table 3: Detailed breakdown of results on the test set for the text classification models.

same topics that were present in the data, resulting in low classification scores. Our text classification approaches and our triplet-trained text similarity approach all outperformed the simple unsupervised model. The triplet loss learning especially improved performance over the submitted model, with its pretraining allowing it to better maximize the distinctions between texts.

For future work, we plan to adapt our systems to other classification tasks. We also plan to explore other methods for training the triplet loss model, such as using a larger model or using a different loss function. Additionally, using a larger dataset for the text classification models could improve their performance.

7 Limitations

We note that our systems are not perfect and have several limitations. For instance, we did not have enough resources to generate sentence paraphrases for all instances in the training set. We also did not have enough resources to run Dolly due to its memory requirements. Additionally, we did not explore other methods for training the triplet loss model, such as using a larger model or using a different loss function. Finally, we acknowledge that we did not try using LLMs for the classification of machine-generated text, which could potentially improve the performance of our systems.

SINAI at SemEval-2024 Task 8: Fine-tuning on Words and Perplexity as Features for Detecting Machine Written Text

Alberto J. Gutiérrez-Megías, L. Alfonso Ureña-López, Eugenio Martínez-Cámara
SINAI Research Group, Advanced Studies Center in ICT (CEATIC)
University of Jaén, Spain

Abstract

This work describes the system submitted by the SINAI team to the subtask A of Task 8 of SemEval 2024, as well as two additional systems evaluated during the training phase of the shared task. We claim that the perplexity score of a text may be used as a classification signal. Accordingly, we conduct a study on the utility of perplexity for discerning text authorship, and we perform a comparative analysis of the results obtained on the datasets of the task. The results of this study motivated us to use as classification features the word embeddings vectors of the input texts and its corresponding perplexity score. Likewise, the submitted system is a fine-tuning version of the XLM-RoBERTa-Large model. The analysis of the results of the evaluation shows large differences among the language probability distribution of the training and test sets. Nonetheless, the results show that perplexity can be used as feature for identifying machine generated text, hence our claim holds.

1 Introduction

In recent years, the use of generative models has increased considerably. The capabilities of this multifaceted tool include summarizing texts, retrieving information through searches, rephrasing texts for specific purposes and so on. However, it is important to recognize the potential threats associated with their application in certain contexts. For example, hallucinations in Natural Language Generation (NLG) models present significant problems, as they damage performance, raise safety issues for its use in the real world and hallucinations introduce privacy violation risks (Ji et al., 2023). Likewise, the very ability to generate natural language represents a threat, since it is increasingly indistinguishable from natural language. Therefore, the development of systems with the capacity to discern the authority of a given text, determining whether it is of human origin or generated by a generative model, is arising peremptory.

The language used by humans follows a probability distribution that differs so far from the distribution of the automated generated language (Rosenfeld et al., 1996). Perplexity measures the uncertainty value of a sample in a probability distribution. Accordingly, it is used in Natural Language Processing (NLP) as a metric to evaluate the effectiveness of linguistic models, for instance in text generation and machine translation tasks (Geluykens et al., 2021; Vaswani et al., 2018; Wang et al., 2019). Hence, it can be used to assess whether a text was generated by a machine, whose perplexity would be low, or written by a human, whose score would be large, since it may differ from that text automatically generated. We thus claim that perplexity can be used as a classification signal to enhance the finding of machine-generated texts (Meister and Cotterell, 2021).

In this work, we present the model submitted by the SINAI team to subtask A of task 8 of SemEval 2024 (Wang et al., 2024). Our proposal is based on the fuse of the word embeddings vectors stemmed from the fine-tuning of XLM-RoBERT-Large language model and the perplexity score of the input text. We use the Multimodal-Toolkit library (Gu and Budhkar, 2021) to fuse this two set of features.

After obtaining relevant results in the training phase and finding a clear difference between machine-generated and human-written texts, the results obtained have not been satisfactory. In part, this is due to the difference between the training and test datasets, which is analyzed later. Nevertheless, the exploration of the results obtained by merging textual content and associated perplexity raises the idea of using more novel linguistic models to calculate textual perplexity (see section 7).

The rest of the paper is organized as what follows: section 2 presents the works that support our proposal. Section 3 describes the data of the task, and section 4 is focused on the systems evaluated

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1505–1510

and the submitted one. Section 5 presents the results reached during the training phase, and Section 6 the official reached ones as well as an analysis of them. We summarize the conclusions in Section 7. We release the source code at GitHub.[1]

2 Related Work

The language generation capacity of large language models is unceasing improving (Crothers et al., 2023). Hence, machine-generated text detection is key as a fundamental countermeasure to mitigate the misuse of NLG models, accompanied by notable technical challenges and a multitude of unresolved issues.

We find a wide range of strategies to differentiate human-written text from machine-generated text (Jawahar et al., 2020) from the most simple ones based on bag-of-words models to the latest ones grounded in the fine-tuning of linguistic models.

The paper (Mitrović et al., 2023) has shown that different observable patterns make up generative models of language, either grammatically or through the meaning of sentences. For example, perplexity is usually lower in texts generated by artificial intelligence and their texts rather express feelings and use unusual words. This paper also shows a difference in performance between perplexity-based and machine learning-based classification, the latter being better than perplexity-based classification. However, it shows the capacity of perplexity score to distinguish among natural language text and machine-generated text.

3 Data and Task Description

Task 8 is focused on the identification of machine-generated text. In this work, we manage the subtasks of monolingual (English) and multilingual classification.

The dataset for the monolingual English task consists of 119,757 training instances, complemented by another 5,000 evaluation instances (Wang et al., 2023). In the multilingual task, the corpora comprise a total of 172,417 instances, with an allocation of 4,000 instances for the evaluation phase. This multilingual dataset is composed of 77.48% English text, with Bulgarian as a secondary language. The rest of the training dataset also incorporates languages such as Chinese, Indonesian, and Urdu. In addition, the evaluation dataset includes texts in Russian, German, and Arabic.

Each instance includes the *text*, along with its corresponding *source* according to five categories: *Wikihow*, *Wikipedia*, *Reddit*, *Arxiv*, *Peerread*. In the multilingual task, we can find additional sources: *Bulgarian*, *Urdu*, *Indonesian*, and *Chinese*. Also has a category that attributes the text to a specific large language model: *ChatGPT*, *Cohere*, *Bloomz*, *Davinci*, *Dolly*, or *Human* in another case. The *gold label* is 1, if the text is machine-generated and 0 otherwise. The dataset presents an even distribution, with cases annotated as human or machine being approximately equal in the training and development corpora.

4 System Description

Our proposed system to subtask A of task 8 is based on the wide success of fine-tuning methods on language models and in our claim of using perplexity as a feature to separate texts written by humans from machine-generated texts. (Min et al., 2023).

We use the XLM-RoBERTa-Large base as a language model, and we first assess its performance by fine-tuning the training data on it. Then, we evaluate the use of the perplexity as a classification signal, and the third one, which we submit to the shared-task, is based on joint use the resulting features of the fine-tuning phase and the perplexity score of each sentence.

In the next subsections, we argue the use of perplexity as feature in Section 4.1, we present all the systems studied in Section 4.2 and we describe all the implementation details in Section 4.3.

4.1 Perplexity as Feature

According to (Mitrović et al., 2023), the perplexity of human-written text tends to be higher than the one of machine-generated text. We evaluate this assertion by calculating the perplexity of the documents from the training and development sets. Table 1 shows the perplexity of texts written by humans and machines. The results for monolingual and multilingual subtasks confirm a substantial gap in perplexity in both classes, which entails that perplexity can be used as a classification signal. We use the python Language Model Perplexity library (LM-PPL)[2] to calculate the perplexity. From all the large language models available to calculate the perplexity, we use GPT2 (Radford et al., 2019).

[2] https://pypi.org/project/lmppl/

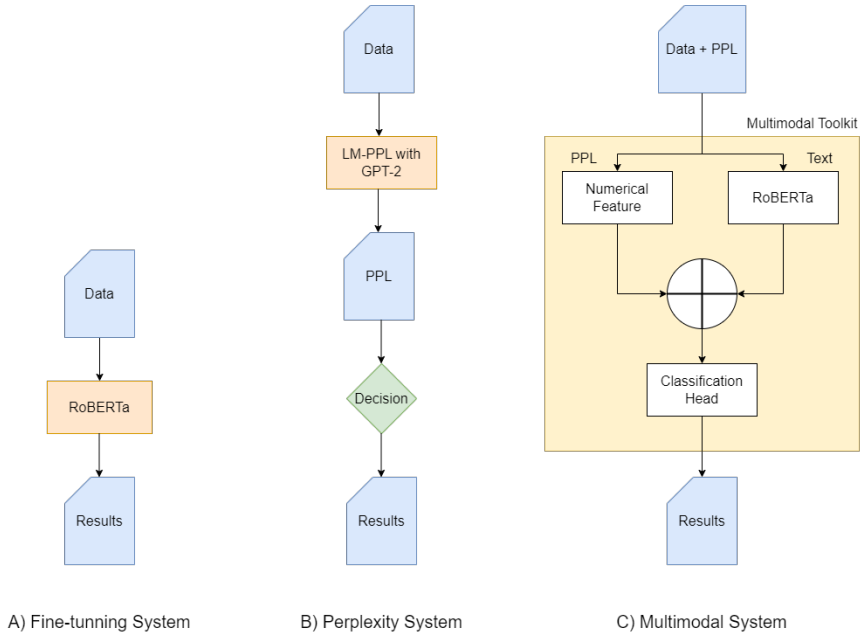

Figure 1: System diagrams used in developing phase.

Perplexity by classification	Mean
Human Monolingual	32.3613
Machine-Generated Monolingual	16.1494
Human Multilingual	35.8514
Machine-Generated Multilingual	20.9105

Table 1: Text perplexity for different classifications.

The results of Table 1 entails that the perplexity score can be use as classification signal, since it separates samples from the two classes. Accordingly, we propose a system based on the joint use of word embedding vectors and perplexity as feature.

4.2 Machine-Generated Text Detection systems

We have developed and evaluated three different systems. The first system is only based on fine tuning (system one), the second one only uses the perplexity score of the input sentences (system two) and the third one fuses the two set of features (system three). Figure 1 depicts the three systems.

System one based on fine-tuning and system two based on the use of perplexity as a classifier have been developed for the monolingual data only. Once the results of them have been obtained, the final system proposed for the task has been tested for the monolingual and multilingual subtasks.

System one - fine-tuning It is based on fine-tuning the XLM-RoBERTa-Large language model on the data of the task.

System two - perplexity For one of our systems only used the perplexity as a classifier, we established a threshold range based on the average perplexity of the dataset. The final choice of this strategy is to assign texts with perplexity at or below 20 as machine-generated, while those above this threshold are considered to be human-written.

Proposed system - fine-tuning and perplexity It is built upon two distinct features: word embedding vectors and the perplexity score of the input texts. The textual data is processed using the XLM-RoBERTa-Large transformer, and the result is sent to the combination module with the numerical features, in our case the perplexity.

The combination module uses the MultimodalToolkit library, and in particular the option[3] that separately encodes the two set of features and concatenate them before the final classification layer.

We submitted the classification results of our system based on fine-tuning and perplexity for the monolingual and multilingual subtasks.

4.3 Training and Implementation Details

We use Python to develop the proposed system and all the models evaluated during the development phase of the task. Likewise, we use the Transformers HuggingFace library (Wolf et al., 2020).

[3]Option name: *individual_mlps_on_cat_and_numerical_feats_then_concat*.

Optimized models	Epochs	Learning Rate	Weight Decay	Adam Epsilon	PP threshold
System one - fine-tuning	10	1.19e-05	6.18e-03	1.98e-07	-
System two - perplexity	-	-	-	-	20
Proposed system - Monolingual	10	6.89e-06	4.99e-02	1.13e-10	-
Proposed system - Multilingual	1	1.28e-05	8.67e-12	2.67e-07	-

Table 2: The values used for the hyperparameters of each model.

.

We optimize all the hyperparameters that drive the training of the models which involve transformers using the Optuna library (Akiba et al., 2019) following a grid search approach. This search has been performed using the English dataset, and once the optimized hyperparameters for each of the systems have been obtained, the same hyperparameters have been used for the multilingual task. For the sake of the reproducibility of the experiments, we describe the value exploration strategy of the values of the hyperparameters as what follows:

- Epochs [8, 16]: They represent the count of iterations required to traverse the entire training dataset for model training within a single cycle.
- Learning Rate [5e-6, 5e-5]: They govern the rate at which an algorithm updates or learns the parameter estimate values.
- Weight Decay [1e-12, 1e-1]: It constitutes a regularization technique that introduces a minor penalty term to the loss function.
- Adam Epsilon [1e-10, 1e-6]: It is a short positive value to forestall division by zero during the optimization process.

Table 2 shows the selected values, for the three systems that we evaluated during the development phase. We clarify that we independently optimized them, since they differ in their architecture (system one vs. proposed system) and the training objective (monolingual vs. multilingual).

5 Development results

Once we optimized the hyperparameters of each model, we assessed the performance of each system on the development data. We use accuracy as an evaluation measure, since it is the evaluation measure of the shared-task. Table 3 shows the results of this initial evaluation.

As detailed previously, the results of systems one and two are based on monolingual data, while the proposed system has been tested on both sets (see section 4.2).

System	Accuracy
System one - fine-tuning	0.8002
System two - Perplexity	0.6894
Proposed system - Monolingual	0.8698
Proposed system - Multilingual	0.6789
Task baseline monolingual	0.7400
Task baseline multilingual	0.7200

Table 3: Results in train phase with the dev. dataset.

As we indicated below, system one is only grounded in fine-tuning the XML-RoBERTa-Large model on the training data. The results are over the task baseline, which means that the incorporation of knowledge from the domain with the optimal values of the hyperparameters may reach competitive results and to overcome the task baseline.

The system that only uses perplexity as a classification signal reached poorer results than the baseline system. However, its performance is close to 70% accuracy, which means that the perplexity may be used as a feature to discriminate among human written text and machine-generated text, as we claim.

The proposed system jointly uses words and perplexity as features. In the monolingual scenario, this fusion of features reaches strong results far away from the task baseline. Nonetheless, the results for the multilingual scenario were not as strong as the monolingual one. According to the results of the monolingual data, we use as proposed system the one based on the fusion of words and perplexity as features.

6 Analysis and Discussion

The final results revealed unexpected differences compared to the results observed during the development phase. In the system that jointly uses

perplexity and text, the accuracy achieved in the monolingual task was 0.744631, which was lower than expected based on performance during development. In contrast, a poorer result was observed on the multilingual task, which achieved an accuracy of 0.801689 on the final test data set. Both results are lower than the baseline obtained by the competitors, with 0.8846 accuracy for the monolingual test and 0.8088 for the multilingual test.

Recognizing these discrepancies, our initial action consisted of an examination to determine the causes. The main advantage of our system resides in the incorporation of perplexity as classification signal along with the textual data. Consequently, our analysis primarily focused on examining the perplexity to elucidate possible factors contributing to the observed errors, as well as observing which class is more difficult to recognize, human-written or machine-generated texts.

Perplexity Performance Analysis The main limitation of our system is the use of perplexity. This metric depends on the characteristics of the reference large language model used for its calculation. Hence, we argue that there is a large disparity between the large language model used to generate the training and development sets and the documents of the test set.

We analyzed the perplexity of the documents of the test set, and we show them in Table 4. The results show a large discrepancy between the perplexity reached on the training dataset and the ones obtained on the test data. We stand out for the unexpectedly high perplexity of the machine-generated text, which is also over the human-written text. This is a sign that the large language model used to generate the documents of the test set may be more sophisticated than the one used to prepare the training dataset, or at least it was not the same large language model. This unexpected tendency to perplexity between the training and test data is behind the degradation of the performance of our proposed system on the test data, since the perplexity is a relevant feature of our porposed system.

We also explain the better performance of our proposed system in the multilingual subtask with the behavior of the perplexity on the test data. Although machine-generated text reaches again higher perplexity than human-written text, the difference is thin. Hence, the behavior of the perplexity is nearer to our claim, and the performance of our proposed system is thus stronger on multilingual data.

	Mean Perplexity	
	Human	M. Generated
Train Monolingual	32.3613	16.1494
Train Multilingual	35.8514	20.9105
Test Monolingual	35.8071	44.7824
Test Multilingual	58.4526	59.0258

Table 4: Mean perplexity in the test set for each task in comparison with the train datasets

Before generating the final results, we analyzed the prediction distribution to determine whether our system showed any tendency to predict a class in particular. In the monolingual tasks, we observed 17,978 instances of correct predictions, with only 22 false positives, with false positives being texts written by humans predicted to be machine-generated. Similarly, in the multilingual tasks, we found only 19 false negatives, the main finding was the occurrence of many false positives. Most of the predictions were obtained as machine-generated. We also highlight that the proposed system does not have any false negatives, which means that it is able to identify all the machine-generated text. However, since the disparity among the large language models to generate the training and test sets, we will keep working on reducing the false positives.

7 Conclusion

We have described the system submitted to subtask A of task 8 of SemEVAL. The system is grounded in the claim that perplexity may be a discriminant feature in identifying machine-generated texts. Hence, our submitted system is built upon the fine-tuning of a XML-RoBERTa-Large language model on a fusion of words and perplexity as features. The results reached during the development phase convinced us that our claim holds.

The official results show that the fusion of words and perplexity as features were not as good as the assessment on the development set. According to our analysis results, it may be caused by the use of a different large language model to generate the text documents. It pushes us to study the influence of the reference large language model used for the calculation of the perplexity and also to analyze the possibility of combining different perplexity calculated using a wide diverse set of large language models.

Abstract

This paper introduces the system developed by USTC-BUPT for SemEval-2024 Task 8. The shared task comprises three subtasks across four tracks, aiming to develop automatic systems to distinguish between human-written and machine-generated text across various domains, languages and generators. Our system comprises four components: DATeD, LLAM, TLE, and AuDM, which empower us to effectively tackle all subtasks posed by the challenge. In the monolingual track, DATeD improves machine-generated text detection by incorporating a gradient reversal layer and integrating additional domain labels through Domain Adversarial Neural Networks, enhancing adaptation to diverse text domains. In the multilingual track, LLAM employs different strategies based on language characteristics. For English text, the LLM Embeddings approach utilizes embeddings from a proxy LLM followed by a two-stage CNN for classification, leveraging the broad linguistic knowledge captured during pre-training to enhance performance. For text in other languages, the LLM Sentinel approach transforms the classification task into a next-token prediction task, which facilitates easier adaptation to texts in various languages, especially low-resource languages. TLE utilizes the LLM Embeddings method with a minor modification in the classification strategy for subtask B. AuDM employs data augmentation and fine-tunes the DeBERTa model specifically for subtask C. Our system wins the multilingual track and ranks second in the monolingual track. Additionally, it achieves third place in both subtask B and C.

1 Introduction

The burgeoning capabilities of large language models (LLMs), exemplified by ChatGPT (OpenAI, 2022), GPT-4 (OpenAI, 2023) and Llama (Touvron et al., 2023a), have made machine-generated text more fluent and human-like, which has led to an increasing concern about the abuse of LLMs such as misinformation spread (Bian et al., 2023; Hanley and Durumeric, 2024; Pan et al., 2023) and disruption in education system (Perkins et al., 2023; Vasilatos et al., 2023). So far humans perform only slightly better than chance when distinguishing between text generated by LLMs and human (Mitchell et al., 2023), so it calls for an automatic system to identify machine-generated text.

To this end, MBZUAI NLP department holds SemEval-2024 Task8, which consists of three subtasks. Subtask A focuses on determining whether a full text is human-written or machine-generated. The biggest challenge lies in the domain difference between the training set and test set while the multilingual track requires strong adaptation to text across various languages. It demands the model to have a strong capability of generalization in out-of-domain scenarios. Subtask B aims at doing multi-way machine-generated text detection and brings a new challenge of identifying the text source without knowing the domains in the test set. Subtask C proposes human-machine mixed text detection, which gives a text where the first part is human-written and the second part is machine-generated. The goal is to robustly determine the boundary where the change occurs using a fairly small training set. A detailed description can be found in the task description paper (Wang et al., 2024).

Currently, training-based machine-generated text detection strategies such as fine-tuning RoBERTa model (Solaiman et al., 2019) underperform in the out-of-domain scenario. Prominent zero-shot methods (Mitchell et al., 2023; Yang et al., 2023) can only discriminate whether a text is produced by a specific LLM or by a human. Sniffer (Li et al., 2023) and SeqXGPT (Wang et al., 2023a) appear to handle the problem of subtask B and C, but the claimed result is based on the assump-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1511–1522

tion that we know the origins of the text. Therefore, we propose our system, which consists of **D**omain-**A**daptive **Te**xt **D**etection (**DATeD**), **L**LM-Powered **L**anguage-**A**ware **M**odel (**LLAM**), **T**hree-stage **L**LM **E**mbeddings (**TLE**) and **Au**gmented **D**eBERTa **M**odel (**AuDM**). It performs outstandingly in out-of-domain scenarios, especially in subtask A.

In DATeD, we enhance performance by innovatively incorporating Domain Adversarial Neural Networks (DANN) (Ganin et al., 2016) into the task of machine-generated text detection. DANN consists of a feature extraction layer and a category predictor, forming the backbone network to predict classification labels. Furthermore, the domain classifier is connected to the backbone network through a gradient reversal layer for classifying domain labels. This enables the model to learn transferable features between the training and development set, effectively overcoming challenges in out-of-domain scenarios. We achieve **second** place out of **126** participants.

In LLAM, we handle text from various languages in a distinct manner. For English text, we employ LLM Embeddings, leveraging the powerful representation capabilities of LLM by directly extracting embeddings from the last layer of a proxy LLM, and we classify the text using a two-stage CNN. For text in other languages, we utilize LLM Sentinel, which reframes the classification task as a next-token prediction task. We win the **first** place in the track among **59** participants.

In TLE, we utilize the LLM Embeddings method mentioned above, with only a minor difference in the classification strategy. We rank **third** out of **70** participants.

In AuDM, we fine-tune a DeBERTa-base (He et al., 2021) model with a linear layer for token classification. This is an easy but effective system and ranks **third** out of **30** submissions.

In short, our contributions are as follows:

(1) We come up with a comprehensive system for machine-generated text detection in varies scenarios (Section §3), which significantly improves the performance compared to the baseline in all subtasks (Section §5).

(2) We utilize DANN in machine-generated text detection in DATeD (Section §3.1), and employ two adaptive strategies leveraging LLM capabilities in LLAM (Section §3.2).

(3) Extensive experimental analysis demonstrates the effectiveness of DATeD and LLAM (Section §5).

2 Related Work

2.1 Detecting LLM-Generated Text

The detection of machine-generated text is often expressed as a classification task. One way to solve this problem is to use supervised learning to train classification models on datasets that contain both machine-generated and human-written text. For example, GPTZero (Tian, 2023) collects human-written text from a variety of domains, including student-written articles, news articles, and question-and-answer datasets across multiple disciplines. G3Detector (Zhan et al., 2023) claims to be a general-purpose gpt generated text detector implemented by fine-tuning RoBERTa-large (Liu et al., 2019), however, the effect of text detection generated by multiple generators will be poor. T5-sentinel (Chen et al., 2023) trains RoBERTa and T5 (Raffel et al., 2023) classifiers on the OpenGPTText dataset they built, and then uses the T5 model's ability to predict the conditional probability of the next word to classify multiple text sources. SeqXGPT (Wang et al., 2023a) introduces the sentence-level detection challenge by synthesizing a dataset containing documents that have been polished with a Large Language Model. SeqXGPT uses sequence annotation methods to train its model and selects the most frequent class as sentence class, which provides a scheme for subtask C. However, a model explicitly trained to detect machine-generated text may overfit the training distribution of its domain (Bakhtin et al., 2019), resulting in poor generalization.

In addition, (Solaiman et al., 2019) notes the surprising power of a simple zero-shot method for machine-generated text detection, which thresholds candidate paragraphs based on their average log-probability under a generative model, a powerful baseline for many zero-shot learning machine-generated text detection tasks. DetectGPT (Mitchell et al., 2023) demonstrates that text sampled from LLMs tends to occupy regions of negative curvature of the model's log-probability function. Building upon this observation, a new curvature-based criterion is defined to determine whether a paragraph is generated by a given LLM. Its outstanding performance can only be guaranteed by a large disturbance function and a large number of perturbations, so more computational resources are required.

2.2 Domain Adversarial Neural Networks

Machine learning models typically assume that the training and test sets come from the same data distribution. However, labeled data is scarce, and it is the norm for unlabeled data, which may not align with the distribution of labeled data (HassanPour Zonoozi and Seydi, 2023), to constitute the majority of the data. In the task of machine-generated text detection, there are cases where the sources and generators differ between the source domain and the target domain. For instance, in the monolingual track of subtask A, the test set may include sources and models, such as BLOOMZ (Muennighoff et al., 2022), that are not present in the training set. Across data generated by different models, significant differences may exist in content style, text length, word frequency, and other distributions. This discrepancy results in models trained on labeled training data failing to generalize well to detect text data generated by other models. The core issue addressed by domain adversarial neural networks (Ganin et al., 2016) is mitigating the impact of inconsistent data distributions between the training and test sets on the performance of machine learning models. This enables models to learn sufficiently robust text representations and reduce differences in data distributions at the representation level. Introducing domain adversarial neural networks into monolingual generated text detection enhances the model's ability to generalize and transfer across different machine-generated text models (Chen et al., 2020).

3 System Overview

Our system consists of four components: DATeD, LLAM, TLE and AuDM. Each of these components addresses one of the four tracks of the task respectively.

