B Error Analysis

In this discussion, we first delve into a detailed error analysis in subsection B.1, examining model performances across different sections and types of clinical trial data. The results presented is on the practice held-out test set. Following this, in subsection B.4 we explore the prediction agreement among the various TLDR models.

B.1 Error Analysis

The first part of our error analysis focuses on the performance of TLDR methods and ablation DeBERTa models across different sections of clinical trial reports: Eligibility, Adverse Events, Results, and Interventions. The analysis is grounded in Macro F1 scores, average premise lengths, and average statement lengths, as detailed in the Tables 4,5,6,7.

Eligibility Section In the Eligibility section, the TLDR method using flan-T5-base for zero-shot distinct premises achieved the highest Macro F1 score (0.626), indicating its effectiveness in summarizing and understanding eligibility criteria. Notably, this model and the best fine-tuned SciFive-base model managed to significantly reduce the average premise length while maintaining high performance, suggesting that effective summarization can aid in dealing with long premises typically found in this section.

Adverse Events Section The Adverse Events section saw the highest Macro F1 score (0.775) with the TLDR method using T5-small, best fine-tuned. This model also had one of the shortest average premise lengths, indicating that fine-tuning on specific data, even with shorter premise lengths, can yield high accuracy in identifying adverse events. The DeBERTa models performed relatively well in this section but were outperformed by the TLDR approaches.

Results Section For the Results section, the TLDR method with fine-tuned SciFive-base, showed the best performance with a Macro F1 of 0.67. Interestingly, this model also had the shortest average premise length, suggesting a strong correlation between effective summarization and model performance. The low performance of the SciFive-base zero-shot model indicates that domain-specific fine-tuning is crucial for understanding complex results data that we gain from generating summaries similar to the entailment statements. Note that similar to (Zhou et al., 2023) where they observed SciFive showed superior performance for results with numerical data, we also see the gain in using SciFive when used for the results section.

Intervention Section In the Intervention section, the TLDR flan-T5-base method for zero-shot combined premises showed the highest Macro F1 score (0.647). This suggests that the model's ability to synthesize information from combined premises is particularly effective in understanding intervention-related data.

In the second part of our error analysis, distinct trends are revealed in the performance of the DeBERTa and TLDR models when dealing with single and comparison premises in clinical trial reports. This distinction is crucial as single premises present a straightforward context, whereas comparison premises involve juxtaposing and interpreting two separate contexts. These results are presented in the appendix in Table 3.

Single Premises In the single premise category, the TLDR methods generally outperform their ablated counterparts using DeBERTa models. The TLDR method using flan-T5-base for zero-shot distinct premises and the best fine-tuned SciFive-base model both achieved a Macro F1 score of 0.642, the highest in this category. This indicates their robustness in handling singular, focused clinical contexts. Notably, these models significantly reduced the average premise length, with the best fine-tuned SciFive-base model achieving the shortest length, which suggests an effective summarization capability that preserves essential information that we achieve by attempting to generate summaries that are aligned with the entailment statements.

Comparison Premises For comparison premises, where the task involves analyzing and relating two different contexts, the TLDR models still outperform the DeBERTa models, but with a slight decrease in overall effectiveness compared to single premises. The highest Macro F1 score is 0.631 with the TLDR flan-T5-base for zero-shot distinct premises. The best fine-tuned models, both T5-small and SciFive-base, also show strong performance in this more complex scenario. Interestingly, the average premise lengths are longer for comparison premises across all models, underscoring the increased complexity and information content in these types of premises.

Across both single and comparison premises, TLDR methods demonstrate superior performance, especially in handling and effectively summarizing complex clinical data. The shorter average premise lengths in the best-performing models suggest that their summarization strategies are successful in distilling essential information without losing context crucial for NLI tasks. This is particularly evident in the comparison premises, where managing two contexts simultaneously is a challenging task. In conclusion, the type of premise (single or comparison) significantly impacts the model's performance, with TLDR methods showing robustness in both scenarios. The findings emphasize the importance of tailored summarization techniques and model fine-tuning to handle the varying complexities in clinical trial reports.

B.2 Results Split By Type

Below in Table 3 we include results that were obtained split on whether the data instance was a single instance meaning only a primary premise was given or a comparison instance where both a primary and a secondary instance was given.

B.3 Results Split By Section Type

Below in Tables 4, 5 6, 7 we include results that were obtained split on Eligibility, Adverse Events, Results, and Intervention sections respectively. These are the different sections in the Clinical Trial Reports that the statement in the data instance is referring to

B.4 Prediction agreement across various model

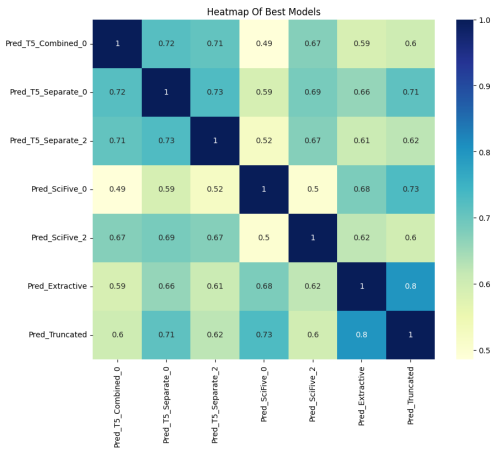

Figure 2: Heatmap comparing the model predictions

In our comparative analysis of model predictions, depicted in Figure 2, we observe distinct patterns of agreement among the various models tested. Notably, T5-based models exhibit a high degree of consistency in their predictions, as evidenced by the darker blue 3x3 square in the top left corner of the heatmap. This suggests a strong underlying

similarity in how these models process and interpret the summaries for the test data. In contrast, the SciFive-based models display a marked divergence in their prediction patterns. The fine-tuned version of the SciFive model, in particular, demonstrates a significant shift in its predictions, aligning with the positive performance changes highlighted in previous sections. Furthermore, the two ablated versions employing either truncated premises or extractive summarization exhibit a high level of agreement in their predictions, as indicated by the dark blue 2x2 square in the heatmap's bottom right corner. This consistency points to the robustness of these ablation methods in maintaining prediction alignment. Overall, these findings underscore the varying degrees of prediction agreement across different model architectures and highlight the impact of model-specific features and training approaches on prediction outcomes in clinical NLI tasks.

ignore at SemEval-2024 Task 5: A Legal Classification Model with Summary Generation and Contrastive Learning

Abstract

This paper describes our work for SemEval-2024 Task 5: The Legal Argument Reasoning Task in Civil Procedure. After analyzing the task requirements and the training dataset, we used data augmentation, adopted the large model GPT for summary generation, and added supervised contrastive learning to the basic BERT model. Our system achieved an F1 score of 0.551, ranking 14th in the competition leaderboard. Our system achieves an F1 score improvement of 0.1241 over the official baseline model.

1 Introduction

In Task 5 of SemEval-2024: The Legal Argument Reasoning Task in Civil Procedure (Bongard et al., 2022), we expect to reason about legal arguments in civil actions, as shown in Table 1. The dataset for this task comes from a textbook for law students, and we believe it is a complex task that can be benchmarked against modern legal language models. Task 5 proposes a novel NLP task from the US civil procedure domain that is beneficial to the quest to improve modern legal language models.

The foundation model we choose is Legal-BERT (Chalkidis et al., 2020), which collects different English LEGAL texts from multiple domains (e.g., legislation, court cases, contracts) for pre-training. Compared with other models such as LEGAL-RoBERTa (Chalkidis* et al., 2023), it can handle this task data better. Based on that, a great variety of strategies have been tested along with our exploration, such as summary generation, data augmentation (DA), and contrastive learning.

Data analysis for this task revealed that the dataset size was relatively small (only 666 entries), yet each data point contains substantial information. In such a language environment, we realize using and enriching data fully is very important. We used generative summarization, contrastive learning, and data augmentation to train the model, which led to our system ranking 14th in this task.

2 Related Work

Legal information is mostly expressed in the form of text, such as legal cases, bills, contracts, legislation, and so on. Therefore, legal text processing is an important area of NLP, including classifying legal topics (Nallapati and Manning, 2008), generating rulings based on what the court has already done (Ye et al., 2018), etc. In the past, some traditional machine learning methods like SVM bag of words (Aletras et al., 2016; Medvedeva et al., 2018) performed worse than neural models on legal tasks. The use of generic pre-trained models becomes the new paradigm, such as Legall Longformer (Chalkidis* et al., 2023) and Italian-Legal-BERT (Licari and Comandè, 2022). Data augmentation is a mature method for expanding a dataset when there is little training data, and in this case, we are not using external data but rather taking full advantage of the various fields of the provided data.

Task 5 is a small sample task, and we adopt contrastive learning to distinguish them from different samples by grouping similar samples together, hoping to learn from the intrinsic structure of the data. We use triples as a loss function(Schroff et al., 2015), and according to the characteristics of our task, we use a supervised contrast learning(Khosla et al., 2020) algorithm, where the triples are anchor points, positive samples, and negative samples.

3 System Overview

Our baseline system simply feeds Legal-BERT with two pieces of text, classifies its output [CLS] tokens, and scores their similarity with the human-annotated data by cross-entropy loss training. All the optimized strategies discussed below are based on this framework, and the overall framework of our final system is shown in Figure 1. After train-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 530–535

key	value
Introduction	My students always get confused about the relationship between removal to federal court and personal jurisdiction. Suppose that a defendant is sued in Arizona and believes that she is not subject to personal jurisdiction there .[...]Fed. R. Civ. P. 4(k)(1)(A). I've stumped a multitude of students on this point. Consider the following two cases to clarify the point.
Question	7. A switch in time. Yasuda, from Oregon, sues Boyle, from Idaho, on a state law unfair competition claim, seeking $250,000 in damages. He sues in state court in Oregon.[...] Five days after removing, Boyle answers the complaint, including in her answer an objection to personal jurisdiction. Boyle's objection to personal jurisdiction is
Answer Candidate	not waived by removal, but will be denied because the federal courts have power to exercise broader personal jurisdiction than the state courts.
Label	0

Table 1: An example in the training set.

ing with all positive policies, we ensemble the best model on each fold for the final prediction.

3.1 Data Augmentation

In this task, we augment the training data in two ways. First, we combine the explanation, the question, and the complete analysis corresponding to the answer to form new positive sample data by utilizing the fields of the complete parsing of the answer. Second, the analysis corresponding to the wrong answer is combined with the answers to other questions to form new negative sample data.

In the original training dataset, the data ratio of positive and negative samples is 505:161 (505 samples have a label of 0). Through the above data augmentation methods, the data is expanded and the data set is balanced.

3.2 Summary Generation

The task requires giving a question and possibly correct answers to determine whether the answer is correct or incorrect. We should also consider short introductions to the question topic rather than directly using the question and answer fields of the sample data. For legal texts, the same question will have different answers in different contexts, and the differences in the answers are often huge.

We plan to concatenate the explanation and the question together to form the text for the first input system and the answer as the text for the second input. We choose Legal-Bert to handle up to 512 tokens, while most of the training data have more than 512 tokens, and the distribution of sample lengths in the training data set is shown in figure 2. We tried different truncation methods (direct truncation, sliding window truncation) to improve the performance of the model and finally found that using GPT3.5 to generate a summary of the context can achieve a better result than truncation processing.

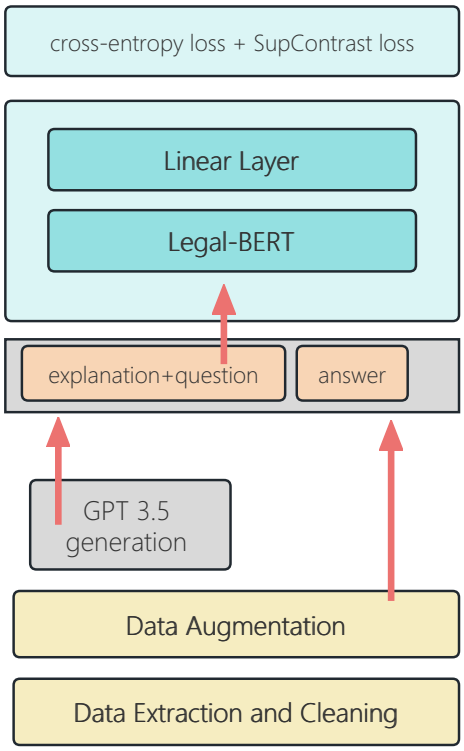

Figure 1: The overall framework of our system proposed for SemEval-2024 Task 5.

The specific treatment we adopt in direct and sliding window truncation is as follows. In direct truncation, we used the explanation and the question field 'l' space. Then, after the mosaics of the

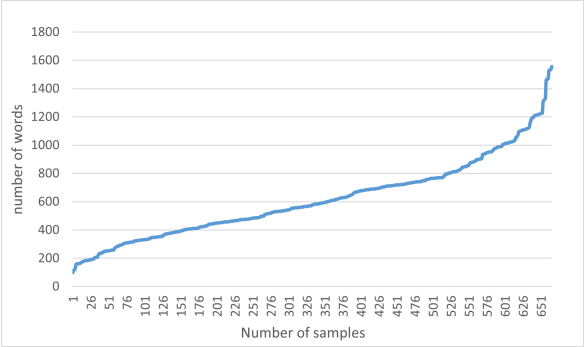

Figure 2: Sample length in the training dataset

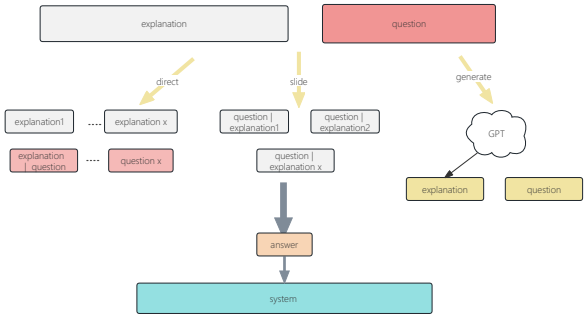

Figure 3: Explanation processing method

strings, separated by spaces counting more than 150 words, as a new sample data, the "id complete" field is used to identify the segmentation. In the sliding window, the basic strategy is the same as the above. Still, in each segmentation, the question's existence is guaranteed, and the part of the 150 words minus the question is explained on the concatenation. The specific process is shown in the figure 3.

However, we found their shortcomings in the above two processing methods. Directly truncating the simple truncated data will lead to the information in the question field with some sample data, either only the context or only the original question information. In sliding window truncation, although the original question field is preserved, we believe that the key information of the explanation is not uniformly distributed in the sentence. Therefore, we adopt GPT3.5 to generate the corresponding summary explanation according to the question pair context.

We believe that the important information to be extracted from the introduction usually involves key sentences, general sentences, and important details, which will affect whether the candidate's answer to the question is correct or not. Abstract generation for introducing a problem uses large models' good generalization ability to extract and compress this general knowledge. This can preserve the integrity of the information and capture the information from a broader perspective than the segmentation method.

3.3 Supervised Contrastive Learning

Contrastive learning aims to learn a data representation by maximizing the similarity between relevant samples and minimizing the similarity between irrelevant samples. In order to better fit this classification task, we use the Supervised Contrastive Learning strategy (Khosla et al., 2020; Chen et al., 2020), in which points belonging to the same class are pulled together in their own space. In contrast, points belonging to different classes are separated.

In a batch input, we treat the samples containing the original answer field as anchors, the newly added complete analysis of the answer as positive samples, and the remaining samples under the same question as negative samples. The contrastive loss under this triplet is shown in Eq 1, which is:

$$L_A = -\frac{1}{N}\sum_{i=1}^{N}\log\frac{e^{s(f(x_i),f(x_i^+))}}{e^{s(f(x_i),f(x_i^+))}+\sum_{j=1}^{N}e^{s(f(x_i),f(x_j^-))}}$$

where x_i is the input anchor, x_i^+ is the positive sample, x_i^- is the negative sample, $s(f(x_i), f(x_i^+))$ is the similarity measure function, and the inner product is commonly used.

We want to evaluate from an overall point of view, so we combine the cross-entropy loss and contrastive loss as the loss function of the model to train, and the loss function of the model is shown in Eq 2:

$$L = \frac{1}{2}\cdot(L_{CE}(y_i,\hat{y}_i) + L_A(x_i, x_i^+, x_i^-))$$

Where y_i is the ground truth, $\hat{y}_i$ is the predicted value, and x_i, x_i^+, x_i^- are the anchors, positive samples, and negative samples in the upper segment. Each data in the dataset has y_i and $\hat{y}_i$ after training, but only one kind of sample corresponds to the contrastive loss.

4 Experimental setup

4.1 Dataset Description

The training and validation sets contain 666 and 84 samples, respectively. Each sample contains a question, answer, label, analysis(excerpt from complete analysis relevant to answer candidate), complete

analysis(Glannon's explanation for the solution of the question), and explanation(topical introduction, additional context for question, potentially empty) fields. The test set contains 98 examples and has only question, answer, and explanation fields.

The task purpose is, given a question with a likely correct answer and a short introduction to the question topic, to determine whether the answer candidate is correct or incorrect. Each of these sample data does not exist independently, and most of them are 4 to 6 samples in the same group. This means that the questions and contexts of these four data are consistent, and the answers and analyses are different. Specific examples are shown in Table 2.

The following are the specific available fields and what they represent for the samples in the dataset:

- <question> 6. Any port in a storm. Cullen, a Vermont citizen, has an accident with Barnabas, a citizen of California, and Tecumseh, a New Yorker, in California. She sues Barnabas and Tecumseh for negligence in state court in Albany, New York, alleging negligence. She serves Barnabas with process in the ...
- <answer> a motion to transfer the case to a California court under 28 U.S.C. §1404(a).
- <analysis> A isn't right either. Section 1404(a) is a federal statute, authorizing a federal court to transfer a case to another federal court. It does not govern the state courts. There is no transfer statute allowing state courts in one state to transfer cases to ...
- <complete analysis> This question provides a nice little recap of various jurisdiction and venue issues. Barnabas wants out of the New York state court. What motion is likely to do the trick? Removal seems like an option, though of course he'd still have to litigate in New York. Remember that you can only ...
- <explanation> So, venue is the "third ring" in choosing a proper court, along with personal jurisdiction and subject matter jurisdiction. If all three rings are satisfied, the court has the power to hear the case. However, it doesn't always do so. Sometimes a case is filed in a court that has subject matter jurisdiction over the case, personal jurisdiction over the defendant, and is a proper venue under ...

Table 2: Components of the dataset.

- <label> False

4.2 Dataset Split

We split the processed training set and validation data set into 10 subsets without intersection and randomly split them into units of the same background-size, which ensures that each set has the same proportion of positive and negative samples as the original full set. Ten-fold cross-validation is used, and the results are shown as averages to ensure that the strategy used is maximally effective on the final test set.

4.3 Pre-processing

The legal data in all datasets were provided to us by email by the task organizers. After getting the original file in CSV format, we remove the file headers and re-add the file headers based on data splitting or summarization. After the initial processing of the data, we split the data into a mini-batch of 8 according to the needs of contrastive learning, where the first data is the anchor, the second data is the positive example, and the third to six data are the negative examples. In the cleaning process, we mainly remove some dirty format data, such as some missing field data.

4.4 Evaluation Metrics

Task 5 has two evaluation metrics which are F1 score and precision, The F1 score is common in evaluating binary classification tasks, especially when the classes are imbalanced, it is more representative than precision or recall. The F1 score can range from 0 to 1, with values closer to 1 indicating better performance.

4.5 Others

Hyperparameter tuning was not a critical point of our work. Still, we tested several values over a small range as they did influence our decisions

System	F1 score
pratice augmentation	
Baseline	42.69
+ DA	46.96
evaluation augmentation	
Baseline	42.96
+ DA	50.33
+ Summary Generation	53.59
+ SupContrast Learning	**55.10**

Table 3: Best results with training methods we used.

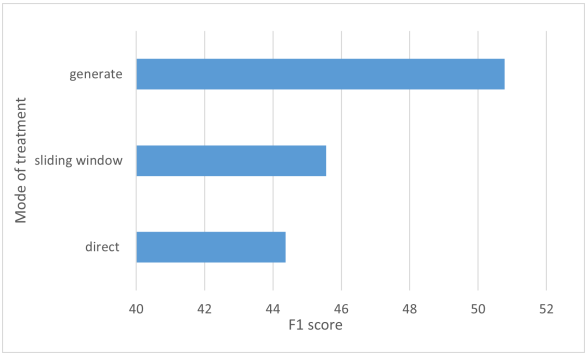

Figure 4: Summary generation effect comparison

about how well the policy worked (see Appendix). In addition, to help the reader replicate our experiments, details of tools and libraries are provided (see Appendix).

5 Results

5.1 Overall Performance

Finally, according to the official scoring system, our system got 0.551 on the test set and ranked 14th. As results are shown in Table 3, all the strategies presented in Section 3 produced positive effects, and we discuss the effects of these strategies one by one in the following subsections. For convenience, all the results from our experiments are multiplied by 100.

5.2 Data Augmentation

To verify whether the augmented dataset plays a positive role, we train with the augmented dataset in the Practice phase of the competition, which provides the official baseline, and this is the gap between the two baselines in Table 3.

As you can see from the top of Table 3, there is a significant increase, which is consistent with our inference that a richer training set is beneficial to build a more accurate system, and the way we augment the data is to some extent a multi-perspective supplement to the original data (from the analysis of the problem).

5.3 Summary Generation

As introduced in Section 3.2, we are aware of the importance of the corresponding explanation of the question. We propose several different ways to include segmentation fields and generate summaries. However, we are not sure which method is effective in collecting the characteristics of the data. Therefore, we tried each method, and the results are shown in Figure 4. Compared with direct truncation, the sliding window truncation method has an improvement of about 1 point, and the generated summary can be improved by about 4 points on this basis.

Obviously, through comparison, it is found that compared with direct truncation and sliding window truncation, the context summary generated by using a large model can better represent the features of the data. By comparing the direct truncation method and the sliding window truncation method, it can also be seen that the effect of the sliding window is better than the direct truncation to a certain extent, which conforms to our basic cognition that explanation is crucial in problem reasoning. Whether a candidate answer to a question is correct or not depends on the context of the question, that is, the relevant introduction.

5.4 Supervised Contrastive Learning

As mentioned in Section 3.3, contrastive learning is incorporated into our system. The loss function of our system is composed of a combination of cross-entropy loss and contrastive loss. We show the output of the cross-entropy loss and contrastive loss in some epochs of training and find that the contrastive learning function values are larger than the cross-entropy loss, and their magnitude is usually about double.

Through our final experimental results, as shown in the table, we can find that after the addition of contrastive learning, our system can learn more general features by reducing the distance between positive examples and away from the distance between negative examples, which increases the adversarial robustness of the model.

6 Conclusion

By deploying various optimization methods, including data augmentation, summary generation,

and supervised contrastive learning, we build a conceivably powerful system to reason about the task of legal argumentation in civil litigation. And ranked 14th in the evaluation stage competition with a 0.551 F1 score in the officially organized competition.

In future work, one is that law is a serious domain, and we plan to guide the model by prior knowledge. We also plan to incorporate domain-specific knowledge into the exercises and analyses of the law school textbooks under study. Second, we consider whether we can better model long texts by using tools external to the model to assist in processing long texts and optimizing the model.

Abstract

In human-computer interaction, it is crucial for agents to respond to human by understanding their emotions. Unraveling the causes of emotions is more challenging. A new task named Multimodal Emotion-Cause Pair Extraction in Conversations is responsible for recognizing emotion and identifying causal expressions. In this study, we propose a multi-stage framework to generate emotion and extract the emotion causal pairs given the target emotion. In the first stage, Llama-2-based InstructERC is utilized to extract the emotion category of each utterance in a conversation. After emotion recognition, a two-stream attention model is employed to extract the emotion causal pairs given the target emotion for subtask 2 while MuTEC is employed to extract causal span for subtask 1. Our approach achieved first place for both of the two subtasks in the competition.

1 Introduction

Comprehending emotions plays a vital role in developing artificial intelligence with human-like capabilities, as emotions are inherent to humans and exert a substantial impact on our thinking, choices, and social engagements (Wang et al., 2023b). Dialogues, being a fundamental mode of human communication, abound with a variety of emotions (C. et al., 2008; Poria et al., 2019; Zahiri and Choi, 2017; Li et al., 2017; Xia and Ding, 2019; Ding et al., 2020; Wei et al., 2020; Fan et al., 2020). Going beyond simple emotion identification, unraveling the underlying catalysts of these emotions within conversations represents a more complex and less-explored challenge (Wang et al., 2023b). Hence, (Wang et al., 2023a, 2024) introduces a novel undertaking known as Recognizing Emotion Cause in Emotion-Cause-in-Friends (ECF). ECF contains 1,344 conversations and 13,509 utterances where 9,272 emotion-cause pairs are annotated, covering textual, visual, and acoustic modalities. All utterances are annotated by one of the seven emotion labels, which are neutral, surprise, fear, sadness, joy, disgust, and anger. Within ECF, a significant task is identified as Emotion-Cause Pair Extraction in Conversations (ECPEC). ECPEC is responsible for identifying causal expressions related to a specific utterance in conversations where the emotion is implicitly expressed. ECPEC provides two Multimodal Emotion Cause Analysis in Conversations (ECAC) subtasks:

- Subtask 1: Textual Emotion-Cause Pair Extraction in Conversations. Given a conversation containing the speaker and the text of each utterance $U = [U_1, U_2, ...U_n]$, the model is aim to predict emotion-cause pairs, which include emotion utterance's emotion category and the textual cause span in a specific cause utterance (e.g. U3_joy, U2_"You made up!").
- Subtask 2: Multimodal Emotion Cause Analysis in Conversations. Given a conversation including the speaker, text and audio-visual clip for each utterance, the model is aim to predict emotion-cause pairs, which include emotion category and a cause utterance (e.g. U5_Disgust, U5).

To address the above problem, Wang et al. (2023a) proposed a two-step approach. First, they extract the emotional utterances and causal utterances by a multi-task learning framework and then pair and filter them. Zhao et al. (2023) proposes an end-to-end method by leveraging multi-task learning in a pipeline manner. However, these methods still suffer from low evaluation performances.

Motivated by the phenomenon that the performance of the emotion recognition of utterances in

Shen Zhang is in charge of the basic subtask-emotion recognition in conversation (ERC) and Haojie Zhang is responsible for the pipeline framework and causal pair extraction and causal span extraction subtasks.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 536–546

a conversation harnessed by the traditional manner is generally poor, we design a new pipeline framework. Firstly we utilize the Llama-2-based InstructERC (Lei et al., 2023a) to extract the emotion category of each utterance in a conversation. Then we consider the emotion causal pair extraction as the causal emotion entailment subtask and employ a two-stream attention model to extract the emotion causal pairs given the target emotion. For the causal span extraction, we employ MuTEC (Bhat and Modi, 2023) which is an end-to-end multi-task learning framework.

2 Related Works

2.1 Emotion Recognition in Conversation

Emotion recognition in conversation (ERC), which is a task to predict emotions of utterances during conversations, is crucial in both of the two ECAC subtasks. The existing methods can be divided into graph-based, RNN-based, Transformer-based, LLM-based, and knowledge-injecting methods.

Graph-based methods (Shen et al., 2021b; Li et al., 2024; Zhang et al., 2019; Taichi et al., 2020; Ghosal et al., 2019) aims to represent the correlations between emotions of utterances and speakers in the conversations. RNN-based methods (Hu et al., 2023; Lei et al., 2023c; Majumder et al., 2019; Hazarika et al., 2018; Poria et al., 2017) using GRU and LSTM (Wang et al., 2020) to capture the dependency of interlocutors and emotions of utterances. To model the emotional states during long-range context, Transformer-based methods (Song et al., 2022; Liu et al., 2023b; Chudasama et al., 2022; Shen et al., 2021a; Hu et al., 2022) utilize encoder-decoder framework or encoder-only models, such as BERT (Li et al., 2020) and RoBERTa (Kim and Vossen, 2021), to establish the correlation between long-range emotional states during conversations. Considering more than seven utterances in single conversation input, InstructERC (Lei et al., 2023b) defines the ERC task as a generative task based on LLMs, which unifies emotion labels between three common ERC datasets and utilizes auxiliary tasks (speaker identification and emotion prediction) by using instruction template to capture speaker relationships and emotional states in future utterances. Knowledge-injecting methods (Freudenthaler et al., 2022; Ghosal et al., 2020; Zhong et al., 2019; Zhu et al., 2021; Lei et al., 2023b) use external knowledge to analyze conversation scenarios.

2.2 Emotion Causes in Conversations

Poria et al. (2021) introduces the task of recognizing emotion causes in conversations and introduce two novel sub-tasks: Causal Span Extraction (CSE) and Causal Emotion Entailment (CEE), designed to identify the emotion cause at the span-level and utterance-level, respectively.

Causal Emotion Entailment Poria et al. (2021) define CEE as a classification task for utterance pairs and establish robust Transformer-based baselines for it. Wang et al. (2023a) introduces a multimodality conversation dataset Emotion-Cause-in-Friends (ECF) and propose a two-step approach to extract the causal pairs. They first extract the emotion utterances and the potential causal utterances individually and then pair and filter them. Li et al. (2022) introduce the social commonsense knowledge to propagate causal clues between utterances. Zhao et al. (2023) propose the Knowledge-Bridged Causal Interaction Network (KBCIN), which integrates commonsense knowledge (CSK) as three bridges called semantics-level bridge, emotion-level bridge and action-level bridge.

Causal Span Extraction involves identifying the causal span (emotion cause) for a given non-neutral utterance. Poria et al. (2021) first introduces the subtask and employs the pre-trained Transformer-based model to formulate the Causal Span Extraction as the Machine Reading Comprehension (MRC). Bhat and Modi (2023) propose a multi-task learning framework to extract the causal pairs and causal span in an utterance in a joint end-to-end manner. Besides, they also propose a two-step approach consisting of Emotion Prediction (EP), followed by Causal Span (CSE).

3 System Overview

3.1 System Architecture

The overview of the architecture of our proposed model is shown in Figure 1. The InstructERC aims to extract the emotion of utterances. TSAM model is a two-stream attention model utilized to extract the causal pairs given the predicted emotion utterance. The MuTEC is an end-to-end network designed to extract the causal span based on the causal pair extraction.

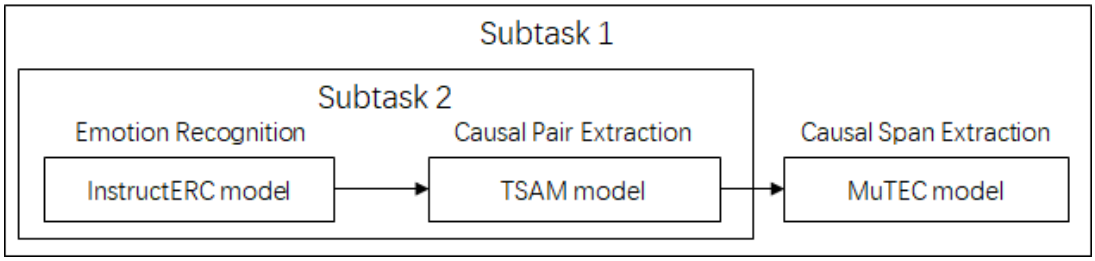

Figure 1: The overview of proposed model framework.

3.2 Emotion Recognition in Conversations

3.2.1 InstructERC for Emotion Recognition

InstructERC (Lei et al., 2023b) reformulate the ERC task from a discriminative framework to a generative framework and design a prompt template which comprises job description, historical utterance window, label set and emotional domain retrieval module. Besides emotion recognition task, InstructERC also utilizes speaker identification and emotion prediction tasks for ERC task. The performance of emotional domain retrieval module, which is based on Sentence BERT (Reimers and Gurevych, 2019), rely on the abundance of corpus. Taking into account that no additional data can be used, we only retain job description, historical utterance window and label statement in the instruct template.

3.2.2 Hierarchical Emotion Label

The hierarchical classification structure is shown in Figure 2. The emotion labels in dataset can be split into three categories: neutral, positive and negative, which positive set consists of surprise and joy while negative set includes fear, sadness, disgust and anger.

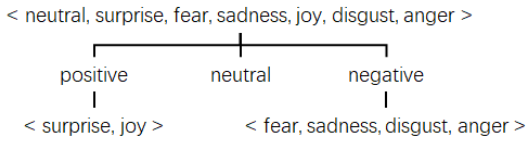

Figure 2: The Hierarchical Structure of Emotion labels.

3.2.3 Auxiliary Tasks and Instruct Design

Auxiliary tasks are proven as one of the efficient data augment methods (Lei et al., 2023b). Besides emotion recognition and speaker identification tasks, we add three auxiliary tasks in training data: sub-label recognition, positive recognition, and negative recognition tasks. The instruct template is depicted in Figure 3.

For emotion recognition and speaker identification task, we follow the format of instruct template in InstructERC, which consists of job description, historical content and label statement. For sub-label recognition (SR), positive recognition (PR) and negative recognition (NR) tasks, we utilize the corresponding label set which is mentioned in Section 3.2.2 to replace the label statement separately. The number of Speakers in the dataset is 304. The number of utterances from other speakers except the protagonist is far lower than the number of protagonists. Therefore, we unified all speakers other than the protagonist into 'Others'.

Visual data also plays an essential role in ERC. For video clips, we utilize LLaVA to generate descriptions of background, speaker movement and personal state. Therefore, we add background description, movement description and personal state description in instruct template. The background exhibits the information of scene in the conversation. The movement description depicts the action of speakers during corresponding utterances. The personal state description provides the observation of speakers' facial expressions. Considering the influence of the context, we have generated two sets of descriptions. The input of the first group only includes the clips corresponding to the utterances, while the second group adds the clips sequence corresponding to the historical utterances to the input of second group.

3.3 Emotion Cause Span Extraction

Emotion cause span extraction aims to extract the start position and end position of the causal utterance in a conversation. Typically, we can utilize a pipeline framework which firstly predicts the emotion and then predicts the cause span. For the cause span predictor, we can use SpanBERT (Joshi et al., 2020), RoBERTa (Liu et al., 2019) as the feature extractor and employ two heads on the top of them to extract the start and end positions given the causal

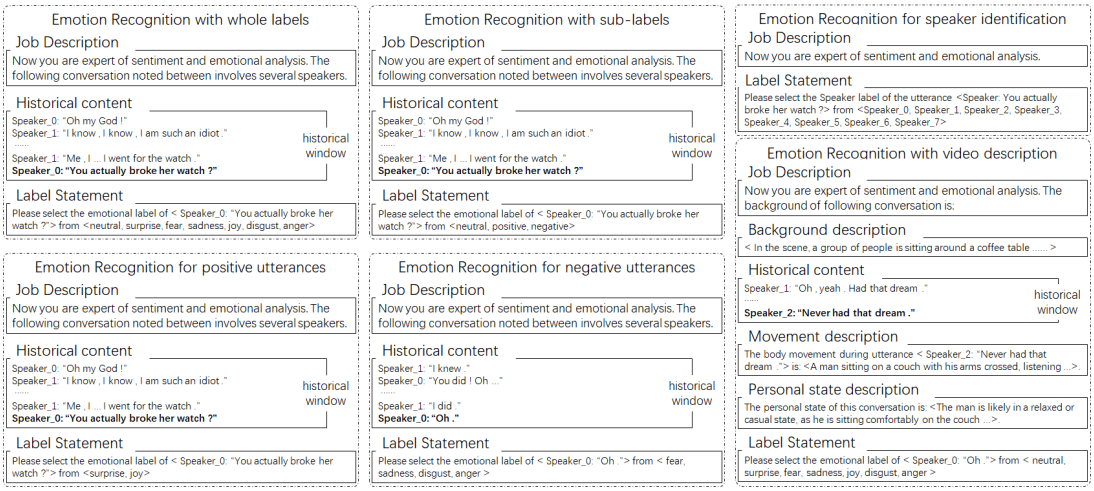

Figure 3: The Schematic of Instruct Template for ERC.

utterance. The two-step model offers an advantage in its modularity, allowing the application of distinct architectures for the emotion predictor and cause span predictor. However, it comes with two drawbacks: 1) Errors in the first step can propagate to the next, and 2) This approach assumes that emotion prediction and cause-span prediction are mutually exclusive tasks. In our system, we follow MuTEC Bhat and Modi (2023) and use an end-to-end framework in a joint multi-task learning manner to extract the causal span in a conversation.

During the training period, the input comprises the target utterance U_t, the candidate causes utterance U_i, and the historical context. MuTEC employs a pre-trained model (PLM) to extract the context representations. For emotion recognition, which is an auxiliary task, it employs a classification head on the top of the PLM. The end position is predicted by the prediction head of the concatenated representations of the given start index and the sequence output from the PLM. In this stage, the golden start index is used as the start index. The training loss is a linear combination of the loss for cause-span prediction and emotion prediction: $\mathcal{L}_{Loss} = \mathcal{L}_{CSE} + \beta\mathcal{L}_{Emotion}$.

During the inference period, as the start index is unknown, it uses top k start indices as the candidate start indices and gets k candidate end indices. Finally, it gets the final start-end indices by argmaxing the $k \times k$ start-end pairs.

3.4 Emotion-Cause Pair Extraction

3.4.1 TSAM Model

In our pipeline framework, for Subtask2, we first extract the emotion of the utterance and then extract the causal pairs given the emotional utterance in a conversation. The causal pairs extraction is typically modelled as the causal emotion entailment (CEE) task. In our system, we employ TSAM model from Zhang et al. (2022) as the causal pair extractor. TSAM mainly comprises three modules: Speaker Attention Network (SAN), Emotion Attention Network (EAN), and Interaction Network (IN). The EAN and SAN integrate emotion and speaker information simultaneously, and the subsequent interaction module efficiently exchanges pertinent information between the EAN and SAN through a mutual BiAffine transformation (Dozat and Manning, 2016).

Contextual Utterance Representation The pre-trained RoBERTa is employed as the utterance encoder, and we obtain contextual utterance representations by inputting the entire conversational history U_t, into the RoBERTa (Liu et al., 2019), separated by a special token [CLS], where $i = 0, 1, 2, ..., t$. We use the representation of [CLS] as the contextual representation of the utterance, which can be denoted as $h_u^i \in H_u$.

Emotion Attention Network To represent emotions, the EAN utilizes an emotion embedding network as the extractor of emotion representations, $X_e^k = Embedding(e_k)$, where e_k represents k-th emotion label. The embedding network can be considered as the lookup-table operation. The emotion embedding matrix is initialized using a random initializer and is fine-tuned throughout the training process. Employing a multi-head attention mechanism (Devlin et al., 2018), the EAN treats utterance representations as query vectors and emotion

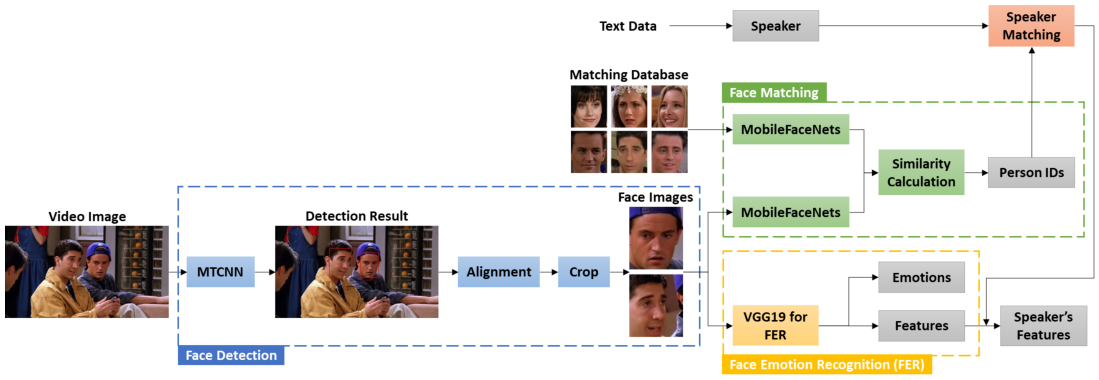

Figure 4: The framework of the face module.

representations as key and value vectors. The calculation process of the EAN mirrors that of a typical multi-head self-attention module (MHSA).

$$H_e = MHSA(Q, K, V) \tag{1}$$

where $Q = H_u, K = V = H_e$.

Speaker Attention Network The SAN facilitates interactions between utterances to incorporate speaker information by applying attention over the speaker relation graph. There are two types of relation edges: (1) Intra-relation type, which signifies how the utterance influences other utterances, including itself, expressed by the same speaker; (2) Inter-relation type, indicating how the utterance influences those expressed by other speakers. The speaker representation given a relationship can be formulated by the graphical attention mechanism (Zhang et al., 2022).

$$\begin{aligned} h_s^i &= \sum_{i \in \mathcal{R}} \sum_{j \in \mathcal{N}_i^r} \alpha_{ijr} W_r h_j^u \\ \alpha_{ijr} &= softmax(ReLu(\alpha_r^T W_r [h_i^u || h_j^u])) \end{aligned} \tag{2}$$

Interaction Network To efficiently exchange pertinent information between the EAN and SAN, a mutual Bi-Affine transformation is applied as a bridge (Dozat and Manning, 2016). In our Interaction Network, we integrate a masking mechanism to accommodate the existence of empty utterance speakers in some instances, which differs from the original approach. We denote this approach as the Masking Interaction Network (MIN).

$$\begin{aligned} \dot{H}_e &= softmax(Mask(H_e W_1 H_s^T)) H_s \\ \dot{H}_s &= softmax(Mask(H_s W_2 H_e^T)) H_e \end{aligned} \tag{3}$$

Cause Predictor The ultimate utterance representation for U_i is acquired by concatenating the output $\dot{H}_e$ and $\dot{H}_s$ from the L-layer TSAM. Subsequently, the concatenated vector undergoes classification using a fully-connected network. Given the target utterance U_i, the causal probability of the U_j can be formulated as follows:

$$p_{i,j} = sigmoid(fc(H_s^j || H_e^j)) \tag{4}$$

Multi-task Learning Auxiliary Task (MTLA) One drawback of the pipeline framework is that the extraction of utterance emotion and causal information are treated as separate tasks, potentially limiting the exploration of implicit relationships between them. Therefore, we incorporate emotion prediction as an auxiliary task within a multi-task learning framework. For emotion prediction, we utilize a classification head atop the Transformer-based model and apply the Dice loss (Li et al., 2019) as the multi-category classification loss.

3.5 Infusion of Video and Audio Information

The video data potentially carries rich knowledge for emotion analysis and existing research (Caridakis et al., 2007) has underscored the significance of multi-modal information in augmenting the semantic prediction capabilities of models. Our study leverages the visual and auditory cues present in conversational contexts with the aim of bolstering the efficacy of our language models in emotion analysis tasks.

3.5.1 Embedding and Concating Strategy

We set up specific embedding and fusion strategies for different language models. For BERT, we use the concatenation of textual and multi-modal features in the hidden layer. For Large Language Models (LLMs), our approach is characterized by the utilization of visual captions as supportive prompts, thereby furnishing the LLMs with an enriched informational context.

Models	LLM	w-avg F1	Accuracy
Origin InstructERC	Llama-2-7B-chat	53.83	50.87
Origin InstructERC	Llama-2-13B-chat	55.50	48.93
Ours-ERC-7B	Llama-2-7B-chat		
+ 3 auxiliary tasks		56.88	61.38
+ 3 auxiliary tasks & historical clips desc		57.74	57.02
+ 3 auxiliary tasks & utterance clips desc		58.42	57.92

+ 3 auxiliary tasks		57.85	**61.45**
+ 3 auxiliary tasks & historical clips desc		**58.64**	60.83
+ 3 auxiliary tasks & utterance clips desc		58.50	61.04

Table 1: Results of ERC task on test set without neutral utterances.

3.5.2 Extract Audio Feature Set

Audio data contains valuable information for emotion analysis, including tone, pitch, speed, and intensity of speech, as well as non-linguistic sounds and pauses, which together convey rich emotional cues. We use openSMILE (Eyben et al., 2010) to extract two comprehensive feature sets: GeMAPS (Eyben et al., 2016) and ComParE (Schuller and Batliner, 2013). GeMAPS is proposed for its effectiveness in capturing emotion-relevant vocal characteristics and ComParE encompasses a wide range of descriptors.

3.5.3 Video Image to Text

Integrating multi-modal features directly into the hidden layers of Large Language Models (LLMs) presents a significant challenge, primarily due to the prohibitive requirements for data and computational resources, such as GPUs. Although some finetuning strategies like prompt tuning could achieve it by addiing features to the input layer, we convert video to text with captioning where we can leverage our well-trained ERC model.

The performance of image captioning has been further enhanced with the outstanding NLU ability of LLMs. Large VLMs like LLaVA (Liu et al., 2023a) provide GPT-4 level multi-modal capability by visual instruction tuning. Furthermore, the Audio-Visual Language Model, Video-Llama (Zhang et al., 2023a), integrates both visual and audio encoders, enabling the comprehensive fusion of entire video content into LLMs. Without further training the VLMs as lack data, a well-designed prompt instructs the model to generate an emotion-related description. Our prompt asks the model to generate information from the front-ground event and place to character movements, the main character, facial expression, and finally emotion. The use of Chain-of-Thought (Wei et al., 2022) prompting further guides the model through a step-by-step process to derive the final emotion label. The output generated at each step is then incorporated into the ERC model, enriching it with a more detailed informational context.

3.5.4 Video image to Face Embedding

The faces in the video images contain rich emotion-related information, so pre-trained models are used to extract the face embeddings and correspond the identity of the face to the speaker in the text. The framework of the face module is shown in Figure 4.

Firstly, the Multi-Task Convolutional Neural Network (MTCNN) (Zhang et al., 2016) is used to detect the bounding boxes and key points of the faces. Next, the face images are affine transformed to a forward and intermediate state, and the faces are cropped and resized. The cropped images are then used for two subtasks: face matching and Face Emotion Recognition (FER). During face matching, two images of each protagonist are selected to build a matching database. With the help of MobileFaceNets (Chen et al., 2018), the embeddings of the face images are extracted, and the identity of each face image is obtained by calculating its similarity with the embeddings of faces in the matching database. During FER, the emotion-related embedding of the face image corresponding to the speaker is extracted by VGG19 (Simonyan and Zisserman, 2015) for subsequent multimodal analysis. When the speaker is a supporting character that is not included in the matching database, the features of the face image with the largest area are selected. When no face is detected or the speaker cannot be matched, the output features are filled with 0.

3.6 Model Ensemble

Ensembling models has been proven to be effective in boosting system performance across various tasks (Zhang et al., 2023b). For the extraction of

Model	Pre-trained Model	Test Pos.F1*	Eval Pos.F1**
Origin TSAM	RoBERTa-base	74.3	-
Ours-CEE	base

+MIN & MTLA & Ensemble	RoBERTa-large	**78.0**	**38.7**
Ours-CSE	BERT-base	-	31.62 (w-avg.)
Ours-CSE	RoBERTa-large	-	**32.23 (w-avg.)**

* The results are based on ground truth emotion labels.
** The results are based on emotion labels given by ERC.

Table 2: Results of our models for the causal emotion entailment subtask.

causal pairs, we utilize various models for ensemble learning. We utilize a majority voting mechanism to determine the final prediction, aiming for optimal performance on the test dataset.

4 Experimental Setup

4.1 Training Data

The split of dataset is same as SHARK (Wang et al., 2023b). The ECF dataset is divided into training, validation and test sets, which incclude 9966, 1087, 2566 utterances.

4.2 Training Details

For ERC task, we use InstructERC with Llama-2-7B-chat and LLamMA2-13B-chat, which retain default parameters. We finetune ERC model by peft on single A100 with batch size 8. The length of historical window is 12.

For both the causal emotion entailment subtask and the causal span extraction subtask, we adopt the default hyperparameter settings from the respective original papers. We found that conducting a hyperparameter grid search did not yield any additional performance improvements.

5 Results and Discuss

5.1 Emotion Recognition

We use weight average F1 score and accuracy to evaluate the performance of the model. It should be noted that according to the rules of the competition, we removed the neutral utterances when computing F1 score and accuracy. The result of ERC on test set is shown in Table 1. All models is trained on four auxiliary tasks mentioned by in Section 3.2.3. The best weight average F1 score is 58.64, which is achieved by Llama-2-13B with historical clips descriptions. The descriptions which contains information with the emotions of speakers improve 0.79 (from 57.85 to 58.64). As for accuracy, the Llama-2-13B without video clips descriptions achieves the highest score of 61.45. Compared with InstructERC's training data strategy, we have added additional auxiliary tasks and improve 12.52 on accuracy.

5.2 Emotion Cause Span Extraction

We utilize an end-to-end framework for cause span extraction and achieve a final performance of 32.23 in weighted average proportional F1 score on the official evaluation dataset as is shown in the Table 2. Our result significantly surpasses the result of 26.40 above $\sim +6.0$ achieved by the second-place participant. Furthermore, our results achieved the highest scores across all other official evaluation metrics, validating the effectiveness of our approach for subtask 1.

5.3 Causal Emotion Entailment

In our initial experiments focusing solely on text modality, we utilize the TSAM model as our baseline for the causal pair extraction subtask. As is shown in Table 2, After incorporating the MIN, our positive F1 score improves by $+1.2$. Furthermore, with the introduction of emotional multi-task learning as an auxiliary task, our result sees an additional improvement of $+0.4$. Furthermore, we achieve an additional improvement of approximately $\sim +1.1$ in the official final evaluation dataset through model ensembling.

We also conduct experiments involving other modalities, including audio and vision, as is show in Table 3. For both audio and vision features, we concatenate them with the pure textual features. Regarding audio, we experiment with two public feature sets: GeMAPS and ComParE. The GeMAPS feature has a dimension of 62, while the ComParE

Modality	Feature Set	Feature Selection	Feature Dimension	Test Pos.F1
Audio	GeMAPS	×	62	39.0
	ComParE	×	top 1000	62.4
	ComParE	√	352	67.6
	ComParE	√	296	70.5
	ComParE	√	128	**73.9**
Vision	Max Img	×	128	70.7
	Speaker Img	×	128	74.3
	Emotional Speaker Img	×	512	**74.8**

Table 3: Results of multi-modality experiments for the causal emotion entailment subtask.

feature has a dimension of 6373. For the ComParE features, we employ an L1-based logistic regression classifier for feature selection, and we find that the best performance is achieved with a feature selection dimension of 128, resulting in a performance of 73.9. For the vision modality, we achieve a performance of 74.8, which is comparable to the result of the audio modality. However, upon introducing either audio or visual modalities, we observe a decreasing trend compared to the pure textual modality. This observation inspires us to develop a more reasonable approach to incorporate multi-modality in conversation analysis.

6 Conclusion

In this paper, we propose a joint pipeline framework for Subtask1 and Subtask2. Firstly, we utilize the Llama-2-based Instruct ERC model to extract the emotional content of utterances in a conversation. Next, we employ a two-stream attention model to identify causal pairs based on the predicted emotional states of the utterances. Lastly, we adopt an end-to-end framework using a multi-task learning approach to extract causal spans within a conversation. Our approach achieved first place in the competition, and the effectiveness of our approach is further confirmed by the ablation study. In future work, we plan to explore the integration of audio and visual modalities to enhance the performance of the task.

Abstract

Recent advancements in Large Language Models (LLMs) have propelled text generation to unprecedented heights, approaching human-level quality. However, it poses a new challenge to distinguish LLM-generated text from human-written text. Presently, most methods address this issue through classification, achieved by fine-tuning on small language models. Unfortunately, small language models suffer from anisotropy issue, where encoded text embeddings become difficult to differentiate in the latent space. Moreover, LLMs possess the ability to alter language styles with versatility, further complicating the classification task. To tackle these challenges, we propose **G**ated **M**ixture-**o**f-**E**xperts **F**ine-tuning (GMoEF) to detect LLM-generated text. GMoEF leverages parametric whitening to normalize text embeddings, thereby mitigating the anisotropy problem. Additionally, GMoEF employs the mixture-of-experts framework equipped with gating router to capture features of LLM-generated text from multiple perspectives. Our GMoEF achieved an impressive ranking of #8 out of 70 teams. The source code is available on https://gitlab.com/werkzeug1/gmoef.

1 Introduction

The advancements in Large Language Models (LLMs) have made generating human-level text more accessible and cost-effective than ever before. These advancements, coupled with techniques such as chain-of-thought (Wei et al., 2022) and instruction tuning (Zhang et al., 2023), have enabled LLMs in producing high-quality text on various topics. However, in the real world, using LLM-generate text is not always acceptable. Thus, there is an urgent need for an easy yet reliable way to detect LLM-generated text.

The SemEval-2024 task 8 (Wang et al., 2024) aims to find methods that can detect machine-generated text. In this work, we followed the most common black-box detection paradigm, which regards such problem as a classification task. We argue that current methods all suffer from the following issues: (1) Anisotropy of the text embeddings (Li et al., 2020; Jiang et al., 2022; Gao et al., 2021). Using small pretrained language models (PLMs) to encode text is the very first step for all classification models, however, PLM may suffer from anisotropy issue, which makes text embeddings clustering in a small cone in the latent space, and compromise the classification performance. (2) Language style of LLM-generated text is dynamic. As aforementioned, LLM can generate text that accommodates various topics and contexts; different LLM may have different optimization targets during pre-training *w.r.t.* text generation. In other words, finding a regular pattern for LLM-generated text is difficult.

To this end, we propose **G**ated **M**ixture-**o**f-**E**xperts **F**ine-tuning (GMoEF) to tackle these problems. GMoEF first uses the PLM to encode the text, then employs parametric whitening transformation to normalize the embedding distribution, in order to mitigate the anisotropy issue; furthermore GMoEF adopts Mixture-of-Experts equipped with gating router to capture features of LLM-generated text from multiple perspectives. Our GMoEF achieved an impressive ranking of #8 out of 70 participating teams on subtask B.

2 Related Work

Typically, LLM-generated text detection is regarded as a classification task aimed at distinguishing between LLM-generated text and human-written text (Jawahar et al., 2020). With the advancement of LLMs, their text generation capabilities have reached a level comparable to hu-

*Equal contribution.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 547–552

man writing (Achiam et al., 2023), making it even challenging for humans to differentiate between LLM-generated text and human-written text. Consequently, there is a need to develop effective detectors to mitigate the potential misuse of LLM (Wu et al., 2023). Recently, owing to the construction of numerous high-quality benchmarks and innovations in detection methods, significant progress has been made in LLM-generated text detection technology.

High-quality datasets play a crucial role in advancing research on detecting LLM-generated text. HC3 dataset (Guo et al., 2023), represents one of the pioneering open-source efforts aimed at comparing ChatGPT-generated text with human-written text.The CHEAT dataset (Yu et al., 2023) comprises academic abstracts written by humans sourced from IEEE Xplore, and is committed to detecting artificially generated deceptive academic content from ChatGPT. Additionally, there are numerous datasets containing text generated by various LLMs, such as monolingual datasets DeepfakeText-Detect-Dataset (Li et al., 2023), GPT-written dataset (Liu et al., 2023b), and M4 (Wang et al., 2023), used in this competition.

Focusing on recently proposed detection methods, these primarily encompass zero-shot (Corston-Oliver et al., 2001), fine-tuning LMs (Qiu et al., 2020), adversarial learning (Hu et al., 2023), and LLMs as detectors (Koike et al., 2023). DetectGPT (Mitchell et al., 2023) is dedicated to the detection of LLM-generated text by analyzing the structural attributes inherent in the probability functions of LLMs. Fagni et al. (2021) noted that fine-tuning RoBERTa (Liu et al., 2019a) resulted in optimal classification outcomes across diverse encoding configurations. Recent studies (Liu et al., 2023a; Chen et al.) have additionally supported the outstanding performance of fine-tuned variants within the BERT family, such as RoBERTa, in discerning LLM-generated text. Yang et al. (2023) conducted an adversarial data augmentation process on LLM-generated text, and the results showed that models trained with augmented data exhibited enhanced robustness.

3 Methodology

In this section, we present our GMoEF in details. We first introduce the overall architecture of the proposed GMoEF, then give a comprehensive insight of the adopted parametric whitening and gated mixture-of-experts

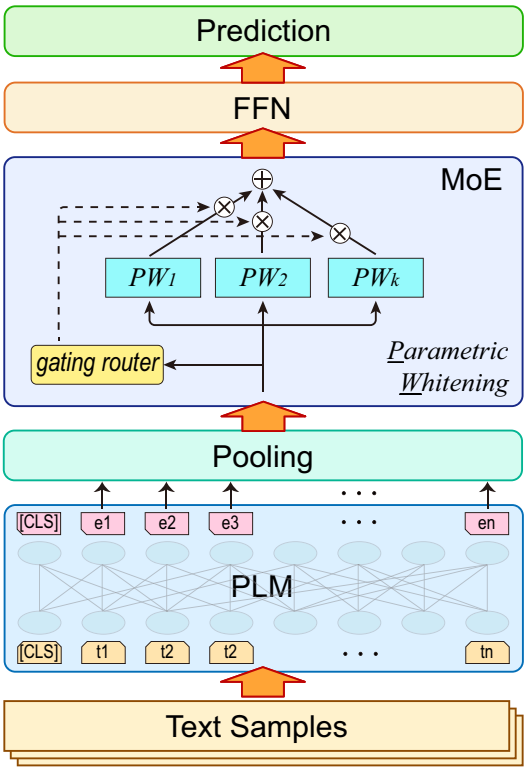

Figure 1: The main architecture of GMoEF.

3.1 System Architecture

The overall architecture is shown in Figure 1. Basically, our GMoEF follows the fine-tuning PLM as the classifier paradigm. We first employ a PLM as the text encoder. For text sample s_i, we take the last layer output at each token position through a mean pooling layer to obtain the text embedding x_i. Notably, we do not take the commonly adopted `[CLS]` position output as the text embedding. Further discussion can be found in section 4.3. On acquiring the text embedding, we put it through a gated mixture-of-expert layer, in which we adopt parametric whitening module as the expert, to learn the language feature of LLM-generated text. Finally, we employ a feed-forward network to give the final probability score $\widehat{y}_i$. We then use the cross-entropy loss as the optimization target.

$$\mathcal{L} = -\sum_{i=1}^{k} y_i \log(\widehat{y}_i) + (1 - y_i) \log(1 - \widehat{y}_i). \quad (1)$$

3.2 Parametric Whitening

While we can utilize a PLM to encode texts into embeddings, current studies have revealed that PLMs induce a non-smooth, anisotropic semantic space

for general texts(Li et al., 2020). Anisotropy issue makes the embeddings occupy a narrow cone, resulting in a high similarity between any embedding pairs. Consequently, this situation can have a negative impact on downstream classification tasks (Jiang et al., 2022). The problem is further exacerbated when mixing texts generated by multiple LLMs and written by humans. Drawing inspiration from recent studies that aim to improve PLM-generated text embeddings through whitening-based methods (Su et al., 2021; Huang et al., 2021), we incorporate a simple linear transformation to transform the original PLM generated embeddings for deriving isotropic representations. Unlike previous whitening-based methods, we make mean and variance as two learnable parameters, for better generalizability. We define the whitening transformation as:

$$\widetilde{x_i} = (x_i - \mathbf{b}) \cdot \mathbf{W}_1, \tag{2}$$

where $x_i \in \mathbb{R}^d$ is the original text embedding, while $\mathbf{b} \in \mathbb{R}^d$ and $\mathbf{W}_1 \in \mathbb{R}^{d \times d'}$ are all parameters to learn. $\widetilde{x_i}$ is the transformed text embedding.

3.3 Gated Mixture-of-Experts

As mentioned earlier, the dynamic language style of LLM-generated text poses a significant challenge for all detecting methods. We contend that conventional methods are only capable of capturing limited or partial aspects of the pattern. To this end, we employ multiple parametric whitening layers to learn a series of whitening embeddings. Each embedding will focus on a certain aspect of the language style, and we make the final decision based on all these embeddings to draw a more robust conclusion.

To implement our idea, we employ the mixture-of-experts (MoE) architecture (Jacobs et al., 1991; Eigen et al., 2013). More sepcifically, we employ k parametric whitening layers as the *experts*, then employ a gating router (Shazeer et al., 2016; Hou et al., 2022) to aggregate them. For text sample s_i, the gated mixture-of-expert output v_i is defined as:

$$v_i = \sum_{j=1}^{k} g_j \widetilde{x_i}^{(j)}, \tag{3}$$

where $\widetilde{x_i}^{(j)}$ represents j-th whitening transformed embedding for text sample s_i. g_j is the weight derived from the gating router, which is defined as follows:

$$\boldsymbol{g} = \text{Softmax}(x_i \cdot \mathbf{W_2} + \boldsymbol{\delta}), \tag{4}$$

$$\boldsymbol{\delta} = \boldsymbol{\epsilon} \cdot \text{Softplus}(x_i \cdot \mathbf{W_3}). \tag{5}$$

where $\boldsymbol{g} \in \mathbb{R}^k$ is the routing vector. We employ two learnable parameters $\mathbf{W_2}$ and $\mathbf{W_3}$ to dynamically adjust the weight for each expert. Inspired by Inoue (2019), we incorporate a series of noises $\boldsymbol{\delta}$ in the gating router to balance these experts and avoid overfitting.

4 Experiment

4.1 Experimental setup

Dataset and Evaluation. A sampled version of M4 (Wang et al., 2023) dataset provided by the organizer was adopted. Comprehensive statistics regarding the dataset can be found in Table 1. Subtask A focuses on detecting single-model generated text while subtask B focuses on the multi-model generated text distinguish. However, subtask C has a very different optimization target comparing to subtask A and B, we opted not to conduct experiments on this particular subtask. As mentioned in the official task description, we employed Accuracy as the evaluation metric to assess the quality of the detection.

Subtask	#Train	#Dev	#Test
A (mono.)	119,757	5,000	34,272
A (multi.)	172,417	4,000	42,378
Subtask B	71,027	3,000	18,000

Table 1: Statistics on subtask A (monolingual & multilingual) and subtask B.

Implementation details. We implemented the GMoEF model based on RoBERTa[1] (Liu et al., 2019b) and XLM-R[2] (Conneau and Lample, 2019) for monolingual and multilingual scenarios respectively, with Pytorch (Paszke et al., 2019) and the Huggingface Transformers library (Wolf et al., 2020). To facilitate distributed training, we utilized the pytorch-lightning framework (Falcon and The PyTorch Lightning team, 2019).

For optimization, we used the AdamW optimizer with an initial learning rate of $2e^{-4}$ for the RoBERTa part and $2e^{-5}$ for the non-RoBERTa parts. The learning rate was linearly decayed with 10% warm-up steps. The hyperparameter settings

[1] https://huggingface.co/FacebookAI/roberta-large
[2] https://huggingface.co/FacebookAI/xlm-roberta-large

Hyperparameter	Symbol	Value
Maximum words (tokens)	-	512
# of experts	k	3
# of epochs	-	3
weight decay	-	$1e^{-2}$
seed	-	42
batch size	-	$32^{\dagger}$
hidden dim	d'	256
PLM embedding dim	d	1024

Table 2: The hyperparameters of the experiment. †: on a single GPU.

we employed are summarized in Table 2. All models are trained on two NVIDIA-SXM4-A100 GPUs.

4.2 Main Results

The main results on test set are shown in Table 3. Our GMoEF exhibits impressive results in both subtask A and subtask B. However, our original submissions (*orig. sub.*) for subtask A is not satisfying as expected. We attribute this discrepancy as two folds: 1) It is possible that we failed to identify the optimal checkpoint for generating predictions on the test set due to a substantial disparity between the number of training and evaluation samples. 2) We searched for the optimal number of experts (k) from 4 up to 10 during submission stage, however, the best result shows up at $k = 3$.

We further find out that our GMoEF shows more significant performance improvements on subtask A (multilingual) and subtask B over the baselines. However, interestingly, the GMoEF does not exhibit significant advantages in subtask A (monolingual). It may indicates that the GMoEF is better suited for complex scenarios, for instance, the texts are *multilingual* and may generated by *multiple models*.

4.3 Ablation Study

In order to validate the unique contribution of each module, we conduct experiments on the following variants of GMoEF:

- Without parametric whitening (*w/o* PW). In this variant, we substitute all parametric whitening layers into the linear layers.
- Using `[CLS]` position output as the text embedding (*alt.* PLM).

As shown in Table 3, all variants will lead to immediate performance drop on all subtasks, which further validates the necessity and effectiveness of all proposed model components. Through these results, we have several noteworthy observations: (1) The multilingual and multi-model cases exhibit more severe anisotropy issue. Removing the PW layer can lead to a substantial decline in performance. (2) The utilization of the `[CLS]` token for text encoding proves to be coarse-grained when it comes to capturing language styles or features in the LLM-generated text detection task. In this context, our token position pooling strategy emerges as a more suitable alternative.

Model	**A** (mono.)	**A** (multi.)	**B**
baseline	0.885	0.809	0.746
orig. sub.	0.806	0.768	0.822
GMoEF	**0.903**	**0.892***	**0.848***
improv.	2.03%	10.3%	13.7%
w/o PW	0.896	0.848	0.732
alt. PLM	0.845	0.808	0.711

Table 3: Experimental results on subtask A (monolingual & multilingual) and subtask B. The best results are marked in **boldface**. *w/o* stands for "without"; *alt.* stands for "alternative". "*" denotes that the improvements are significant at the level of 0.01 with paired *t*-test.

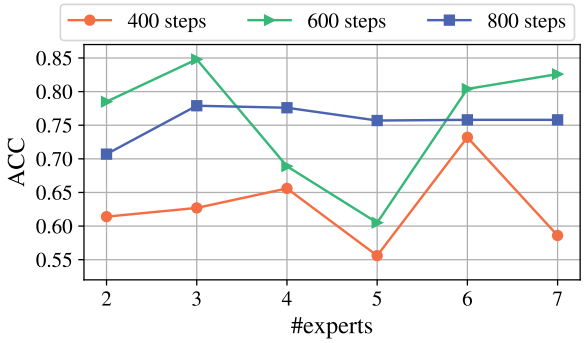

Figure 2: Experimental results on subtask B with different numbers of experts (k). Each line indicates start testing after training for certain steps. Notably, a whole training epoch takes ~1,110 steps under our setup.

4.4 Case Study on Number of Experts (k)

To reveal the effectiveness of our proposed gated mixture-of-experts fine-tuning, we further conduct experiments with different numbers of experts. Detailed results are shown in Figure 2, from these results, we have the following observations: (1) With the assistance of multiple experts, the model tends to converge much earlier, often requiring less

than a full epoch of training. The complete training process for subtask B takes about 1,110 steps. However, as shown in Figure 2, the optimal result is achieved at the 600th step with 3 experts. By the 800th step, the performance becomes expert-agnostic and suboptimal, indicating overfitting. (2) Our GMoEF achieves best performance with $k = 3$. With fewer experts, GMoEF can hardly capture the dynamic language features of LLM-generated text, and revert to conventional fine-tuning models. On the other hand, increasing the number of experts does not necessarily guarantee a better outcome. For instance, when $k = 5$, these experts may reach conflicting conclusions, leading to the worst result. While adding more experts may mitigate this phenomenon, it also introduces additional noise, ultimately resulting in suboptimal performance.

5 Conclusion and Future Work

In this work, we find out that current LLM-generated text detection methods may suffer from anisotropy issue, and they fail to capture the dynamic language features. To this end, we propose GMoEF, which incorporates parametric whitening to mitigate the anisotropy issue. GMoEF further adopts the Mixture-of-Experts equipped with gating router to model the pattern of LLM-generated text from multiple aspects. Our GMoEF exhibits an impressive #8 out of 70 participating teams on the multi-model generated text detection subtask. Extensive experiments show that our GMoEF is suitable for complicated scenarios where texts are multi-lingual and may generated by multiple possible LLMs.

In the future, we aim to extend our observations to other text classification tasks, and incorporate LLM itself to detect machine-generated text.

Abstract

This paper presents a transformer-based classifier for recognizing emotions in Hindi-English code-mixed conversations, adhering to the SemEval task constraints. Leveraging BERT-based transformers, we fine-tune pre-trained models (mBERT and indicBERT) on the dataset, incorporating tokenization and attention mechanisms. Our approach achieved competitive performance (weighted F1-score of 0.4), showcasing the effectiveness of BERT in nuanced emotion analysis tasks within code-mixed conversational contexts. This F1-score was ranked 16^{th} among the 39 submissions.

1 Introduction

Recognition of emotions from conversation enables advancements in sentiment analysis, mental health monitoring, chatbot development and ultimately enhances user experiences and well-being. The EDiReF shared task (Task 10) at SemEval 2024(Kumar et al., 2024) comprises three subtasks: Emotion Recognition in Conversation (ERC)(Kumar et al., 2023) and Emotion Flip Reasoning (EFR)(Kumar et al., 2022) in both Hindi-English code-mixed conversations and English conversations. ERC involves assigning emotions to each utterance from a predefined set, while EFR aims to identify trigger utterances for emotion flips in multi-party conversations. This task is vital for understanding emotional dynamics in conversational contexts, particularly in multilingual settings like Hindi-English code-mixed conversations.

This paper proposes a classifier for ERC that adopts a BERT-based transformer architecture (Lee, 2022) for emotion recognition task. By fine-tuning pre-trained BERT models, like mBERT (DevlinJ et al., 2018) and indicBERT (Kakwani et al., 2020), on the given dataset, we leverage transfer learning to understand and reason about emotions effectively in multilingual conversational contexts like Hindi-English code-mixed conversations.

We participated in sub-task 1 (ERC) of Task 10 (EDiReF) and competed with 38 other teams within the provided time frame. Our system achieved rank 16 for this sub-task with a range of weighted F1-scores between 0.3 and 0.4 using BERT-based models. While we successfully utilized BERT-based models for emotion recognition in Hindi-English code-mixed conversations, our system encountered challenges in accurately capturing emotional contexts, which affected our overall performance.

2 Background

Sub-task 1 challenges participants to provide emotions as output for particular utterances in conversations. Both training and validation datasets are provided, with both datasets in textual format. The training set includes 343 conversations with 8505 utterances, while the validation set contains 46 conversations with 1354 utterances. Each conversation in both datasets comprises episodes, speakers, utterances, and emotions. Utterances are in Hindi-English code-mixed (e.g., *"Namaste, how are you?"*). The emotion distribution and utterance length distribution for both datasets are summarized in Figure 1 and Figure 2, respectively. Notably, the emotion distribution in both datasets is prominently skewed towards 'neutral', as indicated by the larger area in the distribution. Upon analysis, the emotions involved in both datasets are identified as *['neutral', 'contempt', 'sadness', 'fear', 'joy', 'surprise', 'anger', 'disgust']*.

3 Related Work

In recent years, emotion recognition in conversational contexts has seen significant contributions. (Maheshwari and Varma, 2022) focused on emo-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 553–557

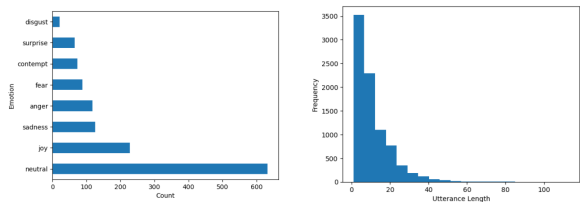

Figure 1: Emotion distribution and Utterance length distribution in training dataset

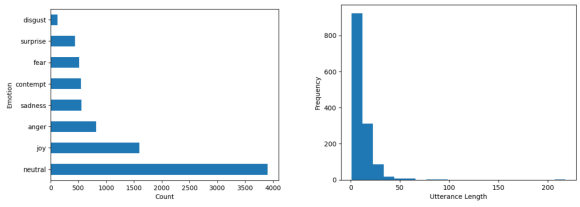

Figure 2: Emotion distribution and Utterance length distribution in validation dataset

tion recognition in tweets, emphasizing the importance of context. (Poria et al., 2019) survey offers a comprehensive overview of emotion recognition systems in dialogues, covering deep learning approaches and challenges. (Wang et al., 2023) study explores using transformers for emotion recognition in conversations, highlighting their effectiveness.

While deep learning has revolutionized the field, earlier works laid the foundation. (Thelwall et al., 2012) and (Pang and Lee, 2008) explored traditional approaches to Emotion Recognition (ER) using hand-crafted features and rule-based systems. (Mohammad and Turney, 2013) and (Tang et al., 2016) marked a shift towards deep learning for ER, focusing on Convolutional Neural Networks (CNNs) and Recurrent Neural Networks (RNNs) for learning emotion representations from text data.

(Wadhawan and Aggarwal, 2021) introduces a new dataset for analyzing emotions in Hindi-English tweets and proposes a transformer-based approach using BERT to achieve state-of-the-art accuracy in emotion detection, outperforming other deep learning models like CNNs, LSTMs, Bi-LSTMs.

(D. et al., 2019) also contribute to the field by applying traditional and deep machine learning approaches to identify offensive language in social media, demonstrating the versatility of these techniques in analyzing online sentiment. This aligns with our work on emotion recognition in code-mixed social media data, as both studies explore methods for sentiment analysis in similar contexts.

And the recent case study, (Tatariya et al., 2024) mentions the challenges in code-mixed data for emotion classification. The study investigates the effectiveness of pre-trained language models in understanding sociolinguistic contexts. The findings underscore the importance of considering linguistic diversity and sociolinguistic factors in developing and interpreting emotion recognition models.

(Vijay et al., 2018) pioneered the work on emotion recognition in Hindi-English code-mixed social media text. Their work established a benchmark by creating a corpus of annotated data and proposing a classification system for emotion detection.

Building on Wadhawan and Aggarwal's success with BERT with the help of works done by (**?**) in SemEval 2021 and (Lee, 2022) in emotion recognition in conversations, our mBERT model aims to further improve emotion detection by addressing the cultural nuances and fine-tuning on a larger code-mixed hindi-english dataset while addressing the limitations highlighted by Tatariya et al.

4 System Overview

This section provides an overview of our BERT-based transformer system and justifies our selection of pre-trained BERT models. After data-preprocessing, our system takes conversations as input in form of sequence of tokens and produces emotion class as output for emotion classification. This processs is illustrated in Figure 3.

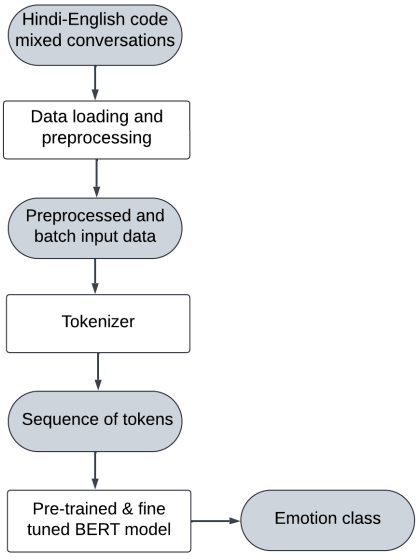

Figure 3: BERT-based Transformer System Overview

For Hindi-English Code-mixed language, we

used mBERT (DevlinJ et al., 2018) and indicBERT (Kakwani et al., 2020). Due to multilingual understanding of mBERT and IndicBERT which is designed for Indic languages, enabling them to process both Hindi and English as well as their mixtures effectively. Their cross-lingual transfer learning capabilities ensure robust performance with minimal fine-tuning, while their rich representations of language capture essential contextual information across language boundaries.