In subtask A, we aim to do machine-generated text detection on mono/multilingual data. In the monolingual track, the domains in test set differ a lot from ones in training set. We innovatively apply DANN to the detection in DATeD. This is achieved by adding a gradient reversal layer on top of the base model. Additionally, besides category labels, we incorporate extra domain labels into the dataset (training set: 0, development set: 1), enabling the model to learn transferable features between the training and development set (Section §3.1).

In the multilingual track, another challenge is that the model is supposed to have robust generalization capabilities to adapt to the distinct characteristics of different languages, especially low-resource languages. We propose LLAM, which employs different methods for different languages. For text identified as English, we feed it into a proxy LLM to extract embeddings from the last layer and subsequently pass it through a two-stage CNN for classification. In the case of non-English text, we redefine the classification task as a next-token prediction task (Section §3.2).

In multi-way text detection, texts originate from human, ChatGPT, Cohere, Davinci, BLOOMZ and Dolly (Conover et al., 2023). The challenge lies in distinguishing texts generated by various LLMs. Therefore we conduct a three-stage classification based on the LLM Embeddings method (TLE) mentioned in the multilingual track to better fit the scenario of multi-classification (Section §3.3).

In human-machine mixed text detection, the target is to do fine-grained detection. Inspired by the wide use of BERT (Devlin et al., 2019) in sequence labeling task, we fine-tune a DeBERTa model with data augmentation (AuDM) to classify each token in a text (Section §3.4).

3.1 Domain-Adaptive Text Detection

The overall process of Domain-Adaptive Text Detection is illustrated in Figure 1. The model comprises three components: a feature extraction layer (such as RoBERTa) acquires text representation, a category predictor determines whether the given text is machine-generated, and a domain classifier is employed to mitigate differences in data distribution between the training and development sets, thereby enhancing the generalization capability of machine-generated text detection.

The feature extractor and label predictor constitute a feedforward neural network serving as the backbone of machine-generated text detection, utilized to classify data from the source domain. The label predictor employs MLP for classification, aiming to predict labels accurately. Following the feature extractor, we append an additional branch called the domain classifier. The domain classifier is interconnected through a gradient reversal layer to classify data in the feature space, determining whether it originates from the source domain or the target domain.

Forward propagation During forward propagation, given an input text of $\boldsymbol{n}$ tokens $\boldsymbol{x} = \{x_1, \cdots, x_n\}$, we initially input the text $\boldsymbol{x}$ into the model. We opt for RoBERTa as the

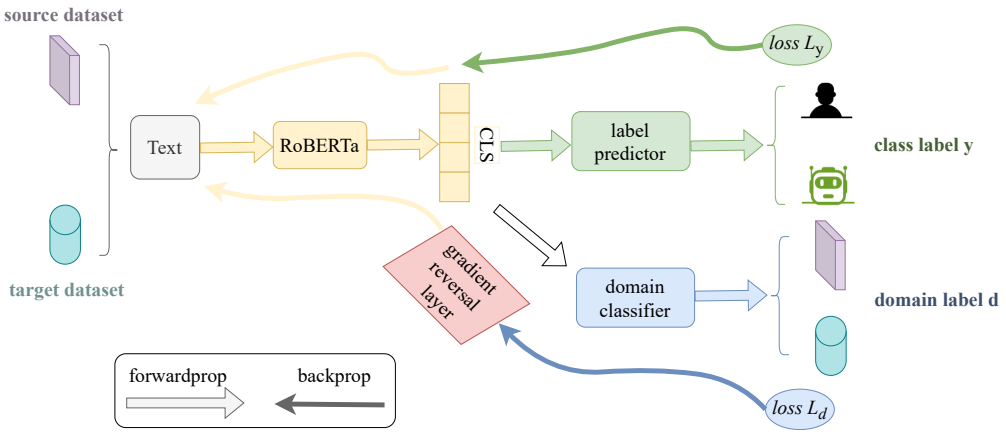

Figure 1: Overall architecture of DATeD

feature extractor $G_f(\cdot)$, utilizing the output vector corresponding to the CLS token as the semantic representation of the input text, denoted as $G_f(\boldsymbol{x})$. Subsequently, $G_f(\boldsymbol{x})$ is simultaneously fed into the label predictor $G_y(\cdot)$ and the domain classifier $G_d(\cdot)$, yielding $G_y(G_f(\boldsymbol{x}))$ and $G_d(G_f(\boldsymbol{x}))$, representing the category label $\boldsymbol{y}$ and the domain label $\boldsymbol{d}$, respectively (as shown in the green and blue sections depicted in Figure 1).

Back propagation During back propagation, the cross-entropy loss function is computed by comparing the category labels $\boldsymbol{y}$ predicted by the category predictor with the actual labels in the source domain, resulting in category loss (Ganin and Lempitsky, 2015). Additionally, we calculate the cross-entropy loss function by comparing the domain labels $\boldsymbol{d}$ classified by the domain classifier with all data from both the source and target domains, obtaining domain loss. It is worth mentioning that the gradient reversal layer behaves like a feedforward neural network during forward propagation. However, during backward propagation, the gradients are reversed (we achieved by multiplying by a negative identity matrix). Finally, the model updates its label predictor and domain classifier by summing up their respective losses (as shown in Formula 1). This setup enables the label predictor to distinguish categories in the source domain data (Ganin et al., 2016), while rendering the domain classifier unable to discern the origin domain of the data.

$$\mathcal{L}_{all} = \mathcal{L}_y + \lambda \mathcal{L}_d \tag{1}$$

$\mathcal{L}_y$ represents the label predictor loss in the source domain, $\mathcal{L}_d$ represents the domain classifier loss, λ is a hyperparameter.

3.2 LLM-Powered Language-Aware Model

In the multilingual machine-generated text detection task, we propose our model LLAM, which employs the language identification tool langdetect [1] to determine the language of the input text first. Then, we utilize LLM Embeddings and LLM Sentinel to detect English and non-English text respectively. The overall architecture of LLAM is depicted in Figure 2.

LLM Embeddings For English text, we use Llama-2-70B (Touvron et al., 2023b) as the proxy LLM to obtain embeddings of the input text. Given an input text of $\boldsymbol{n}$ tokens $\boldsymbol{x} = \{x_1, \cdots, x_n\}$, we initially input the text $\boldsymbol{x}$ into the proxy LLM to get the token embeddings from the last layer. Subsequently, we calculate the average of token embeddings $\boldsymbol{h}$ to serve as the text representation. This representation is then inputted into a two-stage CNN for classification. In the first stage, the CNN extracts relevant features from the input representation $\boldsymbol{h}$. This process is accomplished through the utilization of three convolutional and pooling layers. In the second stage, the extracted feature is fed into three fully connected linear layers to output class probabilities $\boldsymbol{p}$. The model is trained by minimizing the cross-entropy loss.

LLM Sentinel (Chen et al., 2023) have proposed utilizing the base LLM's inherent next-token prediction ability for detection, advancing the field by choosing the T5 model as the base LLM. Drawing inspiration from this approach, for non-English text, we choose the mT5-large model as our proxy LLM. LLM Sentinel relies on the LLM's capability to predict the conditional probability of the next token. Given an input text of $\boldsymbol{n}$ tokens

[1] https://pypi.org/project/langdetect/

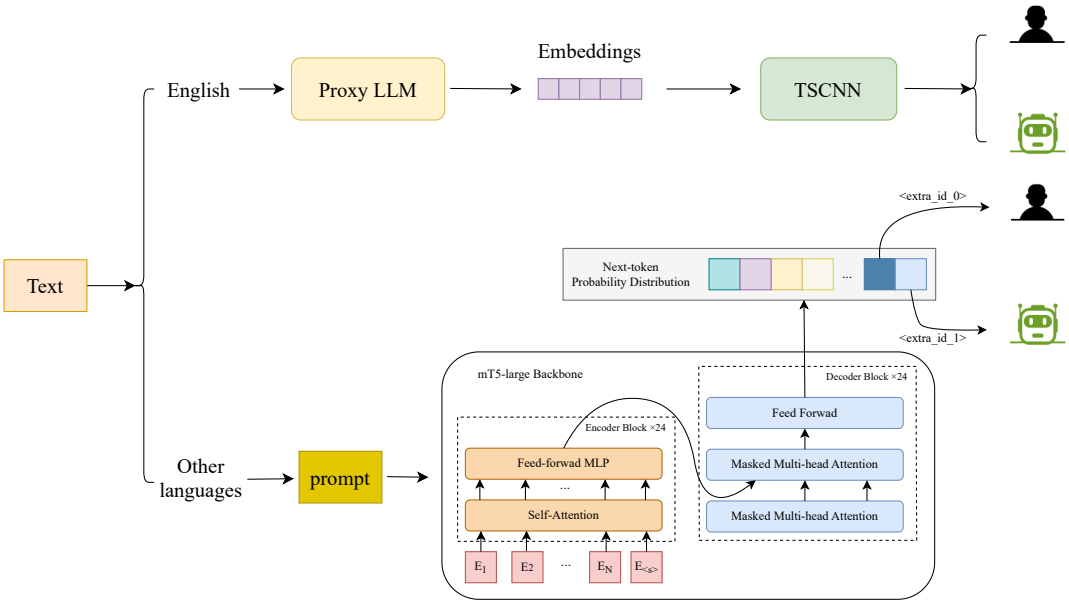

Figure 2: Overall architecture of LLAM

$\boldsymbol{x} = \{x_1, \cdots, x_n\}$, let Y denote the set of labels in this particular task, which contains "human" and "machine". We can establish a bijection $f : Y \rightarrow \mathcal{Y}$, where $\mathcal{Y}$ serves as a stand-in for the labels. Consequently, we reframe the binary classification task $\boldsymbol{x} \rightarrow Y$ as a next-token prediction task $\boldsymbol{x} \rightarrow \mathcal{Y}$. To accomplish this, we employ reserved tokens, $\mathcal{Y}$, which are not present in the text dataset. Specifically, We use $< extra\_id\_0 >$ for human and $< extra\_id\_1 >$ for machine. Therefore, the binary classification task can be effectively tackled using the LLM:

$$\hat{y} = f^{-1}\left(\arg\max_{y \in \mathcal{Y}} \mathbb{P}(y|\boldsymbol{x})\right) \tag{2}$$

Besides, in order to adapt to the characteristics of natural language, our team add a prompt before the detected text to fine-tune the LLM to perform it. The prompt used by our team is "Discern whether the following text is authored by a human or a machine. If human-written, respond with $< extra\_id\_0 >$; if machine-generated, respond with $< extra\_id\_1 >$: 'text'". Regarding the model's output, the decoding space consists of token probabilities for the entire dictionary. We simply need to extract the probability distribution over the set $\mathcal{Y}$, corresponding to the token probabilities for $< extra\_id\_0 >$ (human) and $< extra\_id\_1 >$ (machine). We then compare their magnitudes and select the larger of the two as the prediction result.

3.3 Three-stage LLM Embeddings

Building upon the LLM Embeddings approach outlined in Section 3.2, TLE additionally employs a three-stage classification process to address subtask B. Firstly, we distinguish between human-generated and machine-generated text. Subsequently, we categorize ChatGPT and Cohere as a single class for a four-class classification, differentiating them from Davinci, BLOOMZ, and Dolly. Given the challenges we encountered in distinguishing between Cohere and ChatGPT in our initial experiments, we proceed with a binary classification specifically focusing on ChatGPT and Cohere.

3.4 Augmented DeBERTa Model

In human-machine mixed text detection, we set up a model with a DeBERTa-base layer and a linear layer. The human token is classified as 0 and the machine token is classified as 1. The boundary is where the change of 0 to 1 occurs. We also perform data augmentation by employing Llama-2-7B to further generate training data.

4 Experimental setup

4.1 Datasets and Evaluation Metrics

Datasets The dataset for this task is an extension of the M4 (Wang et al., 2023b) dataset. Unlike the M4 dataset, this task samples human data to ensure data balance. New domains, generators, and languages appear in the test set to evaluate the generalization

ability of the algorithm. See Table 1 and Table 4 for the division of the dataset. See Appendix A for more details.

	Train	Dev	Test
Human	63351	2500	16272
Machine	56406	2500	18000
Total	119757	5000	34272

Table 1: Dataset division of monolingual track for subtask A.

	Train	Dev	Test
Human	83846	2000	20238
Machine	88571	2000	22140
Total	172417	4000	42378

Table 2: Dataset division of multilingual track for subtask A.

	Train	Dev	Test
Human	11997	500	3000
ChatGPT	11995	500	3000
Cohere	11336	500	3000
Davinci	11999	500	3000
BLOOMZ	11998	500	3000
Dolly	11702	500	3000
Total	71027	3000	18000

Table 3: Dataset division of subtask B.

Train	Dev	Test
3649	505	11123

Table 4: Dataset division of subtask C.

Evaluation Metrics The evaluation metrics for subtask A and B are accuracy. Accuracy is the ratio of the number of samples that the model predicts correctly to the total number of samples. Subtask C is evaluated using the MAE metric, which calculates the absolute difference between the predicted and actual boundary positions for each sample and takes the average value. The performance is better when MAE is smaller.

4.2 Training

Domain-Adaptive Text Detection In the monolingual track of subtask A, we initially define the training set and development set as the source domain and target domain respectively. Apart from the class labels provided by the dataset, we augment both the source and target domain datasets with additional domain labels. Specifically, the domain labels for the source domain samples are categorized into one class (e.g., labeled as 0), while the domain labels for the target domain samples are categorized into another class (e.g., labeled as 1). Since the overall loss computation includes both the label loss from the source domain and the domain loss from both the source and target domains, an equal number of samples from both the source and target domains is necessary to calculate the total loss. Therefore, it is imperative to balance the proportion of samples between the source and target domains. Please refer to Appendix B.1 for detailed settings.

LLM-Powered Language-Aware Model LLAM is composed of two parts: the LLM Embeddings model and the LLM Sentinel model. During the training process of our LLM Embeddings model, we split the training set into new training and development sets in a 9:1 ratio. The highest accuracy attained on the new development set during training is used to select the best checkpoint. Our final LLM Sentinel model is trained with the complete training set of this subtask and undergoes validation on the entire development set of the same subtask after each epoch. The final model chosen is the one demonstrating the optimal performance on the development set. For more details about the experiment, please refer to Appendix B.2.

Three-stage LLM Embeddings Our final model is trained in three stages, utilizing data from the corresponding categories in the subtask B dataset for each stage. See more details in Appendix B.3.

Augmented DeBERTa Model For our final submission, we do augmentation by adding the development set to the training set and using Llama-2-7B to continue generating based on training data. The checkpoint with the lowest MAE on the development set is chosen for submission. More details are in Appendix B.4.

5 Results

In this section, we report our results on all three subtasks and discuss our findings of the current

System	Accuracy
Baseline	88.46

work. We provide the final submission results, as well as the results from several top-ranked systems.

5.1 Subtask A: Monolingual Track

In this part, we present a portion of the official results from the monolingual track and analysis of the selection process for target domain data.

5.1.1 Main Results

There are 126 teams that participate in the monolingual track. Due to the limited space, we only compare our system with the systems from teams Genaios, mail6djj, QUST and L3i++. The official results are shown in table 5. Our system achieves an accuracy of 96.10% and secures second place in the official ranking, surpassing the baseline of 88.46% by 7.64%. This indicates that adding domain adversarial neural networks solves the impact of inconsistent data distribution between the training and test set, enabling the model to learn transferable features between the two sets, thus significantly improving model performance. Upon reviewing the methods published by other participants, we find that our result (96.10%) is not far from Genaios (96.88%). Notably, while Genaios utilizes the larger Llama-2-13B model, we achieve similar performance using the smaller RoBERTa-base model.

5.1.2 Target Domain Data Selection

We conduct a series of experiments regarding qualitative and quantitative data selection. **Qualitative analysis** aims to verify whether the target domain utilizes the development set or the test set. This is because the generative models utilized in the training set and the test set may overlap. Using the test set directly as the target domain could result in texts generated by the same generative model (belonging to the same domain) being assigned different domain labels. According to our submitted results, training with the development set as the target domain results in the best performance with an accuracy of 96.10%. However, training with the test set as the target domain results in an accuracy of only 88.70%. Observing the distribution of generative models in the test set further validates these findings. The test set comprises existing models such as ChatGPT, Cohere, and also features the emergence of a new generation model, GPT-4. Thus, utilizing the test set as the target domain could lead to misdefined domain labels.

Quantitative analysis aims to explore how many repetitions of the target domain could yield better results. This is because updating the loss necessitates domain label loss from both the source domain and target domain, as discussed in Section §4.2 about DATeD, which requires an equal number of samples from each. Hence, the number of target domain samples to be duplicated needs exploration. According to our submitted results, repeating the target domain 15 times yields nearly the same number of samples as the source domain, resulting in the best performance with an accuracy of 96.10%. When repeated three times, the detection accuracy in the test set decreased to 91.75%.

5.2 Subtask A: Multilingual Track

In this part, we offer partial results from the leaderboard in the multilingual track and perform an ablation study.

5.2.1 Main Results

There are 59 teams that participate in the multilingual track. Due to the limited space, we only compare our system with the systems from teams FI Group, KInIT, priyansk, L3i++. The official results are shown in Table 6. Our system achieves the best result in the official ranking with 95.99% accuracy, surpassing the baseline by 15.10%. This showcases the powerful representational capacity of LLMs and encourages us to explore further strategies to leverage it.

System	Accuracy
Baseline	74.61
AISPACE	**90.85**
Unibuc-NLP	86.96
dianchi	83.48
L3i++	83.12
USTC-BUPT (ours)	84.33
w/o three-stage strategy	80.94

Table 7: Part of the official results for subtask B.

System	MAE
Baseline	21.535
TM-TREK	**15.684**
AIpom	15.940
Fine-tuned RoBERTa-large	20.876
Fine-tuned DeBERTa-large	18.075
USTC-BUPT (ours)	17.702
with Bi-LSTM	16.556

Table 8: Part of the official results for subtask C.

5.2.2 Ablation Study

We conduct extensive ablation experiments to show the effectiveness of LLM Embeddings and LLM Sentinel respectively. The results are shown in Table 6. When we remove the language discriminator and only use the LLM Sentinel method, the accuracy drops to 92.03%. Since mT5 is designed for multilingual text-to-text tasks, its training corpus may be more biased towards encompassing texts in diverse languages rather than focusing on a specific language, such as English. Consequently, this could result in inferior performance on English text classification tasks due to the model's lack of exposure to a sufficient amount of English texts for optimal training. However, when we solely utilize the LLM Embeddings method, the accuracy decreases to 82.05%. Since most of the training data for Llama-2-70B is in English, its ability to comprehend other languages is limited. The potential of other multilingual LLMs awaits exploration in future research. A more detailed discussion is in the Appendix C.

5.3 Subtask B: Multi-Way Track

Our final submission achieves an accuracy of 84.33%, marking a 9.72% improvement over the baseline, as shown in Table 7. This indicates that LLM can capture subtle differences between different models, allowing for classification based on these distinctions. Furthermore, rather than directly implementing multi-classification, we embrace a three-stage strategy. This results in an enhancement in model performance from 80.94% to 84.33%, suggesting that we can prioritize the classification of categories with a significant gap before handling the others.

5.4 Subtask C: Mixed Track

After the release of the golden label, we test the performance of our model with a Bi-LSTM (Zhou et al., 2016) layer. The MAE of our final submission is 17.702, and the new result is 16.556, only slightly larger than the SOTA benchmark by TM-TREK but saliently smaller than the baseline as seen in Table 8. This shows the strong ability of DeBERTa to extract effective contextualized features, while LSTM (Hochreiter and Schmidhuber, 1997) helps process sequential information in the text. The result compared with DeBERTa-large also shows that the effectiveness of the encoder model is not linear with the scale.

6 Conclusion

In conclusion, this paper presents the development and performance of our system for the SemEval-2024 Task 8. Our system wins the multilingual track and secures second place in the monolingual track. Additionally, we attain third place in both subtask B and subtask C. We demonstrate the efficacy of incorporating DANN, which significantly enhances out-of-domain accuracy by introducing a gradient reversal layer and integrating additional domain labels. Leveraging LLM embeddings proves to be a straightforward yet effective method, harnessing the representation capabilities of LLM without fine-tuning. Furthermore, our implementation of LLM Sentinel exhibits remarkable performance, especially in low-resource language scenarios. In the future, we plan to investigate the application of DANN to multi-label classification scenarios and explore more effective strategies to leverage LLM embeddings.

A Data

In the monolingual track of subtask A, the dataset contains both human-written and machine-generated text. Different from the training and development set, all the data in the test set comes from a new area: student essays Outfox, and a new generator GPT-4 appears to generate machine text.

In the multilingual track, the text is not only in English, but also in Chinese, German, Russian and other languages. Compared to the training and the development set, two new fields of Outfox and Italian text appear in the test set, and new generators Llama-2-finetune and Jais-30B (Sengupta et al., 2023) are used to generate machine text.

In the dataset of subtask B, the generators remain the same in the training set, development set and test set, including Human, ChatGPT, Cohere, Davinci, BLOOMZ and Dolly. However, the text of the test set is only from the student essays Outfox instead of wikiHow, etc.

Each text of the subtask C dataset is composed of human-written text and machine-generated text, and its label is an index, representing the boundary where the change occurs.

Tables 9 to 12 detail the data sources and the distribution of the model, which is conducive to evaluating the model's generalization ability.

B Detailed Experimental Setup

B.1 Domain-Adaptive Text Detection

Typically, the number of samples in the training set far exceeds that in the development set, which can also be observed in this competition dataset. The imbalance between the domain labels of the source and target domains is substantial, with 119,757 samples in the source domain and only 5000 samples in the target domain. To address this issue, we innovatively repeat the target domain 15 times to achieve a nearly 1:1 ratio of domain labels between the source and target domains, without compromising the genuine domain and classification label values of the target domain.

We opt to utilize the pre-trained model RoBERTa-base as the feature extraction layer for DANN to extract features from the text to be detected. Subsequently, we input the text information separately into the label classifier and the domain classifier. Apart from the batch size, which is set to 32, which differs from the baseline, all other hyperparameters remain consistent with the baseline. Specifically, the learning rate is set to 2e-5, and the optimizer selected is AdamW (Loshchilov and Hutter, 2017). The maximum token truncation length for the text is set to 512 tokens. We conduct training for 10 epochs on a single NVIDIA A40 40GB GPU.

B.2 LLM-Powered Language-Aware Model

LLM Embeddings We utilize the int8 quantized variant of Llama-2-70B as the proxy LLM for obtaining embeddings on a single NVIDIA A800 80GB GPU, with the maximum length set to 1024. For the two-stage CNN, the input channel is set to 1. A total of three convolutional layers are employed, with the number of kernels being 32, 64, 96 respectively. The sizes of their corresponding kernels are 24, 16, 8. We use the AdamW optimizer with a linear warmup decay learning schedule and a dropout of 0.1. The batch size and learning rate are set to 128 and 3e-4, and models are trained for 50 epochs.

LLM Sentinel We fine-tune the mT5-large model for 15 epochs using two NVIDIA A40 GPUs. Throughout this process, we utilize the Adafactor optimizer (Shazeer and Stern, 2018) to minimize GPU memory usage and expedite training. The optimizer utilizes the following hyperparameters: a learning rate of 1e-3, stability parameters of (1e-30, 1e-3), gradient clipping threshold of 1.0, learning rate decay rate of -0.8, momentum parameter set to None, weight decay of 0.0, relative step set to False, parameter scaling set to False, and warm-up initialization set to False. The maximum length constraint is set to 1024.

B.3 Three-stage LLM Embeddings

The hyper-parameters of this experiment are consistent with the method mentioned above for LLM embeddings. Please refer to Appendix B.2 for more details.

B.4 Augmented DeBERTa Model

All hyper-parameters synchronize with the baseline. We only change the model structure and fine-tune it using a single NVIDIA GeForce RTX 3090 GPU.

Method	Accuracy
T5-small (directly)	77.06
T5-small (prompt)	**87.76**
LLM Embeddings (English)	**97.30**
LLM Sentinel (English)	82.04
mT5-large	**90.58**
mT5-xl	73.56

Table 13: Performance comparison of different methods on the development set.

C More Analysis of Multilingual Track

C.1 Prompt Impact

In the initial stages of the experiment, we compared the impact of adding prompts on model performance for monolingual binary classification tasks. We trained and tested the T5 model using the monolingual training and development sets, respectively. The experimental results (Table 13) indicate that adding prompts could effectively enhance the model's performance on this task. Therefore, for multilingual task, we directly adopt the approach of adding prompts.

C.2 Language-Aware Strategy

During the experimental phase, we compared the performance of LLM Embeddings and LLM Sentinel on English texts. We trained them using the monolingual training set of subtask A and validated the monolingual development set. The experimental results are presented in Table 13. The results demonstrate that LLM Embeddings outperform LLM Sentinel. Consequently, for English text, we opt for LLM Embeddings.

C.3 LLM Selection

In the later stages of the experiment, we also explored larger models, such as mT5-xl. Considering that the test set in the competition does not include Russian, we evaluated the performance of mT5-xl on languages other than Russian for this task. We trained the mT5-xl model using the whole multilingual training set and utilized texts from languages other than Russian in the multilingual development set as the new development set. The training was conducted with the same experimental parameters as mT5-large (see details in Appendix B.2). We compare the best accuracy results of mT5-large and mT5-xl on the new development set (Table 13). The experimental results indicate that employing larger models with more parameters does not yield better experimental outcomes for this task. Therefore, we choose mT5-large as our LLM.