5 Experimental Setup

In this section, we present the implementation details of our system. During the training phase, we used the provided training dataset to fine-tune the BERT models and the validation set for evaluation. Later, both the training and the validation sets were used to fine-tune the BERT models which were submitted for testing using the test set.The stages involved in experiments are detailed below.

5.1 Data Pre-processing steps

5.1.1 JSON Parsing

To facilitate quick access to data samples, the given JSON dataset, containing information on episodes, speakers, utterances, and emotions, will be transformed into a text file with three columns: speakers, utterances, and emotions. A blank line in the text file will serve as the separator between different conversations.

5.1.2 Emotion loading for Specific Utterances and Retaining Previous Dialogue Context

Following JSON parsing, the data loader organizes input by loading the emotion associated with each dialogue alongside its utterances. Utterances undergo text cleaning, removing punctuations and stopwords in Hindi-English code-mixed languages. To grasp the current dialogue's emotion context, the loader loads the sequence of previous dialogues, including their utterances and speaker names. Speaker names are indexed starting from zero *(e.g., 0 for Ram, 1 for Divya)*, facilitating the mapping of utterances to their corresponding speakers. Additionally, the data loader maintains a set of emotions involved in the previous dialogue context.

5.2 Neural Architecture for emotion recognition in conversations

We downloaded the pre-trained mBERT[1] and indicBERT[2] models from the huggingface transformer library. We adopted the code of the transformer model for the Emotion Recognition Challenge (Lee, 2022) to implement our system. We processed the batch tokens through multiple layers of Transformer blocks, including self-attention mechanisms and feed-forward neural networks. For evaluating the performance metrics of every epoch while training, we used precision, recall, and weighted f1 score of the validation set. We used cross entropy loss for loss function and with the help of AdamW optimizer, we have updated the weights involved. The final layer of the BERT model determines the number of emotion classes using a data loader that tracks emotions in the input data, outputting the class label for classification. Class labels are then converted into emotions for analysis in the ERC task.

We conducted our experiments on Google Colab using the T4 GPU runtime mode. We trained the chosen BERT models with a batch size of 1 and a learning rate of 1e-6.

6 Results

We trained both the mBERT and indicBERT models according to the experimental setup. During training, we recorded and stored the weighted F1 scores of both the models on the validation set, which are detailed in Table 1. Notably, mBERT's performance improves until around 7-8 epochs, while indicBERT's score remains stable. Additionally, in Table 2, the final scores for precision, recall, and weighted F1 are detailed. Using the trained mBERT model, we achieved the 16th rank with a weighted F1 score of 0.4 in subtask 1 of task 10, whereas the top ranked system achieved a score of 0.78.

We examined the emotions predicted by two models, mBERT and indicBERT, and compared them to the actual test labels. We visualized the results using a confusion matrix of mBERT in Figure 4.

After normalizing the emotion distribution of the training dataset and mBERT correct predictions, we observed that their patterns appear similar in

Epochs	mBERT	indicBERT
1	29.44	28.34
2	35.35	29.1
3	35.49	29.1
4	38.68	29.1
5	40.72	29.1
6	41.4	29.12
7	41.56	29.18

Table 1: weighted f1 scores of mBERT and indicBERT for 7 epochs

Model	Precision (%)	Recall (%)	Weighted F1 Score (%)
M-BERT	41.46	47.56	42.47
IndicBERT	21.85	46.75	29.78

Table 2: mBERT and indicBERT - Final Performance metrics

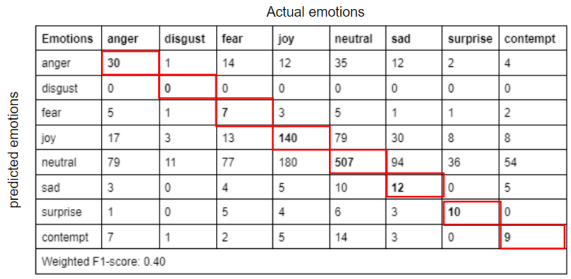

Figure 4: Confusion matrix with Highlighted correctly predicted emotions by mBERT

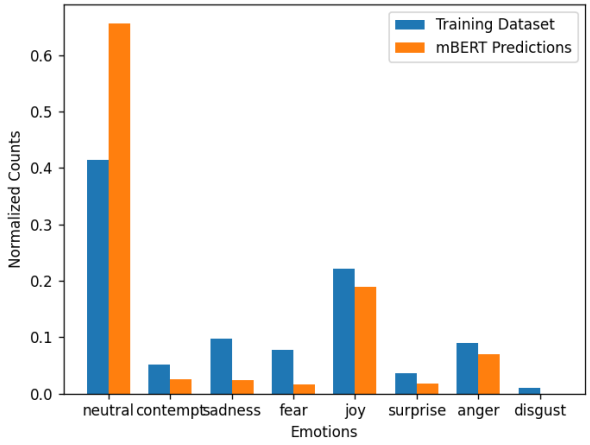

Figure 5: Normalized Emotion distribution of training dataset and mBERT correct predictions

Figure 5. However, *disgust*, *contempt*, *fear*, *sadness*, and *surprise* exhibit the lowest areas in the distribution, indicating that it is challenging for the model to identify utterances with these emotions. Therefore training datasets with a more balanced emotion distribution may possibly enhance the performance of mBERT.

The confusion matrix of indicBERT showed 0 for all the entries except for neutral where 656 test cases were predicted correctly. This clearly indicates that indicBERT has not learnt the contextual representations of utterances in the training dataset. This is primarily due to the fact that indicBERT was trained using Hindi unicode, whereas our dataset uses transliterated Hindi. We will try to resolve the issue in the future.

7 Conclusion

In our study on understanding emotions in Hindi-English conversations for SemEval 2024 Task 10, we used BERT-based models. Our system ranked 16th in subtask 1. However, accurately capturing nuanced emotions posed challenges, suggesting areas for improvement.

For future work, we plan to enhance our system in several ways. First, we aim to expand our dataset with more Hindi-English code-mixed tweets to expose the model to a wider range of expressions. Second, we'll refine our data preprocessing by translating Hindi-English utterances into plain English to reduce ambiguity. Additionally, we'll explore models beyond BERT, like LLAMA and GPT-2, known for text generation and question answering tasks. We'll also investigate specialized models like HingBERT and its family models for improved accuracy in Hindi-English code-mixed text analysis.

In essence, our future research focuses on dataset expansion, preprocessing improvements, and exploring diverse models to better understand emotions in multilingual conversations.

KInIT at SemEval-2024 Task 8: Fine-tuned LLMs for Multilingual Machine-Generated Text Detection

Michal Spiegel[1,2] and **Dominik Macko**[1]
[1] Kempelen Institute of Intelligent Technologies
[2] Faculty of Informatics, Masaryk University
michal.spiegel@intern.kinit.sk, dominik.macko@kinit.sk

Abstract

SemEval-2024 Task 8 is focused on multigenerator, multidomain, and multilingual black-box machine-generated text detection. Such a detection is important for preventing a potential misuse of large language models (LLMs), the newest of which are very capable in generating multilingual human-like texts. We have coped with this task in multiple ways, utilizing language identification and parameter-efficient fine-tuning of smaller LLMs for text classification. We have further used the per-language classification-threshold calibration to uniquely combine fine-tuned models predictions with statistical detection metrics to improve generalization of the system detection performance. Our submitted method achieved competitive results, ranking at the fourth place, just under 1 percentage point behind the winner.

1 Introduction

Recent large language models (LLMs) are able to generate high-quality texts that are not easily detectable by human readers. A problem arises when such generated texts are misused for academic exams (Achiam et al., 2023), plagiarism (Wahle et al., 2022), disinformation spreading (Vykopal et al., 2023), etc. Therefore, it is crucial to develop automated means to detect machine-generated texts.

SemEval-2024 Task 8 (Wang et al., 2024) consists of three subtasks: A) binary human-written vs. machine-generated text classification, B) multi-way machine-generated text classification, and C) human-machine mixed text detection. In our work, we have focused on subtask A, especially its multilingual track. It covered 8 known languages for training (Arabic, Bulgarian, Chinese, English, German, Indonesian, Russian, Urdu), multiple domains (e.g., Wikipedia, news, abstracts), and multiple text generators (e.g., GPT-3, ChatGPT, BLOOMZ).

During our participation in the shared task, we have explored various alternatives. Our best submitted solution (illustrated in Figure 1) combines two fine-tuned LLMs (green-colored) with statistical detection (orange-colored) using a two-step majority voting (purple-colored) based ensemble method. Such a system achieved fourth place in the final leaderboard, with a performance of 95% in accuracy, within 1 percentage point range behind the winning system. We have published the source code for easier replication purposes[1]. We have used the statistical detection methods implemented in the recently published IMGTB framework[2] (Spiegel and Macko, 2023), which will be extended to also support all the fine-tunning options that we have used in this work.

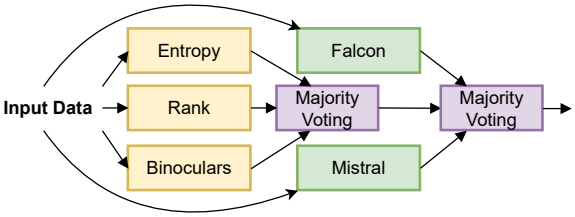

Figure 1: System components overview.

Our key contributions include:

- We have **proposed a unique way of combining the statistical and fine-tuned detection methods** using a two-way majority voting and a per-language threshold calibration.
- We have **proposed and compared three ensemble system alternatives** to cope with multilingual machine-generated text detection (additional two in the post-deadline study).
- We have **experienced a remarkably good performance of fine-tuned LLMs** of 7B parameters in this task.

[1] https://github.com/kinit-sk/semeval-2024-task-8-machine-text-detection
[2] https://github.com/kinit-sk/IMGTB

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 558–564

- We have proposed **the best-performing single-model system** called rMistral (Mistral-7B fine-tuned in a robust way – using both the train and dev sets and obfuscating 20% of the train data), achieving **0.97 AUC ROC** on the test data.

An interesting observation regarding our rMistral system is that although our per-language threshold calibration method would not bring the best accuracy on the test set (0.93), the threshold fixed to 1.0 (only predictions with a probability of 1, i.e. 100% confident, are marked as machine-generated) would win the competition (accuracy of 0.97). Nevertheless, we have noticed such a threshold performance only after the deadline and we considered the model being over-fitted (we would not submitted the results) which turned-out to be false.

2 Background and Methodology

For the machine-generated text detection task, three main groups of methods are nowadays used (Uchendu et al., 2023). The first one is a *stylometric detection*, which uses linguistic features (e.g., n-grams) to differentiate between human and machine writing styles (Fröhling and Zubiaga, 2021; Kumarage et al., 2023). The second group is a *statistical detection*, which uses statistical distribution based on a pre-trained language model (e.g., GPT2) to calculate various metrics (e.g., entropy) that can be used even without training (i.e., better generalization) to differentiate machine and human written texts (Mitchell et al., 2023; Hans et al., 2024). The last group is a *fine-tuned detection*, which further trains an already pre-trained language model for the detection task (Uchendu et al., 2020; Macko et al., 2023).

In the SemEval2024 Task 8 (Wang et al., 2024), we have focused on the multilingual track of Subtask A, which aimed at a binary classification to differentiate between human-written and machine-generated texts. The provided dataset (not allowing additional training data) contained the predefined splits of train, dev, and test sets. The train and dev sets officially contained 8 languages (3 languages in the dev set only), while unknown number of languages is contained in the test set.

Due to a multilingual nature of the data and our previous experience in multilingual machine-generated text detection (Macko et al., 2023), we wanted to try-out something new in this shared task. Our initial idea was to experiment with a per-language "mixture-of-experts", which would consist of multiple models, fine-tuned in a monolingual way per each official language in the train and dev sets. Since it was expected that surprise languages will be present in the test set, we would have used an additional multilingually fine-tuned model for other languages. However, we have started the experiments only few weeks before the deadline, which gave us little time to cope with the problems such as over-fitting and hyper-parameter optimisation (shown as severe towards the deadline).

Therefore, while training these per-language models, we also started to fine-tune the Falcon-7B model (Almazrouei et al., 2023) for the machine-generated text detection task, inspired by the winning system (Gagiano and Tian, 2023) of the recent ALTA 2023 shared task (although English monolingual). Since Falcon-7B is pre-trained on two languages only (English and French), we did not want to use it in a standalone way due to uncertain cross-lingual capability. Therefore, we have similarly fine-tuned the Mistral-7B model (Jiang et al., 2023), which is similarly sized generative model outperforming even some 13B parameters models in common benchmarks. We have not previously experimented with such a "big hammer" for the task; therefore, it was an interesting new experience for us. We have further combined these LLMs with statistical detectors to ensure better generalization of the system, which is described in the following sections.

3 System Overview

Our best system (see Figure 1) combines the predictions of two fine-tuned LLMs (Falcon-7B and Mistral-7B) with the selected statistical metrics (Entropy, Rank, Binoculars) by using **a two-step majority voting**. Firstly, a single majority-voted prediction results out of the three statistical metrics. Then, the final majority-voted prediction is a combination of the previous one with the Falcon and Mistral predictions.

Each prediction uses a separate classification-decision threshold, which is applied on prediction probabilities and statistical metrics. These **thresholds are calibrated in a per-language way**, meaning that separate thresholds are used for each language officially present in the train and dev sets, plus an additional threshold for unknown languages (i.e., not officially present in the train and dev sets). The thresholds are calibrated based on the machine-

System	Description
∗LLM2S3	The system described in this paper. It is an ensemble using two-step majority voting for predictions, consisting of 2 LLMs (Falcon-7B and Mistral-7B) fine-tuned using the train set only, 3 zero-shot statistical methods (Entropy, Rank, Binoculars) using Falcon-7B and Falcon-7B-Instruct for calculation of the metrics, utilizing language identification and per-language threshold calibration.
PLMoE	Our initial idea representing a per-language mixture of experts. It uses Electra-Large-Discriminator for English and XML-RoBERTa-Large for each of other languages officially present in the train and dev sets. Models for languages present in the dev set only are trained using the dev set. For unknown languages the Mistral-7B fine-tuned using the whole train set is used.
rLLM2S3	The same ensemble system as LLM2S3; however, the LLMs are fine-tuned using both the train and dev sets. Also, to increase the robustness of the system, we have obfuscated 20% of the train samples during fine-tuning, by using HomoglyphAttack and inserting zero-width-joiner character, inspired by our recent work (Macko et al., 2024).
rLLM2B-ES	The post-deadline ensemble system similar to rLLM2S3; however, the Llama-2-7B is used instead of Falcon-7B and Binoculars is used solely in the statistical part (instead of a combination of 3 methods). Moreover, the fine-tuning process used the early stopping mechanism to alleviate the over-fitting.
LLM2B1	The post-deadline ensemble system using the original LLM2S3 fine-tuned Falcon-7B and Mistral-7B models; however, classification thresholds are not calibrated, but only predictions with a probability of 1 (i.e., 100% confident) are marked as machine-generated. Such predictions are combined with Binoculars zero-shot prediction using the per-language threshold calibration.

Table 1: Description of system alternatives. The main system described in this paper is denoted by ∗. The last two alternatives were evaluated post-deadline.

class prediction probabilities and statistical metrics for samples in the train and dev sets combined. The calibration maximized the difference between true positive rate (TPR) and false positive rate (FPR) based on the ROC (receiver operating characteristic) curve. The texts with probabilities (or statistical metrics) outreaching the thresholds are considered machine-generated, otherwise they are considered human-written. The thresholds are saved and used for prediction of test samples.

Due to unknown languages in the test set and using the per-language threshold calibration, we have utilized the FastText[3] **language identification**. Since it is not fully accurate, we have used such language information only if the prediction probability was greater than 0.5, otherwise the language was handled as unknown.

As mentioned, the system includes **two fine-tuned LLMs**, namely Falcon-7B and Mistral-7B. For the fine-tuning process, we have used a parameter efficient fine-tuning (**PEFT**) technique called **QLoRA** (Dettmers et al., 2023) to minimize the computational costs of our system training.

To enhance the system performance generalization, we have integrated a **statistical part** of the system, which is based on the three statistical metrics, namely Entropy (Lavergne et al., 2008), Rank (Gehrmann et al., 2019), and recently proposed Binoculars (Hans et al., 2024). The statistical metrics are calculated using the Falcon-7B as a base model. Since Binoculars requires two models, it also uses Falcon-7B-Instruct (as a performer model).

Besides the described best submitted system, we have tried multiple system alternatives, which are briefly described in Table 1. In addition to those ensembles, we have evaluated single detectors, namely Falcon, Mistral, S5 (a combination of 5 statistical metrics – likelihood, entropy, rank, log-rank, and llm-deviation), and Binoculars. After the deadline, we have also finished fine-tuning of Llama-2-7B and retrained the detectors using the early stopping (patience of 5) to prevent overfitting. Also, when knowing the gold labels of the test set, we have evaluated various combinations of the trained detectors to see whether we have done the right decision for the submission.

4 Experimental Setup

For the experimental purpose, we have used the defaults splits of the provided dataset, namely the train and dev sets in the pre-deadline experiments, and the gold labels of the test set for the post-deadline evaluation of the pre-deadline system alternatives. The main system described in this paper uses only the train set in the training process; however, uses both the train and dev sets for the classification threshold calibration. Some of the

[3] https://pypi.org/project/fasttext-langdetect/

system alternatives used both the train and dev sets in the training process, as described in Table 1.

As the key evaluation metric in the shared task is **accuracy**, we have also used this metric for the preliminary system evaluation and selection of the alternative for submission. Since classification task is sensitive to the used classification threshold, we have also used **AUC ROC** (area under curve of the receiver operating characteristic) as a threshold independent metric, providing better information about the classification capability.

For the fine-tuning process, we have used the official baseline script[4], modified to export machine-class prediction probabilities in addition to the predictions. Since, it was not clear which version of the XLM-RoBERTa model was marked as a baseline in the multilingual track (with the known accuracy of 0.72), we have trained both the base (*XLM-R-B*) and large (*XLM-R-L*) versions. In addition, we have also included mDeBERTa-v3-base (*mDeBERTa*) model in our baselines, since it performed the best in our previous work (Macko et al., 2023).

To perform per-language models fine-tuning, we have used the source field of the train and dev data to select data only for the specific language. Other parameters of the fine-tuning process remained unchanged. The FastText language identification is used for a prediction, which uses the machine-class probability of the corresponding language-specific model.

The used QLoRA PEFT fine-tuning process used the binary cross entropy with logits for loss calculations and 4-bit quantization using BitsAndBytes[5]. The LoRA configuration[6] used an *alpha* of 16, a *dropout* of 0.1, *r* of 64, and the *task type* of sequence classification. Unlike the baseline fine-tuning, this version used half-precision training, gradient accumulation of 4 steps, and evaluation each 1,000 steps. Other parameters were the same.

Due to time constraints, we have not done any hyper-parameter optimization; thus, further improvements of the system are very likely possible.

5 Results

The experimental results are provided in Table 2. It must be noted that the results in the bottom part of the table are not part of the competition, since those experiments were performed after the submission deadline of the shared task. Also, the performance results using the test set were not known before the deadline; gold labels have been released only afterwards. Therefore, the design decisions could be made purely using the dev set.

Due to high accuracy and high AUC ROC metrics using the dev set, we considered *rFalcon* and *rMistral* over-fitted; therefore, we decided not to submit our *rLLM2S3* system. This turned-out to be a mistake, since it performed slightly better than the submitted *LLM2S3* on the test set. On the other hand, our suspicion of over-fitting *PLMoE* (due to the similar observations) turned-out to be valid, since it performed much worse using the test set. Therefore, it seems that per-language monolingually fine-tuned (i.e., lower amount of samples than multilingually fine-tuned) models require optimization of hyper-parameters to prevent over-fitting and to better generalize to unseen texts.

As an ablation study, we also provide the results for individual components of our system alternatives. As the results show, the ensembling into more complex systems of *LLM2S3* and *rLLM2S3* helped generalization of the classification performance. Individual methods would not outperform the submitted system.

5.1 Post-Deadline Study

In the post-deadline experiments (already knowing the gold labels of the test set for evaluation), we have finished Llama-2-7B model fine-tuning and retraining all three robust-version LLMs using the early stopping (to minimize the over-fitting). The results revealed that the *rLlama-2* model does not suffer by over-fitting as much. Based on the test set evaluation and by examining various combinations, the retrained *rLlama-2-ES* and *rMistral-ES* seemed like good candidates to combine with Binoculars (*rLLM2B-ES*), outperforming the winning system in the competition.

Early stopping helped a lot in boosting performance generalization (i.e., reducing over-fitting) of our per-language mixture-of-experts ensemble system (*PLMoE-ES*), achieving one of the highest AUC ROC using the test set. Nevertheless, in the accuracy as an official metric, it would not outperform the other system alternatives.

In addition, we have noticed that optimal thresholds for fine-tuned LLMs are often set to 1.0 by using purely the dev set samples machine-class

Table 2: Detection performance evaluated using the dev (pre-deadline) and test (post-deadline) splits separately. The main system described in this paper is denoted by ∗, the systems using the per-language threshold calibration are denoted by •, systems using fixed threshold of 1.0 are denoted by "1". "-ES" denotes using of early-stopping mechanism to prevent over-fitting. "N/A" denotes not available values due to prediction-based majority voting (i.e., no probabilities to calculate AUC ROC). The gray color denotes unrepresentative performance values due to training on the dev set.

probabilities. Therefore, we have fixed the thresholds to 1.0 for the *LLM2B1* system (containing only models we have trained before the deadline), meaning that the machine-class predictions of the LLMs are used only when having 100% confidence (otherwise considered human-written). Such predictions, when combined with Binoculars, achieved even higher performance using the test set data (0.9708). Thus, we had such a system trained before the deadline; however, we have not noticed such a threshold bringing the best performance in time. Moreover, when looking at the accuracy for the dev set, we do not see why we would select such a system for the submission. It can be just a coincidence that it performs so well using the test set data. Further experiments are required to examine this phenomenon using independent out-of-distribution data.

Also, even when our *rLLM2B-ES* system alternative or the *rMistral1* single-model system would win the competition, we are now not sure that we would be confident enough (about not being overfitted) to submit it as the final system without evaluation on the external dataset. Thus, we have submitted best what we could at the time.

5.2 Per-language Analysis

For a deeper insight of the proposed system (*LLM2S3*) performance, we have performed an analysis per each language identified in the test set. The results are provided in Figure 2. Interesting is that it achieved the highest accuracy for the Italian surprise language (*it*). Lower accuracy is evident for German and Arabic languages, although present in the dev set. It must be noted that this version of the system was not trained using the dev set, only the classification threshold calibration used such data. Therefore, the robust versions of system alternatives are expected to provide higher performance especially in those languages.

6 Conclusion

To cope with the problem of multilingual, multidomain, and multigenerator machine-generated text detection, we have proposed an ensemble sys-

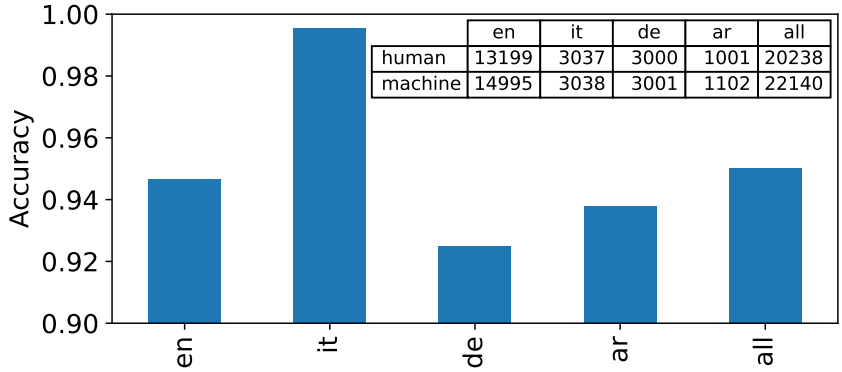

Figure 2: Per-language test-set performance (*it* is a surprise language, *de* and *ar* are in the dev set only). Axis scale for Accuracy is shown from 0.9 to 1.0. The per-class samples counts are provided in the top-right table.

tem using 2 LLMs (Falcon-7B and Mistral-7B) fine-tuned for the binary sequence classification task. We have further combined the predictions with the statistical metrics of Entropy, Rank, and Binoculars using a two-stage majority voting. The classification thresholds in our system have been calibrated in a per-language manner, for which we have utilized the FastText language identification. A combination of fine-tuned LLMs and statistical detection seems to be the right way to cope with generalization of the detection performance. Out of the evaluated single-model systems, Mistral-7B is the best candidate for fine-tuning, which by itself can bring a remarkable classification performance. Further improvements of the system could be easily achievable by hyper-parameters optimization, which we have not done in the submitted system due to lack of time.

A Computational Resources

For experiments regarding model fine-tuning and inference processes, we have used $1\times$ NVIDIA GeForce RTX 3090 24GB GPU and $1\times$ A100 40GB GPU, cumulatively consuming around 10,000 GPU-core hours. For combining the results and analysis, we have used Jupyter Lab running on 4 CPU cores, without the GPU acceleration.

Abstract

Detecting Machine-Generated Text (MGT) has emerged as a significant area of study within Natural Language Processing. While language models generate text, they often leave discernible traces, which can be scrutinized using either traditional feature-based methods or more advanced neural language models. In this research, we explore the effectiveness of fine-tuning a RoBERTa-base transformer, a powerful neural architecture, to address MGT detection as a binary classification task. Focusing specifically on Subtask A (Monolingual - English) within the SemEval-2024 competition framework[1], our proposed system achieves an accuracy of 78.9% on the test dataset, positioning us at 57th among participants. Our study addresses this challenge while considering the limited hardware resources, resulting in a system that excels at identifying human-written texts but encounters challenges in accurately discerning MGTs.

1 Introduction

Recent advancements in large language models (LLMs) have endowed them with an impressive capability to generate written text that closely resembles human writing (Adelani et al., 2019; Radford et al., 2019). However, this technological progress brings along significant challenges, as the proliferation MGT poses various threats in digital environments. MGTs have been implicated in spreading misinformation in online reviews, eroding public trust in political or commercial campaigns, and even facilitating academic fraud (Crothers et al., 2022; Song et al., 2015; Tang et al., 2023). The identification of MGT remains a pressing concern, as distinguishing between human-written and machine-generated content is often challenging for humans. Consequently, there is a growing imperative to develop automatic systems capable of discerning MGT (Mitchell et al., 2023). In this study, we address this challenge within the English language context using the dataset provided by Wang et al. (2023).

As highlighted in Wang et al. (2024b) overview paper on the task, recent approaches to MGT detection predominantly employ binary classification methods. Existing literature highlights the superior performance of transformer-based methods over alternative approaches Wang et al. (2024a). However, a significant challenge in utilizing these models lies in the requirement for GPU hardware and computational resources. Our study aims to address this challenge within the constraints of limited hardware capacity. Keeping this in mind, we propose a system that leverages fine-tuning of the RoBERTa transformer model (Liu et al., 2019) to automatically classify input text as either human-written or machine-generated. Our system architecture involves augmenting the RoBERTa-base model with a Classifier Head. The Embeddings component facilitates contextual understanding of texts, while the Encoder component processes input texts in parallel, and the Classifier Head performs binary classification by linearly outputting a single value.

Our proposed system achieves an accuracy of 78.9% on the test data, surpassing the average results provided by the task's baseline and ranking 57th among 140 participants. The area under the

[1] https://semeval.github.io/SemEval2024/

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 565–572

ROC curve (AUC) metric is measured at 0.69. While the ROC curve analysis demonstrates our model's capability to classify substantial portions of positive cases, its proximity to the diagonal line indicates room for further improvement. Notably, our primary challenge stemmed from computational constraints, which limited our ability to implement larger token sizes or batch sizes. Further discussions reveal that our system encounters difficulties in accurately detecting MGTs. To facilitate reproducibility and further research in this area, the code for our system is available on GitHub[2].

2 Background

2.1 Dataset Overview

SemEval-2024 Task 8 (Wang et al., 2024b) comprises three subtasks, with our investigation centering on Subtask A: binary classification of human-written versus MGT. Specifically, we concentrated our efforts on analyzing English monolingual data, as outlined dataset is provided by Wang et al. (2023).

Subtask A encompasses a dataset consisting of 119,757 training examples and 5,000 development examples, all presented in JSON format. Each data instance includes the following attributes:

- *id*: An identifier number for the example.
- *label*: A binary label indicating whether the text is human-written (0) or machine-generated (1).
- *text*: The actual textual content.
- *model*: The AI machine responsible for generating the text.
- *source*: The web domain from which the text originates.

2.2 Related Work

MGT detection is feasible through both traditional feature-based methods and neural language models. Fröhling and Zubiaga (2021) and Nguyen-Son et al. (2018) discussed how feature-based methods leverage statistical techniques. These methods primarily utilize frequency features such as TF-IDF, linguistic cues, and text style (Fröhling and Zubiaga, 2021). However, feature-based methods have limitations, as different samplings in language models can lead to varied generated outputs (Holtzman et al., 2019). In contrast, methods that harness neural language models, particularly those employing transformer models, have shown high effectiveness (Crothers et al., 2022). Neural language model methods often involve zero-shot classification or fine-tuning pre-trained language models (Sadasivan et al., 2023). Grover by Zellers et al. (2019), RankGen by Krishna et al. (2022), and DetectGPT (Mitchell et al., 2023) are prominent examples of zero-shot methods. However, these methods may be misleading at times and exhibit limited performance in out-of-domain tasks (Crothers et al., 2022; Wang et al., 2023).

Bakhtin et al. (2019) demonstrated outstanding performance in MGT detection by harnessing bidirectional transformers. Additionally, Solaiman et al. (2019) highlight that the zero-shot methods often fall short compared to a simple TF-IDF baseline when detecting texts from diverse domains. He argues that bidirectional transformers offer significant advantages for MGT detection, advocating for the fine-tuning of these models as a superior alternative to zero-shot methods. In this regard, Rodriguez et al. (2022) observed a significant enhancement in performance of cross-domain MGT detection by fine-tuning the RoBERTa detector.

Jawahar et al. (2020) conducted a comprehensive survey of various approaches to developing MGT detectors. Their findings suggest that fine-tuning the RoBERTa detector consistently delivers robust performance across diverse MGT detection tasks, surpassing the efficacy of traditional machine learning models and neural networks. Additionally, Crothers et al. (2022) reported a notable trend towards the increased utilization of bidirectional transformer architectures, particularly RoBERTa, in MGT detection tasks. Lastly, Wang et al. (2024a) conducted a comprehensive benchmark of supervised methods on M4 dataset. Their findings revealed that transformer models such as RoBERTa and XLM-R exhibited superior performance across all tests, respectively achieving 99.26% and 96.31% accuracy in MGT binary classification.

While this review does not provide a comprehensive examination of all aspects of

[2] https://github.com/Sharif-SLPL/Sharif-MGTD

MGT detection, prior research underscores the prevalence of transformer-base methods, like RoBERTa and XLM-R, in comparison to alternative approaches, especially in supervised tasks. Moreover, the superiority of RoBERTa over other models is evident. A significant challenge for studies utilizing pre-trained transformer models lies in the necessity for robust GPU hardware and computational resources.

3 System Overview

This section presents an overview of our system's architecture, highlighting implementation details and challenges. Drawing on the preceding works discussed above, which showed the efficacy of fine-tuning RoBERTa models, our system aims to attain peak performance in MGT detection while optimizing configurations for limited hardware resources.

The decision to employ the transformer architecture for detecting synthetic texts is motivated by its capacity to capture intricate dependencies within textual data. This choice seems logical considering that such texts often exhibit semantic features that can be harnessed for fact-checking, cohesion, coherence, and other properties that may unveil their origin (Raj et al. (2020). In contrast to traditional architectures, the transformer model overcomes the constraints of fixed window sizes or sequential processing, enabling it to utilize contextual information from the entire input sequence. Additionally, the self-attention mechanism empowers the model to selectively focus on pertinent segments of the input, rendering it highly effective for tasks necessitating long-range dependencies and contextual comprehension.

As for RoBERTa, it is specifically chosen for its extensive training duration, broader dataset coverage, ability to handle longer sequences, and focus on Natural Language Understanding tasks, making it more suitable than other BERT-based models. Additionally, a wealth of research, such as the recent study of Wang et al. (2024a), has further highlighted the inherent potential of RoBERTa for this specific task.

3.1 Core Algorithms and System Architecture

At the core of our system lies the concept of binary classification, distinguishing input texts as either machine-generated or human-written through fine-tuning a pre-trained RoBERTa transformer (Liu et al., 2019). Our system architecture entails augmenting the RoBERTa-base model with a Classifier Head. The RoBERTa model's Embeddings component incorporates a 768-dimensional embedding matrix, alongside position and token type embeddings, enhancing contextual understanding. The Encoding component features a 12-layer RoBERTaEncoder, each layer employing a multi-head self-attention mechanism. This facilitates simultaneous attention to different parts of the input text, crucial for analyzing textual similarities. Intermediate sub-layers utilize a fully connected feed-forward network with GELU activation, followed by an output sub-layer for feature transformation and normalization.

The Classifier Head, integrated into the Encoder for sequence classification, comprises a linear layer with 768 input features and a dropout layer to mitigate over-fitting. The final output is generated through an additional linear layer with a solitary output neuron, making it conducive to binary classification tasks. In essence, the primary model processes input data, with the Classifier Head making predictions. When viewed as a regression task, the Classifier produces a linear output tailored for a singular class, providing a probabilistic value. Implementation of the system is facilitated using PyTorch, incorporating specific parameters such as the AdamW optimizer (Radford and Narasimhan, 2018) and the CrossEntropyLoss function (Hui and Belkin, 2020). AdamW, renowned for training deep neural networks, integrates weight decay to mitigate over-fitting. The Cross Entropy Loss function, commonly employed in multi-class classification scenarios, combines softmax activation with negative log-likelihood loss. The training process involves iterating through the entire dataset for two epochs, with early stopping mechanisms in place to terminate training at the optimal point.

3.2 System Challenges

While larger machine-generated documents often exhibit more discernible patterns and clues, such as incoherence or repetition, they also entail substantial computational costs. Our primary challenge lay in efficiently processing these large documents using cost-effective computing systems. To mitigate this challenge, we explored strategies such as reducing token size and batch size. However, these adjustments necessitate trade-offs, potentially leading to reduced accuracy or

increased processing time.

Our system was trained using a token size of 512, but optimal performance could potentially be achieved with larger token sizes, such as 1024 or 2048, given sufficient computing resources.

4 Experimental Setup

4.1 Dataset

Table 1 presents detailed statistics on the dataset used for each class.

Class/Split	Train	Test	Development
Human-Written Text	57075	6276	2500
Machine-Generated Text	50706	5700	2500

Table 1: Dataset Statistics

As shown in Table 1, nearly 90% of the dataset is dedicated to training, while the remainder is used for evaluation. To enhance model performance, we utilized the entire development dataset for model selection, compensating for the scarcity of training data.

4.2 Pre-processing and Hyper-Parameter Tuning

Input texts are tokenized using the RoBERTa tokenizer before processing, both during training and inference. Our hyper-parameter tuning process involved a comprehensive exploration across various parameter ranges. Specifically, we conducted experiments with learning rates ranging from 0.0001 to 0.00004, dropout rates spanning from 0.1 to 0.3, batch sizes varying between 4 and 16, and token sizes ranging from 64 to 1024. Through experimentation and analysis, we determined the optimal hyper-parameter settings, which are as follows: a learning rate of 0.00004, a dropout rate of 0.1, a token size of 512, a batch size of 10, and a weight decay of 0.01. Further details are given in Appendix A.

As illustrated in Appendix A, the number of training instances is correlated with the input token size and may influence the model accuracy. Given the length of input texts, a suitable token size is essential to capture all tokens adequately. However, computational costs associated with larger token sizes present a significant challenge during model training. Consequently, we selected 512 as the optimal token size. Truncation was employed during tokenization to accommodate the chosen token size, ensuring efficient model training without compromising data representativeness.

4.3 Training Procedure

For training the model, we utilized the Task dataset Wang et al. (2023), which underwent preprocessing by tokenizing the text into sub-word units and padding sequences to a fixed length. CrossEntropyLoss was employed as the loss function. The implementation also involved the AdamW optimizer, known for its effectiveness in training deep neural networks and its incorporation of weight decay to address over-fitting. The Adam optimizer was utilized with a learning rate of 4e-05. During training, the loss was monitored on a held-out validation set, and early stopping was applied to prevent over-fitting. Early stopping was implemented with the condition that the training loss reached a specific threshold (0.35 in this case), typically occurring around the third epoch. Therefore, if there was no improvement in the validation loss for a certain number of epochs, training was halted to prevent over-fitting of the model.

4.4 Evaluation Measures

The evaluation of our model involves calculating its accuracy in predicting whether a text is human-written or machine-generated. Accuracy, a fundamental metric in classification tasks, assesses the overall correctness of predictions and is calculated as:

$$Accuracy = \frac{ni}{N} \times 100 \quad (1)$$

where n_i represents the number of correctly classified instances, and N is the total number of instances.

5 Results

Using the official accuracy metric of SemEval-2024 Task 8 (Wang et al., 2024b), our system achieved the following accuracy scores on different data splits:

Language /Split	Devset	Testset
English	74.8%	78.9%

Table 2: Accuracy Metric

A direct comparison of our results with prior works is challenging due to the unique nature of

our research. To the best of researchers' knowledge, the most comprehensive benchmark on supervised MGT detection is presented by Wang et al. (2024a) using the M4 dataset and employing RoBERTa, XLM-R, GLTR-LR, GLTRSVM, Stylistic-SVM, and NELA-SVM. However, our primary objective was to determine strategies for addressing limited hardware resources as discussed in Appendix A.

As a contribution to this field, through repeated experiments, we identified that among hyperparameters, token size plays a slightly more significant role in model accuracy. While the system's accuracy is influenced by increasing the token size, drawing meaningful scientific conclusions necessitates further controlled experiments. Additionally, the expansion of token size is restricted by hardware limitations, requiring a detailed investigation with robust computational resources like GPU or TPU. Considering the constraints of Google Colab's[3] Free runtimes, we opted for a token size of 512 as a balance between hardware limitations and time constraints. Consequently, based on the official accuracy metric of SemEval2024 Task 8 (Wang et al., 2024b), our system achieved the following accuracy scores on various data splits:

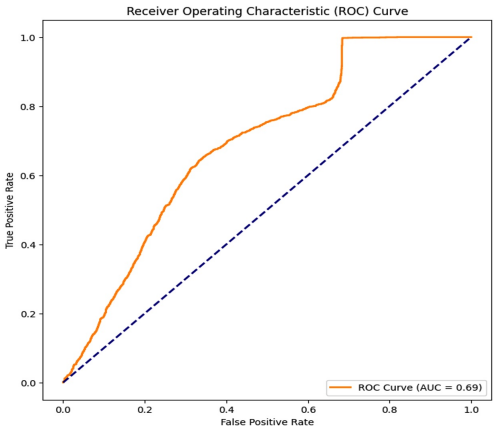

Figure 1: The ROC Curve Plot

The evaluation of our model also included analysis of the Area Under the Curve (AUC), a crucial metric that reflects the discriminative power of a binary classification model. Our fine-tuned RoBERTa model demonstrated an AUC of 0.69, suggesting its ability to effectively distinguish between positive and negative instances. Figure 1 illustrates the Receiver Operating Characteristic

[3] https://colab.research.google.com

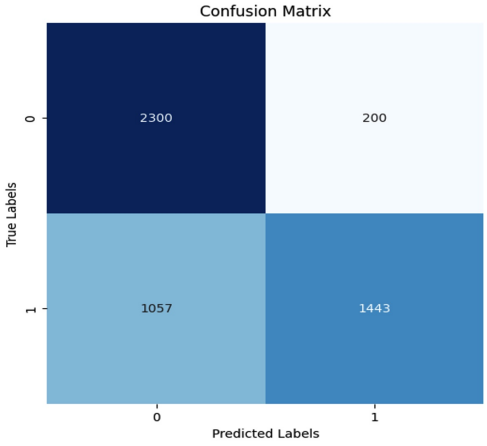

Figure 2: The Confusion Matrix Plot

(ROC) Curve, depicting the model's capability to accurately classify a significant proportion of positive cases. However, the proximity of the curve to the diagonal line suggests opportunities for further enhancement.

Interestingly, analysis of the confusion matrix, as depicted in Figure 2, revealed notable patterns in our model's classification tendencies. While our system effectively identified human-written documents with low False Positives, it exhibited difficulties in correctly identifying MGTs. This observation suggests potential areas for refinement, particularly in enhancing the model's ability to detect subtle cues and characteristics unique to machine-generated content.

Overall, our study contributes to the ongoing efforts in the field of NLP by showcasing the effectiveness of fine-tuned transformer models, particularly RoBERTa, in MGT detection tasks. Moving forward, future research directions could explore novel approaches to mitigate computational costs and further improve the performance of MGT detection systems, ultimately advancing the capabilities of NLU models in real-world applications.

6 Conclusion

In summary, our study focused on fine-tuning a RoBERTa-base transformer model for binary classification, specifically in distinguishing human-written from MGT. While our system showed promise in identifying human-written text, it faced challenges with accurately classifying machine-generated content. As discussed in Appendices A and B, we recommend exploring larger token sizes to improve model performance, albeit with

awareness of computational costs. Additionally, we advocate for the development of low-cost algorithms capable of efficient processing across hardware platforms. Our findings contribute to advancing MGT detection, with implications for combating misinformation and enhancing cybersecurity in the digital age.

Acknowledgments

We appreciate the Speech and Language Processing Laboratory at Sharif University of Technology[4] for providing us with this opportunity for collaborative work.

A Hyper-Parameter Tuning

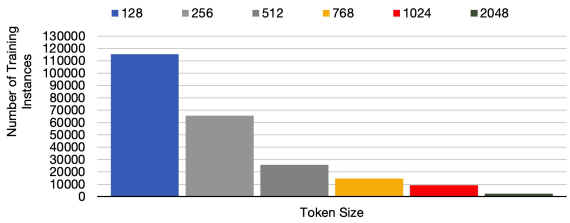

Figure 3: Number of Training Instances by Token Size

To determine the appropriate settings for hyper-parameters, we utilized Google Colab's free GPU runtime. Free Colab users have access to GPU and TPU runtimes without charge for a maximum of 12 hours. The GPU runtime includes an NVIDIA Tesla K80 with 12GB of VRAM. [Date: 5 Dec 2023]. We were unable to use premium runtime accounts due to financial issues arising from Iran sanctions. Therefore, we couldn't change our model's token size to larger than 512 due to the 12-hour time limit in free Colab. To understand the impact of increasing token size, we aimed to experiment on a local laptop GPU.

During the experiments aimed at finding the proper token size, we encountered the "CUDA error: device-side assert triggered" frequently, which was resolved by restarting the session. Our experiments were conducted using an RTX 2060 mobile with 6 GB of VRAM. Throughout all experiments, we maintained fixed parameters, including Number of Epochs = 3, Train Split = 0.7, and Learning Rate = 4e-05. Increasing the Max Length from 512 to 1024 in this experimental setup resulted in an improvement in Test Accuracy by at least 2%. However, this enhancement came at the cost of a nearly 15-fold decrease in training speed, making it challenging to implement on limited hardware. Additionally, this requires plenty of controlled experiments by researchers to shed light on finding the proper hyper-parameters.

B Detect-GPT as a Zero-Shot Method

In our pursuit of effective MGT detection, we also experimented with Mitchell et al. (2023)Detect-GPT model, a zero-shot approach utilizing probability curvature analysis. Training the model resulted in an accuracy rate of 60%, and when applied to a test dataset of approximately 1500 samples, it achieved a remarkable accuracy of approximately 84%. We conducted a comprehensive analysis by implementing 10 perturbations for each dataset. To address data and mask filling tasks, we employed the T5 small model, leveraging its robust capabilities. Furthermore, to accurately assess the log likelihood, we utilized the GPT-2 model, ensuring precise calculations and reliable results.This method surpassed alternative text detection methodologies, demonstrating superior accuracy and reliability in identifying MGT. Notably, the inclusion of threshold configuration added granularity to the experiment, enabling fine-tuning of detection sensitivity across varying threshold settings.

IRIT-Berger-Levrault at SemEval-2024: How Sensitive Sentence Embeddings are to Hallucinations?

Abstract

This article presents our participation to Task 6 of SemEval-2024, named SHROOM (*a Shared-task on Hallucinations and Related Observable Overgeneration Mistakes*), which aims at detecting hallucinations. We propose two types of approaches for the task: the first one is based on sentence embeddings and cosine similarity metric, and the second one uses LLMs (Large Language Model). We found that LLMs fail to improve the performance achieved by embedding generation models. The latter outperform the baseline provided by the organizers, and our best system achieves 78% accuracy.

1 Introduction

In recent years, with the emergence of the foundation models, the generation of hallucinated text has become an increasingly prominent and alarming issue. Despite the state-of-the-art performances achieved by the latest text generation models, such as GPT-4 (Achiam et al., 2023) or Llama 2 (Touvron et al., 2023), the problem of hallucinations remains open, making these models challenging to apply in real-world applications.

Hallucination is defined as a segment of text that appears fluent and natural but contains incoherent and inconsistent information compared to the provided context (Ji et al., 2023). The problem of hallucinations appears in several NLG tasks such as text summarization (Cao et al., 2021; Zhang et al., 2022) and machine translation (Xu et al., 2023). The shared-task Shroom[1] falls within the scope of these tasks.

The aim of Shroom is to identify samples containing hallucinations with regard to the provided context through a binary classification. The task is established in a post hoc setting, where models have already been trained to generate text based on the provided context. Three text generation tasks are considered: machine translation (MT), paraphrasing generation (PG), and definition modeling (DM). One can find in Table 1 a sample of data for the Machine Translation task. Participants should find the *label* of the *hypothesis* that was generated by the model, given the *target* or the *source*. For instance, here the aim is to determine if the hypothesis (*I've got the floor and the furniture.*) is a hallucination given the source (*J'ai poli le plancher et les meubles.)* or the target (*I polished up the floor and furniture.*). In this example, the hypothesis is labeled as hallucination (*label*) with regard to the assessments made by 3 annotators (*labels*).

Source : J'ai poli le plancher et les meubles.
Target : I polished up the floor and furniture.
Hypothesis : I've got the floor and the furniture.
Ref : Either
Labels : [Hallucination, Hallucination, Hallucination]
Label : Hallucination
p(hallucination) : 1.0

Table 1: Data sample

The binary classification can be performed in two different tracks: the model-aware and model-agnostic tracks. In the model-aware track, the checkpoint of the model that generated the hypothesis is provided and can be used in the classification system, which is not the case for the model-agnostic track. For more information on task 6 of SemEval-2024 Shroom as described by its organizers, we invite the reader to consult the paper by (Mickus et al., 2024).

In the literature, detecting hallucinations in sentences mainly relies on comparing segments of text. Among these approaches, one can cite those based on named entities (Nan et al., 2021): the idea is to determine if the generated text contains incon-

[1] https://helsinki-nlp.github.io/shroom/

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 573–578

sistent entities compared to the source. Other approaches are based on question-answering methods, where the aim is to answer a set of questions and evaluate the difference between the two texts (Wang et al., 2020). However, data provided for the Shroom task are of a particular nature as it consists of very short texts, composed of one or two concise sentences. This characteristic limits the use of several detection methods, such as those based on named entities, since they are very rare in these texts. The same goes for question-answering methods. This observation has led us to turn to simpler methods, involving capturing the semantics of sentences in a general way.

In this paper, we present the two lines of approaches we investigated for the task:

- The first one is based on embedding models. We solve the hallucination classification task using the cosine similarity metric between sentence embeddings of the reference and hypothesis (see Section 4.1),
- The second one relies on Large Language models with specified prompts to classify the generated text that contains hallucinations. We use Llama 2 and Mistral using 2 different prompts inspired by SelfCheckGPT (Manakul et al., 2023).

Our sentence embedding approaches outperformed our LLM ones. The former have proven to be very relevant given the shortness of the sentences and the low risk of losing information. Our best performing system obtained the accuracy of 78% in both tracks which puts us in position 22/48 in the model-agnostic track and 22/45 in the model-aware track.

2 Related Work

Approaches in the literature can be classified depending on the hallucinatory content to detect (Ji et al., 2023). Some works focus on the detection and comparison of existing entities between the context and the generated hypothesis, such as (Nan et al., 2021). They are based on the assumption that human brain is sensitive to different types of information, such as named entities and proper nouns when reading, and mistakes concerning named entities are striking to human users (Ji et al., 2023). (Feng et al., 2023) go further by evaluating facts (entities and relations). Another line of works focuses on the use of question-answering as an indicator to identify hallucinations (Wang et al., 2020; Scialom et al., 2021), or the use of text entailment, which consists in determining whether the generated text is a hallucination if it cannot be entailed by the source (Falke et al., 2019).

Other approaches focused on the classification of hallucination types (whether they are intrinsic or extrinsic (Maynez et al., 2020)), or factual or non-factual (Cao et al., 2021).

Large Language Models have also been used to determine whether the generated text contains hallucinatory content. The aim of these methods is to set up prompts to compare the sources and the hypotheses (Manakul et al., 2023; Chern et al., 2023). Other methods make specific prompts to ask the LLM to "think" and judge whether a given text contains hallucinations, justifying its answer by producing a chain-of-thought (CoT) explanation (Friel and Sanyal, 2023).

In this paper, we explore a simpler method that consists in calculating the embeddings of the hypothesis and the reference, and computing their semantic similarity using the cosine similarity metric. Contextual embeddings have been successfully used in various NLP tasks, such as sentiment analysis (Carrasco and Dias, 2023) or topic modeling (Schneider, 2023). Our underlying idea here is to see how sensitive the semantic similarity is to the hallucinated content in sentences and to what extent the cosine similarity metric reflects this sensibility.

3 Data Description

The organizers of Shroom provided data from 3 different NLG tasks : Machine Translation, Paraphrasing Generation, Definition Modeling. Each task is divided into two tracks: model-aware track and model-agnostic track. We were provided 5 datasets in the development phase : train-aware, train-agnostic, trial, dev-aware and dev-agnostic, containing 30000, 30000, 80, 501 and 499 samples respectively and 2 different test datasets in the evaluation phase: test model-aware and test model-agnostic, containing each 1500 samples.

For each sample, the model-generated hypothesis was annotated by 3 (trial dataset) or 5 different annotators (dev and test datasets) (*labels* in Table 1). Annotators were asked to assess whether the generated hypothesis was consistent with the reference and to provide a label {hallucination, not-hallucination}. At the end of the annotation process, the most preponderant label is chosen as the

final label (*label* in Table 1), with an assigned probability corresponding to the proportion of annotators who considered this specific datapoint to be an hallucination (*p(hallucination)* in Table 1).

4 System Overview

As the training dataset provided by organizers is not labeled, we decided to experiment unsupervised approaches, either using sentence embeddings or LLMs.

4.1 Embedding-Based Approach

We first generate the contextual embeddings of the reference and the hypothesis. For the paraphrasing generation task, we consider the source as the reference, while for the other two tasks, the target is taken as the reference. Next, we calculate the cosine similarity between these two embeddings. If this similarity does not exceed a predefined threshold, we assign the label "hallucination". We evaluated various embedding models namely Sentence-T5 XL (Ni et al., 2021), a specialized variant of the T5 model designed specifically to generate representations of sentences; BGE-base; BGE-large (Xiao et al., 2023); E5-base; E5-large and SF E5 (Wang et al., 2022). We compared their performances to determine their effectiveness in our task using different cosine similarity thresholds (see Section 5.2). This comparison enabled us to select the most appropriate model with the cosine threshold that maximizes the classification accuracy.

Participants were also asked to estimate a probability of the predicted labels. To estimate this probability, we apply an empirical rule. Let t be our threshold, $cossim$ the value of the cosine similarity, l our predicted label et $p(l)$ the probability of hallucination. Algorithm 1 details the rules we applied.

The idea behind this rule is that the further we are from the cosine similarity threshold, the more certain we are that the hypothesis generated by the language model is a hallucination.

4.2 LLM-Based Approach

We tested two LLMs, Llama-2-13b (Touvron et al., 2023) and Mistral-7b (Jiang et al., 2023), with 2 different prompts inspired by SelfCheckGPT (Manakul et al., 2023). This enabled us to make a direct comparison with the baseline system given by the organizers, which is based on a variant of Mistral fine-tuned with the same first prompt we used.

Algorithm 1 Hallucination Probability Estimation

if $cossim \geq t$ **then**
  $l \leftarrow Not\ Hallucination$
  if $cossim \leq t + \epsilon$ **then**
    $p(l) \leftarrow 0.33$
  else
    $p(l) \leftarrow 0.0$
  end if
else
  $l \leftarrow Hallucination$
  if $cossim \geq t - \epsilon$ **then**
    $p(l) \leftarrow 0.66$
  else
    $p(l) \leftarrow 1.0$
  end if
end if

As our method uses only the generated hypotheses and the references to detect hallucinations, we used a single model for both model-aware and model-agnostic tracks.

5 Experiments and Results

5.1 Experimental Setup

For all the models used, we retrieved the checkpoints from the HuggingFace website [2].

- For the embedding-based approach, we experimentally fix ϵ to 0.05 (see Algorithm 1) using the dev-set. t is also fixed experimentally. Experiments conducted to determine its value are detailed in section 5.2.

- For the LLMs approach, we use the Langchain framework [3] to set up the prompts and query the LLMs. Table 2 describes the two prompts we used. Prompt 1 is directly taken from SelfCheckGPT's system (Manakul et al., 2023) which serves as Baseline. The idea of the work of (Manakul et al., 2023) is to ask the LLM an explicit and simple question. They show that with this kind of prompts, LLMs better understand the task they are asked to perform. With regard to prompt 2, we wanted to experiment whether introducing the concept of "hallucination" in the prompt and specifying its definition helps the LLM better classify.

Prompt 1 (Manakul et al., 2023)	Context:{} Sentence:{} Is the Sentence supported by the Context above? Answer using ONLY yes or no:
Prompt 2	Context:{} Sentence:{} Is the Sentence a hallucination (which means it contains inconsistent or incoherent information) compared to the Context above? Answer using ONLY yes or no:

Table 2: Prompts used to perform the binary classification.

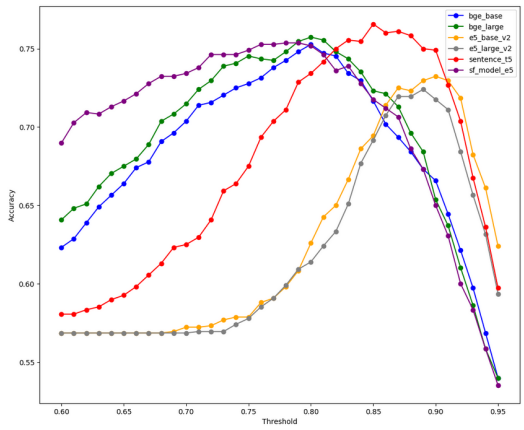

Figure 1: Variation of the threshold of the cosine similarity metric maximizing the accuracy of the classification system as a function of the models over the Trial and Dev datasets.

5.2 Preliminary Experiments

In this section, we describe the experiments made to determine the threshold of the cosine similarity metric that maximizes classification accuracy (t in Algorithm 1). We defined an interval ranging from 0.6 to 0.95. Then, for each value of the interval by step of 0.01, we performed the classification and calculated its accuracy. This experimentation was conducted on the 3 labelled datasets, namely trial, dev-aware and dev-agnostic. The graph in Figure 1 shows the evolution of accuracy as a function of the cosine similarity threshold used to define hallucination. We can see that the models behave in a similar way: accuracy rises progressively with the threshold values used, reaching a peak around the [0.78, 0.9] interval. We can also see that for the models for which we used two variants as BGE-base, BGE-large as well as E5-base and E5-large, the behavior of the variants is almost identical with a few small differences. Table 3 reports the selected threshold for each model applied on the test dataset in the evaluation phase.

5.3 Results

Two evaluation metrics are used for the task: the accuracy of the classification and the Spearman correlation of the system's output probabilities with the proportion of the annotators marking the item as hallucinated. The official ranking was made on the basis of the accuracy, with a tie-breaker between systems having obtained the same score using the Spearman correlation. As we did not provide classification probabilities for the LLMs approach, we only report them for the embedding-based approach.

Table 3 shows the results we obtained with the different embedding models submitted. We can see that all the models exceed the baseline on the two metrics used, with the best performance coming from the Sentence-T5 model. Given that the baseline consists in the use of an LLM with a prompt, we can say that the embedding models used with the right threshold distinguish fairly well between hallucinated and non-hallucinated hypotheses compared to LLM with the used prompts. Since organizers published official results and released the test sets, we re-ran our experiments varying t, threshold used with the cosine metric. The results, not reported here, are consistent with those of the trial and dev collections. This leads us to believe that our approach of threshold selection is robust.

Table 4 shows the results obtained with the LLMs we used. We can see that they do not perform as well as the embedding models, and do not exceed the baseline. Regarding the prompts we used, no conclusion can be drawn for the moment. Further experiments are required.

With the scores obtained by the sentence-T5 model, we were ranked 22/45 and 22/48 in the model-aware and model-agnostic tracks respectively. It is worth noting that the first half of the ranking is extremely tight. It often takes 4 decimal digits to separate the accuracy of the various participants.

6 Conclusion

In this paper, we summarize our participation to task 6 of the SemEval-2024 evaluation campaign:

Model	Value of t for Aw	M-Aw	SC-Aw	Value of t for Ag	M-Ag	SC-Ag
Baseline	/	0.745	0.487	/	0.696	0.402
Best system	/	0.812	0.699	/	0.847	0.769
Worst system	/	0.483	-0.06	/	0.460	0.133
BGE-Base	0.77	0.750	0.552	0.79	0.754	0.563
BGE-Large	0.77	0.766	0.569	0.78	0.766	0.581
E5-Base	0.87	0.742	0.494	0.90	0.748	0.531
E5-Large	0.87	0.754	0.510	0.89	0.751	0.525
Sentence T5 XL	0.86	**0.781**	**0.601**	0.85	**0.782**	**0.636**
SF E5	0.75	0.758	0.523	0.79	0.762	0.540

Table 3: Results obtained (accuracy (M) and Spearman correlation (SC)) with each embedding model using the selected threshold, in comparison to the Baseline, best and worst submitted systems. Results are reported for the model-aware (Aw) and model-agnostic (Ag) tracks.

Model	M-Aw	M-Ag
Llama-2-13b-chat Prompt 1	0.618	0.557
Llama-2-13b-chat Prompt 2	0.555	0.536
Mistral-7b-instruct Prompt 1	0.627	0.519
Mistral-7b-instruct Prompt 2	0.676	0.618

Table 4: Results obtained (accuracy M) for each LLM with the two prompts used. Results are reported for the model-aware (Aw) and model-agnostic (Ag) tracks.

Shroom. We presented two different approaches: one based on the use of embedding models with a cosine similarity threshold to perform the binary classification, and the other based on LLM using simple prompts to detect hallucinatory content. We showed that on the data used for the task, embedding generation models perform better than LLMs. In future work, we will explore this approach a little further, by fine-tuning the models used for instance.

Abstract

This study explores Task 2 in NumEval-2024, which is SemEval-2024(Semantic Evaluation) Task 7 , focusing on the Reading Comprehension of Numerals in Text (Chinese). The dataset utilized in this study is the Numeral-related Question Answering Dataset (NQuAD), and the model employed is BERT. The data undergoes preprocessing, incorporating Numerals Augmentation and Feature Enhancement to numerical entities before model training. Additionally, fine-tuning will also be applied. The result was an accuracy rate of 77.09%, representing a 7.14% improvement compared to the initial NQuAD processing model, referred to as the Numeracy-Enhanced Model (NEMo).

1 Introduction

Numeric information holds a crucial significance within narratives across various domains, including medicine, engineering, and finance. (Chen et al., 2021) Numerals presented in tables (Ibrahim et al., 2019) and the content (Lamm et al., 2018) of a document have garnered considerable attention from researchers. Machine-based numeral comprehension stands out as an emerging research area, still in its nascent stages. NumEval-2024 Task 2(SemEval-2024 Task 7) focus on reading comprehension of the numerals in text, models are required to identify the correct numerical value from four given options, based on a provided news article. The dataset utilized for this task is NQuAD (Chen et al., 2021), which is in Chinese.

The initial model devised for addressing this task is referred to as the Numeracy-Enhanced Model (NEMo), which achieves an accuracy of 69.95%.(Chen et al., 2021) In this study, a pre-trained BERT model will be employed to undertake the task, with the objective of enhancing accuracy through data preprocessing, Numeral Augmentation, Feature Enhancement, and fine-tuning. [1]

[1]†Contact Author

The remaining sections of this study are structured as follows: In the second section, we delve into a discussion of the data and its preprocessing. The data undergoes denoising through the removal of special symbols.

Moving on to the third section, we thoroughly examine the methodology employed, the results obtained, and the subsequent discussion. The data undergoes further denoising through stop word removal. Additionally, numeral augmentation and feature enhancement are introduced. Numeral augmentation reduces dependence on specific numerical values, while feature enhancement aims to compel the model to pay attention to numerals. As a result, our model achieves an accuracy of 77.09% on the NQuAD dataset.

The concluding section presents a summary of the insights gained, along with considerations for future research endeavors. Although the model is performing well, there are opportunities for further enhancement. We will delve into these matters in the Error Analysis and Discussion section.

2 Data Preparation

2.1 Data Source

The dataset employed in this study is the Numeral-related Question Answering Dataset (NQuAD). This dataset poses greater challenges compared to numeral-related questions in other datasets. All data were sourced from news articles spanning the period from June 22, 2013, to June 20, 2018, encompassing a total of 75,448 Chinese news articles. Notably, 59.74% of news headlines include at least one numeral, while numerals are present in 99.80% of news contents. The dataset comprises 43,787 news articles and 71,998 questions.(Chen et al., 2021)

The NQuAD dataset encompasses six columns: "news_article","question_stem","answer_options", "ans","target_num" and "sentences_containing_the

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 579–585

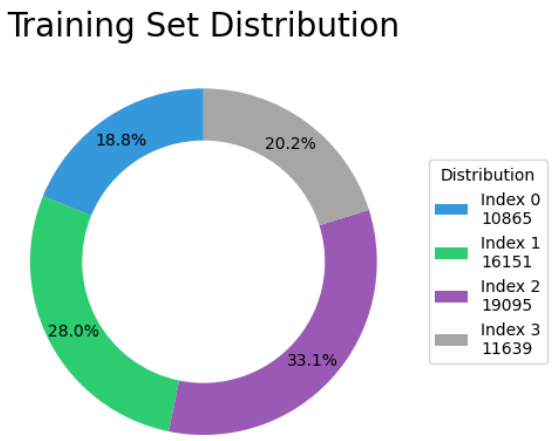

Figure 1: Training Set Distribution

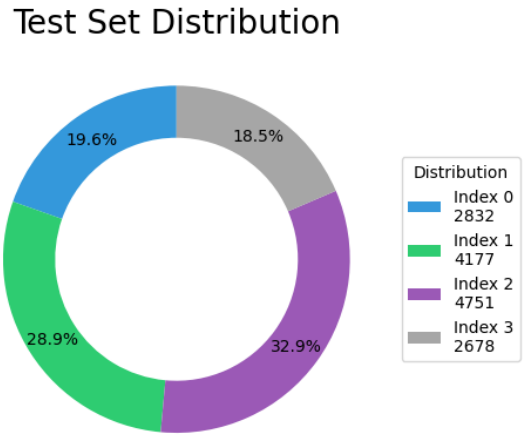

Figure 2: Test Set Distribution

_numeral_in_answer_options". The "news_article" column contains the content of the article, while the "question_stem" column represents the questions posed. The "answer_options" column consists of a list of four answer choices, with the "ans" column indicating the index of the correct answer within the "answer_options." The "target_num" column contains the content of the correct answer, and the "sentences_containing_the_numeral_in_answer_options" (scao) is a list of sentences in the article that include the correct answer.

NQuAD provides both a training set and a test set. The training set comprises 57,750 samples, while the test set includes 14,438 samples, maintaining an approximate 8:2 ratio. The distribution of the four categories varies within the training set, encompassing 10,865 instances where the correct answer index is 0, 16,151 instances for index 1, 19,095 instances for index 2, and 11,639 instances for index 3. In the test set, there are 2,832 instances with the correct answer index at 0, 4,177 instances at index 1, 4,751 instances at index 2, and 2,678 instances at index 3. The data depicted in Figure 1 and Figure 2 reveals that approximately 20% is attributed to both index 0 and index 3, while around 30% is associated with both index 1 and index 2.

2.2 Data Preprocessing

The dataset used in this study, NQuAD, provides the "scao" column, which constitutes a list of sentences within the article containing the correct answers. A new column, denoted as "article", is formed by combining the contents of the "scao", "question_stem" and "answer_options" columns. The "article" column serves as the input for the model. Additionally, the "ans" column, representing the index of the correct answer within the "answer_options" column, is employed to generate a new column named "label". The "label" column functions as the output for the model.

After creating the new input column "article", the content of the "article" column undergoes preprocessing. Special symbols such as "[# &" are removed, taking care not to eliminate symbols that may affect the semantics, such as "+ - . % $". Subsequently, HTML tags are removed, along with excess whitespaces within sentences. Finally, commas in numbers are removed, for instance, in cases like "1,000", to facilitate subsequent batch processing.

Please be aware that pre-processing will be applied to both the training set and the test set.

3 Method

In this study, the pretrained BERT model served as the baseline. To enhance model performance, two steps were implemented. First, BERT with stop word removal (BERT-SWR) was introduced. This step contributes to improved model performance through Dimensionality Reduction, Noise Reduction, and Enhanced Generalization. Building upon BERT-SWR, additional measures were taken, including numerals augmentation and feature enhancement(BERT-NAFE). Numerals in the text were replaced with a special symbol and the corresponding answer index. This substitution aimed to eliminate the model's consideration of the meaningless numerical values in the article. The use of the special symbol, represented as cashtag, compelled the model to prioritize attention to

the numerals within the text. This additional step further increased the model's accuracy. Please be aware that prior to evaluation, fine-tuning was applied to each model.

3.1 BERT

A pretrained BERT model was used as the baseline model. The complete designation for BERT is Bidirectional Encoder Representations from Transformers, a bidirectional unsupervised language representation model based on transformers, initially introduced by Google. It undergoes predominantly pre-training through the application of both the Masked Language Model (MLM) and Next Sentence Prediction (NSP) techniques. In contrast to word2vector (Pennington et al., 2014) and GloVe (Mikolov et al., 2013), which operate without considering context, BERT exhibits the capability to leverage contextual information during inference. This contextual understanding contributes to its superior performance across diverse tasks (Devlin et al., 2019).

3.2 Stop Word Removal

The preprocessing technique known as removing stop words in natural language processing (NLP) is intended to exclude commonplace yet generally uninformative words, such as "和", "你", "而是", etc., from the textual content. By eliminating these words, low-level information is excluded from the text, enabling a heightened emphasis on crucial information. This step is undertaken with the aim of enhancing model performance.

In this study, a tokenizer named jieba (Sun, 2020) was employed to segment the sentences. A stop-word list sourced from Sichuan University (goto456, 2019) was utilized to determine phrases that should be eliminated. The Python OpenCC package is employed to perform the translation from simplified Chinese to traditional Chinese for the stop-word list. For example, let's examine a phrase: "而是前一世代的iPhone 6s." Subsequent to the processing, the term "而是" is eliminated, resulting in the refined expression "前一世代的iPhone 6s."

3.3 NA and FE

3.3.1 Numerals Augmentation

Reducing the model's excessive reliance on specific numerical values and addressing numerical ambiguity are pivotal objectives in Numeral Augmentation for tasks related to Numeral Reading Comprehension.

擬每股配息___元 ,
0 , 1 , 2 , 3

Figure 3: artical after NAFE pre-processing.

In this study, each answer's numeral will be replaced by its corresponding index, ranging from 0 to 3. By addressing these aspects, Numeral Augmentation contributes to enhancing the model's robustness and interpretative capabilities when confronted with diverse numerical contexts in reading comprehension tasks. For example, as illustrated in Figure 3, the numerical values in the answer options were replaced with their corresponding indices. Upon examining the processed article, the numbers 0, 1, 2, and 3 were underscored, indicating the replacements for the actual answers in the article.

3.3.2 Feature Enhancing

In this study, Feature Enhancement has been applied to numerical values. Specifically, the digits representing the answers in the text are augmented with cashtag both preceding and following them. Due to the attention mechanism of the model, there is a likelihood that attention may concentrate in the vicinity of these markers, thereby directing the model to place increased emphasis on processing the content surrounding the markers. This, in turn, enhances the model's capability for recognizing numerical. For instance, as demonstrated in Figure 3, ashtag were added both before and after the replaced answer. This step involves referencing the Tokenization Tricks presented in (Jiang et al., 2020).

3.4 Fine-tuning

Fine-tuning refers to the process in deep learning where a pre-trained model is utilized and further trained to adapt to specific tasks or domains. In this study, models based on BERT have undergone fine-tuning to enhance their ability to recognize numerical content in articles. The scrutinized parameters are delineated in Table 2. Further elaboration on these details will be provided in the Experimental Setup section.

3.5 BERT-NAFE

The optimal model in this study is BERT-NAFE. Details will be discussed in this section. Commencing with the data, symbols were eliminated during the data pre-processing, resulting in a refined dataset suitable for model training and evaluation. Expanding upon the foundational BERT model, the removal of stop words was implemented, resulting in a significant 3% increase in accuracy. Additionally, Feature Enhancement was employed, followed by Numerals Augmentation. During Numerals Augmentation, numerals were substituted with their index in the answer list, while being omitted from the article text. Cashtag were inserted before and after the substituted numeral as part of Feature Enhancement. This procedural refinement led to a notable 6% boost in accuracy and was shown to be the most effective in enhancing overall performance.

4 Experimental setup

4.1 Environment

The experimental setup is adaptable to both Google Colab and local environments. For local setup, a minimum of 6GB of GPU memory is necessary for model fine-tuning. The versions of each tool employed in the experiment will be detailed in the accompanying Table 1.

Parameters	Values
python	3.9.18
tensorflow	2.10
cudatoolkit	11.2
cudnn	8.1.0
ktrain	0.40.0

Table 1: Tools Versions Employed in the Experiment.

Parameters	Values
BERT Model	base
Batch size	3
Max length	250
Max learning rate	2e-5
epochs	2

Table 2: Parameters Value of Model Training.

4.2 Hyperparameter

For the fine-tuning parameters, a batch size of 3 and maximum sequence length of 250 were utilized in order to reduce computational expenses during fine-tuning. A max learning rate of 2e-5 was adopted based on hyperparameter tuning performed using the Ktrain learner. This approach was taken to identify the optimal learning rate, as visualized in Figure 4.

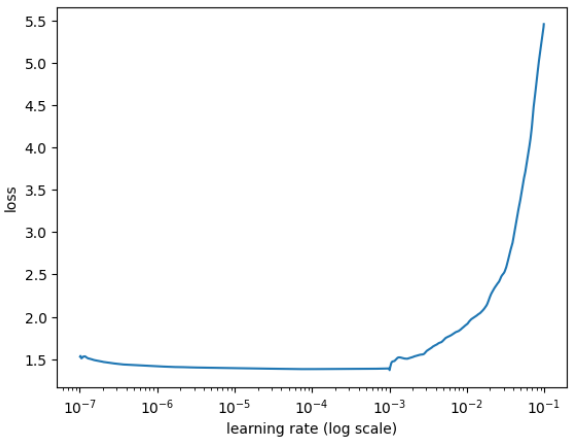

Figure 4: The loss vs. learning rate chart for finding best learning rate in our training processing experiment.

An assessment of validation performance across epochs indicated that achieving satisfactory model performance could be accomplished within just 2 epochs, as depicted in Figure 5. Additional epochs did not meaningfully improve results and instead prolonged training without benefit. Therefore, 2 epochs were deemed adequate for the model to learn from the data effectively.

Regarding the batch size, we conducted a search across values of 3, 4, 8, 16, and 32, all of which exhibited comparable performance. Consequently, we opted to utilize a batch size of 3 for our experiments.

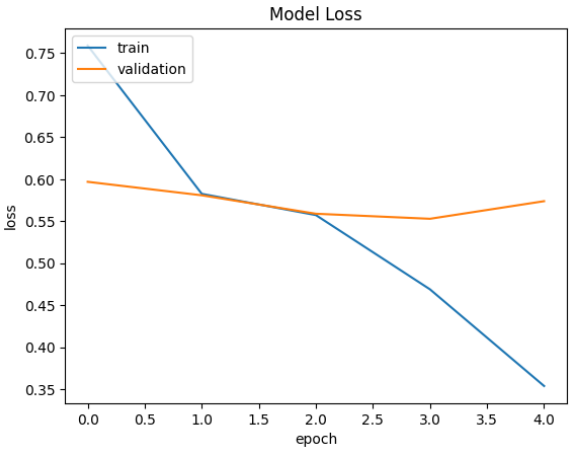

Figure 5: The loss vs. epochs chart during training.

5 Result

Table 3 illustrates the performance of each model developed in this study, comparing them with the initial NEMo model, which was created by the subsequent study (Chen et al., 2021), as indicated by the underlined model in Table 3. The BERT model exhibited an accuracy of 67.95%, a 2% decrease compared to the NEMo model. Upon removal of stop words, the BERT-SWR achieved an accuracy of 70.83%, presenting a marginal improvement of less than 1% compared to the NEMo model. In the case of the BERT-NAFE model, an accuracy of 77.09% was attained, reflecting a 7.14% increase compared to the NEMo model. The Jupyter Notebook employed in this investigation has been made publicly available on GitHub. For further reference, please consult the Appendix.

Model	Accuracy
Initial Model	
NEMo(Chen et al., 2021)	69.95%
Our Model	
BERT	67.95%
BERT-SWR	70.83%
BERT-NAFE	77.09%

Table 3: Comparison of model performance. (All models were fine-tuned except for NEMo.)

Therefore, it can be asserted that the removal of stop words, Numerals Augmentation, and Feature Enhancement are effective in enhancing accuracy, surpassing the performance of the existing model.

6 Discussion and Error Analysis

6.1 Discussion

The baseline model, BERT, achieved an accuracy of 67.95% after fine-tuning, closely approaching the initial model NEMo. Upon the removal of stop words from the text, there was a notable improvement of approximately 3% in accuracy. Considering dimensionality reduction, stop words, characterized as high-frequency terms, pervade most texts. Their exclusion significantly diminishes the dimensionality of the feature space, thereby reducing computational complexity. Consequently, this eases the requirements on both model training and inference processes.

The elimination of stop words contributes to noise reduction. These words often lack essential information, and retaining them may introduce interference, hindering the model's ability to concentrate on learning crucial information. Their removal enables the model to focus its attention and learning capacity on genuinely meaningful vocabulary. Additionally, excluding stop words during model training enhances the comprehension and generalization of the text. Stop words frequently serve as grammatical connectors without conveying specific semantic information. Their removal allows the model to more effectively concentrate on learning the actual relationships between words, unburdened by the intricacies of entire sentence structures.

In addition to BERT-SWR, Numerals Augmentation and Feature Enhancement were incorporated to further elevate the accuracy to 77.09%. Two reasons account for this enhancement. To address the model's inclination to overly rely on particular numerical values encountered during training, Numeral Augmentation aims to counteract this fixation. This is achieved by introducing variations in the representation of numbers, guiding the model to develop a less rigid fixation on specific instances and fostering a more generalized understanding of numerical information.

Another central focus of the augmentation process is the mitigation of numerical ambiguity. Numerals within a given context may have multiple interpretations or ambiguous meanings. To alleviate this ambiguity, the augmentation process exposes the model to diverse representations of numbers. This exposure aids the model in adapting to different contexts and facilitates the disambiguation of numeral meanings based on the surrounding textual

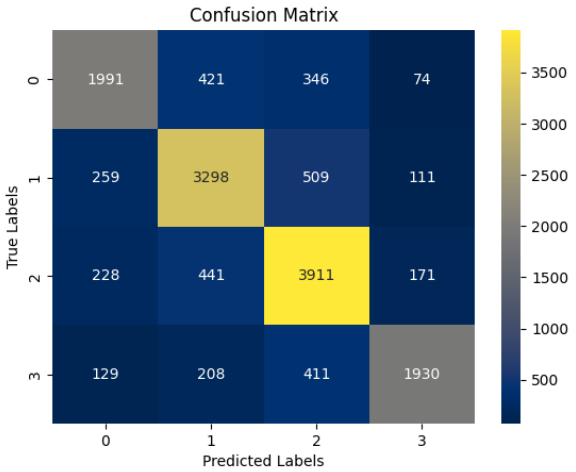

Figure 6: Confusion Matrix of model BERT-NAFE.

information.

After computing the current precision and recall from Figure 6 , it was observed that the system tends to produce class 2 outputs at a rate of 35.9%, surpassing the training set's rate of 33.1%. Conversely, the system's output proportion for class 3 is notably low, standing at only 15.8%. Perhaps adjusting the training set's distribution to a balanced 1:1:1:1 ratio could enhance the system's performance. It is worth noting that the numerical labels 0, 1, 2, and 3 used in the Numerals Augmentation step lack intrinsic significance and merely denote positions. For future work, adjusting the distribution ratio should be a straightforward task.

Various symbols and triple symbols for feature enhancement were also experimented with. In the case of different symbols, comparable performance was observed. However, when employing triple symbols, there was a slight decrease in accuracy, with approximately 74%, representing a 3% decline.

answer_options: ['0.88', '2', '5.06', '7.6']
target_num: 2

Figure 7: Example of Bad Sample

6.2 Error Analysis

In certain instances among the samples, the "scao" columns do not encompass the answers to the questions, requiring the model to predict the answer through estimation. For example, as illustrated in Figure 7, the question pertains to improving profit, yet the content in the "scao" column does not include this information.

To address this issue, the "news_article" can be employed as a substitute for the "scao" column. However, this substitution would result in an increase in token length, leading to a rise in training costs, encompassing GPU memory usage, and extending model training time.

7 Conclusions

This study has achieved significant performance improvements through fine-tuning the BERT model and optimizing text processing methods. Firstly, during the fine-tuning process, we observed a notable increase in model accuracy by removing stop words from the text, particularly high-frequency vocabulary. The exclusion of stop words not only reduced the dimensionality of the feature space, lowering computational complexity, but also contributed to noise reduction, enabling the model to better focus on meaningful vocabulary.

Secondly, the introduction of Numerals Augmentation and Feature Enhancement further elevated the model's accuracy. Numerals Augmentation, by introducing variations in the representation of numbers, assisted the model in overcoming overreliance on specific numerical values, fostering a more generalized understanding of numeric information. Additionally, Feature Enhancement strategies helped alleviate numerical ambiguity, allowing the model to adapt to different contexts and accurately interpret numeric meanings.

In summary, our research findings suggest that, building upon the BERT model, fine-tuning and text processing optimizations can effectively enhance performance in numeral reading comprehension.

Abstract

This paper describes the approach of the UniBuc team in tackling the SemEval 2024 Task 2: Safe Biomedical Natural Language Inference for Clinical Trials. We used SOLAR Instruct, without any fine-tuning, while focusing on input manipulation and tailored prompting. By customizing prompts for individual CTR sections, in both zero-shot and few-shots settings, we managed to achieve a consistency score of 0.72, ranking 14th in the leaderboard. Our thorough error analysis revealed that our model has a tendency to take shortcuts and rely on simple heuristics, especially when dealing with semantic-preserving changes.

1 Introduction

Clinical trials are prospective studies that aim to compare the effectiveness of an intervention against a control group in clinical patients (Friedman et al., 2015). ClinicalTrials.gov[1] hosts more than 480,000 clinical trials, making it challenging to analyze and extract information from them manually. Natural language inference has emerged as a valuable tool for interpreting evidence from clinical trials (Jullien et al., 2023a).

The second task of SemEval 2024 focuses on improving the understanding of clinical trial data through the second edition of NLI4CT (Natural Language Inference for Clinical Trials) (Jullien et al., 2024). This challenge is specifically designed to test the natural language inference capabilities of large language models (LLMs) and their ability to understand clinical text. The data used for the challenge was carefully annotated by clinical domain experts, and semantic interventions were performed to evaluate the safety and robustness of the models.

We employed LLMs, achieving the best results with SOLAR-Instruct, and focused on two key strategies:

- **Targeted Summarization**: Summarizing both CTRs and the hypothesis (retaining only the first 'trial' sentence) aided the model's focus on essential information.
- **Tailored Prompting**: We used both zero-shot and two-shot prompting, tailoring prompts to individual CTR sections for optimal results.

We were surprised to find that causal models significantly outperform masked language models on this type of task. This is probably because the task requires reasoning capabilities that BERT-based models do not have. Our model's biggest challenges were with numerical reasoning and rephrasing (discussed in Section 6), but despite those, we still secured the 14th place (out of 32) in the leaderboard. We make our code publicly available on GitHub[2].

2 Related Work

Recent work on clinical trial analysis includes detecting contradictions in medical publications (Makhervaks et al., 2023), automating eligibility assessment with LLMs (Wang et al., 2023; Datta et al., 2024), and assessing model hallucinations and reasoning capabilities in healthcare settings (Pal et al., 2023; Feng et al., 2023). The previous SemEval NLI4CT task (Jullien et al., 2023b) included a similar entailment task, with most submissions leveraging pre-trained language models. A small minority of approaches used ontologies and rule-based algorithms.

Few of the language model-based approaches include preprocessing of the data prior to using it as input to the models. In our approach for the current

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 586–595

task, we also attempt solutions based on both discriminative and generative language models, and in addition perform preprocessing of the input clinical trial data before feeding it to the models, such as summarization. While most of the best performing systems in last year's task employ some in-domain pre-training on medical data, we find that, from the models we experimented with, general LLMs perform as well as or better than medical ones. This could be explained by their larger size and instruction tuning techniques, but also because of the recent advances in general LLMs. However, we do not perform an exhaustive comparison of the two kinds of models (we use few medical LLMs in our experiments), so a definitive conclusion can not be drawn on this comparison.

The NLI4CT dataset (Jullien et al., 2023a) is a unique benchmark dataset for Natural Language Inference (NLI) in the clinical domain that contains data from Clinical Trial Reports (CTRs). In contrast, the MedNLI (Romanov and Shivade, 2018) dataset is another benchmark dataset for NLI in the clinical domain, but it only contains clinical notes. To ensure that NLI models are robust and safe, the organizers of the NLI4CT task perform semantic-preserving and semantic-altering interventions of the hypotheses. According to Jullien et al. (2023a), NLI models for clinical trials require not only biomedical reasoning but also numerical reasoning capabilities, as CTRs contain a large amount of quantitative information. In this regard, we conduct experiments using SOLAR 10B (Kim et al., 2023), which was trained on question-answer pairs from the mathematical domain to enhance its mathematical capabilities.

3 Data and Task Description

The data used for this task is comprised of 1,000 breast cancer CTRs collected from ClinicalTrials.gov with 24,000 entailment relations annotated by clinical domain experts (Jullien et al., 2023a). Each CTR is comprised of 4 sections: eligibility criteria, intervention, results and adverse events.

Each sample from the NLI4CT dataset consists of the CTR premise (one of the 4 sections of the CTR), a statement, and an entailment label (Entailment or Contradiction). The premise can refer to only one CTR in the *Single* type instance, or to a primary and a secondary trial in the *Comparison* type. The purpose of the current task is to evaluate the consistency of models and their ability to perform faithful reasoning (Jullien et al., 2024). For this purpose, different semantic altering (Contradiction Rephrasing and Numerical Contradiction) or semantic preserving interventions (Paraphrase, Numerical Paraphrase and Definition) have been conducted on the evaluation data. The NLI4CT dataset consists of 1,700 entailment relations in the training split, 200 in dev, and 5,500 in the test split.

To assess the performance of the models in the shared task, two metrics have been proposed: **Faithfulness** and **Consistency** (Jullien et al., 2024), besides F1-score. Faithfulness measures the model's ability to adjust its predictions accurately after a semantic-altering intervention. Consistency measures the capacity of the system to predict the same label for both the original and contrast statements, in the case of semantic-preserving interventions.

4 Methodology

In this section, we present the different approaches used to predict the entailment relations.

4.1 Pre-trained Masked Language Models

Our first approach for the task of entailment relations prediction is using pre-trained models. Previous research has shown that domain-specific pretraining is beneficial for biomedical tasks (Gu et al., 2022; Romanov and Shivade, 2018).

We use pre-trained models, such as PubMedBERT (Gu et al., 2021), XLM-RoBERTa (Conneau et al., 2020), Deberta V3 Large (He et al., 2021), and fine-tune them on the training data. The fine-tuning process is done in 2 steps, as suggested in (Sun et al., 2020). Firstly, we stack a fully connected layer on top of the pre-trained model and train it for 4 epochs while the weights of the pre-trained model are frozen with a learning rate of 10^{-3}. For the second step, we train the fully connected layer along with the last layer of the pre-trained model at a lower learning rate of $2 * 10^{-4}$ for one more epoch.

Inspired by the approach taken by Pahwa and Pahwa (2023), who demonstrated that the performance of fine-tuned cross-encoders is comparable to that of GPT-3.5 in the few-shot setting, we experiment with the sentence-transformer model BioBERT[3] trained on 6 benchmark NLI datasets (Deka et al., 2022) for sentence similarity tasks.

[3] pritamdeka/BioBERT-mnli-snli-scinli-scitail-mednli-stsb

We train a cross-encoder model using the sentence embeddings from BioBERT on the NLI4CT train data for sentence-pair classification for 20 epochs.

We also utilized SciFive (Phan et al., 2021), a T5 model designed for biomedical literature-related tasks. This model was pre-trained on a large corpus of PubMed abstracts and PubMed Central full-text articles from biomedical and life sciences domains. It achieved state-of-the-art results on the MedNLI benchmark dataset (Romanov and Shivade, 2018). We used the SciFive model trained on MedNLI[4] in zero-shot setting to predict the entailment relations for the NLI4CT data.

4.2 Large Language Models

LLMs have achieved promising results in biomedical tasks, such as named entity recognition, relation extraction, text classification, and question answering (Jahan et al., 2023). We conducted experiments using LLaMa-2 7B[5] (Touvron et al., 2023), Mistral 7B[6] (Jiang et al., 2023) and SOLAR (Kim et al., 2023), which have shown promising results in various language tasks. LLaMa-2 is a competitive model that has performed well across multiple benchmarks such as commonsense reasoning, word knowledge, and reading comprehension. Mistral, on the other hand, has surpassed LLaMa-2 in all the tested benchmarks. We choose SOLAR-Instruct since it is a state-of-the-art model that is instruction-tuned specifically to have improved mathematical capabilities, with rephrased examples using a similar process to MetaMath (Yu et al., 2023). The team behind SOLAR developed a unique scaling technique, called depth up-scaling (DUS), which combines architectural changes with continued pre-training and obtained better results than larger models like Mixtral (Kim et al., 2023).

LLaMa-2 and Mistral were evaluated only in zero-shot settings on the NLI4CT test data. The same prompt was used in the experiments, regardless of the section the statement was referring to and it is presented in Appendix B. While the experiments from LLaMa-2 and Mistral were using the entire sections of CTRs and statements, we had a different approach for SOLAR, which involved CTRs summarization. We expand on the methodology below.

Section content summarization approach. This approach consists of two stages. First, we summarize the text of each section to reduce the number of tokens. Next, we perform the classification task on the shortened text using two-shot prompting with examples from the training set. Both stages of this pipeline use the SOLAR 10.7B Instruct v1.0 model (Kim et al., 2023) in GGUF format[7] with 5-bit quantization (Q5_K_M) using llama.cpp.

CTR summarization. We summarize the sections of each CTR in the evaluated datasets (train, development, test) to a maximum of 350 tokens. The main reason for performing summarization is to provide the model with a shorter context and a task that is easier to solve. To validate this statement, we perform preliminary runs on the development set on Single CTRs for the Results section. We obtain an F1-score of 0.55 on single results CTR without a summary, while we are able to reach 0.63-0.72 F1-score with the summarization approach.

Another motivating factor is the time required to run the inference in order to perform multiple experiments. Full CTR inference for one example can take up to 20-30 seconds. Conversely, shortened CTRs are evaluated in roughly 5 seconds. As generating summaries is a one-time cost, the time difference is compensated for after a few iterations. Evaluating on CTR summaries instead of the full CTR allowed us to dedicate more time in designing and refining prompts used for the entailment task. For these reasons, we do not conduct additional experiments on full CTRs.

The obvious drawback of summarization is the risk of discarding essential information. In the initial experiments for this approach, we tried to mitigate this by conditioning the summary to be related to the hypothesis statement. Unfortunately, this strategy caused the model to include the statement in the summary and at times even output contradictory phrases. Moreover, we did not try to continue with contextualized summaries because it would require generating a new summary for each statement instead of a summary for each CTR section. Given that the evaluation relies on using the same section with multiple statements, we need to generate only one summary per section if the summary does not depend on the hypothesis.

Inference. We solve the entailment task through zero-shot and two-shot prompting. As some statements might contain irrelevant sentences, we only keep the first sentence that contains the word "trial".

[4] razent/SciFive-large-Pubmed_PMC-MedNLI
[5] meta-llama/Llama-2-7b
[6] mistralai/Mistral-7B-Instruct-v0.2
[7] TheBloke/SOLAR-10.7B-Instruct-v1.0-GGUF

We are aware that it is not an ideal approach and we lose important information in some examples where 2 or more sentences are crucial for the task. We found that the model works better if we keep only the "trial" sentence rather than not performing this step at all. We also tried a more robust approach by asking the model to extract the relevant sentences from the hypothesis. While this tackles the issues encountered by our simple heuristic mentioned before, we limit our system setup to sentence splitting since it is significantly faster.

We limit the output grammar of the model to only "Yes" and "No" to ease processing. For each of the four sections and example types (Single or Comparison), we apply different prompts for summarization and evaluation. The final prompt templates are listed in Appendix B. The advantage of this approach is that we can analyze and tune the prompts independently for each section, without running the inference step for the whole dataset.

5 Results

Model	Setting	F1	Faithfulness	Consistency
PubMedBERT	fine-tuned	0.63	0.53	0.62
XLM-RoBERTa	fine-tuned	0.63	0.55	0.63
Deberta V3 Large	fine-tuned	0.63	0.54	0.62
BioBERT	fine-tuned	0.65	0.52	0.63
SciFive Pubmed PMC	zero-shot	0.56	0.61	0.56
Llama-2 7B	zero-shot	0.65	0.19	0.44
Mistral 7B	zero-shot	0.65	0.18	0.44
Mistral 7B Instruct-0.2	zero-shot	**0.72**	0.68	0.66
SOLAR 10B *	zero-shot	0.63	**0.90**	**0.72**
SOLAR 10B	few-shot	0.71	0.83	**0.72**

Table 1: Results of our submissions for the SemEval-2024 Task 2: Safe Biomedical Natural Language Inference for Clinical Trials. Best results are presented in **bold**, and second-best results are presented in underline. Results with asterisk (*) were not submitted.

The official results of our team can be found in Table 1. Our results indicate that using pre-trained models on clinical text does not significantly improve the performance on this particular task, despite research confirming that domain-specific language model pre-training can be beneficial for other biomedical tasks (Gu et al., 2022). In line with last year's findings (Jullien et al., 2023b), we observe that instruction-tuned models pre-trained on generic datasets perform better than discriminative models pre-trained on biomedical datasets. With respect to LLaMa-2 and Mistral models used in zero-shot settings, they achieve high F1 scores of 0.65 and 0.72. However, these models are not robust enough and achieve low performance on Faithfulness and Consistency metrics, which are the metrics the organizers focused on. We further expand on the results of our best-performing model, SOLAR.

Control set. We obtain an F1-score of 0.71, with the highest score for comparisons of adverse events (0.79 F1) and the lowest score for comparisons of interventions (0.62 F1). Our team reaches the 16th place out of 32 participants in the official leaderboard. Compared to last year, we would be ranked on 5th place while using little to no training data and modest computational resources. Similar to last year, we report a higher Recall (0.73) than Precision (0.70).

Contrast set. Our system achieves a Faithfulness score of 0.83 (10th place out of 32 teams) and a Consistency score of 0.72 (14th place out of 32 teams). This shows that the model is more reliable when dealing with semantic-altering transformations compared to semantic-preserving changes, with only one CTR section having a faithfulness score below 0.79 (eligibility comparisons - 0.71). We observe a similar behavior in 22 other submissions where faithfulness is higher than consistency.

6 Error Analysis and Discussion

In this section, we analyze the types of errors made by the SOLAR model according to the provided metrics based on each intervention target.

Definition interventions. These interventions simply append a sentence to the statement. The model is capable of extracting the relevant sentence containing references to clinical trials if asked explicitly through a separate pre-processing step, but this incurs an additional runtime cost. Ultimately, we tackle this issue with a simple heuristic (see the inference details in 4.2).

Numerical interventions. Even though the SOLAR model has been tuned for mathematical reasoning, we identified several shortcomings. The model performs poorly with measurement units that express the same quantity in different ways. It appears to understand the meaning of symbols (e.g. "positive" instead of "+"), but if domain-specific acronyms are lowercase instead of uppercase (e.g. "hr", "her2", "mcs", "pdr"), the prediction changes.

Another interesting example is related to how entailment is affected when numbers have similar semantic meanings in other contexts. In one of the intervention trials, it is specified that a treatment

cycle takes 21 days. The statement asks whether the trial has a 30-day cycle, with the model classifying it as entailment. Slightly tweaking the number in the statement reveals that this is not regarded as entailment if the values do not match semantically: only the pairs 21-28, 21-30 and 21-31 are considered entailment; the other pairs from 21-26 to 21-34 are classified as contradiction. Nonetheless, if we change the number in the trial (21) instead of the statement, it always predicts an entailment, even when the value is nonsensical. This appears to be a drawback of long contexts as the issue only manifests with 2-shot prompting.

For numerical paraphrasing, we have 0.67 Consistency, 0.54 F1-score, 0.63 Recall and 0.47 Precision. Conversely, for numerical contradictions, the model obtains 0.80 Faithfulness, 0.85 Consistency, 0.91 F1, 1.0 Recall and 0.83 Precision[8].

Paraphrasing and contradiction interventions. We notice a similar behavior to the numerical interventions: very high scores for contradictions, but significantly lower results for rephrases. Thus, paraphrases have 0.70 Consistency, 0.69 F1, 0.72 Recall, and 0.66 Precision, while contradictions have 0.83 Faithfulness, 0.78 Consistency, 0.89 F1, 1.0 Recall, and 0.80 Precision.

Our results suggest the model is overly sensitive to any wording change between the hypothesis and premise, mistakenly interpreting them as conflicting. This also explains the perfect recall scores.

In the remainder of this section, we present a few high-level remarks related to our design decisions.

Few-shot prompting might improve results compared to zero-shot prompting. We used two examples from the training set, an entailment and a contradiction. This approach improved the results on average on the development set in terms of F1, regardless of model, model size or summarization configuration. Adding more examples to few-shot prompting might further increase the results at the expense of slower inference speed. However, with 6-shot prompting, the performance degrades even if we do not reach the context limit of 4096 tokens. We assume this is caused by the complexity of the task and the model "forgetting" what task it must solve. We do not further explore 6-shot prompting because of poor preliminary performance and increased runtime on a subset of the development data.

[8]We adapted the evaluation script to use `pos_label` as 0 for contradictions and numerical contradictions.

On the test set, it appears that few-shot prompting degrades the results in terms of Faithfulness and Contradiction, although it improves paraphrasing scores. We argue that a higher Faithfulness score in itself does not imply better results because the model could simply predict more Contradictions when the input is altered.

Instruction order is significant. We observed the best results when the instructions were placed at the start of the prompt, followed by the CTR (or CTR summary) and then the hypothesis. This strategy constantly provides improved predictions across most of the evaluated prompts. There is a drop of 4 F1 percentage points on the development set when the hypothesis is placed before the CTR summary in the prompt template. Separately, the predictions are also affected if the instruction is placed at the end of the prompt, after the hypothesis. Repeating the instruction before and after the CTR-hypothesis pair is as effective as simply placing the instruction before the CTR text.

Larger models obtain better results, but smaller models are still useful for prototyping. We use the 3-bit quantization version of the same SOLAR model (Q3_K_M) to experiment with more prompts, taking advantage of faster inference times. This approach has been very useful in designing the summarization prompts because the summarization step is the most expensive one in terms of computational resources. We also experimented with hybrid systems, where the summaries are generated with a smaller model and the inference task is done by a larger model. The performance of the hybrid strategy is comparable to running the entire pipeline with the larger model.

There are no hard constraints for summaries prompts, as long as they do not depend on the hypothesis. There appears to be no substantial difference in the final results when changing the prompt used to generate CTR summaries. We apply some of the following restrictions in each summarization prompt: use abbreviations, avoid verbs, use short sentences, be brief, maximum N words. Rephrasing the prompt does not seem to have a relevant impact for this task. As previously mentioned, it is paramount that the summaries preserve the meaning of the original text. The absence of relevant information in summaries is a major source of errors in our system. Unfortunately, for most sections the model was unable to create contextualized summaries conditioned by the hypothesis without mentioning the hypothesis in the summary.

For the Results section with a single CTR, conditioning the summary on the hypothesis looked promising. However, the next example from the test set confirms our concerns about this strategy, where a single summary for multiple hypotheses is not appropriate due to conditioning on the first hypothesis in the dataset. Our generated summary is: "There is no information in the given CTR report that relates to the statement about all patients treated with GTx-024 1mg gaining lean body mass over a 10 year period". The model is distracted by the "10 year period" from one of the hypotheses, altering the original meaning completely, even though the word "year" does not appear anywhere in the initial CTR section. See appendix A.1 for the full CTR text and associated hypotheses.

7 Conclusions and Future Work

In this paper, we presented our approach for the SemEval 2024 Task 2 (Jullien et al., 2024) aimed at understanding large language models behavior in clinical contexts. We explored several types of models and prompting techniques in order to determine whether fine-tuning is more feasible than zero-shot or few-shot prompting in a limited resource setting.

Our findings suggest that, while LLMs exhibit remarkable clinical NLI capabilities at a surface level, the proposed metrics and interventions uncover a tendency of the models to take shortcuts and rely on simple heuristics, especially when faced with semantic-preserving changes. We intend to investigate further methods of evaluating the reliability of large language models in future work.

To address the inherent weak numerical reasoning of our model (and all generative models), a promising strategy is to offload complex mathematical hypotheses to a specialized model like xVal (Golkar et al., 2023). This approach involves representing numbers as individual digits (e.g., 123 becomes ["1", "2", "3"]), replacing them with a generic [NUM] token, and scaling the token according to the original numerical value. Their results showed a 70-fold improvement over standard models. We can extend this strategy to create an ensemble where other weaknesses of our model (like rephrases) are offloaded to specialized models.

A Additional examples

A.1 Summary mismatch example

The Results section of the CTR with ID "NCT00467844" is the following:

> Outcome Measurement: The Efficacy of GTx-024 on Total Body Lean Mass. Change in total body lean mass as measured by dual energy x-ray absorptiometry (DEXA)from baseline to 4 months. Time frame: Baseline to Four Months.
>
> Results 1: Arm/Group Title: GTx-024 1 mg Arm/Group Description: [Not Specified] Overall Number of Participants Analyzed: 32 Median (Full Range) Unit of Measure: kg 1.55 (-2.06 to 12.64)
>
> Results 2: Arm/Group Title: GTx-024 3 mg Arm/Group Description: [Not Specified]

Overall Number of Participants Analyzed: 34 Median (Full Range) Unit of Measure: kg 0.98 (-4.84 to 11.54)

The summary is conditioned on the following hypothesis: "all patients treated with gtx-024 1mg in the primary trial gained lean body mass over a 10 year period". However, other hypotheses are concerned with other quantities: "at least one patient treated with GTx-024 1mg in the primary trial gained over 10 kilos of Lean body Mass". For the latter, our summary is misleading because the "10 kilos" information is missing. This could be mitigated by refraining to summarize short sections.

B Prompt templates

The prompt templates used to obtain the final leaderboard results for SOLAR are shown in tables 4 and 5.

We started with a single prompt template for all sections and summaries. When the results did not further improve, we analyzed the F1-score of each section, shown in Tables 2 and 3. Due to time constraints, we only create summaries for the first 50 examples in the train set.

While the single CTR summaries for the results section depend on the hypothesis, due to an implementation choice, all examples use the same CTR summary, regardless of the hypothesis (only the first hypothesis is used). We believe that this issue is not essential, since all the hypotheses for a CTR focus on the same information.

Initial summary prompt: "Instruction: You are given a clinical trial report. You must summarize the report. Use abbreviations. Be brief. Report: {premise}. Summary (max 350 words):".

Initial evaluation prompt: "Instruction: You are given a Clinical Trial Report and a hypothesis. ##Report: {premise}. ##Hypothesis: {hypothesis}. ##Can the hypothesis be inferred from the report? Respond only with Yes or No. ##Response (Yes or No):". This prompt was also used for our experiments with LLaMa-2 and Mistral.

C Infrastructure

In terms of infrastructure, we use a system with 16 GB RAM and an NVIDIA GTX 1060 MQ GPU with 6 GB VRAM. Out of the 5500 examples on the test set, this method only requires generating summaries for 251 examples comprising different CTR sections. On the development set, we need to create 100 summaries for the 200 samples, making the summarization step more expensive in this regard.

Section	F1

Adverse events (Single)	0.5835
Adverse events (Comparison)	0.6969

Table 3: Initial results for the development set

The inference time for a summary varies with the length of the CTR section, with a minimum time of 30 seconds per sample and a total time of about 7 hours, but it should be noted that this stage is a one-time cost. The inference time for one example is approximately 5 seconds, meaning that the evaluation on the test set takes roughly 9 hours, with the total time reaching 12 hours when applying 2-shot prompting, since the sequence length increases.

Fralak at SemEval-2024 Task 4: combining RNN-generated hierarchy paths with simple neural nets for hierarchical multilabel text classification in a multilingual zero-shot setting

Katarina Laken

Universidade de Santiago de Compostela / Santiago de Compostela, Spain
alaken@fbk.eu

Abstract

This paper describes the submission of team fralak for subtask 1 of task 4 of the Semeval-2024 shared task: 'Multilingual detection of persuasion techniques in memes'. The first subtask included only the textual content of the memes. We restructured the labels into strings that showed the full path through the hierarchy. The system includes an RNN module that is trained to generate these strings. This module was then incorporated in an ensemble model with 2 more models consisting of basic fully connected networks. Although our model did not perform particularly well on the English only setting, we found that it generalized better to other languages in a zero-shot context than most other models. Some additional experiments were performed to explain this. Findings suggest that the RNN generating the restructured labels generalized well across languages, but preprocessing did not seem to play a role. We conclude by giving suggestions for future improvements of our core idea.

1 Introduction

Task 4 of the Semeval 2024 workshop deals with the identification of persuasion techniques in meme data (Dimitrov et al., 2024). Subtask 1 regarded only the textual content of the memes. Training, validation and development data is only available in English, but the test phase includes data in three more languages (Bulgarian, North Macedonian and Arabic) for multilingual zero-shot classification. The 20 persuasion techniques are organized in an hierarchical directed acyclic graph (available on the task website). Each meme can have zero, one or multiple persuasion techniques associated with it, making this a hierarchical multilabel classification problem. Assigning a parent node of the target label results in partial points.

Our system (team fralak) implements an ensemble model including a seq2seq module, using some innovations to avoid common pitfalls and exploit the hierarchy information. Our approach transforms the problem by restructuring the labels into strings in a way that captures all possible paths through the hierarchy and uses these as target sequences to train a RNN that learns the relationships between the labels on different levels. It combines the power of a RNN with a simple fully connected architecture. These non-sequential modules are also expected to mitigate the error propagation effect (also called exposure bias), where a wrongly predicted label in the beginning of the generated sequence results in more errors down the line (Xiao et al., 2021). RNNs for multilabel classification also depend on the ordering of the labels, even though the class labels are essentially an unordered set (Wang et al., 2021a). We address this by sorting the labels by frequency. The textual content of the memes is represented using multilingual sentence embeddings. Although we only participated in subtask 1, our architecture can easily be expanded to also take into account the visual content of the meme (subtask 2a+b)[1]. Our system performed below average on the English-only test set, but generalized better than most other systems. The goal of this paper is to explain our methodology and system architecture (sections 2 and 3) and explore why the system performs relatively well at the zero-shot task (section 5).

1.1 Background

Hierarchical multilabel classification is applied in many domains, from biology (genomics) (Romero et al., 2023; Wang et al., 2021b) to the classification of images (Lanchantin et al., 2021) or text data (Xiao et al., 2021; Omar et al., 2021). A challenge of this type of data is that the data is virtually always unbalanced on all levels of the hierarchy (Tarekegn et al., 2021). Labels also tend to be correlated.

[1] although the performance of the system on these multimodal tasks remains to be seen

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 596–601

There are several approaches to hierarchical multilabel classification. Some studies transform the problem, for example by creating a chain of binary classifiers, whereas others adapt the classification algorithm (Bogatinovski et al., 2022). Some approaches construct a model for each label, but this becomes very computationally expensive: once the amount of labels grows, it is difficult for labels with very few instances, and it is difficult to capture relationships between the labels (Chen and Ren, 2021). The hierarchy can be leveraged for classification. For example, Giunchiglia and Lukasiewicz (2020) use prediction on the lower classes in the hierarchy to make predictions on the upper ones. Seq2seq models are popular for multilabel classification (Chen and Ren, 2021; Chen et al., 2023; Huang et al., 2021). The main idea behind the employment of seq2seq models is that they are able to capture the correlations between labels (Chen and Ren, 2021). Huang et al. (2021) found that a seq2seq model using a biLSTM outperformed other SOTA approaches using chains of classifiers.

The past years have seen the rise of transfer learning, where some model is used for the classification of a different type of data than the data it was trained on (Iman et al., 2023). A common approach to multilingual transfer learning is the use of mapping words or sentences to vectors in a vector space that aligns embeddings for different languages. Training some model on these representations in language A then allows it to make predictions about data in unseen data B, as long as its embeddings are meaningfully mapped to the same vector space (Reimers and Gurevych, 2019).

2 Methodology

We aimed to implement rather simple NN modules in order to explore their usefulness for a complicated task like this. The main idea behind our system is to transform the labels into strings that reflect the hierarchical acyclic graph containing the different persuasion techniques. These are be used to train an RNN that is supposed to learn the relationships between both the labels and the different levels of the hierarchy. We expect that the relations between labels are a feature that generalizes especially well across languages, making our approach especially adapt for multilingual zero-shot learning for this specific task.

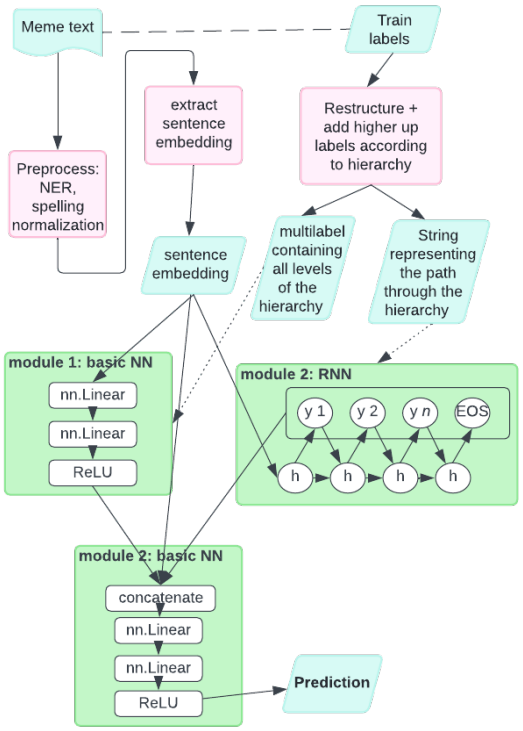

Figure 1: The hierarchical directed acyclic graph containing the persuasion techniques

2.1 Preprocessing

The preprocessing consisted of three main steps: spelling normalization, named entity recognition (NER), and adding the sentence embeddings. Since we wanted the system to be able to be applied to other languages as well, preprocessing was limited to some regular expressions capturing characters that repeated more than twice, irregular white spaces, and regularizing different kinds of *haha*'s to a simple 'haha'[2].

The NER was performed using a pretrained multilingual model for token classification by Babel[3], accessed through the Huggingface API. We compiled a list of the 10 people most commonly occurring in the training data and made a dictionary that 'translated' all of their names to one token (so 'Barack Obama' or 'Barack Hussein Obama' etc. would both be 'translated' to 'Obama'). All person entities (recognized with a certainty of over .8) that did not appear in this list were replaced by the name 'Mark', in order for them to be mapped to

[2] t = re.sub(r'[AaHhJjXxAa]*[HhJjXx]?[AaAa]+[HhJjXx] + [AaAa]+[AaHhJjXxAa]*', 'haha', t) ; the double a's are because one is the Cyrillic A and the other is the Latin A

[3] https://huggingface.co/Babelscape/wikineural-multilingual-ner

some kind of baseline name rather than the OOV token[4].

Meme data is expected to contain a lot of non-normative language. We chose to represent it using multilingual sentence embeddings, as these are typically better at dealing with OOV tokens. We used the multilingual variation of the sentence embeddings by (Reimers and Gurevych, 2019)[5].

These embeddings were used as the input for a neural architecture consisting of three separate modules (see 1). Module 1 consisted of a simple neural network (of hidden size 128), trained over 45 epochs, with one input layer, one output layer, and a ReLU activation. The input consisted of the sentence embedding for the meme; the output was a simple multiclass classification with one output for each activated node (meaning the target label and all of its progenitore nodes).

2.2 Restructuring of the labels

The central innovation of our approach is the inclusion of hierarchy information by way of transforming the labels to strings reflecting all possible paths through the hierarchy. Module 2 was an RNN that learnt to generate a sequence reflecting the labels and the hierarchy they were embedded in. First, all labels were sorted by frequency in the training data; multiword labels were turned into one-word labels (for example, 'thought terminating cliché' became 'cliché'). We then added the labels from the levels above them (as represented in the label hierarchy graph). As the hierarchy has different levels, this means that every meme was doubled or tripled in the training data, but with different labels. For instance:

Sequence: VISIT RUSSIA\n\nBEFORE RUSSIA VISITS YOU
Label 1: *Only labels*
'repetition and black and appeal EOS'
Label 2: *Labels + red level*
'logos namely repetition and logos namely black and logos and pathos namely appeal EOS'
Label 3: *Labels + red level + blue level*
'logos namely repetition and logos namely reasoning namely black and logos namely justification and pathos namely appeal EOS'
Label 4: *Labels + red level + blue level + green level*
'logos namely repetition and logos namely reasoning namely simplification namely black and logos namely justification and pathos namely appeal EOS'

The idea of this doubling of labels was that higher-up levels would appear more often and thus become more likely to be predicted by the module. However, preliminary testing showed that it made hardly any difference to use only labels of type 4 or all kinds of labels, likely because lower level labels inherently appear less often due to them governing less nodes.

2.3 System architecture

A simple RNN (hidden size = 128) was trained over 25 epochs to generate restructured labels. The model generates labels either until the max string length (manually set to 50) was reached, or until the EOS token was generated[6]. This module was supposed to learn the relationships between labels both at the same and at different levels of the hierarchy; we expected this knowledge to transfer rather well to the unseen multilingual data.

The final module (module 3 in figure 1) concatenates the meme embedding with the outputs of the modules 1 and 2 and the meme embedding and passes it through two fully connected layers (hidden size = 128) and a ReLU activation function (dropout = 0.2). This module, that was trained over 50 epochs, outputs the final prediction of the labels.

3 Experimental setup

The training+validation data consisted of 7,500 memes. After restructuring the labels this gave us 21,968 training instances. Including the development data (1,000 memes) resulted in 24,664 instances spread over 8,500 memes. All of these instances were in English. As typical for multilabel settings, the class labels are extremely unbalanced: the most common label, *Smears*, occurs 1,990 times in the training data, whereas the least common label, *Intentional vagueness*, occurred only 21 times. Our teams original test submission was only trained on the train and validation data, as we used the development data to validate our approach, but we added the development data in subsequent experiments as we theorized that having

[4]this step did not take into account different alphabets
[5]Accessed through the Huggingface API (model card)
[6]in the training of the module we used teacher enforcement, so there was no maximum string length; however, we did use this when generating the training data for the final module, so the final module had not seen RNN-generated inputs of over 50.

Type	Rank	F1	P	R
Dev (English)	27/33	0.55	0.47	0.66
Test English	25/33	0.56	0.48	0.67
Test Bulgarian	10/20	0.46	0.37	0.61
Test North Maced.	4/20	0.46	0.36	0.66
Test Arabic	3/20	0.43	0.31	0.70

Table 1: Table showing the main results of our official submissions. The rank x/y shows our position x and the total amount of teams that made a test submission y

more training data would give more robust results; as we did not do additional finetuning for the post-hoc experiments, no development set was used (see section 5). Due to the way the Semeval challenge was set up, the validation set was a dataset that was available from the beginning, whereas the gold labels for the development set only became available a couple of weeks before the test submission closed; we only used the validation set for some preliminary testing and setup, after which it was joined with the test set. All results are reported on the test data.

The modules were trained separately, but on the same data. We conducted some preliminary experiments training module 1 and 2 on 75% of the data and module 2 on the remaining 25% (random split) but this led to a drop in performance. The optimal amount of epochs for each module was decided based on plots of the average loss per epoch. Each separate module took less than 30 minutes to train on an Apple M3 8-core CPU. We used an Adam optimizer with a learning rate of 1e-3. Modules 1 and 3 were trained with a CrossEntropyLoss; module 2 with a SmoothL1Loss.

The task evaluation metric was the hierarchical-F1, calculated using hierarchical precision and recall (Kiritchenko et al., 2006). This measures gives partial points for assigning a label higher up in the hierarchy, and full points for assigning the specific technique.

4 Results

Table 1 shows the outcomes of our official submissions on the test and dev sets (before 1/2/2024). There was originally an issue with the Arabic gold labels; the reported scores correspond to the corrected version of the gold labels. For the English data, the test results were very much in line with the results on the dev leader board, with only 0.01 point difference in the hierarchical-F1. The results on the zero-shot test submissions were more surprising: although the F1 was (expectedly) lower

Table 2: Table showing the results of subsequent experiments on the test set

than for the English data, the ranking showed that the system still generalized considerably better than most other approaches. Section 5 discusses some possible explanations and describes additional experiments aimed at shining light at this question.

5 Discussion

We hypothesize that two mechanism that might have contributed to the system's generalization capacity. First, the preprocessing (particularly the NER step) might have made the model more generalizable. Second, the seq2seq RNN module to learn the labels might have been particularly good at capturing the relationships between the labels

In order to investigate these hypotheses, we ran additional experiments in which we left out parts of the system to investigate what happened to the performance. The results are summarized in table 2. All of these models were trained on train, validation and development set and tested on the test set (there was no development set as no additional fine-tuning was performed). Note that this is different from the original submission, that was trained on the training and validation set, validated on the development set, and tested on the test set; the manipulations made in the post-hoc experiments should thus be compared to the results in the upper row of table 2, which is a re-run of the model as described in section 2, but trained on the 1000 more memes of

the development set.

Our first hypothesis was that the preprocessing, especially the NER, helped the system generalize better to unseen languages. However, this seems not to be the case. Taking out only the NER module let to a slight drop in performance in English, but a better performance in the other languages. A possible explanation is the non-ubiquity of the name Mark: replacing people with 'Mark' might not actually be helpful if 'Mark' is not adapted to the specific language. Skipping all preprocessing steps (other than adding the embeddings) actually improved performance for English (even though taking out only the NER led to a drop, suggesting this might actually have been a very helpful step for the English data), but made hardly any difference for the other languages when compared to the setting without NER.

Our second hypothesis was that the RNN module was especially helpful for generalization. Either module alone performed worse than the three modules combined for all languages (apart from the first module, that reached the same F1 for Arabic), so the influence of the label-generating RNN should not be overestimated. On the other hand, when comparing the performance of module 1 with the performance of module 2, we see that the difference is the same for English and Bulgarian, and bigger for both Macedonian and Arabic. This might mean towards the second module actually being a bit more important in the zero-shot setting, but more research is required.

Our full model had remarkably high recall, but low precision. Looking at the performance of modules 1 and 2 separately suggests that this is mainly due to module 1 (and, possibly, module 3, that is very similar to module 1 in architecture). This pattern is the same across languages and modifications. This is not very surprising; erroneously generating the EOS token once makes the module stop predicting labels, and given that every training instance has an EOS token, it is very common and the chance of it being produced erroneously is relatively high. Moreover, the RNN stops generating strings when the maximum string length of 50 is reached. We thus re-ran the base model (including development model) with a maximum string length of 100 for the RNN (table 2). This resulted in the best model thus far for the zero-shot setting due to improved precision, but the performance for the English test data fell marginally. This is a further indication that the RNN module is indeed crucial to the zero-shot classification.

Adding the development data (i.e. training the model on more data) seems marginally helpful for English (+0.01 point F1) but marginally unhelpful for Macedonian (-0.01 point F1) and Arabic (-0.03 point F1). If the strength of our system indeed lies in it learning the relationships between the labels of the hierarchy, it is likely that a smaller amount of data was just enough to learn this, and adding more data just makes the model overfit.

6 Conclusion

This paper described the system used to generate the test submissions for subtask 1 of task 4 of SemEval 2024 'multilingual detection of persuasion techniques in memes'. We proposed a system consisting of different neural modules, the most innovative of which was an RNN that was trained to generate sequences that reflect the position of the relevant labels in the hierarchy. Our model did not perform particularly well on the English data, but compared to the other teams, it generalized unexpectedly well to other languages in a zero-shot setting. We conducted some additional experiments to find out what might have contributed to this. We found that our preprocessing steps (normalization and NER) did not make the model more generalizable, but we did find some evidence that the RNN module might have played a role as hypothesized.

We see plenty of possibilities to improve on our original idea in the future. First of all, we would like to explore the performance of different types of embeddings. We found that our system as a whole had a high recall, but a low precision; however, the RNN module showed the exact opposite pattern, having high precision and low recall. Allowing the RNN output in module 3 to be longer (up to 100 tokens) partially alleviated this problem and improved performance. We hypothesize this is because the EOS token is generated too easily. Somehow raising a barrier for the module to generate the EOS token might help to improve its recall. Implementing an attention mechanism in the final module could also help aleviate this problem. Other options to explore are a NER preprocessing step that better generalizes to other languages than just replacing people with "Marks". Finally, it would be interesting to explore the capabilities of a hierarchical-path generating RNN with more sophisticated layers (GRU or LSTM), or combined with a convolutional model.

Funding and acknowledgements

This research was carried out in the context of the HYBRIDS project. Abstract

This paper presents our approach to classifying hierarchically structured persuasion techniques used in memes for Task 4 Subtask 1 of SemEval 2024. We developed a custom classification head designed to be applied atop of a Large Language Model, reconstructing hierarchical relationships through multiple fully connected layers. This approach incorporates the decisions of foundational layers in subsequent, more fine-grained layers. To improve performance, we conducted a small hyperparameter search across various models and explored strategies for addressing uneven label distributions including weighted loss and thresholding methods. Furthermore, we extended our preprocessing to compete in the multilingual setup of the task by translating all documents into English. Finally, our system achieved third place on the English dataset and first place on the Bulgarian, North Macedonian and Arabic test datasets.

1 Introduction

Memes are widely used for communicating in the digital age, often laced with sarcasm and humor. However, beyond their role in everyday conversation, memes are increasingly recognized for their persuasive and manipulative potential. They hold power to subtly influence opinions, incite reactions, or shape public discourse and perception. Given this dual nature of memes as both funny communication tool and vehicle for manipulation, there arises a need to dissect and understand the persuasion techniques embedded within them. A proper understanding of this domain enhances the ability to reflect on and emotionally defend against manipulation. In this context, Large Language Models (LLMs) emerge as valuable assets in analyzing and deciphering the persuasive elements within memes. Their automated, rapid processing capabilities make them well-suited for parsing through vast amounts of meme data, extracting patterns, and discerning underlying features. Recognizing the importance of this topic, the SemEval 2024 Task 4 Subtask 1 focuses on identifying persuasion techniques used in memes (Dimitrov et al., 2024). The aim of the first subtask is to classify the textual content from memes into various hierarchically structured persuasion techniques. In this paper, we provide a detailed description of our system including the custom classification head we designed in order to incorporate the hierarchy of the labels. Our system was able to achieve the third place on the English test dataset. Furthermore, we outperformed all other systems on the Bulgarian, North Macedonian and Arabic test sets. In summary, (i) we created a custom classification head well-suited for hierarchical settings, (ii) developed a strategy for languages where less training data is available, (iii) analyzed the influence of different hyperparameters and strategies in the context of multi-label classification problems. Our code is publicly available[1].

2 Related Work

In the context of multi-label classification, the primary aim is to identify all relevant classes associated with a given sample. Additionally, in a hierarchical classification setting the labels are partially ordered, ranging from broader generic categories to narrowed specific instances (Kiritchenko et al., 2006). There is a large variety of approaches for this task. While earlier methods were based on tree-structures and graphs, more recent approaches rely on deep learning models (Liu et al., 2023). This section introduces various models adaptable to the task of hierarchical multi-label classification.

These authors contributed equally to this work.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 602–612

2.1 Models

Transformer models consist of an encoder and decoder which can individually be adapted for sequence classification tasks (Vaswani et al., 2017).

Encoder-only Models are well-suited for sequence classification. These models directly generate a representation of the input sequence, which is then passed through a classification head for prediction. As huggingface (Wolf et al., 2020) allows us to easily test different models, we compared a variety of encoder-only models. This includes different *BERT* (Devlin et al., 2019) and *RoBERTa* (Liu et al., 2019) models. As the memes in our dataset often contain hateful or toxic content, we include specifically pre-trained *BERT-base* models. While *hateBERT* (Caselli et al., 2021) is re-trained on explicitly hateful content from banned reddit communities, *bert-hateful-memes-expanded* (limjiayi, 2021) was fine-tuned on multiple datasets containing hateful memes.

Decoder-only Models like *LLaMA 2* can be adapted for sequence classification tasks by utilizing the logits of the last token from the input sequence (Huggingface). We evaluated the performance of the 7b and 13b parameter versions of *LLaMA 2* (Touvron et al., 2023).

3 Dataset

The organizers provided English datasets for training, validation and testing (7000/500/1500, train/val/test). Additionally a dev set (1000) was published to enable comparison of participating systems on a separate leaderboard ahead of the final submission on the test data. Each sample within these datasets consists of an unique id, the URL linking to the source of the meme, the transcribed text content and a list of associated labels. For example, the text: *Stay on high moral ground and we will win - Raphael Warnoc*, has the associated labels: *Appeal to authority* and *Glittering generalities (Virtue)*. The labels of the memes are structured hierarchically, with *Ethos*, *Pathos* and *Logos* in the first layer. In total, there are 28 labels with 20 persuasion techniques in the last layer, which we will refer to as *leaves*. It is important to note that the leaves are not distributed equally within the datasets. While *Smears* (1990), *Loaded Language* (1750) and *Name calling/Labeling* (1518) appear most frequently in the training data, *Presenting Irrelevant Data (Red Herring)* (59) and *Obfuscation, Intentional vagueness, Confusion* (21) occur most rarely. The final submissions were made on the English test dataset. In addition, the hosts released testing data for North Macedonian (259), Bulgarian (436) and Arabic (100) (Dimitrov et al., 2024).

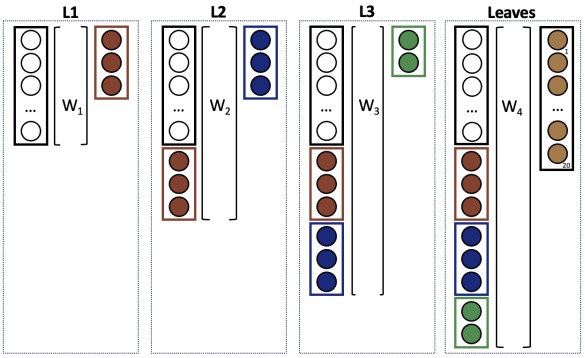

Figure 1: Illustration of our custom classification head. The depicted parts represent different layers, where **L1** corresponds to the first hierarchy layer: Ethos, Pathos, Logos. **L2** maps to the second layer, and **L3** to the third. Finally, all features are mapped to the **Leaves**. This design allows us to incorporate previously made decisions into subsequent layers. For simplicity, W_{1-4} represent fully connected layers.

4 System Overview

This section provides an in-depth description of our system. To integrate the hierarchical structure of the labels, we introduce a custom classification head that is designed to be applied atop various pre-trained Large Language Models.

4.1 Pre-Processing

We tested our system with two different pre-processing approaches: In memes, lines of text are often broken due to space limitations on the image. Therefore, we assume that most newline characters do not carry any semantic information and thus remove them in the first pre-processing variation (*cleaned*). As preliminary experiments indicated that certain LLMs might exhibit enhanced performance with all-lowercase input, the second version incorporates an additional step to convert the text to lowercase letters (*all_lower*).

4.2 Custom Classification Head

The fundamental concept of our classification head entails intuitively reconstructing the hierarchy across multiple fully connected layers. As depicted in Figure 1, the basic architecture unfolds as follows: In the initial layer (**L1**), the sequence embedding provided by the backbone LLM serves as

input, producing logits for the three highest nodes of the hierarchy, namely: Ethos, Pathos and Logos. Logits for the next layer (**L2**), Ad hominem, Justification and Reasoning, are obtained by passing a concatenation of the sequence embedding and the logits of the preceding layer through another feed-forward layer. This process is repeated for the last parent nodes, Distraction and Simplification (**L3**). Finally, the logits for the 20 individual leaf nodes (**Leaves**) are obtained using another linear layer, which incorporates the concatenation of sequence embeddings and the logits of all previous layers. Accessing decisions from upper levels of the hierarchy enables logits in the fine-grained layers to be shaped by the choices made for more foundational categories. Crucially, the loss is calculated over all nodes, not solely leaf nodes, enabling the model to learn the hierarchy effectively. The head outputs logits for all 28 labels, which are then transformed into probabilities using a sigmoid function. Lastly, the probabilities are converted into labels using thresholds, where labels with a probability above the threshold are included in the final prediction. Notably, all classes in the hierarchy, including leaf nodes with low parent probabilities and vice versa, can be predicted. This design principle ensures that decisions made at higher levels serve as guidance without imposing restrictions, thereby maintaining the autonomy of lower-level decisions within the hierarchical structure.

4.3 Loss function

We aimed to address the unequal label distribution by testing both the standard binary cross-entropy loss as well as its weighted variant. Each class was weighted depending on their inverse frequency, assigning a higher penalty to misclassifications of minority classes, with the goal of enhancing the performance of these less represented classes.

4.4 Ensemble

To further enhance the robustness of our predictions we employed an ensemble approach where we utilize majority voting across four different models. Each of these models was trained with the same hyperparameters but with different random seeds. As described above (Section 4.2) our model outputs labels for each sample. To combine the suggestions of multiple models, we experimented with various boundary levels to determine the number of model predictions needed for a label to be included in the final prediction. Our experiments revealed that requiring at least two of the four models to vote for a label is the most effective.

4.5 Handling Different Input Languages

To extend the applicability of our system for the multilingual setting, we integrated an additional pre-processing step. The provided non-English test datasets were translated into English using GPT-4 (OpenAI et al., 2023), using the following prompt: *You are a bilingual humorist, adept at translating meme text between languages while preserving the original humor, cultural nuances, and any slang or idiomatic expressions. Ensure the translation is accurate, contextually appropriate, and retains the meme's playful tone. Avoid adding explanations or additional commentary and provide only the translation.*

5 Experimental Setup

In order to approximate optimal parameters for the LLaMA 2 models, we conducted a grid-search for various BERT and RoBERTa models as these require less computational resources. During training, we utilized gradient accumulation to reach a gradient update every 128 samples. All models were trained for ten epochs, with a learning rate of either 5×10^{-4} or 5×10^{-5} and the Adam optimizer (Kingma and Ba, 2014). We further included the two different pre-processing styles as well as the binary-cross entropy loss and its weighted variation as hyperparameters. Lastly, we performed all experiments with and without our custom classification head. Training was conducted on either NVIDIA GeForce RTX 4090 or NVIDIA A100 GPUs. Due to the large size of the LLaMA 2 models, we used Low-Rank-Adaptation to greatly reduce the number of trainable parameters for this model-family (Hu et al., 2021). We used the provided training dataset for training and the validation dataset to test generalization capabilities after each epoch. In the final stage, we assessed our system's performance on the dev dataset, utilizing a hierarchical version of the F1-score metric (hF1) following (Kiritchenko et al., 2006). The full set of hyperparameters we used is shown in Table 3.

5.1 Determining Optimal Thresholds

For each sample, our model outputs one logit for each class. Thus, we need to decide on a threshold, determining the decision boundary for assigning labels to instances based on their predicted probabilities. As the commonly used threshold of 0.5

Table 1: Comparison of hF1-scores and averages across all languages of our system and other top-performing systems. The corresponding ranks are provided in brackets.

System	en	bg	md	ar	Avg
Ours	0.697 (3)	**0.568 (1)**	**0.512 (1)**	**0.476 (1)**	**0.563 (1.5)**
NLPNCHU	0.663 (6)	0.517 (3)	0.462 (5)	0.475 (2)	0.529 (4.0)
914isthebest [2]	**0.752 (1)**	0.463 (11)	0.369 (14)	0.360 (13)	0.486 (9.75)
BCAmirs [3]	0.699 (2)	0.448 (13)	0.393 (12)	0.396 (9)	0.484 (9.0)

appeared non-optimal for our task based on preliminary testing, we implemented different strategies aiming to find optimal thresholds on the validation dataset. To systematically find the best threshold, we predetermined a spectrum of threshold levels to investigate. We experimented with (i) picking the same global threshold for all classes, and (ii) optimizing the threshold for each class individually. We computed the accuracy and F1-score for each threshold-label combination and selected the best outcomes for both metrics respectively. For both variants, we output all classes with probabilities above the threshold as well as all parents of the selected nodes.

6 Results

This paragraph discusses the influence of various hyperparameters, our ranking on the leaderboard and provides a detailed error analysis.

6.1 Influence of Hyperparameters

We tested the influence of both pre-processing styles, the two variants of the loss calculation, different learning rates and the custom classification head we designed. As shown in Table 5, the pre-processing variant has a negligible impact, with all models performing almost identical for both *cleaned* and *all_lower* data. Surprisingly, all models perform worse when weighting classes based on their inverse frequency in the binary cross-entropy loss. A possible reason for this is the high imbalance of our dataset (see Section 3). Weighted loss prioritizes minimizing the loss for minority classes, potentially compromising accuracy for majority classes, leading to sub-optimal overall results. The addition of our custom classification head improves our results up to eleven percent points and two percent points on average. Strikingly, *bert-large-cased* performs the worst and models pre-trained on hateful content can outperform their foundation counterparts. While *bert-hateful-memes-expanded* achieves even better results than models with a higher parameter count, *hateBERT* performs worse than the BERT-base model. Lastly, 5×10^{-5} was the best learning rate for all models tested in the grid search. Nevertheless, first experiments with LLaMA 2 revealed, that a learning rate of 5×10^{-4} works better for this model family. Using these findings, we decided to train a LLaMA 2 13b model using the *all_lower* pre-processing style with our custom classification head, a learning rate of 5×10^{-4} and no weighted loss. The LLaMA 2 models outperform the other models with the chosen parameter selection. We further observed that global thresholds consistently yielded superior performance compared to selecting single thresholds for each class. The optimal thresholds of our experiments range between 0.2 and 0.4 and vary depending on the base model and other parameters. We assume that the inferior performance of individual thresholds stems from our methodology of including all ancestors of a predicted leaf in the output, regardless of their assigned probabilities. As a result, inaccuracies at the lowest hierarchy level disproportionately affect our system's precision due to the compounded errors in ancestor predictions.

6.2 Main Results

A total of 33 teams competed in the subtask. Table 1 compares our system against other top-performing systems across all evaluated languages using the official test results. Our framework consistently ranks among the top three across all languages, securing the top position for Bulgarian (bg), North Macedonian (md) and Arabic (ar) datasets. It achieves the highest average hierarchical F1-score and the highest average leaderboard ranking. This demonstrates the versatility of our approach, underlining our methodology's effectiveness and adaptability to non-English languages. Table 2 presents

[3](Dailin Li and Lin, 2024)

[3](Amirhossein Abaskohi and Carenini, 2024)

hierarchical performance on the dev dataset for our four distinct models trained using varied seeds, in addition to their ensemble which was used for the final submission.

The highest performing individual model records a hF1 of 0.682, while the ensemble demonstrates an enhanced score of 0.690. This indicates that leveraging the outputs from multiple independently trained models can lead to improved results. Despite similar hF1 scores across models, variations of up to four and seven percent points in hierarchical precision (hP) and hierarchical recall (hR) respectively suggest differing error patterns and strengths among the models. This disparity highlights the efficacy of our ensemble approach, showcasing its capacity to amalgamate diverse insights from the dataset.

6.3 Error Analysis

In this chapter, we will dive deeper into the shortcomings of our system regarding the performance of our ensemble model on the dev dataset (Figure 2). Overall, the distribution of labels predicted by our system closely aligns with the ground truth. However, our system exhibits a bias towards predicting classes with a larger number of samples, leading to a higher frequency of these labels in our output. Conversely, labels with fewer occurrences in the training data are underrepresented in our predictions, leading to lower F1-scores in comparison. Some leaves with very few training samples such as *Presenting Irrelevant Data (Red Herring)* (59) and *Obfuscation, Intentional vagueness, Confusion* (21) are never predicted by our system, leading to a F1-score of zero. Interestingly, despite *Appeal to authority* only occurring very rarely in the training data (850), our system achieves an F1-score of 0.892 in this class. This label describes that a claim is being stated as true simply because a valid authority or expert on the issue said it was true, without any other supporting evidence offered (Dimitrov et al., 2024). We therefore assume the label to be easier to predict than other classes, as the occurrence of certain authorities or names in particular at the end of a sentence are a strong indicator for this persuasion technique. It is noticeable, that our model is able to differentiate well at the first hierarchy level: Ethos, Pathos and Logos, achieve F1-scores of over 60%. Similar observations can be made for the non-English test datasets (Figure 3, Figure 4, Figure 5).

Table 2: Hierarchical results on the dev dataset for our four distinct models trained using various seeds and the ensemble of these four models.

System	hP	hR	hF1
1	0.623	0.745	0.679
2	0.661	0.673	0.667
3	0.643	0.698	0.669
4	0.631	0.740	0.682
Ensemble	0.636	0.754	0.690

7 Conclusion

In this paper, we introduced a robust system to classify hierarchically structured persuasion techniques in a meme-corpus for the SemEval challenge 2024 Task 4 Subtask 1. Our system achieved a top-three ranking for each language individually and outperforms every other system averaged over all languages. A key aspect of our approach is the incorporation of the label hierarchy using a custom classification head that models the individual layers of the hierarchy. This classification head can be used atop of different LLMs and improves the performance by up to 11 percent points. We employed a grid-search across various models and hyperparameters to approximate optimal parameters for a LLaMA 2 13b model that then produces the embedding for the classification head. Interestingly, weighting the loss to increase the influence of classes with fewer samples did not improve the overall performance. In addition, picking the same classification threshold for each class worked better than searching one for each label individually.

There are multiple possibilities to build upon the success of our system: First, the organizers suggested similar data sources that could be used for pre-training. Additionally, upgrading to a bigger LLM, such as LLaMA 2 70b, known for its superior performance over smaller LLaMA 2 variants, could further elevate our system's capabilities. Moreover, extending our hyperparameter tuning could uncover better model configurations. Our methodology for parent-node selection could be refined by discarding parent nodes selected by children if the ancestor itself has low confidence. Lastly, feature stacking could be used to create a powerful model that incorporates features generated by other models in its classification head.

D-NLP at SemEval-2024 Task 2: Evaluating Clinical Inference Capabilities of Large Language Models

Duygu Altinok
Deepgram Research, USA
duygu.altinok@deepgram.com

Abstract

Large language models (LLMs) have garnered significant attention and widespread usage due to their impressive performance in various tasks. However, they are not without their own set of challenges, including issues such as hallucinations, factual inconsistencies, and limitations in numerical-quantitative reasoning. Evaluating LLMs in miscellaneous reasoning tasks remains an active area of research. Prior to the breakthrough of LLMs, Transformers had already proven successful in the medical domain, effectively employed for various natural language understanding (NLU) tasks. Following this trend, LLMs have also been trained and utilized in the medical domain, raising concerns regarding factual accuracy, adherence to safety protocols, and inherent limitations. In this paper, we focus on evaluating the natural language inference capabilities of popular open-source and closed-source LLMs using clinical trial reports as the dataset. We present the performance results of each LLM and further analyze their performance on a development set, particularly focusing on challenging instances that involve medical abbreviations and require numerical-quantitative reasoning. Gemini, our leading LLM, achieved a test set F1-score of 0.748, securing the ninth position on the task scoreboard. Our work is the first of its kind, offering a thorough examination of the inference capabilities of LLMs within the medical domain.

1 Introduction

Large language models (LLMs) have brought about a paradigm shift in the field of Natural Language Processing (NLP) (Kojima et al., 2023; Wei et al., 2022). Their exceptional performance across various tasks has led to a surge in real-world applications utilizing LLM-based technology. However, a notable drawback of LLMs is their propensity to generate plausible yet incorrect information, commonly referred to as "hallucinations" (Ji et al., 2023).

The remarkable breakthrough of LLMs has raised questions regarding their "intelligent" capabilities, particularly in reasoning and inference (Zhao et al., 2023; Chang et al., 2023; Laskar et al., 2023). Two specific areas that have garnered significant attention in relation to LLMs' reasoning abilities are numerical-quantitative reasoning and natural language inference. These areas are considered integral to human intelligence, prompting researchers to establish benchmarks and evaluate LLM performance in these domains (Stolfo et al., 2023; Yuan et al., 2023). LLMs often exhibit limited performance in solving arithmetic reasoning tasks, frequently producing incorrect answers (Imani et al., 2023). Unlike natural language understanding, math problems typically possess a single correct solution, making the accurate generation of solutions more challenging for LLMs. Regarding NLI, performance reduction can be observed due to shortcut learning (Du et al., 2023) and hallucinations (McKenna et al., 2023). These investigations aim to discern whether LLMs are mere memorizers of training data or possess genuine logical reasoning abilities.

The volume of medical publications, including clinical trial data, has experienced a significant upsurge in recent years. The SemEval-2023 Task 7, known as Multi-Evidence Natural Language Inference for Clinical Trial Data (NLI4CT), aimed to address the challenge of large-scale interpretability and evidence retrieval from breast cancer clinical trial reports (Jullien et al., 2023). This task required multi-hop biomedical and numerical reasoning, which are crucial for developing systems capable of interpreting and retrieving medical evidence on a large scale, thereby facilitating personalized evidence-based care. While the previous iteration of NLI4CT resulted in the development of LLM-based models (Zhou et al., 2023;

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 613–627

Kanakarajan and Sankarasubbu, 2023; Vladika and Matthes, 2023) achieving high performance (e.g., F1-score $\approx 85\%$), the application of LLMs in critical domains, such as real-world clinical trials, necessitates further investigation. Consequently, the second iteration of NLI4CT, SemEval-2024 Task 2, titled "Safe Biomedical Natural Language Inference for Clinical Trials" (Jullien et al., 2024) is proposed, featuring an enriched dataset that includes a novel contrast set obtained through interventions applied to statements in the NLI4CT test set. Our work involves the evaluation of various popular open-source and closed-source LLMs on the development and test sets to explore their reasoning capabilities in the domain of medical NLI. We present the results by thoroughly analyzing the performance on the development set, with the best-performing LLM ranking ninth on the task leaderboard. We have made the results on the development set available on our GitHub repository[1].

Another aspect of our work was that we deliberately refrained from investing significant effort into prompting or experimenting with different prompts. Additionally, we aimed to showcase the remarkable development of LLMs, demonstrating their capacity to effectively engage with the task while minimizing dependence on the prompt.

2 Related Work

With the emergence of large language models (LLMs), there has been a growing interest in exploring their capabilities within the clinical domain. Recent studies have delved into both the potential of LLMs and the associated risks when applied in clinical settings. For instance, (Hung et al., 2023) conducted experiments utilizing GPT-3.5 on various medical NLP datasets, assessing metrics such as factuality and safety, ultimately highlighting the high level of safety offered by GPT-3.5 [2]. (Pal et al., 2023) focused on the challenges posed by hallucinations in LLMs and proposed a benchmark dataset called Med-HALT (Medical Domain Hallucination Test) to evaluate popular LLMs on this front.

Regarding the reasoning capabilities of LLMs, (Kwon et al., 2024) introduced a diagnostic framework that prioritizes reasoning and employs prompt-based learning. The study specifically focused on clinical reasoning for disease diagnosis, where the LLMs generate diagnostic rationales to provide insights into patient data and the reasoning path leading to the diagnosis, known as Clinical Chain-of-Thought (Clinical CoT), using GPT-3.5 and GPT-4 (OpenAI, 2024). Notably, none of the previous studies simultaneously examined the performance of both open-source and closed-source LLMs, particularly with a comprehensive focus on inference. Consequently, our work stands as the first of its kind in this regard.

3 Task and Dataset Description

The clinical trials used to construct the dataset were sourced from ClinicalTrials.gov[3], a comprehensive database managed by the U.S. National Library of Medicine. ClinicalTrials.gov contains information on various clinical studies conducted worldwide, both publicly and privately funded. The dataset specifically focuses on clinical trials related to breast cancer and includes a total of 1,000 trials written in English.

- **Eligibility Criteria:** This includes a set of conditions that determine the eligibility of patients to participate in the clinical trial. These criteria may include factors such as age, gender, and medical history.
- **Intervention:** This field provides information about the type, dosage, frequency, and duration of treatments being studied within the clinical trial.
- **Results**: The results section of each CTR reports the outcome of the trial, including data such as the number of participants, outcome measures, units of measurement, and the observed results.
- **Adverse Events**: This field documents any unwanted side effects, signs, or symptoms observed in patients during the course of the clinical trial.

For the task at hand, each CTR may contain one or two patient groups, known as cohorts or arms, which may receive different treatments or have different baseline characteristics.

The dataset consists of a total of 7,400 statements. These statements were divided into a training dataset comprising 1,700 statements, a development dataset containing 200 statements, and a

Mixtral 8x7B	0.604	0.899	0.73

Table 3: Macro F1-score, faithfulness and consistency results on the test set for each LLM.

hidden test dataset consisting of 5,500 statements. The statements can be categorized into two types: those that are solely related to a single CTR and others that involve a comparison between two different reports. Each statement in the dataset is labeled as either "entailment" or "contradiction". Figure 1 shows an example statement from the training set.

The task primarily involves binary classification, aiming to predict whether the label corresponds to entailment or contradiction. The evaluation process encompasses three aspects. Initially, the macro F1-score is computed based on the binary classification results. Subsequently, two semantic evaluations are conducted: faithfulness and consistency. Faithfulness assesses the system's ability to arrive at accurate predictions for the correct reasons, while consistency measures the system's ability to produce consistent outputs for semantically equivalent problems. The task organizers evaluate faithfulness by providing semantically altered instances, and consistency by providing preserved instances for comparison.

4 Language Model Performance Evaluation

This section aims to provide a detailed analysis of the performance achieved by each individual LLM. Based on the evaluation of various LLMs, including closed-source models like GPT-3.5 (ChatGPT), Claude (Anthropic, 2023), and Gemini Pro (Gemini Team, 2023), as well as open-source models like Falcon 40B (Almazrouei et al., 2023), Mixtral 8x7B (Jiang et al., 2024), and Llama 2 70B (Touvron et al., 2023), the performance of these models was assessed on the dev and test sets. Table 1 provides comprehensive information regarding the release dates and parameter sizes, measured in token size, for each LLM.

All conversations took place on the Poe.com platform, providing users with a seamless chat experience. To transmit both the development set and the test set instances, we utilized an API wrapper code in a Python script, which can be accessed in our GitHub repository. As mentioned earlier, we intentionally avoided extensive prompting and instead employed a straightforward, consistent prompt for all instances. Each model's chat session commenced with a greeting, followed by a brief introductory sentence regarding the task, and subsequently, all instances were dispatched via the Python script. Appendix A provides information regarding the prompts.

Table 2 and Table 3 presents a concise overview of the results obtained on the dev and test sets. Gemini Pro emerged as the best-performing model, ranking first on both the dev and test sets. Following Gemini Pro, Claude and PaLM, two closed-source LLMs, secured the second and third positions, respectively. Falcon 40B, an open-source LLM, achieved the fourth place and outperformed GPT-3.5. The last two positions were occupied by two open-source LLMs, Llama 2 70B and Mixtral 8x7B.

In the next section, we delve into the detailed performance analysis of the language models on the development set, focusing on specific cases of

Mixtral 8x7B	69

Table 4: Number of incorrect predictions on the development set of 200 instances for each LLM.

interest.

4.1 General Performance Evaluation

Among the top-ranking LLMs, namely Gemini Pro, Claude, PaLM, and Falcon 40B, their performance on the development set was indeed remarkable. The number of inaccurate predictions made by each LLM on the development set of 200 instances is presented in Table 4. There were only 3 instances in the development set that were incorrectly predicted by all LLMs.

Among the top-performing LLMs, a set of 12 instances emerged as particularly challenging, denoted as "difficult instances". These instances present a significant challenge, as none of the top three performer LLMs in the set - Gemini Pro, Claude and PaLM, were able to accurately predict their outcomes. Within this subset, 2 instances involved medical abbreviations, 3 featured numerical entities, and the remaining 7 were categorized as "plain instances". The subsequent subsections will delve into a detailed analysis of the difficult instances encompassing numerical entities and abbreviations. For the present discussion, our attention will be directed towards the plain difficult instances.

One particular difficult instance is illustrated in Figure 1, where the top two performing LLMs provided the answers given by Figure 2.

Gemini made a somewhat fair mistake by incorporating knowledge from the training data, suggesting that PET includes orally administered tracer drugs. However, it should be noted that tracer drugs do not qualify as any form of medication for treating cancer or other diseases. In this case, Gemini falters by "assuming too much" and "relying too heavily on prior knowledge." It is important to clarify that this is not a hallucination. On the other hand, Claude correctly deduced that there were no oral medications in the primary trial and that oral medication was administered in the secondary trial. However, Claude failed to synthesize this information and draw a conclusion, indicating a breakdown in reasoning from evidence. Similarly, PaLM and Falcon 40B encountered the same issue as Claude. While they accurately pointed out the evidence, they failed in the reasoning process. In the case of PaLM, it did not provide any indications of en-

GEMINI
Contradiction. The statement “the primary trial participants are not administered any oral medication whereas the secondary trial patients only receive treatment orally” is a contradiction of the given trial information. The primary trial intervention section states that patients will receive Positron Emission Mammography, which involves various PEM views being performed on both the breast and axilla. This indicates that the primary trial participants are administered some form of oral medication, as the PEM views are likely to involve the use of a radioactive tracer that is taken orally. Therefore, it is not accurate to say that the primary trial participants are not administered any oral medication. Hence, the statement is a contradiction of the trial information.
CLAUDE
Contradiction. The primary trial intervention specifies: - Positron Emission Mammography scans. The secondary trial intervention specifies: - Exemestane 25mg oral daily for 5 years.- Anastrozole 1mg oral daily for 5 years. The statement claims:- Primary trial does not administer oral medications\n- Secondary trial only provides oral treatments. However, the primary trial does not mention any oral or other medications. And the secondary trial clearly describes oral aromatase inhibitors as the interventions. As the primary trial information does not validate the negative claim about oral medications, and the secondary trial positively describes oral treatments, the statement is contradicted. Therefore, the answer is contradiction - the trial intervention details conflict with the assertions made in the statement.

Figure 2: An example comparison task from the training set with two CTRs.

gaging in reasoning. Falcon 40B made a literal mistake by becoming mired in the intricacies of the language. Its answer includes the statement, "the statement cannot be directly entailed from the intervention information provided. Specifically, while the primary trial does not mention oral medication, the secondary trial does not exclusively mention oral medication, contradicting the statement."

These mistakes range from overthinking, failure to follow the evidence, inadequate reasoning, to becoming excessively focused on minute details—a clear manifestation of the inherent challenges that LLMs face. The less performing LLMs, namely GPT-3.5, LLama 2 70B, and Mixtral 7x8B, demonstrated a decent performance considering the task difficulty. However, they exhibited a relatively higher frequency of failures in reasoning and inference compared to the top-performing LLMs.

Having examined the plain difficult instances, we now turn our attention to evaluating the performance of the LLMs on instances containing medical abbreviations.

4.2 Abbreviated Instances Performance Evaluation

In our development set, we identified 31 instances that contained medical abbreviations. We used the ScispaCy package’s abbreviation detector to extract these instances.

Among the top performers, Gemini, Claude, PaLM, and Falcon 40B made 4, 6, 7, and 8 mistakes, respectively, in handling these abbreviations. The bottom performers, GPT-3.5, Llama 2 70B, and Mixtral 8x70B, made 10, 8, and 8 mistakes, respectively.

Upon closer examination, we found that all of the LLMs were able to correctly resolve the meanings of the medical abbreviations. However, they made mistakes due to other reasoning problems.

For example, none of Gemini’s four mistakes in handling abbreviations were related to resolving their meanings. Similarly, the other LLMs also failed the task primarily due to quantitative-numerical reasoning failures. Appendix B showcases a more comprehensive example of this particular type of occurrence and the corresponding failure.

Overall, the performance of all LLMs in resolving abbreviations was commendable. However, as mentioned before, the majority of failures stemmed from challenges in numerical-quantitative reasoning.