ALF at SemEval-2024 Task 9: Exploring Lateral Thinking Capabilities of LMs through Multi-task Fine-tuning

Abstract

Recent advancements in natural language processing (NLP) have prompted the development of sophisticated reasoning benchmarks. This paper presents our system for the SemEval 2024 Task 9 competition and also investigates the efficacy of fine-tuning language models (LMs) on BrainTeaser—a benchmark designed to evaluate NLP models' lateral thinking and creative reasoning abilities. Our experiments focus on two prominent families of pre-trained models, BERT and T5. Additionally, we explore the potential benefits of multi-task fine-tuning on commonsense reasoning datasets to enhance performance. Our top-performing model, DeBERTa-v3-large, achieves an impressive overall accuracy of 93.33%, surpassing human performance. The code and models associated with this study are publicly available at https://github.com/alifarrokh/SemEval2024-Task9.

1 Introduction

The SemEval 2024 Task 9, BrainTeaser, is a multiple-choice question-answering task, organized by (Jiang et al., 2024) and based on the BrainTeaser benchmark (Jiang et al., 2023) that aims to test the ability of NLP models to exhibit lateral thinking, a creative type of human reasoning process that often requires looking at problems from a new perspective. Unlike similar benchmarks for computational creativity, such as RiddleSense (Lin et al., 2021), which focus on problems resolvable through commonsense associations, the BrainTeaser benchmark comprises questions that challenge models to defy default commonsense associations and linear inference chains (Jiang et al., 2023).

The task includes two subtasks: Sentence Puzzle and Word Puzzle. While the puzzles in the first subtask focus on the meaning of sentences, the word puzzles concentrate on the letter composition of questions and their choices. The following are examples of questions in each subtask.

- **Example Sentence Puzzle**
  Question: A man shaves everyday, yet keeps his beard long. How is that possible? (A) He is a barber. (B) He wants to maintain his appearance. (C) He wants his girlfriend to buy him a razor. (D) None of above.
  Answer: A

- **Example Word Puzzle**
  Question: What part of London is in France? (A) The letter O. (B) The letter N. (C) The letter L. (D) None of above.
  Answer: B

(Lin et al., 2021) discusses three types of popular methods for commonsense question answering: 1) Fine-tuning pre-trained language models such as BERT (Devlin et al., 2018) and RoBERTa (Liu et al., 2019), 2) Fine-tuning text-to-text question answering models such as T5 (Raffel et al., 2020), 3) Incorporating knowledge graphs for graph-based language reasoning similar to KagNet (Lin et al., 2019) and MHGRN (Feng et al., 2020). An advantage of using graph-based reasoners is the interpretability of their results due to the symbolic structures of knowledge graphs. Motivated by the superior performance achieved by fine-tuning language models or text-to-text models in achieving the best results on the RiddleSense benchmark, our study investigates the vertical thinking capabilities of these models. We accomplish this by fine-tuning them on the BrainTeaser dataset.

We solely engage in the first subtask of BrainTeaser (Sentence Puzzles) and, due to resource constraints, confine our experiments to models with fewer than one billion parameters. In the subsequent section (Section 2), we provide a brief discussion of the models we fine-tuned. Subsequently, we offer a more detailed introduction to the task in

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1523–1528

Section 3. Section 4 delves into the specifics of our experiments and their outcomes, while Section 5 presents our results in the competition alongside a concise error analysis.

2 System Overview

Inspired by the recent progress in pre-trained language models, our work investigates the performance of fine-tuned language models on the BrainTeaser task. Specifically, we fine-tuned two groups of models, i.e., BERT-based and T5-based models.

2.1 BERT-based Models

The models included in this group are ALBERT v2 (Lan et al., 2019)[1], RoBERTa (Liu et al., 2019), and DeBERTa v3 (He et al., 2023). We refer to this group as BERT-based models because all of them are inspired by BERT, a pre-trained bidirectional transformer encoder (Vaswani et al., 2017), with slight improvements in their pre-training objectives or architectures. The overall process of fine-tuning BERT-based models for multiple choice question answering is illustrated in Figure 1.

Note that for the experiments in which multiple datasets with different numbers of choices are used during fine-tuning, we have to normalize the questions so they consist of the same number of choices, and the model can be fine-tuned with a shared linear projection layer. This is simply achieved by either randomly removing extraneous options from questions with too many choices or by adding dummy options to other ones. Since dummy options are constant in all the questions, the model can easily learn to ignore them and assign a zero probability to them.

As a side note, we also fine-tuned BERT in a sequence classification format where all options are fed into the model so it can infer the correct one by looking at the others. However, the performance was suboptimal in this case, so we did not include the results in the paper.

2.2 T5-based Models

This group includes Flan T5 (Chung et al., 2022) and Unified-QA v2 (Khashabi et al., 2022), pre-trained encoder-decoder transformers that convert all NLP problems into a text-to-text format. These models are fine-tuned to generate the correct choice conditioned on the input question (Figure 2).

[1]ALBERT v2 was introduced in their GitHub repository at https://github.com/google-research/albert

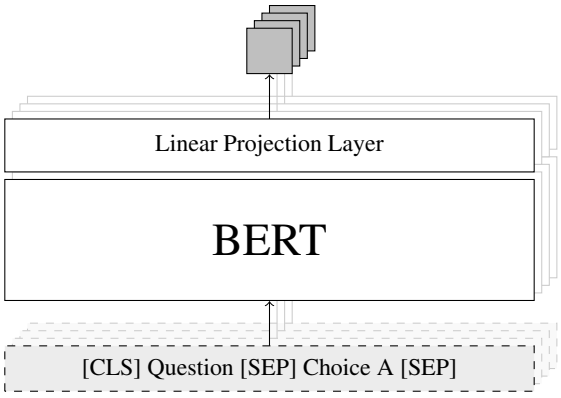

Figure 1: Fine-tuning BERT for multiple-choice question answering involves computing n forward passes simultaneously for questions with n choices. The output embeddings are then projected into a vector of size n, which is fed into a SoftMax function to compute the Cross-Entropy Loss. This optimization process aims to maximize the score of the correct choice.

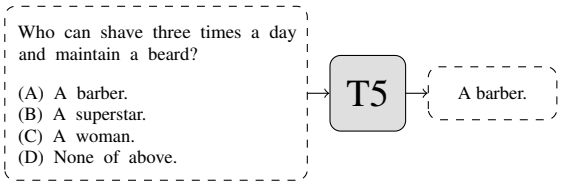

Figure 2: Fine-tuning T5-based models for multiple choice question answering.

3 Task Overview

3.1 Adversarial Examples

The BrainTeaser dataset includes two types of adversarial examples for each original data: *Semantic Reconstruction* and *Context Reconstruction*. In semantic reconstruction, the original question is rephrased so that it conveys the same meaning with the same answer. Extraneous options (i.e., other choices) are kept unchanged in this construction method. In context reconstruction, on the other hand, both the original question and choices are changed so that they describe a new situational context with the same reasoning path as the original question.

3.2 Dataset

The BrainTeaser dataset (Sentence Puzzle) consists of train and test splits, containing 169 and 40 original data along with their adversarial examples, totaling up to 507 and 120, respectively. The test set was released after the evaluation phase was over. Furthermore, a subset of the training data consisting of 102 examples was selected as the validation set during the evaluation phase. However,

Model	BS	LR
ALBERT v2 xlarge	48	1e-5
ALBERT v2 xxlarge	48	1e-5
DeBERTa v3 base	48	25e-6
DeBERTa v3 large	48	11e-6
RoBERTa base	64	1e-5
RoBERTa large	64	1e-5
Flan T5 base	24	5e-4
Flan T5 large	8	4e-4
Unified QA v2 base	24	5e-4
Unified QA v2 large	8	4e-4

Table 1: The hyper-parameters used for fine-tuning our models. LR indicates the Learning Rate and BS shows the Batch Size.

as described in Section 4.2, we chose to employ k-fold cross-validation instead of relying solely on the validation set for model development.

3.3 Evaluation Metrics

The task organizers have defined two types of accuracy metrics to evaluate the performance of models: *Instance-based accuracy*, where each question is considered a separate instance, and *Group-based accuracy*, where each question and its adversarial instances form a group and systems are given an accuracy of one only when they correctly predict all questions in the group.

We refer to the instance-based accuracy on all examples as `overall` accuracy and the instance-based accuracy on `original`/`semantic`/`context` examples as `ori`/`sem`/`con` accuracy. Correspondingly, `ori-sem` and `ori-sem-con` denote the group-based accuracy of their corresponding questions.

4 Experimental Setup and Results

4.1 Implementation Details

All models were implemented in Python using the Transformers (Wolf et al., 2020) library. AdamW (Loshchilov and Hutter, 2017) was used for optimization, and all models were fine-tuned for 4 epochs. Due to resource constraints, we only tuned the effective batch size and Learning Rate (LR) of models using grid search. See Table 1 for the list of hyper-parameters used for fine-tuning models.

Dataset(s)	# Samples	CV Accuracy
RS	3,510	**81.43**
CSQA	9,741	79.66
PIQA	16,113	79.48
SIQA	33,410	79.95
HellaSWAG	39,905	78.48
SWAG	73456	76.51
BrainTeaser		75.53

Table 2: The 5-fold cross-validation accuracies of models fine-tuned on a union of different commonsense datasets and BrainTeaser (BT), compared with the accuracy of a model fine-tuned on BrainTeaser only.

4.2 Reliability of Experiments

During the development of our models, we noticed that the limited number of training and validation examples led to noisy results when evaluating the original validation set. Consequently, relying solely on this set for model development was deemed unreliable. Therefore, we used 5-fold cross-validation to perform our experiments in the evaluation phase of the competition. Data folds were created by splitting the 169 groups into five sections, ensuring that questions from the same group would not appear in both the training and validation sets. Moreover, we observed that the random initialization of linear projection layers in BERT-based models causes significant variations in the performance of models. Therefore, we repeated the experiments related to BERT-based models three times and averaged the results to increase the reliability.

4.3 Auxiliary Datasets

In contrast to prior vertical thinking datasets, such as PIQA (Bisk et al., 2020) and RiddleSense (Lin et al., 2021), solving BrainTeaser's lateral thinking puzzles requires more creativity and defying preconceptions (Jiang et al., 2023). Our hypothesis is, however, that although combining vertical thinking datasets with BrainTeaser may not directly improve our model's performance, it can provide our model with some knowledge that might be helpful during the reasoning process. For instance, solving the example puzzle in Figure 2 requires the model to have some common sense about what barbers do and what they do not. Another reason why using auxiliary datasets during fine-tuning might be helpful is that fine-tuning large models on small datasets, such as BrainTeaser's training set, can

increase the risk of overfitting, which may be prevented by using more training data.

Some datasets that cover various aspects of commonsense reasoning are RiddleSense (RS) (Lin et al., 2021) for computational creativity, CommonSenseQA (CSQA) (Talmor et al., 2018), SWAG (Zellers et al., 2018), and HellaSWAG (Zellers et al., 2019) for general commonsense knowledge, Social IQA (SIQA) (Sap et al., 2019) for social psychology knowledge, and Physical IQA (PIQA) (Bisk et al., 2020) for physical knowledge. To determine which ones can be effective for our task, we fine-tuned a `Flan-T5-base` model on the union of BrainTeaser's training set and each of the mentioned dataset's training data, and compared their accuracies with a similar model fine-tuned on BrainTeaser only (Table 2). As expected, fine-tuning on a combination of BrainTeaser and commonsense datasets enhances the model's performance in all cases. It is also notable that, despite being the smallest dataset, RiddleSense improves the model's accuracy more than any other dataset, possibly because of its distribution overlap with BrainTeaser, as they both have been collected from public websites and deal with computational creativity.

Following (Khashabi et al., 2020), we generate training batches so that each one contains almost the same number of examples from each dataset.

The datasets mentioned in our study serve as valuable resources for enhancing the performance of our multiple-choice QA (MCQA) models. Among these datasets, RS, CSQA, and PIQA are inherently structured as MCQA datasets, making them suitable for direct use in our experiments. However, to incorporate SWAG, HellaSWAG, and SIQA into our study, we need to transform their formats into MCQA. For SWAG, we consider `sent1` as the question and concatenate `sent2` with all potential endings to create the options. Similarly, in HellaSWAG, `ctx-a` is treated as the question, while `ctx-b` is prepended to each possible ending to form the options. Finally, in SIQA, the combination of the `context` and `question` fields in each sample constructs the final question.

4.4 Model Selection

As discussed in Section 2, we fine-tuned two groups of models, BERT-based and T5-based models. Following the results of the previous section (Section 4.3), all models were fine-tuned on a combination of BrainTeaser and RiddleSense. Despite the potential performance improvement from including other datasets, we limited our training set to RiddleSense and BrainTeaser for computational feasibility.

Metric	Accuracy	Ranking
ori	92.5	4
sem	95.0	3
con	82.5	6
ori-sem	92.5	4
ori-sem-con	82.5	5
overall	90.0	7

Table 3: The accuracies and rankings of our submission based on different official metrics. Refer to Section 3.3 for more details about the evaluation metrics.

The reported results in Table 4 indicate that Unified-QA's performance is approximately on par with or outperforms Flan T5. This is expected because Unified-QA-v2 was specifically trained for question answering on many QA datasets, including CSQA, PIQA, and SIQA (Khashabi et al., 2022), which can enhance the performance on BrainTeaser as shown in the previous section. In the case of BERT-based models, not only does DeBERTa-v3 surpass all other BERT-based models, but it also achieves the highest test accuracy among all models and slightly outperforms the human performance, suggesting the effectiveness of its architecture for this task.

5 Results and Error Analysis

5.1 Competition Results

We submitted our DeBERTa-v3-large [2] model (Table 4) during the competition, ranking 7 in the official leaderboard. See Table 3 for more details.

5.2 Error Analysis

There is a 12.5% gap between the accuracies of our best DeBERTa-v3 model on `ori-sem` and `con` (see Table 5), signifying that even though our model learns the semantics of puzzles very well, it sometimes fails to generalize the underlying reasoning paths to other similar situations. This gap is much narrower (5%) for our Unified-QA-v2 model, which outperforms the DeBERTa-v3 on context-

[2]Please note that the DeBERTa-v3-large checkpoint used in our submission was selected before the release of the official test set. For analysis of our best checkpoint, refer to Section 5.2.

Model	# Params	CV Accuracy	Test Accuracy [1]
ALBERT v2 xlarge	59M	79.38	75.83
ALBERT v2 xxlarge	223M	76.06	83.33
RoBERTa base	125M	81.42	80.83
RoBERTa large	355M	83.47	86.67
DeBERTa v3 base	184M	85.90	87.50
DeBERTa v3 large [2]	434M	**89.47**	**93.33**
Flan T5 base	223M	81.43	82.50
Flan T5 large	750M	82.22	84.17
Unified QA v2 base	223M	80.49	84.17
Unified QA v2 large	734M	80.64	90.08
Human (Jiang et al., 2023)	-	-	91.98

Table 4: The overall 5-fold cross-validation and test accuracies of BERT-based and T5-based models
[1] Best accuracies on the official test set released after the evaluation phase
[2] Our submission during the evaluation phase

reconstruction adversarial examples by 2.5% despite underperforming it on original and semantic-reconstruction examples, suggesting that T5-based models may learn to generalize the reasoning paths in the BrainTeaser task better than BERT-based models.

The Unified-QA-v2 model also outperforms DeBERTa-v3 on questions to which *"None of above."* is the answer (see Table 5), which is expected because T5-based models have access to all possible choices while BERT-based models can only see one choice at a time (see Figure 1 and Figure 2).

Five of the six groups that included incorrect predictions from DeBERTa-v3 and Unified-QA-v2 (see Table 5) are identical, and among the errors made in these five groups, six out of seven wrong predictions belong to the same questions, which indicates that the two models almost made the same mistakes. Analyzing those six questions shows us that half of them are related to the models' understanding of math.

Metric	DeBERTa-v3	Unified-QA-v2
ori	97.5	92.5
sem	97.5	92.5
con	85.0	87.5
ori-sem	97.5	92.5
ori-sem-con	85.0	85.0
overall	93.3	90.8
choice d[1]	87.0	93.0
false answers	8	11
false groups	6	6

Table 5: A comparison between the performance of our best models - [1]Overall accuracy of questions to which *"None of above."* is the answer.

6 Conclusion

In this study, we investigated the effectiveness of fine-tuning various language models (including BERT-based and T5-based models) on the BrainTeaser benchmark. We demonstrated the efficacy of multi-task fine-tuning on additional commonsense datasets and its impact on performance in BrainTeaser.

Although our best models achieved performance surpassing human levels, it's important to note that our study was limited to language models with fewer than one billion parameters and training sets comprising at most two datasets combined. Future research could explore extending this study in these directions, as well as investigating other aspects of computational creativity and question-answering.

We hope that our work inspires future research in these areas and contributes to the ongoing advancement of natural language understanding and reasoning.

Abstract

We present an intuitive approach for hallucination detection in LLM outputs that is modeled after how humans would go about this task. We engage several LLM "experts" to independently assess whether a response is hallucinated. For this we select recent and popular LLMs smaller than 7B parameters. By analyzing the log probabilities for tokens that signal a positive or negative judgment, we can determine the likelihood of hallucination. Additionally, we enhance the performance of our "experts" by automatically refining their prompts using the recently introduced OPRO framework. Furthermore, we ensemble the replies of the different experts in a uniform or weighted manner, which builds a quorum from the expert replies. Overall this leads to accuracy improvements of up to 10.6 p.p. compared to the challenge baseline. We show that a Zephyr 3B model is well suited for the task. Our approach can be applied in the model-agnostic and model-aware subtasks without modification and is flexible and easily extendable to related tasks.

1 Introduction

Language Models Are Outstanding, but[2] they can hallucinate, i.e. generate texts that are not supported by the input or the context. Hallucinations can undermine the credibility and usefulness of LLMs, especially for applications that require high accuracy and reliability, such as summarization, question answering, or dialogue. Therefore, there is a pressing need for developing methods to detect and mitigate hallucinations in LLMs, as well as to understand the causes and effects of this phenomenon.

In this SemEval challenge (Mickus et al., 2024), the task is to detect LLM hallucinations based on the input task given to the LLM, the LLM response, and the ground truth answer. Here, the input tasks can be *definition modeling (DM)*, *machine translation (MT)* or *paraphrase generation (PG)*. Each task contains multiple examples that are fed through an LLM and its response is classified as hallucination or not by five annotators. There are two subtasks in this challenge: In the *model-aware* subtask, access to the generating model is given, while in the *model-agnostic* subtask, the generating model is unknown. We approach both subtasks in the same way, by removing the model information from the model-aware subtask. While we are certain that access to the generating model can be beneficial, we argue that the model-agnostic setting has better transferability in practice.

As the competition baseline (which uses SelfCheckGPT by Manakul et al. (2023)), we frame the task of hallucintion detection as a "consistency checking" problem with the given information, where the goal is to check whether an LLM generation is supported by the ground truth. If the generation is not supported by the ground truth, new and thus probably false information must be present; the LLM has hallucinated its response.

For building an intuition for our approach, we imagine the same setting in the real world: A person responds to a question and our goal is to detect if this is a hallucination, i.e., the response is not supported by the truth. With this real-world setting in mind, we formulate three intuitions that we later transfer to the challenge baseline:

(I) Instead of one person, we ask multiple different experts to check the response's consistency with the truth and weight the different expert responses based on their past performance to make a final decision.

(II) Each expert gives a certainty for their response, so we can take this into account

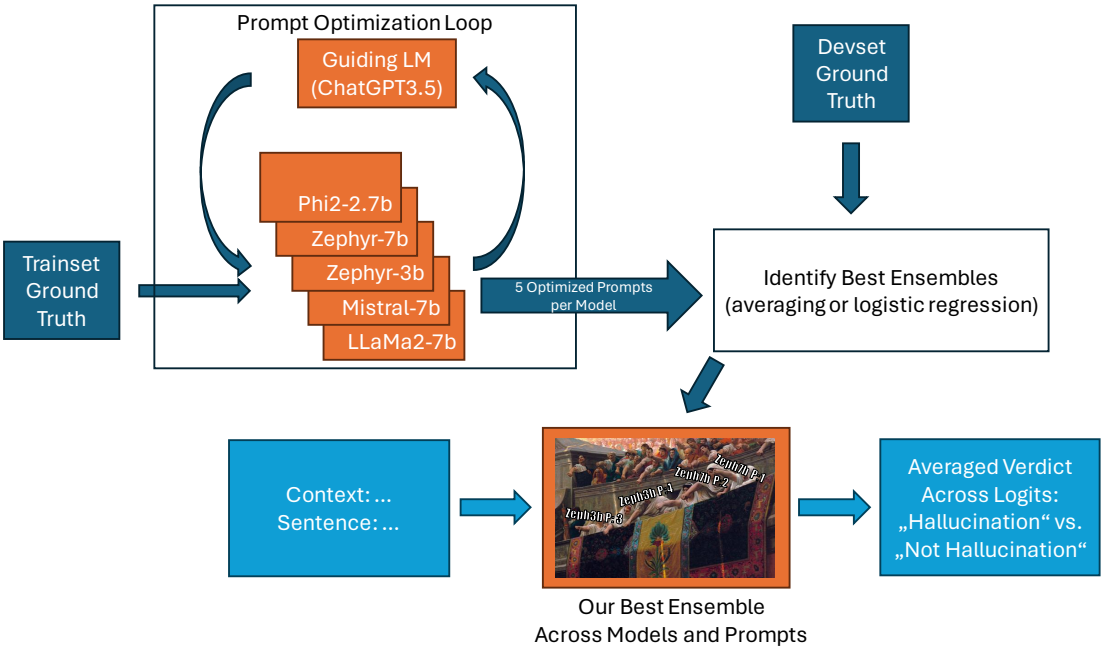

Figure 1: Overview of our approach. We automatically optimize the prompts of multiple "expert" LLMs to check the consistency of the given model output with the ground truth. We combine multiple experts (models-prompt-combinations) in a uniform or weighted manner and select the best ensemble on an internal validation set. This ensemble performs the final collective verdict, as illustrated by a part of Jean-Leon Gerome's painting "Pollice Verso" (1872), which represents the Ancient Roman gesture for judgment on defeated gladiators[1].

when combining multiple experts' responses into one final judgement.

(III) Since each expert is trained differently and has different skills, a suitable explanation of the task to the expert is beneficial.

2 System Description

Given this intuition regarding a potential approach to the task in the real world, we now connect these steps to our submitted system. An overview is found in Figure 1.

(I) We construct ensembles of multiple LLMs that are independently asked to check the response's consistency with the truth. For each ensemble of models, we combine the responses of the LLMs using averaging or by training a logistic regression (see Section 2.5).

(II) Compared to the task baseline method, we modify the procedure for how the LLMs produce their output to obtain better probability estimates (see Section 2.3).

(III) In addition to the baseline prompt, we use an automatic prompt optimization technique to create five additional, well-working prompts and use them as additional options for our ensemble selection (see Section 2.4).

2.1 Provided Baseline

In general, our system is based on the baseline provided by the task organizers. Here, a Mistral 7B model is given the following prompt:

```
Context: [GROUNDTRUTH]
Sentence: [MODELOUTPUT]
Is the Sentence supported by the context
above? Answer using ONLY yes or no:
```

The next token is then generated by the LLM and checked whether it is "yes" or "no" (possibly with additional whitespace or capitalization). If it is a "yes", the output label is set to "Not Hallucination" and its log-probability $logprob$ is converted to the probability $p(Hallucination) = 1 - e^{logprob}$. If it is a "no", the output label is set to "Hallucination" and its log-probability $logprob$ is converted to $p(Hallucination) = e^{logprob}$. If the next token is neither a "yes" or "no", the output label is chosen randomly and $p(Hallucination)$ is set to 0.5.

In the following, we apply our three intuitions to the baseline setup in order to achieve better results. To have a better understanding of which datasets

are used, we introduce them in the following section.

2.2 Data Splits

The task organizers provide multiple datasets from which we use the labeled "val.model-agnostic.json" and "val.model-aware.v2.json" files. We randomly split the model-agnostic file into two equal datasets, stratified by the task, such that both datasets have similar numbers of items with the same task.

These two datasets are our "training" and "validation" datasets, respectively. The full model-aware file is used as our internal "test" dataset, in order to estimate the performance of our system without making a submission.

The "training" dataset is used to optimize the prompts of the models. The "validation" dataset is used to train logistic regressions to weight each member of the ensemble. The "test" dataset is then used to evaluate our results internally without submitting all ensembles of models to the competition leaderboard.

2.3 Intuition (II): Better Output Generation

The task baseline from the organizers generates the most probable next token and checks if it is "yes" or "no". When running the task baseline code, we find that in 21 of the 499 examples from the "val.model-agnostic.json" file, the model does not return a "yes" or "no" directly as the highest scoring token, which means that the output label is chosen randomly and "P(Hallucination)" is set to 0.5.

We argue that it is not necessary to rely on the model to generate a "valid" token at the beginning and only hope for a definite answer. Instead, we take the models' output probability distribution over all available tokens. From this, the combined probability of relevant tokens can be accessed and computed, so even if "yes" or "no" are not the most probable tokens, a definite answer can be derived.