4.3 Numerical Instances Performance Evaluation

Our development set contained 78 instances with numerical entities. We employed the spaCy package (Honnibal and Montani, 2017) and its NER component to identify these entities. To ensure comprehensive semantic evaluation, we combined

ScispaCy and spaCy models.

Among the top-performing LLMs, Gemini, Claude, PaLM, and Falcon 40B made 13, 14, 18, and 19 mistakes, respectively. Notably, the bottom performers, GPT-3.5, Llama 2 70B, and Mixtral 8x70B, made significantly more mistakes (21, 26, and 24, respectively).

Interestingly, the top performers, Gemini and Claude, made the same mistakes on numerical instances in the development set. Upon examining their responses, we observed that they performed arithmetic operations and reasoned based on the calculated results. In Appendix B, Figure 8 and Figure 9 portray instances of successful outcomes achieved by our LLMs. These figures demonstrate accurate performance in arithmetic operations and logical deduction.

However, even the top performers made occasional errors. For instance, Gemini provided an incorrect answer where there was no evidence of arithmetic operations or reasoning: "The primary trial adverse events section shows that there were 10 patients in cohort1 who suffered adverse events out of a total of 67 patients. Therefore, it is accurate to say that over 1/6 patients in cohort1 of the primary trial suffered adverse events." This suggests that Gemini did not calculate 1/6 of the total number of patients (67).

Among the numerical instances incorrectly predicted by Gemini and Claude, we found no instances where arithmetic calculations were performed. Conversely, correctly predicted instances, such as the one shown in Figure 13 in Appendix B, involved at least one mathematical operation that was logically connected to the rest of the argument. We determined these logical connections by analyzing the dependency tree of the answers, as explained in Appendix B. Our findings indicate that when LLMs demonstrate signs of performing arithmetic operations, their results are generally reliable. Conversely, when there is no evidence of arithmetic operations, the result is likely incorrect.

The other top performers, PaLM and Falcon 40B, exhibited similar behavior to Gemini and Claude. They performed arithmetic operations and made deductions based on those operations. When they failed, they did not provide any numerical clues.

The bottom performer, GPT-3.5 was able to perform arithmetic operations. However, it struggled with simple quantity comparisons, such as n<m for random integers. Mixtral 8x7B also faced similar challenges.

Llama 2 70B performed particularly poorly on numerical instances. For the example in Figure 9, where other LLMs succeeded by performing arithmetic operations, Llama failed completely. It provided an incorrect answer without any evidence of subtraction or comparison. In fact, Llama generally struggled with numerical examples, succeeding primarily in quantitative comparisons where operands were provided directly in the context without requiring mathematical processing.

In conclusion, while other LLMs demonstrated proficiency in handling numerical entities, Llama 2 70B failed to meet expectations.

5 Conclusion

Our detailed analysis of LLMs' performance on various reasoning tasks in the medical domain reveals that they are not merely passive memorizers. They possess the ability to perform numerical-quantitative reasoning, general reasoning, and abbreviation resolution, even in a highly specialized domain with unique vocabulary. Notably, Falcon 40B, an open-source LLM, demonstrated impressive performance, rivaling top closed-source LLMs.

Despite their successes, LLMs are not without limitations. Occasional nonsensical predictions highlight the need for caution when using them in high-stakes domains such as medicine. However, the results of our study are highly promising and suggest that with increased training data and computational power, LLMs have the potential to become invaluable tools in the medical field.

The future of LLMs in medicine holds exciting possibilities. As these models continue to evolve, we anticipate that they will play an increasingly significant role in healthcare, transforming the way we diagnose, treat, and prevent diseases.

6 Limitations

As mentioned in earlier sections, we utilized the Poe platform for interacting with LLMs. All the work was accomplished within the confines of a monthly subscription fee of $20. The results of GPT-4 are not included in this study due to the messaging limit imposed by the platform, which was exceeded by the number of instances in the test set.

A Prompts

We employed two prompts, the prompts for the individual task and comparison tasks outlined as follows:

"Below find section_name section of the primary trial of a clinical trial. Infer if the following statement entails from the given trial information. Answer should be either entailment or contradiction. Please justify the answer based on numbers. PRIMARY TRIAL section_name: trial_value STATEMENT: statement"

"Below find section_name sections of a primary trial and a secondary trial belonging to same clinical trial. Infer if the following statement entails from the given trial information. Answer should be either entailment or contradiction. Please justify the answer based on numbers. PRIMARY TRIAL section_name: trial_value1 SECONDARY TRIAL section_name: trial_value2 STATEMENT: statement".

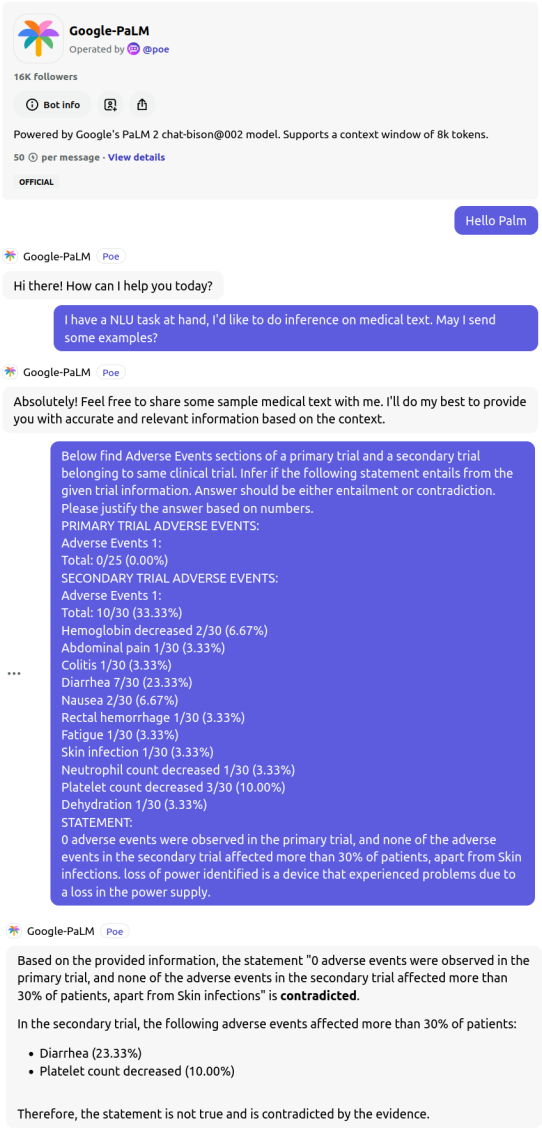

Figure 3: Initiation of the conversation with PaLM.

Figure 3 illustrates the initiation of a chat with PaLM and the method by which instances are provided during the conversation. As evident in the interaction, we maintained minimal prompting and limited additional interactions.

B Example Instances

In this section of the appendix, we present specific instances from the development set to provide readers with a concrete understanding of the performance of LLMs. Firstly, we present a challenging instance, which none of the LLMs in our study were able to correctly predict. Figure 4 depicts

this instance, which involves making an inference about the results section of a single CTR. The inference relates to PFS, a time range spanning from 7.0 to 9.9 months, with an average of 8.4 months. Consequently, the statement presents an entailment. Surprisingly, all the LLMs failed to address this instance. As depicted in Figure 5 and 6, the LLMs struggled to calculate the difference due to various reasons, such as difficulties in numerical deduction or becoming overly focused on linguistic details.

It is worth noting that this instance also includes an abbreviation, PFS, which is fully explained in the body of the CTR. Despite the LLMs demonstrating some understanding of this abbreviation, they ultimately failed due to their inability to perform the necessary numerical inference.

Subsequently, we present a numerical case study depicted in Figure 7 to showcase the numerical reasoning capabilities of the Language and Logic Models (LLMs). Impressively, almost all LLMs accurately predicted this particular case. However, Llama 2 70B exhibited a complete failure, displaying no signs of any numerical inference whatsoever. Figures 8 and 9 illustrate how other LLMs meticulously explained their reasoning step by step. They initiated the process by performing the subtraction $89\% - 88\% = 1\%$ and subsequently compared the result to the claimed amount of 13.2%.

To process numerical instances, we adopted the following approach: firstly, we utilized spaCy's Matcher component to extract all numerical expressions [4]. This component, being part of the pretrained spaCy pipelines, is incredibly helpful in extracting expressions based on patterns. These patterns can involve characteristics such as token shape, POS tags, and even entity types if the token forms part of an entity. By leveraging spaCy's built-in NER component, we could extract various numerical entity types, including cardinal numbers, ordinal numbers, percentages, and quantities. We formulated two general Matcher patterns, namely *NUMERIC OP NUMERIC* and *NUMERIC OP NUMERIC = NUMERIC*, and then generated all possible combinations of numerical entities and mathematical expressions by taking the cross product between numeric entity types and mathematical operator tokens. This comprehensive approach facilitated the extraction of all numerical expressions from the LLM answers. For identifying medical entities, we utilized the ScispaCy package, as medical entities are not included in spaCy's general-purpose NER models.

Following this, we parsed the dependency tree of the answer and determined the syntactic head of the numerical expression. We then examined whether the numerical expression attached meaningfully to the rest of the answer. For a detailed explanation of the reasoning process, refer to Figure 13.

Moving on to our list of examples, we encounter an intriguing case worth mentioning. Figure 10 presents a CTR with an empty adverse events section, making it a particularly interesting example. As depicted in Figures 11 and 12, all LLMs, except for Falcon 40B, demonstrate impressive intelligence by correctly interpreting "0/0" as indicating the absence of any adverse events, thereby resulting in an empty adverse events section. This example highlights the remarkable general language understanding and common sense reasoning abilities of LLMs, transcending the boundaries of the medical domain.

[4] https://spacy.io/api/matcher

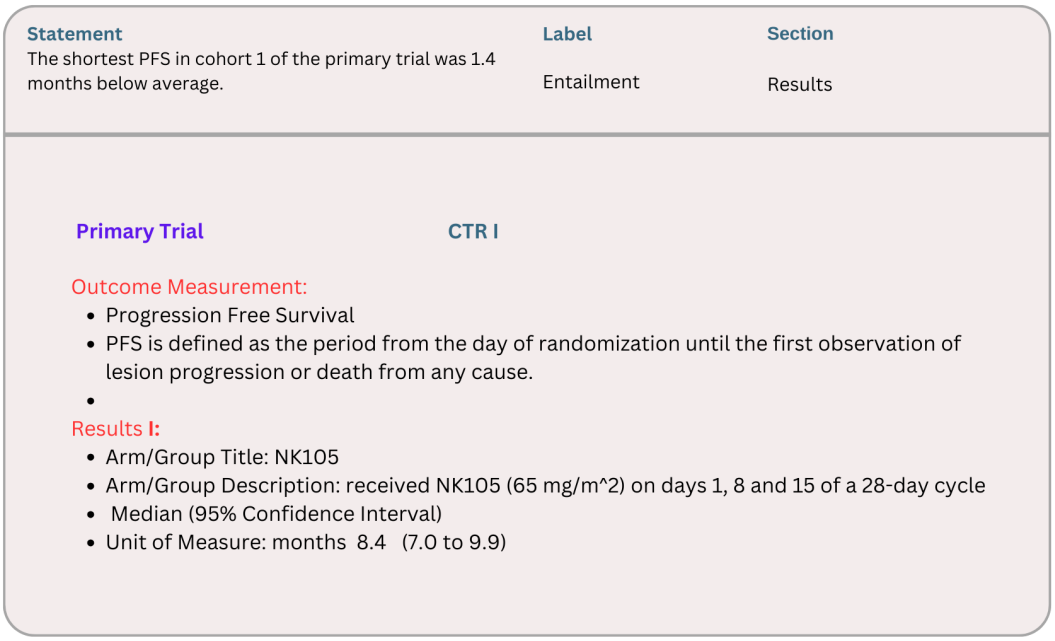

Figure 4: A challenging instance that was incorrectly predicted by the top-performing LLMs.

GEMINI
Contradiction. The statement "The shortest PFS in cohort 1 of the primary trial was 1.4 months below average" is a contradiction of the given trial information. The primary trial results section shows that the median PFS in cohort 1 was 8.4 months (95% CI: 7.0 to 9.9 months). Therefore, it is not accurate to say that the shortest PFS in cohort 1 of the primary trial was 1.4 months below average. Hence, the statement is a contradiction of the trial information.
CLAUDE
Contradiction. The primary trial results reported: - Outcome Measurement: Progression Free Survival (PFS) - Arm 1 Participants Analyzed: 211 - Arm 1 PFS Median: 8.4 months (7.0 to 9.9) - Arm 2 Participants Analyzed: 211 - Arm 2 PFS Median: 8.5 months (6.9 to 11.5). The statement claims the shortest PFS in cohort 1 was 1.4 months below average. However, the results reported PFS as medians with confidence intervals, not averages. There is no information provided about specific individual PFS durations. Since the results do not include data to validate the claim of any patient being 1.4 months below average, this contradicts the statement. Therefore, the trial results do not substantiate the assertion made in the statement. The answer is contradiction, as the reported outcomes conflict with the statement.
PALM
Contradiction. The text states that "Median (95% Confidence Interval) 8.4 (7.0 to 9.9)" in the primary trial results 1 and "Median (95% Confidence Interval) 8.5 (6.9 to 11.5)" in the primary trial results 2. This means that the shortest PFS in cohort 1 of the primary trial was not 1.4 months below average.

Figure 5: Responses of the top-performing LLMs to the selected challenging instance, where all models failed to exhibit any signs of numerical inference.

FALCON 40B
Median PFS reported is 8.4 months with a 95% CI of 7.0-9.9 months. Results 2: - Paclitaxel arm analyzed 211 participants- Median PFS reported is 8.5 months with a 95% CI of 6.9-11.5 months. Based on the numbers directly reported: - No cohort or arm assignments are specified - Median values reported are 8.4 and 8.5 months - No PFS of 1.4 months below any average is stated. Therefore, upon my precise numerical analysis, the statement cannot be logically entailed from the PFS results explicitly shared and appears to contradict them.
GPT-3.5
The statement "The shortest PFS in cohort 1 of the primary trial was 1.4 months below average" contradicts the given trial information. Justification: Based on the given trial information, the median PFS for cohort 1 (NK105 arm) is reported as 8.4 months (with a confidence interval of 7.0 to 9.9), while the median PFS for cohort 2 (Paclitaxel arm) is reported as 8.5 months (with a confidence interval of 6.9 to 11.5). Neither of these results indicates the shortest PFS being 1.4 months below the average. Therefore, the statement contradicts the given trial information as it incorrectly suggests that the shortest PFS in cohort 1 was 1.4 months below the average.
LLAMA 2 70B
Contradiction. The statement "The shortest PFS in cohort 1 of the primary trial was 1.4 months below average" implies that the shortest PFS in cohort 1 was 1.4 months less than the average PFS in cohort 1. However, the results provided in the PRIMARY TRIAL RESULTS section show that the median PFS for cohort 1 (NK105) was 8.4 months, and the median PFS for cohort 2 (Paclitaxel) was 8.5 months. Since the median PFS for both cohorts is above 8 months, it is not possible for the shortest PFS in cohort 1 to be 1.4 months below average.
MIXTRAL 8x7B
The statement The shortest PFS in cohort 1 of the primary trial was 1.4 months below average" cannot be inferred from the given trial information. The results show that the median PFS for Arm/Group Title: NK105 was 8.4 (7.0 to 9.9) and for Arm/Group Title: Paclitaxel was 8.5 (6.9 to 11.5). Neither of these results indicate that the shortest PFS was 1.4 months below average.

Figure 6: Responses of the low-performing LLMs to the selected challenging instance, which were not significantly different from the answers provided by the top LLMs.

Figure 7: A numerical example extracted from the development set, focusing on inferring information from a single CTR's results section.

GEMINI
Contradiction. The statement "there is a **13.2%** difference between the results from the two the primary trial cohorts" is a contradiction of the trial information provided. To calculate the difference between the results from the two primary trial cohorts, we can subtract the event-free survival rate in the exemestane arm from the event-free survival rate in the anastrozole arm: **89% - 88% = 1%**. Therefore, the difference between the results from the two primary trial cohorts is **1%**, not **13.2%**. Hence, the statement is a contradiction of the trial information.

CLAUDE
Contradiction. The primary trial results provide event-free survival percentages of 87-89% for the exemestane cohort and 88-90% for the anastrozole cohort. These ranges show overlap between the results of the two cohorts. There is no information given that directly states or implies a 13.2% difference.

PALM
Contradiction. The text states that the event-free survival rate in the exemestane arm was **88% (87 to 89)**, while the event-free survival rate in the anastrozole arm was **89% (88 to 90)**. This means that the difference between the two arms was only **1%**, **not 13.2%**.

FALCON 40B
The statement "there is a 13.2% difference between the results from the two primary trial cohorts" would be a contradiction. The results reported a range of **87-89%** for the exemestane cohort and **88-90%** for the anastrozole cohort. This shows only a difference of **1-2%** between the lowest and highest estimates provided. **13.2%** is much greater than the actual difference observed between these two cohorts for the 5 year event-free survival endpoint.

Figure 8: Responses of the top-performing LLMs to the selected numerical instance, showcasing impressive performance in numerical inference across all models.

GPT-3.5
To determine if there is a **13.2%** difference between the results from the two primary trial cohorts, let's compare the percentages provided in the results. In Results 1 (Exemestane group), the percentage of participants analyzed is **88% (87 to 89**), and in Results 2 (Anastrozole group), the percentage of participants analyzed is **89% (88 to 90)**. The difference between these two percentages can be calculated as follows: **89% - 88% = 1%**. Based on the provided numbers, the calculated difference is **1%**, not **13.2%**. Therefore, the statement "there is a 13.2% difference between the results from the two primary trial cohorts" contradicts the information given in the primary trial results.

LLAMA 2 70B
ENTAILMENT. The statement mentions a **13.2%** difference between the results from the two primary trial cohorts, which is within the margin of error for the confidence interval provided in the results (**87-89%** for exemestane and **88-90%** for anastrozole). Therefore, the statement entails from the given trial information.

MIXTRAL 8x7B
Contradiction. The statement is not correct. The difference between the two groups is actually **1 percentage** point (**89%** for anastrozole minus **88%** for exemestane), which is a relative difference of about **1.12%** (**1/88 * 100**). This is not the same as a **13.2%** difference as stated

Figure 9: Responses of the bottom-performing LLMs to the selected numerical instance, where all models, except for Llama 2 70B, successfully performed the subtraction operation and made the corresponding numerical inference.

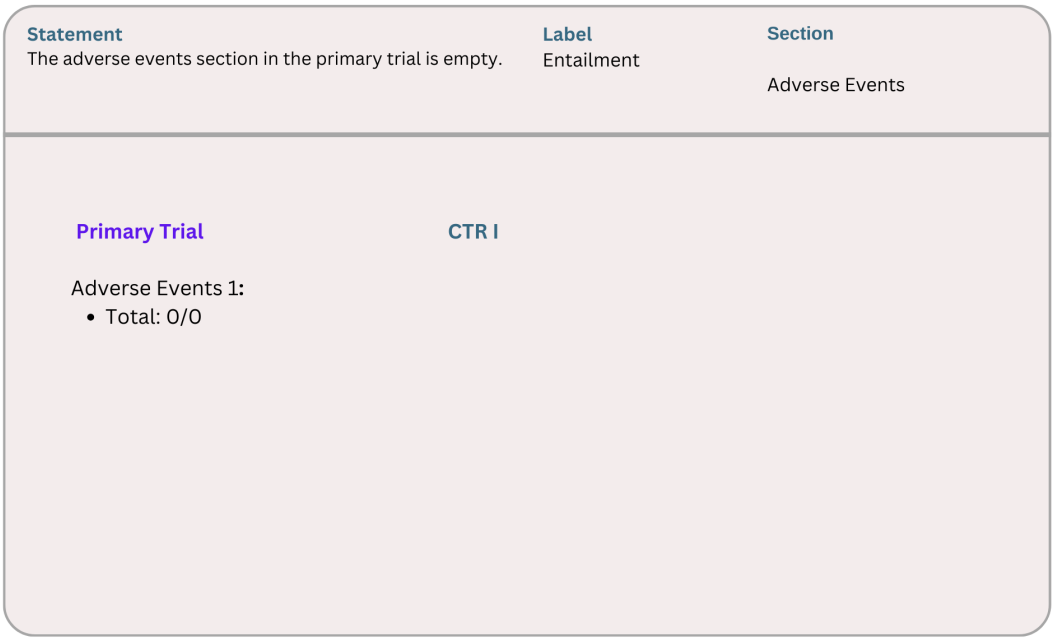

Figure 10: A CTR from the training set that is both interesting and uninteresting. It is interesting because the value of 0 denotes emptiness, but uninteresting because humans can understand 0 as representing null.

GEMINI
Entailment. The statement "The adverse events section in the primary trial is empty" is an entailment of the given trial information. The primary trial adverse events section shows a total of 0 adverse events. Therefore, it is accurate to say that the adverse events section in the primary trial is empty
CLAUDE
Entailment. The adverse events section provided reports: Adverse Events 1: Total: 0/0. The statement says "The adverse events section in the primary trial is empty". Since the only information given in the adverse events section is: Adverse Events 1: Total: 0/0. And there are no other details listed, this directly matches the statement that the adverse events section is empty. Therefore, the statement can be directly substantiated and entailed by the adverse events data shown, which contains no reported events. The answer is entailment, as the content or lack of content in the adverse events section supports the claim made in the statement.
PALM
Entailment. The text states that "Total: 0/0". This means that the adverse events section in the primary trial is empty.

Figure 11: Responses from the top-performing LLMs, demonstrating high intelligence and deliberate reasoning.

FALCON 40B
Here, the statement is that "The adverse events section in the primary trial is empty". Since the section provided does contain information (Adverse Events 1 and a total of 0/0), even if no specific adverse events are listed, it cannot logically be considered empty. Therefore, based on reviewing the details shared, the statement that "The adverse events section in the primary trial is empty" would contradict the content presented in the PRIMARY TRIAL ADVERSE EVENTS.
GPT-3.5
Based on the given adverse events section from the primary trial, the statement The adverse events section in the primary trial is empty" entails from the trial information. Here's the justification: In the adverse events section provided for the primary trial, the data is presented as follows: Adverse Events 1: Total: 0/0. The total number of adverse events reported is indicated as 0/0. This suggests that no adverse events were reported in the primary trial. Since there are no adverse events mentioned or reported, it can be inferred that the adverse events section in the primary trial is indeed empty.
LLAMA 2 70B
The Adverse Events section in the primary trial is shown to be empty, with a total of 0/0 adverse events reported. Therefore, the statement is true and entails from the given information.
MIXTRAL 8x7B
Entailment. The adverse events section of the primary trial does not list any adverse events, indicating that no adverse events were recorded during the trial.

Figure 12: Responses from the low-performing LLMs, where all models, except for Falcon 40B, achieved success comparable to the top performers.

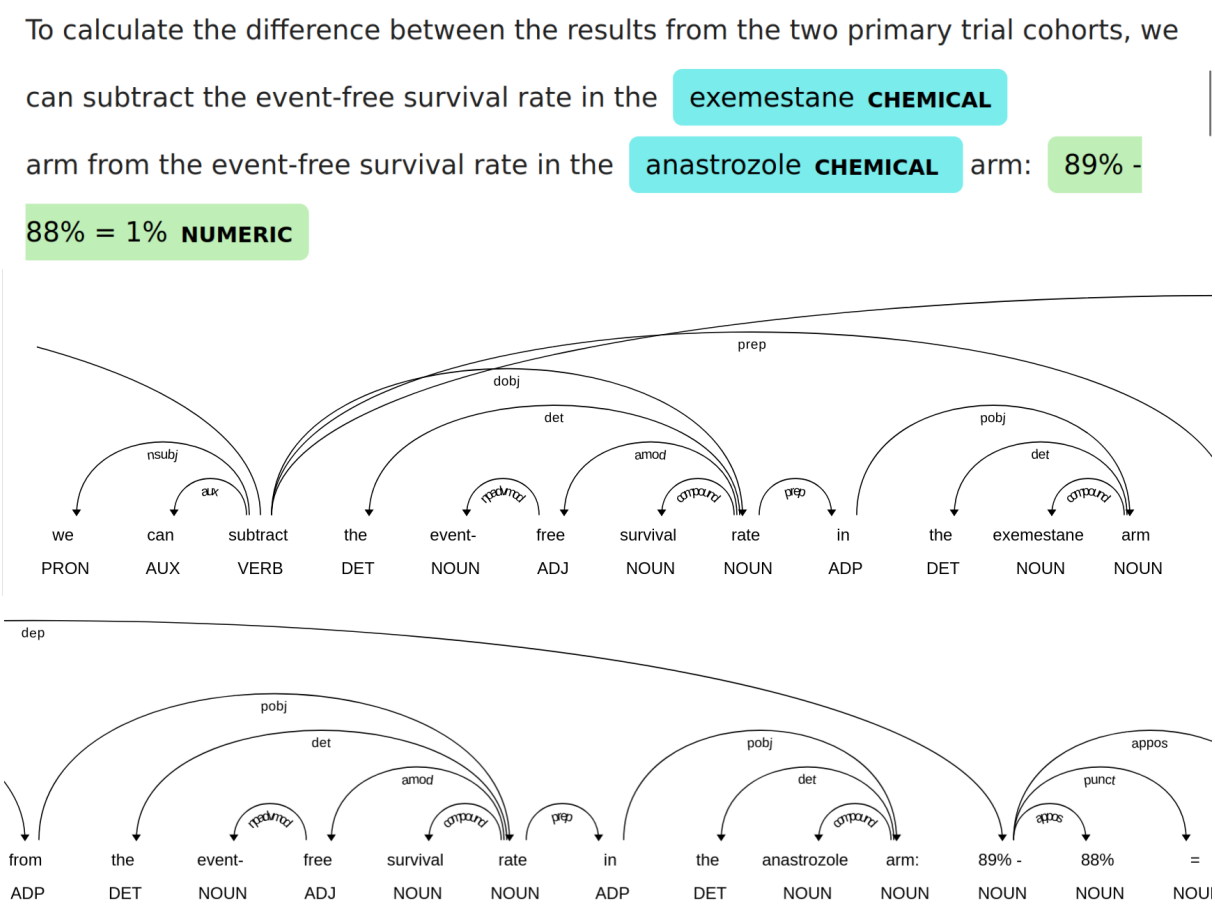

Figure 13: Semantic parse of a successful answer by Gemini. Named entities are highlighted in the above picture, where dependency tree of the sentence is exhibited in the below pictures. In the dependency tree, head token of the numerical expression **89% - 88% = 1%** is **89%** and syntactic head of **89%** is **subtract**, which is the mathematical operation. By following the syntactic parent of the numerical expression, we reach the explanation of the chain of mathematical operations, hence we can deduce that Gemini put down a valid argument and numerical reasoning.

LMEME at SemEval-2024 Task 4: Teacher Student Fusion - Integrating CLIP with LLMs for Enhanced Persuasion Detection

Abstract

This paper describes our system used in the SemEval-2024 Task 4 Multilingual Detection of Persuasion Techniques in Memes. Our team proposes a detection system that employs a Teacher Student Fusion framework. Initially, a Large Language Model serves as the teacher, engaging in abductive reasoning on multimodal inputs to generate background knowledge on persuasion techniques, assisting in the training of a smaller downstream model. The student model adopts CLIP as an encoder for text and image features, and we incorporate an attention mechanism for modality alignment. Ultimately, our proposed system achieves a Macro-F1 score of 0.8103, ranking 1st out of 20 on the leaderboard of Subtask 2b in English. In Bulgarian, Macedonian and Arabic, our detection capabilities are ranked 1/15, 3/15 and 14/15.

1 Introduction

Memes are one of the most popular content types in online disinformation activities. They thrive on social media platforms, effortlessly reaching vast audiences. Memes within disinformation activities employ various rhetorical and psychological techniques, such as oversimplification of causation, insults, and defamation, to achieve their impact on users. In this context, meme detection is crucial for identifying and reducing the spread of false information.

The SemEval-2024 Task 4 (Dimitrov et al., 2024) is a multilingual detection task involving persuasion techniques in memes, and we participate in Subtask 2b, the binary classification task, to identify whether it contains a persuasion technique or no technique.In addition to English, the task also includes three test datasets in different languages, which are only released together with the test data in the final phase of the task.The purpose of this design is to evaluate the model's performance in zero-shot scenarios, specifically its capability on languages it has not encountered before.

The key to meme detection lies in uncovering rich correlations within memes between seemingly unrelated text and image components, particularly when there is no apparent connection between the text and image. In cases where the implicit meaning needs deeper exploration and understanding, traditional detection methods often fall short, as they approach meme detection in a straightforward end-to-end manner, overlooking a profound comprehension of meme text and images. Recently, Large Language Models (LLMs) have found success in complex reasoning. They could reveal the underlying implicit meanings beneath the surface of memes, enabling the assessment of whether persuasion techniques are present. Inspired by heuristic teaching (Pintrich and Schunk, 1996), where a teacher with rich experience can impart to students correct thinking and reasoning based on questions and corresponding answers, the students then learn how to deduce their own ways to the correct answers from questions.

To better harness the powerful reasoning capabilities and knowledge reservoir of LLMs, we proposed a Teacher Student Fusion detection system based on the CLIP (Radford et al., 2021) model and LLMs. This system operates in two stages: in the first stage, as the teacher model, the LLM is used to extract prior background knowledge related to persuasion techniques from memes; in the second stage, leveraging this prior knowledge, we fine-tune a smaller student model to detect whether memes contain persuasion techniques.

2 Related Work

2.1 Meme Classification Methods

Meme classification has emerged as a rising multimodal task in recent years. Early multimodal ap-

proaches include models like concatBERT (Kiela et al., 2019), which simply concatenates features from both images and text. Li et al. (2019) introduce the VisualBERT model, touted as the first image-text pretraining model. It utilizes Faster RCNN (Girshick, 2015) for image feature extraction, combines the extracted image features with text embeddings, and then inputs the concatenated features into a single Transformer structure initialized by BERT (Devlin et al., 2018) for classification. Lee et al. (2021) propose the DisMultiHate model, which enhances the classification capability and interpretability of hate memes by introducing entity detection in memes and incorporating statistics on race and gender information as supplementary data. Zia et al. (2021) employ the CLIP encoder to obtain features from both images and text, then simply concatenate these features and pass them to a logistic regression classifier. However, current solutions only capture the superficial signals of different modalities in memes in an end-to-end manner, failing to guide the model in-depth understanding of the complex and diverse relationships between visual and textual elements.

2.2 Large Language Models

Recently, LLMs (Brown et al., 2020) have demonstrated remarkable reasoning capabilities, generating high-quality reasoning steps to augment input prompts to LLMs and improve their few-shot or zero-shot performance (Wei et al., 2022; Kojima et al., 2022; Wang et al., 2022b). Reasoning steps have also been employed for additional fine-tuning to "self-improve" LLMs (Zelikman et al., 2022; Huang et al., 2022). Unfortunately, the large size of LLMs restricts their deployment on detecting memes with diverse modalities. Knowledge distillation has been successfully used to transfer knowledge from larger, more competent teacher models into smaller student models affordable for practical applications (Buciluǎ et al., 2006; Hinton et al., 2015; Beyer et al., 2022). However, existing researches on knowledge distillation from LLMs (Wang et al., 2022a; Ho et al., 2022; Magister et al., 2022) only consider the language modality. To accommodate multimodal features, we conduct abductive reasoning from LLMs, extracting underlying rationales as prompt arguments to assist in meme detection when fine-tuning smaller language models (LMs) for meme detection.

3 System overview

We define a meme detection dataset that potentially contains persuasion techniques as a set of memes where each meme $M = \{I, T, y\}$ is a triplet representing a visual content I that is associated with the textual T, and a ground-truth label $y \in \{propagandistic, non\_propagandistic\}$.

The core idea of our teacher student fusion model is to reason and develop a cognition-level rationale beyond the recognition-level perception (Davis and Marcus, 2015) by constraining the relationships between visual and textual elements in memes. To better utilize multimodal reasoning distilled from LLMs, this task is formulated as a natural language generation paradigm, where our model takes the text T and image I as the input and generates a textual output of the label y to clearly express whether at least one persuasion technique is present in the meme or not. In this paper, we propose to utilize abductive reasoning from LLMs with multimodal inputs to train smaller downstream models. Our overall framework is illustrated in Figure 1, which consists of abductive reasoning from LLMs and model fine-tuning.

3.1 Stage 1: Abductive Reasoning from the Teacher Model

We activate explicit reasoning knowledge in LLMs as the teacher model. Through prompt learning in causal reasoning, the LLM acquires meme-related context and hidden information, to guide student model in detecting persuasion techniques. Given a meme sample M from the training data, we first extract the text caption $\hat{I}$ of the image I to represent the visual content by off-the-shelf captioning model[1]. Specifically, based on the triplet $\left\{\hat{I}, T, y\right\}$, we design a prompt p:

"*Given the textual of a meme: [T], which is embedded in its image: [$\hat{I}$], labeled as [y]. Please provide a streamlined rationale for inferring the meme as [y], incorporating prior background knowledge related to persuasion techniques but without explicitly indicating the label.*"

It prompts the LLMs to generate a rationale R including rich contextual background knowledge, enabling the inference of whether persuasion techniques are present in memes.

[1] https://huggingface.co/nlpconnect/vit-gpt2-image-captioning

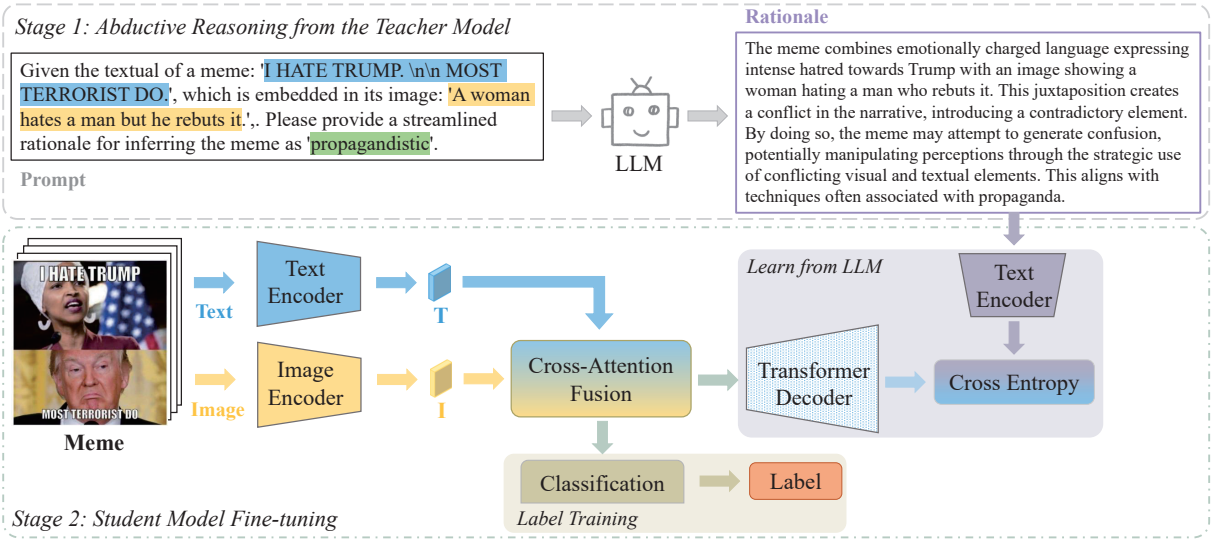

Figure 1: The framework of our method involves two stages. We first conduct abductive reasoning from the teacher model to extract rationales (purple) by the prompt consisting of the meme text (blue), the image caption (yellow), and the label (green). Utilizing the generated rationales, we then train the student model and predict whether memes contain persuasion techniques.

3.2 Stage 2: Student Model Fine-tuning

To facilitate the interaction between meme text and images, we fine-tune a smaller student model for persuasion detection tasks. By using the reasons generated by the teacher model as background knowledge, we aid in uncovering the rich interrelationship between text and vision modalities of memes. For a meme sample M,we first use the encoder of the CLIP model to encode the text T and image I input to obtain the embedding vector H_T and H_I.The advantage of attention mechanism in modality fusion and alignment lies in its ability to dynamically allocate and adjust weights for different modalities, allowing the model to flexibly focus on specific parts of the input. By emphasizing relationships between modalities, the attention mechanism helps improve the effectiveness of modality fusion and enhances the model's ability to capture important information. Therefore, we adopted a cross-attention mechanism for the fusion of textual and visual features.

$$Q_T = W_Q H_T + b_Q \quad (1)$$

$$K_I = W_K\ H_I + b_K \quad (2)$$

$$V_I = W_V\ H_I + b_V \quad (3)$$

$$H_o = Softmax\left(\frac{(K_I)^T Q_T}{\sqrt{d}}\right) V_I \quad (4)$$

Among them, d is the dimension of the feature, softmax is the activation function.

Learn from LLM By inputting the fused features H_o to the transformer decoder for decoding,we obtain the decoded output. Subsequently, we calculate the cross-entropy loss between this output and the given reason, as expressed by the following formula. Minimizing the cross-entropy loss between the meme feature and the generated reason feature facilitates the extraction of prior knowledge from the generated reason. This process helps the model transfer the contextual background information from the generated reason to the meme feature.

$$\mathcal{L}_{llm} = CrossEntropy(decoder(H_o), R) \quad (5)$$

Label Training Through the aforementioned process, our model has acquired the reasoning ability to extract persuasion techniques from LLM. As the objective of the task is to determine whether a meme contains persuasion techniques, label prediction becomes essential. This process shares the same model architecture as the preceding steps, with the introduction of a classifier during the decoding phase for label prediction. During the training process, we optimize the model by minimizing the cross-entropy loss between the predicted labels and the ground truth labels. The loss function is expressed as follows.

$$\mathcal{L}_{label} = CrossEntropy(y^{pre}, y^{true}) \quad (6)$$

Through the above process, for the data samples to be predicted, we can directly predict the labels

of the model without generating corresponding rationales.

4 Experiments

4.1 Dataset and Evaluation

The dataset from the Task 4 of SemEval-2024 contains memes potentially employing persuasion techniques. After training on the English dataset, the model is tested across four languages: English, Bulgarian, North Macedonian and Arabic. As mentioned in the official task description, we employ macro-F1 to evaluate the performance of binary classification Subtask 2b.

In the experiments, we consider the 7b LLaMa2 model (Touvron et al., 2023) as the teacher model. For the task-specific student model, we utilize the CLIP-ViT-B/32 (Radford et al., 2021) architecture as the foundational framework. During the training phase, we evaluate the performance of the model every 100 steps and retain the parameters of the model that performed best on the validation set. The hyperparameters settings adopted are detailed in Table 1. All models are trained on NVIDIA GeForce GTX 3090 GPU.

Dataset	Model	Macro-F1
Bg - Test	baseline	0.1667
	LMEME(w/o llm)	0.6250
	LMEME	0.6710
NM - Test	baseline	0.0909

	LMEME(w/o llm)	0.2933
	LMEME	0.3620

Table 3: Main experimental results in Bulgarian, North Macedonian and Arabic.

4.2 Results and Analysis

Table 2 shows the English detection capabilities of our system in Persuasion Techniques in Memes. A noticeable improvement is observed when comparing it to the scenario without the incorporation of prior knowledge from the LLM, our system in this study demonstrates superior performance. This indicates that leveraging background knowledge obtained from the teacher model can enhance the model's understanding of persuasion techniques to some extent, assisting the model in more accurately detecting memes. Furthermore, the combination of CLIP's encoding capability and the design of cross attention fusion using attention mechanisms enables the system to better align semantic features between text and visuals, facilitating more effective meme persuasion detection.

Table 3 displays our system's zero-shot capability in Bulgarian, North Macedonian, and Arabic. It can be observed that our system exhibits a significant improvement over baseline results in Bulgarian and North Macedonian, ranking 1/15 and 3/15 in the task. In comparison, there is also an improvement in results for Arabic, although not as pronounced as in the first two languages. The potential reason for this lies in the fact that English is an inflectional language with some agglutinative and analytic features. Bulgarian and Macedonian also share some features as inflected languages. However, Arabic introduces agglutinative features onto its inflectional foundation. Since our model has been trained on an English dataset, its effectiveness in detecting agglutinative features might be slightly inferior compared to inflectional languages. Additionally, the ablation results on these

three datasets also indicate the superiority of introducing prior knowledge. This further validates the effectiveness of the teacher student fusion system proposed in this paper.

5 Conclusion

This paper provides a detailed exposition of our approach in addressing Subtask 2b of Semeval2024 Task 4. Our teacher student fusion system initially leverages the Large Language Model as the teacher model to generate background knowledge regarding whether memes contain persuasion techniques. Subsequently, we incorporate this knowledge to fine-tune the student model by minimizing cross-entropy loss, sharing learned parameters with the predictive parameters of the model. Finally, we proceed with predictions using the trained model.

In the future, we will explore alternative encoding methods, better aligned image and textual semantic fusion methods, LLMs of different sizes and types, and different ways of prompting LLMs to generate enhanced background knowledge for meme persuasion detection.

Abstract

In this paper, we introduce our system for all three tracks of the SemEval 2024 EDiReF Shared Task 10, which focuses on Emotion Recognition in Conversation (ERC) and Emotion Flip Reasoning (EFR) within the domain of conversational analysis. Task-Track 1 (ERC) aims to assign an emotion to each utterance in the Hinglish language, a code-mixed language between Hindi and English, from a predefined set of possible emotions. Tracks 2 (EFR) and 3 (EFR) aim to identify the trigger utterance(s) for an emotion flip in a multiparty conversation dialogue in Hinglish and English text, respectively. For Track 1, our study spans both traditional machine learning ensemble techniques, including Decision Trees, SVM, Logistic Regression, and Multinomial NB models, as well as advanced transformer-based models like XLM-Roberta (XLMR), DistilRoberta, and T5 from Hugging Face's transformer library. In the EFR competition, we developed and proposed two innovative algorithms to tackle the challenges presented in Tracks 2 and 3. Specifically, our team, Innovators, developed a standout algorithm that propelled us to secure the 2nd rank in Track 2, achieving an impressive F1 score of 0.79, and the 7th rank in Track 3, with an F1 score of 0.68.

1 Introduction

With advancements in science and technology, the rise of social media has increased remote conversations with different people, resulting in a great deal of linguistic diversity. India is the country with the highest number of users on multiple social media platforms like Facebook, WhatsApp, Instagram, etc. Hinglish remains the most widely used code-mixed language on social media platforms.

A primary challenge associated with code-mixed languages revolves around the misidentification of parts of speech (POS) Atrey et al., 2012. This issue arises when individuals attempt to simultaneously utilize the vocabulary of both languages, leading to the failure of current state-of-the-art machine learning algorithms. Another significant problem identified in code-mixed language is the absence of context within conversations. Unlike traditional emotion detection ML models for pure languages, where a single sentence might suffice to detect emotion, this approach proves inadequate for code-mixed languages like Hinglish. In Hindi-based conversations, context plays a pivotal role in determining emotion Bansal and Lobiyal, 2021.

The data provided by the organizers of SemEval 2024 Task 10 Kumar et al., 2024 for the task comprised conversational episodes, each containing multiple utterances from different speakers. For Track 1 Kumar et al., 2023b, the data included a list of speakers and their utterances, with emotion being the target variable. In contrast, Track 2 Kumar et al., 2022 and Track 3 Kumar et al., 2023a provided utterances and emotions, with triggers as our target variable. Upon examining the training data, we identified an imbalance in the emotion classes, particularly illustrated in Table 1. To address this discrepancy, we applied a range of sampling techniques to effectively rectify the imbalance. Further details about the data are discussed in Section 2.

For Track 1, we employed two approaches: ensemble methods and the transformer approach. In the ensemble methods, we utilized classic ML models such as Random Forest, SVM, Multinomial Naive Bayes, and Logistic Regression, complemented by hyperparameter tuning. For our transformer approach, our main strategy involved creating a pipeline consisting of two main parts: the first deals with converting Hinglish to English, and the second detects emotion from the English output provided by the first. Thus, the pipeline takes Hinglish as input and outputs the corresponding emotions.

For tracks 2 and 3, where we had to detect emotion flips in Hinglish and English conversations, respectively, we developed an algorithm that identifies the last emotion flip of every user. The algorithm takes entire episodes as input and outputs the presence of triggers.

Upon evaluating our approach on the testing set with F1-score as the evaluation metric, we obtained a score of 0.28 for Track 1, 0.79 for Track 2, and 0.68 for Track 3.

The rest of the paper is organized as follows: Section 2 talks discusses the dataset provided by organizers for all three tracks , and Section 3 deals with existing research for several code-mixed tasks focusing on Hinglish text. Further in the paper, we discuss our

proposed solutions in Section 4. Section 5 gives the experimental setup .Then Section 6 describes the performance of the different approaches along with key findings. Finally in Section 7 we have concluded our discussion.

2 Background

The dataset provided for Track 1 was supplied by the organizers. It consisted of episodes, each containing several sets of utterances in Hinglish. For every utterance, the dataset included the speaker responsible for the utterance, all formatted in JSON. Table 2 offers a glimpse into the Track 1 dataset for one of the episodes.

For Track 2, the data was similar but included an additional column for triggers. A trigger was set to 1 for the last emotion flip of every speaker, while it remained 0 for all other utterances. The primary distinction for Track 3 was the language of the utterances, which was English.

Upon analyzing the dataset, we identified eight emotions: Neutral, Joy, Sadness, Anger, Fear, Contempt, Surprise, and Disgust.

In addition to the organizer's data, we utilized the Hinglish-Top dataset. This dataset features two columns: English (en) and Hinglish (hi-en). We primarily employed this dataset for the Hinglish-to-English conversion component within our pipeline architecture.

3 Related Work

The task of emotion detection and classification has been extensively researched in the context of monolingual data. However, studies focusing on code-mixed text, especially in Indian languages like Hindi mixed with English, are limited due to the scarcity of sufficient data and the absence of a standardized approach for processing code-mixed text.

Foundational research on emotion identification within social media content written in a code-mixed Hindi-English pattern was conducted by Sasidhar et al., 2020. They compiled a dataset of 12,000 code-mixed Hindi-English texts from various sources, annotating them with emotions such as happiness, sadness, and anger. Their study utilized feature vectors generated by a pretrained multilingual model, and the classification models were derived from deep neural networks. Notably, the CNN-BiLSTM approach achieved a classification accuracy of 83.21%, outperforming other models tested in their research.

Wadhawan and Aggarwal, 2021 introduced a deep learning-based technique to recognize emotions in Hindi-English code-mixed tweets. This technique leverages transformer-based models along with bilingual word embeddings produced by Word2Vec and FastText techniques. Their experimentation with CNNs, LSTMs, bi-directional LSTMs, and a variety of deep learning models and transformers, including BERT, RoBERTa, and ALBERT, revealed that the transformer-based BERT model surpassed all others, achieving an accuracy of 71.43% according to their findings.

Bohra et al., 2018 focused on detecting hate speech in social media content that mixes Hindi and English codes, using two distinct classifiers: the Random Forest Classifier and the Support Vector Machines (SVMs). Due to the large feature vectors generated by their study, they employed the chi-square feature selection technique to reduce the size of their feature vector to 1,200. Their findings indicated that SVMs, when utilizing all attributes, outperformed the Random Forest classifier with a maximum accuracy of 71.7% . Additionally, they discovered that Word N-Grams were more effective with the Random Forest Classifier, while Character N-Grams achieved the best results in SVM.

Patil et al., 2023 conducted a comparative analysis of numerous transformer-based language models pre-trained through unsupervised methods, focusing on Hindi and English with mixed codes. Their study included non-code-mixed models such as AlBERT, BERT, and RoBERTa, as well as code-mixed models like HingBERT, HingRoBERTa, HingRoBERTa-Mixed, and mBERT. Models based on HingBERT, specifically trained on authentic code-mixed text, yielded state-of-the-art results on related datasets.

Employing the SentiMix code-mixed dataset, Ghosh et al., 2023 proposed a transformer-based multitask framework for sentiment identification and emotion classification. They enhanced the pre-trained cross-lingual embedding model, XLMR, using task-specific data to improve overall efficiency and leverage transfer learning more effectively.

Singh, 2021 discusses the outcomes of various methods used for sentiment analysis on Hinglish-written social media content, with Twitter serving as a primary example. The data was converted using Fasttext embeddings, count vectorizers, one hot vectorizers, doc2vec, word2vec, and tf-idf vectorizers. Singh employed a range of machine learning techniques, including SVM, CNN, Decision Trees, Random Forests, Naïve Bayes, Logistic Regression, and ensemble voting classifiers, to create the models. The evaluation was based on the F1-score (macro), with the ensemble voting classifier achieving the highest F1-score of 69.07%.

Speaker	Utterances	Emotions
Indu	Wo great hoga! Thanks!	Joy

4 System Description

4.1 Transformer Approach

To translate Hinglish to English and subsequently identify emotions from the translated text, we have developed a two-stage pipeline leveraging the power of transfer learning and pre-trained models from Hugging Face

In the first stage, we utilize the model developed by sayanmandal [1] as our foundational model from Hugging Face. This choice was motivated by its initial proficiency in translating between Hindi and English. To tailor its capabilities more closely to our Hinglish dataset, we applied transfer learning techniques, training it on the Hinglish TOP. dataset[2] by Agarwal et al., 2023.This process resulted in a notable improvement in translation accuracy, as evidenced by achieving a BLEU score of 18.0863%. The model adeptly takes Hinglish as input and outputs the corresponding English text, laying the groundwork for the subsequent emotion analysis.

For the second stage, the English text output from the first model is processed to extract emotional context. We employed the model of j-hartmann [3] from Hugging Face as the baseline for this task. Originally, this model, based on distilRoBERTa, was trained on a diverse array of datasets sourced from Twitter, Reddit, student self-reports, and TV dialogue utterances. However, it did not include 'contempt' among the eight emotion classes specified by the project's guidelines. Therefore, we adapted and further trained this model to recognize the additional emotion class, ensuring a comprehensive analysis of the emotional spectrum in the translated English text.

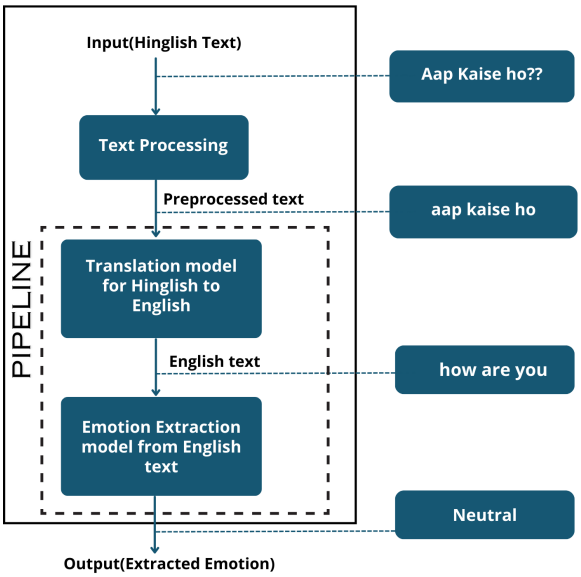

Figure 1: Transformer Architecture along with an example

4.2 XLM-Roberta

XLM-Roberta Conneau et al., 2020 has the ability to process text in Hinglish, a smooth blend of Hindi and En-

[1] sayanmandal/t5-small_6_3-hi_en-to-en
[2] Hinglish TOP dataset
[3] j-hartmann/emotion-english-distilroberta-base

glish, since it is proficient in over 100 languages, including Hindi and English. Its deep linguistic knowledge, reinforced by 2.5 terabytes of training data, enhances its comprehension of Hinglish's emotional nuances. In our work, we trained XLM-Roberta on a particular Hinglish emotion detection dataset using pre-trained weights. It was able to perform better and comprehend Hinglish emotions better as a result.XLMR model helped us to improve the overall performance significantly.

4.3 T5

T5 Raffel et al., 2020 demonstrates an impressive ability to comprehend the subtleties of Hinglish, a language that combines Hindi and English.It served as a good option for translating Hinglish because of its encoder-decoder architecture, which can easily handle code-switching, non-standard syntax, and transliteration. In our work, we fine-tuned the T5 model proposed by $sayanmandal$[2] on Hugging face with hyperparameters given in Table 6 on the external Hinglish TOP Dataset [2], which comprises 3,92,439 translations of Hinglish text into English. As a result, the model outperformed generic models in its ability to comprehend the particular complexities and differences in the dataset.

4.4 Distilroberta

DistilRoBERTa is computationally efficient and perfect for evaluating the frequently enormous amounts of translated text data because it is smaller as compared to RoBERTa and is capable of recording long-range dependencies in text. DistilRoBERTa was pre-trained on two enormous text corpora: BookCorpus and the English Wikipedia making the model more exposed to a wider range of linguistic patterns and improving its understanding of the semantic relationships found in text, both of which help the model identify different emotions. We used the j-hartmann [3] model of Hugging Face in our approach to recognize emotion from translated Hinglish text to English because of its inherent ability to recognize emotions. This helped us navigate any possible emotional nuances that were offered during translation, which strengthened our pipeline approach and increased the accuracy of the detection.

4.5 Random Forest

In Random Forest every tree conducts an independent examination of the data and makes predictions using predetermined feature criteria. A majority vote among all trees determines the final decision, providing resistance against noise and overfitting.Based on certain features like Word frequencies, part-of-speech tags, and sentiment lexicons, the model branches out and divides the input recursively until it reaches leaf nodes, which stand for expected emotions. The layered structure allows you to investigate the characteristics that contribute most to various emotion categories, providing you with a certain level of interpretability. Furthermore, we received higher results from the Random Forest Cutler et al., 2012 trials than from several other methods.

4.6 SVM

Support Vector machines (SVMs) are a useful tool for emotion identification applications because they can quickly scan high-dimensional text input and generate respectable results even with a limited amount of training data. SVMs Evgeniou and Pontil, 1999 excel at determining which feature space hyperplane most effectively separates different emotional classes, capturing the key characteristics that set each emotion apart.SVM proved to have a pretty decent F1 score as compared to other ensemble methods. It is so because of its robust hyperplane-based classification approach. The algorithm then uses statistical techniques to select the optimal line to split the different groups represented in Hearst et al., 1998.

4.7 MNB

Multinomial Naive Bayes (MNB) Kibriya et al., 2005 is a computationally efficient method for handling large datasets with great appropriateness. Using word frequency, it determines the likelihood that a text belongs to each emotion class. The steps in MNB include calculating the likelihood of every word, utilizing the Bayes theorem, and normalizing the probabilities. The final probabilities, which indicate the likelihood that a text belongs to each emotion, are produced by subtracting the estimated probability for each class from the total of the probabilities for all classes.

4.8 Logistic Regression

The linear classification model Logistic Regression Maalouf, 2011 offers a trustworthy and understandable solution for our emotion detection challenge. To forecast the likelihood of each emotion class, it uses a linear combination of input features extracted from the data. The objective variable (or output) in a classification problem, y, can only accept discrete values for a specific set of features (or inputs), X Cox, 1958. Only when a decision threshold is added does logistic regression transform into a classification technique based on the sigmoid function.

4.9 UnderSampling and Oversampling

In our experimental endeavors, we explored both oversampling and undersampling techniques Mohammed et al., 2020 to address class imbalances within our training dataset. The necessity for such interventions became evident as the 'neutral' class dominated the dataset—outnumbering instances of emotions like 'sad' and 'anger' by nearly double, and 'disgust' by an astounding factor of thirty. This disproportion threatened to skew the learning process, potentially biasing the model towards the overrepresented classes.

To mitigate this, we employed oversampling strategies, particularly focusing on the minority classes. By replicating instances from these underrepresented categories, we aimed to achieve a more equitable distribution across all emotions. This technique not only

Algorithm 1

Require: A dictionary of episode data with each entry containing a speaker, utterances, and the emotion associated with that speaker.

Ensure: A list indicating the trigger points, where each trigger point is set to 1.0 in case of a flip trigger and 0.0 elsewhere.

Initialization:
Initialize **context**: A dictionary to store each speaker's emotions and their indices like {emotion : indices}.
Initialize **lastFlipForEverySpeaker**: An empty list to store the indices of the last emotion change for each speaker.
Build Context:
for each speaker in the episode data **do**
    if the speaker is not in context **then**
        initialize their context
    end if
    append a dictionary {emotion: index} to the context for the current speaker
end for
Identify Last Emotion Changes:
for each speaker in the context **do**
    Initialize **lastFlip** to 0 and **lastEmo** to 'null'.
    for each emotion index in the speaker's context **do**
        Extract emotion and index from the context.
        if lastEmo is not equal to emotion **then**
            Set lastFlip to index.
            Set lastEmo to emotion.
        end if
    end for
    Append lastFlip - 1 to lastFlipForEverySpeaker.
end for
Initialize Trigger List:
Initialize **trig** as a list of 0.0s with a length equal to the number of speakers.

Mark Trigger Points:
for each speaker index **do**
    if the speaker's index is in lastFlipForEverySpeaker **then**
        set the corresponding element in trig to 1.0.
    end if
end for
return trig as the list of trigger points.

Algorithm 2

Require: A dictionary episodes with keys 'speakers' and 'labels'.

Ensure: A list of triggers for each episode, where each trigger list has a 1.0 for the second last conversation and 0.0 for the rest.

Algorithm:
Determine the number of speakers in the episode.
Initialize an empty list named **trig** to store trigger flags.
for each speaker in the episodes['speakers'] list **do**
    if the speaker is not the second-to-last one **then**
        append "0.0" to the trig list, indicating a non-trigger condition.
    else
        append "1.0" to the trig list, indicating a trigger condition.
    end if
end for
return a tuple consisting of the trig list from the episodes dictionary.

prevented the majority class from monopolizing the learning dynamics but also ensured that the model received ample exposure to each emotion. As a result, the capability of our model to accurately recognize emotions that were previously underrepresented saw significant improvement. Conversely, undersampling was also considered a method to harmonize the dataset. This approach involves reducing the instances of the majority class to match the numbers of the minority classes, thereby leveling the playing field. However, while undersampling can effectively reduce bias towards overrepresented classes, it also entails the risk of losing valuable information by discarding data.

Overall, we concluded that oversampling helped in the training process by giving each emotion class equal weight, and unlike undersampling, there was no loss of data.

4.10 Metrics Used F1 Score

For evaluating our model, we used the F1 score as our metric, which is given as the harmonic mean of precision and recall.

$$F1 = 2 \times \frac{precision \times recall}{precision + recall} \quad (1)$$

Here, precision is the number of samples correctly predicted out of the number of samples predicted in that category. Recall is the number of samples predicted correctly out of the number of samples present for that class.

5 Experimental Setup

5.1 Data Preprocessing

Data preprocessing steps like lowercasing,stopword removal,punctuation removal and stemming were per-

Figure 2: Data Preprocessing Overview

formed before feeding text data into ensemble learning methods as shown in Figure 2. Emotion classification improves model performance by reducing noise, normalizing text, and enhancing feature extraction because of data prerocessing.

5.2 Vectorisation for ensemble methods

Word2Vec translates words into numerical vectors that represent their relationships to other words as well as their meanings. These vectors are valuable because they convey semantic understanding rather than merely indicating word presence. CBOW Mikolov et al., 2013, which predicts words based on context, and Skip-gram are two significant Word2Vec architectures. In our experiment, Word2Vec was utilized to convert processed text into vectors, which were then inputted into ensemble learning models for emotion prediction.

6 Result

	Track1	Track2	Track3
Our F1 Score	0.28	0.79	0.68
Our Rank	27	2	7
Max F1 Score	0.78	0.79	0.79

Table 4: Leaderboard Results

6.1 Key Findings

Our models demonstrated enhanced efficiency when the input data was augmented using minority oversampling. The input data exhibited a significant class imbalance, leading the model to predominantly recognize the dominant class. To address this issue, we employed both undersampling and oversampling techniques. Oversampling notably improved model performance, as indicated in Table 5, because it enabled the model to learn about the minority classes more effectively. We adjusted all feature sizes to match that of the dominant class size (in this case, 'neutral').

As illustrated in Figure 3 and Figure 4, our Algorithm 1 approach for Tracks 2 and 3 showed a considerable number of false positives, or negative samples incorrectly predicted as positive, amounting to 959. This figure was substantially higher than that observed in Algorithm 2, which was only 68. The count of false negatives in Algorithm 1 was comparable to that in Algorithm 2 (68 and 99, respectively), though Algorithm 1

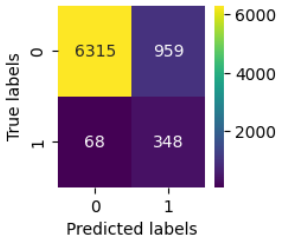

Figure 3: Confusion Matrix for Algorithm 1 on test data of track 2

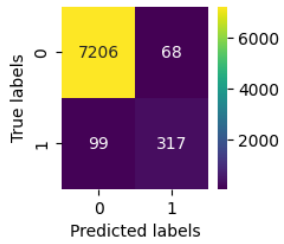

Figure 4: Confusion Matrix for Algorithm 2 on test data of track 2

was slightly more effective than Algorithm 2 in reducing false negatives.

In summary, instances of being erroneously classified as 0s were marginally higher in Algorithm 2, whereas instances of 0s being wrongly classified as 1s were significantly higher in the case of Algorithm 1.

7 Conclusion

In our participation in SemEval 2024 Task 10, we embraced two approaches: first, ensemble methods, and next, a transformer pipeline for our experiments in Track 1. Our analysis revealed a compelling insight: even marginal enhancements in translation accuracy can lead to substantial improvements in emotion classification outcomes. This underscores not only the importance of the sentence itself but also the critical role of contextual understanding in accurately leveraging this foundational insight. We developed and proposed two distinct algorithms designed to adeptly navigate the challenges of emotion flip recognition in Tracks 2 and 3.

Furthermore, our experiments highlighted the effectiveness of oversampling as a strategy to counteract the dataset's imbalance—a challenge characterized by a striking 30:1 ratio between dominant and minority classes. This technique emerged as a performance enhancer, enabling our models to achieve a more balanced understanding and representation of all emotional classes. Through these methodical and strategic efforts, we contributed valuable insights to the field and also demonstrated our algorithms' potential to transform emotion recognition practices.

Abstract

The development of social platforms has facilitated the proliferation of disinformation, with memes becoming one of the most popular types of propaganda for disseminating disinformation on the internet. Effectively detecting the persuasion techniques hidden within memes is helpful in understanding user-generated content and further promoting the detection of disinformation on the internet. This paper demonstrates the approach proposed by Team DUTIR938 in Subtask 2b of SemEval-2024 Task 4. We propose a dual-channel model based on semi-supervised learning and model ensemble. We utilize CLIP to extract image features, and employ various pretrained language models under task-adaptive pretraining for text feature extraction. To enhance the detection and generalization capabilities of the model, we implement sample data augmentation using semi-supervised pseudo-labeling methods, introduce adversarial training strategies, and design a two-stage global model ensemble strategy. Our proposed method surpasses the provided baseline method, with Macro/Micro F1 values of 0.80910/0.83667 in the English leaderboard. Our submission ranks 3rd/19 in terms of Macro F1 and 1st/19 in terms of Micro F1.

1 Introduction

Social networks play a significant role in our society. The development of social platforms has facilitated the dissemination of information, but it has also fueled the proliferation of disinformation (Da San Martino et al., 2020; Dimitrov et al., 2021). The dissemination mechanism of disinformation involves the use of propaganda techniques. "Propaganda" is defined as a dissemination pattern referring to stakeholders influencing public opinion to support specific agendas and ideas by adopting persuasion techniques, such as disseminating one-sided, biased, or even fake news. Research on detecting propaganda techniques contributes to combating network disinformation (Da San Martino et al., 2021).

Among all types of content on social networks, memes play a significant role. Memes typically exist in the form of images, possibly with overlapping text, and convey information in the form of jokes, irony, etc. In the current era of social media, they spread rapidly and can influence many people without awareness. Memes are one of the most popular content types in online disinformation propaganda activities and serve as a powerful medium for promoting ideological and cognitive persuasion techniques (Moody-Ramirez and Church, 2019). Therefore, research on automatically detecting persuasion techniques hidden in memes is of significant importance, which contributes to understanding user-generated content and further aids in detecting network disinformation.

Subtask 2b of Semeval-2024 Task 4 aims to promote research on computational methods to detect persuasion techniques in memes (Dimitrov et al., 2024), which is modeled as a binary classification problem. Due to the complexity and subjectivity inherent in persuasive language, single multimodal model may struggle to capture all relevant features effectively. To address this issue, we propose a dual-channel model based on semi-supervised learning and model ensemble in this paper. Within the image channel, we use CLIP (Radford et al., 2021) to extract image features from memes. Concurrently, in the text channel, we employ diverse pretrained language models and conduct task-adaptive pretraining utilizing certain corpora provided by the task. We execute feature extraction from the pretrained language model, employing a variety of methodologies to capture sentence features, followed by a concatenation and fusion process of the extracted features, subsequently fed into the classification layer. We implement a semi-supervised pseudo-labeling ap-

*Corresponding Author

proach, wherein pseudo-labels are assigned to the test set, thereby augmenting the training data to achieve data augmentation. Furthermore, to bolster each model's robustness, We employ Fast Gradient Method(FGM) as our adversarial training strategy, introducing perturbations to the embedding layer of the model. Lastly, We design a two-stage soft-voting ensemble strategy to amalgamate the predictions of multiple models, augmenting the model's generalization capacity and performance.

We applied our proposed method to the English dataset. Our proposed method ranked 3rd/19 in terms of Macro F1 and 1st/19 in terms of Micro F1 in the English leaderboard for Subtask 2b.

2 Related Work

Transformer (Vaswani et al., 2017) is a deep learning model based on the self-attention mechanism, which is known for its ability to effectively capture long-range dependencies in sequential data. Based on Transformer, pretrained language models such as BERT (Kenton and Toutanova, 2019) have been proposed, which capture the contextual information of each token in the text through self-attention. Subsequent pretrained language models have mainly been modified on pretraining tasks, such as RoBERTa (Liu et al., 2019), DeBERTa (He et al., 2020), and so on. These text models improve upon BERT by enhancing semantic feature representation in text feature extraction.

Existing image feature extraction methods mostly rely on multiple convolutional neural networks (Li et al., 2021), such as VGG (Simonyan and Zisserman, 2015) and ResNet (He et al., 2016). Vision Transformer (ViT) (Dosovitskiy et al., 2020) is an image processing model based on the traditional Transformer, dividing the input image into image patches and using multi-head self-attention mechanisms to capture global relationships between images. ViT represents a significant advancement of Transformer in the field of computer vision, bringing new ideas and methods to image processing tasks. CLIP (Radford et al., 2021) is a multimodal model which is trained through contrastive learning on 400 million pairs of images and text. CLIP achieves high-performance cross-modal semantic feature extraction for images and text.

3 System Overview

In this section, we will introduce the overall structure of our proposed system. Our system is divided into two stages. (1) Training of our Text-Image Multi-modal Classification Model. During the training process, we introduce several training strategies, including task-adaptive pretraining, pseudo-labeling and adversarial training. (2) Model Ensemble. We use k-fold cross-validation for model training and design a two-stage soft-voting strategy to globally integrate the models obtained in the first stage.

3.1 Model Architecture

The architecture of our model is shown in Figure 1. Our proposed text-image multi-modal classification model can be divided into two modules: feature extraction module and cross-modal fusion module. In the feature extraction module, we employ a parallel architecture to perform feature extraction separately for image and text channels using pretrained models.

For image inputs, we utilize the pretrained CLIP model. Before inputting images into the CLIP image encoder, they are resized and normalized, resulting in one-dimensional features of dimensionality 512. For text inputs, we experiment with various pretrained language models and their variants, including BERT, RoBERTa, DeBERTa, XLM (Conneau et al., 2020), DistilBERT (Sanh et al., 2019), etc. Based on their performance on the validation and dev sets, we ultimately select two general domain models and two models pretrained using political domain related corpora as text encoder models: CLIP text encoder, Deberta-v3-large (He et al., 2022), politicalBiasBERT (Baly et al., 2020), and xlm-twitter-politics-sentiment (Antypas et al., 2023). We select the latter two models because the vast majority of persuasion techniques are reflected in political domain.

The output of the CLIP text encoder is a one-dimensional vector of 512 dimensions, while for three BERT-like models above, the encoder's output is a two-dimensional vector that needs to be converted into a one-dimensional vector through pooling operation. Common pooling operations include cls, pooler, last layer average and first-last layer average.The optimal pooling method is selected for each BERT-like model as the model's pooling strategy. After the pooling layer, the text features are ultimately obtained as one-dimensional features of 512 dimensions.

The cross-modal fusion module aims to integrate features from two modalities. We concatenate the output image features with the text features and em-

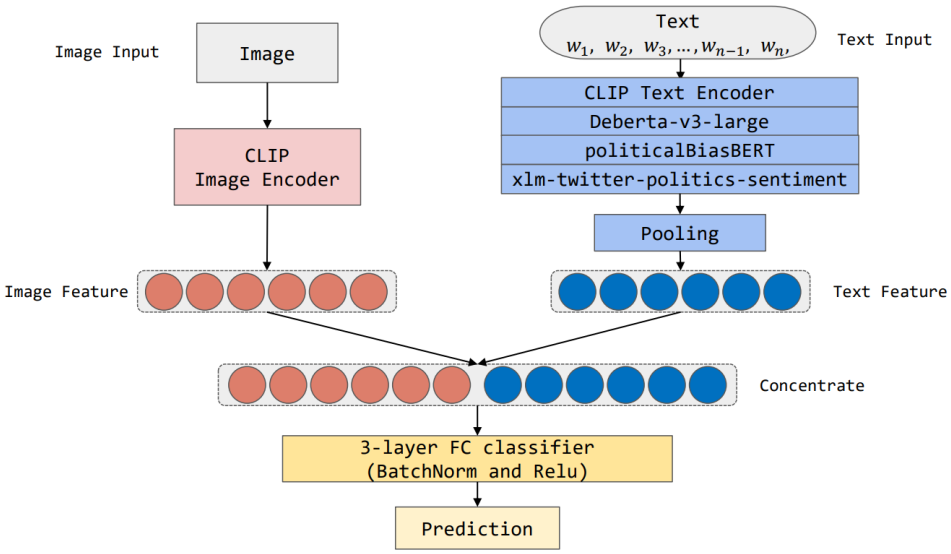

Figure 1: The architecture of our Text-Image Multi-modal Classification Model.

ploy a three-layer fully connected network as the classifier to map the final representation obtained from the fusion layer to a scalar, which is then bounded between 0 and 1 through a sigmoid function. The formula of cross-modal fusion module is defined as:

$$\hat{y}_c = \text{sigmoid}\left(W\left[h^I, h^T\right] + b\right)$$

Where h^I is image feature and h^T is text feature. Finally, the model would be fit with the binary cross-entropy loss function.

3.2 Training strategies

To further improve the performance of our model, we adopt three training strategies:

Task-adaptive Pretraining(TAPT): Certain research has proved that further pretraining models on the unlabeled task data itself or task related data, called TAPT, can improve the performance of model in downstream tasks (Gururangan et al., 2020). In this task, we adopt TAPT for three BERT-like text models. The purpose of this task is to detect persuasion techniques in memes. Therefore, we perform TAPT on text models using the provided dataset. Specifically, we collect and utilize all texts from task1, task2a, and task2b for pretraining our models with masked language model(MLM). By conducting MLM pretraining, these models can not only better fit the distribution in the task, but also learn rich knowledge and semantic information, thereby performing better on the task.

Pseudo-labeling: Pseudo-labeling is a semi-supervised method aimed at predicting labels for unlabeled data using a model trained on labeled data and adding the labeled data to the training set to achieve data augmentation. Considering the diversity of samples in the test sets, we adopt a semi-supervised pseudo-labeling method for data augmentation. We train four models on the original training set and then ensemble the four trained models using soft-voting for inference on unlabeled samples, i.e., test set samples. Subsequently, we consider samples with output probabilities greater than or equal to 0.8. Finally, we obtain 393 pseudo-labeled test set samples, which are re-incorporated into the training set for training.

Adversarial Training: Adversarial training is a common method to improve the robustness of neural networks. By adding perturbations in the embedding layer, we can obtain more stable embedding representations and more universal models, improving the performance of models on unseen data. In this task, we introduce FGM (Miyato et al., 2016) to enhance the model's robustness. The adversarial perturbation δ on s is defined as:

$$\delta = \epsilon \cdot g/\|g\|_2 \quad where \quad g = \nabla_s L(s, y)$$

where ϵ is a constant that controls the degree of perturbation suppression. The idea of FGM is to increase the perturbation direction along the gradient, where increasing along the gradient means maximizing the loss.

3.3 Ensemble Learning

To integrate the learning abilities of each model and improve the generalization ability of the final sys-

tem, we design a two-stage soft-voting strategy to ensemble the four models saved from k-fold cross-validation. In this task, due to the small size of the dataset, we use k-fold cross-validation to train models, ensuring that all data participate in training and validation to effectively avoid over-fitting. In the first stage, we average output probability values generated by the four models in each fold of the k-fold cross-validation, resulting in the probability values for each fold. In the second stage, we aggregate the probability values from each fold by averaging, yielding the final output. We determine the optimal binary classification threshold by testing on the validation set for various thresholds.

4 Experimental setup

4.1 Data description and Evaluation

The dataset is provided by Subtask 2b of Semeval-2024 Task 4. In the original dataset partition, there are 1200 samples in the training set, 150 samples in the validation set, 300 samples in the dev set, and 600 samples in the test set. After pseudo-labeling, 101 samples in the test set are labeled as non-propagandistic and 292 samples are labeled as propagandistic. We aggregate the training set, validation set, dev set, and the test set augmented with pseudo-labels into a new dataset for k-fold cross-validation. The label distribution of this dataset is shown in Table 1.

The official evaluation metrics for this task are Macro F1 and Micro F1, with a focus primarily on the performance of Macro F1 in our experiments. Both Macro F1 and Micro F1 performances are presented in the final test set ranking.

4.2 Implementation

During validation, we conduct 8-fold cross-validation on the dataset and consistently use the average measure from the first fold as the new validation set to evaluate the performance of our model. We preserve the model parameters to achieve optimal performance. During the testing phase, we train each model separately and predict the test set through the two-stage soft-voting strategy we purposed, resulting in the final prediction by averaging the probabilities from all trained models in 8 folds. After comparing the overall performance under different thresholds, we set the final threshold as 0.5, which yields the optimal average performance on the validation set under 8-fold cross-validation.

We implement our model using the transformer package[1]. We select the following four models as text encoder models: CLIP text encoder, Deberta-v3-large, xlm-twitter-politics-sentiment and politicalBiasBERT. And we select CLIP ViT-L/14@336px as the image encoder model. We sequentially combine each text encoder with the image encoder, and four final models are sequentially as follows: CLIP_{img}+$\text{CLIP}_{\text{text}}$, CLIP_{img}+$\text{DeBERTa}_{\text{text}}$, CLIP_{img}+XLM_{text} and CLIP_{img}+$\text{BERT}_{\text{text}}$. As for the pooling method, we test various options and selected the optimal one for each model based on performance on the validation set. Specifically, CLIP_{img}+$\text{DeBERTa}_{\text{text}}$ and CLIP_{img}+$\text{BERT}_{\text{text}}$ performed optimally with first-last layer average pooling, while CLIP_{img}+XLM_{text} performs optimally with pooler. We employ early stopping to retain the model parameters that exhibited the best performance on the validation set. Details of the hyper-parameter settings are provided in Table 2. We used a weighted binary cross-entropy loss using the class distribution. By default, We set ϵ to 1.0 in FGM. All experiments are conducted on an RTX 4090 with 24GB of memory.

5 Results

The overview statistics of four different models on the new validation set are shown in Table 3. Among all base models, CLIP_{img}+$\text{CLIP}_{\text{text}}$

[1]https://huggingface.co/

Setting	$CLIP_{img}$+$CLIP_{text}$	$CLIP_{img}$+$DeBERTa_{text}$	$CLIP_{img}$+XLM_{text}	$CLIP_{img}$+$BERT_{text}$
Base	0.8524	0.8375	0.8505	0.8385
+FGM	**0.8534**	0.8555	0.8435	0.8455
+TAPT	/	**0.8574**	0.8465	0.8505
+FGM+TAPT	/	0.8515	**0.8515**	**0.8586**

Table 3: Macro F1 for four models on the new validation set. "Base" indicates no training strategy added, "+FGM" indicates the addition of FGM, "+TAPT" indicates the addition of TAPT.

performs best, and $CLIP_{img}$+XLM_{text} likewise exhibits impressive performance. Additionally, $CLIP_{img}$+$BERT_{text}$+FGM+TAPT attains the highest Macro F1 score of 0.8586. The politicalBiasBERT model with FGM and TAPT strategies showcased its robust reasoning capability in detecting persuasion techniques in memes.

Experimental results highlight the effectiveness of TAPT and FGM strategies. Introducing FGM to the $CLIP_{img}$+$CLIP_{text}$, $CLIP_{img}$+$DeBERTa_{text}$ and $CLIP_{img}$+$BERT_{text}$ lead to significant performance enhancements. Both the $CLIP_{img}$+$DeBERTa_{text}$ and $CLIP_{img}$+$BERT_{text}$ models demonstrate performance improvements after introducing TAPT, and $CLIP_{img}$+$DeBERTa_{text}$with TAPT achieves the second-best overall performance. When both TAPT and FGM are employed simultaneously, all three models with BERT-like text encoder demonstrate substantial performance improvements compared with base model, while $CLIP_{img}$+XLM_{text} and $CLIP_{img}$+$BERT_{text}$ achieve their respective optimal performance levels, showcasing the effectiveness of adding FGM and TAPT to base model.

Regarding model ensemble, our analysis, illustrated in Table 4, demonstrates a significant enhancement in performance with the adoption of our two-stage global integration approach. Moreover, the scalability and robustness of our integration method are validated by the observed performance scalability relative to the number of integrated models. Results shows that all model ensemble performed best, which demonstrates the effectiveness of our model ensemble strategy.

We employed all-model ensemble as the final model of our system and submitted the result file of the test set predicted by the final model. The official rankings are shown in Table 5. We ranked 3rd in terms of Macro F1 and 1st in terms of Micro F1. Results show that our system demonstrates outstanding performance in detecting persuasion techniques in memes, and the integration of TAPT, FGM and model ensemble techniques further enhances the detection capability of our system.

Method	Macro F1	Micro F1
$CLIP_{img}$+XLM_{text}	0.8515	0.8711
Two-Model Ensemble	0.8515	0.8711
Three-Model Ensemble	0.8596	0.8789
All-Model Ensemble	**0.8654**	**0.8789**

Table 4: Results for model ensemble on the new validation set. Two-model ensemble refers to integrating $CLIP_{img}$+XLM_{text} and $CLIP_{img}$+$BERT_{text}$. Three-model ensemble adds $CLIP_{img}$+$DeBERTa_{text}$. For all-model ensemble, all four models are integrated for ensemble.

Rank	Team	Macro F1	Micro F1
1	LMEME	0.81030	0.82500
2	SuteAlbastre	0.80964	0.83500
3	**DUTIR938**	**0.80910**	**0.83667**
4	BCAmirs	0.80337	0.82500
5	Snarci	0.79860	0.82667

Table 5: Results of top 5 teams for subtask2b English leaderboard on the test set.

6 Conclusion

The paper presents our system designed for Subtask 2b of Semeval-2024 Task 4. We propose a dual-channel model based on semi-supervised learning and model ensemble. Our framework leverages multiple pretrained models served as feature extractors for images and texts. We integrate a semi-supervised pseudo-labeling approach for data augmentation, and introduce TAPT and FGM adversarial training to significantly enhance the model's performance and robustness. Finally, to enhance the generalization capability of our system, we design a two-stage soft-voting model ensemble strategy. Our system achieves excellent performance in detecting persuasion techniques in memes, and we ranked 3rd in terms of Macro F1 and 1st in terms of Micro F1 in the test set for Subtask 2b. Our future research will be directed towards exploring the cross-modal fusion mechanisms within the model.

Abstract

This paper outlines the approach of the ISDS-NLP team in the SemEval 2024 Task 10: Emotion Discovery and Reasoning its Flip in Conversation (EDiReF). For Subtask 1 we obtained a weighted F1 score of 0.43 and placed 12 in the leaderboard. We investigate two distinct approaches: Masked Language Modeling (MLM) and Causal Language Modeling (CLM). For MLM, we employ pre-trained BERT-like models in a multilingual setting, fine-tuning them with a classifier to predict emotions. Experiments with varying input lengths, classifier architectures, and fine-tuning strategies demonstrate the effectiveness of this approach. Additionally, we utilize Mistral 7B Instruct V0.2, a state-of-the-art model, applying zero-shot and few-shot prompting techniques. Our findings indicate that while Mistral shows promise, MLMs currently outperform them in sentence-level emotion classification.

1 Introduction

Task 10 from SemEval 2024 competition (Kumar et al., 2024) addresses the complex challenge of identifying the emotions within dialogues (English and Hindi). This task comprises two primary objectives: firstly, assigning an emotion label to each utterance within a dialogue, and secondly, discerning the trigger utterance or utterances responsible for an emotion-flip within the dialogue (Kumar et al., 2022). Emotions play a crucial role in human interaction and one can understand more from a text if one knows the underlying sentiment of the writer. In contexts where disagreements may arise, such as customer service platforms, virtual assistant chats or forums, identifying trigger utterances for emotion flips can help mediate conflicts and prevent escalation. A chatbot dealing with an angry customer would benefit from knowing how to speak in order to generate empathetic responses. If it knows that the chatbot's current sentence can trigger an emotion flip from neutral to anger, the chatbot should refine it, or if the emotion flip is from anger to joy, the chatbot should be more confident in such a response in the future.

Both types of models we tried for Subtask 1 were based on transformers. The first one used BERT-like models and we achieved the best accuracy with them, while the second one is a state of the art causal model (Mistral, (Jiang et al., 2023)) that was tested in zero-shot and few-shot settings with poorer results.

Although in the first task our system worked well, placing 12th in the leaderboard, the other 2 tasks were much harder and we placed 14th on the second subtask. We believed that with a better strategy to prevent overfitting (like under or oversampling), our system would have improved. Our code is open source and available to use on GitHub.

2 Background

The competition had 3 subtasks explained in Figure 1 and we participated in all of them with the best results on subtask 1 where we placed 12th with an F1 score of 0.43.

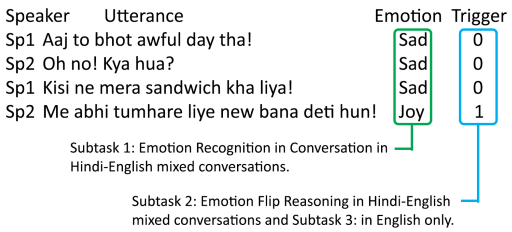

Figure 1: Three sub-tasks explained

2.1 Dataset

The dataset contains English and Hindi code-mixed conversations for Subtask 1 and 2 and English only conversations for Subtask 3 (Table 1). The dataset is quite small, except for the training dataset for

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 649–654

Table 1: Datasets sizes used in this competition by tasks.

	Subtask 1	Subtask 2	Subtask 3
Train	8506	98777	35000
Dev	1354	7462	3522
Test	1580	7690	8642

Subtask 2 and 3. If we were to combined them for Subtask 1, our F1 score would reach 0.97, but it wasn't allowed. This fact shows that with more data our model would do really well. The dataset is based on MELD, a known emotion recognition dataset, which was then augmented with triggers for the emotion-flip task.

There were 8 distinct emotions to predict: neutral, anger, surprise, fear, joy, sadness, disgust, and contempt. By far the most predominant emotion is neutral, followed by joy and anger (Figure 2). If we look at Subtask 2, most often the emotion flips are from neutral to joy or anger (Figure 3).

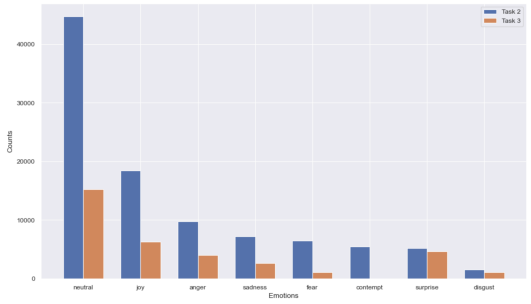

Figure 2: Emotion Distribution Comparison between Task 2 and Task 3

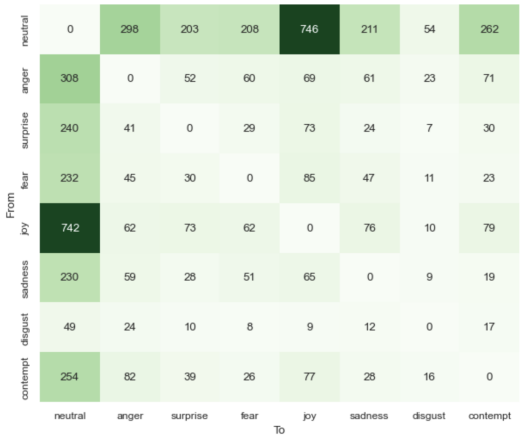

Figure 3: Task 2: Emotion-flip counts

2.2 Previous Work

Since the release of the first small datasets for emotion recognition in 1992 (Ekman, 1992), the field has evolved substantially, marked by significant contributions from big companies in the form of extensive datasets (Demszky et al., 2020). In the beginning, lexicon based methods were used in which there was a manually curated dictionary which associates words with specific emotions. The algorithm was simply picking the most expressed emotion according to the dictionary. This method had severe limitations because it was ignoring context, sentence structure and negations which can flip a sentiment. Today, state of the art models are based on transformer architecture and use either Masked Language Modelling (BERT based models (Devlin et al., 2018)) or Causal Modelling (GPT (Brown et al., 2020)) which can capture dependencies and nuances missed by word-level approaches.

While traditional emotion recognition tasks are well-established, research on emotion flip recognition is still in its early stages because it is a new task within the field of emotion analysis. Research (Kumar et al., 2021) has found that a transformer based classifier with 6 encoder layer (EFR-TX) works well, obtaining an F1 score of 40 when trained on MELD-FR dataset and tested on IEMOCAP-FR dataset.

3 System overview

We tried two approaches, both of them based on transformer architecture: Masked Language Modelling and Casual Modelling. We chose these two architectures because of their recent successes in NLP.

3.1 Masked Language Modelling

We used pre-trained BERT-like models in a multilingual setting so that it can tokenise Hindi sentences. These pre-trained models will give us the features from sentences and then we pass them through a classifier which will do the prediction for each task Figure 4.

Figure 4: Model architecture

3.1.1 Input

Analysis of dialogue sentences reveals a predominantly short length, with a sharp decline in frequency after 30 tokens (see Figure 5). To optimize performance, various maximum sequence lengths were tested, with 55 tokens yielding the best results (Figure 6). Data preprocessing, (such as lemmatization, removing punctuation or stopwords) didn't help the model learn better so we kept the input as is. Probably this is because punctuation and stopwords contain useful information that the models is able to learn.

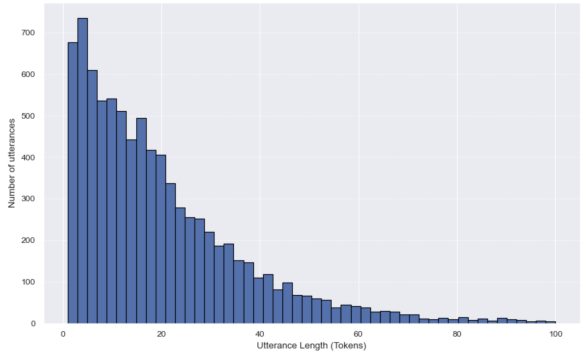

Figure 5: Distribution of utterances lengths.

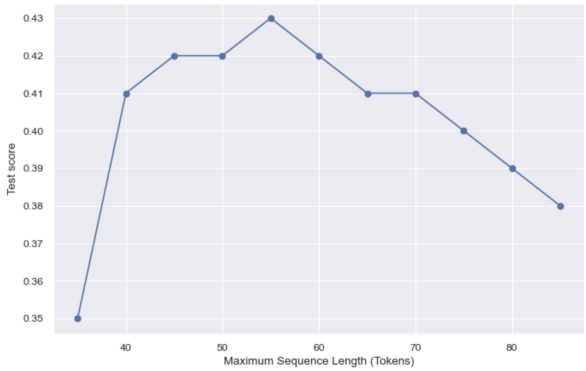

Figure 6: Best model score with different maximum utterances lengths.

3.1.2 Output

Selecting the optimal hidden state layer is crucial for leveraging the pre-trained model's results. Our experiments demonstrated that using the final layer's output yielded the strongest performance, with accuracy declining in earlier layers. For MLM-type models, the [CLS] token encodes the features, which is what we pass to our classification layer.

Among various classifiers tested (Table 2), fully connected layers excelled, likely due to their ability to model complex, non-linear relationships. The top-performing model employed a fully connected layer with 0.5 dropout and a Softmax activation function.

Table 2: Test scores of different classifiers.

Classifier	Extra features	Score
Fully Connected	Dropout(0.5)	0.43
Fully Connected	Dropout(0.7)	0.42
Fully Connected	Dropout(0.2)	0.40
Fully Connected	-	0.40
RandomForest	-	0.23
LogisticRegression	-	0.21
KNeighbors	-	0.20

3.1.3 Fine-tuning

The large pre-trained language models we employed offer a robust foundation for understanding language in general. Through fine-tuning, we adapt them to the nuances of our emotion recognition task. Inspired by the strategy presented in (Sun et al., 2020), we initially train only the classifier with a larger learning rate (5e-5) and a warm-up period of 10,000 steps over 'k' epochs (we tried a range of 'k' from 1 to 10). Subsequently, we fine-tune both the classifier and the transformer's final layer using a smaller learning rate (2e-5). Our goal in freezing the transformer weights at first, and then training them with a reduced learning rate, is to minimize the risk of overfitting.

3.2 Causal Modelling

Given the success of generative models we also tried Mistral 7B Instruct V0.2 which is believed to be state of the art in its category of models (Jiang et al., 2023). These type of LLMs have had success in a large number of NLP tasks, but seem to still lag Masked Language Models in sentence classification.

3.2.1 Prompting

In Causal Modelling, how you prompt the model significantly influences its performance. We tested different prompting strategies in both zero-shot and few-shot settings:

- **Zero-Shot Learning:** Here, we provide the model with a single example and ask it to predict the emotion without any additional references. For zero-shot learning the best prompting technique was: "[INS] Given the following sentence: `{sentence}`. ### Predict which emotion is expressed. Chose one

of the following options: neutral, anger, surprise, fear, joy, sadness, disgust, and contempt. Answer in one word only. Answer: [\INS]"

- **Few-Shot Learning:** In this setting, we give the model several examples – one for each emotion – along with their corresponding labels. This leverages the model's in-context learning ability, potentially boosting its performance for unseen samples. For few-shot learning the best prompting technique was: "[INS] This is an example of a sad sentence: {sentence} {repeat for every emotion}. ### Predict the emotion of the following sentence: sentence. Chose one of the following options: neutral, anger, surprise, fear, joy, sadness, disgust, and contempt. Answer in one word only. Answer: [\INS]"

4 Experimental setup

4.1 Data Split Strategy

We employed a classic data split approach:

- **Initial Development**: We combined the training and development sets and shuffled the data. Subsequently, we used 70% for training, 10% for validation, and the remaining 20% as a held-out test set.
- **Competition Test Set Release**: Upon the competition's test set release, we directly evaluated our models using the platform. To maximize training data, we trained on the combined training set with a 20% validation split.
- **Final Model**: Once we selected our best model, we re-trained it on the entire dataset without validation. This re-training didn't yield significant improvements

4.2 Subtask 1

We'll focus on Subtask 1, where we achieved strong results. The key hyperparameters used:

- **Batch Size**: A batch size of 64 provided the best balance. Smaller sizes hurt performance, while larger sizes exceeded our memory constraints.
- **Fine-Tuning**: We trained for 4 epochs with frozen model weights, followed by 3 epochs with only the last layer unfrozen (as detailed in section 3.1.3).
- **Classifier**: Our classifier used 128 neurons, 0.5 dropout, and a softmax activation.
- **Optimization**: We used cross-entropy loss, the AdamW optimizer, and experimented with different learning rates (see section 3.1.3).
- **Evaluation**: We measured performance using the MulticlassF1Score with 8 classes and 'macro' averaging.

5 Results

Our top-performing model (Table 3) was a fine-tuned FacebookAI/xlm-roberta-large (Conneau et al., 2019). This highlights the superiority of fine-tuned Masked Language Models (MLMs) over Mistral for sentence classification tasks. The results suggest that smaller Causal models remain less effective than fine-tuned MLMs in this domain. We also see that few-shot Mistral is worse than zero-shot, probably because too much data in the prompt confuses the model.

Model	Train	Validation	Test
xlm-roberta	0.74	0.57	**0.43**
mdeberta-v3	0.74	0.56	0.42
bert-multi	0.66	0.48	0.35
Mistral zero-shot	-	-	0.32
Mistral few-shot	-	-	0.31
distilbert-multi	0.6	0.47	0.29

Table 3: Results for Subtask 1 - Masked Language Models and Causal Models (Mistral).

In terms of number of epochs, our best model was overfitting when finetuned for too many epochs (Table 4) and we finally trained for 4 + 3 epochs.

Frozen	Fine-tunning	Training	Validation	Test
3	2	0.67	0.53	0.4
3	3	0.71	0.55	0.42
4	3	0.74	0.57	**0.43**
4	4	0.78	0.60	0.42
4	5	0.85	0.45	0.38
5	3	0.71	0.56	0.42

Table 4: Finding the optimal number of epochs to avoid overfitting. First column contains epochs when training only the classifier. Second columns contains epochs when training the classifier and the last transformer layer.

5.1 Error analysis

Our confusion matrix (Figure 7) reveals that the model overpredicts the 'neutral' emotion, likely due to its prevalence in the training data. This created a bias, leading the model to misclassify instances of other emotions as 'neutral'. While we attempted to mitigate this with class weights in the loss function, it proves insufficient. In the future, we should explore more robust techniques like oversampling or undersampling to address the class imbalance.

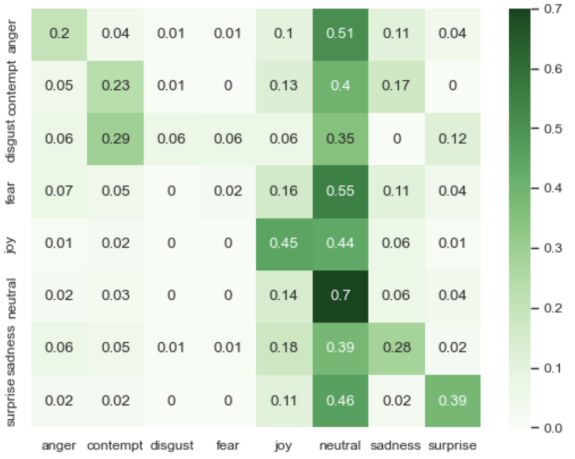

Figure 7: Confusion matrix. On y-axis true labels, on x-axis predicted labels. Values are normalised.

As seen in the emotion accuracy chart (Figure 8), the model performs best on the dominant 'neutral' class, along with well-represented emotions like 'joy' and 'sadness'. Conversely, the model struggles to predict the 'disgust' emotion, which aligns with its under-representation in the training data. This suggests a direct correlation between dataset frequency and model proficiency for each emotion.

6 Conclusion

Overall, our system achieved encouraging results in Subtask 1, despite exhibiting some overfitting for dominant labels. While performance on the emotion-flip detection tasks (Subtasks 2 and 3) highlights areas for improvement, we still placed in the first half of the leaderboard. Looking ahead, we plan to investigate hybrid transformer-LSTM architectures for a more nuanced understanding of emotion-flip triggers. Additionally, enriching the data by incorporating a broader conversational context through multi-turn analysis could enhance our model's capabilities. Not least, even though we tried Mistral, there are newer causal models like

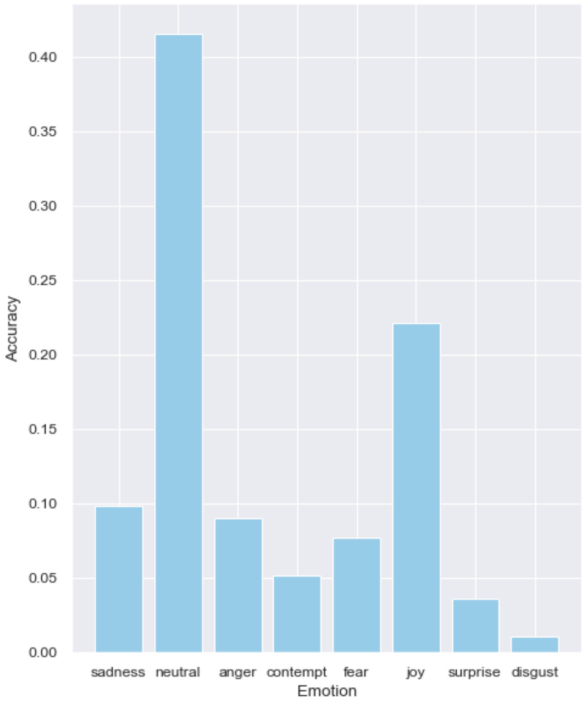

Figure 8: Accuracy by emotion. Accuracy directly correlates with the frequency of each emotion in the training set.

Mixtral (Jiang et al., 2024) and Solar (Kim et al., 2023) which could perform better at this type of task.

Abstract

In this manuscript we describe the UMUTeam's participation in SemEval-2024 Task 4, a shared task to identify different persuasion techniques in memes. The task is divided into three subtasks. One is a multimodal subtask of identifying whether a meme contains persuasion or not. The others are hierarchical multi-label classifications that consider textual content alone or a multimodal setting of text and visual content. This is a multilingual task, and we participated in all three subtasks but we focus only on the English dataset. Our approach is based on a fine-tuning approach with the pre-trained RoBERTa-large model. In addition, for multimodal cases with both textual and visual content, we used the LMM called LlaVa to extract image descriptions and combine them with the meme text. Our system performed well in three subtasks, achieving the tenth best result with an Hierarchical F1 of 64.774%, the fourth best in Subtask 2a with an Hierarchical F1 of 69.003%, and the eighth best in Subtask 2b with a Macro F1 of 78.660%.

1 Introduction

The rise of social media has facilitated the rapid spread of information. However, its unconstrained nature has also led to the spread of information whose accuracy is difficult to verify. As a result, misinformation and disinformation have become serious problems in everyday life. For example, during the COVID-19 pandemic, social media enabled healthcare professionals to quickly communicate professional information to the public; however, studies also revealed the spread of inaccurate health-related information (Ferrara et al., 2020).

A special case of spreading misinformation is the use of memes. Memes consist of images overlaid with text created by Internet users and have become one of the primary forms of content in online disinformation campaigns. Designed specifically to actively spread inaccurate information, "disinformation memes" are particularly effective on social media platforms, where they can quickly reach large audiences (Qu et al., 2022). Using various rhetorical and psychological techniques such as causal oversimplification, name-calling, and smear tactics, memes play a pivotal role in influencing users' perceptions and beliefs.

To address this phenomenon, the Multilingual Detection of Persuasion Techniques in Memes shared task has been organized at SemEval-2024 (Dimitrov et al., 2024). The goal of this task is to develop models for detecting persuasion techniques in the textual content of a meme, as well as in a multimodal setting where both textual and visual content are analyzed together. The task is divided into three main subtasks:

- **Subtask 1**. This is a unimodal hierarchical multi-label classification. The goal is to identify which of the 20 persuasion techniques are present using only textual features.
- **Subtask 2a**. This is a multimodal hierarchical multi-label classification. The goal is to identify which of the 22 persuasion techniques are present using textual and visual multimodal features.
- **Subtask 2b**. This is a multimodal binary persuasion identification task, where the goal is to determine whether a meme contains a persuasion technique or not.

To solve the English challenge, we propose an approach based on fine-tuning Transformer models for binary and hierarchical multi-label classification problems of persuasion techniques using textual and visual content. During training for subtasks 2a and 2b, we used a Large Multimodal Model (LMM) called LlaVa (Liu et al., 2023) to extract textual and visual features from the memes. We then refined the monolingual model, as RoBERTa-large (Liu et al., 2019), to identify persuasion techniques and their type.

In multimodal classification problems, our experiments showed that including the textual description of the meme obtained by an LMM improves the overall performance. In our experiments, this strategy achieved better results and required fewer resources than merging the image and text embeddings into the same vector space.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 655–666

The rest of this paper is organized as follows. Section 2 provides a summary of important details about the task setup. Section 3 provides an overview of our system for two subtasks. Section 4 presents the specific details of our systems. Section 5 discusses the results of the experiments, and finally the conclusions are presented in section 7.

2 Background

Recently, there has been a significant increase in the use of memes on social media as a means of spreading misinformation. Memes consist of a combination of text and images that together have a meaning that is very difficult to automatically verify. In addition, the image and text of the meme in isolation may convey a benign meaning, but their combination may be derogatory, or vice versa. Fake news and hate speech purveyors use memes as a tool to spread misinformation and hateful content. They may spread hate to create unrest among the people, and such hateful content may target communities or individuals based on religion, ethnicity, race, national origin, affiliation, sexual orientation, gender, sex, disability, and disease (Hamza et al., 2023).

Many studies have focused on identifying memes that contain negative content or misinformation. For example, the authors of (Hamza et al., 2023) published a dataset of religiously hateful memes and evaluated it fine-tuning VisualBERT, which was pre-trained on the Conceptual Caption (CC) dataset for the top-down classification task. Visual features were extracted using ResNeXT-152 Aggregated Residual Transformations based Masked Regions with Convolutional Neural Networks (R-CNN) and BERT without textual encoding for the early fusion model. Regarding multimodal approaches, there have been tasks previously organized in the same area of interest. MAMI (Multimedia Automatic Misogyny Identification) at SemEval-2022 (Fersini et al., 2022), which explored the detection of misogynistic memes on the web using available text and images; and DravidianLangTech at EACL-2021 (Suryawanshi and Chakravarthi, 2021), which explored the detection of offensive language and classification of troll memes.

The novelty of this shared task is the focus on disinformation propaganda through memes. Propaganda uses psychological and rhetorical techniques to achieve its goal. These techniques include the use of logical fallacies and appeals to the audience's emotions. Logical fallacies are often difficult to detect because the argument seems correct and objective at first glance. However, careful analysis reveals that the conclusion cannot be deduced from the premise without the misuse of logical rules. Therefore, memes are a perfect medium for spreading disinformation because they consist of an image superimposed on text, and the image can be deceptive, reinforcing or complementing one or more persuasive techniques in the text or image. Thus, the goal of this task is to identify the existence and type of persuasion techniques through memes with different subtasks. The persuasion techniques can be viewed on the official task page.[1]. It is worth noting that a similar propaganda technique was used in Dipromats 2023 (IberLEF) (Moral et al., 2023).

The dataset used for this task is the one provided by the organizers. It consists of a set of texts and images labeled with their corresponding persuasion techniques and a binary annotation for Subtask 2b. The data set provided by the organizers is divided into train, dev, and validation. Note that we do not actually need two datasets for validation (dev and validation), since the dev set was used for the development phase. Therefore, we have combined the train and dev sets into a single training set. The training dataset contains 8000 examples for subtasks 1 and 2a and 1499 examples for subtask 2b. Figure 1 shows the distribution of the training set for subtasks 1a and 2a and Figure 2 for subtask 2b.

3 System overview

Figure 3 shows the architecture of our system for the three subtasks. We can see that for Subtask 1, only the text of the memes is used, which is a multi-label classification problem of different persuasion techniques. To address subtask 1, we have fine-tuned RoBERTa-large (Liu et al., 2019). For Subtasks 2a and 2b, we have used a similar approach as in Subtask 1, but including textual and visual features. We rely on LlaVa (Liu et al., 2023) to extract the image description and then concatenate this information with the textual content of the memes, as shown in Figure 4. LlaVa is an end-to-end multimodal Large Language Model (LLM) that incorporates a vision encoder for general pur-

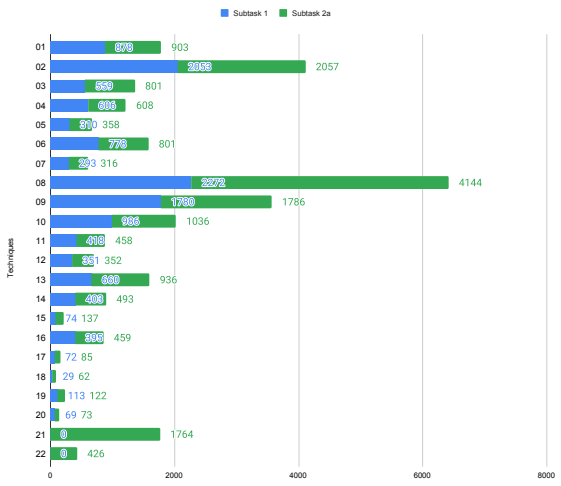

Figure 1: Distribution of training for Subtasks 1 and 2a. The techniques are: (01) Black-and-white Fallacy / Dictatorship; (02) Loaded Language; (03) Glittering generalities (Virtue); (04) Thought-terminating cliché; (05) Whataboutism, (06) Slogans, (07) Causal Oversimplification; (08) Smears; (09) Name calling/Labeling; (10) Appeal to authority; (11) Exaggeration/Minimisation; (12) Repetition; (13) Flag-waving; (14) Appeal to fear/prejudice; (15) Reductio ad hitlerum; (16) Doubt; (17) Misrepresentation of Someone's Position (Straw Man); (18) Obfuscation, Intentional vagueness, Confusion; (19) Bandwagon; (2) Presenting Irrelevant Data (Red Herring); (21) Transfer; (22) Appeal to (Strong) Emotions.

pose visual and language understanding. LlaVa has demonstrated impressive multimodal conversational capabilities, sometimes exhibiting behavior similar to the multimodal GPT-4 on unseen images/instructions, and achieving a relative score of 85.1% compared to GPT-4 on a synthetic multimodal instruction-following dataset (Liu et al., 2023). It is worth noting that the output model as a binary classification problem and in subtask 2b as a multi-class hierarchical classification problem like subtask 2a.

4 Experimental setup

In this work, we used only the dataset provided by the organizers and we did not rely on external data except for the use of LLM and LMM models that were pre-trained with general purpose data.

Before fine-tuning, we performed a preprocessing step to remove line breaks, hashtags, symbols, references, and hyperlinks. Next, for all the subtasks, we performed the fine-tuning process using an epoch-based evaluation strategy with the Hug-

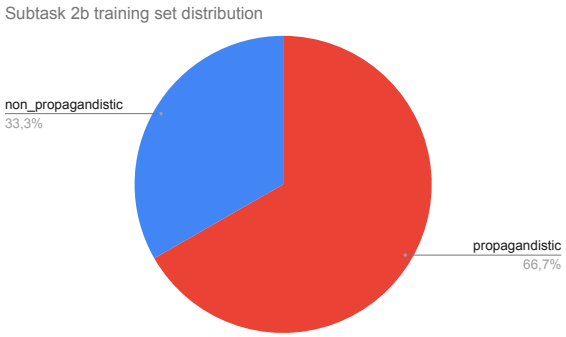

Figure 2: Distribution of training for Subtask 2b.

gingface Trainer library[2]. This involves training the pre-trained model for a certain number of epochs and performing an evaluation with the evaluation set after each epoch. Once all epochs have been completed, the model with the best macro F1 score in the evaluation set is selected. In this way, overfitting or underfitting resulting in low variance and high bias can be avoided.

We used the same hyperparameters for fine-tuning in all the subtasks: (1) a batch size of 8 for both training and validation, (2) 10 epochs, (3) a learning rate of 2e-5, (4) and a weight decay of 0.01. During training, we used macro-F1 as a reference. For the evaluation of subtasks 1 and 2a, the organizers used hierarchical-F1 as the primary evaluation metric, and for subtask 2b, macro-F1. It should be noted that in order to ensure the reproducibility of the experiment, we modified the LlaVa generation configuration by setting the value of `do_sample` to False.

Hierarchical precision, recall and F1 (H-P, H-R, and H-F1) are metrics used in hierarchical classification problems where classes are organized in a hierarchical structure (Kiritchenko et al., 2006). H-F1 considers both precision and recall of the prediction for each class in the hierarchy, taking into account the relationship between parent and child classes in the hierarchy.

The binary task (subtask 2b) is evaluated using the macro F1 score, which is an evaluation metric used in classification problems to measure the precision and recall of a model in predicting multiple classes. It assigns equal weight to each class, meaning that all classes have the same impact on the final metric, regardless of their size or distribution in the data.

5 Results

Table 1 shows the official ranking table for Subtask 1. We can see that we have ranked tenth position with a H-F1 score of 0.64774 and a H-P of 70.817%. We outperformed the baseline by almost 50% in terms of H-F1 and are 10.473% away from the best result, which is 75.247%, achieved by the '914isthebest' team.

		...		
Baseline	-	44.706	68.778	33.116

For subtask 2b, which is a binary classification problem to identify the presence of persuasion techniques in memes, we obtained a macro-F1 score of 78.660%, which puts us in eighth place according to the official ranking table (see Table 3). Furthermore, we can see that our system has improved by up to 53.66% compared to the baseline and is only 2.37% behind the first place (LMEME with a M-F1 of 81.030%).

Based on the results obtained, it's clear that combining image descriptions with textual content im-

proves overall performance in a multimodal setting. This approach does not impose any restrictions on embedding images and text together in the same vector space when fine-tuning or training persuasion classification techniques. Rather, we merge the text from the meme with its description and use this combined dataset as input for fine-tuning the pre-trained transformer-based model.

6 Error analysis

As far as we know, the organizers did not provide the gold labels of the test set to the participants. Therefore, we did a bug analysis based on the results of the development set.

Table 4 shows the results and the ranking we got with our development set approach.

In subtask 1 our approach is based on a fine-tuned model of RoBERTa-large. We obtained an H-F1 of 62.201 and an M-F1 of 35.514. From the confusion matrices (see Figure 5), we can see that the model didn't correctly predict any instances of the classes `Misrepresentation of Someone's Position (Straw Man)`, `Obfuscation, Intentional vagueness, Confusion`, `Presenting Irrelevant Data (Red Herring)`, and `Reductio ad Hitlerum`, indicating a possible class imbalance or lack of representative features for these classes. In addition, the F1 score of the `Whataboutism` and `Causal Oversimplification` class is relatively low compared to other classes, suggesting that the model has difficulty correctly identifying instances of this class, possibly due to ambiguous or overlapping features with other classes.

Subtask 2a is a hierarchical multi-label classification problem, but unlike Subtask 1, it uses a multimodal dataset, i.e. it uses both textual and visual multimodal features to identify 22 persuasion techniques. In this case, our model achieved an H-F1 of 67.902 and an M-F1 of 36.841, which is an improvement over the unimodal approach (Subtask 1). However, similar to the model in Subtask 1 (see Figure 6), it failed to predict any instances of the classes `Misrepresentation of Someone's Position (Straw Man)`, `Obfuscation, Intentional Vagueness, Confusion`, and `Presenting Irrelevant Data (Red Herring)`, and it obtained a lower F1 score in `Casual Oversimplification` and `Appeal to (Strong) Emotions`, except for the class `Reductio ad Hitlerum`, for which it correctly predicted 2 instances. This could be due to insufficient training data or ineffective feature representation for these classes.

Regarding Subtask 2b, a multimodal binary classification problem, our approach achieved an M-F1 of 76.836, and in Figure 7 we can see that the model misclassified 40% of the examples as non-propagandistic and 9% as propagandistic.

7 Conclusion

In this paper, we describe our participation in a SemEval task focused on identifying persuasive techniques in memes using a multimodal approach. For all three subtasks, we used the fine-tuning approach with the RoBERTa-large model for text features and LlaVa to extract image descriptions and combine them with the meme text. Our system achieved the tenth best result with an H-F1 of 64.774%, the fourth best in Subtask 2a with an H-F1 of 69.003%, and the eighth best in Subtask 2b with a macro-F1 of 78.660%.

As further work, we will evaluate the relationship between the persuasion techniques used in the different domains evaluated by our team. In this sense, we propose to re-annotate the Spanish SatiCorpus 2021 (García-Díaz and Valencia-García, 2022) and the PoliticES 2022 dataset (García-Díaz et al., 2022), which are focus on figurative language and politics respectively, with the 22 persuasion techniques and evaluate the reliability of using binary and hierarchical multi-label classification approaches. Another area where persuasion techniques may be present is in the identification of misogyny (García-Díaz et al., 2023).

Table 4: Results for dev split.

-	Rank	H-F1	H-P	H-R	M-F1	m-F1
Subtask 1	14	62.201	71.111	55.276	35.514	52.439
Subtask 2a	4	67.902	75.151	61.929	36.841	57.124
Subtask 2b	11	-	-	-	76.836	80.667

Abstract

This paper presents our winning submission to Subtask 2 of SemEval 2024 Task 3 on multimodal emotion cause analysis in conversations. We propose a novel Multimodal Emotion Recognition and Multimodal Emotion Cause Extraction (MER-MCE) framework that integrates text, audio, and visual modalities using specialized emotion encoders. Our approach sets itself apart from top-performing teams by leveraging modality-specific features for enhanced emotion understanding and causality inference. Experimental evaluation demonstrates the advantages of our multimodal approach, with our submission achieving a competitive weighted F1 score of 0.3435, ranking third with a margin of only 0.0339 behind the 1st team and 0.0025 behind the 2nd team.

1 Introduction

Emotion-Cause pair extraction in conversations has garnered significant attention due to its wide-ranging applications, such as optimizing customer service interactions and tailoring content recommendations based on user emotions (Xia and Ding, 2019). However, a fundamental challenge lies in identifying the causal determinants of emotional states. Recent research emphasizes the exploration of causes triggering emotions from multimodal data (Li et al., 2022), followed by further generation tasks based on multimodal emotional cues (Xu et al., 2024).

Practical conversations often exhibit multimodal cues through facial expressions, vocal changes, and textual content. Recognizing the significance of multimodal information, Wang et al. (2023) proposed the task of Multimodal Emotion-Cause Pair Extraction in Conversations (MECPE) as a critical step towards understanding the fundamental elicitors of emotions. The Emotion-Cause-in-

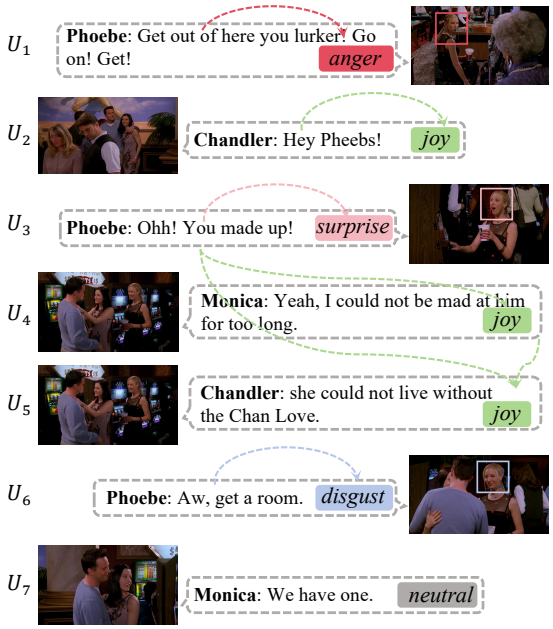

Figure 1: An example of an annotated conversation from the ECF dataset. Dashed lines connect each emotion label to its corresponding cause utterance, illustrating the emotion-cause pairs present in the conversation. The image modality provides additional context and cues for understanding the expressed emotions.

Friends (ECF) dataset, introduced in SemEval 2024 Task 3 (Wang et al., 2024), incorporates additional modalities such as images and audio alongside the original textual data, enabling a more realistic and comprehensive approach to emotion understanding. Figure 1 illustrates an example of an annotated conversation in the ECF dataset, where variations in facial expressions directly mirror the emotions expressed by the characters.

To address the MECPE task, we propose the Multimodal Emotion Recognition-Multimodal Cause Extraction (MER-MCE) framework, building upon the two-step approach introduced by Wang et al. (2023). Our method adopts a two-stage process to predict emotions and identify emotion causes in multimodal conversations. In the first stage, MER-MCE leverages text, audio, and image modalities

(a) multimodal emotion recognition (MER) (b) multimodal cause extraction (MCE)

Figure 2: The architecture of our proposed MER-MCE framework for multimodal emotion-cause pair extraction in conversations. The framework consists of two main stages: (a) Multimodal Emotion Recognition (MER), which utilizes specialized emotion encoders to extract modality-specific features from text, audio, and visual data, and (b) Multimodal Cause Extraction (MCE), which employs a Multimodal Language Model to integrate contextual information from the conversation and visual cues to identify the utterances that trigger the recognized emotions.

for emotion prediction, utilizing state-of-the-art models specifically designed for capturing emotional cues from each modality. This approach sets our work apart from the first-place team in the competition, who relied solely on the textual modality for emotion recognition, and the second-place team, who employed a general-purpose model, ImageBind (Girdhar et al., 2023), for extracting visual and audio features.

In the second stage, considering the complexity of analyzing emotion causes for each utterance, we employ a Multimodal Large Language Model (LLM) to dissect the visual and textual modalities and discern the origins of each emotion. By leveraging the power of Multimodal LLMs, our approach can effectively capture the intricate relationships and dependencies present in real-world conversations, enabling a more nuanced and accurate identification of emotion causes.

The MER-MCE framework achieved notable results in Subtask 2 of SemEval 2024 Task 3, ranking third with a weighted F1 score of 0.3435, only 0.0339 behind the first-place team and 0.0025 behind the second-place team. We evaluate the two stages of our model separately to analyze their efficacy and limitations, providing valuable insights into the inherent challenges of the MECPE task. The main contributions of this paper are as follows:

- We propose the MER-MCE framework, a novel two-stage approach for Multimodal Emotion-Cause Pair Extraction in Conversations, leveraging state-of-the-art models for emotion recognition and Multimodal LLMs for cause extraction.
- We demonstrate the effectiveness of incorporating multiple modalities, including text, audio, and visual information, in both emotion recognition and cause extraction stages, leading to improved performance compared to approaches relying on a single modality or general-purpose feature extractors.
- Through comprehensive evaluation and analysis of the MER-MCE framework on the ECF dataset, we provide valuable insights into the challenges and opportunities in the field of multimodal emotion-cause pair extraction, paving the way for future research and advancements.

2 System Overview

In this work, we propose a Multimodal Emotion Recognition and Multimodal Cause Extraction (MER-MCE) framework for the task of multimodal emotion cause prediction and extraction (MECPE) in conversational settings. As illustrated in Figure 2, our MER-MCE model comprises two key modules: a multimodal emotion recognition (MER) module and a multimodal cause extraction (MCE) module, designed to work in tandem to tackle the intricate challenge of identifying emotions and their underlying causes from multimodal conversational data. Following we describe the structure of the entire system in detail.

2.1 Multimodal Emotion Recognition

Textual Modality. To comprehensively capture the rich semantic and contextual information present in real-world conversational content, our multimodal emotion recognition (MER) module adopts a carefully designed approach that leverages state-of-the-art models tailored for different modalities. For the textual modality, we employ the InstructionERC model proposed by Lei et al. (2023), which incorporates a domain demonstration recall module based on semantic similarity to enhance feature extraction. The textual features are extracted in the form of logits, capturing the nuanced semantic representations of the conversational utterances.

Auditory Modality. Recognizing the importance of auditory cues in conveying emotions, we utilize the HuBERT model proposed by Hsu et al. (2021) to process the audio modality and extract hidden states as acoustic features. These acoustic features encapsulate the rich tonal and prosodic information present in the audio signals, complementing the textual and visual modalities.

Visual Modality. For the visual modality, we first employ the OpenFace (Baltrusaitis et al., 2018) open-source tool to extract facial regions from video clips, allowing our visual model to focus specifically on facial expression recognition. Subsequently, we leverage the expMAE (Cheng et al., 2023) model to extract both static and dynamic features of facial expressions simultaneously. This dual-feature extraction approach captures the nuanced and time-varying aspects of facial expressions, which are known to be crucial indicators of emotional states.

Multimodal Fusion Mechanism. To effectively fuse the complementary information from these diverse modalities, we employ an attention-based multimodal fusion mechanism, as depicted in Figure 2(a). The input features from each modality are first mapped to a common 128-dimensional space, and ReLU activation and dropout regularization are applied to introduce non-linearity and improve generalization. We then compute attention weights via dot products between the features, allowing the model to dynamically attend to the most relevant and informative cues from each modality. The resulting fused representation captures the synergistic and complementary information across modalities, enabling a comprehensive understanding of the expressed emotions.

2.2 Multimodal Cause Extraction

Building upon the predicted emotions from the multimodal emotion recognition module, we propose a generative approach for multimodal cause extraction (MCE), harnessing the power of Multimodal Language Models (LLMs). As depicted in Figure 2(b), we adopt the MiniGPTv2 (Chen et al., 2023) model, a state-of-the-art multimodal LLM based on the LLaMA-2 (Touvron et al., 2023) architecture, as the backbone of our MCE module. This model is designed to integrate both visual and textual information, enabling it to extract emotional causes from multimodal conversational data.

Image Processing. The image processing component of our MCE module employs the Vision Transformer (ViT) (Dosovitskiy et al., 2020) model, which divides the input image into patches and extracts visual tokens representing these patches. Notably, in contrast to the image preprocessing approach used in the multimodal emotion recognition stage, we feed the complete image to the ViT encoder. This design choice allows our model to capture comprehensive scene information and relationships among individuals, providing a holistic visual context for emotion cause extraction. The extracted visual tokens are then mapped to the textual space using a linear projection layer, facilitating the seamless integration of visual and textual information within the multimodal LLM architecture.

Text Processing. To effectively incorporate contextual information from the conversation, we adopt a prompt-based approach in the textual processing component. The prompt template, illustrated in Figure 3, consists of two key elements: the prompt and the target utterance being queried. The prompt encompasses the conversation content preceding the target utterance, the speaker associated with the queried utterance, and the predicted emotion label obtained from the multimodal emotion recognition module.

Multimodal Cause Extraction. The integration of image and textual data is facilitated by a trainable LLaMA2-chat (7B) model, which processes the multimodal inputs and generates natural language responses to the posed inquiries. These responses are then subjected to a similarity matching process against utterances from the historical conversation dataset. This step allows us to identify the most relevant utterance that potentially triggered the recognized emotion, culminating in the extraction of the ultimate emotion cause utterance. By

seamlessly integrating visual and textual contextual information, our model can capture the intricate relationships and dependencies present in real-world conversations, enabling a more nuanced and flexible representation of emotion causes. This generative approach paves the way for more accurate and interpretable emotion cause extraction, a critical component in the overall task of multimodal emotion cause prediction and extraction.

prompt: Now you are expert of sentiment and emotional analysis. The following conversation noted between [***conversation***] involves several speakers.
Please infer, considering the conversation content and the facial expressions of the characters in the image, which utterance leads to [***speaker***] feeling [***emotion***].
target: [***conversation*** U_i].

Figure 3: Prompt template for guiding the Multimodal LLM in sentiment analysis and emotion cause extraction from conversational data.

3 Experiments

3.1 Experimental Setup

We evaluate our MER-MCE model on the Emotion-Cause-in-Friends (ECF) dataset (Poria et al., 2018), an extension of the multimodal MELD dataset that includes emotion cause annotations in addition to the original emotion labels. The dataset provides annotations for utterances that trigger the occurrence of emotions, enabling the study of emotion-cause pairs in conversations. For Subtask 2, the labeled data is divided into "train," "dev," and "test" subsets, containing 1001, 112, and 261 conversations, respectively.

Our experimental setup involves extracting features from textual, audio, and visual modalities using various state-of-the-art pretrained models. For the textual modality, we use models such as XLNet (Yang et al., 2019), RoBERTa (Liu et al., 2019), BERT (Devlin et al., 2018), and InstructERC (Lei et al., 2023) to capture semantic and contextual information. For the audio modality, we employ models like VGGish (Hershey et al., 2017), wav2vec (Schneider et al., 2019), and HUBERT (Hsu et al., 2021) to extract features that encapsulate tonal and prosodic information. In the case of the visual modality, we use pretrained visual models, such as MANet (Zhao et al., 2021), ResNet (He et al., 2016), and expMAE (Cheng et al., 2023), to capture nuanced and time-varying aspects of facial expressions conveying emotional information.

3.2 Evaluation Metrics

The primary objective of Subtask 2 is to predict emotion-cause pairs for non-neutral categories based on the provided conversations. The performance of the participating models is evaluated using a weighted average of the F1 scores across six emotion categories: anger, disgust, fear, joy, sadness, and surprise. This weighted average F1 score provides a comprehensive evaluation of the model's ability to accurately predict emotion-cause pairs while considering the imbalanced nature of the dataset.

Further details on the dataset, experimental setup, and evaluation metrics can be found in the supplementary material.

3.3 Emotion Recognition Analysis

We conducted an extensive experimental evaluation of the Multimodal Emotion Recognition (MER) component within the MER-MCE framework. Table 1 presents the weighted F1 scores for various state-of-the-art models evaluated in the emotion recognition task, leveraging features extracted from textual, audio, and visual modalities.

Our analysis reveals that the textual modality, which captures rich semantic information conveyed through conversations, plays a crucial role in emotion recognition. The inherent ability of the textual modality to encapsulate abstract semantic information facilitates the extraction of emotional features, resulting in higher scores compared to other modalities in unimodal emotion recognition.

To exploit the complementary nature of different modalities, we performed multimodal feature fusion. The experimental results (Table 1) demonstrate that increasing the number of modalities leads to a significant improvement in emotion recognition accuracy, empowering the model to effectively discern emotions within more complex samples. Notably, even features that exhibit relatively lower precision in unimodal emotion recognition contribute positively when integrated into the multimodal fusion framework, highlighting the importance of multimodal approaches in capturing fine-grained emotional nuances.

However, our analysis also uncovers challenges in the visual and audio modalities. In sitcoms containing multiple characters, the OpenFace tool struggles to accurately identify the current speaker, leading to noise in the visual features. Similarly, canned laughter from the audience contributes to

noise in the audio modality. Consequently, models trained on these modalities exhibit subpar performance compared to the textual modality.

3.4 Cause Extraction Analysis

In the MCE stage, we conducted a comparison of the cause extraction capabilities between different models and the state-of-the-art MECPE-2steps model (Wang et al., 2023), with the test results presented in Table 2. Initially, we employed the same attention model (Lian et al., 2023) structure as in MER for cause extraction. However, this relatively simple model struggled to capture the relationships between utterances. We then explored the ALBEF model (Li et al., 2021) based on the transformer structure, which allowed the model to focus on the connections between different utterances. Nevertheless, limited training data and imbalanced data distribution led to overfitting.

To address these challenges, we transformed the emotion cause extraction task from a traditional discriminative architecture to a generative architecture based on Multimodal LLM, resulting in improved cause extraction accuracy. We utilized the historical conversation window in the Multimodal LLM prompt to retain contextual information within the conversation. Ablation experiments were conducted to investigate the impact of varying numbers of historical conversation windows on cause extraction (Figure 4). To accurately assess the true influence of MCE, we employed the

Method	F1	w-avg. F1

Table 2: Multimodal cause extraction results

actual labels from the test dataset for cause extraction instead of relying solely on the emotions predicted in MER. Our experiments revealed that the effectiveness was maximized when the number of historical windows reached 5. However, as the number of windows increased further, the effectiveness gradually decreased due to the complexity of conversations with a larger historical context.

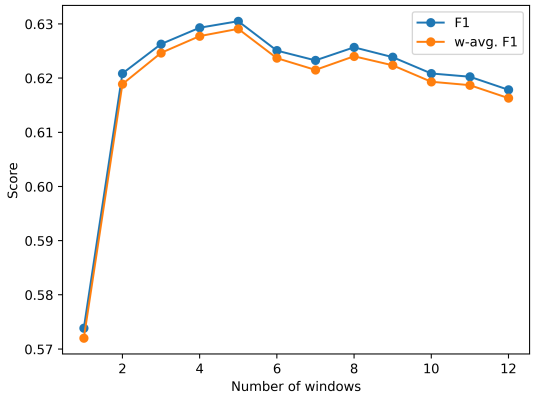

Figure 4: The line graph depicting scores and historical conversation windows.

3.5 Error Analysis of the Entire System

We conducted quantitative and qualitative error analysis on the two stages of our MER-MCE framework to identify key limitations.

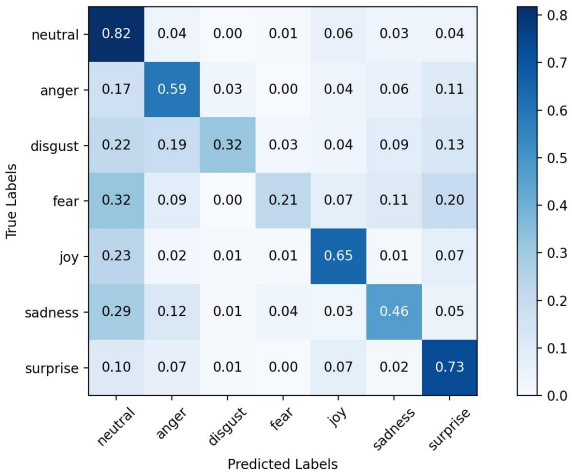

Figure 5: The confusion matrix of multimodal emotion recognition result.

Visual Modality	Historical Conversation Content	Label Pair	Pred Pair
	U4: Cat. U5: Yes! You are so smart! I love you. U6: I love you too.	target: U6 emotion: joy cause: U5	target: U6 emotion: joy cause: U5
	U1: I have no idea what you just said. U2: Put Joey on the phone.	target: U2 emotion: anger cause: U1	target: U2 emotion: anger cause: None
	U2: You know what? It really creeps me out ... U3: Sorry. U4: I am so exited!	target: U4 emotion: joy cause: U5	target: U4 emotion: joy cause: U4
	U9: Sure. Okay. U10: Uh , are you crazy? Are you insane? ... U11: Yeah, I ..., I just know it would make me happy.	target: U11 emotion: neutral cause: None	target: U11 emotion: joy cause: U11

Table 3: Analysis of typical predicted emotion-cause pairs generated by the model, with emphasis on samples labeled as 'neutral' that do not have an associated emotion cause.

Analysis of the emotion recognition results using a confusion matrix (Figure 5) revealed that approximately 20% of non-neutral emotion categories were misclassified as neutral, hindering the subsequent cause analysis stage and impacting the overall recall rate. Additionally, class imbalance in the dataset adversely affected the performance of the "disgust" and "fear" categories, which had the lowest number of annotations.

Further analysis of the final Emotion-Cause Pair, based on representative samples in Table 3, highlighted the impact of different scenarios on our model. Facial occlusion in the visual modality (second sample) led to erroneous emotion classification, suggesting the need for more robust visual processing techniques. Strong emotional distractors in the textual modality (fourth sample) misled the model, emphasizing the importance of sophisticated language understanding methods to disambiguate distractors effectively. The real-time setting posed challenges in capturing long-range dependencies and identifying causes in future utterances (third sample), indicating the need for techniques that can model long-range dependencies and incorporate future context.

Despite these challenges, our MER-MCE model demonstrated the ability to accurately predict emotion-cause pairs by leveraging contextual information from both visual and textual modalities (first sample in Table 3). It identified key areas for improvement, including handling facial occlusion, disambiguating emotional distractors, and capturing long-range dependencies in real-time settings.

4 Conclusion

This paper introduces the MER-MCE model for emotion cause analysis in conversations, developed for SemEval 2024 Task 3. Our model leverages multimodal information and Language Models (LLMs) to identify emotion causes in conversational data, considering textual, visual, and audio modalities. MER-MCE achieves a weighted F1 score of 0.3435, ranking third in the competition. The results demonstrate the effectiveness of multimodal approaches in capturing emotional dynamics. Future work will focus on enhancing generalizability and robustness by exploring additional modalities and advanced techniques. We plan to investigate the incorporation of pose estimagesture recognition and facial expression analysis to improve the model's ability to detect emotions.

A Appendix

A.1 Experimental Data

The ECF dataset, an extension of the multimodal MELD dataset (Poria et al., 2018), includes emotion cause annotations in addition to the original emotion labels. It provides annotations for utterances that trigger the occurrence of emotions, enabling the study of emotion-cause pairs in conversations.

For Subtask 2, the labeled data is divided into "train," "dev," and "test" subsets, containing 1001, 112, and 261 conversations, respectively. We followed this partition to train, validate, and test our MER-MCE model. To evaluate results, we submitted predictions for an additional 655 unlabeled conversations to the CodaLab platform[1].

A.2 Experimental Setup

To evaluate the effectiveness of our MER-MCE model for the MECPE task, we employed various state-of-the-art pretrained models to extract features from the textual, audio, and visual modalities.

For the textual modality, we directly used the conversation text from the annotated files as input to models such as XLNet (Yang et al., 2019), RoBERTa (Liu et al., 2019), BERT (Devlin et al., 2018), and InstructERC (Lei et al., 2023) to extract textual features that capture semantic and contextual information.

For the audio modality, we extracted audio files from the video clips using FFMPEG[2] and fed them into models like VGGish (Hershey et al., 2017), wav2vec (Schneider et al., 2019), and HUBERT (Hsu et al., 2021) to obtain audio features that encapsulate tonal and prosodic information.

In the case of the visual modality, we used the OpenFace toolkit to extract facial features from the video clips while masking out the background. We then employed pretrained visual models, such as MANet (Zhao et al., 2021), ResNet (He et al., 2016), and expMAE (Cheng et al., 2023), which were initially trained on facial expression datasets, to extract visual features that capture nuanced and time-varying aspects of facial expressions conveying emotional information.

By leveraging these diverse pretrained models across multiple modalities, we aim to comprehensively capture the rich emotional cues present in the conversations and evaluate the effectiveness of our MER-MCE model in integrating these multimodal features for emotion-cause pair extraction.

A.3 Evaluation Metrics

The primary objective of Subtask 2 is to predict emotion-cause pairs for non-neutral categories based on the provided conversations. Each emotion-cause pair ($p_i = eu_i, ec_i, cu_i$) consists of three essential elements: the index of the emotion utterance eu_i, the emotion category ec_i, and the index of the cause utterance cu_i.

The performance of the participating models is evaluated using a weighted average of the F1 scores across the six emotion categories: anger, disgust, fear, joy, sadness, and surprise. The F1 score for each emotion category j is computed as follows:

$$F_1^j = \frac{2 \times precision^j \times recall^j}{precision^j + recall^j},$$

where $precision^j$ and $recall^j$ are the precision and recall scores for emotion category j, respectively.

The overall performance is determined by the weighted average F1 score, which takes into account the number of samples in each emotion category:

$$w\text{-}avg.F_1 = \frac{\sum_{j=1}^{6} n^j \times F_1^j}{\sum_{j=1}^{6} n^j},$$

where n^j denotes the number of samples of category j. This weighted average F1 score provides a comprehensive evaluation of the model's ability to accurately predict emotion-cause pairs across different emotion categories while considering the imbalanced nature of the dataset.

Abstract

In these working notes we describe the UMUTeam's participation in SemEval-2024 shared task 6, which aims at detecting grammatically correct output of Natural Language Generation with incorrect semantic information in two different setups: model-aware and model-agnostic tracks. The task is consists of three subtasks with different model setups. Our approach is based on exploiting the zero-shot classification capability of the Large Language Models LLaMa-2, Tulu and Mistral, through prompt engineering. Our system ranked eighteenth in the model-aware setup with an accuracy of 78.4% and 29th in the model-agnostic setup with an accuracy of 76.9333%.

1 Introduction

Recently, the emergence of Large Language Models (LLMs) has brought about a paradigm shift in Natural Language Processing (NLP), leading to unprecedented advances in Natural Language Understanding (NLU) (Huang et al., 2023) and Reasoning (Zhang et al., 2023). In general, LLMs refer to a set of general-purpose models based on the Transformer architecture and pre-trained on large text corpora, such as GPT-3 (Brown et al., 2020), LLaMa (Touvron et al., 2023), PaLM (Chowdhery et al., 2023) and GPT-4 (Achiam et al., 2023). By scaling the amount of data and model capacity, LLMs demonstrate incredible emergent capabilities, typically including In-Context Learning (ICL) (Brown et al., 2020), chain-of-thought prompting (Wei et al., 2022), and instruction following (Peng et al., 2023).

Natural Language Generation (NLG) faces two related challenges. First, current models often produce output that is fluent but inaccurate. Second, the metrics used to evaluate the LLMs performance prioritize fluency over correctness, exacerbating the problem of "hallucination", in which LLMs produce fluent but incorrect output. Consequently, significant research in underway to automatically detect such errors. In many NLG applications, output correctness is paramount, as in cases such as machine translation, where producing a plausible but inconsistent translation compromises the utility of the system.

Thus, the SHROOM shared-task focuses on identifying grammatically correct outputs that contain incorrect semantic information, regardless of whether the model producing the output is accessible or not (Mickus et al., 2024). To this end, the organizers have adapted a post-hoc environment in which the models have already been trained, and the outputs have already been produced. The participants' task is a binary classification problem to identify cases of hallucinations, i.e. to detect grammatically correct outputs that contain incorrect or unsupported semantic content, in two different setups: model-aware and model-agnostic tracks.

To address the SHROOM challenge, our team used a zero-shot learning (ZSL) approach with LLaMa-2 (Touvron et al., 2023), Mistral (Jiang et al., 2023), and Tulu (Ivison et al., 2023) LLMs to detect grammatically correct output that contains incorrect semantic information through the prompt. The ZSL technique refers to the ability of LLMs to perform tasks without being explicitly trained on them, meaning that the model can generate responses or make predictions on topics or domains that were not part of its explicit training. This is achieved by exploiting the general knowledge that the models have acquired during their massive pretraining on large text corpora.

During our experiments, we observed that these LLMs were able to identify hallucinations. In particular, Tulu is the one best suited for this task.

The rest of this paper is organized as follows. Section 2 provides a summary of important details about the task setup. Section 2 gives an overview of our system for two subtasks. Section 4 presents the specific details of our systems. Section 5 dis-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 675–681

cusses the results of the experiments, and finally, the conclusions are presented in Section 6.

2 Background

NLG is a branch of Artificial Intelligence (AI) and computational linguistics that deals with the automated generation of text in human language. NLG covers a wide range of tasks, such as text generation for chatbots, automatic summarization, machine translation, story generation, and others. NLG relies on models and algorithms that enable machines to understand and generate text that is coherent and intelligible to humans. However, current models can produce inaccurate but fluent output, while the metrics tend to describe fluency rather than correctness. This leads to models producing "hallucinations", i.e. generated content that appears nonsensical or unfaithful to the given source content.

In general, hallucinations in NLG tasks can be divided into two main types (Ji et al., 2023): intrinsic hallucinations and extrinsic hallucinations. On the one hand, intrinsic hallucinations refer to the output of LLMs that conflict with the source content. On the other hand, extrinsic hallucinations refer to LLM generations that cannot be verified from the source content.

The SHROOM task aims to automatically detect hallucinations and related observable overgeneration errors. To achieve this, the organizers have provided a collection of checkpoints, inputs, references and outputs from systems covering three different NLG tasks: (1) definition modeling (DM), (2) machine translation (MT), and (3) paraphrase generation (PG), trained with different levels of accuracy. The development set includes binary annotations from at least five different annotators and a majority vote gold label.

The generalizability of LLMs is very attractive because it allows us to adapt state-of-the-art methods to specific goals. For example, an LLM trained on multilingual texts can perform translations without being explicitly trained to do so (known as zero-shot capability, ZSL). Another possibility is to guide models by providing them with examples of the input and the desired output (known as few-shot learning, FSL). For example, in (García-Díaz et al., 2023), LLMs have shown good performance in a ZSL scenario for identifying hate speech in Spanish and English. In this sense, it is possible to ask for a sentence and its translation before asking it to translate another sentence. This additional information helps to improve the quality of the output. For text classification tasks, the ability to make such predictions with little or no training makes these models particularly promising for empirical research, as they have the potential to perform accurately without the need for costly and time-consuming annotation procedures.

Therefore, we took advantage of this ZSL classification capability of LLMs to detect hallucinations and related observable overgeneration errors.

The following models are evaluated:

- **Mistral** (Jiang et al., 2023). Higher model performance often requires an escalation in model size. However, this scalability tends to increase computational cost and inference latency, raising the barriers to implementation in practical real-world scenarios. Mistral 7B is a high-performance LLM that maintains efficient inference. Mistral 7B outperforms the 13 billion parameter LLaMa-2 model on all benchmarks. In addition, Mistral 7B approaches the coding performance of Code-Llama 7B without sacrificing performance on non-code benchmarks.

- **LLaMa-2** (Touvron et al., 2023). Llama 2 and Llama 2-Chat are pre-trained and fine-tuned LLMs, both at scales of up to 70B parameters. In several benchmarks tested, Llama 2-Chat models generally outperformed existing open-source models. For our system, we used an instructively fine-tuned version of LLaMa-2 with 7B parameters from the Orca (Mukherjee et al., 2023) set called "stabilityai/StableBeluga-7B[1]".

- **Tulu** (Ivison et al., 2023). TuLu is a family of pre-trained and fine-tuned LLMs. Unlike other existing LLMs, distilled data mixtures from TuLu have been shown to significantly improve downstream performance over instruction and datasets available, with a new mixture outperforming its predecessor by an average of 8%. In addition, TuLu models use a fine-tuned version of Direct Preference Optimization (DPO) that scales to 70 billion parameter models and significantly improves open-response generation metrics without compromising model performance, im-

[1] https://huggingface.co/stabilityai/StableBeluga-7B

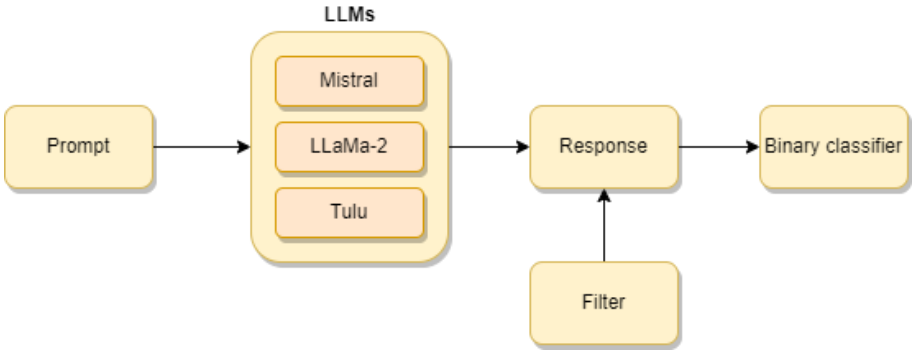

Figure 1: System architecture approach

proving AlpacaEval performance by an average of 13% across all model scales. For this task, we have evaluated the 7 billion parameter DPO version of Tulu with called "tulu-2-dpo-7b".[2]

3 System overview

Figure 1 shows the architecture of our system. We can see that we have introduced a specific prompt for each LLM to generate a response with the desired structure. Then we have a module called "filter" that extracts a binary response based on the response and the correlation value.

3.1 Prompt

The prompt in the context of LLMs refers to a specific input provided to the model to elicit a desired response or to guide the text generation. This prompt can be a sentence, a question, or even a fragment of text that sets the context or direction for the model's text generation. In our proposal, we use prompt engineering, which involves the design and careful wording of these prompts to elicit specific model responses and optimally influence the model's response.

Figure 2 shows the prompts used for each LLM, in which we can see that each LLM has its own control tokens to indicate which parts are system control sequences and which parts are user questions. For example, in LLaMa-2 "`### System`" is used to indicate the control sequence, and "`### User`" is used to indicate the user question. However, Mistral and Tulu do not have tokens to indicate system control sequences, but we can append the control sequence to the user question.

In our system, we have used the same prompt structure for all LLMs: (1) **System control sequence**. It is used to specify the context and instruct the model to respond only with "yes" or "no" at the beginning of the response; and (2) **User question**. It is used to introduce the text and specify the question "the Sentence supported by the Context above". Once the response generated by the LLMs is obtained, it is passed through the filter module, which identifies the first word of the response and classifies it as "Hallucination" or "Not Hallucination". To obtain the correlation value, we have used the same approach as the baseline provided by the organizers, which consists of extracting the log probability value of the first token of the response generated by the LLM.

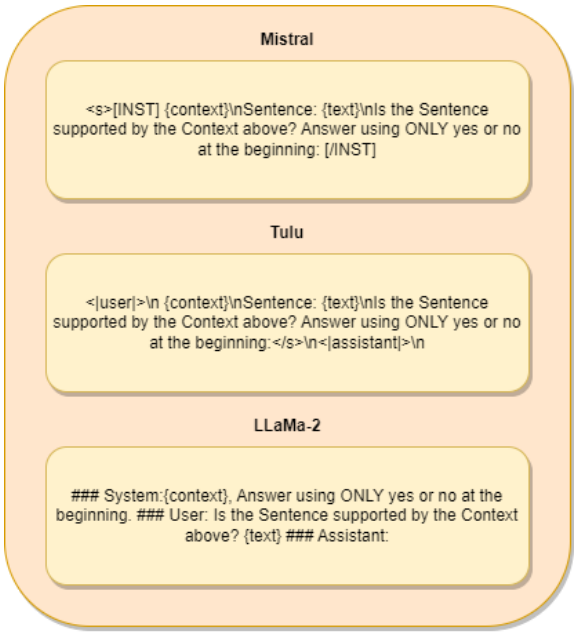

Figure 2: Examples of prompts for each LLMs

4 Experimental setup

In this section, we explain the dataset used, the hyperparameters used in the LLMs to generate re-

[2] https://huggingface.co/allenai/tulu-2-dpo-7b

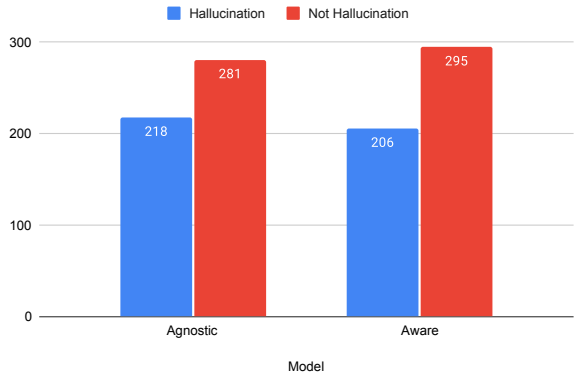

Figure 3: Validation set distribution

sponses, and details of the metrics used by the organizers for evaluation.

In this task, the organizers provided participants with unlabeled train data, trial data, and validation data for both the model-aware and model-agnostic setups. We have only used the validation data to evaluate the performance of different models using a ZSL approach. Figure 3 displays the distribution of the validation set.

The hyperparameters used in the LLMs to generate the response are 0.95 for top_p, 0 for top_k, 256 for max_new_tokens and the default temperature for each LLM.

The evaluation metrics used are accuracy for binary classification and rho to evaluate correlation. The rho metric, commonly known as the rho correlation coefficient (ρ), is a statistical measure that evaluates the relationship between two ordinal variables. It is particularly useful when the variables are not continuous but are divided into ordered categories.

5 Results

Table 1 shows the results of different LLMs in the validation set with two different configurations: (1) model-aware and (2) model-agnostic tracks. Thus, the system has to identify when a text is grammatically correct but contains incorrect information inconsistent with the source input, either with or without access to the model that produced the text. We can see that the Tulu performed best in both the model-aware and model-agnostic configurations. It obtained an accuracy of 76.6467% and a rho of 0.521104 in the model-aware configuration and an accuracy of 73.7475% and a rho of 0.553962 in the model-agnostic metric.

According to the results with development, we used Tulu in the task. Table 2 shows the official ranking for the task. We achieved the eighteenth best result out of a total of 46 teams in the model-aware setup, with a precision of 78.4% and a rho of 0.506895. Compared to result to the best result, our model is 2.866% worse in precision and 19.25% worse in rho. Regarding the model independent setup, our system achieved the nineteenth best result out of 49 participants, with a precision of 76.9333%, which is 7.8% worse than the best team (ahoblitz), and a rho of 0.560945, which is 20.86% worse than the best team.

Table 1: Results obtained with different LLMs in the validation set.

LLM	Accuracy	Rho
Aware		
Mistral	52.2954	0.345239
Tulu	**76.6467**	**0.521104**

5.1 Error analysis

We perform an error analysis of our system. For this, we extracted the confusion matrix from Tulu on the test set of the two configurations (model-aware and model-agnostic).

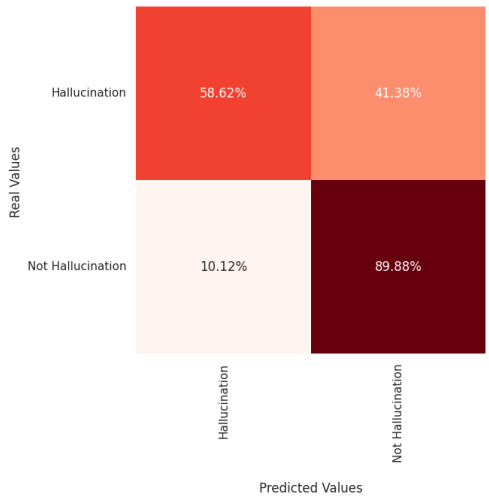

Figure 4: Confusion matrix of Tulu with test dataset in model-aware setup.

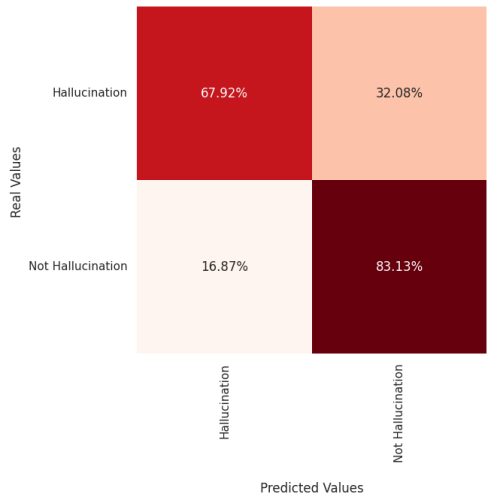

Figure 5: Confusion matrix of Tulu with test dataset in model-agnostic setup.