Let $\mathbf{T}$ be a mapping of all available LLM tokens to their corresponding log probabilities, which is accessed using $\mathbf{T}[x]$ for token x. Out of the LLM vocabulary, we identify tokens indicating a positive and negative reply, i.e. all tokens that boil down to "yes" or "no" in any capitalization and with any added whitespace. We call the sets of tokens $\mathcal{P}$ and $\mathcal{N}$ for positive and negative tokens, respectively. The probability for the answer being positive is then computed using a modified softmax function s, which takes only the positive and negative tokens into account:

$$s(\mathbf{T}) = \frac{\sum_{p \in \mathcal{P}} \exp(\mathbf{T}[p])}{\sum_{t \in (\mathcal{P} \cup \mathcal{N})} \exp(\mathbf{T}[t])} \quad (1)$$

This way, even if the token with the highest probability is not a "yes" or "no", a meaningful probability $s(\mathbf{T}) \in [0, 1]$ can be computed. This makes our system more reproducible than the organizer's baseline code, since no randomly selected labels can occur. The predicted output label is then "Not Hallucination" when $s(\mathbf{T}) \geq 0.5$ and "Hallucination" else.

2.4 Intuition (III): Prompt Optimization

We further improve the performance of our approach by "finetuning" the used prompts for each model we use in our ensemble independently. To this end, we follow the OPRO approach (Yang et al., 2023), which aims to automatically optimize the prompts with the help of a "guiding" language model. First, we take the baseline prompt as an initial starting prompt and evaluate the accuracy of the model on a split of our training dataset. Next, the guiding language model, in turn, is prompted to optimize the prompt that the model is acting upon. For this, it has access to the 20 best previously evaluated prompts, as well as the accuracy the model achieved when using this prompt. The task of the guiding language model is now to generate a new prompt that outperforms all previous prompts. Finally, the new prompt is evaluated and added to the list of tried prompts for the next optimization step.

We employ this approach to optimize the prompts for every used model separately, as the optimal prompt for one model does not have to be working well for other models. As guiding language model we select ChatGPT3.5-Turbo[3] and evaluate the prompts on our holdout set. We slightly adapt the original OPRO optimization prompt as we found the "meta" prompt submitted to the guiding language model to be very hard to decipher in our case. This stems from nested references to "below instructions" which in turn referenced the "Context above", although the samples are usually appended. As there are no clearly reserved delimiters in this prompt, this can be confusing when reading this optimization prompt — even for a human. Hence we slightly change this prompt by introducing a json-structure where fit (empty newlines have been stripped here):

[3] https://platform.openai.com/docs/models/gpt-3-5-turbo

Table 1: The best five prompts found by the prompt optimization method OPRO for the Zephyr 3B model. Overall, the optimization was run for ten iterations. Shown are also the iteration in which they were proposed and their respective accuracies on our holdout set.

Iter.	Acc.	Prompt
2	0.714	Decide whether the given sentence is directly supported by the provided context. Answer with a simple "yes" or "no".
8	0.714	Determine if the sentence provided is supported by the given context. Respond with a clear "yes" or "no".
1	0.694	Based on the given context and sentence, determine if the statement is supported or not. Please respond with a simple yes or no.
1	0.694	Based on the given context, determine if the sentence is correctly supported. Respond with a simple 'yes' or 'no'.
1	0.694	Is the Sentence consistent with the provided Context? Answer with either "yes" or "no".

```
Your task is to generate the instruction
<INS>. Below are some previous
instructions with their scores. The
score ranges from 0 to 100.
[
 {
  "<INS>": "Is the Sentence supported by
the Context above? Answer using ONLY yes
or no:",
  "score": 74
 },
 ...
]
Below are some problems commonly
solved incorrectly when using above
instructions.
[three incorrectly solved examples and
their correct label formatted as json]
Generate an instruction that is different
from all the instructions <INS> above,
and has a higher score than all the
instructions <INS> above. The instruction
should begin with <INS> and end with
</INS>. The instruction should be concise,
effective, and generally applicable to
all exemplary problems above.
```

Table 1 shows the five best performing prompts for the Zephyr 3B model found by OPRO.

2.5 Intuition (I): Ensemble Strategy

Our intuition is to ask multiple experts instead of one to assess whether the model output is hallucinated. This is implemented as an ensemble approach, where different models are asked to identify hallucinations. Their outputs are later combined to one output label and probability.

Considered Models Since there are plenty of open source language models available, we limit ourselves to five different models. We select these models from the "New & Noteworthy" section of LM Studio, a desktop application that allows to run LLMs efficiently on CPUs using quantized model weights.[4] We define several criteria to select our final models:

- In order to keep inference times low, we only consider models smaller than or equal to 7B parameters.
- To make use of the newest models, the selected models can at most be half a year old. Based on our selection date of January 10, 2024, the models have to be released (according to LM Studio) after July 10, 2023.
- We only take the newest version of a model (e.g. Mistral v0.2 is used instead of v0.1).
- We try to diversify the model architectures and training datasets by eliminating mostly Llama 2/Mistral finetuned models.
- We select general purpose LLM for the English language, i.e., no explicit code generation models or models for creative writing.

This selection process gives five models for which we download their weights in the "Q6_K"[5] quantized version: Phi 2[6], Mistral 7B Instruct v0.2[7], StableLM Zephyr 3B[8], Zephyr 7B β[9], Llama 2 7B Chat[10].

[4] The list of models can be found at https://github.com/lmstudio-ai/model-catalog/tree/205a13027c9fcd7d0c4a1874d6bb0ae45922deee/models (accessed: 2024-01-10)

Combining LLM Responses For each of the five models, we test overall six prompts: The baseline prompt from the organizers as well as the five best performing prompts found by OPRO. For each prompt, we compute the output labels ("Hallucination" or "Not Hallucination") and probabilities "p(Hallucination)" for the validation and test datasets. Given these 30 outputs per dataset, we combine all subsets of up to five model responses by either averaging all hallucination probabilities (*mean*) or training a logistic regression on the validation dataset (*logreg*) for a more sophisticated combination. We then evaluate all combinations on our validation and test datasets.

3 Results

We overall have three dimensions in which we can select the best model/prompt ensemble for challenge submission:

1. validation (*val*) vs. test dataset (*test*) results
2. accuracy (*acc*) vs. correlation (*rho*) as evaluation metrics
3. mean ensemble (*mean*) vs. logistic regression ensemble (*logreg*) vs. single model (*single*)

The resulting model selections as well as the organizer's baseline with their metrics for our validation and test datasets as well as the official task results are shown in Table 2. Besides the model names, if a different prompt than the baseline prompt has been used, we encode the prompt used for the model in its name ("P:0" to "P:4" with "P:0" being the automatically optimized prompt that performed best on our holdout set). We can make multiple observations in the results table.

First, the last two rows of the table show that our proposed output generation method mostly improves the baseline scores slightly. Second, all of our model ensembles are better than the organizer's baseline, showing that the ensemble and logistic regression implementations help in this setting. Note that sometimes, the best model ensemble for different dimensions is the same, e.g. Zephyr 3B P:4 is the best model when evaluated on the validation correlation, regardless of the ensemble strategy.

Third, nearly all selected model ensembles contain the Zephyr 3B model in some form, which is surprising, as the most other models have more than twice the parameters. This shows that in this task, the model size does not correlate with performance. Overall, both Zephyr (3B and 7B) models are well-suited for the task, even though they are not trained by the same companies and thus not directly related.

In terms of official task results, the model ensemble chosen by the best test accuracy (and then by correlation) shows the best accuracy of our submissions on the model-agnostic task (80.3%). It is an ensemble consisting of two versions of the Zephyr 3B model as well as three versions of the Zephyr 7B model, combined through a logistic regression. It ranks 41 out of all 260 submissions for the model-agnostic task of the challenge.

For the model-aware task, our best model ensemble again consists of a Zephyr 3B and 7B version. These models are combined using the mean ensemble strategy, leading to 0.777 accuracy as official results. This submission ranks 103 out of 295 task submissions. Given that our approach is completely model-agnostic and thus not specifically designed for this subtask, the results are fairly good.

4 Analysis

We present a comparative analysis of the predicted versus actual probabilities of hallucination across the three tasks given in the challenge datasets. To this end, we plot the predictions for the ensemble that achieved the highest accuracy on our test set (test/acc/logreg in Table 2). In Figure 2 the overall gold label distribution for the probability of hallucination (p(Hallucination)) is depicted on the left, contrasting starkly with the more extreme predicted label distribution shown in the right plot. This polarized nature of predictions suggests a tendency for our model to forecast outcomes with heightened certainty, a trait observable across all ensemble models examined.

Particularly noteworthy is the paraphrase task's label distribution, which significantly deviates from the other tasks. This unique distribution is reflected not only in the ground truth data but also in our model's predictions, indicating a consistent model response to the characteristics of this task.

Figure 3 underscores a clear positive correlation between the predicted probabilities of hallucination and the ground truth scores for all task types. Hallucination detection on the machine translation task exhibits the strongest correlation, suggesting a higher predictive performance, whereas for definition modeling and paraphrase generation the scores correlate slightly less closely.

5 Discussion and Future Work

Our proposed system is easy to understand and implement, can be applied both in model-agnostic and model-aware scenarios, and is flexible in terms of different metrics: By using smaller and fewer models in the ensemble, the runtime can be achieved. By choosing the models based on a given metric, the performance given this metric can be optimized.

In the following, we want to discuss two areas: Runtime optimization and task realism. The runtime of our system depends on the number of models. Here, we have shown that small and single models can already lead to very good results. Currently, we only use one type of quantization for all models. Exploring the effects of different quantization methods might be interesting, since usually, with higher quantization, the model size gets smaller and the model gets faster, but performance degrades. Since the Zephyr 3B model is the best model for this task, maybe another quantization can optimize the runtime of our system even further. Additionally, since most of our models contain multiple versions of a prompt for the same model, we could employ batching of these prompts. This could also reduce the runtime of the system.

Currently, our prompt that is fed into the models contains the model output as well as the ground truth. The model then is instructed to check whether the model output is grounded in the ground truth. This approach follows the baseline provided by the organizers. Consequently, our prompt optimization only uses these two inputs as well. It might be interesting to evaluate, whether using the model input as an additional prompt input can increase the performance of the system.

Overall, we argue that in a realistic use case of our system, the ground truth is not known when checking for hallucinations. Instead, the system should check whether the provided model output is a correct answer to the model input. Since our approach is very flexible, it is possible to enable this use case in our system by altering the model prompt to contain both the model input and its generated output, removing the ground truth. Then, our system could be used as a validator step after the output of a LLM, which catches hallucinated inputs or at least outputs the "p(Hallucination)" score along with the LLM output.

6 Related Work

Hallucination detection and automated prompt optimization in LLMs are both vivid research topics, which became popular with the high demand for reliable LLM applications.

Hallucination Detection We mainly follow the survey by Huang et al. (2023) who categorize hallucinations in LLMs into two main categories: Factuality Hallucination, where the model output is factually incorrect, and Faithfulness Hallucination, where the model output might be correct but does not follow the user's directives or does not take provided context into account. For both types of hallucinations, there is research to detect them. External knowledge can help with identifying Factuality Hallucinations, since the model output can be checked against verified knowledge sources. In this challenge, external knowledge in form of the ground truth answer is given. Uncertainty estimation of the model output can also help with identifying Factuality Hallucinations, since the model is usually not certain when producing wrong output. For this, some methods use access to the model to identify

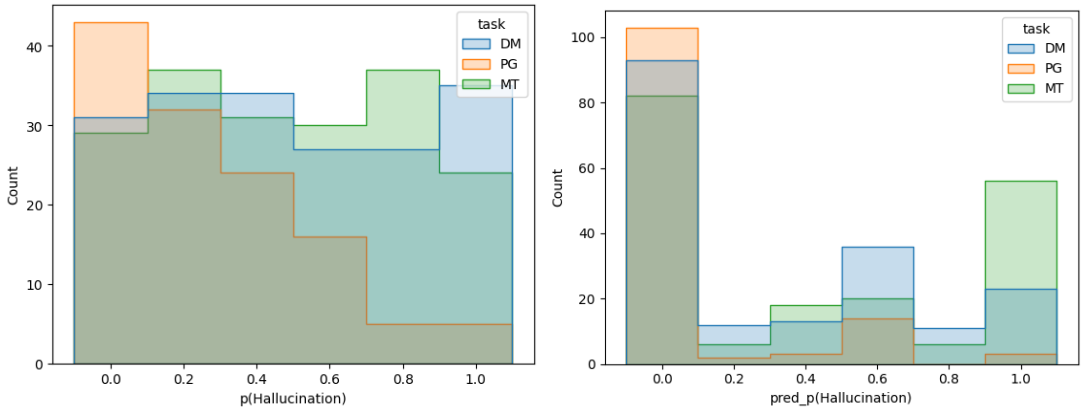

Figure 2: Gold label distributions vs. model predictions (left and right, respectively), with distinct behaviors observed for the different tasks.

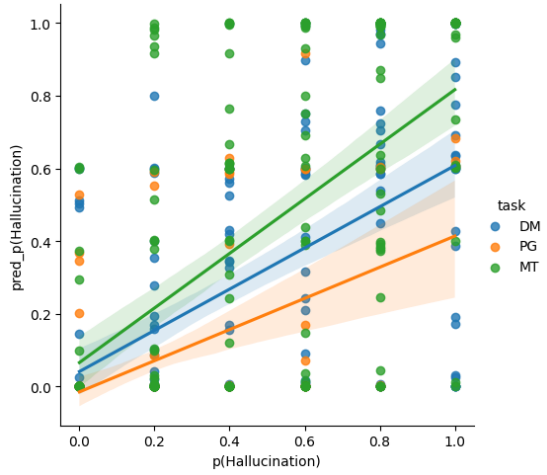

Figure 3: Positive correlation between predicted and actual hallucination probabilities for all tasks.

the uncertainty, other methods use the behavior of the model as an uncertainty indicator. The latter methods thus are model-agnostic.

For Faithfulness Hallucination, different metrics based on different methods such as word overlap or neural classifiers have been proposed. They try to identify logical misbehavior in the model output given the provided context by estimating the semantic or logical difference between the model input and its output. The idea is that Faithfulness Hallucinations stem from models not following the provided input and thus, the generated output is less consistent with its input than when the model does not hallucinate.

Prompt Optimization In the domain of prompt optimization for enhancing the reasoning capabilities of LLMs, a variety of strategies have emerged, notably in efforts to refine these models' performance through advanced prompting techniques (Qiao et al., 2023). Among these strategies, two prominent methods have recently gained attention for their novel approach to automatic prompt optimization, both leveraging a "guiding language model". This model, by having insight into the LLM's predictions, iteratively refines the prompt to achieve optimal outcomes.

The methodology introduced by Pryzant et al. (2023) draws inspiration from the principles of gradient descent and backpropagation. Initially, the guiding language model reviews the existing prompt alongside the LLM's errors, tasked with pinpointing specific shortcomings within the prompt — akin to identifying textual gradients. Following this, the same model is prompted to propose modifications that could rectify these identified issues, mirroring the process of backpropagation. This cycle of evaluation and refinement continues until the process reaches a state of "convergence".

Conversely, OPRO (Yang et al., 2023) simplifies this procedure by equipping the guiding language model with a repository of previously tested prompts and their corresponding effectiveness scores, in addition to a set of example problems. This repository provides the model with a richer context for decision-making, enabling it to discern more effectively between more and less successful prompts with each optimization iteration (as described in Section 2.4). This approach allows for a more informed and potentially more efficient refinement process.

7 Conclusion

We have introduced our system to detect hallucinations in LLMs using an ensemble strategy over multiple LLMs to decide whether the provided model output is hallucinated or not. Here, we employ a softmax over multiple relevant tokens to better capture the certainty of the models. We also employ an automatic prompt optimization scheme that finds well working prompts for each ensemble member.

We have found that the small Zephyr 3B model performs very well on this task, which motivates future exploration of its capabilities and reasons for them. Due to its simplicity, our system can be easily extended to new ensemble models and prompt templates as well as applied to new tasks, such as hallucination detection without access to ground truth.Future work might explore runtime optimizations such as batching or different model quantizations. Finally, instead of independently optimizing the model prompts, future work might jointly optimize all prompts for an ensemble, leading to different experts for different tasks.

Abstract

In this paper, we detail the methodology of team *whatdoyoumeme* for the SemEval 2024 Task on Multilingual Persuasion Detection in Memes. We integrate hierarchical label information to refine detection capabilities, and employ a cross-lingual approach, utilizing translation to adapt the model to Macedonian, Arabic, and Bulgarian. Our methodology encompasses both the analysis of meme content and extending labels to include hierarchical structure. The effectiveness of the approach is demonstrated through improved model performance in multilingual contexts, highlighting the utility of translation-based methods and hierarchy-aware learning, over traditional baselines.

1 Introduction

Persuasion techniques in politics have a significant impact on democratic processes, which was particularly evident in contexts such as the 2020 US elections, where cognitive dissonance and media messages played a crucial role in influencing voter behaviour and attitudes (Perloff, 2013; Center, 2023). These techniques, which utilise psychological insights, align people's attitudes with their actions and thus influence political affiliations and opinions. The interplay of crises – pandemic, economic downturn, protests against racial justice, and debates over electoral legitimacy – has further highlighted the impact of persuasive narratives on public perception and democratic resilience (Jamieson et al., 2023). This complicated relationship underscores the crucial role of persuasion in political discourse and its potential to shape democratic outcomes at crucial historical moments in society.

Manually recognizing persuasion in textual content is increasingly challenging due to the vast amount of information generated daily and the nuanced nature of persuasion techniques. Efforts in this area have expanded to include the development of collaborative tasks(Da San Martino et al., 2019a) aimed at recognizing persuasion across languages and levels of hierarchy, reflecting the global and complex nature of persuasive communication in digital spaces.

In the past, researchers have used statistical text analysis methods that focused on lexical and syntactic features to identify patterns and markers of persuasive language (Jacobs, 1992). While these approaches provided basic insights, they were often not deep enough to fully capture the subtleties of human language and persuasion. The detection of persuasion in texts has shifted from statistical text analysis to the use of Large Language Models (LLMs), such as BERT (Devlin et al., 2019) and GPT (Brown et al., 2020). These models use deep learning to understand the context, semantics and complex interplay of language elements, providing more effective means of recognizing persuasive tactics in text.

The collective effort in data collection and the joint tasks have contributed significantly to belief detection, with initiatives such as the SemEval joint tasks fostering community-wide collaboration. The NLP4IF-2019 shared task(Da San Martino et al., 2019a) was another example of the collective effort to refine detection methods through standardised tasks. The task was divided into two parts: the identification of propagandistic text fragments and their specific techniques at fragment level and a binary classification at sentence level to recognise sentences containing propaganda. The joint task attracted a large participation and showed that most of the systems were able to significantly outperform the established baselines. Alhindi et al. (2019) found that for some propaganda techniques, it is not enough to look at just one sentence to make an accurate prediction (e.g. repetition) and therefore the whole article needs to be included as context. Da San Martino et al. (2019b) presented a novel method for detecting propaganda at the level of fragments in news articles that goes be-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1537–1543

yond traditional document-level detection. Their method addressed the need for more nuanced and explainable analysis by manually annotating news articles with specific propaganda techniques and developing a multi-granularity neural network model that outperformed BERT-based baselines. Koreeda et al. (2023) showed that cross-lingual and multi-task training combined with an external balanced dataset can improve genre recognition and framing, on a recently proposed task by Piskorski et al. (2023).

Recent studies have shown that translating texts from low-resource languages to a high-resource language, such as English, improves performance of end-to-end approaches on tasks such as classification (Ghafoor et al., 2021; Jauregi Unanue et al., 2023) and document similarity (Zosa et al., 2022). Koloski et al. (2023) show that cross-lingual validation can lead to improvement on classification performance for some tasks. Some earlier works also confirm this to be true for non transformer architectures (Moh and Zhang, 2012). The rest of this article is organised as follows: Section 2 describes the task, while Section 3 presents the proposed method and the results. Finally, the conclusion and proposed future work in Section 4.

2 Task description

SemEval-2023 Task 4 (Dimitrov et al., 2024) focuses on multilingual detection and classification of persuation techniques in memes.

It is composed of three subtasks. **Subtask 1** was a multi-label text classification task. The text was extracted from the image data that contained the original meme. Although the text contains less information than original image, the annotation procedure accounted for this and allows for differences between labels in the text-only data and image data that provides additional context. **Subtask 2a** was a multimodal extension of the *Subtask 1* by providing both a text and the image data. It is also a multi-label classification task, with the labels annotated based on both text and image data. **Subtask 2b** was also a multimodal task with the same inputs as *Subtask 2a*, but the task was a simpler binary classification task to detect if any persuasion technique is used.

Although only English dataset was provided for training, the evaluation was additionally done on three surprise test datasets in Bulgarian, Macedonian, and Arabic.

Dataset split	English	Bulgarian	Macedonian	Arabic
Train	7000	0	0	0
Validation	500	0	0	0
Development	1000	0	0	0
Test	1500	436	259	100

Table 1: Number of examples for each of the dataset split across languages. Notably, only English data contains data for train/val/dev split while other languages require a zero-shot approach.

We further focus only on the *Subtask 1* and its data as this was the only task we participated in.

2.1 Dataset

The input data for *Subtask 1* is the text extracted from the meme. The training, the development and the test sets were distributed as JSON files. Each of the files encoded a list of examples where each one contained text of a meme and a list of labels, together with additional metadata not used in the model (unique id of the example and URL).

Table 1 shows dataset sizes with numbers of examples in each of the dataset split for each of the languages present in the task.

Labels provided with the dataset were organized in a hierarchy that was not visible from the dataset files and the full overview of the relationships between labels was provided in the accompanying subtask description. Although 20 classes were present in the training data, their ancestors in the hierarchy provided 8 additional classes for a total of 28 classes. Submission files could provide any of the 28 classes as prediction. Predicting an ancestor class of the ground truth labels instead of the leaf-node ground truth label was counted as a partial match.

Figure 1 shows the distribution of label counts in the data. Most common labels like *Smears*, *Loaded Language*, and *Name Calling/Labeling* are almost two times more frequent than any other label. The least frequent labels like *Reductio ad hitlerum*, *Straw man*, *Red herring*, and *Obfuscation* contain less than 100 examples in train, development and validation sets combined.

2.2 Evaluation

The labels are organized in a hierarchy that can be represented as a directed acyclic graph (DAG)- a tree-like structure. Datasets presented in the shared task contained data annotated with leaf labels, but the prediction can take any of the DAG nodes: either leaf or parent. For this reason, a hierarchical

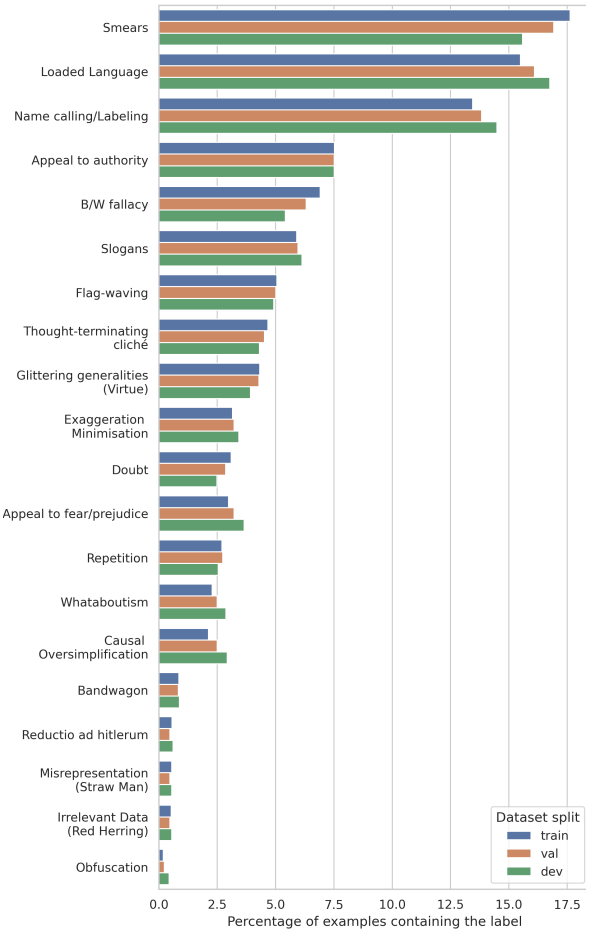

Figure 1: Label distribution shows a noticeable imbalance between class frequencies.

F_1 score (hF_1) (Kiritchenko et al., 2006) was used to take into account partially correct results, and leverage both the distance and the depth between true and predicted labels in the label hierarchy. The difference from standard, or flat, F_1 score is that the standard version considers each example as being a member of its assigned class. In contrast, the hierarchical version considers an example as a member of all parent classes in addition to its assigned leaf class. Formally, hierarchical (micro-average) version of precision (hP) and recall (hR) can be defined as:

$$hP = \frac{\sum_i |Y_A \cap \hat{Y}_A|}{\sum_i |\hat{Y}_A|} \quad hR = \frac{\sum_i |Y_A \cap \hat{Y}_A|}{\sum_i |Y_A|}$$

Where Y_A and $\hat{Y}_A$ represent a set of ground-truth and predicted labels, respectively, extended to contain all ancestors of included leaf nodes. Finally, we can define hierarchical F_1 score (hF_1) as:

$$hF_1 = 2 \cdot \frac{hP \cdot hR}{hP + hR}$$

This formulation effectively views the hierarchical classification as a multi-label setup by implicitly including hierarchy ancestor labels as additional labels.

3 Methodology and Results

Pre-trained language models, such as BERT (Devlin et al., 2018) and its variants, have shown remarkable performance across many NLP tasks. We evaluate several BERT-like models and their performance on the task. We are particularly interested in the impact of the hierarchy on model performances. We describe three approaches to understand the role of hierarchy information in the task.

First, we establish a baseline using BERT and mBART (Liu et al., 2020; Tang et al., 2020) models without using any hierarchy information and grid search to tune the hyperparameters. We explore different tokenization strategies and evaluate the model with micro-F_1.