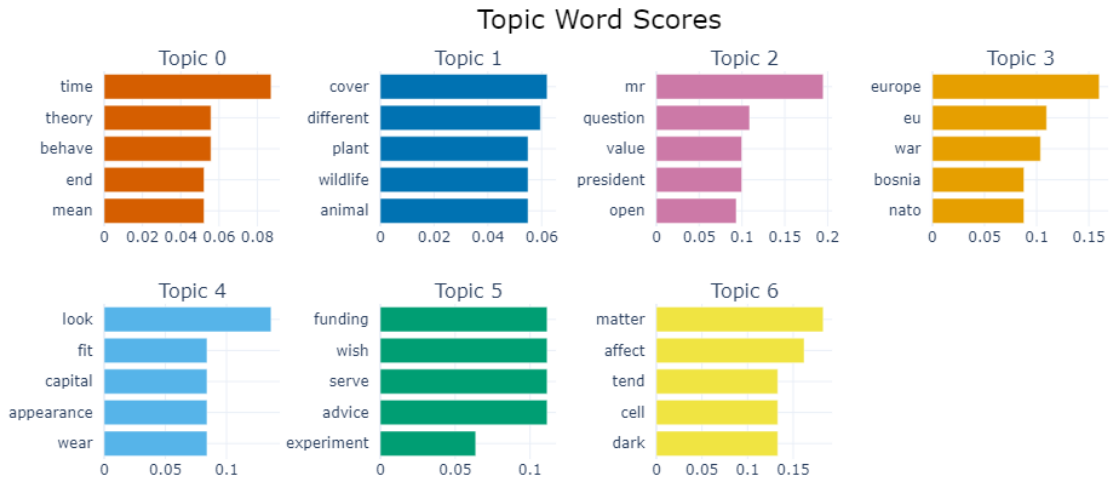

Figure 6: The most frequent topics associated with misclassification in model-aware setup.

Figure 4 shows the confusion matrix of TuLu from the test set in the model-aware setup. This approach tends to confuse hallucinations with non-hallucinations with a probability of 41.38%. However, it performs very well at detecting “not hallucination” with a probability of 89.88%. Regarding the model-agnostic setup, our model tends to confuse hallucinations with "not hallucination" with a probability of 32.08%, but is able to identify “not hallucination” with an accuracy of 83.13%.

The Tulu model from the test set in the model-aware setup has obtained a total of 324 misclassifications, of which 165 are of the definition modeling type, 100 are of the machine translation type, and 59 are of the paraphrase generation type. Therefore, we have a total of 165 misclassifications with the Flan-T5[3] model, 100 with the NLLB[4] model, and 59 with the Pegasus Paraphrase[5] model. In order to know the most common topic that the model comments on the classification error, we used the BERTopic model to identify and group topics in the context of the failed cases. In Figure 6 we can see the 7 topics in which the TuLu model usually misidentifies.

Regarding the model-agnostic setup, our ap-

[3] ltg/flan-t5-definition-en-base
[4] facebook/nllb-200-distilled-600M
[5] tuner007/pegasus_paraphrase

proach has obtained a total of 346 misclassifications, of which 138 are of the definition modeling type, 107 are of the machine translation type, and 101 are of the paraphrase generation type. In contrast to the model-aware setup, there is an increase in the accuracy of the identification of definition modeling misclassifications, but a decrease in the identification of paraphrase generation misclassifications. Figure 7 shows the three most common topics associated with the classification errors.

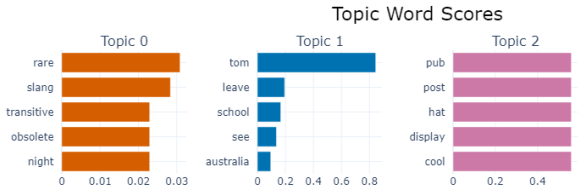

Figure 7: The most frequent topics associated with misclassification in model-agnostic setup.

6 Conclusion

Here we describe the UMUTeam's participation in SHROOM (SemEval 2024), concerning the development of models for detecting grammatically correct output from NLGs, but with incorrect semantic information in two different setups: model-aware and model-agnostic tracks. We have used the ZSL approach with LLaMa-2 (Touvron et al., 2023), Mistral (Jiang et al., 2023), and Tulu (Ivison et al., 2023) LLMs to detect output that contains incorrect semantic information through the prompt. Tulu performed best in the evaluation set. Using this model, we ranked eighteenth in the model-aware setup with an accuracy of 78.4% and nineteenth in the model-agnostic setup with an accuracy of 76.9333%.

As further work, we propose to investigate hallucination detection in the political domain. In politics, automated content generation can help politicians to generate text on a variety of political topics, which can help political campaigns, think tanks, and government agencies quickly produce tailored content. Hallucination detection can help to mitigate misleading or fabricated content. In this sense, we propose to generate political discourse that imitates politicians from different political wings (García-Díaz et al., 2022) and to identify the generated hallucinations by different LLMs.

Abstract

The NLI4CT task at SemEval-2024 emphasizes the development of robust models for Natural Language Inference on Clinical Trial Reports (CTRs) using large language models (LLMs). This edition introduces interventions specifically targeting the numerical, vocabulary, and semantic aspects of CTRs. Our proposed system harnesses the capabilities of the state-of-the-art Mistral model (Jiang et al., 2023), complemented by an auxiliary model, to focus on the intricate input space of the NLI4CT dataset. Through the incorporation of numerical and acronym-based perturbations to the data, we train a robust system capable of handling both semantic-altering and numerical contradiction interventions. Our analysis on the dataset sheds light on the challenging sections of the CTRs for reasoning.

1 Introduction

Over the last decade, Natural Language Processing (NLP) has seen significant advancements, beginning with the introduction of word embeddings (Mikolov et al., 2013), followed by transformer architectures like BERT (Vaswani et al., 2017; Devlin et al., 2019), and specialized language models (LMs) such as BioBERT (Lee et al., 2020) and PubMedBERT (Gu et al., 2021) tailored for the biomedical domain. The advent of large language models (LLMs) like GPT-3 (Brown et al., 2020), commonly known as Chat-GPT, has further pushed the boundaries of NLP, showcasing capabilities in diverse NLP tasks and even reasoning. However, LLMs adapt to shortcut learning easily instead of understanding the task at hand and resorting to shallow lexical heuristics for making a prediction (Tsuchiya, 2018; Poliak et al., 2018; Naik et al., 2018). Additionally, we have seen generative models like Chat-GPT hallucinating, making false claims, and struggling with providing factual information (Elazar et al., 2021; Wang et al., 2023). Tackling these challenges is essential for ensuring the reliable deployment of large language models, particularly in critical fields like biomedicine, where the margin for error must be minimized.

The SemEval-2024 Task 2: *Safe Biomedical Natural Language Inference for Clinical Trials* is focused on improving the understanding and evaluation methodologies for Large Language Models in clinical Natural Language Inference (NLI) (Jullien et al., 2024). This task targets aspects such as numerical and quantitative reasoning, domain-specific terminology, syntax, and semantics. It aims to analyze models' robustness, consistency, and faithfulness in reasoning within the clinical domain.

Our approach to this task involved leveraging instruction fine-tuned LLMs along with an auxiliary model that focuses on "hard" instances to develop a more resilient NLI system. "Hard" instances refer to those examples in the dataset where the model fails. Building on the methodology outlined by Kanakarajan and Sankarasubbu (2023), we assessed the zero-shot performance of various instruction-tuned LLMs to identify the most effective model. Upon selecting the best LLM, we introduced an auxiliary module during the fine-tuning process, which emphasized learning "hard" examples. Taking inspiration from Korakakis and Vlachos (2023), who experimented with various configurations for the auxiliary module and highlighted its substantial impact on the final NLI system's performance, we explored various architectures for this auxiliary module. To improve the robustness of the system and address challenges related to numerical reasoning and domain-specific terminology, we introduced numerical and semantic perturbation to the NLI4CT dataset and trained our system on these. Our system ranked 11th in *macro* F_1 *score*, 12th in *Faithfulness*, and 19th *Consistency* out of 31 participants. Our final system struggled when dealing with semantic-preserving interventions on

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 682–696

the test data yet demonstrated strong performance on semantic-altering interventions.

2 Background

We now provide a description of the shared task, followed by a brief overview of the NLI4CT dataset. We then explore existing research, assessing their strengths and limitations while also drawing connections to our proposed method.

2.1 Task and Dataset Description

This task is a continuation from SemEval-2023 Task 7 (Valentino et al., 2023), which introduced the NLI4CT dataset (Jullien et al., 2023) derived from Clinical Trial Reports (CTRs) on breast cancer. The dataset contains 999 CTRs, each of which consists of four sections: `Eligibility Criteria`, a set of conditions for patients to be allowed to take part in the clinical trial; `Intervention`, information concerning the type, dosage, frequency, and duration of treatments being studied; `Results`, the number of participants in the trial, outcome measures, units, and the results; and `Adverse Events`, signs and symptoms observed in patients during the clinical trial. The dataset comprises two types of training instances: *single* and *comparison*. In the *single* instances, one section of the CTR serves as the premise, while a corresponding human-annotated statement is presented as the hypothesis. On the other hand, in the *comparison* instances, the same section of two CTRs is utilized, and the hypothesis typically involves a human-annotated comparative statement between the two CTRs. Each instance is labeled either **entailment** or **contradiction**, with an equal distribution of proportions between the two labels (more details in Appendix A.1). A sample instance for *single* is shown in Figure 1.

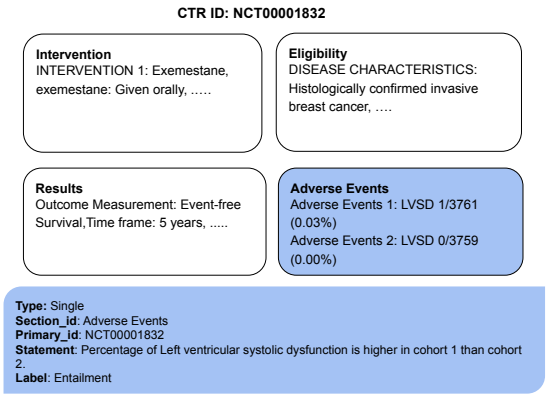

Figure 1: A sample instance from the NLI4CT dataset. Each instance consists of four sections: `Intervention`, `Eligibility criteria`, `Results`, and `Adverse Events`. The data are split into two types: *single* (depicted) and *comparison*. In *single*, one section of the CTR serves as the premise (in this case, `Adverse Events`). A human-annotated hypothesis for this premise is given (Statement), which is then to be classified into either **entailment** or **contradiction**.

2.2 Related Works

The NLI4CT dataset (Jullien et al., 2023) was introduced in SemEval 2023 Task 7 (Valentino et al., 2023), where multiple submissions highlighted the aforementioned challenges associated with language models. The second-ranked team from SemEval 2023 Task 7, Saama AI Research (Kanakarajan and Sankarasubbu, 2023), initially evaluated an instruction-tuned LLM in a zero-shot setting. Subsequently, they fine-tuned the model using the best instruction with T5 (Raffel et al., 2020) and Flan-T5-XXL (Chung et al., 2022). Motivated by their methodology and drawing inspiration from recent advancements, we employed instruction-tuned LLMs such as Llama (Touvron et al., 2023) and Mistral (Jiang et al., 2023), which represent state-of-the-art LLMs. Additionally, building upon the work of Korakakis and Vlachos (2023), who introduced a learner-auxiliary model framework to enhance the robustness of NLI, we aimed to integrate this framework alongside the use of instruction-tuned LLMs in our approach.

The challenge of word distribution shift from the general domain to the biomedical domain has posed a significant obstacle to the effectiveness of NLP methods applied to the biomedical field. The prevalence of aliases and acronyms in biomedical text prompted Jin et al. (2019) to propose a model that automatically collects context for abbreviations from PubMed abstracts and employs a BiLSTM classifier for abbreviation expansion. Additionally, Grossman Liu et al. (2021) presented a Medical Abbreviation and Acronym Meta-Inventory[1], constituting a comprehensive database of medical abbreviations encompassing 104,057 entries, each linked to 170,426 corresponding senses. We leveraged this Meta-Inventory to incorporate acronym-based perturbations into the NLI4CT dataset. Additionally, we also incorporated a pre-finetuning phase

[1] https://github.com/lisavirginia/clinical-abbreviations

into our approach by fine-tuning on the MedNLI[2] dataset (Shivade et al., 2019). This step aims to familiarize the model with clinical data.

3 System Overview

In light of recent advancements in large language models and drawing insights from the results of the SemEval 2023 Task 7 (Valentino et al., 2023), we implemented the approach outlined in the work of Kanakarajan and Sankarasubbu (2023). Our approach involved evaluating state-of-the-art LLMs, including Mistral (Jiang et al., 2023), Llama (Touvron et al., 2023), and Lemma (Azerbayev et al., 2024), alongside their variants. We experimented with different instructions for each model and subsequently compared their zero-shot performance based on their respective best-performing instruction (see final instruction template in Appendix A.3). Mistral emerged as the top-performing model among all others evaluated with the highest F_1 score (0.69). Furthermore, we implemented the MinMax algorithm (Korakakis and Vlachos, 2023) by adding an auxiliary model alongside the Mistral model to create a more robust system. This auxiliary model is designed to amplify the loss incurred in input spaces where the Mistral model encounters difficulties, effectively directing its focus towards areas of higher loss. To further boost the performance of the system, we pre-finetuned using MedNLI dataset. Additionally, we conducted an error analysis to identify easy and difficult instances in the train set to provide a basis for further research.

4 Experimental Setup

Training an LLM can be both costly and resource-intensive. However, recent advancements in methodologies, such as Parameter-Efficient Fine-Tuning (PEFT), have emerged to reduce the computational cost of fine-tuning (Mangrulkar et al., 2022). For fine-tuning the Mistral model, we employ a PEFT method known as Low-Rank Adaption (LoRA, Hu et al. (2022)). We adopted a similar approach for implementing the auxiliary model as described by Korakakis and Vlachos (2023). We experimented with the parameters of the system to obtain an optimal architecture, details of which can be found in Appendix A.5.4.

[2] https://physionet.org/content/mednli/1.0.0/

4.1 Data Perturbation

Utilizing the Meta-Inventory of Grossman Liu et al. (2021), we extracted the short forms from 358 NLI4CT hypotheses, resolving them to their corresponding long forms based on the cosine similarity. This resulted in 352 perturbed instances with consistent labels. Additionally, 181 negative instances were generated by selecting the least similar long forms, resulting in a total of 533 new instances for the acronym-based perturbation. For numerical perturbations, we employed an English Named Entity Recognition model (Raza et al., 2022) trained on Maccrobat to extract 27 unique biomedical entities from hypotheses. We perturbed numerical values and introduced semantic alterations that generated 355 new instances with labels flipped. For more details, see Appendix A.4.

4.2 Fine-tuning Strategies

We performed various experiments involving different combinations of fine-tuning methodologies. Initially, we fine-tuned only the Mistral model (*NLI4CT-FT*) on NLI4CT without incorporating the auxiliary model. An extension of this initial setup involved N-step fine-tuning, where, for example, in a two-step fine-tuning approach, we first fine-tuned the model with the MedNLI dataset and subsequently fine-tuned it further with the NLI4CT dataset (*MEDNLI-FT-NLI4CT*). We proceeded to add more steps by fine-tuning on perturbated datasets, such as the acronym-perturbed dataset (*MEDNLI-NLI4CT-FT-ACR*) or the numerically-perturbed dataset (*MEDNLI-NLI4CT-FT-NUM*). The MinMax algorithm requires that the base model be trained for a few epochs or steps. We utilized the best-performing models from previous N-step experiments to adapt this strategy effectively. This way, we already have a model that is trained on the dataset and add the auxiliary model to enhance the robustness of the whole system. Details of all the models that we fine-tuned with different strategies can be found Appendix A.2.

4.3 Evaluation Strategies

In our initial experiments, we observed that Mistral 7B exhibited superior performance compared to Mistral Instruct 7B post-fine-tuning. Consequently, we primarily trained most models using Mistral 7B. However, during the evaluation phase, we attached the PEFT fine-tuned adapter with both Mistral and Mistral Instruct 7B to compare their results. To sta-

Model	Dev F_1	Test F_1	Consistency	Faithfulness
NLI4CT-FT	0.69	0.74	0.68	0.75
NLI4CT-FT-ACR	0.73	0.76	0.67	0.71
MEDNLI-FT-NLI4CT	0.75	0.75	0.68	0.78
MEDNLI-FT-NLI4CT-ACR-NUM	0.75	0.74	0.68	0.78
MEDNLI-NLI4CT-FT-ACR	0.74	0.75	0.67	0.74
MEDNLI-NLI4CT-FT-NUM	0.74	0.73	0.69	0.79
MEDNLI-NLI4CT-FT-ACR-NUM	0.75	**0.76**	**0.70**	0.75
MINMAX-MEDNLI-FT-NLI4CT	0.75	0.75	0.68	**0.82**
MINMAX-MEDNLI-FT-NLI4CT-BC	**0.77**	0.75	0.68	0.78
MINMAX-MEDNLI-NLI4CT-FT-ACR-NUM-BC	0.74	0.74	0.68	0.75

Table 1: Final results on the NLI4CT dataset. **Dev** F_1 and **Test** F_1 represent the *macro* F_1 score on the development and test set, respectively. **Consistency** measures the ability to predict same labels for *semantic preserving* interventions and **Faithfulness** measures the ability to correctly change the labels for *semantic altering* interventions. Both *Consistency* and *Faithfulness* results are on the test set.

bilize the model's generation behavior, we conduct evaluations on the development set five times and select the label predicted most frequently across these five runs. Similarly, for test data, we perform three runs.

5 Results

During both the fine-tuning and evaluation phases, we observed improvements in the model trained with the MinMax algorithm compared to other models. From Table 1, we can see the model (*MINMAX-MEDNLI-FT-NLI4CT-BC*) trained with the MinMax algorithm achieved the highest F_1 score on the dev set. When comparing the base model (*MEDNLI-FT-NLI4CT*) with the MinMax model (*MINMAX-MEDNLI-FT-NLI4CT*), we noted a slight improvement in *Consistency* and a significant improvement in *Faithfulness*. Although the F_1 score did not exhibit improvement, the enhancements in the other metrics indicate that the MinMax algorithm contributed to the development of a more robust system and was able to handle the semantically altering intervention much better. Regarding the models trained with perturbed data, we observed a negative effect on the overall performance of the MinMax-trained model (*MINMAX-MEDNLI-NLI4CT-FT-ACR-NUM-BC*) compared to the base model (*MEDNLI-NLI4CT-FT-ACR-NUM*). For our final submission to the leaderboard, we submitted the MinMax model (*MINMAX-MEDNLI-FT-NLI4CT*), which ranked 11th in *macro* F_1 *score*, 12th in *Faithfulness*, and 19th in *Consistency*.

5.1 Impact of Data Perturbation

To assess the impact of acronym-based perturbed data, we initially trained the model using the original NLI4CT dataset and subsequently fine-tuned it with the acronym-based data. Evaluation of both models was conducted on the test data, which comprise the following intervention types introduced by the task's organizers: Control, Contrast, Paraphrase, Contradiction, Numerical Contradiction, Numerical Paraphrase, and Definitions. For accessing a model trained on acronym-based perturbed data, we look at the metrics for the intervention types Paraphrase (*Para*) and Definitions. Table 4 in Appendix A.4.3 shows that acronym perturbation notably enhanced results for the intervention-type Definitions. Similarly, with numerical-based perturbation, we look at metrics for intervention-type Numerical Paraphrase (*Num_Para*) and Numerical Contradiction (*Num_Cont*). While no changes were observed in the results of semantic-altering interventions, there was some improvement noted in semantic-preserving interventions. Lastly, we investigated the combined impact of both perturbations and their influence on all four interventions. Overall, we observed that combined fine-tuning improved the Definition and Paraphrase intervention type more than the Numerical intervention types. However, there was a negative impact observed on semantic-altering numerical interventions.

5.2 Performance across Interventions and Sections

Table 5 in Appendix A.6 presents the results of the test data across various interventions and sections. The `Adverse Events` section exhibits the highest F_1 score at 0.73, whereas the `Eligibility` section demonstrates the lowest score at 0.66. In terms of interventions, Numerical_contradiction achieves the highest score at 0.93, while Definition attains the lowest at 0.63. Among the interventions fea-

turing both labels, Paraphrase achieves the highest performance with an F_1 score of 0.72. Moreover, it is the only intervention type that achieves a higher score for **entailment**. Conversely, all other sections and interventions exhibit better performance for the **contradiction** label.

6 Error Analysis

To understand the model's behavior across different sections, interventions, and labels/relations, we examined the dataset.

6.1 Dataset Difficulty

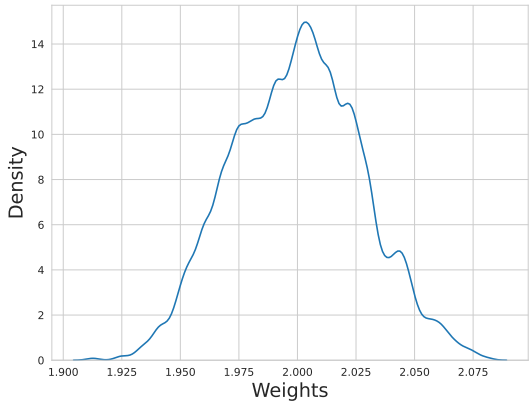

Figure 2: Weight distribution of NLI4CT data instances generated by the auxiliary model after 3 epochs of training. Lower weights correspond to easy examples, and higher weights correspond to hard examples.

One application of the MinMax algorithm is its capability to classify data points into hard and easy examples. Figure 2 illustrates the weight distribution of data instances from the auxiliary model after three epochs of training. Data instances with higher weights represent hard examples, where the model incurs a high loss, while instances with lower weights denote easy examples.

Following the data cartography procedure outlined in Swayamdipta et al. (2020), we replicated their method using the best MinMax model trained for three epochs. We collected probability values for the gold label on each epoch and calculated confidence, variability, and correctness values. In Figure 3, the upper region with red data points represents easy-to-learn instances, while the bottom region with blue data points represents hard-to-learn examples. Data points with high variability are depicted as ambiguous examples.

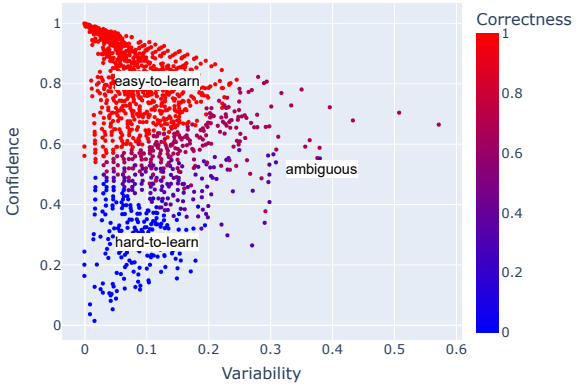

Figure 3: Data map for the NLI4CT dataset following (Swayamdipta et al., 2020).

6.2 Analysis of Easy and Hard Samples

We conducted a comparison between the two dataset difficulty methodologies by extracting easy and hard examples from both strategies. We found 322 instances common to both strategies as easy examples or easy-to-learn instances. As for hard examples or hard-to-learn examples, there were 96 instances common to both. We performed a three-level analysis using these instances, especially the hardest ones, to understand the in-depth dataset difficulty and the model's behavior.

First, we looked at the structural level of the dataset concerning these instances and found that instances focusing on the `Eligibility` section were identified as the most easy-to-learn for the model, whereas those targeting `Adverse Events` proved challenging. Additionally, learning the **contradiction** relation was more difficult than **entailment** (see Table 7). Next, we compared the word overlap between the premise and hypothesis of the easy and hard examples. We found that the word overlap was higher in the easy examples compared to the hard examples. Furthermore, the easy examples exhibited a higher frequency of **entailment** relations, suggesting that the model might have established a correlation between word overlap and **entailment** relations (see Figure 4). One potential solution to mitigate this issue could involve perturbing the instances with high word overlap by introducing synonyms into the dataset.

Combining observations from these analyses provides some interesting insights. As previously discussed in 5.2, the results from the test data reveal that the `Eligibility` section obtained the lowest F_1 score, while `Adverse Events` performed the

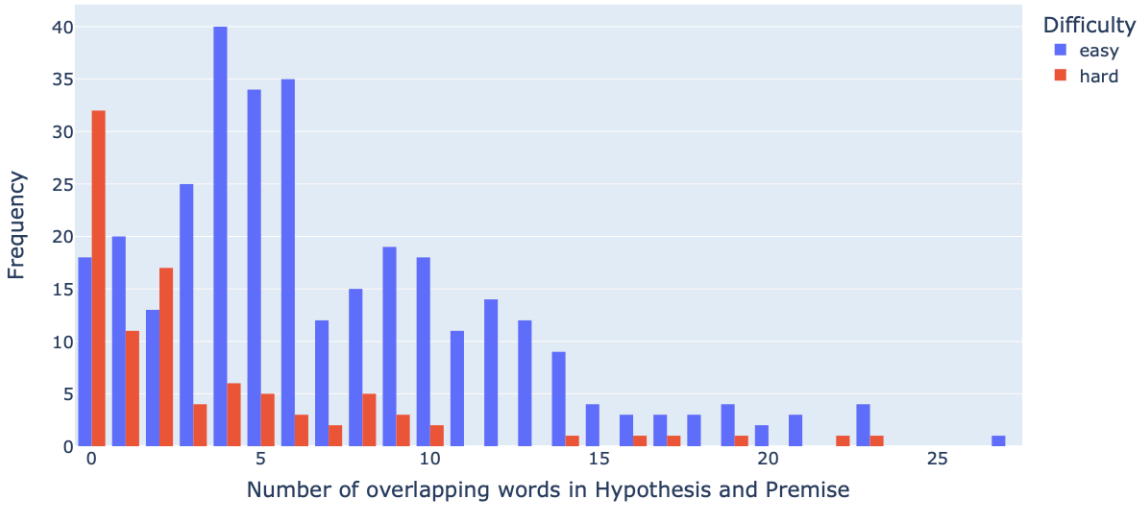

Figure 4: Word overlap between the hypothesis and the premise in the easy and the hard examples.

best. Given that the instances of the `Eligibility` section in the training set were easy to learn, it is plausible that the model did not learn many features from this section. Conversely, as the instances of `Adverse Events` were more challenging to learn, the model likely attempted to extract more features from this section. A similar rationale can also be applied to the **entailment** and **contradiction** relation. However, another factor contributing to the higher scores on the **contradiction** relations in the test data could be the greater number of the true **contradiction** relations.

Finally, we manually analyzed the ten most difficult examples. We discovered that the predominant error made by the model involved the confusion between the cohorts and the trials. Specifically, the instances that involve a comparison between two trials, each comprising two cohorts, often led the model to misinterpret the second cohort of the first trial as the secondary trial. Overall, the model struggled with numerical reasoning, particularly in scenarios involving numerous variables that require calculations. More details on the analysis of dataset difficulty can be found in Appendix A.8.

7 Conclusion

In this study, we introduced a large language model-based system designed to address the natural language inference task through text generation. Our approach prioritized model robustness, which was achieved by incorporating an auxiliary model that directs the LLM to focus on challenging instances in the input space. Moreover, we enhanced the system's robustness against adversarial samples by introducing numerical and semantic perturbations to the NLI4CT dataset during training. Our findings revealed the system's superior robustness against semantic-altering interventions compared to semantic-preserving ones. Additionally, through dataset analysis, we identified instances targeting the `Eligibility` section in Clinical Trial Reports as the the easiest to learn but more challenging to predict accurately. Conversely, the `Adverse Events` section posed greater difficulty in learning but was relatively easier to predict accurately. These findings offer valuable insights for future research on improving the robustness by focusing more on challenging sections of CTRs.

Acknowledgments

Our work was funded by the Deutsche Forschungsgemeinschaft (German Research Foundation) DFG-442445488 under the trilateral ANR-DFG-JST AI research project KEEPHA. Furthermore, we gratefully acknowledge funding from the German Federal Ministry of Education and Research under the grant BIFOLD24B.

Limitations and Ethical Considerations

We do not rule out the possible risk of sensitive content in the data. Furthermore, the Mistral-based models in our experiments, which were pre-trained on a wide variety of source data, might have inherited biases from these pretraining corpora. We

further acknowledge that prompts used to generate responses with Mistral models might result in different responses when the prompts are slightly modified or set up differently.

A Appendix

A.1 Dataset Statistics

We highlight the basic statistics of the NLI4CT dataset in Table 2.

A.2 Descriptions of the Fine-tuned Models

We implemented various fine-tuning strategies across multiple models. Below, we provide descriptions for each of these models:

- **NLI4CT-FT**: Mistral-7B model fine-tuned on the NLI4CT dataset.
- **MEDNLI-FT**: Mistral-7B model fine-tuned on the MEDNLI dataset.
- **NLI4CT-FT-ACR**: NLI4CT-FT model fine-tuned on acronym based perturbations.
- **MEDNLI-FT-NLI4CT**: MEDNLI-FT fine-tuned on the NLI4CT dataset.
- **MEDNLI-FT-NLI4CT-ACR-NUM**: MEDNLI-FT fine-tuned simultaneously on the NLI4CT dataset, acronym and numerical perturbations.
- **MEDNLI-NLI4CT-FT-ACR**: MEDNLI-FT-NLI4CT model fine-tuned on acronym perturbations.
- **MEDNLI-NLI4CT-FT-NUM**: MEDNLI-FT-NLI4CT model fine-tuned on numerical perturbations.
- **MEDNLI-NLI4CT-FT-ACR-NUM**: MEDNLI-FT-NLI4CT model fine-tuned on acronym and numerical perturbations simultaneously.
- **MINMAX-MEDNLI-FT-NLI4CT**: MEDNLI-FT fine-tuned using Mistral-7B and the auxiliary model on the NLI4CT dataset.
- **MINMAX-MEDNLI-FT-NLI4CT-BC**: MEDNLI-FT fine-tuned using Mistral-7B and the auxiliary model on the NLI4CT dataset using the best configuration obtained from hyperparameter tuning.
- **MINMAX-MEDNLI-NLI4CT-FT-ACR-NUM-BC**: MINMAX-MEDNLI-FT-NLI4CT fine-tuned using Mistral-7B and the auxiliary model on acronym and numerical perturbations simultaneously using the best configuration obtained from hyperparameter tuning.

### Input:
{premise}

Question: Does this imply that
{hypothesis}?

### Response:
{label}</s>
```

Figure 5: Final design for prompting.

A.3 Final Instruction Template

After running experiments with different prompt formats, we finalized the template as shown in Figure 5. Instead of directly tackling the NLI task, we frame it as a text generation problem. We begin by giving general instructions, which describe the task to be performed. The next two sections of the prompt consist of the premise, providing context for the task, and the hypothesis presented as a question. The model is then trained to generate either "Yes" for an **entailment** relationship between the premise and hypothesis or "No" for a **contradiction**. While fine-tuning our model with the MedNLI dataset, we only utilized entailment and contradiction instances, excluding those labeled as neutral, to ensure consistency with the NLI4CT dataset.

A.4 Data Perturbation Details

In Table 3, we show full statistics of data perturbation on NLI4CT dataset. In the following section, we describe the data perturbation methodology.

A.4.1 Acronym Based Perturbations

We utilized a Medical Abbreviation and Acronym Meta-Inventory (Grossman Liu et al., 2021) containing short forms (SF) and corresponding long forms (LF) commonly used in the biomedical domain. With regular expressions, we extracted short forms present in the hypotheses of the NLI4CT dataset, resulting in 358 hypotheses. Given that the meta-inventory often includes multiple long

Data	No of Samples	Type	Section				Label

Data	No of Samples	Type	Section				Label	
			Count	Intervention	Eligibility	Adverse Events	Results	contradiction	entailment
ACR	533	*single*	357	67	103	20	167	178	179
		comparison	176	46	70	53	7	93	83
NUM	355	*Single*	268	51	67	39	111	267	1
		comparison	87	24	25	31	7	86	1

Table 3: Statistics for Acronym the (ACR) and Numerical (NUM) based perturbed dataset across different sections, labels, and instance types.

forms for a single short form we computed the cosine similarity between the short forms in the hypotheses and their corresponding long forms in the meta-inventory. For each unique short form identified in the hypotheses, we determined the most similar long form and manually verified its correctness within the context of the hypothesis. Subsequently, we resolved the short forms in the format: 'SF (LF)'. This process yielded 352 perturbed instances with consistent inference labels. Such perturbations are intended to assist models in avoiding potential confusion by ensuring that short forms are resolved, even when their corresponding long forms are present in the premise. Likewise, for each unique short form, we identified the least similar long form and generated a negative instance following the same format as before. This process resulted in approximately 181 new negative instances, where labels were flipped. Consequently, when combining both acronym-based perturbations, we created a total of 533 new instances.

A.4.2 Numerical Perturbation

The Math Word Problem (MWP) task has been introduced in NLP to enhance models' numerical reasoning capabilities (He-Yueya et al., 2023; Yao et al., 2023). Within our dataset, numerous instances involve comparisons of numerical entities, which inherently qualify as MWPs. To augment these instances, we introduce noise to the numerical entities in various forms. Utilizing an English Named Entity Recognition model (Raza et al., 2022) trained on Maccrobat, specifically tailored for biomedical entities (107 entities), we extracted 27 unique entities from the hypotheses. Our focus was on identifying entities that can alter the hypothesis's meaning concerning numerical reasoning, such as Age, Dosage, Lab_value, Duration, and Date. For numerical values associated with these entities, we applied basic mathematical operations like addition or subtraction. Additionally, words comparing these numerical entities were replaced with their opposites; for example, 'lower' was substituted with 'higher', and 'more than a week' was replaced with 'less than a week', and so forth. This process resulted in a total of 355 new perturbed instances, each with its label flipped.

A.4.3 Data Perturbations Results

Table 4 presents results for various interventions introduced in test data. *Base* in the table refers to *MEDNLI-FT-NLI4CT*.

A.5 Model and Experiment Details

We provide information regarding the models, the minmax algorithm, and experiments.

A.5.1 Mistral 7B and Mistral Instruct 7B

Mistral 7B, as the name suggests, has 7 billion parameters and stands out as a language model engineered for exceptional performance and efficiency. Central to its architecture are the grouped-query attention (Ainslie et al., 2023) and sliding window attention mechanisms (Child et al., 2019; Beltagy et al., 2020). Mistral models demonstrate remark-

Model	F_1				Faithfulness		Consistency	
	Def	Para	Num_Para	Num_Cont	Def	Para	Num_Para	Num_Cont
Base	0.42	0.72	0.54	0.88	0.59	0.72	0.68	0.90
Base + ACR	0.49	0.73	**0.59**	0.82	0.61	0.71	0.68	0.88
Base + NUM	0.46	0.73	0.56	**0.88**	0.60	0.72	0.68	**0.91**
Base + ACR + NUM	**0.58**	**0.73**	0.58	0.83	**0.64**	**0.72**	**0.68**	0.90
MinMax + ACR + NUM	0.51	0.73	0.56	0.83	0.62	0.71	0.68	0.88

Table 4: Acronym (ACR) and Numerical (NUM) perturbed dataset results

able adaptability and consistently outperform counterparts like Llama-13B. Moreover, the ease with which Mistral can be fine-tuned is evidenced by the Mistral Instruct 7B version, which is fine-tuned on publicly available instruction datasets and achieves a significant performance boost over the base version. Utilizing the capabilities of Mistral models, we fine-tuned both versions of the models on NLI4CT through a series of experiments aimed at determining the optimal version for final system development. Details of the Mistral models are shown in Table 6.

A.5.2 Low Rank Adaption

LoRA operates by freezing the weights of the pretrained model and introducing trainable rank decomposition matrices into each layer of the Transformer architecture. This strategy significantly reduces the number of trainable parameters for downstream tasks, leading to lower memory usage and accelerated fine-tuning speed. We utilize the HuggingFace implementation of PEFT, which incorporates LoRA configurations to initialize LoRA-based fine-tuning of the Mistral model. By applying LoRA, we were able to reduce the number of training parameters from 3,837,112,320 to 85,041,152 (2.22% of the total), which are subsequently optimized using the AdamW optimizer.

A.5.3 MinMax Algorithm

Beyond solely relying on the Mistral model, we introduced an auxiliary model into the fine-tuning process following the implementation of the MinMax algorithm introduced by Korakakis and Vlachos (2023) to enhance the model's robustness in NLI training. This auxiliary model is designed to amplify the loss incurred in input spaces where the Mistral model encounters difficulties, effectively directing its focus towards areas of higher loss. The objective function for training is defined as:

$$J(\theta, \phi) = \min_{\theta} \max_{\phi} \frac{1}{n} \sum_{i=1}^{n} g_{\phi}(x_i, y_i) \cdot \mathcal{L}(f_{\theta}(x_i), y_i)$$

Here, θ denotes the mistral model parameters while ϕ denotes the auxiliary parameters that are optimized using standard optimization methods. $\mathcal{L}(f_{\theta}(x_i), y_i)$ is the cross entropy loss and $g_{\phi}(x_i, y_i)$ generates weights for each instance in the range (0,1).

A.5.4 Experiment Details

Here we provide the parameters used in our experiments for both the base and auxiliary models. For the base Mistral model, we used a LoRA configuration with the following parameters:

```
rank: 32
lora_alpha: 64
target_modules: [ q_proj, k_proj, v_proj,
o_proj, gate_proj, up_proj, down_proj,
lm_head ],
lora_dropout: 0.05
```

Parameters for fine-tuning mistral and auxiliary models are as follows:

```
Mistral:
    learning_rate: 3.3e-5
    batch_size: 4
    number_of_epoch: 1
    max_steps: 1000
Auxiliary:
    learning_rate: 5.8e-3
    hidden_size_1: 1024
    hidden_size_2: 64
```

Further system training and hyperparameter tuning details can be found at https://github.com/Bhuvanesh-Verma/RobustLLM

A.6 Results of Best Model with respect to Interventions and Sections

We examined the results on test data across various sections and interventions. Table 5 indicates that the `Adverse Event` section and *Numerical Contradiction* interventions yield the best performance.

	Type	No of Samples	F_1 Score		
			entailment	contradiction	macro avg
Section	Intervention	1542	0.58 (512)	0.75 (1030)	0.67
	Eligibility	1419	0.58 (485)	0.73 (934)	0.66
	Results	1235	0.58 (405)	0.80 (830)	0.69
	Adverse Events	1304	0.65 (439)	0.81 (865)	0.73
Intervention	Contradiction	1500	0 (0)	0.84 (1500)	0
	Numerical_contradiction	276	0 (0)	0.93 (276)	0
	Numerical_paraphrase	224	0.58 (91)	0.74 (133)	0.66
	Paraphrase	1500	0.73 (750)	0.70 (750)	0.72
	Text_appended	1500	0.57 (750)	0.70 (750)	0.63

Table 5: Intervention and Section-based results on test data using best model across both labels. Along with the F_1 score we also show number of instances.

Model	Token Length	Mode	Dev F_1
Mistral-7B-v0.1	1024	Remove	0.71
Mistral-7B-v0.1	1024	Truncate	0.72
Mistral-7B-v0.1	2048	Remove	0.72
Mistral-7B-v0.1	2048	Truncate	**0.73**

Table 6: Impact of different token length and strategy for handling long text

A.7 Handling Long Premise-Hypothesis Pairs

One of the challenges of processing CTRs is their extensive length when paired up to form a premise-hypothesis pair. The Mistral model allows for token lengths of up to 4096. We experimented with different token lengths to see how they impacted the model's performance. We trained models with token lengths of 1024 and 2048 and evaluated their performance on the dev set. From Table 6, we can see that increasing token length improved the results. We also tested the impact of truncating or removing text if it exceeded the token length. We observed that removing long text had a slight negative impact on the performance of the model. We used a token length of 4096 for our system development, with a truncation strategy in place for text that exceeds the token length limit.

A.8 Dataset Difficulty Analysis Details

For the MinMax weights approach, we first calculated the mean weight of correctly predicted instances. Every correctly predicted instance with a weight lower than the mean weight was selected as an easy instance (670). Similarly, for incorrectly predicted instances, we calculated their mean weight. Every incorrectly predicted instance with a weight higher than the mean weight was selected as a hard example (190).

With the data cartography strategy, we calculated the mean confidence for correctly predicted instances. Every instance with a confidence higher than the mean confidence was considered an easy-to-learn example (666). Similarly, every incorrectly predicted instance with a confidence lower than the mean confidence of incorrectly predicted instances was considered hard to learn (179).

Furthermore, we manually examined four examples, two from each method Minmax and data-cartography labeled as most hard or difficult to learn. Three out of the four examples target the Adverse Events section, with one targeting the Results section. Notably, all four examples involved numerical reasoning, suggesting that the model still struggles with numerical reasoning despite demonstrating promising results on numerical interventions in the test data. For more details, see Table 7.

A high overlap between the premise and hypothesis can lead to incorrect predictions of **entailment** relations, while low overlap can result in incorrect **contradiction** (Naik et al., 2018). Analysis of the hard examples in Figure 6 revealed that instances with high overlap predominantly belong to **contradiction** relations, however, were incorrectly predicted as **entailment** relations by the model. This phenomenon could be attributed to the model associating higher word overlap with **entailment** relations, as evidenced by the easy examples in Figure 6. However, such a correlation was not observed in the low word overlap region.

Using our trained model (*MINMAX-MEDNLI-FT-NLI4CT*), we generated explanations alongside

Difficulty	Type	Section				Label	
		Count	Intervention	Eligibility	Adverse Events	Results	contradiction	entailment
Easy	*single*	234	50	132	8	44	61	173

responses for each of these ten instances by increasing the number of generated tokens during the inference [3]. As outlined in the work of Swayamdipta et al. (2020), hard examples with low confidence scores may suggest mislabeled instances. We show two of these potential mislabeled instances in the Appendix A.9. Similarly, we also show the instances where the model confused cohorts and trials in Appendix A.10.

[3]This part was added after the first submission.

A.9 Potential Mislabeled Instances

<s>### Instruction: Read the input text and answer the following question with Yes or No.

Input:
Primary trial evidence are Outcome Measurement: Number of Participants With Objective Response Based on Data Review Committee's Assessment Number of participants with objective response based on assessment of confirmed complete response (CR) or confirmed partial response (PR) according to Response Evaluation Criteria in Solid Tumors version 1.0 (RECIST). CR is defined as disappearance of all target and non-target lesions. PR is defined as 30% decrease in sum of the longest dimensions (LDs) of the target lesions taking as reference the baseline sum LD according to RECIST. Confirmed responses are those that persist on repeat evaluation 4 weeks after initial documentation of response. Time frame: Day 1 of Cycle 2, every 6 weeks after Cycle 2, and at the end of Cycle 8.Results 1: Arm/Group Title: SUNITINIB+CAPECITABINE Arm/Group Description: Sunitinib was administered orally from Day 1 at the starting dose of 37.5 mg/day on a continuous daily dosing schedule in 21-day cycles. Capecitabine was administered orally from Days 1 to 14 every 21 days at a starting dose of 2,000 mg/m^2/day. Participants were monitored for toxicity, and sunitinib and/or capecitabine dosing could be interrupted or reduced according to individual tolerance. Participants with progressive disease (PD) or intolerable toxicity were considered for discontinuation from the study. Overall Number of Participants Analyzed: 63 Measure Type: Number Unit of Measure: participants Total Number of Participants with CR+PR: 19 Complete Response (CR): 0 Partial Response (PR): 19

Question: Does this imply that on assessment 0 the primary trial Participants had a confirmed disappearance of all target and non-target lesions.?

Response: No

Abstract

These working notes describe the UMUTeam's participation in Task 8 of SemEval-2024 entitled "Multigenerator, Multidomain, and Multilingual Black-Box Machine-Generated Text Detection". This shared task aims at identifying machine-generated text in order to mitigate its potential misuse. This shared task is divided into three subtasks: Subtask A, a binary classification task to determine whether a given full-text was written by a human or generated by a machine; Subtask B, a multi-class classification problem to determine, given a full-text, who generated it. It can be written by a human or generated by a specific language model; and Subtask C, mixed human-machine text recognition. We participated in Subtask B, using an approach based on fine-tuning a pre-trained model, such as RoBERTa, combined with syntactic features of the texts. Our system placed 23rd out of a total of 77 participants, with a score of 75.350%, outperforming the baseline.

1 Introduction

In the area of Natural Language Generation (NLG), advances such as GPT-2 (Radford et al., 2019), GPT-3 (Brown et al., 2020) and InstructGPT (Ouyang et al., 2022) have provided support for various writing tasks. The widespread adoption of Large Language Models (LLMs) such as ChatGPT and GPT-4 (Achiam et al., 2023) has led to an increase in machine-generated content across various platforms, including news, social media, education and science. While these models produce remarkably fluid responses, concerns have arisen about their potential to spread misinformation and disrupt established systems. Concerns remain about their misuse, particularly in scenarios such as academic dishonesty and scientific research, where AI-generated content may be presented as original work. The emergence of AI-generated scientific texts raises ethical and integrity concerns in academic publishing, requiring tools or models to distinguish between human-generated and AI-generated content (Ma et al., 2023).

Efforts to detect AI-generated text have primarily involved fine-tuning pre-trained models and developing detection systems. Recent studies have presented datasets and methods specifically designed for the detection of AI-generated scientific documents. However, challenges remain in achieving high performance and interpretability across different domains and models (Ma et al., 2023).

For this reason, Task 8 of SemEval (Wang et al., 2024), entitled "Multigenerator, Multidomain, and Multilingual Black-Box Machine-Generated Text Detection", aims at identifying automatic systems for the detection of machine-generated text in order to mitigate its potential misuse. To this end, the task is divided into three subtasks that address two text generation paradigms: (1) full text, where a text is considered to be entirely written by a human or generated by a machine; and (2) mixed text, where a machine-generated text is refined by a human, or a text written by a human is paraphrased by a machine.

This shared task is divided into three subtasks:

- **Subtask A: Binary Human-Written vs. Machine-Generated Text Classification**. Determine whether a given full-text was authored by a human or generated by a machine. It offers two tracks: monolingual (English source only) and multilingual.
- **Subtask B: Multi-Way Machine-Generated Text Classification**. Given a full text, determine who generated it. It can be human-written or generated by a specific language model.
- **Subtask C. Human-Machine Mixed Text Detection**. Given a mixed text containing both human-generated and machine-generated

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 697–702
June 20-21, 2024

segments, identify the boundary where the transition from human-generated to machine-generated content occurs.

In this competition, the UMUTeam participated only in the **Subtask B** with an approach based on fine-tuning a pre-trained model such as RoBERTa combined with syntactic features of the text. Syntax features of the text refer to the writing style, such as token-level features (e.g. word length, part of speech, function word frequency and stop word ratio) and sentence-level features (e.g. sentence length).

During our experiments, we found that the syntactic features of texts can complement and improve the performance of pre-trained Transformer-based models and that RoBERTa is more suitable for this type of task.

The rest of this paper is organized as follows. First, Section 2 provides a summary of important details about the shared task setup. Second, Section 3 gives an overview of our system. Section 4 presents the specific details of our systems. Section 5 discusses the results of the experiments, and finally, the conclusions are presented in section 6.

2 Background

Recent advances in AI technology, particularly in the field of Natural Language Processing (NLP), have led to the emergence of many models capable of generating natural language using LLMs. These can produce remarkably fluent responses, and this has led to an increase in machine-generated content across multiple domains and platforms, including news, social media, education, and science.

LLMs face several technical and social challenges as they advance in NLP tasks. Recent research has shown that pre-trained LLMs can not only learn linguistic knowledge, but also reason about large amounts of acquired knowledge (Lewis et al., 2020). However, LLMs have other problems, such as hallucination, producing texts that contain information or details that are not based on reality or are completely invented; and asserting falsehoods as facts, which means that they can involuntarily produce texts that present false information as true.

The latest generative LLMs, such as GPT-3, are capable of producing highly fluent text, but they can produce inaccurate, toxic or unhelpful content. Some researchers have explored the use of reinforcement learning from human feedback (RLHF) (Ouyang et al., 2022) to adjust language models to better match user intent. ChatGPT, one of OpenAI's models based on GPT-3 and trained with RLHF, performs well in conversations with humans, demonstrating an understanding of user instructions and generating useful, reliable, honest and harmless text content.

Therefore, a growing number of studies have been conducted to analyze, recognize and identify text generated by AI, especially text generated by GPT. Current research focuses on two main areas: human behavior for recognizing text generated by AI and recognition models for identifying text generated by LLMs. For example, in (Guo et al., 2023), an approach was proposed to determine whether a text (in English and Chinese) was generated by ChatGPT or written by a human across different domains, while in (Shijaku and Canhasi, 2023), a model was developed to identify whether TOEFL essays were written by humans or generated by ChatGPT on a small dataset (126 essays for each).

There are other studies that focus on detecting fake information or fake news generated by LLMs. For example, in (Zellers et al., 2019), the Grover model was proposed to generate and detect examples of fake news. After the release of GPT-2, OpenAI proposed the GPT-2 generated text detector, which achieved a high F1 score. This detector was fine-tuned based on RoBERTa in a binary text classification format. In addition, many studies also use various data augmentation techniques to improve model performance in the classification task through external data that complements the model or simply increases the training set (Bayer et al., 2022). In paper (Ma et al., 2023), an approach was proposed to detect text generated by language models using different text features such as writing style, coherence, consistency, and argument logistics. The model with only syntax features (writing style) achieved the best result.

For this shared task, we used a fine-tuning approach of transformer-based models such as RoBERTa to create a detector for text generated by different LLMs. Unlike other existing studies on LLM-generated text detection, we have concatenated syntactic features during the fine-tuning process to improve its performance. The model evaluated for Subtask B is **RoBERTa** (Liu et al., 2019), a model based on Transformers, which was pre-trained on a large corpus of English data with Masked Language Model (MLM) goal. For this task, we evaluated the *base* version.

3 System overview

Figure 1 shows the architecture of our system. First, we extracted the syntactic features of the texts using the syntactic feature extractor and encoded the texts into a vector containing the dense representation of all the information contained in the text by the pre-trained models, i.e., the last hidden state of the model with text as input. Second, once the vector and syntactic features were obtained, we normalized the syntactic feature values and concatenated them with the text vector. Third, the fine-tuning process is performed, and a sequence classification layer is added on top of the pre-trained model. This layer takes the sequence representation generated by the pre-trained model and performs a classification based on the labels of the specific classification task. Finally, a performance evaluation is performed using the validation set.

3.1 Syntactic feature extractor

Syntactic linguistic features are those aspects related to the grammatical structure and organization of words in a sentence or paragraph (García-Díaz et al., 2022b). This can include elements such as sentence length, the frequency of certain parts of speech, the presence of function words, the number of stop words, etc. All of these features reflect the writing style that distinguishes different texts. In general, syntactic linguistic features have proven effective in NLP tasks such as author analysis (García-Díaz et al., 2022a) or hate speech identification (García-Díaz et al., 2023b).

The features used in this task are:

- **Average word length**. This is the average number of characters the words in the text have. It is calculated by adding the length of all words in the text and dividing that sum by the total number of words in the text.
- **POS tag frequency**. This is the frequency of Part of Speech (POS) grammatical tags in the text. Grammatical tags represent the grammatical categories of words in a text, such as nouns, verbs, adjectives, and so on. The frequency of POS tags indicates how often different grammatical categories occur in the text and can provide information about the structure and style of the text.
- **Average sentence length chars**. This is the average length of the sentences in the text, measured in characters. It is a measure of the complexity and readability of the text.
- **Average sentence length words**. This is the average length of the sentences in a text, measured in words. This metric shows the average number of words per sentence in the text.
- **Percentage of stopwords**. This is the percentage of stopwords in the text, relative to the total number of words in the text. Stopwords are common words that are often filtered out or eliminated during natural language processing because they occur so frequently and have little contextual meaning.
- **Punctuation Frequency**. Refers to the number of times that different punctuation marks, such as commas, periods, semicolons, etc., occur in a given text.
- **Special character Frequency**. Refers to the number of times characters other than letters and numbers occur in a given text. These special characters can include punctuation marks, mathematical symbols, control characters, emoticons, and other non-alphabetic symbols.

For the syntactic features, we used an open source tool called *authorstyle*[1], a package that allows to handle digital text forensics and stylometric corpora to extract stylometric features.

The embeddings of the texts refer to the numerical representation of the words or tokens in a high-dimensional vector space obtained by the tokenizers of the models. For this task, we normalized the syntactic feature values and concatenated them with the embeddings obtained by the tokenizers to perform RoBERTa fine-tuning to identify the author. It can be written by humans or generated by a specific language model.

4 Experimental setup

For Subtask B, we used the dataset provided by the organizers, which consists of two subsets: training and validation. Figure 2 shows the distribution of the training and validation sets. We can see that both the training and validation sets are balanced and that there are a total of 5 types of texts generated by different LLMs or by humans. The types

[1] https://github.com/mullerpeter/authorstyle

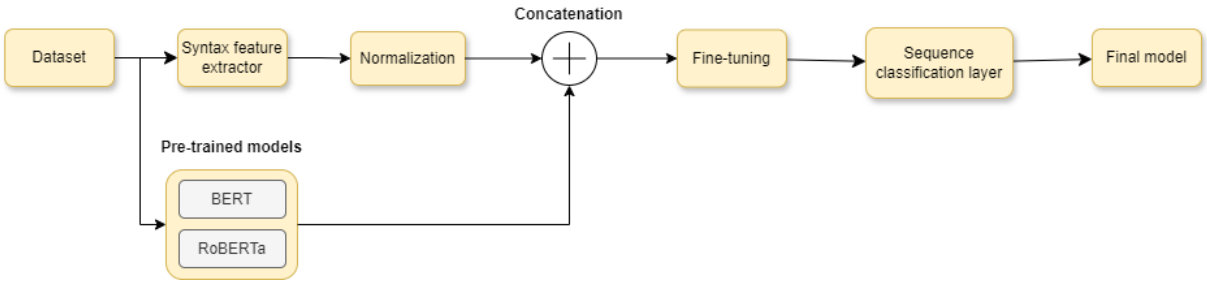

Figure 1: System architecture

are: davinci, bloomz, human, chatGPT, dolly and cohere.

We used the following fine-tuning hyperparameters: a batch size of 16 for both training and validation, 10 epochs, a learning rate of 2e-5, and a weight decay of 0.01.

During training, we used Macro-F1 as a reference. Macro-F1 is a measure used to evaluate the performance of a model in a multi-class classification problem. It calculates the average F1 score for each class individually, and then averages these scores to obtain an overall score. The macro F1 Score assigns equal weight to each class, regardless of its size or distribution in the data set. This means that all classes are equally important in the final scoring metric.

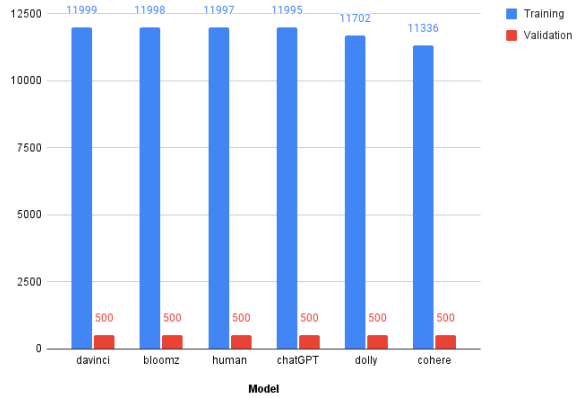

Figure 2: Training and validation set distribution of Subtask B.

5 Results

In the Table 1 we can see the official ranking of Subtask B. With a total of 77 contestants, we have achieved the twelfth-third best result, with an accuracy of 75.350, which is 0.744% higher than the baseline and 15.5% lower than the first.

In order to perform an error analysis and to observe the behavior of our model in predicting different classes of texts, we have generated the confusion matrix for our model based on the test set, as shown in Figure 3. Our analysis shows that our model has a strong predictive performance for texts generated by Bloomz, Dolly, ChatGPT and Davinci, reaching accuracies above 90%. However, when it comes to human-generated texts, our model shows a 27.73% tendency to misclassify them as generated by the Dolly model. In particular, when predicting texts generated by Cohere, our model tends to misclassify them as generated by Davinci at a rate of 70%, leading to a decrease in overall accuracy.

Table 1: Official results for the Subtask B.

Team	Rank	Accuracy

6 Conclusion

This paper describes the participation of the UMUTeam in the 8th shared task of SemEval 2024, focused on the identification of automatic systems for the recognition of machine-generated text in order to mitigate its potential misuse. The task consisted of three subtasks: Subtask A, a binary classification task to determine whether a given full-text was written by a human or generated by a machine; Subtask B, a multi-class classification problem to determine, given a full-text, who gen-

Figure 3: The confusion matrix of our RoBERTa-based system in the test set.

erated it. It can be written by a human or generated by a specific language model; and Subtask C, mixed human-machine text recognition. In this shared task, we participated in Subtask B, using a approach based on fine-tuning a RoBERTa pretrained model with syntactic features of texts. In terms of results, our system achieved the 23rd position with a score of 75.350%, outperforming the baseline.

Due to our line of research, we will evaluate our system on texts containing figurative language (García-Díaz and Valencia-García, 2022) and financial language (García-Díaz et al., 2023a). On the one hand, the ambiguity and creativity of figurative language poses a challenge to the recognition of automatically generated text, as LLMs may have difficulty replicating the creative nuances of human-generated content. On the other hand, the recognition of automatically generated financial and business text is challenging due to specialized vocabulary and complex technical concepts. Ideally, LLMs must have deep domain-specific understanding to produce accurate content that requires regulatory compliance and accuracy, which requires careful review and validation against authoritative sources.

Abstract

These notes describe the participation of the UMUTeam in EDiReF, the 10th shared task of SemEval 2024. The goal is to develop systems for detecting and inferring emotional changes in the conversation. The task was divided into three related subtasks: (i) Emotion Recognition in Conversation (ERC) in Hindi-English code-mixed conversations, (ii) Emotion Flip Reasoning (EFR) in Hindi-English code-mixed conversations, and (iii) EFR in English conversations. We were involved in all three and our approach is based on a fine-tuning approach with different pre-trained models. After evaluation, we found BERT to be the best model for ERC and EFR and with this model we achieved the thirteenth best result with an F1 score of 43% in Subtask 1, the sixth best in Subtask 2 with an F1 score of 26% and the fifteenth best in Subtask 3 with an F1 score of 22%.

1 Introduction

Emotion, often defined as an individual's mental state associated with thoughts, feelings and behavior, has been categorized in various ways throughout history. Modern classifications include Plutchik's (Plutchik, 1982) eight primary types and Ekman's (Ekman, 1993) emphasis on facial expressions. In Natural Language Processing (NLP), emotion recognition has gained popularity for its applications in opinion mining, healthcare, etc. Although textual emotion recognition has been studied extensively, attention has recently shifted to Emotion Recognition in Conversation (ERC), driven by the availability of conversational data (Yeh et al., 2019) (Chen et al., 2018).

Conversation or dialogue is the main mode of information exchange between individuals, highlighting the prevalence of code-mixed (Kasper and Wagner, 2014), where multiple languages are integrated into the conversation. Despite extensive research on ERC, previous studies have largely focused on monolingual dialogues, neglecting code-mixed conversations. However, in the paper (Kumar et al., 2023a), the authors propose ERC models adapted to code-mixed dialogues, highlighting the need for datasets and resources in this area. Furthermore, they propose to incorporate common sense knowledge to better understand the emotions evoked in the conversation, and present a process to adapt existing English-based common sense knowledge graphs for code-mixed input.

ERC aims to identify emotions in sequences of utterances or dialogues rather than in isolated texts. In many cases, it is necessary to understand the emotional changes in a conversation is necessary in addition to identifying the speaker's emotion. However, understanding the emotional changes in a conversation is an challenging task that requires detailed analysis. Hence, the task of Emotion Flip Reasoning (EFR) (Kumar et al., 2022), which focuses on identifying the cause of a speaker's emotional change in a dialogue.

The EDiReF shared task (SemEval 2024) focuses on discovering and explaining the emotion change in the conversation (Kumar et al., 2024). It is divided into three subtasks: (1) **Subtask 1: ERC in Hindi-English code-mixed conversations**. Given a Hindi-English code-mixed dialog, the goal is to assign an emotion to each utterance from a predefined set of possible emotions (Kumar et al., 2023c); (2) **Subtask 2: EFR in Hindi-English code-mixed conversations**. Given a Hindi-English code-mixed dialog, the goal is to identify the trigger utterance(s) for an emotion flip in a multi-party conversation dialog (Kumar et al., 2022, 2023b); and (3) **Subtask 3: EFR in English conversations**. Given an English conversation, the goal is to identify the trigger utterance(s) for an emotion flip in a multi-party conversation dialog (Kumar et al., 2022, 2023b).

For this task, we propose an approach based on fine-tuning pre-trained Transformer-based models.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 703–709

In a nutshell, fine-tuning is a process by which a pre-trained model, previously trained on a specific task, is adjusted to adapt to a related but different task using a labeled dataset. In addition, a text processing process has been performed where, if possible, past and future conversations or emotions are added to the current user's sentence as input to the model. In this way, the model can have the context of the user's emotion in the past and future states.

These working notes are organized as follows. In Section 2, the reader will find a summary of important details about the task setup. Section 3 gives an overview of our system. Next, Section 4 presents the specific details of our systems. The results are then discussed and presented in Section 5. Finally, the conclusions are presented in Section 7.

2 Background

Sentiment Analysis (SA) is the study of human attitudes and feelings in specific situations, focusing on understanding emotions expressed through speech, voice, facial expressions and behavior. It typically identifies positive, negative and neutral emotions (Fu et al., 2023). In contrast, Emotion Recognition (ER) attempts to identify more nuanced emotions such as joy, hate and disgust, and modern classifications include Plutchik's (Plutchik, 1982) eight primary types and Ekman's (Ekman, 1993) emphasis on facial expressions. Emotion recognition spans text, audio and video modalities and differs from sentiment analysis in that it considers the context and interdependence between speakers within a conversation.

Multimodal emotion recognition has become an important research topic, mainly due to its potential applications in many challenging tasks such as dialog generation, user behavior understanding, multimodal interaction, and others. Therefore, a conversational emotion recognition system can be used to generate appropriate responses by analyzing the user's emotions. According to (Poria et al., 2019), ERC poses several challenges such as modeling the conversational context, emotion shifts of interlocutors, and others, which make the task more challenging. Recent works propose solutions based on multimodal memory networks (Hazarika et al., 2018). However, they are mostly limited to dyadic conversations and are therefore not scalable to ERC with multiple interlocutors. Furthermore, previous studies have largely focused on monolingual dialogues, neglecting code-mixed conversations (Kumar et al., 2023a).

In a conversation, utterances generally depend on the context of the conversation. This is also true for the emotions associated with them. In other words, the context acts as a set of parameters that can influence a person to make an utterance while expressing a certain emotion. This context can be modeled in different ways, for example using Recurrent Neural Networks (RNN) and Memory Networks (Hazarika et al., 2018) (Serban et al., 2017). Public datasets available for multimodal emotion recognition in conversation, such as IEMOCAP (Busso et al., 2008) and SEMAINE (McKeown et al., 2010), have facilitated a significant number of research projects, but they also have limitations due to their relatively small number of total utterances and the lack of multipart conversations.

Understanding the emotional flips in a conversation requires a detailed analysis. This is where Emotional Flip Reasoning (EFR) comes in, which focuses on identifying the cause of a speaker's emotional flip in a dialogue. The EFR process consists of three stages (Kumar et al., 2022): identifying the utterance in which the emotional flip occurs, identifying the triggers responsible for the change, and assigning psychologically motivated instigator labels to the triggers to explain the emotional flip. Therefore, the EFR task has the potential to improve the user experience in a conversational dialog system, especially in the generation of empathetic responses (Lin et al., 2019), (Ma et al., 2020).

In recent years, with the rapid development in the field of NLP, many pre-trained models based on Transformer have emerged. These models are trained on large corpora of unlabeled text and, due to their transfer learning capability, can be adapted to different tasks such as classification, translation, response generation without the need of a large training corpus. For example, (García-Díaz et al., 2023) and (García-Díaz and Valencia-García, 2022) demonstrated the effectiveness of Transformers-based models for identifying hate speech and satire. Therefore, in this study, different pre-trained models were evaluated for the ERC and EFR tasks.

The models evaluated are: (1) XLM-RoBERTa-base (Conneau et al., 2019); (2) DeBERTa-V3-base(He et al., 2021); and (3) BERT (Devlin et al., 2018). For the ERC and EFR tasks, we evaluated the basic version and the version without the mask,

which removes the accent markers.

3 System overview

Figure 1 shows the general architecture of our approach for the three subtasks, which is mainly divided into two modules: data processing and fine tuning.

In the processing module, for Subtask 1 (ERC), we first translated the statements into English, since most language models are pre-trained in English and have shown good performance in the emotion identification and sentiment analysis tasks. They were then grouped by user, as this provides a coherent context for analyzing their emotional state, rather than adding conversational context from other speakers. Therefore, by examining all the interventions made by the same speaker, we gain a deeper understanding of their emotional state at the time of the target intervention. Furthermore, we believe that adding more context could introduce noise and reduce the performance of the models. Once grouped, for each current statement of the user, the previous statement was concatenated with the next by a semicolon. For example, for statement U3 from a particular user, the input to the model would be `U2;U3;U4`. For subtasks 2 and 3 (EFR) in addition to concatenating the previous and subsequent statements from the same user for each current statement, the emotion of each statement is added. For example, for statement U3, the input to the model would be `U2-e2;U3-e3;U4-e4`, where *e* represents the user's emotion at that moment. The figure 2 shows examples of processing for the user *Ross* in a specific conversation.

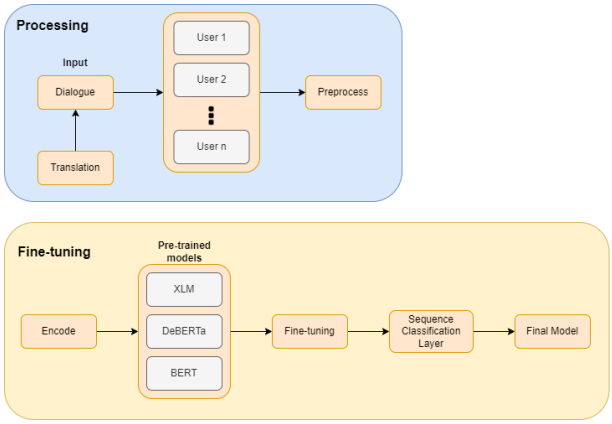

Figure 1: System architecture

In the fine tuning module (see Figure 1), the inputs are first tokenized according to the tokenizers of the pre-trained models. Next, the pre-trained model is loaded as the basis for the classification task. Next, a sequence classification layer is added on top of the pre-trained model. This layer takes the last hidden state generated by the pre-trained model and performs classification based on the labels of the specific classification task. In this case, we used the sequence classification layer from the *Transformers*[1] library for each pre-trained model. Finally, the tuning is performed out and a performance is evaluated using the validation set.

4 Experimental setup

To train the three subtasks, we used the data set provided by the organizers, which consists of a training set and a validation set. In Figure 3 and Table 1 we can see the distribution of the training and validation sets for the three subtasks.

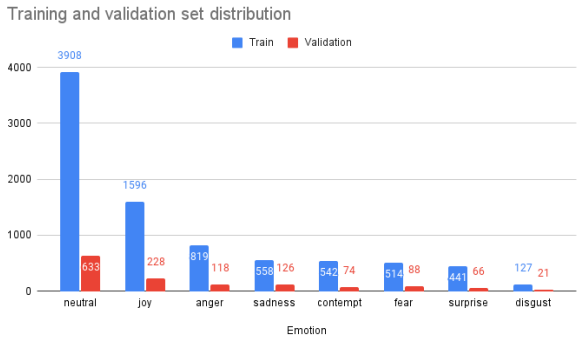

Figure 3: Training and validation set distribution of Subtask 1.

Table 1: Training and validation set distribution of Subtask 2 and 3.

Set	Triggers	No triggers
Subtask 2		
Train	6542	92235
Validation	434	7028
Subtask 3		
Train	5575	29416
Validation	494	3027

For all three subtasks (1, 2, 3), we used the same fine-tuning hyperparameters, namely: a batch size of 8 for both training and validation, 10 epochs, a learning rate of 2e-5, and a weight decay of 0.01. During training, we used the weighted F1 as a reference. To evaluate the three subtasks, the organizers

[1] https://github.com/huggingface/transformers

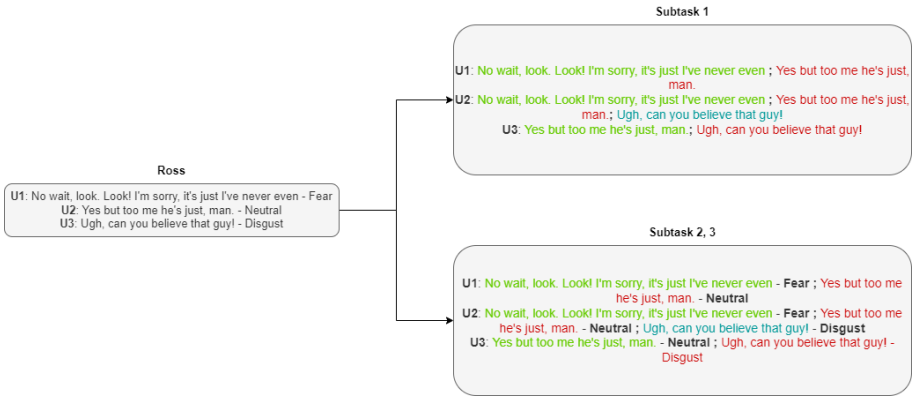

Figure 2: Examples of processing for subtasks 1, 2, and 3.

used the weighted F1, an evaluation metric used in classification problems that takes into account the class imbalance in the data. While the traditional F1 score calculates the harmonic mean of precision and recall for all classes equally, the weighted F1 score weights these measures according to the number of samples in each class.

5 Results

Table 2 shows the results obtained on the test set with different models for Subtask 1 on the ERC. We can see that the XLM-R model obtained the best result with a weighted F1 score of 42.878%, followed by BERT with a weighted F1 score of 42.691%.

Table 2: Evaluation of different pre-trained models in test set of Subtask 1.

Model	W-R	W-P	W-F1
Subtask 1			
XLM-R	**44.9367**	42.1941	**42.878**
DeBERTa	43.5443	41.0664	41.7686
BERT	44.8734	**42.4540**	42.6910

Table 3 shows the results of Subtask 2, which is an EFR task, on a dataset of Hindi-English code-mixed conversations. The evaluation metric is the F1 score of the triggers, and it can be seen that BERT is the only model that obtained a score greater than 0, with 25.8721% in F1 score. The XLM-R and DeBERTa models were not able to predict emotion change triggers well because they were fine-tuned with the same hyperparameters, so it may be necessary to use different hyperparameters, such as a smaller learning rate. Therefore, as a future line, it is proposed to perform hyperparameter tuning to fine-tune the models to achieve better performance.

Regarding Subtask 3, which has the same objective as Subtask 2, but on a dataset of English code-mixed conversations, it can be observed that BERT and DeBERTa are the only two models that have obtained an F1 score greater than 0, with 22.4764% for BERT and 17.1111% for DeBERTa (see Table 3).

Table 3: Evaluation of different pre-trained models in test set of Subtask 2 and 3.

Model	Recall	Precision	F1
Subtask 2			
XLM-R	0.0	0.0	0.0
DeBERTa	0.0	0.0	0.0
BERT	**21.3942**	**32.7206**	**25.8721**
Subtask 3			
XLM-R	0.0	0.0	0.0
DeBERTa	13.1737	24.4057	17.1111
BERT	**19.3328**	**87.9103**	**22.4764**

Therefore, we have chosen the BERT model for this task, since it outperforms the other models in all three subtasks, except for the first, where it is 0.187% worse than XLM-RoBERTa, which does not exceed 1%. In this case, we have obtained the thirteenth position in Subtask 1, the sixth in Subtask 2 and the fifteenth in Subtask 3.

6 Error analysis

For error analysis, we extracted the confusion matrix from BERT using the Subtask 1's test sets. A confusion matrix is a tool used in error analysis, especially in classification scenarios, by illustrating

the performance of a model in predicting true class labels compared to the model-predicted classes.

In Figure 4, we can see that our system tends to confuse the *Neutral* emotion in the ERC task, due to the unbalanced training set provided by the organizers, where the *Neutral* emotion occupies the highest percentage. Furthermore, the disgust emotion was not correctly identified in any case.

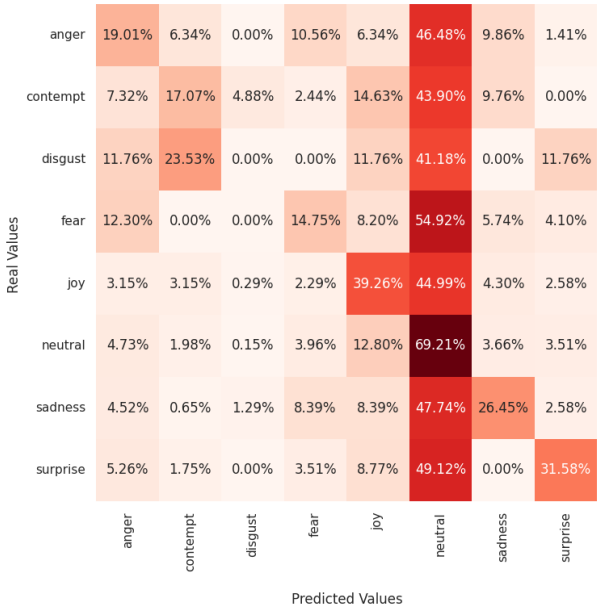

Figure 4: BERT confusion matrix in the test set of subtask 1.

Table 4 shows a classification report of our model in the EFR task of Hindi-English code-mixed conversation (Subtask 2). We can see that our system tends to identify instances as "No triggers" and has a higher recall due to the imbalance in the training set, which contains more instances of "no triggers". As for Subtask 3, the same phenomenon occurs as in Subtask 2, as shown in Table 5.

Table 4: BERT's classification report of Subtask 2 in the test set.

	Precision	**Recall**	**F1**
No triggers	95.5918	97.4842	96.5287
Triggers	32.7206	21.3942	25.8721
Macro avg	64.1562	59.4392	61.2004
Weighted avg	92.1907	93.3680	92.7065

Table 5: BERT's classification report of Subtask 3 in the test set.

	Precision	**Recall**	**F1**
No triggers	87.9103	91.7570	89.7924
Triggers	26.8409	19.3328	22.4764
Macro avg	57.3756	55.5449	56.1344
Weighted avg	79.6494	81.9602	80.6866

7 Conclusion

We have described the UMUTeam's participation in the 10th shared task 10 of SemEval 2024, the goal of which was to develop models for detecting and reasoning about the emotion change in the conversation. The task consists of three subtasks: (i) Emotion Recognition in Conversation (ERC) in Hindi-English code-mixed conversations, (ii) Emotion Flip Reasoning (EFR) in Hindi-English code-mixed conversations, and (iii) EFR in English conversations.

For all three subtasks, we used the fine-tuning approach of pre-trained models and performed a text processing process where, where possible, previous and future conversations or emotions are added to the current user's sentence as input to the model. In terms of results, our system achieved the thirteenth best result in Subtask 1 with an F1 of 43%, the sixth best in Subtask 2 with an F1 of 26%, and the fifteenth best in Subtask 3 with an F1 of 22%.

The study of emotional shifts provides a valuable insights for understanding psychographic characteristics in author profiling in the political context. Political communication is inherently intertwined with emotional appeals, and the ability to identify patterns of emotional shifts provides insight into the psychological makeup of political authors. Therefore, we plan to further validate the effectiveness of emotion flip inference by applying it to our PoliticES 2022 and 2023 datasets (García-Díaz et al., 2022; Garcia-Díaz et al., 2023) thus, contributing to a more comprehensive understanding of the ideologies, motivations, and communication strategies of political figures.

TM-TREK at SemEval-2024 Task 8: Towards LLM-Based Automatic Boundary Detection for Human-Machine Mixed Text

Xiaoyan Qu and **Xiangfeng Meng**
Samsung R&D Institute China-Beijing
{xiaoyan11.qu, xf.meng}@samsung.com

Abstract

With the increasing prevalence of text generated by large language models (LLMs), there is a growing concern about distinguishing between LLM-generated and human-written texts in order to prevent the misuse of LLMs, such as the dissemination of misleading information and academic dishonesty. Previous research has primarily focused on classifying text as either entirely human-written or LLM-generated, neglecting the detection of mixed texts that contain both types of content. This paper explores LLMs' ability to identify boundaries in human-written and machine-generated mixed texts. We approach this task by transforming it into a token classification problem and regard the label turning point as the boundary. Notably, our ensemble model of LLMs achieved first place in the 'Human-Machine Mixed Text Detection' sub-task of the SemEval'24 Competition Task 8. Additionally, we investigate factors that influence the capability of LLMs in detecting boundaries within mixed texts, including the incorporation of extra layers on top of LLMs, combination of segmentation loss, and the impact of pretraining. Our findings aim to provide valuable insights for future research in this area.

1 Introduction

Large language models (LLMs), particularly since the debut of ChatGPT, have made significant advancement and demonstrated the ability to produce coherent and natural-sounding text across a wide range of applications. However, the proliferation of generated text has raised concerns regarding the potential for misuse of these LLMs. One major issue is the tendency of LLMs to produce hallucinated content, resulting in text that is factually inaccurate, misleading, or nonsensical. Inappropriate utilization of LLMs for text generation purposes, such as in news articles (Zellers et al., 2019), social media posts (Fagni et al., 2021), and app reviews (Martens and Maalej, 2019), can propagate misinformation and influence public perceptions. Furthermore, the use of machine-generated text can also facilitate academic dishonesty. Therefore, accurately distinguishing between human-authored and machine-generated texts is crucial in order to address these challenges effectively.

The majority of existing studies addressing this challenge have approached it as a machine-generated text classification problem, aiming to determine whether a given text is generated by LLMs or not. However, this approach assumes that the text is either completely machine-generated or entirely human-written. With the increasing collaboration between humans and AI systems, mixed texts containing both human-authored and machine-generated portions have emerged as a new scenario that simple machine-generated text classification methods cannot effectively address (Dugan et al., 2023). Therefore, a more nuanced approach to machine-generated text classification for mixed texts is necessary.

This study addresses the challenge of token-level boundary detection in mixed texts, where the text sequence starts with a human-written segment followed by a machine-generated portion. The objective is to accurately determine the transition point between the human-written and LLM-generated sections. To achieve this, we frame the task as a token classification problem, thus the turning point of the label sequence will be the boundary. Through experiments utilizing LLMs that excel in capturing long-range dependencies, we demonstrate the effectiveness of our approach. Notably, by leveraging an ensemble of multiple LLMs to harness the robust of the model, we achieved first place in Task 8 of SemEval'24 competition.

Furthermore, we explore factors that impact the effectiveness of LLMs in boundary detection, including the integration of additional layers on top of LLMs, the combination of segmentation loss and pretraining techniques. Our experiments indicate

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 710–715

that optimizing these factors can lead to significant enhancements in boundary detection performance.

The main contribution of this papers include:

1) We explore LLMs' capability to detect boundaries within human-machine mixed texts, compare the performance of various LLMs, and present a benchmark based on the new released data set. And we rank 1st in the corresponding SemEval'24 competition (Wang et al., 2024).

2) We examine factors that impact boundary detection in mixed texts, including additional layers on top of LLMs, introduce of segment loss functions, and pretraining technique. We aim to provide valuable insights for future research in this field.

2 Related Work

Previous research has predominantly focused on machine-generated text classification (Crothers et al., 2023; Jawahar et al., 2020), where the text is attributed to either human authors or large language models. The objective is to determine whether a given text is human-written or specifically generated by a particular LLM. These studies can be classified into two main categories: metric-based methods and model-based methods. Metric-based approaches leverage metrics such as word rank, predicted distribution entropy, and log-likelihood (Mitchell et al., 2023; Gehrmann et al., 2019; Venkatraman et al., 2023). On the other hand, model-based methods involve training models on labeled data (Liu et al., 2022). However, these methods are not directly applicable to boundary detection for mixed human-machine texts.

Recently, there are a few works investigating the detection of mixed human-machine text. These texts consist of both human-written and machine-generated content, and the objective is to accurately identify the boundary between these two segments. Dugan et al. (2023) delved into the human ability to discern boundaries between human-written and machine-generated text. Their study revealed significant variations in annotator proficiency and analyzed the impact of various factors on human detection performance. Zeng et al. (2023) were the first to formalize the task as identifying transition points between human-written and AI-generated content within hybrid texts, and they examined automated approaches for boundary detection.

One limitation of these studies is that the transitions typically occur between sentences rather than at the word level. This paper aims to address the token-level boundary detection of mixed texts.

3 Methodology

3.1 Task Formulation

The task is presented as a sub-task 'Subtask C: Human-Machine Mixed Text Detection' in SemEval'24 Task 8[1]. The task is defined as follows: for a hybrid text $< w_1, w_2, ..., w_n >$ with a length of n that includes both human–written and machine-generated segments, the objective is to determine the index k, at which the initial top k words are authored by humans, while the subsequent are generated by LLMs. The evaluation metric for this task is Mean Absolute Error (MAE). It measures the absolute distance between the predicted word and the actual word where the switch between human and machine occurs.

We transform the task of boundary detection in mixed texts into a token classification task, aligning it with the competition baselines. Token classification involves assigning a label to each token within a text sequence. In boundary detection tasks, we utilize two labels to indicate whether each token was written by humans or generated by LLMs. By predicting the label of each token in the text sequence, we can identify the specific word that signifies the boundary between the human-written and machine-generated portions of the text.

3.2 LLM based Boundary Detection

We explores LLMs' capability to detect boundaries for human-machine mixed texts. The framework of this paper is shown in Figure 1. Given the labeled dataset containing boundary indices, we first map these indices to assign each token a label denoting whether it originates from human writing or LLM generation. Subsequently, we harness the capabilities of LLMs by fine-tuning them for the task of classifying each token's label. To enhance performance further, we employ an ensemble strategy that consolidates predictions from multiple fine-tuned models. Additionally, we explore various factors that impact the effectiveness of LLMs in boundary detection.

3.2.1 LLMs Supporting Long-range Dependencies

Our objective is to facilitate boundary detection in long text sequences, thereby necessitating the

[1] https://github.com/mbzuai-nlp/SemEval2024-task8/tree/main

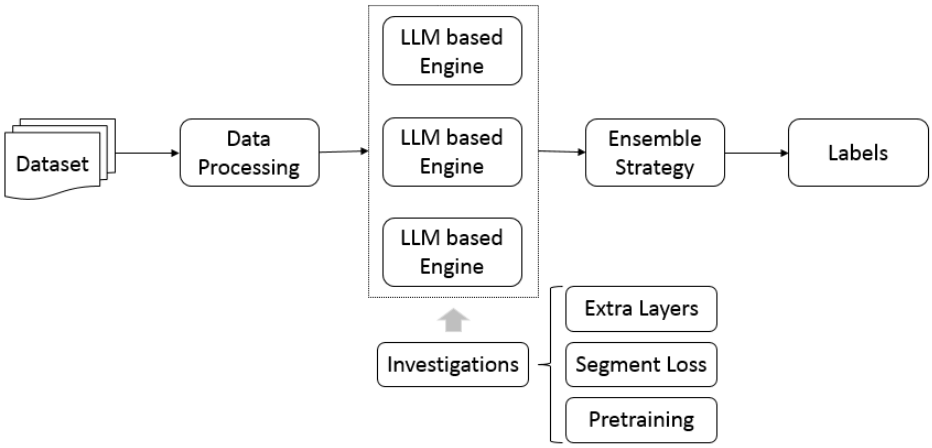

Figure 1: Framework of this paper

utilization of LLMs capable of handling long-range dependencies. Within this study, we investigate the performance of Longformer, XLNet, and BigBird models on boundary detection.

Longformer (Beltagy et al., 2020) utilizes a combination of global attention and local window-based attention mechanisms, which enables the model's capability to capture both short-range and long-range dependencies effectively.

XLNet (Yang et al., 2019) introduces a new training objective called permutation language modeling, and considers all possible permutations of the input tokens during training. This allows XLNet to capture bidirectional context more effectively and mitigate the limitations of autoregressive models.

BigBird (Zaheer et al., 2020) introduces a novel sparse attention mechanism that allows the model to scale to longer sequences while maintaining computational efficiency.

3.2.2 Exploration of Potential Factors

Except for the direct usage of LLMs, we investigate factors that may influence the capability of LLMs in boundary detection task.

Extra Layers on top of LLMs While LLMs demonstrate remarkable proficiency in comprehending semantics and generating coherent text, the addition of supplementary layers on top of LLMs has the potential to yield further improvements for downstream tasks. Therefore, we evaluate the impact of additional layers, such as LSTM and CRF, when integrated with LLMs, to ascertain their potential contributions to enhancing performance in boundary detection tasks.

Segment Loss Function Token classification involves assigning specific categories to individual tokens within a text sequence based on their semantic content. Typically, evaluation metrics gauge the average accuracy of category assignments across all tokens. However, in the context of boundary detection, the labels of tokens situated at or in proximity to the boundary hold greater significance. To bridge this gap, we introduce loss functions capable of assessing segment accuracy for both the human-written and machine-generated segments, such as the dice loss function. These loss functions, commonly utilized in image segmentation tasks that entail dividing an image into distinct segments, are anticipated to enhance performance in boundary detection tasks.

Pretrain and Fine tune Within the SemEval'24 competition, a total of 4,154 cases are presented for this task. The remaining sub-tasks revolve around human-machine text classification and aim to classify a given text into either human-generated or LLM-generated. A natural idea is to initiate pretraining utilizing the text classification data, followed by fine-tuning on the bounary detection data to enhance the model's overall generalization capability.

Two distinct pretraining approaches are employed. In the Pretrain 1, human-written texts and machine-generated texts are concatenated to form a new boundary detection dataset in sentence level. Within this novel dataset, boundaries are identified at the juncture where human-written and machine-generated sentences merge. Models are trained initially on the sentence-level dataset and subsequently fine-tuned using the 4,154 cases provided.

	Training data	Dev data
Number	3649	505
Average Length	263	230
Max Length	1397	773
Average Index	71	68

Table 1: Statistics of the boundary detection data set

	Train	Dev
binary text classification	119,757	5,000
multi-way text classification	71,027	3,000

Table 2: Statistics of two other data sets for human-machine text classification tasks

Method	MAE
Longformer (baseline)	4.11
Longformer-large	3.58
XLNet-large	**2.44**
BigBird-large	5.91

Table 3: Performance of varied LLMs

Method	MAE
XLNet-large	2.44
XLNet-large vote [2]	2.22

Table 4: Performance of multiple XLNet ensembles

In the Pretrain 2, a binary text classification model incorporating both an LLM and a linear layer atop the LLM is initially trained. Subsequently, the weights of the LLM are utilized for fine-tuning in the boundary detection task.

4 Experiments

4.1 Dataset

The data is an extension of the M4 dataset (Wang et al., 2023). It consists of 3,649 train cases and 505 dev cases, each with text content and gold boundary index. The boundary index denotes the position of the word split caused by a change, with white space serving as the delimiter. Data statistics are shown in Table 1.

In addition, SemEval'24 Competition also presented two datasets related to binary and multi-way text classification tasks. We investigate whether these additional datasets could potentially enhance boundary detection performance by pretraining techniques. The details of the two supplementary datasets are shown in Table 2.

4.2 Experimental Results

4.2.1 Performance of different LLMs

We investigate three LLMs renowned for their ability to handle long-range dependencies: Longformer, XLNet, and BigBird. We exclusively employ the large versions of these models. Moreover, as a benchmark for the competition, we utilize Longformer-base. The performance metrics of these four models are outlined in Table 3.

As depicted in Table 3, we observe that Longformer-large outperforms Longformer-base, owing to its increased parameter count. Among the four algorithms, XLNet achieves the best performance, with an MAE of 2.44. This represents a reduction of 31.84% compared to Longformer-large and a substantial 58.71% decrease compared to BigBird-large. One potential explanation is that the consideration of all possible permutations of input tokens during training help XLNet capture bidirectional context more effectively.

The winning approach in SemEval'24 Competition is founded on ensembles of 2 XLNet with varied seeds. It involves a simple voting process of the output logits from the diverse XLNet models. As shown in Table 4, the voting strategy results in a decrease in MAE from 2.44 to 2.22.

4.2.2 Performance of LLMs with extra layers

We select Longformer-large as our baseline model and examined the impact of incorporating extra LSTM, BiLSTM, and CRF layers(Huang et al., 2015) on boundary detection. The experimental results are detailed in Table 5. Integration of LSTM and BiLSTM layers with Longformer leads to significant improvements, with a decrease in MAE by 10.61% and 23.74%, respectively. Conversely, the addition of a CRF layer to Longformer-large yields unsatisfactory results. One plausible explanation could be the lack of clear dependencies between the two labels (0 and 1) in the token classification task, unlike in tasks such as named entity extraction.

4.2.3 Performance with segment loss functions

We investigate the impact of employing segment loss functions commonly utilized in image segmentation (Jadon, 2020) on boundary detection. The selected loss functions consist of BCE dice loss, Jaccard loss, Focal loss, Combo loss and Tversky loss. Additionally, we introduce a novel loss function BCE-MAE by simply adding BCE and MAE.

[2]The approach that ranks 1st in sub-task C leaderboard

Method	MAE
Longformer-large	3.58
Longformer-large + LSTM	3.20
Longformer-large + BiLSTM	2.73
Longformer-large + CRF	5.86

Table 5: Performance of adding extra layers

Method	MAE	Method	MAE
base (BCE loss)	3.58	Dice loss	3.80
BCE-dice loss	**3.14**	Jaccard loss	3.60
Focal loss	3.40	Combo loss	**3.09**
Tversky loss	3.69	BCE-MAE loss	**2.99**

Table 6: Performance of different segment loss functions

We utilize Longformer-large as the baseline, which by default adopts the binary cross-entropy loss. We explore the impact of adjusting the loss functions and present the results in Table 6. Among these variations, BCE-dice loss, Combo loss, and the BCE-MAE loss demonstrate superior performance compared to the default BCE loss.

Both BCE-dice loss and Combo loss are initially designed to integrate binary cross-entropy and Dice loss using different weighting schemes to enhance the performance of binary image segmentation. Dice loss serves as a metric for assessing the overlap between the predicted segmentation and the ground truth mask. The introduction of the Dice loss enables a balance between segmentation accuracy and token-wise classification accuracy, resulting in anticipated performance improvements. Compared to the benchmark, the MAE decreases by 12.29% and 13.69%, respectively.

The BCE-MAE loss incorporates MAE loss during the training stage, aligning with the evaluation metric used in the competition. As anticipated, the MAE metric decreases by 16.48%.

4.2.4 Performance of LLMs with pretraining

For both two pretraining approaches, we employ three different settings: directly utilizing Longformer-large for pretraining and fine-tuning; and incorporating additional LSTM and BiLSTM layers, respectively. Table 7 presents the results.

In Pretrain 1, the datasets from the other two subtasks are concatenated to create a new dataset in which the segmentation is on a sentence level, similar to previous studies. Sentence-level boundary detection is akin to token-level boundary detection. So the pretraining of sentence-level data is anticipated to obtain extra gains. The table indicates

Pretraining	Method	MAE
No pretrain	Longformer-large	3.58
Pretrain 1	Longformer-large	3.26
	+ LSTM	2.85
	+ BiLSTM	2.84
Pretrain 2	Longformer-large	68.52
	+ LSTM	3.04
	+ BiLSTM	2.72

Table 7: Performance of Longformer-large with pretraining

that simply employing Longformer-large with pretraining reduces the MAE from 3.58 to 3.26. By incorporating LSTM and BiLSTM layers, the MAE is further reduced to 2.85 and 2.84, respectively.

In Pretrain 2, we initially utilize Longformer to classify whether a given text is human-written or machine-generated. When the pretrained Longformer is fine-tuned directly on boundary detection, only inserting a new linear layer yields poor performance. However, with the inclusion of additional LSTM and BiLSTM layers, it can achieve comparable performance to that of Pretrain 1, reaching 3.04 and 2.72, respectively.

The results of the two pretraining approaches indicate that pretraining on either sentence-level boundary detection or the binary human-machine text classification task can enhance LLMs' capability to detect token-wise boundaries in mixed texts.

5 Conclusion

This paper introduces LLM-based methodology for detecting token-wise boundaries in human-machine mixed texts. Through an investigation into the utilization of LLMs for boundary detection, we have achieved optimal performance by leveraging an ensemble of XLNet models in the SemEval'24 competition. Furthermore, we explore factors that could affect the boundary detection capabilities of LLMs. Our findings indicate that (1) loss functions considering segmentation intersection can effectively handle tokens surrounding boundaries; (2) supplemental layers like LSTM and BiLSTM contribute to additional performance enhancements; and (3) pretraining on analogous tasks aids in reducing the MAE. This paper establishes a state-of-art benchmark for future researches based on the new released dataset. Subsequent studies aims to further advance the capabilities of LLMs in detecting boundaries within mixed texts.

Abstract

While large language models (LLMs) exhibit impressive linguistic abilities, their numerical reasoning skills within real-world contexts remain under-explored. This paper describes our participation in a headline-generation challenge by Numeval at Semeval 2024, which focused on numerical reasoning. Our system achieved an overall top numerical accuracy of 73.49% on the task. We explore the system's design choices contributing to this result and analyze common error patterns. Our findings highlight the potential and ongoing challenges of integrating numerical reasoning within large language model-based headline generation.

1 Introduction

The capacity to understand and manipulate numerical information within natural language text is essential for various NLP applications. Tasks such as news summarization, report generation, and the creation of data-driven narratives increasingly rely on the accurate interpretation and generation of numerical expressions. SemEval 2024 Task 7 (Chen et al., 2024) addresses these challenges through two intriguing subtasks: numerical headline generation and numerical headline number fill-in-the-blanks.

Generating numerical headlines necessitates models capable of synthesizing a succinct and attention-grabbing title that accurately reflects a news article's core numerical quantities and trends. Conversely, the fill-in-the-blanks subtask tests the model's ability to comprehend numerical relationships and infer the missing value to complete a provided headline. These tasks present a complex intersection of numerical reasoning and natural language generation/understanding.

Existing text generation and numerical understanding work often leverage sequence-to-sequence architectures and specialized pre-trained language models. However, SemEval 2024 Task 7's emphasis on numerical reasoning within headlines creates a distinct demand for techniques capable of accurately grounding representations of numbers and quantities within the linguistic context. This paper describes our approach to SemEval 2024 Task 7. We worked on both tasks separately and created two separate models. We used techniques such as parameter-efficient fine-tuning of large language models and then doing Direct Preference Optimization on top to align models better.

The remainder of this paper proceeds as follows. Section 3 reviews related work in numerical reasoning and headline generation. Section 4 details our models and methodology. Section 4 presents our experimental evaluation of the SemEval 2024 Task 7 dataset and includes a thorough analysis of our results. Finally, Section 5 summarizes our findings and outlines potential future research directions.

2 Background and Related Work

Headline generation within NLP has a rich history, evolving from early extractive techniques towards modern abstractive generation methods. Initial extractive approaches primarily focused on selecting the most salient sentences from the source document to compose the headline (Dorr et al., 2003) (Erkan and Radev, 2011; Mihalcea and Tarau, 2004). These methods offered interpretability but lacked the fluency and novelty often desired in generated headlines. The advent of deep learning and sequence-to-sequence models enabled abstractive headline generation, empowering models to synthesize new phrases and expressions (Rush et al., 2015; Nallapati et al., 2016). Attention mechanisms (Bahdanau et al., 2015) proved pivotal in aligning source text and headline generation. Recent advancements in Generative AI have led to significant improvements in this field with state-of-the-

*Equal Contribution

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 716–720

art results (Zhang et al., 2019). *GSum* (Dou et al., 2020), for example, initially performs extractive summarization and then incorporates the extractive summaries into the input for abstractive summarization. *SEASON* (Wang et al., 2022) adopts a dual approach, learning to predict the informativeness of each sentence and using this predicted information to guide abstractive summarization Notably, most of these works focus on the selection of words and the structure of sentences.

3 Numeval

Numeval is part of Semeval 2024; the task we focused on and worked on requires models to generate concise and informative headlines that accurately reflect the core numerical information in news articles. Systems must demonstrate an understanding of how numbers convey meaning and should prioritize the most relevant numerical aspects for inclusion in the headline.

Subtask 1: Numerical Reasoning - models are required to compute the correct number to fill the blank in a news headline.

Subtask 2: Abstractive Headline Generation - models must construct a headline based on the provided news; this headline should incorporate the numerical reasoning within. The organizers released

to generate complete headlines from given news content.

4 Methodology

4.1 subtask 1

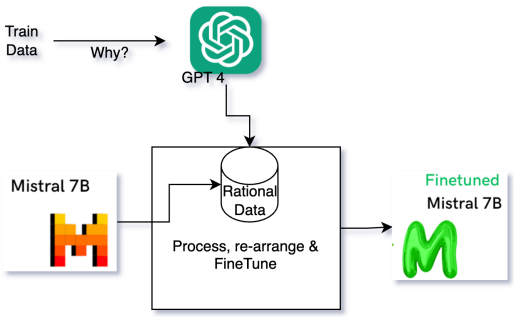

Figure 3: Overall Stage 1 train subtask 1

For this subtask, we start by passing the passage and question in the blank statement with an aligned answer to GPT 4 and ask it to generate a rationale for this given answer. The below prompt is used in this process.