Second, we evaluate approaches based on modifying the set of ground truth labels by extending the labels with ancestors to include hierarchy information and its influence on model performance.

Finally, we translate English train and validation data to Macedonian, Arabic, and Bulgarian with the NLLB-200 model (NLLB Team et al., 2022) and fine-tune our models for the multi-label classification task. We also compare the performance of the performance on translated data to zero-shot cross-lingual approaches using multilingual models and to translation of test sets.

3.1 Baseline Approach

We utilize distilBERT (Sanh et al., 2019) and mBERT (Devlin et al., 2018) for the baseline approach. The models are trained and evaluated without using any hierarchical information. Text data from the task was provided with escaped newlines (i.e. a newline character was represented with two characters '\' and 'n'). We evaluated a few approaches how to preprocess these data: directly tokenizing the provided text without any preprocessing (NoP), replacing the newlines with a space character (NL-Spc), or using a single newline ('\n') character (NL-L).

Both models are initialized with a linear classifier for multi-label classification. We use the AdamW optimizer (Loshchilov and Hutter, 2017) with binary cross-entropy loss and micro-F_1 score as evaluation metrics. We perform a grid search

over the learning rates (lr) [1e-4, 5e-5, 3e-5, 2e-5] and max sentence lengths of [128, 256] using a batch size of 16 over 6 epochs since BERT-based fine-tuning typically leads to decreased micro-F_1 and hF_1 scores after 6 training epochs (Sanh et al., 2019)

Results consistently favoured *lr*s of 5e-5 and 3e-5, with the highest micro-F_1 scores at lr 3e-5 with max length 128 (63.6%) and lr 5e-05 and max length 256 (63.1%) on the English validation set. However, the hF_1 score dropped to 56.9 on the English development set with the best model (see Table 2). Furthermore, we see a drop in the hF_1 on the development set when replacing the escaped newline with whitespace Table 2). We henceforth avoid any preprocessing of the input text.

We additionally compute the performance of mBART-50 (same hyperparameters) without using hierarchical information, where it gets a low mF_1 score on the validation set, but it outperforms the BERT-based models on the development set on hF_1.

Model	**Val** mF_1	**Val** hF_1	**Dev** hF_1
Performance without hierarchical information			
distilBERT (NoP)	63.6	/	56.9
distilBERT (NL-Spc)	63.6	/	50.4
distilBERT (NL-L)	63.6	/	50.4
mBERT (NoP)	59.2	/	/
mBART-50 (NoP)	48.9	59.9	59.9
Performance with hierarchical information			
distilBERT	/	60.1	**61.5**
mBART-25	/	59.8	60.4
mBART-50	**/**	**61.2**	61.0

Table 2: Performance comparison of baseline models on English dataset. Text preprocessing approach is in parentheses - no preprocessing (NoP), concatenating the lines with a single space character (NL-Spc) or using newline-separated lines (NL-L). mF_1 represents the micro F_1 score, and hF_1 indicates the hierarchical F_1 score. mBART-50 was our final submission during the official test phase.

3.2 Hierarchical Label Encoding

To include the hierarchical structure of the labels, we use the persuasion hierarchy digraph to expand the list of target labels such that it also contains all ancestor nodes. For example, [*Loaded Language*, *Name calling/Labeling*] is extended into [*Pathos*, *Loaded Language*, *Ethos*, *Ad Hominem*, *Name calling/Labeling*]. Since some labels have multiple parents, we consider all possible ancestors, and therefore [*Bandwagon*] gets extended into [*Logos*, *Justification*, *Bandwagon*, *Ethos*]. We compare the results of distilBERT and mBART-50 models compared to the approach without hierarchical label encoding. Additionally, we compute the results for mBART-25.

We internally test two approaches, a) one that extends labels for all training and validation examples and b) the one that extends the labels for training examples but not the validation examples. As extending the labels with ancestors only for the training examples consistently leads to better results, we proceed with this version.

As reported in Table 2, when using hierarchical information (extending the labels with ancestors for the training examples), mBART-25 achieves a hF_1 score of 60.4 and mBART-large-50 achieves 61.0 hF_1, on the English development set. The hyperparameters for these specific models had a learning rate of 5e-05, input size of up-to 128 tokens, and a batch size of 64.

Our results show that the hierarchical label encoding strategy consistently leads to performance improvements in this task compared to our baseline approach without hierarchical encoding, as showcased by distilBERT and mBART-50 models (see Table 2 for development set results). Note that distilBERT with hierarchy encoding results were computed in post-evaluation phase.

We submitted mBART-50 results (as it achieved the highest score on the validation set from the models we tested) for official test set evaluation for English. The model achieved 61.7 hF_1 score. We show the performance of the final model on all different language combinations in Table 4.

3.3 Translation and Test Set Results

For the three surprise test sets, we use the NLLB-200's 3.3B model (NLLB Team et al., 2022) to translate the English train and English validation sets into each target language to mimic the test stage scenario. We evaluate three settings (on the English validation sets, see Table 3): training on English and validating on translated data, training on translated data and validating on English data, and training and validating on translated data. We use the same hyperparameter grid search over the learning rates of [3e-5, 5e-5] and max lengths of [128, 256] to produce models fine-tuned for each language. Results indicate that training and validating with both target language translated sets consistently yielded better results when compared

to the other two settings (see Table 3). We use these fine-tuned checkpoints to infer the final submissions achieving results shown in Table 4.

Train	Validation	hF_1 score
EN_{train}	EN_{val}	61.2
$EN_{train} \rightarrow BG$	EN_{val}	54.9
$EN_{train} \rightarrow BG$	**$EN_{val} \rightarrow BG$**	**55.5**
EN_{train}	$EN_{val} \rightarrow BG$	47.1
$EN_{train} \rightarrow MK$	EN_{val}	53.3
$EN_{train} \rightarrow MK$	**$EN_{val} \rightarrow MK$**	**56.5**
EN_{train}	$EN_{val} \rightarrow MK$	51.3
$EN_{train} \rightarrow AR$	EN_{val}	56.2
$EN_{train} \rightarrow AR$	**$EN_{val} \rightarrow AR$**	**56.4**
EN_{train}	$EN_{val} \rightarrow AR$	50.6

Table 3: Evaluating the influence of translation as a strategy for handling low-resource languages. We measure mBART-50 model performance on Bulgarian (BG), Macedonian (MK) and Arabic (AR) by training on the English (EN) dataset translated to the target language using NLLB-200. The model is trained and evaluated on English data, possibly translated to the target language (translated dataset is shown with $\rightarrow$ followed by a target language).

Train	Validation	Test	hF_1 score
Final score on test data			
EN_{train}	EN_{val}	EN_{test}	61.7
$EN_{train} \rightarrow BG$	$EN_{val} \rightarrow BG$	BG_{test}	47.3
$EN_{train} \rightarrow MK$	$EN_{val} \rightarrow MK$	MK_{test}	36.2
$EN_{train} \rightarrow AR$	$EN_{val} \rightarrow AR$	AR_{test}	42.4
Zero-shot performance of the model			
EN_{train}	EN_{val}	BG_{test}	44.2
EN_{train}	EN_{val}	$BG_{test} \rightarrow EN$	44.2
EN_{train}	EN_{val}	MK_{test}	38.4
EN_{train}	EN_{val}	$MK_{test} \rightarrow EN$	33.8
EN_{train}	EN_{val}	AR_{test}	37.8
EN_{train}	EN_{val}	$AR_{test} \rightarrow EN$	36.4

Table 4: Evaluation of the model performance on the final test set. We measure mBART-50 model performance on Bulgarian (BG), Macedonian (MK) and Arabic (AR) by training on the English (EN) dataset. The model is trained and evaluated on English data translated to the target language (translated dataset is shown with $\rightarrow$ followed by a target language). We include final scores on test data achieved by the best-performing translation configuration. We additionally provide post-evaluation zero-shot performances of the model trained on the English data on the target language and the target language translated to English.

Using the approach where the model is trained on both train and validation data translated from English, we notice a significant degradation of the hF_1 scores for the three surprise test sets. The model for English did not use any translated data during training and validation and, as can be seen by comparing scores in Table 3 and Table 4, did not show signs of a similar degradation in performance on the test set.

This can be attributed to the distribution shift of persuasion label categories across the four languages. Our error analysis measuring accuracy for each label shows that the Arabic, Macedonian, and Bulgarian language models work well in identifying smaller classes with high accuracy while failing to generalize to the larger classes (see Table 5)[1]. These may arise from the model/training recipe failing to generalize over specific labels since different languages express persuasion strategies differently, and translations failing to capture some of these nuances.

Additionally, for our zero-shot performance evaluation, we use the model trained on English train and validation data to either directly predict the test datasets, or translating the test datasets to English and then predict. Here, we see that our translation approach works generally better than the zero-shot, except for the Macedonian dataset. This could be due to random seeds, however, larger comparable/parallel corpora are required to investigate this phenomenon.

Our final ranking on the SemEval Test Set Leaderboard are as follows: 17/32 for English, 8/20 for Bulgarian, 15/20 for Macedonian, and 4/17 for Arabic.

4 Conclusion and future work

In this paper, we describe the methods and models used by the *whatdoyoumeme* team in SemEval 2024 Subtask 1 to detect multilingual persuasion in memes. We combined two different approaches to solve this task: 1) machine translation, where we used the NLLB model (NLLB Team et al., 2022) to translate articles from English into the target languages and vice versa, and 2) including hierarchy information, where we extend a set of provided labels with labels corresponding to the ancestors nodes from the hierarchy DAG. We find that with the two proposed strategies, we can outperform both traditional encoder and decoder models, which emphasizes the importance of translation for downstream cross-lingual tasks.

In the future, we would like to extend our work

[1]All models generalize well over *Appeal to fear/prejudice* and *Distraction* but fail to generalize well over *Name calling/Labeling*.

in a few different directions. We would like to explore ensemble modelling techniques by building separate models for each belief category and using their joint predictions to improve overall performance. In addition, we would like to investigate the effects of translation quality and model size on the performance of this task.

Model	Label	Acc	Supp	Freq
mBART-50 Eng. Dev	Appeal to authority	95%	136	13.6%
	Repetition	94%	46	4.6%
	Distraction	92%	72	7.2%
	Simplification	79%	215	21.5%
	Name calling/Labeling	79%	262	26.2%
mBART-50 Arb. Test	Appeal to fear/prejudice	92%	8	8.0%
	Exaggeration/Minimisation	82%	18	18.0%
	Justification	79%	11	11.0%
	Name calling/Labeling	73%	26	26.0%
	Loaded Language	61%	24	24.0%
mBART-50 Mac. Test	Appeal to fear/prejudice	95%	13	5.02%
	Distraction	95%	11	4.25%
	Simplification	90%	10	3.86%
	Name calling/Labeling	63%	83	32.05%
	Loaded Language	61%	110	42.47%
mBART-50 Bul. Test	Appeal to authority	97%	18	4.13%
	Flag-waving	93%	28	6.42%
	Name calling/Labeling	68%	140	32.11%

Table 5: Error analysis of the model performance. Classes with higher accuracy are highlighted in green, while classes with lower accuracy in red. Only a selection of classes is shown, but a similar trend exists across all classes. Accuracy (*Acc*) is calculated using the standard binary accuracy measure. Support (*Supp*) is the number of instances from the dataset (*Train/Val/Dev/Test*) where the labels occur, and where the labels have been extended to include all ancestor nodes. Frequency (*Freq*) is calculated as support divided by the length of the dataset.

Abstract

This paper presents the solution of the LomonosovMSU team for the SemEval-2024 Task 4 "Multilingual Detection of Persuasion Techniques in Memes" competition for the English language task. During the task solving process, generative and BERT-like (training classifiers on top of embedder models) approaches were tested for subtask №1, as well as an BERT-like approach on top of multimodal embedder models for subtasks №2a/№2b. The models were trained using datasets provided by the competition organizers, enriched with filtered datasets from previous SemEval competitions. The following results were achieved: 18th place for subtask №1, 9th place for subtask №2a, and 11th place for subtask №2b. The code for the solutions is available at github[1].

1 Introduction

In the modern world, memes are one of the most popular forms of delivering information to social media users. Unfortunately, memes created using a variety of rhetorical and psychological techniques are also used to conduct disinformation campaigns.

The overall goal of the SemEval-2024 Task 4 competition is to build models to detect rhetorical and psychological propaganda techniques in memes. The competition itself consists of three subtasks:

1. Build a model to detect rhetorical and psychological techniques only in the textual content of the meme. This is a hierarchical multilabel classification problem.

2a. Build a model to detect rhetorical and psychological techniques in both textual and visual contexts of the meme (multimodal task). This is a hierarchical multilabel classification problem.

2b. Build a model to identify the presence of rhetorical and psychological techniques in both textual and visual contexts of the meme in general. This is a binary classification problem.

In this work, experiments were conducted with generative and BERT-like models to solve subtask №1 and classifiers on top of multimodal models to solve subtasks №2a/№2b. BERT-like approaches refer to the creation classifiers over embedder models and will be used further in this article. All tasks were solved for datasets in English. The following results were achieved: 18th place for subtask №1, 9th place for subtask №2a, and 11th place for subtask №2b. The code for the solutions is available in the repository at GitHub[2].

2 Related Works

Supervised fine-tuning (SFT) (Ouyang et al., 2022) is one of the most popular methods for fine-tuning LLMs to solve various tasks. In this work, we conducted fine-tuning of LLMs, such as LLAMA[3] and Mistral (Jiang et al., 2023), for detecting propaganda techniques. Unfortunately, SFT is very resource-intensive, and conducting frequent experiments with fine-tuning LLMs is time-consuming and expensive. To address this problem, a less resource-intensive approach, LoRA (Hu et al., 2021), was used, but unfortunately, the results of this approach were not satisfactory.

In parallel with SFT and LoRA approaches, experiments were conducted on fine-tuning simple classifier layers on top of embedding models: debert (He et al., 2021), CLIP (Radford et al., 2021), BLIP (Li et al., 2022). The results of these experiments yielded comparable results to experiments with LLMs.

3 Tasks solutions

3.1 Subtask №1

This subtask represents a hierarchical classification task. Two approaches were used to solve this task:

1. Generative approach: This approach involves training a generative model to generate explicit responses to questions in JSON format.

2. BERT-like approach: This approach involves training a simple fully connected network on top of a frozen pre-trained embedding model to solve the hierarchical classification task.

3.1.1 Generative approach

Idea. The main idea of this approach is to train a generative model, both in SFT mode (Ouyang et al., 2022) and trained using the LoRA technique (Piskorski et al., 2023), to answer the question: "Does the provided text contain any propaganda techniques, and if so, which ones?"

Dataset. The following combinations of data were used for training the models:

1. For selecting the best candidate model for the final solution, the training dataset provided by the authors was used, along with the dataset from the previous semeval competition [4]. This dataset was filtered, and only samples containing propaganda techniques matching those from the current competition were taken.

2. For training the model for the final solution, the same dataset described earlier was used, along with all samples from the gold dataset added to it.

Data Format. The following prompt phrase was used: "Your goal is to identify rhetorical and psychological techniques in the given text." The model was required to output JSON with propaganda techniques or an empty JSON. The model received texts in the following format: "Your goal is to identify rhetorical and psychological techniques in the given text.\nInput:. . . \nOutput:".

All texts from the dataset were filtered as follows:

1. All unnecessary line breaks in the texts were removed.

2. All unnecessary "\" characters in line breaks were removed. That is, if the text contained a construction of the following form "\\n", it was replaced with "\n".

3. Texts with prompts and responses longer than 4096 characters were not included in the dataset.

Models. LLaMA-2-7b-chat [5] and Mistral-7b-Instruct-v0.2 (Jiang et al., 2023) were used as models.

Training and Inference Parameters. Both models were trained in both SFT mode and using the LoRA technique, using the huggingface transformers [6] and torch frameworks on 4 A100 GPUs for no more than 12 hours per experiment.

In SFT mode, both models were trained with the parameters, presented in Appendix A.1.

When training with the LoRA technique, the models were trained with the same parameters, but with the following LoRA parameters, presented in Appendix A.2.

For inference, the vLLM framework (Kwon et al., 2023) was used with the following parameters presented in Appendix A.3.

3.1.2 BERT-like approach

As a result of training with deberta-base-cased, comparable results to the generative approach were achieved: F1 score of 0.638.

Idea. The main idea of this approach is to train a fully connected layer for hierarchical classification on top of a frozen embedding model for the task of hierarchical multilabel classification.

Dataset. For model training, we utilized the training dataset provided by the authors. The dev dataset was used for selecting the final model. For the final prediction, the model was trained on a mixture of the train and dev datasets.

Data Format. To predict propaganda techniques, we represented the data labels in the format of an acyclic graph, where the nodes of this graph are generalized technique types ("Ethos", "Pathos", ..., etc.), and the leaves are concrete techniques ("Name calling", "Doubt", ..., etc.). Instead of predicting only specific techniques, we predict generalized techniques as well. For example, if the current sample needs to predict the technique {"Whataboutism"}, the model should predict Anc(y) = {"Whataboutism", "Distraction", "Reasoning", "Ad Hominem", "Ethos", "Logos", "Persuasion"}. Thus, datasets are formed as sets of pairs: (x, Anc(y)), where x is the text, and y is the set of techniques contained in the text x.

Model. The frozen model used to obtain embeddings was deberta-base-cased (He et al., 2021).

     given text.\nInput:Tunnel to Schiff\nBunker where our next President will be
     chosen.\nOutput:",
"output": [
        "Causal Oversimplification",
        "Smears"
    ],
"full_input": "Your goal is to identify rhetorical and psychological techniques
    in the given text.\nInput:Tunnel to Schiff\nBunker where our next President
    will be chosen.\nOutput:[\"Causal Oversimplification\", \"Smears\"]"
}
```

Figure 1: Sample from the dataset example

The embedding of the entire text from the embedding model was taken, followed by the application of several dropout layers in parallel, and the results were averaged. At the end, trainable linear layers were used for classification.

Training Parameters. Training parameters of the discussed models can be seen in Appendix A.4.

3.1.3 Results

Generative approach. Experiments with pretraining models using the LoRA technique did not yield the desired result. Consistent responses from the models in JSON format could not be achieved, and there was not enough time to develop rules for formatting their outputs.

The results of the models trained with SFT are presented in the Table 1.

Mistral	LLaMa 2
0.56 F1	0.65 F1

Table 1: Results for subtask №1

BERT-like approach. As a result of training with deberta-base-cased, comparable results to the generative approach were achieved: F1 score of 0.638.

Final Prediction. For the final prediction, the LLaMA-2-7-chat model was fine-tuned on dataset 2 with the same parameters as dataset 1, and with the following parameters, shown in Appendix A.5.

It achieved an F1 score of 0.61339 and secured the 18th position on the leaderboard.

3.2 Subtask №2a

Idea. This task resembles subtask №1, but besides text, it involves meme images. It was tackled using a trainable linear layer for hierarchical classification atop frozen multimodal text-to-image embedding models.

Dataset. For model training, we utilized the training dataset provided by the authors. The dev dataset was used for selecting the final model. For the final prediction, the model was trained on a mixture of train and dev datasets.

Data Format. To represent propaganda techniques, we employed the format of an acyclic graph from the first subtask. The dataset is presented as triples: (img, x, Anc(y)), where img and x represent the image and text of the current meme, and y is the set of techniques contained in the current meme.

Models. CLIP (Radford et al., 2021) and BLIP (Li et al., 2023) were used as models to obtain embeddings for texts and images. The embeddings of the full text and the entire image were concatenated, and several dropout layers were applied in parallel, with the results averaged. At the end, trainable linear layers were used for classification.

Training Parameters. The models were trained on a single P100 GPU on the Kaggle platform. Parameters for BLIP/CLIP were frozen.

Other parameters are shown in Appendix A.6.

Results. The results of the models trained on dataset 1 are presented in the Table 2.

CLIP	BLIP
0.648 F1	0.633 F1

Table 2: Results for subtask №2a

3.3 Subtask №2b

This subtask differs from subtask №1 only in that it requires predicting whether there is any propaganda technique present in the text at all. We used the same approach, the same models with the same

hyperparameters, trained on the same datasets as in subtask №1. The only difference is in the data format - the dataset consists of triples (img, x, y), where img and x are the image and text of the current meme, and y is a flag indicating whether the current meme contains a propaganda technique.

Results. The results of the models trained on dataset 1 are presented in the Table 3.

CLIP	BLIP
0.72 F1	0.748 F1

Table 3: Results for subtask №2b

For the final prediction, the CLIP model was selected, achieving an F1 score of 0.772 and securing the 11th position on the leaderboard.

4 Further research

We did not have time to take more powerful models and experiment with them to solve subtask №1, but we are confident that Mixtral 8x7b or Llama-2-13b-chat would yield better results. Additionally, we did not have time to add data from the PTC (He et al., 2021) corpus to the dataset, but we are sure that it would have provided an even greater improvement. We also did not have time to test generative models that take text with images as input and generate text responses, for example, RUDOLPH (Radford et al., 2021).

A Appendix

This appendix shows the training and generation parameters for the models described above in the text.

A.1 Hyperparameters for models training in SFT mode

- BATCH_SIZE = 4
- GRADIENT_ACCUMULATION = 4
- LEARNING_RATE = 1e-5
- MAX_LEN = 4
- WARMUP_STEPS = 4
- in fp32 and for 2 epochs

A.2 Hyperparameters for models training with LoRA technique

- LORA_R = 8
- LORA_ALPHA = 16
- LORA_DROPOUT = 0.05
- TARGET_MODULES = ["q_proj", "k_proj", "v_proj", "o_proj"]

A.3 Hyperparameters for models output generation with vLLM

- TOP_K = 50
- TOP_P = 1 and 0.9
- MAX_TOKENS = 600
- TEMPERATURE = 1, 0.8, 0.6, and 0.2

A.4 Hyperparameters for BERT-like models training for subtask №1

- Models were trained on a single P100 GPU on the Kaggle platform [7].
- Optimizer: AdamW with linear scheduler
- Learning rate (LR): 2e-5
- Batch size: 8
- Warmup steps: 100

A.5 Hyperparameters for models output generation with vLLM for final prediction

- TOP_K = 50, TOP_P = 0.9
- MAX_TOKENS = 600
- TEMPERATURE = 0.8

A.6 Hyperparameters for BERT-like models training for subtask №2a and №2b

- Optimizer: Adam
- Learning rate (LR): 2e-3
- Batch size: 10

gstam@cs.ntua.gr

Abstract

In this paper, we present our team's submissions for SemEval-2024 Task-6 - SHROOM, a Shared-task on Hallucinations and Related Observable Overgeneration Mistakes. The participants were asked to perform binary classification to identify cases of fluent overgeneration hallucinations. Our experimentation included fine-tuning a pre-trained model on hallucination detection and a Natural Language Inference (NLI) model. The most successful strategy involved creating an ensemble of these models, resulting in accuracy rates of 77.8% and 79.9% on model-agnostic and model-aware datasets respectively, outperforming the organizers' baseline and achieving notable results when contrasted with the top-performing results in the competition, which reported accuracies of 84.7% and 81.3% correspondingly.

1 Introduction

In the era that Large Language Models (LLMs) dominate and shape the trends in the Natural Language Processing (NLP) community, ensuring reliance and accurate functionality of related systems becomes a major concern. Hallucinations of language models have recently received lots of attention (Rawte et al., 2023; Ji et al., 2023; Huang et al., 2023; Ye et al., 2023; Zhang et al., 2023), questioning the trust that humans can pose in highly intelligent yet probabilistic models. At the same time, recent endeavors formally prove that hallucinations are inherent to LLMs and thus inevitable in practice (Xu et al., 2024).

Encompassing the need for detecting and analyzing hallucinations in Natural Language Generation (NLG) tasks, and given the scarcity of related datasets and benchmarks (Li et al., 2023; Cao et al., 2023; Chen et al., 2023; Muhlgay et al., 2024), the SemEval-2024 Task 6 (SHROOM: a Shared-task on Hallucinations and Related Observable Overgeneration Mistakes) (Mickus et al., 2024) addresses the presence of semantically unrelated generations with respect to a given input, covering challenging NLP tasks, such as Machine Translation, Definition Modelling and Paraphrase Generation, which are tested both when the underlying model is known or not.

To this end, we explore efficient and widely adaptable hallucination detection strategies, tailored to the black-box demands of the problem[1]. Based on pre-trained models which contain knowledge regarding semantic relationships related to hallucinations, we achieve ∼80% accuracy in hallucination detection by fine-tuning on labeled SHROOM instances, notably higher than the 74.5% baseline accuracy provided, using an open-source Mistral instruction-tuned model[2]. Specifically, we contribute to the following:

1. We fine-tune models pre-trained on hallucination detection and Natural Language Inference (NLI) datasets, which are semantically related to SHROOM challenges.

2. Tuned models constitute a Voting Classifier, achieving competitive detection accuracy.

3. All our experimentation is time and computationally efficient, while entirely black-box.

4. Decomposition of results per task and analysis of failed and accurately detected instances provide valuable insights into the nature of the involved hallucinations.

Our code is available on GitHub [3].

[1] Even in the model-aware setting of SHROOM, we do not re-generate the outputs using the given models, therefore we continue operating in a completely black-box setup.

2 Related Work

NLP hallucinations is a rapidly evolving field, examining invalid generations from varying perspectives. Categorizations of hallucinations may view hallucinatory outputs as unfaithful to the input, inconsistent with the generated output itself, or conflicting with real-world knowledge (Zhang et al., 2023). Factual hallucinations have gathered the majority of recent breakthroughs, since comparison with existing factual sources (Lin et al., 2022; Lee et al., 2023; Chen et al., 2023; Min et al., 2023; Cao et al., 2023; Muhlgay et al., 2024) renders them accurately detectable and correctable (Chern et al., 2023; Dhuliawala et al., 2023; Li et al., 2024). The more subtle characteristics of other hallucination types constitute the creation of related benchmarks harder, not to mention techniques for automatic evaluation (Azaria and Mitchell, 2023; Kadavath et al., 2022; Manakul et al., 2023; Duan et al., 2024). A limitation tied with such techniques is that in most cases at least model probing is needed, rendering them unusable in cases where the model that produced the reported hallucinations is completely unknown or inaccessible. SHROOM comes to fill this gap, focusing on semantic faithfulness rather than factuality, while requesting a diverging suite of proposed detection techniques that should even cover cases that the model is not given at all. As a trade-off, implementations on the SHROOM dataset require the ground-truth output, since the given input does not contain the necessary semantic information to drive decisions on whether a sample is a hallucination or not. Our proposed approach only considers given *inputs* and *outputs* and does *not* probe any model, contrary to other black-box techniques (Manakul et al., 2023).

3 Task and Dataset description

Driven by upcoming challenges in the NLG landscape, SHROOM dataset focuses on the prevalent issues of models generating linguistically fluent but inaccurate (incorrect or unsupported) outputs. Participants are tasked with binary classification to identify instances of fluent overgeneration hallucinations in *model-aware* and *model-agnostic* tracks. The task encompasses three NLG domains—definition modeling (DM), machine translation (MT), and paraphrase generation (PG)—with provided checkpoints, inputs, references, and outputs for binary classification. The development set includes annotations from multiple annotators, establishing a majority vote gold label.

Data details In all cases, data follow a specific format: *src* is the input given to a model, *hyp* is the output generated by the model, *tgt* comprises the ground truth output for this specific model, *ref* indicates whether target, source or both of these fields contain the semantic information necessary to establish whether a datapoint is a hallucination, *task* refers to the task being solved and *model* to the model being used (in the model-agnostic case the *model* entry remains empty). An example of the data format is given in Table 7. Initially, 80 labeled trial samples were released, followed by unlabelled training data which contain 30k model-agnostic and 30k model-aware instances. Finally, the labeled validation set contains 499 and 501 samples for model-agnostic and model-aware settings respectively, while the test set comprises 1500 model-agnostic and 1500 model-aware labeled samples. Additional information provided in the labeled splits are *labels*, which contains a list of 'Hallucination' and 'Not Hallucination' labels as provided by 5 annotators per sample, the final *label* occurring via majority voting over the aforementioned list and *p(Hallucination)*, denoting the probability of hallucination as the percentage of agreeing annotators on the 'Hallucination' label. A thorough data analysis is provided in the App. C.

Evaluation metrics proposed from the task organizers for SHROOM are accuracy, regarding the classification success in 'Hallucination'/'Not Hallucination' classes and Spearman correlation (RHO), measuring the -positive- correlation between validation and test p('Hallucination') values.

4 Methods

As the core of our system, we propose a universal and lightweight methodology that leverages well-established pre-trained classifiers for hallucination detection. We propose 3 techniques to approach it.

4.1 Fine-tune hallucination detection model

Our first technique employs fine-tuning a pre-trained classifier dedicated to hallucination detection to learn distinguishing patterns between hallucinated/non-hallucinated SHROOM instances. More specifically, we employed a pre-trained model based on microsoft/deberta-v3-base pro-

vided by Hugging Face[4], especially designed for hallucination detection. This model was initially trained on NLI data to ascertain textual entailment. Subsequently, it underwent further fine-tuning using summarization datasets enriched with factual consistency annotations. The output of our employed model is a probability score in the [0, 1] range; a score of 0 indicates the presence of hallucination in the generated content, while a score of 1 signifies factual consistency. This probabilistic nature enables the evaluation of the model's confidence in the veracity of the generated hypotheses.

To tailor the model to the specific demands of our task, we used the provided annotated validation set of 1000 samples for training purposes. This adaptation process aimed to enhance the model's performance by aligning it with the variation and complexity present in SHROOM. Moreover, we applied a thresholding approach to make practical decisions based on the probabilistic outputs of the model. By setting a threshold at 0.5, we categorize predictions with scores above this threshold as indicative of input-output consistency, while the rest are considered as potential hallucinatory instances.

4.2 Fine-tune NLI models

In the context of detecting hallucinated answers, we also employed NLI models, an approach that has witnessed significant advancements, while investigating semantic intricacies close to hallucinations. NLI models play a crucial role in enabling comprehension of the sophisticated connections between sentences, categorizing the relationship between a *hypothesis* and a *premise* into entailment, neutral, or contradiction. In terms of our task, we convert hallucination detection to an NLI problem: given the input (termed as *hypothesis-hyp*) to a model and the premise (named *target-tgt*) we evaluate whether *tgt* entails, contradicts or remains neutral to *hyp*.

To execute this approach in technical terms, we select a pre-trained NLI model available through Hugging Face[5]. This model, based on mDeBERTa-v3-base architecture, was originally trained on a large-scale multilingual dataset, making it well-suited for handling diverse linguistic details. To fine-tune the NLI model and tailor it to the specific intricacies of our task, we employed the annotated validation set, as in the previous case.

[4] https://huggingface.co/vectara/hallucination_evaluation_model

[5] https://huggingface.co/MoritzLaurer/mDeBERTa-v3-base-xnli-multilingual-nli-2mil7

4.3 Voting Classifier

In our final approach, we employed an ensemble technique known as a Voting Classifier. The underlying principle is to aggregate the collective insights derived from each constituent classifier (in our case the previously mentioned models), ultimately predicting the output class based on the highest majority of votes. By doing so, the ensemble not only leverages the individual strengths of each method but also mitigates potential weaknesses, thereby enhancing the overall predictive performance in a deliberate effort to address the inherent complexity and variability within the dataset, contributing to a more nuanced and accurate understanding of the phenomena under investigation.

5 Experiments

5.1 Experimental setup

All our experiments were executed using Google Colab platform with a single Tesla T4 GPU.

Fine-tune hallucination model Our fine-tuned model underwent a rigorous training and evaluation process, utilizing SHROOM data provided by the task organizers. Specifically, the model was trained with the annotated validation set and evaluated against the trial set. In the pre-processing phase, from each data point, we extracted the *hyp* and *tgt* components to serve as inputs to the model.

To optimize the model's performance in terms of both accuracy and p('Hallucination'), we implemented a dual-training strategy. The model was trained twice, employing binary labels (0 for Hallucination and 1 for Not Hallucination) in one iteration and float labels (representing 1-p('Hallucination')) in the other. This dual-training approach allowed us to derive two crucial aspects from the model: the binary label indicating the presence or absence of hallucination, and the corresponding probability score indicating the likelihood of hallucination. The hyperparameters for fine-tuning are comprehensively detailed in Table 1.

Hyperparameter	Value
train dataloader	validation set (1,000 samples)
evaluator	trial set (80 samples)
epochs	5
evaluation steps	10,000
warm-up steps	10% of train data for warm-up

Table 1: Hyperparameters used for the hallucination detection model fine-tuning

Natural Language Inference (NLI) models This NLI model was already trained with the multilingual-nli-26lang-2mil7 (Laurer et al., 2022) dataset and the XNLI validation dataset (Conneau et al., 2018), both containing three different labels: 'entailment', 'neutral' and 'contradiction'. During the training phase, we systematically mapped the 'Hallucination' label to 'contradiction' and the 'Not Hallucination' label to 'entailment', ensuring a binary representation of the hallucinatory nature of the content. This transformation facilitated the training process by providing clear labels for the model to learn the distinctions between hallucinatory and non-hallucinatory instances.

Post-training, the model's predictions were assessed using the entailment score, and a strategically chosen threshold was employed to distinguish between hallucinations and non-hallucinations. Prior to training, we experimented with a wide range of threshold values, concluding that a threshold of 0.8 optimized the accuracy of the trial set. Simultaneously, for the determination of the percentage of Hallucination for each data point, we used the entailment percentage subtracted from 1.

A detailed account of the parameters employed for training this NLI model is outlined in Table 2.

Hyperparameter	Value
train dataset	validation set (1,000 samples)
learning rate	2e-05
epochs	5
warm-up ratio	0.06
weight decay	0.01

Table 2: Hyperparameters used for NLI fine-tuning

Voting Classifier In the final leg of our methodological exploration, the Voting Classifier integrates the pre-trained hallucination detection model, its fine-tuned counterpart from §4.1, and the fine-tuned NLI model described in §4.2.

The Voting Classifier operates on a dual strategy for hallucination categorization. First, for the binary labels, we assigned the majority label ('Hallucination' or 'Not Hallucination') among the three models to each data point. Second, to determine the percentage of hallucination for each data point, we provided two methodologies. For the first one, we implemented a similar methodology to the one used in the validation and trial sets, i.e. the percentage of hallucination derived from the majority vote of the annotators. By emulating the same process, we calculate the percentage of models that labeled a given data point as 'Hallucination'. For the second one, we use the float p('Hallucination') scores of each of the three models constituting the ensemble and extract the average value.

5.2 Results

Baseline System During the evaluation phase, we were provided with a baseline system, which was based on a simple prompt retrieval approach, derived from SelfCheck-GPT(Manakul et al., 2023), using an open-source Mistral instruction-tuned model as its core component (the prompt is shown in Table 6). If the answer starts with'Yes' the sample is classified as 'Not Hallucination' with p('Hallucination') equal to the probability that the token was chosen subtracted from 1, else if the answer starts with 'No' the sample is classified as 'Hallucination' with p('Hallucination') equal to the probability that the token was chosen. If the answer starts with neither, the label is assigned randomly and p('Hallucination') equals to 0.5.

Averaged results for all our experiments are presented in Table 3. The Voting Classifier achieves top results, with a more notable difference in the model-agnostic setting. This is an expected behavior since the ensembling of models is designed to boost the performance of its standalone constituents.

Method	acc.↑	rho↑
Model-aware		
Baseline Model	0.745	0.488
Fine-tune hal-detect model	0.795	0.685
NLI model	0.77	0.591
Voting Classifier-majority vote	**0.799**	0.691
Voting Classifier-averaged percentage	**0.799**	**0.693**
Model-agnostic		
Baseline Model	0.697	0.402
Fine-tune hal-detect model	0.778	0.668
NLI model	0.751	0.548
Voting Classifier-majority vote	**0.78**	0.632
Voting Classifier-averaged percentage	**0.78**	**0.643**

Table 3: Final results for model-aware and model-agnostic variants. **Bold** denotes best results. The two Voting Classifiers differentiate from the method applied to calculate the p('Hallucination) as explained in 5.1

We demonstrate the computational efficiency of our proposed methods regarding the training and inference time needed in Table 4. The Voting Classifier sums the times of all three of its model-voters. Since reported runtimes were achieved using the T4 GPU of the free Google Colab version, our proposed methods can be replicated and utilized by

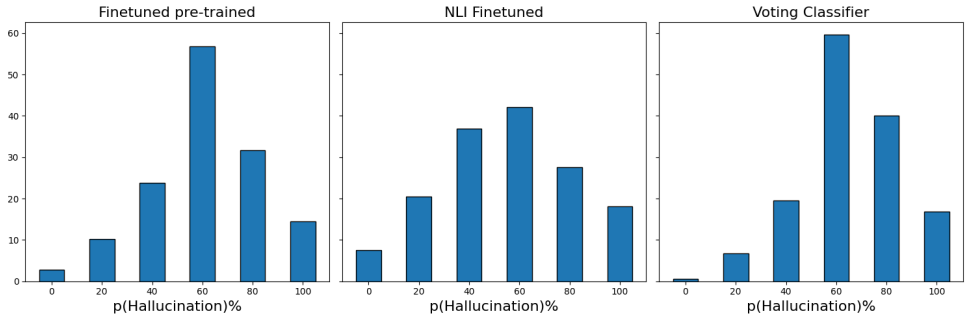

Figure 1: p('Hallucination') for all misclassified samples of model aware dataset.

Table 5: Model-aware accuracy per model and task.

Moreover, per-task and model hallucination detection for the model-aware dataset is presented in Table 5. The PG task demonstrates superior performance compared to the other two tasks, while the DM task reports significantly lower accuracy. This disparity in outcomes can be explained by the inherent characteristics of each task when formulated as a paraphrase problem. The PG task exhibits notably higher results owing to its direct alignment with the paraphrase objective. Similarly, the MT task, which evaluates translations from the LLM against ground truth translation, achieves relatively comparable results. Conversely, the DM task faces the complexities of articulating precise and contextually relevant definitions. Consequently, the DM task exhibits notably lower accuracy due to the intricacies of handling more complex sentence structures. The Voting Classifier remains the top scorer in each of the tasks, highlighting the power of ensembling individual predictors.

Finally, we perform *some error* analysis on the misclassified samples (Figures 1, 2): we measure the p('Hallucination') for misclassifications for all our 3 methods. Ideally, p('Hallucination') values for misclassifications should lie close to the discrimination threshold of 0.5, indicating that their separability is highly uncertain. Indeed, our best performing Voting Classifier presents a peak for p('Hallucination')=0.6 for both model-aware and model-agnostic settings, highlighting that misclassified samples are in any case hard to classify in their correct class. Moreover, the p('Hallucination') values in the range [0.0-0.4] - corresponding to the 'Not Hallucination' label- are lower for the Voting Classifier in comparison to the other two models, denoting that ensembling

reduces misclassifications for non-hallucinatory instances.

6 Conclusion

In this work, we detect and analyze hallucinations from the SHROOM dataset introduced in SemEval 2024 Task 6. We propose a computationally efficient methodology based on fine-tuning models that present semantic cues close to SHROOM's hallucinations, while model ensembling further boosts results in 3 NLG tasks. Our techniques operate in a fully black-box setting, solely requiring inputs and outputs obtained from NLG models. Our error analysis demonstrates that our misclassifications are samples of high uncertainty in terms of hallucination probability and, therefore hard to be discerned overall. In total, we aspire that our simple though efficient technique will assist future research in the crucial hallucination detection field.

A Organizers' baseline

The prompt used by the organizers to construct the baseline Mistral instruction-tuned model is demonstrated in Table 6.

Prompt
Context {tgt} Sentence: {hyp} Is the sentence supported by the context above? Answer Yes or No:

Table 6: Prompt used in the Baselined System

B Data format

In Table 7 we present some examples from the unlabelled training dataset containing model-agnostic and model-aware instances. Regarding the machine translation (MT) task, we could detect a variety of languages, including Russian, Arabic, Chinese, Yorùbá, Telugu, Tsonga, Uzbek, Sinhalese, Quechuan, Mizo and others. Language information was not provided, so we manually explored the *src* samples in terms of linguistic variability.

Model-agnostic definition modeling (DM) hypotheses contain some 'qualifiers', which may guide a model under usage to return a more suitable definition. For example, in the context of the hypothesis containing the definition "(obsolete) An odour," the term "obsolete" indicates that the provided definition is no longer in common use or is outdated. The word "obsolete" is used as a qualifier to convey that the term or concept being defined, in this case, "An odour," was once used to represent a specific meaning but is no longer considered current or applicable in contemporary language.

Another notable observation is that model-aware paraphrase-generation (PG) does not contain any information in *tgt*.

C Exploratory data analysis

Trial set We explore the frequency of each task occurring within samples from different dataset splits, commencing from the initially released trial set. In Figure 3 we present the task distribution of the first 80 trial samples.

Unlabelled data (training set) Figure 4 represents the distribution in the training set. In both model-agnostic and model-aware settings each task contains an equal number of samples (10k samples per task in each setting). In our methodologies, we abstained from utilizing the provided unlabeled training dataset as it did not align with our main approaches.

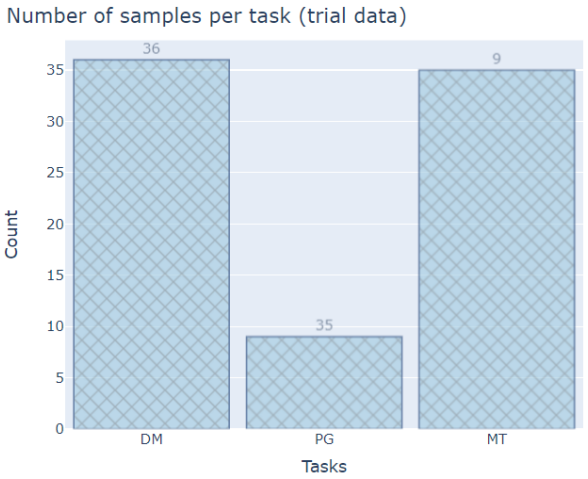

Figure 3: Distribution of per task samples in the initially released trial set.

Validation set Moving on to labeled data, we commence with the validation (dev) set, for which we present per task distributions in Figure 5. We observe a difference in the distribution of labels

Figure 4: Distribution of unlabelled training samples per task in both model-agnostic and model-aware settings.

in comparison to the balanced training set distribution of Figure 4; nevertheless, since we do not exploit any unlabelled instance, this does not pose a limitation for us at this point.