```
PASSAGE: ARTICLE-HERE
QUESTION: FILL_IN_THE_BLANKS-HERE
WHY ANSWER TO THIS IS ANSWER-HERE ?
EXPLAIN\nRESULT:
```

Once we get the reasoning from this module, we restructure the training data in the following manner.

```
PASSAGE: ARTICLE-HERE
QUESTION: FILL_IN_THE_BLANKS-HERE
```

WHY ANSWER TO THIS IS ANSWER-HERE ?
REASON: GPT_RATIONALE_HERE

We use this to train our main model for subtask 1.

4.2 subtask 2

1) **Numerical Reasoning**: The model must demonstrate fluency in numerical calculations.
2) **Headline Matching**: Generated headlines must stylistically align with the data.

We worked on an end-to-end solution leveraging a Large Language Model (LLM) to address these challenges. First, we fine-tune the LLM to enhance its mathematical reasoning capabilities. This approach targets accurately interpreting numerical data and producing suitable headlines.

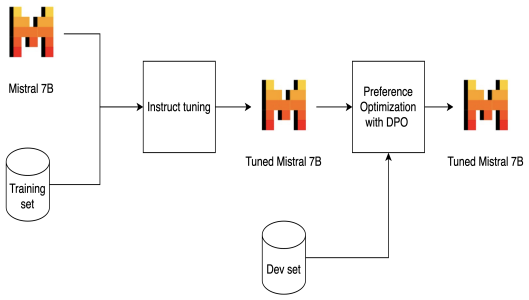

Figure 4: Overall workflow for subtask 2

4.3 Fine-tuning

For both tasks separately, we selected Mistral-7B (Jiang et al., 2023) as our trained LLM based on its strong performance on diverse benchmarks, including those focused on numerical reasoning benchmarks like GSM8K, which suggests a solid foundation for further fine-tuning on our specific numerical headline generation task.

As illustrated in Figure 5, Mistral-7B achieve a lower fine-tuning loss than BART (Lewis et al., 2019), a state-of-the-art text summarization model. This reinforces its suitability for our task.

For efficient fine-tuning, we employ Parameter Efficient Fine Tuning (PEFT). Due to memory constraints, we employed 4-bit QLoRA(Dettmers et al., 2023) quantization (cite reference) with a rank of 128 and an alpha of 256. This quantization technique was applied specifically to the self-attention Query, Key, and Value matrices along with the Linear layers of the model. To optimize the process, we used gradient accumulation (steps=2), a paged 32-bit Adamw optimizer, a cosine learning rate schedule (LR=2e-5), a decay rate of 0.01, and a short 5-step warmup period. The entire fine-tuning process was facilitated using the axolotl library. This technique reduces the model's memory footprint while minimizing performance degradation. This is particularly advantageous when working with LLMs.

Prompt template

> Given the news article, please write an appropriate headline
> {news content}
>
> Headline:

4.4 Direct Preference Optimization (DPO)

For both subtasks, we further aligned our fine-tuned models to learn better using the dev set. We did not use the dev data split in the first train stage. While aligning, we used dev data to first run through the model. We realigned the fine-tuned model with incorrect outcome results, that is, the dev results where the predicted number in the generated headline was incorrect or rejected. We still use the rationale (for subtask 1) for DPO, while DPO training for the second subtask only contains the predicted headline(wrong/rejected) and the correct/choosen headline. One example of the DPO train data for subtask 1 is below.

> PASSAGE:
> Stocks made gains today, extending a winning streak into its fourth day, MarketWatch reports. Merck rose 12.5% on announcement of its merger with Schering-Plough, while General Motors built on recent gains with a 22.9% jump. The Dow closed up 53.92 at 7,223.98.,
> QUESTION:
> "Dow Up ____, Gains 9% for Week
> **Choosen**:54 REASON: rounding off to nearest integer
> **Rejected**: 53.92 REASON:copy from text

To align the generated fill-in-the-blanks/headlines style with the target dataset, we utilize the Direct Preference Optimization (DPO) alignment technique (Rafailov et al., 2023). Direct Preference Optimization (DPO) is a novel approach for aligning large language models (LLMs) with human preferences. Unlike traditional methods that rely on reward models and reinforcement learning, DPO leverages human feedback through preferred and dispreferred outputs to directly train the LLM. This simplifies the training process and avoids the complexities of reward model design. This helps us

fine-tune the model beyond numerical correctness to produce stylistically suitable headlines.

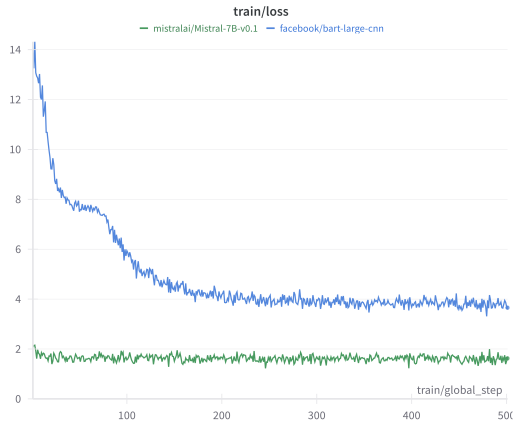

Figure 5: Comparing fine-tuning losses between BART and Mistral-7B

5 Results

For subtask 1, we evaluate our model on two fill-in-the-blank types. One accuracy on Copy, where the answer is directly copied from the article. Second is Reasoning, which includes different reasoning techniques such as addition, subtraction, multiplication, and paraphrasing.

Table 2: Accuracy on tasks type subtask 1

Copy	Reasoning
0.922	0.784

For comparative semeval two-stage evaluations, we scored 0.89 in the open and 0.86 in the hidden stage, respectively.

Table 3: Comparitive num accuracy on subtask 1

Team	Open-Score	Hidden-Score
CTYUN-AI	**0.95**	**0.95**
zhen qian	0.94	0.94
YNU-HPCC	0.93	0.94
NP-Problem(ours)	0.89	0.86

For subtask 2 we performed best in numerical accuracy overall and reasoning scores, we out-shined in reasoning accuracy as difference between 1st and 2nd rank was around 7 points. We open-source our final models on Huggingface [1].

6 Limitations

Since our method is based on 7B LLM, our performance is capped by this model's ability to draw rationale for the numerical reasoning. This limitation is in line with the hardware resource as well; We used an RTX 4090 24GB GPU-based machine for our work, which can load and fine-tune the models with upto 7-10 B parameters as well.

Conclusion

We present a modular solution to the numeral problem with an alignment module to increase the model's ability to understand numerical reasoning across both tasks. We thank the organizing committee of SemEval-2024, along with the task-setting team of Numeval, for allowing us to work on this problem.

OPDAI at SemEval-2024 Task 6: Small LLMs can Accelerate Hallucination Detection with Weakly Supervised Data

Chengcheng Wei, Ze Chen, Songtan Fang, Jiarong He and **Max Gao**
Interactive Entertainment Group of Netease Inc., Guangzhou, China
{weichengcheng, jackchen, fangsongtan, gzhejiarong, jgao}@corp.netease.com

Abstract

This paper mainly describes a unified system for hallucination detection of LLMs, which wins the second prize in the model-agnostic track of the SemEval-2024 Task 6, and also achieves considerable results in the model-aware track. This task aims to detect hallucination with LLMs for three different text-generation tasks without labeled training data. We utilize prompt engineering and few-shot learning to verify the performance of different LLMs on the validation data. Then we select the LLMs with better performance to generate high-quality weakly supervised training data, which not only satisfies the consistency of different LLMs, but also satisfies the consistency of the optimal LLM with different sampling parameters. Furthermore, we finetune different LLMs by using the constructed training data, and finding that a relatively small LLM can achieve a competitive level of performance in hallucination detection, when compared to the large LLMs and the prompt-based approaches using GPT-4.

1 Introduction

The emergence of Large Language Models (LLMs)(Zhao et al., 2023) has sparked a significant transformation in the field of Natural Language Processing (NLP), ushering in a new era of unparalleled advancements in text generation and comprehension. This revolutionary technology has elevated the capabilities of AI systems, enabling them to perform complex reasoning and problem-solving tasks with remarkable proficiency(Zhao et al., 2023). At the heart of this transformation lies the LLMs' ability to compress vast amounts of knowledge into neural networks, effectively turning them into versatile agents capable of engaging in natural language conversations with humans(Hadi et al., 2023). This has broadened the scope of AI applications beyond traditional domains such as chatbots and virtual assistants, into areas previously thought to be the exclusive domain of humans, particularly those involving creativity and expertise. LLMs are not only limited to language-related tasks but can also function as generalist agents, collaborating with external systems, tools, and models to achieve a wide range of objectives set by humans(Triguero et al., 2024).

However, recent advancements in research have uncovered a concerning weakness: their proneness to hallucinate content across a range of applications(Ji et al., 2023). Hallucination is defined as the generation of information that either conflicts with established sources or cannot be substantiated by available knowledge. The occurrence of hallucination in LLMs poses a significant threat to their practical deployment. While prior works have delved into the roots of hallucination within specific, smaller-scale language models and tasks, there is still a notable gap in understanding the exact nature and prevalence of content that LLMs are likely to hallucinate(Cui et al., 2024; Chang et al., 2023).

To address this challenge, we implements a unified system for hallucination detection of LLMs, when there is no labeled training data. This system comprises five parts: *Base Model Selection*, *Prompt Engineering*, *Weakly-supervised Data Generation*, *SFT* and *Ensemble Learning*. We first verify the performance of different base LLMs on this task. Then we select the best LLMs and prompt is optimized to improve the performance. And weakly-supervised dataset is generated by using the selected LLMs. For further improvement, SFT is done based on the constructed dataset and ensemble learning is adopted.

2 Related Work

In this section, we will introduce other work related to the subsequent methods.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 721–729

Mixture of Experts(MoE)(Jacobs et al., 1991) is an AI technique that involves a group of specialized models (experts) being coordinated by a gating mechanism to address various aspects of the input space, in order to optimize performance and efficiency. This approach capitalizes on the idea that an ensemble of weaker language models, each focusing on specific tasks, can yield more precise results, similar to traditional ML ensemble methods. However, it introduces a novel concept of dynamically routing the input during the generation process. In the subsequent methods, we will conduct comparative experiments using the intelligent model base of MoE. This paper(Chen et al., 2022) integrates POS information and word semantic representation using an MoE approach.

Model ensembling combines the predictions from multiple models together. Traditionally this is done by running each model on some inputs separately and then combining the predictions. However, if the candidate models have the same architecture, they can be combined together to create a new model for prediction. Many surveys systematically elucidate the basic concepts of ensemble learning and various methods, including model fusion and model voting(Krawczyk et al., 2017; Dong et al., 2020; Yang et al., 2023).

LoRA (Low-Rank Adaptation of Large Language Models) (Hu et al., 2021) is a widely used and lightweight training technique that markedly reduces the number of trainable parameters. It functions by adding a smaller set of new weights to the model and training only these. As a result, training with LoRA is notably faster, more memory-efficient, and yields smaller model weights (a few hundred MBs), which are more manageable for storage and sharing. Some other methods(Ye et al., 2023; Wang et al., 2023; Chen et al., 2023) have been developed to improve LoRA.

Chain-of-Thought Prompting(CoT)(Wei et al., 2022) is an emerging application of language model technology. The core idea of this method is to encourage the model to not only generate the final answer but also gradually demonstrate its reasoning and the process of reaching conclusions. Subsequent work(Zhou et al., 2022) has applied the idea of CoT, breaking down problems into a series of sub-problems, allowing the model to reason step by step and ultimately provide the correct answer. And another work(Wang et al., 2022) introduces a method called "self-consistency" to further enhance the effectiveness of CoT Prompting. By generating multiple reasoning paths and selecting the most consistent answer, the model can reduce errors and improve the accuracy of reasoning.

3 Task Description

trial data	unlabled train data	validation data	test data
80	60000	1000	3000

Table 1: Dataset provided by SHROOM

SHROOM(Mickus et al., 2024) asked participants to perform binary classification to identify cases of fluent overgeneration hallucinations in two different setups: model-aware and model-agnostic tracks. And three different NLG tasks: definition modeling (DM), machine translation (MT) and paraphrase generation (PG) are covered in both tracks. In model-aware track, the model information is provided. The provided development and test sets include binary annotations from a minimum of five different annotators, along with a majority vote gold label. Table 1 gives an overview of the provided dataset.

4 Methodology

Figure 1 shows the overview of our approach. Our method consists of five main steps. First of all, multiple LLMs are compared on the hallucination detection validation dataset and among which we select the best base model. The LLMs selected in the first step will be utilized in the subsequent steps 2, 3, and 4. In the second step, we designed a Prompt Engineering module consisting of three sub-modules: few-shot prompting, instruction optimization, and the utilization of Chain-of-Thought. The subsequent experiments will demonstrate that prompt engineering significantly enhances the capabilities of the base model.

Then moving on to the Label Generation step, we apply the Prompt Engineering module to the selected best LLMs. We make predictions on the unlabeled training set and ensure the inference consistency among multiple LLMs as well as the inference consistency under different inference parameters of individual LLM. We also ensure label balance in this process.

The following steps are Model Training and Ensemble Learning. We utilize SFT based on the constructed dataset using the LoRA (Hu et al., 2021) method. Finally, we select a few top-performing

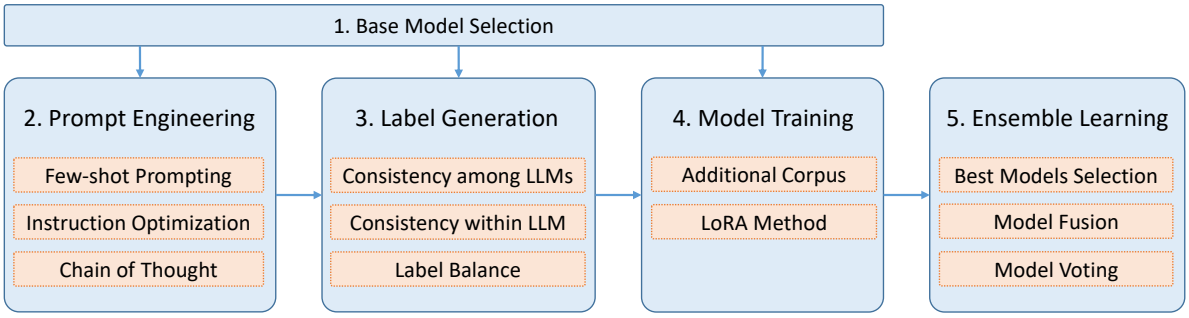

Figure 1: Overview of our proposed method. The method consists of five main steps, each of which comprises several modules that we have designed for SemEval-2024 Task 6.

models and perform fusion at both the model weight level(model fusion) and the model prediction probability level(model voting) in order to seek better performance.

4.1 Prompt Engineering

After experimenting with multiple large-scale language models, we select the best-performing 14B *Mixtral_7Bx2_MoE* as the base model for prompt engineering to achieve better results.

Few-shot prompting. Few-shot prompting can be used as a technique to enable in-context learning where we provide demonstrations from the provided *trial data* in the prompt to steer the base model to better performance. Considering that the trial data contains with labels, we randomly sample the specific task's datapoints for different tasks, ensuring an equal number of data points for "hallucination" and "not hallucination" examples, to serve as few-shot examples for each respective task.

Optimizing the instruction. There are some deficiencies with the instruction introduced in Section 5.1, and we name this version of instruction as the *naive* version. The most obvious issue is that the naive instruction does not include the descriptions of the DM, MT, and PG tasks. The desired task description includes the task definition and all known useful information, rather than just focusing on the sentence and context. We design different instructions for different tasks, which can be found in the Appendix A. In this way, we can append additional information to the prompt to assist the LLM in better understanding the problem.

Chain-of-thought prompting. Chain-of-thought (CoT) prompting(Wei et al., 2022) is a recently developed method that encourages the language model to explain its reasoning. We combine the aforementioned few-shot prompting, developed instruction, and CoT to utilize them together to further enhance the capability of the base model.

4.2 Label Generation and Weakly-SFT

After improving the performance of the base model using prompt engineering, we use the optimal settings to infer on unlabeled training data and obtain weakly supervised labels. These weakly supervised labels are then used to finetune the base model.

Inference consistency in generating labels. During the process of inferring weakly supervised labels for the unlabeled training data, we placed a great emphasis on both the consistency of inference across different LLMs and the consistency of inference within the same LLM but with different parameter settings. To achieve this, we carefully selected several sets of top-performing base models. Leveraging the prompt engineering techniques mentioned earlier, we conducted inference on the same model using various parameter configurations. Subsequently, we handpicked the data points with consistent inferences across different parameter settings to establish the final inference results for that particular LLM. Additionally, we applied a filtering process to the inference results obtained from different LLMs, ensuring that only datapoints with consistent inferences were retained. Through these rigorous steps, we ensured that our generated weakly supervised labels for the training set exhibits robustness to both the choice of LLM base and the specific sampling parameters employed. Finally, we used sampling techniques to balance the data volume of the two categories.

Fine-tuning LLMs. The weak supervision generated by the base model is applied to guide models of equal or smaller scale. The LLMs undergo fine-tuning using the LoRA approach, a popular and lightweight training technique that effectively

Model Name	Model Size	Model-agnostic track		Model-aware track

Table 2: The performance of different-sized LLMs on the validation set. The competition includes two tracks: model-agnostic track and model-aware track. For each track, both prediction accuracy(*acc*) and Spearman's Rho value(*rho*) are provided.

reduces the number of trainable parameters. Despite this reduction, the fine-tuned models maintain comparable training results to those of the full parameter models. The best checkpoint model files are selected from the validation set during this fine-tuning process.

4.3 Ensemble Learning

We also propose an ensemble learning approach for performance improvement, utilizing fusion strategies at both the model level and the inference level.

Model fusion. MergeKit[1] is a toolkit designed for merging trained language models. We carefully selected a few high-accuracy models and utilized MergeKit to perform model fusion using the SLERP (Shoemake, 1985), TIES (Yadav et al., 2023) and linear (Wortsman et al., 2022) methods. Traditionally, model merging often resorts to weight averaging which, although straightforward, might not always capture the intricate features of the models being merged. The SLERP technique addresses this limitation, producing a blended model with characteristics smoothly interpolated from both parent models, ensuring the resultant model captures the essence of both its parents. Meanwhile, the TIES method is proposed to resolve interference issues by resetting parameters, resolving sign conflicts, and merging only compatible parameters. TIES outperforms many existing methods across diverse settings, emphasizing the importance of addressing interference in model merging for enhanced performance and versatility.

[1] https://github.com/arcee-ai/mergekit

Model Voting. In addition to the model-level fusion, we also explored fusion at the probability level of model generation, which can be understood as a form of model voting. We selected another group of highly accurate candidate models and performed linear fusion at the probability level. Specifically, we calculate the weighted summation of the probability values on "existing hallucination" predicted by different candidate models for different tasks. By tuning the linear weight combination, we are able to determine the optimal combination of weights for each task. Finally, combining different tasks together yields the final fusion result. In this way, we implement weighted voting of models at the inference result level.

5 Results and Analysis

In this section, we will present a series of experiments to illustrate the effectiveness of our method.

5.1 Baseline

To begin with, our initial step entails presenting the basic performance of LLMs of varying sizes on the validation set. Subsequently, we will delve into an analysis of the LLMs' capabilities in detecting hallucinations in the given task.

Throughout the experiments, we ensure the generation hyperparameters remain consistent across all LLMs. Additionally, the instruction utilized for detecting hallucinations is sourced from the official *participant_kit*. This version of the instruction is referred to as the "naive instruction" and can be located in Appendix A for reference.

Table 2 illustrates our evaluation of LLMs from both *Mistral* and *SOLAR* families, considering vary-

few-shot	inst.	agnostic_acc	aware_acc
2-shot	naive	0.745	0.774
	ours	**0.770**	**0.806**
4-shot	naive	0.762	0.772
	ours	**0.782**	**0.806**
6-shot	naive	0.764	0.774
	ours	**0.772**	**0.804**
8-shot	naive	0.762	0.772
	ours	**0.774**	**0.804**

Table 3: Our proposed instruction exhibits overall superior accuracy compared to the naive version on the validation set. We applied few-shot prompting in all of the aforementioned experiments. The term "inst." stands for "instruction".

few-shot	CoT	agnostic_acc	aware_acc
2-shot	w/o	0.770	**0.806**
	with	0.770	0.792
4-shot	w/o	**0.782**	**0.806**
	with	0.766	0.796
6-shot	w/o	0.772	0.804
	with	**0.774**	**0.806**
8-shot	w/o	0.774	0.804
	with	**0.792**	0.804

Table 4: CoT demonstrates an improved capability in hallucination detection when provided with a larger number of demonstrations in few-shot prompting and utilizing our proposed instruction. The results are on the validation set.

ing sizes and variants, on the validation set. In general, larger models tend to yield better results. For instance, within the *Mistral*-family, the accuracy and Spearman's Rho value of the 7B model are comparatively lower than those of larger models, a trend observed in both the model-agnostic and model-aware tracks. Furthermore, LLMs of the same size exhibit diverse results in hallucination detection tasks owing to distinct fine-tuning methods employed. This observation holds true in our experiments with the *SOLAR*-family, emphasizing the impact of fine-tuning on performance.

There is a noteworthy observation in Table 2. The medium-sized 14B *Mixtral_7Bx2_MoE* model achieves comparable accuracy to the larger-sized 46.7B models in both the model-agnostic and model-aware tracks. This suggests that the fine-tuning approach and training corpus of the 14B model are well-suited for the hallucination detection task. Furthermore, the 14B model outperforms the 46.7B model in terms of inference speed and training cost. As a result, in the subsequent section, we will further enhance the effectiveness of the 14B model through prompt engineering.

5.2 Performance Improvement

In this section, our focus is on enhancing the accuracy of the 14B *Mixtral_7Bx2_MoE* model through prompt engineering methods.

Few-shot prompting. A few-shot prompting approach is applied by randomly selecting an equal number of positive and negative samples as demonstrations for task definition modeling (DM), machine translation (MT), and paraphrase generation (PG). In the experimental setup, we use 2, 4, 6, and 8 examples for few-shot prompting on the *Mixtral_7Bx2_MoE* model, while keeping the generation hyperparameters consistent with the experiments in Table 2. The accuracy of the few-shot prompting strategy is shown with the *inst.=naive* setting in Table 3, where we observe that experiments with 4, 6, and 8 shots perform better than the zero-shot baseline(acc is 0.747 in Table 2) in the model-agnostic track, and all the few-shot settings experiments achieve better results than the zero-shot baseline(acc is 0.764 in Table 2) in the model-aware track.

Optimizing the instruction. As discussed in Section 4.1, the naive instruction provided by the competition organizers has some limitations. To overcome these limitations, we enhanced the instructions by incorporating task-specific background knowledge and multidimensional information, taking into account the unique characteristics of each task. The improved instructions, as demonstrated with the *inst.=ours* setting in Table 3, yield better performance compared to using the initial naive instruction. Notably, in the 2-shot setting, both tracks exhibited an improvement of over 2 percentage points by leveraging our proposed instructions.

Chain of thought prompting. We adopt the CoT approach, after generating reasons for the presence or absence of hallucinations in the trial data. The experimental results of CoT are presented in Table 4, which indicates that CoT exhibits higher efficacy in the few-shot scenario when there are more demonstrations accessible.

Model Name	Model Size	Model-agnostic track		Model-aware track

voting result	**0.834**

Table 7: Model Voting results for the model-agnostic track on the validation set. The voted results outperform any individual model in terms of accuracy.

5.3 Weakly-supervised Fine-tuning

As mentioned earlier, we enhance the accuracy of hallucination detection by selecting the best baseline model and incorporating additional prompt engineering techniques. Building upon this, we leverage weak supervision by labeling the unlabeled training data for training. Subsequently, the LLMs are fine-tuned using the generated labels to further augment the capability of hallucination detection.

Generating weak supervision for training data. Utilizing the 14B *Mixtral_7Bx2_MoE* model as a foundation, we incorporate few-shot prompting, our proposed instruction, and the CoT strategy to create a supervision model known as the '8-shot' setting, as mentioned in Table 4. This approach is applied to hallucination detection across 60,000 datapoints from both the model-agnostic and model-aware tracks, ensuring a balanced distribution of categories. Additionally, we introduce multiple optimal models, as discussed in Section 4, to ensure consistent inference across multiple models and maintain inference consistency within the same model but with different inference parameters.

Fine-tuning LLMs. The experimental results of weakly-supervised fine-tuning are presented in Table 5, which demonstrates that smaller models can effectively learn from the weak supervision provided by the 14B model. In some cases, these smaller models even outperform the 14B model in terms of accuracy. Notably, the 14B model fails to surpass the performance of equivalently-sized supervisor even when multiple hyper-parameter settings are employed. A comparison between lora training and full-parameter training reveals that the lora-style training yields superior results. Further details can be found in Appendix C.

5.4 Ensemble Learning

In addition to fine-tuning LLMs with weak supervision labels as mentioned in the previous section, we first combine different model checkpoints by the MergeKit tool and then perform model voting strategy to enhance performance.

Model fusion. We implement model merging using different modes of MergeKit, *i.e.*, SLERP, TIES and Linear, in our study. Taking the accuracy optimization of the model-agnostic track as an example, let's begin by selecting three highly capable candidate models. These models are fine-tuned versions of the 7B *Mistral-7B-Instruct-v0.2*, and they are different checkpoints from the same training task. The detailed training setting can be

found in Appendix B.2. By utilizing model fusion techniques, we can achieve a maximum accuracy of 0.814 with the newly merged models. For a detailed overview of the experiments on the model-agnostic track, refer to Table 6.

Model Voting. We also validate the effectiveness of weighted voting at the inference result level. We select the top-performing models from the weakly supervised fine-tuning and model fusion phases. By calculating weighted predictions based on their predicted probabilities, we infer the presence of hallucinations. Table 7 presents the details of the voting experiments on the model-agnostic track. Using the same method, we achieve an accuracy of 0.818 on the model-aware track as well. The SFT models are merged models from different training experimental setups, and the detailed training parameters can be found in Appendix B.3.

Method	agnostic_acc	aware_acc
baseline	0.697	0.745
GPT-4	0.741	0.756
our method	**0.836**	**0.805**

Table 8: Comparison of methods on the test set.

We compared the baseline provided by competition organizers, GPT-4, and our proposed method on the test set in Table 8. It is evident that our proposed method outperforms other mehotds, showcasing a significant enhancement in performance.

6 Conclusion

In this paper, we present a unified system for hallucination detection with LLMs when there is no labeled dataset, which wins the 2nd place with an accuracy score of 0.836 in the model-agnostic track and the 4th place with an accuracy score of 0.8053 in the model-aware track. To begin with, we generate high-quality weakly-supervised dataset by using large-sized LLMs with prompt engineering and few-shot learning. Then we perform weakly-supervised fine-tuning based on the constructed dataset with different LLMs. Our experiments yield several noteworthy findings:

(1) The quality of the weakly-supervised dataset we construct has a direct impact on the performance of the models in this task. To ensure high-quality training data, we employ multiple large LLMs in the construction process.

(2) Relatively small LLMs can deliver competitive performance in this task when trained on the constructed dataset. However, the performance of small LLMs drops dramatically without fine-tuning.

(3) Using the *MergeKit* tool for model fusion proves to be an effective technique in boosting the performance of hallucination detection.

(4) Employing the model voting method leads to improved performance compared to using a single model alone.

A Instructions in Prompt Engineering

A.1 Naive version

Context: {Context}
Sentence: {Sentence}
Is the Sentence supported by the Context above?
Answer using ONLY yes or no:

A.2 Our proposed version

For the PG task, the instruction is as follows:

Given the following information related to Paraphrase Generation task:
Src: Source input sentence
Tgt: Paraphrase Generation standard answer
Hyp: Paraphrase Generation predicted answer
Please determine whether hyp contains unexpected hallucinations based on src and tgt.

Src: {Src}
Tgt: {Tgt}
Hyp: {Hyp}
Is the Hyp supported by the Src and Tgt above?
Answer using ONLY yes or no:

For the MT task, the instruction is as follows:

Given the following information related to Machine Translation task:
Src: Source input sentence
Tgt: Machine Translation standard answer
Hyp: Machine Translation predicted answer
Please determine whether hyp contains unexpected hallucinations based on src and tgt.

Src: {Src}
Tgt: {Tgt}
Hyp: {Hyp}
Is the Hyp supported by the Src and Tgt above?
Answer using ONLY yes or no:

As for the DM task, the instruction is the same as the naive version.

B Training Experiment Setup

B.1 Constructed dataset

We constructed a total of **35,600** weakly supervised samples, ensuring consistency in inference across different LLMs as well as within the same LLM but with different parameter settings.

B.2 SFT models in Table 6

The Mistral-7B-Instruct-v0.2-sft-v1, v2, and v3 models are different checkpoint models obtained from the same training setup. These models were trained on a total of 35,600 weakly-supervised data points. The training process utilized a LoRA rank of 32, a learning rate of $3e^{-5}$, and a total of 5 epochs. The training task was executed using 4 A30 GPUs. Specifically, Mistral-7B-Instruct-v0.2-sft-v1, v2, and v3 models were saved at training steps 1000, 3000, and 4000, respectively.

B.3 SFT models in Table 7

The Mistral-7B-Instruct-v0.2-sft-v4, v5, v6, and v7 models are merged models obtained from different training setups. Each model is created by merging two checkpoints from the same setup. The v4 model was trained with a LoRA rank of 32, a learning rate of $1e^{-4}$, and a total of 5 epochs. The v5 model also had a LoRA rank of 32, a learning rate of $3e^{-5}$, and a total of 5 epochs. The v6 model had a higher LoRA rank of 48, a learning rate of $3e^{-5}$, and lasted for 5 epochs. Lastly, the v7 model had a LoRA rank of 48, a learning rate of $5e^{-5}$, and a total of 5 epochs. All of these models were trained on the constructed dataset.

Abstract

Our paper explores a task involving the analysis of emotions and triggers within dialogues. We annotate each utterance with an emotion and identify triggers, focusing on binary labeling. We emphasize clear guidelines for replicability and conduct thorough analyses, including multiple system runs and experiments to highlight effective techniques. By simplifying the complexities and detailing clear methodologies, our study contributes to advancing emotion analysis and trigger identification within dialogue systems.

1 Introduction

Emotion recognition and trigger detection in conversational data represent critical frontiers in natural language processing (NLP) research, offering profound insights into human-computer interaction, sentiment analysis, and dialogue understanding. In today's interconnected world, where communication transcends linguistic boundaries, understanding the subtle nuances of emotions expressed in code-mixed dialogues becomes increasingly imperative. Code-mixing, characterized by the seamless integration of multiple languages within a single conversation, reflects the rich tapestry of multicultural societies and presents unique challenges and opportunities for computational linguistics. Additionally, in monolingual English dialogues, identifying triggers—key points where emotional shifts occur—serves as a gateway to unraveling the underlying sentiment dynamics and contextual flow of conversations.

1.1 Significance of the Tasks

Our primary task, focuses on emotion recognition in code-mixed dialogues, holds immense significance in deciphering the intricacies of Code-Mixed communication. Accurately discerning emotions such as joy, sadness, anger, and more across diverse linguistic contexts enriches our understanding of cross-cultural expression and human sentiment. Meanwhile, the following tasks extend this exploration to trigger detection within both code-mixed and English dialogues. Identifying triggers not only facilitates the detection of emotional transitions but also provides deeper insights into the contextual triggers and socio-cultural factors shaping conversational dynamics.

1.2 Challenges and Opportunities

The complexity of code-mixed dialogues lies in disentangling the interplay of languages, cultural nuances, and emotional expressions. Herein lies the challenge of accurately recognizing emotions amidst linguistic diversity and cultural variations. Similarly, trigger detection in both code-mixed and English dialogues demands robust models capable of capturing subtle emotional shifts amid the fluidity of conversation. Addressing these challenges presents opportunities to develop sophisticated NLP techniques that transcend linguistic barriers and capture the essence of human emotions in their full complexity.

In our exploration, we experimented with Convolutional Neural Networks (CNN) Suseelan et al. (2019) and BERT models Sivanaiah et al. (2020) to tackle these challenges. However, we encountered some limitations. The CNN model yielded a low weighted F1 score of 0.28, indicating its struggle to effectively capture the nuances of emotional expression in code-mixed dialogues. On the other hand, while BERT showed promise in its ability to understand complex language patterns, it proved to

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 730–736

be computationally intensive, ultimately crashing after extended periods of runtime.

These setbacks highlight the need for further research and development in the field of NLP, particularly in the context of code-mixed dialogues and emotional recognition. Future efforts could explore novel model architectures, optimization techniques, and data augmentation strategies to improve performance and efficiency in emotion recognition and trigger detection tasks within code-mixed conversations. By addressing these challenges, we can pave the way for more accurate and reliable NLP solutions that better reflect the intricacies of human communication across diverse linguistic and cultural landscapes.

2 Overview

2.1 Summary of the task

The task involves recognizing emotions and detecting triggers in conversational data, with a focus on both Code-Mixed and English dialogues. Emotion recognition is structured as a classification task where systems predict the emotions associated with each utterance in a dialogue. Trigger detection entails identifying points in the conversation where emotional shifts occur. The datasets used include MaSaC for Hindi-English dialogues and MELD for English dialogues. The input comprises utterances from dialogues, and the output consists of predicted emotions for each utterance in emotion recognition, while trigger detection, indicates the presence or absence of triggers at each point in the dialogue.

2.2 Impact of the task

This task addresses the critical need for natural language processing (NLP) systems to understand and interpret emotions in conversational data. By focusing on code-mixed dialogues, it highlights the challenges posed by linguistic diversity and cultural nuances in emotion recognition. Additionally, the task emphasizes the importance of trigger detection in understanding the dynamics of conversations and capturing shifts in emotional states. By participating in this task, researchers contribute to advancing the capabilities of NLP systems in recognizing and understanding emotions in diverse linguistic contexts, thereby paving the way for more nuanced and culturally sensitive human-machine interactions.

3 Related Work

Emotion recognition and trigger detection in conversational data have been subjects of active research in natural language processing (NLP) and affective computing. Researchers have explored various approaches and methodologies to tackle these tasks, aiming to understand human emotions expressed in dialogue interactions and detect key points where emotional shifts occur. In this section, we review existing literature, highlighting recent advancements and key findings in the field.

The paper "Towards Sub-Word Level Compositions for Sentiment Analysis of Hindi-English Code Mixed Text" introduces a novel approach to sentiment analysis in code-mixed social media data. They present a Hi-En code-mixed dataset and propose a Subword-LSTM architecture, enabling the model to capture sentiment information from important morphemes. This linguistic-driven approach outperforms traditional methods, achieving a notable accuracy improvement of 4-5% and surpassing existing systems by 18% in sentiment analysis of Hi-En code-mixed text Joshi et al. (2016).

Advancements in sentiment analysis techniques now recognize the temporal variability of emotions in textual data. For example, the SSN MLRG1 team at SemEval-2017 Task 4 introduced a novel approach using the Gaussian Process with fixed rule multi-kernel learning for sentiment analysis of tweets. Their method effectively captures evolving emotions by considering properties such as smoothness and periodicity. This approach aligns with our exploration of emotion recognition and trigger detection in conversational data, emphasizing the importance of incorporating temporal dynamics into sentiment analysis frameworks.S et al. (2017a)

This team also participated in task 5, focusing on fine-grained sentiment analysis. Their system utilizes Multiple Kernel Gaussian Processes to identify optimistic and pessimistic sentiments associated with companies and stocks. Given that comments on the same entities can exhibit varying emotions over time, considering properties like smoothness and periodicity becomes crucial. Their experiments highlight the effectiveness of the Multiple Kernel Gaussian Process in capturing diverse properties compared to a single Kernel Gaussian Process. S et al. (2017b)

In summary, existing research in emotion recognition and trigger detection in conversational data has explored diverse methodologies, including

deep learning, machine learning, rule-based approaches, and multimodal fusion techniques. Recent advancements have demonstrated the potential of context-aware features, multimodal data integration, and hybrid models in improving accuracy and robustness in these tasks. However, challenges such as linguistic diversity, cultural nuances, and ambiguity in emotional expressions continue to pose significant obstacles, warranting further research and exploration in the field.

4 Task Description

The tasks encompass emotion recognition and trigger detection in conversational data, each assessing specific competencies related to understanding emotions and detecting emotional shifts in dialogues.Kumar et al. (2024a)

4.1 Task 1 (ERC for code-mixed)

Objective: This task aims to evaluate the system's capability to recognize emotions in code-mixed dialogues, where multiple languages are used interchangeably.

Description: We were provided with a dataset consisting of code-mixed dialogues, where utterances contain a mix of languages. The task involves identifying the emotions expressed in each utterance accurately. Emotions may include disgust, contempt, anger, neutral, joy, sadness, fear, and surprise. Kumar et al. (2023)

4.2 Task 2 (EFR for code-mixed)

Objective: This task focuses on assessing the system's performance in detecting triggers that indicate emotional shifts in code-mixed dialogues.

Description: We were presented with code-mixed dialogues where emotional shifts occur. The task involves detecting these triggers within the dialogues. Triggers are specific instances or phrases that signal a change in the emotional tone of the conversation.Kumar et al. (2022)

4.3 Task 3 (EFR for English)

Objective: Similar to Task 2, this task evaluates the system's ability to detect triggers indicating emotional shifts. However, the focus is on English-only dialogues.

Description: We were provided with a dataset containing English-only dialogues. The task remains the same as Task 2, requiring us to identify triggers that signify emotional shifts within the conversations.Kumar et al. (2024b)

These tasks aim to assess the robustness and effectiveness of systems in understanding and interpreting emotional nuances within conversational data, particularly in Code-Mixed and English-only settings.

5 Experimental Setup

In this section, we provide a detailed overview of the experimental setup. Refer to 1 for the detailed architecture diagram illustrating the entire process.

5.1 Data Splits

The dataset provided for each task was split into three main subsets: training, development (dev), and testing. The distribution of data among these subsets was as follows:

5.1.1 Training Set

The training set comprised approximately 80% of the total dataset. This sizable portion allowed the models to learn patterns and associations from a diverse range of examples. It contained code-mixed and English-only dialogues with corresponding emotion labels for Task 1 and trigger labels for Tasks 2 and 3.

5.1.2 Development Set

The dev set accounted for around 10% of the dataset. It was utilized for fine-tuning the models' hyperparameters, such as regularization strength and feature extraction settings. This subset enabled us to iteratively adjust the model configurations to improve performance without overfitting to the training data.

5.1.3 Test Set

The test set constituted the remaining 10% of the dataset and was kept completely separate from the training and dev sets. It served as an unseen dataset for the final evaluation of model performance. Its purpose was to assess how well the trained models generalized to new, unseen instances and to provide an unbiased estimate of their performance.

5.2 Preprocessing

Before feeding the data into the machine learning models, we applied several preprocessing steps to ensure consistency and improve model performance:

5.2.1 Text Preprocessing

In our text preprocessing pipeline, we employed several steps to prepare the textual data for model

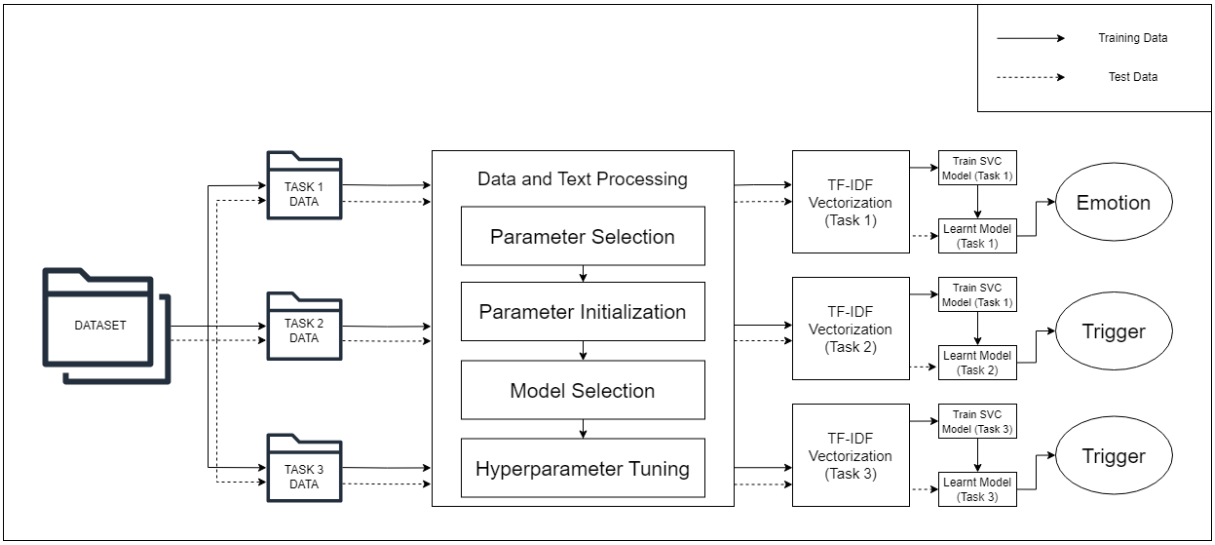

Figure 1: Architecture Diagram illustrating the entire Experimental Setup.

input. First, we tokenized the text using the word_tokenize function from the Garg and Sharma (2020)nltk library, splitting it into individual tokens or words. Next, we removed common stopwords, such as articles, prepositions, and conjunctions, using the predefined stopwords list provided by the nltk library, which helped reduce noise in the data. Additionally, we eliminated punctuation marks from the text to standardize the input and prevent the models from treating punctuation as meaningful features. This step involved removing characters such as periods, commas, and quotation marks. Finally, to ensure uniformity and improve generalization, we converted all text to lowercase, preventing the models from treating words with different cases as distinct features and effectively reducing the dimensionality of the input space.

5.3 Hyperparameter Tuning

Hyperparameter tuning was a crucial aspect of our experimental setup, as it involved optimizing the model's configuration to achieve the best performance on the dev set. We experimented with various hyperparameters, including:

5.3.1 TF-IDF Vectorization Parameters

We explored different settings for the Zhang et al. (2011)TF-IDF vectorization process, such as the $ngram\_range$ parameter, which determined the range of n-grams (contiguous sequences of words) considered during feature extraction. By adjusting the $ngram\_range$, we aimed to capture different combinations of words and phrases to better represent the text.

5.3.2 LinearSVC Parameters

For the Kaibi et al. (2019)LinearSVC classifier, we tuned parameters such as the regularization strength (C) to control overfitting. We also adjusted the *random_state* parameter to ensure reproducibility of results across different runs.

5.3.3 Grid Search with Cross-Validation

To find the optimal combination of hyperparameters, we employed grid search with cross-validation on the dev set Priyadarshini and Cotton (2021). This technique involved exhaustively searching through a specified parameter grid and evaluating each combination using cross-validation to estimate performance.

5.4 External Tools/Libraries Used

Our experimental setup relied on several external tools and libraries to facilitate data processing, model training, and evaluation. We leveraged scikit-learn for implementing various algorithms, data preprocessing tasks, and evaluation metrics. Additionally, the nltk library played a crucial role in performing natural language processing tasks such as tokenization, stopwords removal Mangat et al. (2017), and stemming Rao et al. (2021). We utilized joblib for saving and loading trained models to disk, providing a convenient way to serialize Python objects, including machine learning models. Pandas, a popular data manipulation library in Python, was instrumental in handling and analyzing structured data, enabling us to perform exploratory data analysis and prepare the data for training and evaluation. These external tools and

libraries streamlined our experimental workflow, allowing us to focus on model development and performance optimization.

6 Experimental Workflow

6.1 Task 1 (ERC for Code-Mixed dataset)

Data Preprocessing:

- Load the provided dataset containing code-mixed dialogues and their corresponding emotion labels.
- Perform text preprocessing steps such as tokenization, lowercasing, and removing stop words and punctuation.

Model Training:

- Utilize the preprocessed data to train a machine learning model, such as Linear Support Vector Classifier (LinearSVC), using the training set.
- Use techniques like TF-IDF Vectorization to convert text data into numerical features.

Evaluation:

- Evaluate the trained model's performance using the development set to fine-tune hyperparameters and ensure robustness.
- Evaluate the final model on the test set to measure its ability to accurately predict emotions in code-mixed dialogues.

6.2 Tasks 2 & 3 (EFR for Code-Mixed and English dataset)

Data Preprocessing:

- Load the provided dataset containing code-mixed or English-only dialogues and their corresponding trigger labels.
- Perform text preprocessing steps similar to Task 1.

Model Training:

- Train a machine learning model, such as LinearSVC, using the training set.
- Utilize techniques like TF-IDF Vectorization to convert text data into numerical features.

Evaluation:

- Evaluate the trained model's performance using the development set to fine-tune hyperparameters and ensure robustness.
- Evaluate the final model on the test set to measure its ability to accurately detect triggers indicating emotional shifts in dialogues.

7 Results

7.1 Evaluation

The model's performance is evaluated using accuracy (Acc), precision(P), recall(R), and F1 - Score (F1). These metrics are calculated as follows:

$$P = \frac{TruePositives}{TruePositives + FalsePositives} \quad (1)$$

$$R = \frac{TruePositives}{TruePositives + FalseNegatives} \quad (2)$$

$$F1 = \frac{2 \times P \times R}{P + R} \quad (3)$$

7.2 Task 1 (ERC for code-mixed)

Main Quantitative Findings: The system achieved an accuracy of 48% on the test set. While the recall for the 'neutral' emotion is relatively high (81%), the precision and recall for other emotions are considerably lower, indicating challenges in accurately predicting emotions in code-mixed dialogues.

Quantitative Analysis: Table 1 presents the precision, recall, and F1-score for each emotion category. The results indicate that the model performed relatively well in identifying 'neutral' emotions but struggled with other emotions, particularly 'disgust' and 'sadness'.

Error Analysis: The model seems to have difficulties distinguishing between 'disgust' and 'contempt', as evidenced by low precision and recall for both categories. Further investigation is needed to understand the underlying causes of misclassifications.

7.3 Task 2 (EFR for code-mixed)

Main Quantitative Findings: The system achieved high precision, recall, and F1-score across all emotion categories in detecting triggers indicating emotional shifts in code-mixed dialogues.

Quantitative Analysis: Table 2 presents the precision, recall, and F1-score for each emotion category. The model performed exceptionally well

Table 1: Results for Task 1

Emotion	Precision	Recall	F1-Score
Disgust	0.00	0.00	0.00
Anger	0.34	0.14	0.20
Contempt	0.29	0.09	0.14
Neutral	0.52	0.81	0.63
Joy	0.45	0.29	0.35
Sadness	0.33	0.16	0.22
Fear	0.33	0.13	0.19
Surprise	0.42	0.24	0.31

Table 2: Results for Task 2

Emotion	Precision	Recall	F1-Score
Disgust	0.99	0.92	0.96
Anger	0.98	0.95	0.96
Contempt	0.97	0.94	0.95
Neutral	0.94	0.98	0.96
Joy	0.97	0.93	0.95
Sadness	0.96	0.93	0.95
Fear	0.98	0.92	0.95
Surprise	0.93	0.80	0.86

in identifying triggers for emotions such as anger, contempt, and fear. However, there was a slight decrease in recall for surprise, indicating some challenges in capturing subtle cues for this emotion category.

Error Analysis: The model demonstrated robust performance overall, with minor discrepancies in recall for certain emotion categories. Further investigation is warranted to understand the underlying causes of these discrepancies and refine the model's performance.

7.4 Task 3 (EFR for English)

Main Quantitative Findings: The system exhibited robust performance in detecting triggers indicating emotional shifts in English-only dialogues, achieving high precision, recall, and F1-score across all emotion categories.

Quantitative Analysis: Table 3 presents the precision, recall, and F1-score for each emotion category. The model demonstrated excellent precision and recall for most emotion categories. However, there was a slight decrease in recall for surprise, suggesting challenges in accurately capturing triggers for this particular emotion.

Error Analysis: Similar to Task 2, the model showcased strong overall performance, with minor discrepancies in recall for certain emotion categories. Further investigation is needed to address these discrepancies and enhance the model's accuracy in detecting emotional triggers.

Table 3: Results for Task 3

Emotion	Precision	Recall	F1-Score
Disgust	0.92	0.87	0.90
Anger	0.92	0.84	0.88
Contempt	0.92	0.97	0.94
Neutral	0.82	0.97	0.88
Joy	0.93	0.77	0.84
Sadness	0.92	0.84	0.88
Fear	0.95	0.80	0.87
Surprise	0.92	0.71	0.80

8 Conclusion

The exploration of emotion recognition and trigger detection in conversational data presents significant implications for natural language processing research and human-computer interaction. Our study, encompassing tasks focused on code-mixed dialogues and English-only conversations, sheds light on the challenges and opportunities inherent in understanding the nuanced expressions of human emotions.

Through our experimental endeavors, we have demonstrated the efficacy of machine learning models, particularly Linear Support Vector Classifier (LinearSVC), in recognizing emotions and detecting triggers within dialogues. Despite the complexities posed by linguistic diversity and cultural nuances, our systems have shown promising performance, especially in identifying triggers indicating emotional shifts.

However, our journey does not end here. Future work should delve deeper into understanding the underlying causes of misclassifications and explore innovative approaches to enhance model robustness and generalization. Additionally, incorporating context-aware features and leveraging advanced deep learning architectures could further improve the accuracy and granularity of emotion analysis in conversational data.

In conclusion, our study contributes to the advancement of emotion analysis and trigger detection within dialogue systems, paving the way for more nuanced and culturally sensitive human-machine interactions in diverse linguistic contexts. As we continue to unravel the intricacies of human emotions through computational linguistics,

we embark on a journey toward more empathetic and intuitive artificial intelligence systems.

TüDuo at SemEval-2024 Task 2: Flan-T5 and Data Augmentation for Biomedical NLI

Veronika Smilga and **Hazem Alabiad**
University of Tübingen, Germany
first.last@student.uni-tuebingen.de

Abstract

This paper explores using data augmentation with smaller language models under 3 billion parameters for the SemEval-2024 Task 2 on Biomedical Natural Language Inference for Clinical Trials. We fine-tune models from the Flan-T5 family with and without using augmented data automatically generated by GPT-3.5-Turbo and find that data augmentation through techniques like synonym replacement, syntactic changes, adding random facts, and meaning reversion improves model faithfulness (ability to change predictions for semantically different inputs) and consistency (ability to give same predictions for semantic preserving changes). However, data augmentation tends to decrease performance on the original dataset distribution, as measured by F1 score. Our best system is the Flan-T5 XL model fine-tuned on the original training data combined with over 6,000 augmented examples. The system ranks in the top 10 for all three metrics[1].

1 Introduction

In the recent years, the rapid and triumphant advance of Large Language Models (LLMs) has affected virtually every area of NLP, biomedical NLP included. We aim to prove that Biomedical NLP can still benefit from smaller models of no more than three billion parameters. First, as the saying goes, "You must not use a steam hammer to crack a nut, if a nutcracker would do". In other words, while LLMs' performance is unmatched in complex applications, smaller models may be perfectly sufficient for simpler tasks, such as text classification or natural language inference. Second, being pre-trained on extremely large corpora of unlabelled data, modern LLMs have been shown to exhibit dataset-related bias (Acerbi and Stubbersfield, 2023). In fields with a high error cost, pre-training and fine-tuning models on smaller, carefully curated, high-quality datasets is safer and more predictable than using black-box giant LLMs in a zero-shot or few-shot setting. Finally, as of now, best-performing state-of-the-art LLMs are either largely unavailable to the end-user due to computational constraints (for open-source models) or cost-inefficient (for proprietary models with access via API).

The NLI4CT-2024 Shared Task (Jullien et al., 2024) consists in building a system for natural language inference (NLI) based on a collection of breast cancer Clinical Trial Reports (CTRs) in English. The task's main challenge is the complex and heterogeneous nature of the data. For each datapoint, the premise comes from one of the four sections of a CTR – Intervention, Eligibility, Results, or Adverse Events. Naturally, the sections are different from each other in terms of the mean length, the proportion of numerical data present, and the level of world knowledge required for drawing conclusions. Compared to the previous year's iteration of the task (Jullien et al., 2023), this year's challenge calls for a system robust to alterations in the data. Apart from F1 measure, two new metrics are used to evaluate the model performance: **faithfulness**, "measuring the ability of a model to correctly change its predictions when exposed to a semantic-altering intervention", and **consistency**, "measuring the ability of a system to predict the same label for original statements and contrast statements for semantic preserving interventions".

According to the last year participants' reports, various augmentation techniques have not led to significant performance improvement in terms of F1 and the top-3 best-performing systems did not use data augmentation at all (Jullien et al., 2023). However, given the new metrics that are used in this year's evaluation, it seems reasonable to continue exploring the effect that various kinds of augmentation have on F1, faithfulness, and consistency at the same time. In this paper, we fine-tune mod-

[1]Our code is available at https://github.com/smilni/semeval2024_safe_biomedical_nli

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 737–744

els of Flan-T5 family with and without the use of augmented data automatically generated using GPT-3.5-Turbo. We find that using various kinds of additional data leads to an increase in model's faithfulness and consistency, but a decrease in F1. Our best system is Flan-T5 XL, fine-tuned on 1900 original train and development instances and 6650 automatically generated ones. The system ranks 7th for consistency, 9th for faithfulness, and 10th for F1.

2 Related work

Language Models and Biomedical NLP There has been a surge of LLMs fine-tuned on biomedical data, from relatively small – 7 billion parameter ChatDoctor (Yunxiang et al., 2023), MedAlpaca (Han et al., 2023), PMC-LLAMA (Wu et al., 2023); 6 billion parameter DoctorGLM (Xiong et al., 2023) and OphGLM (Gao et al., 2023) – to extremely large ones – 540B Med-PaLM (Singhal et al., 2023), 175B Codex-Med (Liévin et al., 2022), 80B Med-Flamingo (Moor et al., 2023) – which were reported to break state-of-the-art results on a number of biomedical NLP tasks. Moreover, without any fine-tuning on biomedical data, GPT-4 was reported to have passed every step of the US-medical licensing exam (Nori et al., 2023). However, researchers argue that smaller language models, such as T5 Base and T5 Large, still outperform gigantic all-purpose models when fine-tuned for a specific task (Lehman et al., 2023).

Model Robustness in NLI tasks Many NLI models suffer from bias related to superficial correlations between input text features and labels in the training dataset, which leads to a drop in performance on datasets where these correlations do not hold (Rajaee et al., 2022). Among those are hypothesis only bias, where models rely mostly on the hypothesis without taking premise and premise-hypothesis relations into account (Poliak et al., 2018), and word-overlap bias, where models rely on the presence of shared words or phrases in premise and hypothesis (McCoy et al., 2019). Various techniques may be used to mitigate this bias, such as adversarial training (Stacey et al., 2020) and data augmentation with predicate-argument structures (Moosavi et al., 2020) and syntactic transformations (Min et al., 2020).

3 Experimental setup

In our experiments, we aim to test whether language models of relatively small size, under three billion parameters, can achieve decent performance on a task with a simple objective – as the model chooses between only two options, entailment and contradiction – and complex data – as dealing with Clinical Test Reports requires complex reasoning and understanding of numerical data. As a starting point for the experiments, we have chosen Flan-T5.

3.1 Selecting the model

Flan-T5 (Chung et al., 2022) is an updated checkpoint of T5 (Raffel et al., 2020), instruction-fine-tuned on a number of new NLP tasks, which outperforms baseline T5 models of the corresponding size on a number of benchmarks. It also features improved instruction-following capabilities and generalizes well on new tasks, not present in the training data. On the previous year's iteration of NLI4CTR, the system that featured fine-tuned Flan-T5-XXL (Kanakarajan and Sankarasubbu, 2023) without any biomedical pre-training data augmentation showed an impressive performance, ranking second.

First, we evaluate the model's performance in three scenarios – zero-shot, few-shot and after fine-tuning. Due to computational constraints we limit our experiments to language models of under three billion parameters, so we test only Flan-T5 Small (80M parameters), Flan-T5 Base (250M parameters), Flan-T5 Large (780M parameters), and Flan-T5 XL (3B parameters).

When testing the models in a zero-shot setting, we and use one of the NLI prompt templates provided by Flan-T5 developers [2]. In cases where two CTRs are given, we concatenate them using newline character as a separator. For a few-shot setting, we use the same prompt template as on the previous step, but enhance it with two hand-picked short CTR-hypothesis pairs from the training set – one with entailment and the other with contradiction relation. Refer to Appendix A for the prompts used for querying Flan-T5 in a zero-shot and two-shot setting.

Finally, we carry out fine-tuning with the use of HuggingFace Transformers library on the entire train set. The same set of hyperparameters is used for all models: `auto_find_batch_size`

[2] https://github.com/google-research/FLAN/blob/main/flan/v2/flan_templates_branched.py

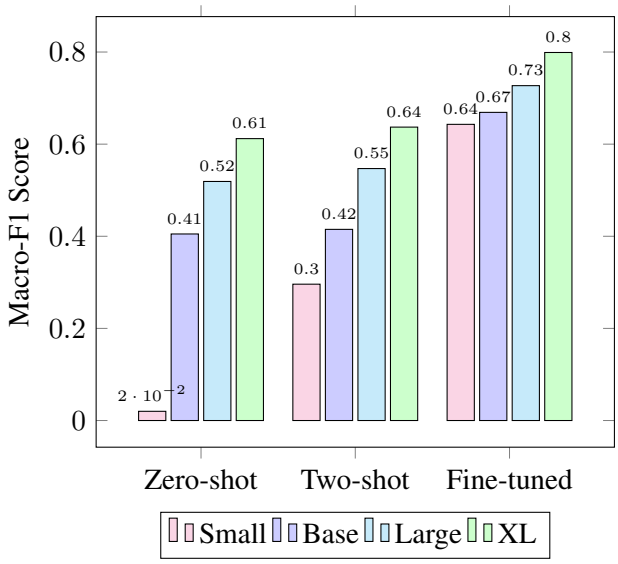

Figure 1: Flan-T5 model family performance, calculated on development dataset

`= True`, `learning_rate = 1e-3`, `optimizer = adamw_torch`. Flan-T5 Small and Flan-T5 Base are fine-tuned for 5 epochs in full precision. Due to computational constraints, Flan-T5 Large and Flan-T5 XL, however, were fine-tuned for 3 epochs using int8 precision and HuggingFace implementation of Low-Rank Adaptors (LoRA) algorithm (Hu et al., 2021).

Figure 1 summarizes the results obtained after evaluating the model on the development set in three different settings: zero-shot, few-shot, and after fine-tuning. There is a clear correlation between the model's performance and its size and between the model's performance and the number of train examples provided to it as well. In all cases, providing two examples from the training data to the model in a few-shot setting improves the performance of the model slightly, while fine-tuning it on all given training data results in a substantial performance boost. The best-performing model so far is fine-tuned Flan-T5 XL.

3.2 Data augmentation

We assume that the training data should be augmented in two key ways to create a **faithful** and **consistent** system. First, we should add paraphrased versions of the original datapoints, with semantic meaning and label preserved. It will ensure that the system is **consistent**, i.e. produces the same output for semantically equivalent inputs. Second, we should include semantically altered versions of the original datapoints, with semantic meaning changed and a reverted label assigned. It will ensure that the system is **faithful**, i.e. change its output when encountering an input semantically different to the one seen before. The presence of these three types of datapoints – original, paraphrased in a semantically preserving way, and paraphrased in a semantically altering way – is expected to improve the model's performance. We assume that these examples will teach the model to consistently handle the semantics of the sentence, mitigating the impact of superficial features like word overlap between a premise and a hypothesis on the model's performance.

We apply four types of alterations to hypotheses:

1. Synonym-based semantic-preserving changes, where certain words within a sentence are substituted with their synonymous counterparts.

2. Syntactic semantic-preserving changes, where the syntactic structure of the sentence is changed while the semantic meaning remains the same.