We proceed with studying the validation set label distribution. Related results are presented in Figure 6, denoting label imbalance in both model-agnostic and model-aware settings.

The distribution of hallucination probability is presented in Figure 7. As expected, low p('Hallucination') values are more common (indicating that fewer annotations voted for the presence of a hallucinatory instance), since 'Not Hallucination' is the majority label in both settings. Ideally, we wish borderline probabilities to be low: The highest the disagreement for a certain sample, the

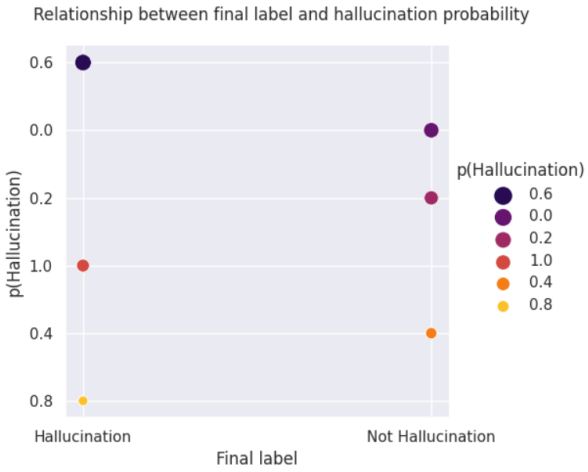
(a) Hallucination probability per label (Model-agnostic).



(b) Hallucination probability per label (Model aware).

Figure 12: Distribution of hallucination probability in each test label ('Hallucination' vs 'Not Hallucination). Annotators significantly agree on whether a sample contains a hallucination or not.

closest to the 0.5 threshold the hallucination probability will be (a p('Hallucination')=0.4 denotes that 3/5 annotators voted for 'Not Hallucination', while the rest 2/5 voted for the opposite; on the other hand, a p('Hallucination')=0.6 denotes that 3/5 annotators voted for 'Hallucination', while the rest 2/5 voted for 'Not Hallucination'. Therefore, the highest uncertainty is observed close to the 0.5 boundary). This requirement is adequately satisfied especially in the model-agnostic case (left plot of Figure 7), where p('Hallucination')=0.6 is the least frequent.

Further insights can be obtained by looking at Figure 8: when smaller dots are assigned to probabilities close to the 0.5 threshold, the annotators' disagreement is lower, therefore classifying a sample as 'Hallucination' or 'Not hallucination' is less uncertain. Indeed, the less frequently appearing p('Hallucination')=0.4 and p('Hallucination')=0.6 values in the model-agnostic case denote high separability between hallucinated and non-hallucinated samples. However, highly certain values, such as p('Hallucination')=0.0 and p('Hallucination')=1.0 only rank in the middle, therefore even if samples are separable with low uncertainty, some minor disagreement persists (1/5 annotators frequently disagrees with the rest). Overall, annotators are almost equally confident in classifying 'Hallucination' and 'Not Hallucination' samples, as indicated by the matching pattern regarding label uncertainty

for both labels. The model-aware case is more confusing, with p('Hallucination')=0.6 scoring the highest; therefore, classifying a sample as 'Hallucination' is often accompanied by high uncertainty. On the contrary, uncertainty is lower for the 'Not Hallucination' label, with p('Hallucination')=0.0 ranking as the second most frequent probability. We can conclude that in the model-aware setting of the validation set, annotators are more confident in recognizing the 'Not Hallucination' class in comparison to the 'Hallucination' one.

Test set As for the test set, Figure 9 represents the number of samples per task for both settings. Note that the test task distribution is similar to the validation distribution of Figure 5with PG being a minority label in all cases.

In terms of ground-truth label (Hallucination vs Not Hallucination), Figure 10 highlights some label imbalance, rendering the prediction of 'Not Hallucination' more possible in a random setup for both model-agnostic and model-aware settings. This label distribution matches the validation set label distribution (Figure 6), for which 'Not Hallucination' was the majority class as well.

Hallucination probability per setting is depicted in Figure 11, with lower hallucination values in the range [0, 0.2) being more common. This is again somehow expected since 'Not Hallucination' is the majority class in test labels. More insights can be obtained by looking at Figure 12, which relates the hallucination probability with the label. Especially in the model-agnostic setting (Figure 12 - left), the p('Hallucination')=0.4 and p('Hallucination')=0.6 values are the lowest (smaller dots), while p('Hallucination')=0.0 is the highest, denoting that annotators are often certain regarding non-hallucinated samples. Certainty for hallucinated samples is somehow lower, as p('Hallucination')=1.0 lies somewhere in the middle. Nevertheless, p('Hallucination')=0.8 is the second more frequent value denoting that 4/5 annotators frequently annotate a sample as 'Hallucination'. By observing the right plot of Figure 12, we conclude that certainty is lower in the model-aware setting. Even though p('Hallucination')=0.0 remains the most frequent probability, indicating high agreement regarding non-hallucinated samples, the p('Hallucination')=0.6 value stands in the second place. Therefore, many samples classified as 'Hallucination' achieved this label with low agreement (3/5 annotators). Also, the p('Hallucination')=0.2 and p('Hallucination')=0.8 are the lowest, denoting that higher agreement (4/5 annotators agreeing) is rare for both 'Hallucination' and 'Not Hallucination' labels. We can assume that model-aware samples are harder by nature to be classified in any of the labels.

D NLI-Hyperparameters

The hyperparameters utilized for the NLI model fine-tuning mirrored those employed during the training of the initial model. The selection of hyperparameters followed a series of experiments, which yielded significantly lower levels of accuracy. Some of the experiments are displayed in the Table 8

epochs	lr	warmup ratio	weight decay	accuracy
5	2e-05	0.06	0.01	0.83
10	2e-06	0.1	0.01	0.75
5	2e-04	0.01	0.05	0.53
5	2e-05	0.05	0.001	0.8
5	2e-06	0.08	0.1	0.79

Table 8: Accuracy on trial-set from experiments with hyperparameters. The first row displays the hyperparameters chosen for finetuning

JMI at SemEval 2024 Task 3: Two-step approach for multimodal ECAC using in-context learning with GPT and instruction-tuned Llama models

Abstract

This paper presents our system development for SemEval-2024 Task 3: "The Competition of Multimodal Emotion Cause Analysis in Conversations". Effectively capturing emotions in human conversations requires integrating multiple modalities such as text, audio, and video. However, the complexities of these diverse modalities pose challenges for developing an efficient multimodal emotion cause analysis (ECA) system. Our proposed approach addresses these challenges by a two-step framework. We adopt two different approaches in our implementation. In Approach 1, we employ instruction-tuning with two separate Llama 2 models for emotion and cause prediction. In Approach 2, we use GPT-4V for conversation-level video description and employ in-context learning with annotated conversation using GPT 3.5. Our system wins rank 4, and system ablation experiments demonstrate that our proposed solutions achieve significant performance gains. All the experimental codes are available on Github.

1 Introduction

Emotion Cause Analysis (ECA) is centered around the extraction of potential cause clauses or pairs of emotion clauses and cause clauses from human communication, enabling a deeper understanding of communication dynamics. By incorporating multimodal cues like visual scenes, facial expressions, and vocal intonation, it facilitates a comprehensive and technically robust analysis of the factors that trigger diverse emotional reactions (Mittal et al., 2021; Zhang and Li, 2023; Zheng et al., 2023b). Despite the considerable amount of research conducted using diverse audio, visual, and text modalities (Gui et al., 2018; Xia and Ding, 2019; Fan et al., 2020; Shoumy et al., 2020; Abdullah et al., 2021), there has been a noticeable gap in the exploration of multimodal ECA in natural settings (human conversations). In this context, Wang et al. (2023a) introduce Multimodal Emotion Cause Analysis in Conversations (ECAC) task and provide Emotion-Cause-in-Friends (ECF) dataset, which incorporates text, audio, and video modalities. This task consists of two sub-tasks: Textual Emotion-Cause Pair Extraction in Conversations (Subtask 1) and Multimodal Emotion Cause Analysis in Conversations (Subtask 2). A detailed description of these sub-tasks can be found in the task description paper (Wang et al., 2024a).

In our submission to Subtask 2 of multimodal ECAC, this paper presents two distinct approaches to address the ECAC problem, giving competitive results. Drawing inspiration from the effectiveness of LLMs in diverse downstream tasks (Wang et al., 2023b, 2024b; Yang et al., 2024), including emotion recognition, we propose two LLM-based approaches that decompose the emotion-cause pair extraction process into two steps. The first step involves predicting the emotions of the utterances in the conversation. In the next step, we utilize these emotion labels to guide cause extraction. **Approach 1** involves instruction-tuning two separate Llama 2 models for emotion and cause prediction, while **Approach 2** leverages the in-context learning (ICL) capabilities (Dong et al., 2023) of the GPT-3.5 model. Additionally, we introduce an efficient technique using the GPT-4V model to extract conversation-level descriptions from video modality.

During the evaluation, our team ranked 4th on the leaderboard competing against more than 25 teams with a weighted-F1 score of 0.2816.

2 Background

2.1 Task definition

The input for the task, D, comprises N conversations. As described by Wang et al. (2023a), given a

[†]Equal contribution

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1561–1576

conversation $D_i = \{u_1, u_2, \ldots, u_M\}$ consisting of M utterances, where each utterance is represented by text, audio, and video, i.e. $u_j = [t_j, a_j, v_j]$, the goal of the task is to extract a set of emotion-cause pairs $P = \{\ldots, (u_k^e, u_k^c), \ldots\}$, where u_k^e denotes an emotion utterance and u_k^c corresponds to the cause utterance.

2.2 Related Work

The detailed Related Work section can be found in Appendix A.

2.3 Dataset

We use the Emotion-Cause-in-Friends (ECF) dataset provided by Wang et al. (2023a), which is summarized in Table 1. This dataset contains 13,509 multimodal utterances that occur in the American sitcom *Friends* with 9272 emotion-cause pairs. Each utterance consists of the text, video, and audio.

Class-distribution The dataset is imbalanced as shown in Fig. 1 wherein around 44% of the utterances have neutral emotion. Disgust and Fear constitute only 3% and 2.7% of the emotions.

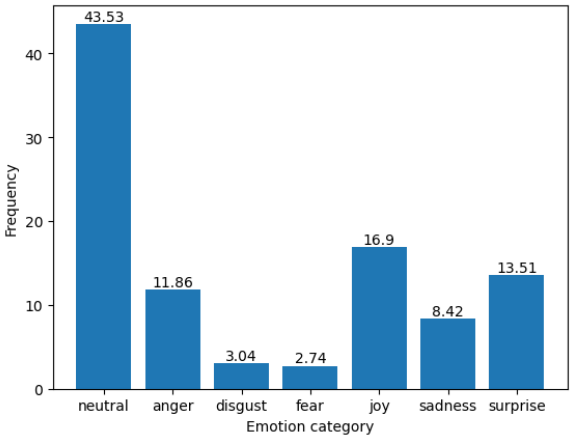

Figure 1: Percentage of each of the seven emotion categories

Relative positions of emotion and causes Interestingly, 49.95% of the causes are self-causes meaning that the same utterance caused itself as shown in Fig. 2. This is also intuitive, as what one speaks or expresses often elicits the emotion of their utterance. Note that the dataset curators have also annotated utterances coming after the emotion utterance as its cause. These constitute only about 2.8% of all causes and are one or two utterances away. 94.95% of the causes are 0-5 utterances behind the emotion utterance. The fact that what you speak or other interlocutors in the conversation speak affects the emotion of subsequent utterances explains this phenomenon.

Items	Number
Conversations	1344
Utterances	13,509
Emotional Utterances	7,690
Self-Causal Utterances	4,892
Non-Self-Causal Utterances	2,189
No Cause Emotional Utterances	609
Later-Causal Utterances	177

Table 1: Statistics of causes for emotional utterances.

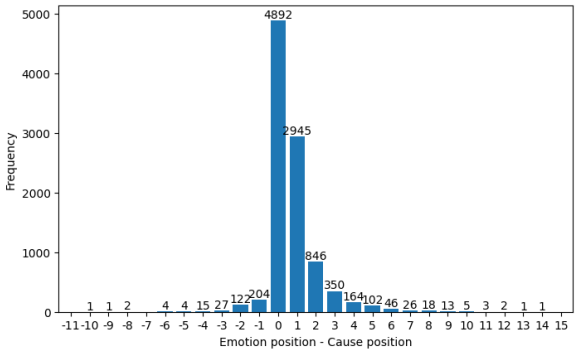

Figure 2: Relative position of emotion and causes

3 Methodology

3.1 Overview

We treat the task at hand as a two-step process. In the first step, we predict the emotion of each utterance in all N conversations. Here, the context C_j for utterance u_j of conversation D_i is the entire conversation itself. Given E target emotion labels and $\hat{y_j^e}$ as the predicted emotion label, the problem can be formulated as (where θ denotes the parameters):

$$\hat{y_j^e} = \arg\max_e \mathcal{P}(y^e | u_j, C_j, \theta) \quad (1)$$

In the second step, given these emotion labels, we predict the causes of each utterance that has an emotion other than neutral. The causes will be a subset of all utterances in the conversation D_i. Let the learned function be $f : U \rightarrow 2^U$, where U is the set of all utterances in the given conversation. It predicts the subset $\hat{y_j^c}$ of cause of emotion utterance u_j where $\hat{y_j^e} \neq$ neutral as:

$$\hat{y_j^c} = \arg\max_{y^c \in 2^U} \mathcal{P}(y^c | u_j, \hat{y_j^e}, C_j, \theta) \quad (2)$$

3.2 Approach 1: Fine-tuned Llama-2

In our first approach, we perform instruction fine-tuning of the Llama 2 Large Language Model, an open-source model developed by GenAI, Meta (Touvron et al., 2023). From the three variants with 7, 13, and 70 billion parameters, we use the 13 billion parameter model due to resource constraints, albeit the performance of this model achieves state-of-the-art results on various downstream NLP tasks compared to other models of similar sizes (Touvron et al., 2023). In addition, we use the Llama 2-chat version of the model[1], which is optimized for dialogue use cases as it aligns with our task. In our approach, we use Llama2 API[2] for prompt engineering. Through zero-shot prompting, we select optimal prompts for emotion identification and cause prediction. We observed that treating these two tasks separately resulted in better model output. This approach involves first identifying the emotions of all utterances in the conversation. We then add these emotion labels to the conversation and prompt the model to predict the causes for each emotion utterance. Consequently, we perform supervised fine-tuning of two separate Llama 2 models for these tasks. Although this increases the inference time, the significant performance gains outweigh the introduced latency. We treat both tasks as conditional generation, where the model generated the emotion label in the first case and the cause list in the second case, given the prompt. Detailed explanations of these approaches are provided in the following sections. The fine-tuning procedure is shown in Fig.3.

3.2.1 Emotion recognition

To perform emotion recognition, we create a dataset where each sample includes an utterance u_j from one of the N conversations D for which the LLM needs to output the emotion label. We incorporate the entire conversation D_i along with speaker information as context in our prompt. This contextual information enhances the model's understanding of the flow of emotions within the conversation, as demonstrated by our ablation studies in Section 5. The instruction I_j^e, which gave the best results, is given in Appendix E.1 along with detailed prompt examples. The prompt consists of the instruction I_j^e and the context C_j for utterance u_j:

$$Prompt_j = (C_j, I_j^e) \tag{3}$$

Using this prompt as the input and the corresponding true emotion label y_j^e, we perform supervised fine-tuning of a Llama 2-13b model.

$$\hat{y_j^e} = \textbf{Llama}_e(Prompt_j, \theta) \tag{4}$$

We use a quantized version of the model due to memory limitations and perform Quantized Low-Rank Adaptation (QLoRA) (Dettmers et al., 2024) as a parameter-efficient fine-tuning technique. The training details are provided in the Section 4.

3.2.2 Cause prediction

To prepare the dataset for cause prediction, we incorporate the emotion labels obtained for each utterance. The conversation context now includes the emotion labels for each utterance u_j excluding those with a predicted emotion label $\hat{y_j^e}$ of *neutral*. This approach enhances the model's ability to analyze causal dependencies and identify which utterances may have contributed to a specific emotion. The output for cause prediction is a list of cause utterance IDs. The instruction is provided in Appendix E.1. The modified prompt for this step consists of this instruction I_j^c along with the conversational context with emotion labels C_j^e:

$$Prompt_j = (C_j^e, I_j^c) \tag{5}$$

Next, we perform supervised fine-tuning of a new Llama 2-13b model using this prompt as the input and the corresponding true list of causes:

$$\hat{y_j^c} = \textbf{Llama}_c(Prompt_j, \theta) \tag{6}$$

3.2.3 Adding video captions

To integrate cues from the videos corresponding to each utterance, we experimented using video captions generated using GPT-4 Vision as additional context for the model. However, we observed a notable decrease in performance since descriptions for individual utterances were somewhat noisy and did not effectively guide the predictions. Moreover, the captions often contained multiple emotions causing confusion for the model. As a result, we do not utilize these during training.

3.3 Approach 2: In-Context-Learning GPT

Our second approach (Fig. 4) tackles subtask 2 by obtaining conversation-level video captions using the GPT-4V(ision) model by OpenAI (Yang

[1]https://huggingface.co/meta-llama/Llama-2-13b-chat-hf
[2]https://www.llama2.ai/

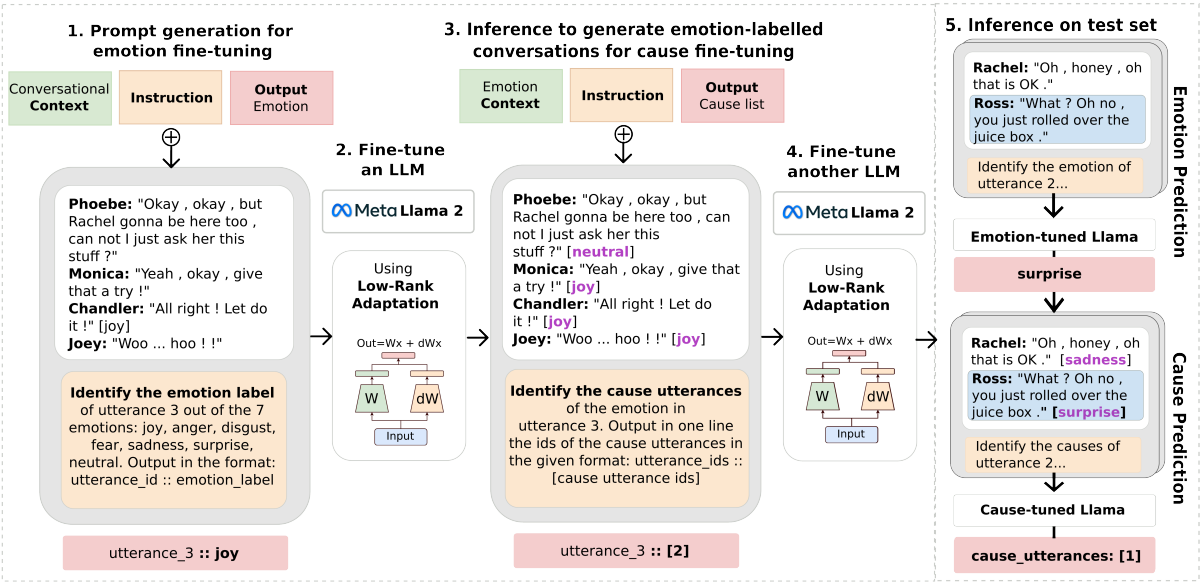

Figure 3: Pipeline for fine-tuning Llama (Approach 1)

et al., 2023). For emotion prediction, we retrieve a semantically similar conversation from the training set whose emotion annotations are explained as demonstration examples in the prompt for the GPT-3.5 model[3]. For each predicted emotional utterance, we perform cause prediction within a context window around the emotional utterance. Due to the complex nature of the task, we leverage in-context-learning (Dong et al., 2023) by retrieving similar context windows from the training set whose cause annotations are explained as demonstration examples in the prompt for the GPT-3.5 model. We discuss each step in the subsequent sections.

3.3.1 Video Captioning

GPT-4V has the capability to process video sequences (Yang et al., 2023; Lin et al., 2023). In our approach, we extract conversation-level captions from the videos. However, due to rate limits and the costs considerations, we use a compact image representation for each video associated with the utterances of a conversation. Therefore, these image sequences serve as input to the GPT-4V model, generating a description for the entire conversation. The prompt is shown in the Fig. 5.

For an utterance, we sample nine equidistant frames across its video length. These frames aim to capture the dynamics of the whole video. We arrange these frames in a 3×3 grid, following a row-major order. Additionally, we include the speaker text below the grid to provide further context to GPT-4V. The process is illustrated in Fig. 5.

To accommodate the rate limits of the Vision API, we batch the utterances of a conversation and obtain outputs independently from the Vision model. We stitch all the outputs of a batched conversation into a single caption using GPT-3.5 (Appendix Fig. 16).

3.3.2 Emotion Recognition

GPT tends to be uncontrollable when performing zero-shot recognition of emotions in conversations (Qin et al., 2023) outputting emotions that are not a valid category of labels. To guide and control the process, we leverage in-context learning (ICL) by retrieving a conversation from the training set whose emotions are already annotated. The emotions in these conversations are explained by GPT-3.5 (Appendix Fig. 17). This retrieved conversation and its explanation serve as a demonstration for GPT to learn from, enabling it to recognize emotions in conversations more accurately. In addition, the prompt template includes the video caption as part of the input, as shown in Appendix Fig. 18.

To ensure effective ICL, it is important to provide general and descriptive examples that aid in solving the current task. In our approach, we sampled conversations from the training set containing all emotion categories. These conversations were stored as text-embedding-ada-002 embeddings (Neelakantan et al., 2022) in a vector database. At test time, we compute the embedding

[3]https://platform.openai.com/docs/models/gpt-3-5-turbo

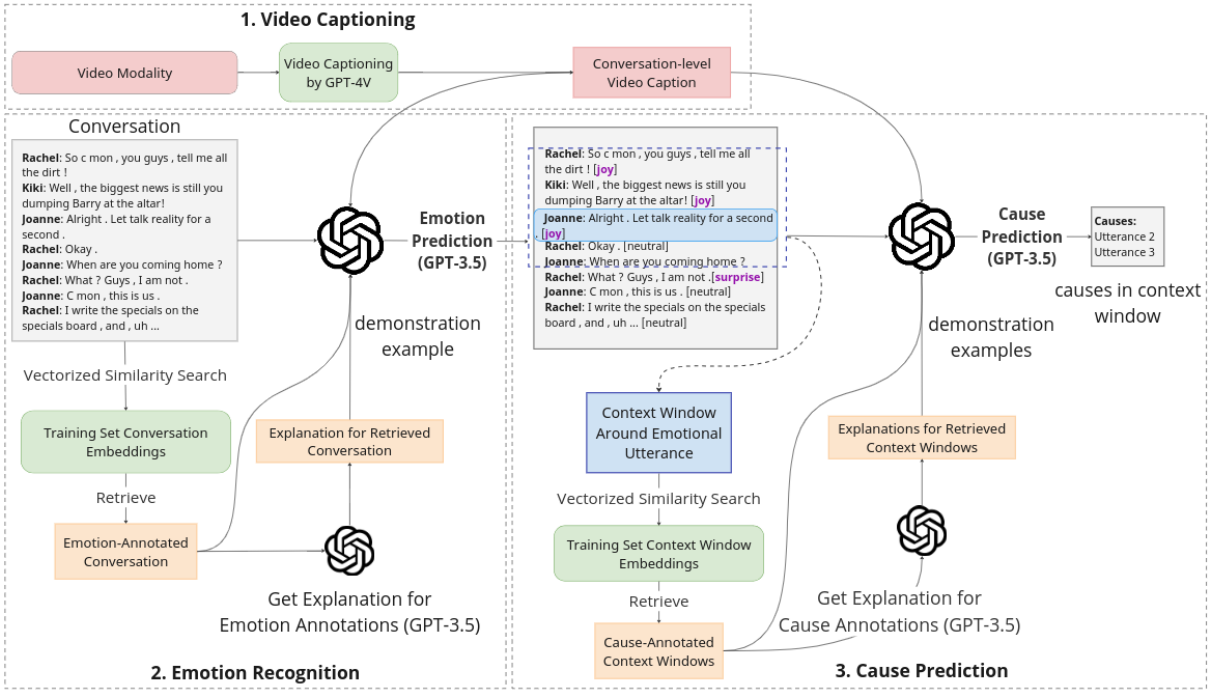

Figure 4: Pipeline of In-Context-Learning GPT Method (Approach 2)

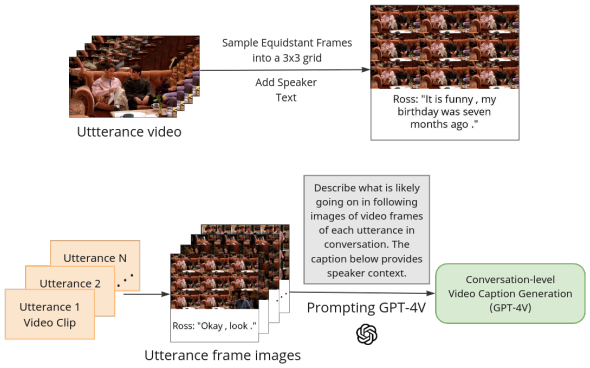

Figure 5: Video Captioning Pipeline

for a conversation and retrieve the closest matching embedding from the database based on Euclidean distance. The retrieved embedding aids ICL in improving emotion understanding and recognition.

3.3.3 Cause Prediction

Following the prediction of emotions, we predict the causes for each emotional utterance within a context window around that utterance. The bounds of the context window are given in Table 2. The bounds were informed by the distribution of the majority of relative positions of causes in the training set (Figure 2).

For predicting the causes of an utterance with emotion e within a given context window c, we retrieve context windows containing utterances with the same emotion e that exhibit semantic similarity to c. This retrieval is accomplished through the Euclidean distance comparison of text-embedding-ada-002 embeddings derived from the training data. The retrieved conversation's causes are explained by GPT-3.5 (Appendix Fig. 19). Learning from the explained retrieved-context windows, cause prediction on c can be performed by GPT-3.5. Video captions are also included in the prompt (Appendix Fig. 20), since the local window may have lost some broader context.

Position	Previous	Next
Beginning	0	2
End	5	0
Middle	5	2

Table 2: Context Window Bounds in each Direction

3.4 Post-Processing

In both our approaches, after getting the causes, we perform a post-processing step where we add the emotional utterance as its own cause which we call self-causes. This gives significant performance boosts as a majority of the causes are self-causes as pointed out in Appendix 2.3.

4 Experimental setup

Training details For approach 1, the data is split into train, test, and validation sets in the ratio 8:1:1.

We use peft library [4] for Parameter-Efficient Fine-Tuning. Due to memory constraints, we fine-tune a 4-bit quantized Llama-2 model using bitsandbytes library [5]. We report the details of the implementation for both approaches in Appendix B.

Evaluation metrics For evaluating, we report the precision, recall, F1-score, and weighted F1 which can be found on the competition website.[6]

5 Results and Discussion

Main results Both of our approaches gave competitive rankings on the official leaderboard for subtask 2 as shown in Table 3. In-context-learning GPT gave better results on the evaluation set compared to Fine-tuned Llama, thus our final position on the leaderboard was rank 4.

System	w-avg F1	F1
1. Samsung Research China-Beijing	0.3774	0.3870
2. NUS-Emo	0.3460	0.3517
3. SZTU-MIPS	0.3435	0.3434
4. GPT-ICL *(Ours)*	**0.2758**	**0.2816**
5. MotoMoto	0.2584	0.2595
6. Fine-tuned Llama *(Ours)*	**0.2558**	**0.2630**

Table 3: Leaderboard Results on Evaluation Data

Ablation study We conduct extensive ablation studies to measure the importance of the techniques we employ summarized in Table 4. For these experiments, we use a subset of our test set containing 528 utterances. It can be seen that the performance of zero-shot Llama as well as GPT is the lowest. Instruction-tuning and ICL clearly improve the performance on the task, showcasing the significance of making LLMs context-aware when tackling downstream tasks. Adding self-causes improves performance in both zero-shot and context-aware cases highlighting their importance. The incorporation of video captions leads to poorer results in context-learning. The detailed table is in Appendix C.

Limitations Our approaches are specific to one dataset and may not generalize well to other datasets. Due to resource limitations, we fine-tune a Llama 13b parameter model instead of 70b and use QLoRA instead of updating all parameters. To save costs, we used GPT-3.5 model instead of GPT-4. Even with extensive prompt engineering, GPT models tend to hallucinate or give unstructured outputs, requiring retry repeatedly.

Approach	F1	w-avg F1
Zero-shot Llama		
- w/o self-causes	0.117	0.116
- w/ self-causes	0.222	0.215
Instruction-tuned Llama		
- w/o self-causes	0.325	0.318
- w/ self-causes	**0.364**	**0.352**
Zero-shot GPT		
- w/o self-causes	0.100	0.097
- w/ self-causes	0.189	0.184

- w/o self-causes w/ video	0.235	0.241
-w/ self-causes w/o video	**0.336**	**0.342**
-w/ self-causes w/ video	0.329	0.334

Table 4: Results on Validation Set.

6 Conclusion

We tackled the Multimodal ECAC task with a two-step framework of recognizing emotions first and then predicting their causes using LLMs. We implemented two approaches: a Llama-2 model which has been fine-tuned with instructions and a GPT model which solves the task by learning from demonstration examples in context. Conversation-level video captions were extracted to provide more context to LLMs. Our second approach was our best submission for the task, placing us at rank 4 with our first approach being placed at rank 6. Our results were under cost constraints and further investigation with larger Llama-2 models and GPT-4 with more sophisticated ICL approaches are a clear follow-up of our work.

A Related Work

Our system is designed to prioritize Subtask 2 which is directly related to text-based and multimodal ECA. In the following sections, we will present relevant research that addresses both unimodal (text-based) and multimodal ECA.

Text-based ECA

Advancements in text-based ECA (Xia and Ding, 2019; Hsu et al., 2018; Peng et al., 2022; Pereira et al., 2022) have made significant strides within the field of sentiment analysis. The task on emotion cause extraction (ECE) was initially proposed by Chen et al. (2010) on a Chinese corpus. Several studies (Li and Xu, 2014; Ghazi et al., 2015; Yada et al., 2017) have explored ECE task, using both rule-based and machine learning approaches that operate at the phrase or word level of the text data. Furthermore, (Gui et al., 2018) reformulated the ECE task as a clause-level classification problem and constructed a Chinese emotion-cause corpus based on the news data. Considering the effectiveness of clause-level units in indicating emotions, Xia and Ding (2019) introduced the task of Emotion-Cause Pair Extraction (ECPE) for extracting potential emotion-cause pairs from texts. Numerous deep learning models (Zhong et al., 2019; Wei et al., 2020; Chen et al., 2020; Singh et al., 2021; Li et al., 2021; Wang et al., 2023c) have been developed to address ECPE tasks. Additionally, graph-based approaches (Zheng et al., 2023a; Hu et al., 2021; Zhao et al., 2023) that utilize graphs to model dialog context and capture interactions between speakers and utterances hold significant potential. The focus on transformer models and the rapid progress in LLMs such as ChatGPT[7] and Llama (Touvron et al., 2023), have significantly boosted the performance of various NLP tasks (Imran et al., 2023) including ECPE (Wang et al., 2023d; Imran et al., 2023; Wu et al., 2024; Zheng et al., 2022).

[7] https://chat.openai.com/

Multimodal ECA

Given the strong association between facial cues and emotion, integrating modalities to improve emotion recognition has attracted a lot of attention (Sebe et al., 2005; Li et al., 2023; Zhang et al., 2023; Fu et al., 2023). Several key multimodal datasets (Wöllmer et al., 2013; Zadeh et al., 2016; Chou et al., 2017; Barros et al., 2018; Poria et al., 2019; Yu et al., 2020) have emerged to support and advance research. The availability of open conversation data has facilitated the expansion of multimodal conversation datasets, which includes various types of conversations such as dyadic interactions (Busso et al., 2008), and multi-participant communications (Hsu et al., 2018; Poria et al., 2019; Firdaus et al., 2020; Zheng et al., 2023b).

Large Language Models

The emergence of Large Language Models such as GPT-4 (Achiam et al., 2023), Llama (Touvron et al., 2023), PaLM (Anil et al., 2023), etc. has transformed the research landscape. Recently, there has been a surge in the application of LLMs to a multitude of domains. Zhang et al. (2024) extend their capabilities to the task of emotion recognition where they fine-tune a Llama 2-7 billion parameter model for emotion prediction. Lei et al. (2023) introduce a retrieval template module along with speaker identification and emotion-impact prediction tasks to improve the performance of LLM. In our work, as part of approach 1, we develop two distinct LLM-based experts separately for emotion and cause prediction.

Qin et al. (2023) investigated the task of zero-shot emotion cause prediction using ChatGPT with limited success. Recently, a new paradigm of in-context learning (ICL) (Dong et al., 2023) has emerged for LLMs that involves learning from a few examples to solve a variety of complex reasoning tasks (Wei et al., 2022b), (Wei et al., 2022a). Wu et al. (2024) proposed a Chain of Thought (CoT) (Wei et al., 2022b) approach for emotion cause pair extraction. Our approach 2 extends the idea of ICL towards solving the task of multimodal emotion cause pair extraction in two steps.

B Implementation details

B.1 Training details for Llama

Both emotion and cause prediction training used one Nvidia A100 40GB GPU for training (Available on Google Colab Pro priced at $11.8/month).

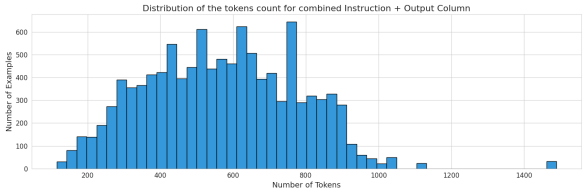

Figure 6: Distribution of token counts for Llama tokenizer

We train for one epoch due to constraints on Colab usage with gradient accumulation steps as 8 with an effective batch size of 8. A cosine learning rate scheduler and Adam optimizer are used. Inference is performed using two Tesla T4 16GB GPUs (Available on Kaggle for free (30 hrs/month)).

The long context length of 4096 tokens of the Llama 2 models, allows us to include the entire conversation as context and input that to the model. We perform experiments to analyze the maximum token counts in the dataset and observe that they do not exceed 1600 as shown in Figure 6. In case the token count exceeds the limit for the LLM we can use a window of utterances around the given utterance as context for predicting its emotion.

Hyperparameter	Value
Lora alpha	16
Lora dropout	0.1
Attention heads	16
Learning rate	1e-3
Epochs	1
LR scheduler	cosine
Warmup ratio	0.03
Weight decay	0.001

Table 5: Hyperparameters for fine-tuning

B.2 Details for in-context learning GPT

We use the LangChain[8] library to implement our three pipelines: video captioning, emotion recognition, and cause prediction. We use the interface provided by LangChain to communicate with OpenAI's API models detailed in Table 6.

Model	API Name
GPT-4V	gpt-4-vision-preview
GPT-3.5	gpt-3.5-turbo-1106
Embeddings	text-embedding-ada-002

Table 6: OpenAI API Model Names

Vector databases For creating vector databases, we use the FAISS Library (Douze et al., 2024). We

[8]https://github.com/langchain-ai/langchain

created a FAISS index containing embeddings of 12 conversations from the training set which contains all emotion categories. For cause prediction, we created a FAISS index for each of the 6 emotion categories and 3 possible positions of emotional utterance giving us a total of 18 indices. Each of these indices contained embeddings of context windows (bounds defined in Table 2) from the training set corresponding to each emotion and position.

C Detailed results

The detailed results on precision, recall, and F1-scores are given in Table 7.

D Error Analysis

We conduct error analysis for the output of emotion recognition using the two approaches. The performance of zero-shot Llama is extremely poor where the model predicts the label joy for almost all utterances (Fig. 7). On adding the conversational context, the model can identify the emotional nuances better, yet often predicts joy or surprise for neutral (Fig. 8). Instruction fine-tuning significantly boosts performance where the model can now differentiate distinct emotions (Fig. 9). The performance on disgust and fear is low due to the class-imbalance problem. In our test subset, the support of disgust and fear is only 13, as shown in Table 8. We observed similar trends in the case of our second approach. Zero-shot GPT (Fig. 10) tends to only identify the neutral utterances accurately and fails in other categories. The incorporation of in-context learning (Fig. 11) improves the accuracy in identifying different emotion categories but there is little to no improvement in identifying disgust or anger utterances.

E Prompt details

E.1 Fine-tuned Llama 2

The general prompt for the Llama chat version is given in Figure 14. The prompts for emotion and cause prediction are given in Fig. 12 and Fig. 13. We provide a specific format for the output so as to ease the post-processing where we extract the first emotion label occurring after the "::" sequence of characters.

E.2 ICL-GPT

We devise prompt templates to be used in the LangChain framework. {} represent placeholders to be replaced when making a prompt. Video

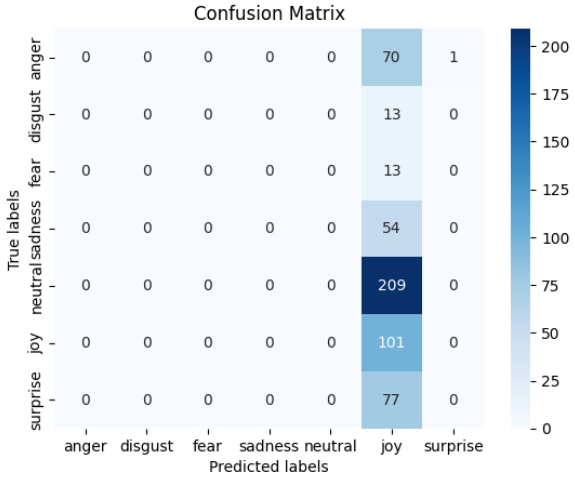

Figure 7: Confusion matrix for zero-shot emotion recognition without context using Llama

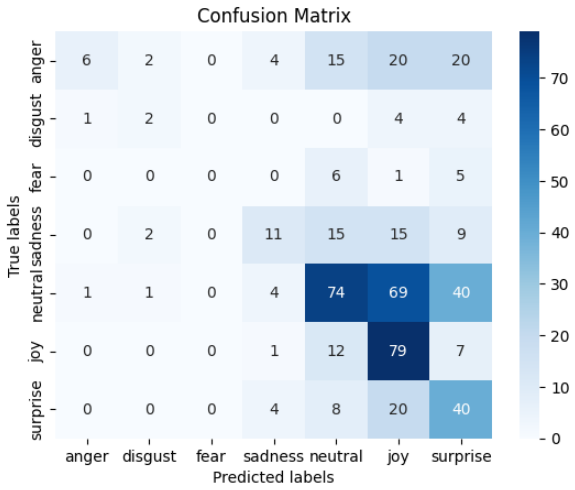

Figure 8: Confusion matrix for zero-shot emotion recognition with context using Llama

captioning prompt is given in Fig. 15. Due to rate limits, we had to batch the utterances, thus we may have multiple disjoint descriptions of a conversation. We prompt GPT-3.5 using the prompt in Fig. 16 to stitch the descriptions into a single caption. For explaining the retrieved conversation with emotion annotated, we use the prompt in Fig. 17. The retrieved conversation and explanation are now used as demonstration examples for the emotion recognition prompt in Fig. 18. For an explanation of causes in the retrieved-context window, we use the prompt in Fig. 19. The explanations of the retrieved windows are used as demonstration examples in the prompt for cause prediction within a context window as shown in the prompt in Fig. 20.

Video Caption Prompt:
You are an expert of Friends TV Show. You can understand a video scene from a few of its frames shown in sequence. You give precise descriptive analysis.
Describe what is likely going on in following images of video frames of each utterance in conversation. The caption below provides speaker context.
Give output as:
Scene Description:

Figure 15: Video Captioning Prompt Template

Caption Stitching Prompt:
Following is a descriptions of video clip from Friends TV show for a particular conversation. The descriptions are broken from each other. Stitch the description into a continous coherent narrative of the whole scene

Figure 16: Batched Video Caption Stitching Prompt Template

Emotion Explanation Prompt:
There are 6 basic emotions: Anger, Disgust, Fear, Joy, Sadness, Surprise.
The emotion of the speaker is determined by the context of the conversation.
If the emotion is not in any category, is a mix of several categories, or is ambiguous it can be categorized as "Neutral".
Analyze the following conversation where emotion of each utterance is annotated in square brackets at the end.
Give reasoning behind the annotation of each utterance.

{conversation}

Output a JSON in the following format:
[{{"utterance_ID": id,
"text" : content,
"speaker": speaker
"emotion": emotion,
"explanation": detailed explanation}}
...
]
No plain text.

Figure 17: Emotion Label Explanation Prompt Template

Emotion Recognition Prompt:
You are a die-hard fan of the popular Friends TV show.
You have all the knowledge of all the seasons and are familiar with all the characters.
Your task is to recognize emotions in utterances.
Here's an annotated example with recognized emotion and explanation:
{example}

Like above example annotate the following Conversation:
Context for the scene is given below:
{scene}

Conversation:
{conversation}

Classify the emotional state of the speaker in each utterance into ONLY one out of the 6 emotions:
Anger, Disgust, Fear, Joy, Sadness, Surprise.
The emotion of the speaker is determined by the context of the conversation.
Give explanation for your classification using the context. Only Use the above 6 emotion categories.
If the emotion is not in any category, is a mix of several categories, or is ambiguous,
classify the state as "Neutral". Sarcastic comments may be categorized as Neutral.
Format the output as JSON as the given example. No plain text.

Figure 18: Emotion Recognition with Context Learning Prompt Template

Cause Explanation Prompt:
You are an expert in analyzing conversations to extract the causes of emotions
in particular utterances by speakers. You give definite confident answers only.
Description of emotional causes:
- Each utterance always has a reason of why it was said and why it had a particular emotion.
- A cause is an utterance that comes before or after the particular utterance in question that best explains to be the reason behind the particular emotion.
- The emotional utterance itself can be a cause of itself if its content ALSO best explains the reason for the particular emotion.
- Sometimes the cause can be beyond the context of the conversation thus an utterance might have no cause within conversation
- There can be multiple causes for an utterance.

Here's a conversation:
{conversation}

Analyze and justify the above annotation concisely.

Figure 19: Cause Explanations Prompt Template

Cause Prediction Prompt:
You are an expert in analyzing conversations to extract the causes of emotions
in particular utterances by speakers. You give definite confident answers only.
Description of emotional causes:
- Each utterance always has a reason of why it was said and why it had a particular emotion.
- A cause is an utterance that comes before or after the particular utterance in question that best explains to be the reason behind the particular emotion.
- The emotional utterance itself can be a cause of itself if its content ALSO best explains the reason for the particular emotion.
- Sometimes the cause can be beyond the context of the conversation thus an utterance might have no cause within conversation
- There can be multiple causes for an utterance.

Here are some examples of how to recgonize causes:
Example 1:
{example_1}

Example 2:
{example_2}

Example 3:
{example_3}

Now, please recognize the causes in following conversation. Heres the context for the whole conversation:
{scene}

Abstract

In this paper, we describe our submission for the NLI4CT 2024 shared task on robust Natural Language Inference over clinical trial reports. Our system is an ensemble of nine diverse models which we aggregate via majority voting. The models use a large spectrum of different approaches ranging from a straightforward Convolutional Neural Network over fine-tuned Large Language Models to few-shot-prompted language models using chain-of-thought reasoning. Surprisingly, we find that some individual ensemble members are not only more accurate than the final ensemble model but also more robust.

1 Introduction

In this paper, we describe our submission to SemEval-2024 Task 2: Safe Biomedical Natural Language Inference for Clinical Trials (NLI4CT 2024) (Jullien et al., 2024). In NLI4CT 2024, every model receives as input one or two clinical trial reports (CTRs) describing a breast cancer study. Further the model gets a hypothesis which makes a claim about the study and the section where the relevant information about the claim can be found in the CTR. Following a classical NLI setup (Bowman et al., 2015), the task of the model is to decide whether the hypothesis is logically entailed by the CTR or whether it contradicts the information in the CTR. NLI4CT 2024 is a continuation of a similar task that was held in 2023 (Jullien et al., 2023) and uses the same training and validation datasets. In contrast to the previous edition, NLI4CT 2024 focuses on the robustness of the submitted models. Specifically, it evaluates whether a model is consistent in its predictions and whether it predicts the correct label for the right reasons via targeted modifications of the test data; see Section 3 and Jullien et al. (2024) for more details.

We approach this task by building a large ensemble of diverse models. Our hypothesis is that ensembling a large variety of strong and weak models would improve robustness. For that we build ensembles of up to 25 models derived from 9 different approaches via different ensembling strategies. These approaches were implemented as part of a Master's course on biomedical Natural Language Processing at LMU Munich. Teams of two to three students chose a broad initial approach such as Convolutional Neural Networks (LeCun and Bengio, 1998; Kim, 2014) or data-centric machine learning (Swayamdipta et al., 2020). Then, they developed multiple models in the confines of the chosen approach while collaborating occasionally with other groups. Finally, evaluated all resulting models individually and as large ensembles on the test set. We find that ensembling generally improves robustness but that some individual approaches achieved even higher performance.

2 Methods

2.1 Approaches

We evaluate an ensemble of nine approaches. When selecting them, we favoured diversity over accuracy based on the assumption that even weaker models could contribute to the ensemble if they were diverse enough (Schapire, 1990). If not stated otherwise for a specific model, we used Adam (Kingma and Ba, 2015) for optimization. All approaches use only the section that contains the relevant information for inferring the NLI relation as provided by the task organizers.

Convolutional Neural Networks In the Convolutional Neural Networks (*CNN*, LeCun and Bengio (1998)) approach, we build on the work of Kim (2014). We modify this CNN-based model by replacing the word embeddings with subword embeddings from the embedding layer of

* Equal contribution. The order of the first-authors was chosen randomly.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1577–1583

BioBERT[1] (Lee et al., 2019). We train all models with Adam (Kingma and Ba, 2015), using a learning rate of $8.26e-6$ and maximum sequence length of 256. *CNN_1*: static cased BioBERT embeddings with kernels of size 3, 4, and 5 (100 each), a batch size of 32 and dropout of 0.5. *CNN_2*: static uncased BioBERT embeddings with kernels of size 3, 5, and 7 (100 each), a batch size of 32, dropout of 0.21 and weight decay of 0.001. *CNN_3*: static and dynamic cased BioBERT embeddings with kernels of size 3, 5, and 7 (100 each), a batch size of 64, dropout of 0.21 and weight decay of 0.001. *CNN_4*: static cased BioBERT embeddings, sequence length of 128, kernel sizes of 3 and 5 (100 each) and dropout of 0.21, trained for 10 epochs. *CNN_5*: static cased BioBERT embeddings, sequence length of 128, kernel sizes of 3, 4, 5 (50 each), batch size of 32, dropout of 0.21, trained for 20 epochs.

Fine-tuned transformers exploiting annotation biases With the *Bias* models, we attempt to exploit possible annotation biases following (Gururangan et al., 2018) who found that frequently a simple text classifier can decide the label for an instance based on the hypothesis alone. Specifically, we fine-tune a pre-trained language model to predict the NLI label using only the hypothesis as input. We optimze the hyperparameters with optuna using 10 runs per model. *Bias_1* uses BERT-base-cased[2] (Devlin et al., 2019) as model, *Bias_2* ClinicalBERT[3] (Wang et al., 2023), *Bias_3* BioBERT-PubMed200kRCT[4] (Deka et al., 2022), and *Bias_4* biomed_roberta_base[5] (Gururangan et al., 2020).

Diverse fine-tuned transformers For the Diverse fine-tuned transformers (*DT*) models, we fine-tune different pre-trained language models on the NLI4CT training data. After preliminary experiments with several transformer models, DeBERTa v3[6] (He et al., 2021) and BioLinkBERT[7] (Yasunaga et al., 2022) emerged as the most promising candidates. For both models, we used a maximum sequence length of 312, 20 epochs, and a learning rate of $2e^{-6}$. For *DT_1*, we use BioLinkBERT-base with a batch size of 4, for *DT_2*, BioLinkBERT-large with a batch size of 4, for *DT_3*, DeBERTa-v3-large with a batch size of 8, and for *DT_4*, DeBERTa-v3-base with a batch size of 4.

DeBERTa-v3 For the DeBERTa (*DeB_1*) model, we fine-tune DeBERTa-v3-large for 30 epochs, using a learning rate of 1e-5, a batch size of 8, and a max length of 312.

Stacking ensemble of two strong models For the *Ens* models, we construct an ensemble of two strong models. To construct this ensemble, we fine-tune DeBERTa-v3-large using a batch size of 8, a learning rate of 6e-6, a max length of 312, and 20 epochs. The other model in the ensemble is Mistral Instruct 7B v0.1[8] (Jiang et al., 2023), which we fine-tune on the NLI4CT training set to generate either "Entailment" or "Contradiction" using the prompt template proposed by Kanakarajan and Sankarasubbu (2023). We use a batch size of 8, a learning rate of 2e-4, and trained for 7.5 epochs. To enhance memory efficiency, we utilize the paged Adam optimizer, employ a sharded model and leverage QLoRa (Dettmers et al., 2023). To ensemble both models, we use both models to generate predictions on the development set of NLI4CT and then train a logistic regression classifier (James et al., 2013) to predict the correct label based on the predictions of both models. We experiment with providing additional metadata about the instance to the logistic regression classifier: the cosine distance between the TF-IDF representation of hypothesis and premise and the number of tokens in the concatenated hypothesis and premise. *Ens_1* is the full ensemble with metadata, *Ens_2* the ensemble without metadata, *Ens_3* only the Mistral model, and *Ens_4* only the DeBERTa model.

Data augmentation using hard instances In this approach, we follow Swayamdipta et al. (2020) and detect challenging data points using data maps with the goal of using this information for data augmentation. For this, we use a DeBERTa-v3 model that was pre-trained on various NLI datasets[9] (Lau-

[9] https://huggingface.co/MoritzLaurer/DeBERTa-v3-base-mnli-fever-anli

rer et al., 2022) and Flan-T5-base[10] (Chung et al., 2022). We fine-tune both models for 10 epochs on the shared task training data using a learning rate of 5e-5, a batch size of 16 and weight decay of 0.01 for DeBERTa and a learning rate of 2e-5, a batch size of 16, and weight decay of 0.001 for Flan. Then, we construct data maps from the resulting training dynamics and inspect hard-to-learn instances (low confidence and low variance) and ambiguous instances (medium-to-low confidence and high variance). We find that the models especially struggle with the following data characteristics: numerical reasoning, understanding synonyms (e.g. relating "cancer" and "carcinoma"), identifying hyponym/hyperonym relations (e.g. identifying "congestive heart failure" as a hypernym for "left ventricula systolic dysfunction), understanding abbreviations, and with specific sections in the CTR. We then use this information to manually construct 140 more instances that contain these specific issues which we use as additional training data. *Hard_1* is the DeBERTa-v3 model trained on the resulting dataset and *Hard_2* Flan-T5-base.

Data augmentation with GPTs for fine-tuned LLMs In this approach, we explore data augmentation with GPT-3.5 (Brown et al., 2020) and GPT-4 (OpenAI, 2023). We zero-shot prompt these models to generate 300 new statements and labels for randomly chosen CTRs. Then, we fine-tune a Mistral-Instruct-7B model on the training data augmented with these 300 new instances. For memory efficiency during fine-tuning, we employ QLora. We use a batch size of 50 and a learning rate of 2e-4. *Aug_1* is the model with the additional 300 new instances and *Aug_2* the same model fine tuned on the non-augmented data.

Fine-tuned LLMs with reasoning distillation from GPT-4 For the reasoning (*Reas*) models, we follow Wadhwa et al. (2023) and fine-tune a Mistral-7B model to use the reasoning of GPT-4 in order to generate the NLI label. For this, we 2-shot prompt GPT-4 to generate the label for all instances in the training data. We add the phrase *You should also show your reasoning process for your judgment* to the instruction and find that with this, GPT-4 generates texts that illustrate the steps involved in its reasoning process. Then, we filter out all 249 instances for which GPT-4 generated the wrong label and use the remaining 1451 as our new training set. Finally, we fine tune Mistral-7B for 8 epochs to generate the reasoning text together with the NLI label using a cosine-scheduled learning rate of 4e-4 and a batch size of 8. *Reas_1* is the model fine-tuned on the reasoning-augmented data whereas *Reas_2* is the same model fine-tuned on the original data.

Few-shot-prompted LLMs For the few-shot prompted LLM model (*Few_1*), we use Flan-T5-large[11] in a 1-shot prompting setting, where we show a randomly chosen example and ask it to generate the NLI label based on the CTR and the hypothesis.

2.2 Ensembling the approaches

We investigate six different variants to construct the ensemble which vary along two axes. The first axis is which models we include, because for most approaches we have multiple model variants. To construct our ensemble, we use a set of models $m \in \mathcal{M}$. For each model we have its predictions $\hat{y}_m \in \{-1, 1\}^n$ for all n test instances and its F1 score on the development set $F_1(m)$. We explore three heuristics to construct $\mathcal{M}$:

- Choose all available models *(all)*.
- For each approach, choose the model with the highest F1 score on the development set *(best)*.
- Choose the five models with the highest F1 score on the development set *(top-5)*. Note that multiple models can be based on the same approach.

The second axis is whether we use a simple majority vote or whether we weight models by their F1 score on the development set. Formally:

$$\hat{y} = sign[\sum_{m \in \mathcal{M}} \hat{y}\,] \quad \textit{(majority)} \quad (1)$$

$$\hat{y} = sign[\sum_{m \in \mathcal{M}} F_1(m) \cdot \hat{y}\,] \quad \textit{(weighted)} \quad (2)$$

We explore all possible combinations along these two axes leading to a total of six submitted ensemble models.

[11] https://huggingface.co/google/flan-t5-large

3 Evaluation protocol

NLI4CT 2024 uses three metrics to evaluate approaches. F1 score measured on the test set of NLI4CT 2023, consistency and faithfulness. Consistency measures whether the model always produces the same label for a set of instances that share the same meaning and thus the same gold label. Formally,

$$Consistency = \frac{1}{N'} \sum_{x'_i} 1 - \left| f(x_i) - f(x'_i) \right|, \tag{3}$$

where both x_i, x'_i share the same meaning and label and N' is the number of available x'_is. Faithfulness on the other hand scores whether the model is right for the right reasons. This metric considers correct predictions of the model and scores whether the model flips its prediction for instances in which semantic alterations lead to a flipped gold label:

$$Faithfulness = \frac{1}{\tilde{N}} \sum_{\tilde{x}_i} |f(x_i) - f(\tilde{x}_i)| \quad , \tag{4}$$

where the prediction for the original instance $f(x_i)$ is correct and $\tilde{x}_i$ is a semantic alteration of x_i that flips the gold label and $\tilde{N}$ is the number of available semantic alterations.

We evaluate all approaches on the hidden test set of NLI4CT 2024. We chose this approach even though frequent test set evaluation has severe downsides (van der Goot, 2021) because consistency and faithfulness could not be computed on the development set.

4 Results

Table 1 displays the results for all evaluated approaches. When considering the average of Test-F1, consistency, and faithfulness, the best performing model is *Reas_1* which fine-tunes Mistral-7b to following reasoning structures of GPT-4 before outputting the label. Its high average score is mainly due to a very high faithfulness score (85.8) paired with moderately high Test-F1 (76.0) and consistency (68.8) values. Its faithfulness is the 8th highest on the official leaderboard[12] whereas it ranks 13th/18th in terms of Test-F1/consistency. Notably, there is no clear winner across all metrics among the evaluated approaches. *Reas_2* achieves the best Dev-F1 score (82.0), *Ens_3* the best Test-F1 (76.8), and *Ens_4* the best consistency (72.0).

top5_wei	-	72.3	**69.9**	73.1	71.8

Table 1: NLI4CT 2024 test set results for all our evaluated approaches in percent. *Cons.* is consistency, *Faith.* is faithfulness and *Avg.* is the average over all three. Individual approaches are the top part of the table whereas the six diverse ensemble approaches are at the bottom. Models included in *best* ensembles are in bold and models included in *top5* are additionally in italics. The highest score per column is in bold.

Large ensemble results Interestingly, *Reas_1* achieves an even better average score (76.4) than the best large ensemble model *best_majority* (73.8). Generally, in terms of average performance, the best large ensemble outperforms all but two single approaches, *Ens_2* and *Reas_1*, where *Ens_2* itself is an ensemble of two strong models and *Reas_1* combines two models via distillation. Furthermore, neither *Reas_1* nor *Ens_2* were included in the *best_majority* ensemble because their Dev-F1 scores were lower than those of other models from the same approach. Based on these observations, we can confirm our initial hypothesis that building a large ensemble improves the average performance. However, for consistency and faithfulness other individual approaches perform better than the large ensembles. In terms of average scores, taking the *best* model per approach performs clearly better than taking *all* or only the *top*5.

Dev-F1 as model selection criterion Unsurprisingly, using only Dev-F1 as the criterion for model selection and hyperparameter tuning is not sufficient for maximizing the average performance over Test-F1 consistency, and faithfulness. In five out of nine approaches, the model that achieves the best Dev-F1 score does not achieve the best average score. This also has consequences for our best-performing ensembling approach *best* because it implies that in five out of nine cases we include a suboptimal model in our ensemble. This suggests that using a development set that allows for measuring consistency and faithfulness for model selection, hyperparameter tuning or ensemble construction could improve these properties at test time.

Overlap between approaches We analyze how similar the predicions of different approaches are. For that, we compute the pairwise Cohen's kappa scores between all evaluated models. A heatmap of the results can be found in Figure 1. As expected, models stemming from the same approach produce similar results, as can be seen from the bright squares around the diagonal of the heatmap. Additionally, the predictions of the CNN models correlate with those of the Bias models, suggesting that the *CNNs* might also mainly consider the hypothesis and disregard context information. Another notable group of correlations is that between the large ensemble and some of the *DT*, the *DeB*, the *Ens*, and the *Reas* models. This could indicate that most of the large ensemble models mainly rely on the predictions of these strongly performing models.

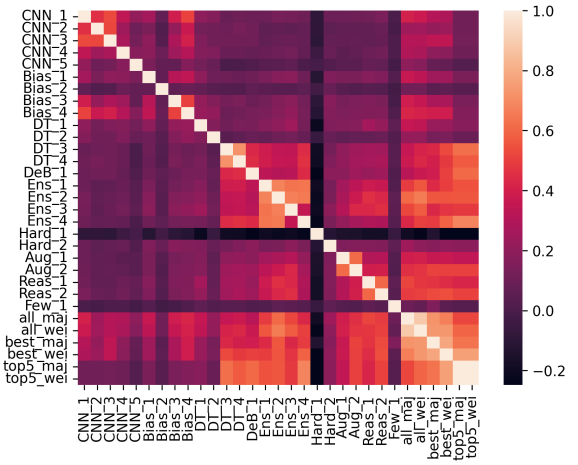

Figure 1: Pairwise Cohen's kappa scores between all evaluated methods.

5 Conclusion

This paper describes our contribution to the SemEval-2024 NLI4CT shared task on robust NLI for clinical trial reports. We investigate whether a large diverse ensemble can improve robustness. Our results largely confirm this hypothesis, but we find that some individual approaches perform even better and more robust than our best ensemble.

In this work, we investigated only ensembling based on voting procedures and completely disregarded the confidences of the individual models. Further, we did not use more sophisticated approaches such as stacking. Finally, we used data-centric approaches only to augment the training data of individual models, but did not use it to evaluate the robustness of models. We believe that all of these could potenetially improve the accuracy and robustnes of NLI models for clinical trial reports.