3. Random fact addition semantic-preserving changes, where a true random fact is appended to the hypothesis without affecting its truth value.

4. Semantic-altering changes, where a sentence contradictory to the original hypothesis is formulated.

Semantic-preserving changes 1), 2), and 3) are applied to all hypotheses, while semantic-altering change 4) is only applied to hypotheses that were

Original hypothesis	Heart-related adverse events were recorded in both the primary trial and the secondary trial. `[entailment]`
Synonym-based alteration	*Cardiovascular* adverse events were *documented* in both the primary *study* and the secondary *study*. `[entailment]`
Syntactic alteration	Both the primary trial and the secondary trial recorded adverse events related to the heart. `[entailment]`
Random fact addition	*Lymphadenopathy is the enlargement of lymph nodes due to infection, inflammation, or cancer.* Heart-related adverse events were recorded in both the primary trial and the secondary trial. `[entailment]`
Semantic-altering change	Heart-related adverse events were *not* recorded in either the primary trial or the secondary trial. `[contradiction]`

Table 1: Examples for each kind of alterations

initially labeled as entailment, changing the label to contradiction. The reason for this decision is that reverting a hypothesis that follows from some text produces a hypothesis that contradicts this text, but not vice versa. You may find examples for each kind of alterations in Table 1.

We access GPT-3.5-Turbo via OpenAI API to generate new hypotheses for each CTR-hypothesis pair, using a distinct hand-crafted prompt for each kind of alteration. You may find the text of each prompt in Appendix B. Four new hypotheses are generated for each "entailment" CTR-hypothesis pair, with both semantic-preserving and semantic-altering changes applied, and three new hypotheses are generated for each "contradiction" CTR-hypothesis pair, with only semantic-preserving changes applied. In all cases, CTR text itself remains unaltered, and only hypothesis is affected.

As a result, we obtain 3400 new entries for 850 original train CTR-hypothesis pairs labelled as entailment and 2550 new entries for 850 original train CTR-hypothesis pairs labelled as contradiction. The process of generating 5950 data points, thus increasing our dataset by 4.5 times, cost $0.86 and took 1.5 hours to complete.

4 Results

4.1 Individual Augmentation Analysis

We fine-tune Flan-T5 XL model on augmented data using the same set of hyperparameters as in Section 3.1. First, we fine-tune the model separately on each type of augmented data (combined with the original data) to estimate how augmentation of each kind affects the performance. The results are presented in Table 2.

Interestingly, only one kind of augmentation, the synonym-based one, had a positive effect on the model's performance on the original dataset, while the others led to a decrease in F1. All kinds of augmentations resulted in a model with higher consistency, i.e. a model better at producing the same output for hypotheses with the same meaning. The alteration that consisted in adding random true facts to hypotheses led to the highest increase in consistency. However, only semantic-altering change resulted in a more faithful model, i.e. a model better at changing its prediction when encountering a similar but semantically different hypothesis. All semantic-preserving changes led to a decrease in the model's faithfulness. Overall, our data augmentation techniques have proven to be efficient in improving the model's robustness. However, they have simultaneously resulted in a worse performance on the original data.

4.2 Final Model Selection

The next step was to try out different combinations of augmented data to reach the optimal performance in terms of the largest increase in both faithfulness and consistency and the smallest decrease in terms of F1. As the goal of the competition was to create a faithful and consistent system, we prioritized these metrics over F1 when choosing the model for the final submission. Thus, we chose the model trained on the entire set of augmented data that demonstrates higher faithfulness and consistency but lower F1. For the final submission, we additionally enriched the dataset with 200 more entries from development data and 700 new augmented entries created using techniques described in Section 3.2. The results obtained after fine-tuning the model on the entire augmented dataset are presented in Table 3.

	F1	Faithfulness	Consistency
Original train data only	0.779	0.780	0.667
Original train data + synonym-based alterations	**0.780**	0.715	0.681
Original train data + syntax-based alterations	0.764	0.748	0.698
Original train data + random facts addition	0.748	0.736	**0.725**
Original train data + reverted meaning alterations	0.735	**0.854**	0.686

Table 2: Flan-T5 XL performance when trained on different kinds of augmented data, calculated on test dataset

	F1	Faithfulness	Consistency
Original train data only	**0.779**	0.780	0.667
Original train data + all augmented train data	0.745	**0.851**	0.748
Original train and dev data + all augmented train and dev data	0.760	0.841	**0.752**

Table 3: Flan-T5 XL performance when trained on all kinds of augmented data, calculated on test dataset

4.3 Other approaches

Numerical inference is a known challenge for large language models. We assumed that the model's performance might vary across different CTR sections, with a decrease in performance for sections that contain most numbers. To check this assumption, we calculated the final model's F1 for each section separately. Calculations were performed on the development dataset as we had no access to test dataset labels during the development and evaluation stages. The results are presented in Table 4.

	F1
Adverse Events	0.711
Eligibility	0.821
Intervention	0.861
Results	0.759
All sections	0.783

Table 4: Final model's performance on each CTR section, calculated on development dataset

Adverse events, the section that, according to our observations, most often contained numbers in premise as well as hypothesis and required numerical inference to determine the relation between them, had the lowest F1 of all.

We attempted to develop a separate model, Flan-T5 XL with the same hyperparameter set as in Section 3.1, to tackle CTR-hypothesis pairs of this kind. The model was first pre-fine-tuned on EQUATE dataset (Ravichander et al., 2019) for 3 epochs in an attempt to enhance its numerical inference capabilities. Then it was further fine-tuned on the original and augmented CTR-hypothesis pairs of Adverse Events category for 3 epochs as well. We then used the original model to produce predictions for Eligibility, Intervention, and Results sections and the new model to produce predictions for Adverse Events section. However, on test data, this approach resulted in a decrease in performance with an F1 of 0.756 (-0.004), faithfulness of 0.781 (-0.06) and consistency of 0.722 (-0.031). We suppose that the decrease in performance is explained by the fact that the second model, trained on ~1/4 of all data (only one section out of four), simply did not encounter enough data to develop robustness comparable to that of the final model trained on the entire dataset.

5 Conclusion

In this paper, we explore the impact of data augmentation on model performance and robustness. Specifically, we focus on leveraging advanced language models like GPT-3.5-Turbo to expand the training set for fine-tuning smaller models such as Flan-T5 XL. Our experiments involve various prompts to generate new CTR-hypothesis pairs. Enriching the training set with new examples that underwent semantic-preserving changes, such as synonym replacement, change in word or clause

order, and random true fact addition, improves the model's consistency. Adding augmented examples that underwent semantic-altering changes, such as meaning reversion, improves the model's faithfulness as well as consistency. However, all kinds of augmentation except for synonym replacement lead to a decrease in model performance in terms of F1 on the original unaltered dataset. The model selected for the final submission is Flan-T5 XL fine-tuned on augmented development and training set. It features higher robustness but lower base performance than Flan-T5 XL fine-tuned on original data only, with faithfulness of 0.841 (+0.061), consistency of 0.752 (+0.085), and F1 of 0.76 (-0.019).

Abstract

This paper reports on an innovative approach to Emotion Recognition in Conversation and Emotion Flip Reasoning for the SemEval-2024 competition with a specific focus on analyzing Hindi-English code-mixed language. By integrating Large Language Models (LLMs) with Instruction-based Fine-tuning and Quantized Low-Rank Adaptation (QLoRA), this study introduces innovative techniques like Sentext-height and advanced prompting strategies to navigate the intricacies of emotional analysis in code-mixed conversational data. The results of the proposed work effectively demonstrate its ability to overcome label bias and the complexities of code-mixed languages. Our team achieved ranks of 5, 3, and 3 in tasks 1, 2, and 3 respectively. This study contributes valuable insights and methods for enhancing emotion recognition models, underscoring the importance of continuous research in this field.

1 Introduction

Emotional analysis has come quite a long way. In the context of natural language processing (NLP), history reveals an evolution of the emotion analysis task. The task has always been about recognizing emotions from text, evolving from those early-day systems that were able to recognize emotions from standalone text (Akhtar et al., 2019; Chatterjee et al., 2019; Mageed and Ungar, 2017; Shankar Biradar and Chauhan, 2021) to the current cutting-edge challenge of Emotion Recognition in Conversation (ERC) (Lei et al., 2023; Hazarika et al., 2018). Well-designed simple methods have demonstrated that recognizing the emotion of a user's expression enables a broad range of practical applications in diverse domains, from e-commerce (Gupta et al., 2013) to healthcare (Khanpour and Caragea, 2018).

ERC plays a significant role in illustrating how the emotion change during the interpersonal communications. By contrast to the isolation of single texts, ERC struggles with how emotions shift through a combination of different speakers in conversation. Motivated by the urgent need to understand the complex interactions of emotions during dialogue, a new issue has arisen—Emotion-Flip Reasoning (EFR) (Kumar et al., 2022a, 2024b). EFR is a novel Endeavour aiming at identifying precisely which utterances transform an emotion within a person's flow of speech. Apart from just emotions, EFR seeks to unravel the complexities of emotion flips, offering valuable insights into the dynamics of human interaction. Emotional flips can result from internal party interactions or from external elements such as speaker gestures or verbal messages.

The practical importance of EFR extends beyond theoretical limitations. In reality, it has applications in a variety of sectors. EFR plays a crucial part in the development of reward and punishment systems, as well as interpretable emotion recognition systems. Further, the widespread use of Hindi-English code-mixed language online shows the cultural change. NLP is facing new challenges in the accurate identification of emotions in a dynamic cultural context. Language switching during the conversation makes the work of emotion recognition systems even more complex. Further building an adaptable system capable of capturing the subtle variations in emotions that emerge in such a hybrid language setting is the need of the hour.

In order to promote research in this field, the organisers of SemEval 2024, Emotion Discovery and Reasoning its Flip in Conversation (EDiReF) [1] organised a shared task. The organisers created three sub-tasks:

- Task 1: Emotion Recognition in Conversation (ERC) in Hindi-English code-mixed conversations

[1]https://lcs2.in/SemEval2024-EDiReF/

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 745–756

- Task 2: Emotion Flip Reasoning (EFR) in Hindi-English code-mixed conversations
- Task 3: EFR in English conversations.

The following is an illustration of the definition for the ERC and EFR tasks:

- Emotion Recognition in Conversation (ERC) is focused on assigning emotions to individual utterances or phrases within a dialogue. It involves analyzing conversation data to identify the emotional states expressed by speakers throughout the interaction. The goal of ERC is to accurately recognize and categorize the emotions conveyed in each utterance.
- Emotion Flip Reasoning (EFR) aims to identify triggers for emotion flips in multi-party conversations. A trigger can be caused by one or more utterances, and some emotion flips might not be triggered by other speakers but by the target utterance itself (self-trigger). EFR analyzes dialogue data to understand the causes behind shifts in emotions, providing insights into the dynamics of emotional exchanges in conversations.

Our team, FeedForward, participated in Semeval-2024 task 10 and achieved rankings of 5, 3, and 3 in subtasks 1, 2, and 3, respectively[2]. For detailed insights and findings regarding this task, please refer to the task description paper of SemEval-2024 Task 10 (Kumar et al., 2024a).To tackle this problem, we propose state-of-the-art techniques such as Sentext-height for emotion recognition in multi-party conversations and ratio-wise splitting in trigger datasets for the EFR task. Additionally, we utilized instruction-based QLoRA training of 7-billion-parameter models for both ERC and EFR tasks.

The outline of the article is as follows: Section 2 offers an in-depth exploration of the background study. In addition, Section 4 comprehensively discusses the proposed methodologies. Finally, the experimental outcomes are illustrated in section 5.

2 Related work

Emotion detection in the standalone text is a well-known challenge in the Natural Language Processing domain (Akhtar et al., 2019; Chatterjee et al., 2019). However, unlike single text, emotion recognition in conversation data requires numerous complicated understandings of contextual information and speakers (Wagh and Sutar, 2023). In accordance with this, the majority of studies used deep neural networks with memory functions to solve sophisticated understandings of conversational text data (Hazarika et al., 2018; Weston et al., 2014). Furthermore, the developers of (Zhong et al., 2019) attempt to include the role of speakers into the conversational model by using memory networks during two-party discussions.

The utilization of external information is also vital in recognizing emotions in multi-party conversations. The authors of (Wen et al., 2023) proposed the DIMMN network for capturing speaker interaction information during multi-party conversations, in addition to text, audio, and video aspects during experiments. Conventional categorical label-based approaches fail to capture quantitative measurements of emotion; to solve this issue, the authors of (Yang et al., 2023) created a low-dimensional cluster-level contrastive learning model incorporating linguistic and factual information. Furthermore, the (Li et al., 2023) established a discourse link between utterances by adding symbolic information into multi-party interactions.

ERC in low-resource code-mixed text has received little attention. The authors of (Ghosh et al., 2023; Saumya et al., 2022) created a Hindi-English emotion-annotated corpus and established a transformer-based end-to-end framework with multitask learning. Furthermore, most existing studies only account for emotion recognition, but very few studies looked beyond emotion recognition to interpret the results. In one such study, (Kumar et al., 2022b; Fharook et al., 2022), the authors introduced a novel Emotion-Flip Reasoning (EFR), which aims to identify past utterances that have triggered one's emotional state to flip at a certain time, in addition to ERC.

3 Dataset

3.1 MaSac_ERC

The organizers of EDiReF of SemEval 2024 have provided the MaSac_ERC dataset (Kumar et al., 2023) for emotion recognition in Hindi-English Code-Mixed Conversations (Task 1). The task is to recognize emotions for speaker utterances in conversations. The train dataset contains 343 conversations and a total of 8506 utterances, which

[2]All proposed models are openly available at: https://huggingface.co/collections/zuhashaik/multi-party-dialoz-65d34c9f74e0888ef4e66da3

contain 8 emotion classes—Neutral, Joy, Anger, Sadness, Contempt, Fear, Surprise, and Disgust. The data set is significantly skewed, and the distribution of emotions across the train, validation, and test data is shown in Figure 1.

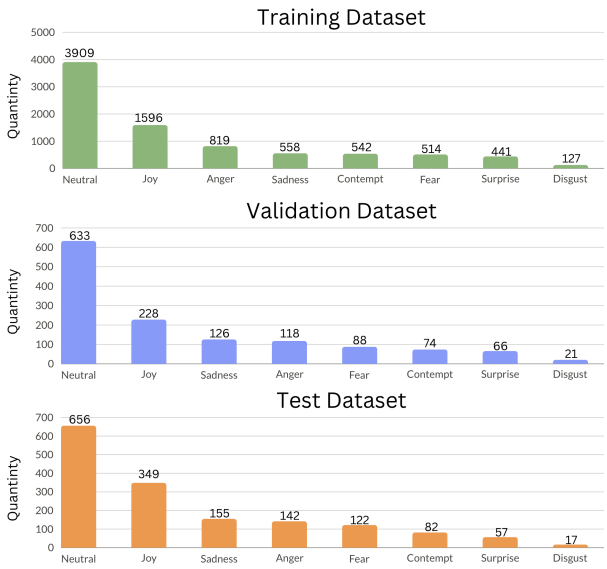

Figure 1: Emotion distribution of the MaSac_ERC

3.2 MaSac_EFR and MELD_EFR

The organizers of EDiReF of SemEval 2024 have provided the MaSac_EFR and MELD_EFR datasets Emotion Flip Reasoning (EFR) in Hindi-English code-mixed conversations (Task 2) and English Conversations (Task 3) respectively. The goal is to find all utterances that trigger a flip in the emotion of a speaker within a conversation. The MaSac_EFR train dataset contains 4,893 conversations having 6,542 triggers and 92,233 non-triggers. And the dataset distribution is clearly illustrated in Table 1. Similarly the MELD_EFR dataset contains 4,000 conversations having 5,575 triggers and 29,425 non-triggers. And the data distribution of triggers and non-triggers is illustrated in Table 2.

Trigger	Train	Validation	Test
Yes (1)	6542	434	416
No (0)	92233	7024	7274

Table 1: MaSac_EFR Label distribution

Trigger	Train	Validation	Test
Yes (1)	5575	494	1169
No (0)	29425	3028	7473

4 Methodology

In this section, a comprehensive study of the methodology employed, focusing on Emotion Recognition in Conversations (ERC) in Hindi-English code-mixed data and Emotion Flip Reasoning (EFR) in Hindi-English code-mixed conversations, as well as in English for Task1, Task2, and Task3, respectively, for SemEval-2024 Shared Task-10.

4.1 Task 1 : ERC in Hinglish

In this study, the focus lies on examining emotions within Hindi-English (Hinglish) code-mixed multi-party conversations using advanced language models. Various methods are explored, including refining BERT derivatives and translating code-mixed utterances for emotion classification. Furthermore, strategies like simplifying emotion labels and utilizing large language models with effective prompts are implemented to improve performance.

4.1.1 BERT derivatives as Baseline

As is commonly known, BERT (Devlin et al., 2019) demonstrates exceptional proficiency in sentiment analysis across various domains in natural language processing (NLP). However, the dataset comprises Hindi-English code-mixed text, necessitating pre-trained BERT derivatives capable of understanding Hinglish.

After an extensive exploration and experimentation phase with various BERT models, several BERT derivatives trained on Hindi or Hindi-English code-mixed datasets were identified. These include bert-base-multilingual-cased[3]**??**, l3cube-pune's hing-mbert-mixed-v2 (Joshi, 2023), lxyuan's distilbert-base-multilingual-cased-sentiments-student, and papluca's xlm-roberta-base-language-detection. Additionally, google's FNet-base (Lee-Thorp et al., 2022) was considered due to its substantial research presence in sentiment analysis, showcasing promising outcomes.

In this approach, each utterance paired with its corresponding emotion was treated as a data point extracted from the MaSac_ERC dataset. Subsequently, this data was utilized to fine-tune BERT derivatives for the emotion classification task, irrespective of its position within the conversation sequence and relevant contextual nuances.

[3]https://huggingface.co/google-bert/bert-base-multilingual-cased

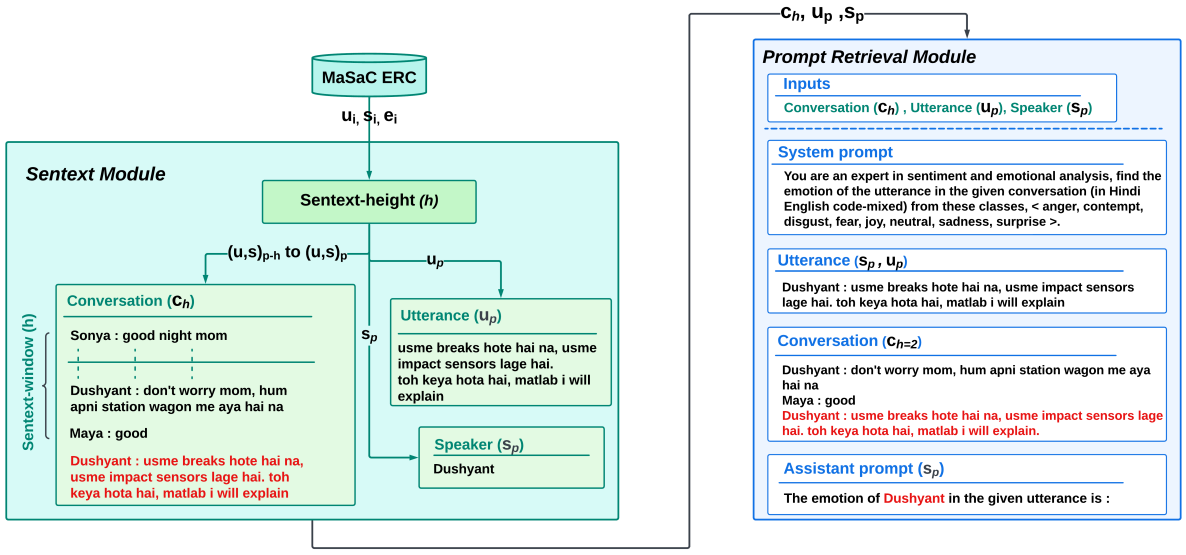

Figure 2: In the overview of the SP Module, the figure illustrates the complete process from slicing conversations with the Sentext Module to obtaining a training-ready prompt from the Prompt Retrieval Module.

In this approach, all layers of the models were retained unfrozen, converging into a feedforward network and subsequently a dense 8-way classifier, empowered by softmax.

4.1.2 Hinglish to English Translation

In the study focusing on Emotion Recognition in Code-Mixed Hindi-English Conversations (ERC), a unique methodology was employed. Rather than following a sequential conversation analysis, the code-mixed utterances were transliterated and then translated using IndicXlit (Madhani et al., 2023) and IndicTrans2 (Gala et al., 2023), respectively from AI4BHARAT organization. The inference of the models and the procedure of converting Hinglish to English are accessible here.[4] The translated utterance with its corresponding emotion was then used as a data point to fine-tune BERT and FNet for the sequence classification task.

4.1.3 Split and concat

In the split and concat approach, the label was coarse-grained (Neutrals, Negatives, Positives) to study the nuances created by the labels and the dataset complexity. Then, Fine grained to only Negatives (Anger, Sadness, Contempt, Fear, and Disgust) and only Positives (Joy, Surprise) were considered.

The main aim of this approach is to create a ensemble architecture (a classifier's tree) that will reduce the complexity of the dataset for the models being used. At the first level, it classify sentences as Neutral, Negative, or Positive. Then, at the second level, it further classify negatives and positives.

For instance, at the first level, An *NNP* (Neu-Neg-Pos) classifier predicts the sentiment of the utterance as Neutral, Negative, or Positive. If it's Neutral, the process stops there as we already classifed the emotion. Otherwise, it proceeds to the corresponding output sentiment classifier (Negs or Pos) to further classify the fine grained emotion.

4.1.4 7Bs enhanced with SP-module

When traditional approaches failed to yield satisfactory results, primarily due to label bias and the complexity of the Hindi-English code-mixed language, which struggled to distinguish between classes effectively, the focus shifted to large language models. 7-Billion (7B) parameter Large Language Models (LLMs) were utilized, taking these models from the shelf and then finetuning using Quantized Low Rank Adaptation QLoRA (Dettmers et al., 2023) on the dataset with effective prompts.

Sentext-height

To enhance the model's performance, a novel concept called *Sentext-height* was introduced. Sentext-height is a new idea that comes from context related to sentiment analysis within a sentence. It determines how many previous

[4]The proposed methodology can be found here: https://github.com/Zuhashaik/Multi-Party-DialoZ

utterance influence the emotion analysis of the present utterance in a given conversation. With this, it is possible to capture the emotion state of a speaker in the past utterances, which can contribute to finding the emotion of the present speaker's utterance.

Prompt-engineerning

LLMs have proven to be significantly reliable for a wide array of tasks in the domain of NLP. While they show significant promise, effective usage requires a carefully curated input. Through extensive experimentation with prompt structures on the foundational models, a conclusion was reached with a prompt that effectively works for the model.

The structure of the Prompt Retrieval Module:

- System prompt: Defines the LLMs role and expected behavior within the interaction, guiding its response.
  <|*system*|>*You are an expert in sentiment and emotional analysis, find the emotion of the utterance in the given conversation (in Hindi-English code mixed) from these classes, [anger, contempt, disgust, fear, joy, neutral, sadness, surprise].*

- Utterance: This contains the present utterance (u_p) with the respective speaker (s_p) attached to it before the utterance.
  <|*utterance*|> *{Speaker}:{Present_utterance}*

- Conversation: This has the conversation that is driven by sentext-height (h). It consists of h+1 utterances with Sentext-window (u_{p-h} to u_{p-1}) along with the current utterance u_p which to be evaluated, each with their corresponding speakers identified to indicate who made those utterances.
  <|*conversation*|> *{conversation, h}*

- Assistant prompt: Provides an incomplete statement or scenario and expects LLM to finish the very next word, making it a classification task that we're interested in.
  <|*assistant*|>*The emotion of {Speaker (s_p)} in the given utterance is :*

  In this case, the probable choices are the various emotions listed in the system prompt. These emotions include anger, contempt, disgust, fear, joy, neutral, sadness, and surprise. The model tries to classify within these emotion categories.

Data preprocessing hence concludes with the setting the sentext-height and selection of the appropriate prompt, collectively referred to as the SP-module (Sentext-Prompt) and clearly illustrated in the Figure 2.

QLoRA and Instruction Finetuning

After preparing the data with the SP-module, we used the prompt-processed dataset to fine-tune 7Bs with Instruction-based QLoRA for classifying emotions. We made 6 datasets, altering the sentext-height (h) from 2 to 7. Each model will train on every dataset, and we'll choose the best sentext-height based on how well the model performs. The models employed in this proposed study include Llama-2-7b-chat-hf (Touvron et al., 2023), zephyr-7b-beta (Tunstall et al., 2023), Mistral-7B-Instruct-v0.1 (Jiang et al., 2023), and openchat_3.5 (Wang et al., 2023).

Due to the challenges posed by *Catastrophic forgetting* (Luo et al., 2023) and computational constraints, the full training of LLMs (7Bs) cannot be carried out. Instead, QLoRA was chosen. This method involves quantizing the model during inference and then applying LoRA. With LoRA, the model parameters are frozen, and an additional low-rank matrix is introduced beside the attention layer weights, rather than training all parameters. This approach significantly reduces training time and memory requirements, often resulting in improved performance compared to traditional fine-tuning methods.

Additionally, a custom classifier was designed, where the last decoder layer in the 7B LLM is connected to an 8-way dense network powered by a softmax classifier. This is distinct from the text-generation LLM, where the 7B LLM is connected to a vocab-sized (32,000 in this case) classifier to predict the next word of the given input, which iterates until the end of sequence tag <eos> arises or the token limit is reached.

The total integration of the Sentext-height, Prompt-module and custom architecture with LoRA are demostrated in the figure 3.

Experimental setup

In this case, all models are inferred and trained in FP16 (Half-precision, float16). Following extensive experiments with various sentext-height

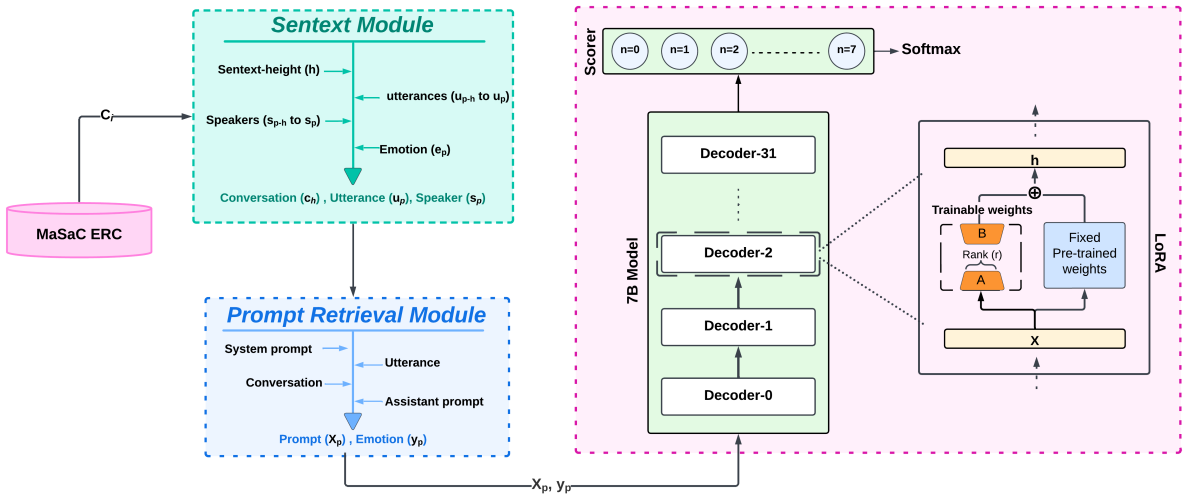

Figure 3: The MaSac-ERC-Z framework, figure displays how the Sentext Module and Prompt Retrieval Module are combined with a 7-billion parameter LLM. It also shows how LoRA is incorporated into the model, with each decoder having a low-rank matrix next to the pre-trained attention weights. This LoRA technique is applied specifically to all 32 decoder layers.

(h={2-7}), the hyperparameters that proved effective for the proposed model have been identified, as outlined in Table 3. Considerable

Hyper parameter	Value
Rank (LoRA config)	16
LoRA Alpha (LoRA config)	64
Dropout (LoRA config)	0.2
Learning Rate	2×10^{-5}
Learning Rate Scheduler	Constant
Batch size	1
Gradient acumulation step	1
adam_beta1	0.9
adam_beta2	0.999
adam_epsilon	1.000×10^{-8}
rms_norm_eps	1.000×10^{-5}

Table 3: Hyper parameters for Training 7Bs

RAM and computing capabilities are leveraged, supported by 3×32G Nvidia Tesla V100 GPUs.

4.2 Task 2 and 3 : EFR in Hinglish and English respectively

Since both task 2 and 3 involve Emotion Flip Reasoning but in different languages, maintaining the core model while adjusting the input is proposed. When providing embeddings to the model, rich semantic information from the text in the same language as the dataset is ensured. This approach enables obtaining language-aware contextual embeddings for the core model under development.

4.2.1 Attention-Based Utterance Fusion

In this approach, the Bert-based embeddings $(e_1, e_2, ..e_n)$ are extracted for each and every utterance $(u_1, u_2, ..u_n)$ in the conversation of n utterances. Consider u_p as the present utterance from the conversation, and the task is to determine whether it is the trigger for the u_n utterance which led to an emotion flip. Now, u_p and u_n are considered, and their embeddings e_p and e_n respectively are obtained. These embeddings are then linearly concatenated and passed through multi-head attention to capture intricate patterns within concatenated utterance pairs. Subsequently, a feed-forward network followed by a binary classifier is applied. Experimentation has been conducted with different BERT derivatives and the number of heads in multi-head attention has been varied.

4.2.2 7Bs for EFR

Following the MaSac-ERC-Z framework used in Task 1 with the 7B language model, the similar architecture is adopted here. However, a 2-way dense softmax classifier is incorporated instead of 8, as the task aims for binary classification (trigger or non-trigger). Furthermore, the focus is solely on identifying triggers rather than analyzing conversational emotion, so the sentext module is omitted. Additionally, a specialized prompt module is introduced to enhance the efficiency of

trigger retrieval for the specific task.

Prompt Module
After extensive experimentation in the playground of the foundational models, a prompt that works effectively for this task was concluded.
The glance of the prompt:

- System prompt: Defines the LLMs role and expected behavior within the interaction, guiding its response.
  <|*system*|>*In your role as an expert in sentiment and emotion analysis, your primary objective is to identify trigger utterances for emotion-flips in multi-party conversations (in Hindi-English code-mixed). Evaluate the provided dialogue by analyzing changes in emotions expressed by speakers through their utterances. Your task is to determine the accuracy of the hypothesis based on these emotional shifts.*
  For Task 3, which is the MELD dataset in English, *(in Hindi-English code-mixed)* from the system prompt is removed, and the remaining architecture will remain the same.

- Hypothesis: This contains the hypothesis and expecting the LLM to evaluate the hypothesis.
  <|*Hypothesis*|> *The utterance <{present_utterance}> is a trigger for the emotion-flip in <{speaker}'s> : <{final_utterance}> in the conversation*

- Conversation: This section contains the entire conversation, ensuring no chance of missing context. The emotions are also provided immediately after each utterance in the conversation, which is crucial for identifying the emotion flip and analyzing which utterance is the trigger.
  <|*conversation*|> *{conversation}, {emotions}*

- Assistant prompt: A sentence is left incomplete, assuming that the LLM has already generated something related to the input task. The expectation is for the LLM to complete this sentence.
  <|*assistant*|> *The given Hypothesis is :*

Instruction and QLoRA finetuning
As discussed, this approach follows a similar method proposed in Task-1, the MaSac-ERC-Z module, where a dataset is created using the prompt module and Instruction-based QLoRA fine-tuning is performed for the 7B model on the dataset. However, the constraint is that there are 98,775 (6,542 Triggers and 92,233 Non-triggers) and 35,000 (5,575 Triggers and 29,425 Non-triggers) datapoints from the MaSac_EFR and MELD_EFR datasets respectively. This can significantly slow down the trainings and take a lot of time to complete. Experimentations would be impractical under these circumstances. To avoid these constraints, the dataset was sliced into an 1:n ratio of Triggers to Non-Triggers, where n = {1,2,..}.
For instance, in the Task 2 dataset (MaSac_EFR), there are 6,542 triggers and 92,233 non-triggers. To preserve all triggers, the same number of non-triggers was selected to create a 1:1 dataset, yielding 13,084 datapoints from a total of 98,775. Similarly, for a 1:2 ratio, 6,542 triggers were retained, and 13,084 non-triggers were selected, and so forth up to a 1:3 ratio. This reduction in dataset size resulted in shorter training times leading to more efficient model training.

5 Results

This section presents a comprehensive study on outcomes from Task 1, Task 2, and Task 3. The weighted-f1 score is used as the standard metric for all tasks, as recommended by the task organizers and utilized to evaluate the submission hosted on Codalab.

5.1 Task 1

The baseline
In the proposed study, BERT derivatives were utilized, among which mBERT exhibited significant performance, yielding a weighted F1 score of 41.70. Consequently, this served as an initial baseline for evaluating the effectiveness of subsequent ideas and models. The corresponding scores are provided in Table 4.

Base-Model	Weighted-F1
mBERT	**41.70**
hing-mbert-mixed-v2	28.76
lxyuan	40.25
papluca	37.39
fnet-base	38.08

Table 4: Weighted-F1 scores of Finetuned models

Translation
Following the initial efforts, the aim was to

enhance performance further, considering the intricate nature of deciphering patterns within code-mixed languages. The approach involved converting Hinglish (a mix of Hindi and English) into English and using transformer-based models to identify the emotions. After this transformation, a weighted-f1 score of 40.03 was achieved with bert-base-uncased and 35.79 with fnet-base. The decline is assumed to be the accumulation of errors across three key processes: transliteration, translation, and classification. These processes inherently carry a high risk of errors, which likely impacted the classification accuracy.

The classifier tree

In the proposed work, *Split and concat* in Task1, the impact of coarse and fine-grained approaches on classification was analyzed. This examination aimed to pinpoint areas for improvement in achieving scores above the baseline. The primary challenge lies in classifying Neutrals within the complex Hindi-English code-mixed context, resulting in a weighted-f1 score of 55.16. Additionally, categorizing fine-grained negatives poses a significant challenge, as evidenced by a weighted-f1 score of 39.87. However, identifying positives proves comparatively easier, with weighted-f1 of 91.28.

The strengths of all three classifiers were combined, resulting in an aggregate score of 41.46 with BERT-Tree. The Ensemble BERT-Tree consists of Hing-BERT as the first-level classifier (NNP) and mBERT for further classifying negatives (Negs) and positives (Pos) at the second level. These models were chosen based on their performance scores in both coarse and fine-grained classification tasks. Nonetheless, this represents a decline from the baseline as discussed earlier. The decrease may be due to the compounding errors from each classifier that affect the final classification.

The detailed investigation of the study is outlined in Table 5. In the table, "Neutral-Negative-Positive" represents the coarse grain classification, while "Negatives (Negs)" and "Positives (Pos)" indicate the fine grain emotion categories.

7Bs enhanced with SP-module

In the analysis, the proposed approaches fell short of delivering satisfactory results, preventing the achievement of a weighted-f1 score in the 50s. The complexity of code-mixed languages posed a significant challenge, and the methods struggled to grasp the nuances of context and sentiments effectively.

Base model	NNP	Negs	Pos
mBERT	49.42	**39.87**	**91.28**
hing-mbert	**55.16**	11.80	79.47
lxyuan	49.71	39.01	90.69
papluca	53.80	32.89	90.35
fnet-base	48.69	26.70	89.91
W-F1 (ALL)			
BERT-Tree (En)		**41.46**	

Table 5: Weighted-F1 scores of Coarse and Fine-Grained Emotion Classification Results, combined all to construct a tree like classifer to classify all 8 emotions. 'En' denotes Ensemble here.

However, upon transitioning to 7Bs for this task and conducting extensive experimentation on various foundational models and sentext-height (choosing n between 2-7), a threshold of 50s was finally surpassed, which elevated the system to the 5th position in the competition. Specifically, a weighted-f1 score of 51.17 was attained using the Zephyr-7b-beta model with a sentext-height of 3.

Based on the analysis presented, Table 6 and figure 4 illustrates the performance of various 7B models across different sentext-height (h) values.

7B Models	Sentext-height (h)					
	2	3	4	5	6	7
llama2	49.0	**49.5**	48.3	49.0	48.3	47.9
zephyr	46.7	**51.2**	45.5	46.0	47.4	46.3
mistral	45.5	45.5	44.5	**46.1**	45.5	47.0
openchat	42.4	46.7	47.3	45.0	43.2	**48.6**

Table 6: Weighted-F1 scores of 7B models with different Sentext-height (h) values.

All-Together

Bringing everything together for Task 1, the study began with mBERT as the benchmark, followed by efforts to refine performance through translation and ensemble techniques, which encountered challenges and resulted in reduced scores. Further exploration into classification strategies revealed difficulties in nuanced identification, leading to mixed outcomes. Finally, incorporating SP-modules helped to surpass the 50s score threshold, reflecting progress in addressing the complexities of code-mixed languages. The comprehensive results for Task 1 can be viewed in Table 7, providing a detailed overview of the study's findings.

Model	Model Names	W-F1	Method
Encoder-Only	mBERT	41.7	Seq-cls
	hing-mbert	28.76	Seq-cls
	lxyuan	40.25	Seq-cls
	papluca	37.39	Seq-cls
	fnet-base	38.08	Seq-cls
	BERT	40.03	Translation
	FNet	35.79	Translation
	BERT-Tree	41.46	Ensemble
Decoder-Only	llama_h3	49.52	QLoRA
	mistral_h3	45.5	QLoRA
	zephyr_h3	**51.17**	**QLoRA**
	openchat_h3	46.73	QLoRA
	mistral_h5	46.07	QLoRA
	openchat_h7	48.58	QLoRA

Table 7: The table provides weighted F1 scores comparison of various methods and models. For Decoder-only models, the sentext-height is specified after the model's name. "Seq-cls" denotes sequence classification.

5.1.1 Task 2 and Task 3

7Bs for EFR

In Task 1, 7Bs demonstrated remarkable performance, motivating the extension of their use to EFR. As outlined in the Methodology, training requires a significant amount of time due to the large number of data points. To address this, the dataset was sliced and implemented a 1:n ratio (Triggers : Non-Triggers), resulting in (1+n)x datapoints (where x represents the number of triggers).

This concept was applied to Task 3 as well, given the similar nature of Task 2 but with English-language data, ensuring consistency in the approach across both tasks.

Task2			
7B models	**1:1**	**1:2**	**1:3**
openchat	57.81	55.60	58.51
zephyr	66.19	66.32	76.96

Table 8: Task 2, Weighted-F1 scores of 7B models with different splitting ratios

Task3			
7B models	**1:1**	**1:2**	**1:3**
openchat	71.52	71.29	72.53
zephyr	70.77	71.97	71.91

Table 9: Task 3, Weighted-F1 scores of 7B models with different splitting ratios

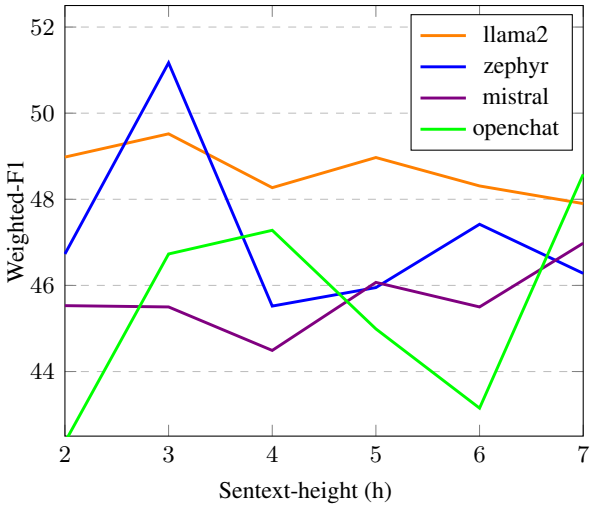

Figure 4: Graphical representation of the performance of 7B models with different Sentext-height (h) values.

For task 3, we considered the validation set and trained with a specific ratio (3:1) and model (openchat_3.5) that resulted in the highest score (72.53), achieving a weighted F1 score of 73.94 From the demonstrated experiments, the ratio of 1:3 yielded the highest scores in both Task 2 and Task 3, resulting in securing the 3rd rank in both tasks respectively. The results of the experiments with various ratio's and 7B models is given in the table 8 for MaSac_EFR which is task2 and table 9 for MELD_EFR which is task3.

6 Conclusion

This paper discusses the proposed work for the competition EDiReF SemEval-2024 hosted on Codalab. The study mainly focuses on emotion and emotion flip-trigger analysis specifically within multi-party conversational data. Through innovative approaches and the utilization of state-of-the-art techniques such as Large Language Models (LLMs), Instruction-based fine-tuning, and Quantized Low-Rank Adaptation (QLoRA), our team achieved promising results in Emotion Recognition in Conversation (ERC) and Emotion Flip Reasoning (EFR) tasks. However, obstacles persist, especially in addressing label bias and capturing nuanced emotions in Hindi-English code-mixed language. The findings underscore the need for further research to enhance model performance, ultimately improving emotional analysis in conversational data.

A Performance of Top model for Task 1

In the following appendix, we present the performance metrics of the instruction-tuned zephyr-7b-beta model (zephyr_h3) with Sentext-height (h=3) which is the top performing model with a Weighted-F1 of 51.17 in sub task 1, Emotion Recognition in Conversation (ERC).

A.1 Confusion Matrix

The confusion matrix in figure 5 visually represents the performance of the zephyr_h3 model in classifying different emotions. We observed a notable amount of confusion primarily between the emotions of joy and neutral, which could be attributed to the prevalence of neutral expressions in the dataset. This suggests a bias towards categorizing ambiguous or mild emotions as neutral, potentially impacting the accuracy of our predictions.

Additionally, there appears to be confusion between the emotions of anger and fear, as well as between contempt and sadness. These overlaps indicate potential similarities in the facial expressions or textual cues associated with these emotions, highlighting areas where our model may require further refinement.

A.2 Classification Report

The comprehensive classification report in table 10 for the zephyr_h3 model, showcasing precision, recall, F1 score, and support across various emotions.

The report further underscores the performance of our model across different emotions. While achieving relatively high precision for joy and neutral emotions, indicating a good ability to correctly identify these categories, our model struggles with emotions such as disgust and fear, as evidenced by lower precision scores. This indicates a tendency

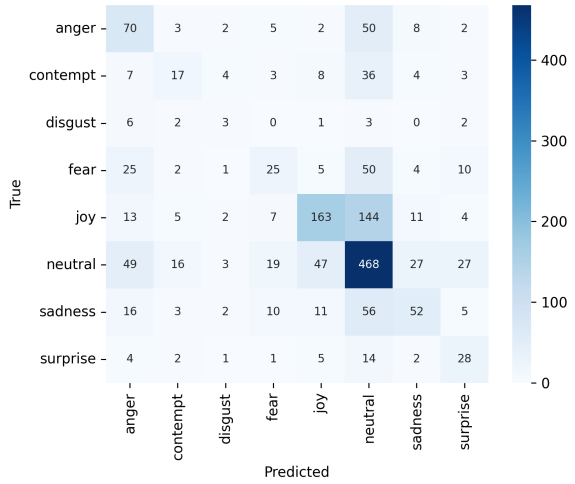

Figure 5: Confusion Matrix

for the model to misclassify instances of these emotions as other classes. Moreover, the overall accuracy of our model is moderate, indicating room for improvement in effectively distinguishing between the diverse emotional states. These findings emphasize the importance of addressing biases in the dataset and further fine-tuning the model to enhance its ability to accurately classify a wider range of emotions.

Emotion	**Precision**	**Recall**	**F1 Score**	**Support**
Anger	0.38	0.52	0.44	142
Contempt	0.33	0.20	0.25	82
Disgust	0.19	0.18	0.18	17
Fear	0.31	0.20	0.24	122
Joy	0.69	0.48	0.56	349
Neutral	0.58	0.72	0.65	656
Sadness	0.47	0.35	0.40	155
Surprise	0.34	0.47	0.39	57
Accuracy		0.53		
Macro Avg	0.41	0.39	0.39	1580
Weighted-Avg	0.53	0.53	0.52	1580

Table 10: Classification Report

A.3 Performance summary

Our classification model demonstrates moderate overall accuracy of 53%, with strengths in identifying joy and neutral emotions, boasting precision scores of 69% and 58% respectively. However, it struggles with emotions such as disgust and fear, showing lower precision scores of 19% and 31% respectively. Confusion primarily arises between joy and neutral emotions, possibly due to dataset biases towards neutral expressions. Further refinement is needed to enhance the model's ability to accurately classify a broader spectrum of emotions. The macro-average F1 score is 39%, while the weighted average F1 score is 52%, indicating room for improvement in capturing the nuances of different emotional states.

YNU-HPCC at SemEval-2024 Task 5: Regularized Legal-BERT for Legal Argument Reasoning Task in Civil Procedure

Peng Shi, Jin Wang and Xuejie Zhang
School of Information Science and Engineering
Yunnan University
Kunming, China
Shipeng1@stu.ynu.edu.cn, {wangjin, xjzhang}@ynu.edu.cn

Abstract

This paper describes the submission of team YNU-HPCC to SemEval-2024 for Task 5: The Legal Argument Reasoning Task in Civil Procedure. The task asks candidates the topic, questions, and answers, classifying whether a given candidate's answer is correct (True) or incorrect (False). To make a sound judgment, we propose a system. This system is based on fine-tuning the Legal-BERT model that specializes in solving legal problems. Meanwhile, Regularized Dropout (R-Drop) and focal Loss were used in the model. R-Drop is used for data augmentation, and focal loss addresses data imbalances. Our system achieved relatively good results on the competition's official leaderboard. The code of this paper is available at https://github.com/YNU-PengShi/SemEval-2024-Task5.

1 Introduction

The task can be formulated as follows: given an introduction to the topic, a question, and an answer candidate, classify if the given candidate is correct (True) or incorrect (False) (Bongard et al., 2022). This task has two main difficulties: 1) The text length of the topic and question is much larger than 512 tokens. 2) The number of positive and negative samples in the data varies widely.

Initially, the online system represented the first attempt to utilize computational methods for addressing legal conundrums (VALENTE et al., 1999). Despite notable advancements in recent years, which have seen a concerted effort to establish objective benchmarks for natural language processing models in the domain of legal language comprehension (Chalkidis et al., 2022), a lack remains in the realm of complex tasks involving argumentative reasoning within legal contexts. However, Legal-BERT has emerged as a forerunner in this domain, demonstrating compelling performance (Chalkidis et al., 2020).

This paper proposes a model based on Legal-BERT. In processing tasks, we used sliding window simple (SWS) and sliding window complex (SWC) to process the original data and solved the problem of the token count of the original data being much larger than 512. In the subsequent process, we found that there was a significant imbalance in the dataset that resulted in the return of the most common label in the training set (in this case, 0). We added R-Drop (Wu et al., 2021) to the model to address this issue and changed the loss function from cross entropy to focal loss (Lin et al., 2017). In the end, we achieved a good result. The best submission for the test set has achieved 0.6166 and ranked 9th in this task.

The remainder of this paper is organized as follows. Section 2 describes the model and method used in our system, section 3 discusses the results of the experiments, and finally, the conclusions are drawn in section 4.

2 System Description

This section delves into the intricate design of the proposed model's architecture. The architecture comprises multiple essential components, namely the text cutting, the tokenizer, the pre-trained Legal-BERT model, the output layer, and the methods. Figure 1 illustrates the comprehensive system model that we have devised.

2.1 Text Preprocessing

Sliding Window Simple (SWS). The process involves dividing the combined question and introduction into discrete segments or chunks. These chunks are then submitted to a classification algorithm, which assigns a category or label to each segment based on its content. Once the classification is complete, the system calculates the average predicted output for all the chunks. This average serves as a comprehensive summary or representa-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 757–762

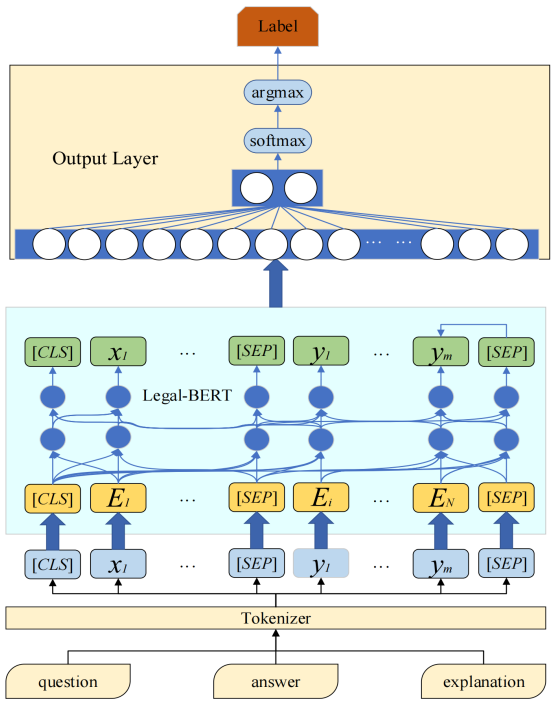

Figure 1: The structure of system

tion of the combined text, capturing the key themes and characteristics. It's a method that leverages machine learning techniques to distill the essence of a complex textual input into a single numerical value, which can be helpful in various applications such as summarization, sentiment analysis, and information retrieval.

Sliding Window Complex (SWC). In this sophisticated text processing workflow, the initial step decomposes the introductory text into discrete segments or chunks. Each chunk is meticulously constructed to include the complete question, flanked by the introduction's segments to provide context. This approach ensures that each chunk is a self-contained unit that retains the connectivity between the question and the supporting information in the introduction (Koay et al., 2021).

Subsequently, these meticulously crafted chunks are subjected to a comprehensive classification process. This process employs advanced machine learning algorithms to analyze the content of each chunk and assign it to one or more predefined categories or labels. The classification is nuanced and context-aware, considering the intricate details and subtle nuances present in the text (Kong et al., 2022).

The system employs a statistical aggregation technique to calculate the average of the predicted outputs for all the chunks. This average is a weighted sum of the individual predictions, giving more weight to chunks deemed more critical or relevant based on the specific application context.

The resulting average is a valuable metric that encapsulates the collective predictions of the model for the given question and introduction. It provides a robust summary of the model's understanding of the text, offering insights into the key themes and conclusions the model has extracted from the input. This average output can be used for various applications, such as generating summaries, making predictions, or informing decision-making processes.

2.2 Tokenizer

In many natural language processing (NLP) tasks, the original text must be processed into digital data before it can be processed by computer. Thus, the tokenizer was applied to divide the text into words and convert it into unique coding. Given a training data $\mathcal{D} = \{X^{(m)}, y^{(m)}\}_{m=1}^{M}$, $X^{(m)}$ is the processed input text. $y^{(m)}$is the corresponding ground-true label, the Bert tokenizer is applied to transform $X^{(m)}$ as,

$$X = [CLS]x_1x_2x_3...x_n[SEP]y_1y_2...y_m[SEP] \quad (1)$$

where x and y represent tokens, n and m represent the length of the first and second sentences, $[CLS]$ special mark indicates the beginning of the text sequence, $[SEP]$ indicates the separator between text sequences, respectively.

2.3 Legal-BERT Model

Legal-BERT is a specialized variant of the BERT model tailored for the legal domain, leveraging a corpus of legal text to facilitate advancements in legal natural language processing research, computational law, and legal technology applications (Chen et al., 2023). This model inherits the parameter weights from BERT-Base, ensuring a solid foundation for legal-specific tasks. In our study, we employed the pre-trained Legal-BERT model, built upon the Transformer library [1], to handle the complexities of legal language. The architecture of Legal-BERT mirrors that of the original BERT model, comprising an essential components: the Transformer encoder block (Vaswani et al., 2017). These blocks work to capture legal text's intricate

[1] https://huggingface.co/nlpaueb/legal-bert-base-uncased

patterns and nuances. The model configuration used in our experiment features 12 layers, 768 dimensions, 12 self-attention heads, and a total of 109 million parameters. This configuration balances model complexity and computational efficiency, enabling us to tackle various legal NLP challenges effectively.

Encoder block. Firstly, Legal-BERT performs the embedding operation after receiving the processed raw data. Through the above processing, we obtained token embedding, segment embedding, and position embedding (Zhang et al., 2021), followed by a series of operations to obtain $\mathbf{H}$, as follows.

$$\mathbf{H} = \mathrm{Enc}(X; \theta) \tag{2}$$

where $\mathbf{H} \in \mathbb{R}^d$ is the logits with a dimensionality of 768.

2.4 Output Layer

The BERT model has two major pretraining tasks: mask language model (MLM) and next sentence prediction (NSP), and the text implication task usually uses the NSP method to predict, that is, use the hidden layer representation of $[CLS]$ bits to predict the text classification (Ma et al., 2021). In our proposed model, the output of the model is first to use a softmax function and then perform argmax on the results after softmax to obtain $\hat{y}$,

$$\hat{y} = \mathrm{argmax}(\mathrm{softmax}(W^o\mathbf{H} + h^o)) \tag{3}$$

The training objective is to optimize the focal loss between the true and predicted labels,

$$\mathcal{L}_{FL} = \begin{cases} -(1-\hat{y}^{(m)})^{\gamma}\log(\hat{y}^{(m)}) & if\ y^{(m)} = 1 \\ -\hat{y}^{(m)^{\gamma}}\log(1-\hat{y}^{(m)}) & if\ y^{(m)} = 0 \end{cases} \tag{4}$$

where $W^o \in \mathbb{R}^d$ represents the weight of the fully connected layer, h^o represents the offset of the fully connected layer, $\mathbf{H} \in \mathbb{R}^d$ is the output representation of $[CLS]$ token in the L-th layer, γ is used to control the weight of difficult-to-classify samples, $y^{(m)}$ are respectively the true label, $\hat{y}^{(m)}$ are respectively the probability distribution of prediction.

2.5 Regularized Dropout (R-Drop)

To solve the problem of highly imbalanced data, R-Drop is added to the output layer of Legal-BERT. As shown in Figure 2, the same input can obtain two logits, $\mathbf{H}_1$ and $\mathbf{H}_2$, respectively, during the R-Drop process. Therefore, the model will output two predicted values $\hat{y}^{(1)}$ and $\hat{y}^{(2)}$, as follows.

$$\hat{y}^{(1)} = \mathrm{argmax}(\mathrm{softmax}(W^o\mathbf{H}_1 + h^o)) \tag{5}$$

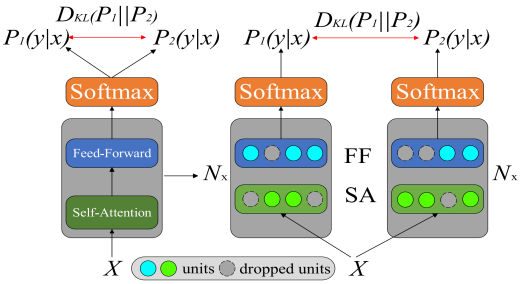

Figure 2: The structure of R-Drop

$$\hat{y}^{(2)} = \mathrm{argmax}(\mathrm{softmax}(W^o\mathbf{H}_2 + h^o)) \tag{6}$$

R-Drop uses a symmetrical Kullback-Leibler (KL) divergence to constrain $\hat{y}^{(1)}$ and $\hat{y}^{(2)}$, as follows.

$$\mathcal{L}^i{}_{KL} = \frac{1}{2}((D_{KL}(\hat{y}^{(1)}||\hat{y}^{(2)}) + D_{KL}(\hat{y}^{(2)}||\hat{y}^{(1)})) \tag{7}$$

Finally, the model will calculate the loss of two predicted values $\hat{y}^{(1)}$ and $\hat{y}^{(2)}$ using focal loss, as follows.

$$\mathcal{L}^1_{FL} = \begin{cases} -(1-\hat{y}^{(1)})^{\gamma}\log(\hat{y}^{(1)}) & if\ y^{(1)} = 1 \\ -\hat{y}^{(1)^{\gamma}}\log(1-\hat{y}^{(1)}) & if\ y^{(1)} = 0 \end{cases} \tag{8}$$

$$\mathcal{L}^1_{FL} = \begin{cases} -(1-\hat{y}^{(2)})^{\gamma}\log(\hat{y}^{(2)}) & if\ y^{(2)} = 1 \\ -\hat{y}^{(2)^{\gamma}}\log(1-\hat{y}^{(2)}) & if\ y^{(2)} = 0 \end{cases} \tag{9}$$

The training loss function for Legal-BERT is as follows.

$$\mathcal{L}_i = \mathcal{L}^1_{FL} + \mathcal{L}^2_{FL} + \mathcal{L}^i_{KL} \tag{10}$$

3 Experimental Result

Datasets. The Legal Argument Reasoning Task in Civil Procedure shared task data set is composed of three CSV files: the size of the training set train.csv sorted by expert comments is 666, the size of the developing set dev.csv is 84, the size of test set test.csv is 98. The data part of the train and dev set mainly includes idx, question, answer, label, analysis, complete analysis, and explanation. The data part of the test set mainly includes idx, question, answer, and explanation. Idx is used to represent the number of each sample. The question is made in the context of the content of the explanation. The answer is a candidate answer in the sample. Label indicates whether the question and candidate

Question: 8. Technical fouls. Eban brings suit against Lorenzo for interference with business relations. Eban's lawyer, Darrow, calls Lorenzo's lawyer, Sadecki, and tells her that he is filing suit that afternoon. In which of the following scenarios may the case proceed without formal service of process?
Answer: Darrow files the complaint and mails a copy of it by certified mail to Lorenzo with two copies of a proper request for waiver. He receives the green postal receipt back in the mail. Darrow files the postal receipt with the court.

Question: 8. Technical fouls. Eban brings suit against Lorenzo for interference with business relations. Eban's lawyer, Darrow, calls Lorenzo's lawyer, Sadecki, and tells her that he is filing suit that afternoon. In which of the following scenarios may the case proceed without formal service of process?
Answer: Darrow files the complaint and mails a copy of it by certified mail to Lorenzo with two copies of a proper request for waiver. He does not send a summons, signed and sealed by the court, with the waiver request. He receives the signed waiver form back and files it with the court.
BERT Predicted label: 0
Legal-BERT Predicted label: 1
True label: 1

answer match, 0 for mismatch, and 1 for matching. Analysis and complete analysis are used for experimenters to understand why the label is 0 or 1. Explanation is used to indicate the subject of the sample to which it belongs.

Evaluation Metrics. The Legal Argument Reasoning Task in Civil Procedure shared tasks are evaluated using the standard evaluation indicators, including Macro F_1-*score* and Accuracy. The submissions of all teams are ranked according to the F_1-*score*. The metrics will be calculated as follows.

$$Precision = \frac{true\ positives}{true\ positives + false\ positives} \quad (11)$$

$$Recall = \frac{true\ positives}{true\ positives + false\ negatives} \quad (12)$$

$$F_1\text{-}score = \frac{2 \times Precision \times Recall}{Precision + Recall} \quad (13)$$

Implementation Details. Initially, explanation and question are concatenated when processing data. The BERT (Devlin et al., 2018) is used as the first model to solve this task. However, without any treatment, the predicted value of the BERT is all 0, and the effect is not ideal. Next, we used the larger models RoBERTa (Liu et al., 2019) and DeBERTa (He et al., 2020), but the predictions and $F1$_scores were identical to BERT. Due to the

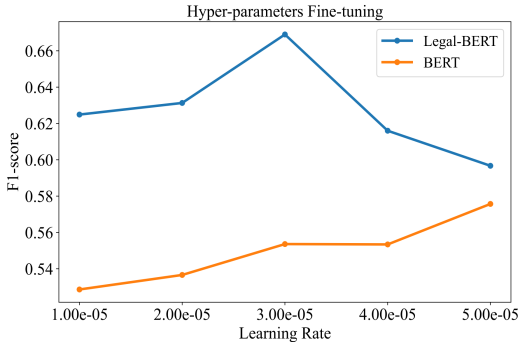

Figure 4: The performance of different learning rates on the F_1-*score*

extreme data imbalance, we found that the cross-entropy loss function could not calculate the loss correctly. Therefore, we changed the loss function for BERT, RoBERTa, and DeBERTa to focal loss and dice loss. The results show that modifying the loss function can slightly improve the score, but the effect is not ideal. To solve the problem of extreme data imbalance further, we change their loss functions to focal loss and dice loss (Li et al., 2020) based on supervised contrastive learning (SCL) (Khosla et al., 2020) and R-Drop. The results show that the combination of pairs can effectively solve the problem of extreme data imbalance, and the score has also been significantly improved. During the experiment, we found that due to the large number of proprietary legal terms in the data text, the above model could not fully segment professional vocabulary using the corresponding tokenizer. Therefore, we believe that the Legal-BERT is the most suitable choice. As expected, Legal-BERT has achieved good results in adding R-Drop and focal Loss technologies, as shown in Figure 3.

Hyper-parameters Fine-tuning. We adjusted different learning rates and epochs to adapt to different models to achieve the expected results. Legal-BERT is better than BERT regardless of the learning rate, as shown in Figure 4. The optimal F_1-*score* was found at 4 with the batch size constantly changing, as shown in Figure 5. We set the best parameters in the final submitted results: warmup steps are 10, weight decay is 0.01, the learning rate is 3e-5, train batch size is 4, and epoch is 100.

Comparative Results and Discussion. The test is first carried out on the development set, whose size is 84. Facing the different predicted results of other models and Legal-BERT, it is clear that Legal-BERT performs better. Regardless of the

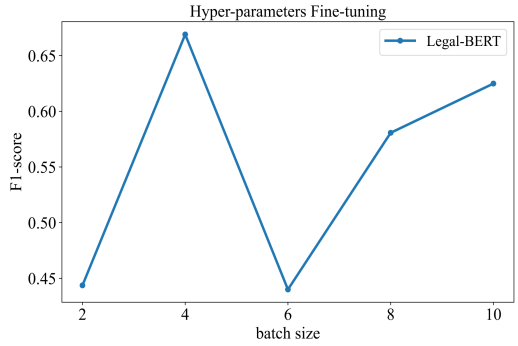

Figure 5: The performance of different batch sizes on the F_1-*score*

Model	Loss	F_1-*score*	Accuracy
BERT	Cross-Entropy	0.4437	0.7976
RoBERTa	Cross-Entropy	0.4437	0.7976
DeBERTa	Cross-Entropy	0.4437	0.7976
Legal-BERT	Cross-Entropy	0.4437	0.7976
BERT	Focal Loss	0.4688	0.8095
RoBERTa	Focal Loss	0.4437	0.7976
DeBERTa	Focal Loss	0.4956	0.7976
Legal-BERT	Focal Loss	0.5599	0.6548
BERT	Dice Loss	0.5468	0.6548

DeBERTa	Dice Loss	0.4830	0.7738
Legal-BERT	Dice Loss	0.4943	0.7421

Table 1: models and methods.

model, as long as the loss function is cross entropy, the final predicted value will be 0. Both dice loss and focal loss can solve the problem of imbalance in data, but focal loss is more effective. When SCL and R-Drop were introduced, R-Drop achieved significantly better results. Legal-BERT can deal with legal vocabulary more thoroughly than other models. Overall, Legal-BERT+R-Drop+focal Loss is the best combination obtained after experiments. The F_1-*score* obtained from the experiments of several models and methods is summarized in Table 1, Table 2, and Table 3, and the result of the best submission is shown in Table 4. Although the sliding window approach helps alleviate the token limitations of Legal-BERT, models specifically designed to handle longer documents, such as Longformer (Beltagy et al., 2020) or Big Bird (Zaheer et al., 2020), might offer superior efficiency. In the future, our team will also use the above model to solve the problem of long text.

4 Conclusion

In this research paper, we introduce a system submitted for evaluation in SemEval-2024 Task 5. Leveraging the powerful pre-trained Legal-BERT

Model	Loss	F_1-*score*	Accuracy
BERT + SCL	Cross-Entropy	0.4437	0.7976
RoBERTa + SCL	Cross-Entropy	0.4437	0.7976
DeBERTa + SCL	Cross-Entropy	0.4437	0.7976
Legal-BERT + SCL	Cross-Entropy	0.4437	0.7976
BERT + SCL	Focal Loss	0.5625	0.6428
RoBERTa + SCL	Focal Loss	0.5460	0.8095
DeBERTa + SCL	Focal Loss	0.4247	0.7381
Legal-BERT + SCL	Focal Loss	0.5296	0.6706
BERT + SCL	Dice Loss	0.4892	0.7302
RoBERTa + SCL	Dice Loss	0.4437	0.7976
DeBERTa + SCL	Dice Loss	0.4437	0.7976
Legal-BERT + SCL	Dice Loss	0.5299	0.6508

Table 2: models and methods.

Model	Loss	F_1-*score*	Accuracy
BERT + R-Drop	Cross-Entropy	0.4437	0.7976
RoBERTa + R-Drop	Cross-Entropy	0.4437	0.7976
DeBERTa + R-Drop	Cross-Entropy	0.4437	0.7976
Legal-BERT + R-Drop	Cross-Entropy	0.4437	0.7976
BERT + R-Drop	Focal Loss	0.5637	0.6746
RoBERTa + R-Drop	Focal Loss	0.4437	0.7976

model as its foundation, our system underwent essential modifications to enhance performance. Specifically, we refined the loss function and incorporated the R-Drop technique to determine the alignment between questions and their corresponding answers accurately. The empirical results obtained from our experiments demonstrate the effectiveness of our proposed system, showcasing its strong performance capabilities. However, when benchmarked against the leading systems in the competition, it becomes evident that there are still notable areas for further improvement. Looking ahead, we are eager to explore the integration of alternative legal-specific models and innovative length text processing strategies. By pursuing these avenues, we aim to achieve even more promising results that can contribute significantly to advancing the field.

Abstract

Emotion Recognition in Conversation (ERC) in the context of code-mixed Hindi-English interactions is a subtask addressed in SemEval-2024 as Task 10. We made our maiden attempt to solve the problem using natural language processing, machine learning and deep learning techniques, that perform well in properly assigning emotions to individual utterances from a predefined collection. The use of well-proven classifier such as Long Short Term Memory networks improve the model's efficacy than the BERT and Glove based models. However, difficulties develop in the subtle arena of emotion-flip reasoning in multi-party discussions, emphasizing the importance of specialized methodologies. Our findings shed light on the intricacies of emotion dynamics in code-mixed languages, pointing to potential areas for further research and refinement in multilingual understanding.

1 Introduction

The ultimate objective of this task EDiReF is to make progress in the field of conversational emotion recognition and reasoning. Analyzing emotions in natural language offers measurable understandings within the typically subjective domain of expressive language, connecting disciplines like psychology, cognition, and linguistics. This focuses on code-mixed Hindi-English dialogues, creating a unique and challenging linguistic setting in which participants must decipher the complexities of emotion recognition (ERC) and emotion flip reasoning (EFR). Code-mixing, or the intentional use of different languages within a single conversation, complicates the process and necessitates novel techniques for effective emotion recognition. This kind of collaborative work is critical because it reflects the changing environment of communication, where diversified language use needs complex models capable of understanding emotions in multilingual discussions resulting in overall development.

Our approach which focuses on the Emotion Recognition in Conversation (ERC) subtask, employs a sophisticated strategy based on deep learning methodologies suited to the intricacies of code-mixed Hindi-English (HI-EN) talks. At its core, our solution employs a Bidirectional Long Short-Term Memory (Bi-LSTM) network, an architecture capable of capturing intricate sequential connections inside text. We chose LSTM as LSTM networks are designed to overcome the limitations of traditional recurrent neural networks (RNNs) by mitigating the vanishing gradient problem and LSTM's ability to retain and selectively update information over time can lead to more accurate predictions of emotional states. We prioritized preprocessing, which includes tokenization and sequence padding, to help the model understand speech contexts. To enhance linguistic representation, the embedding layer is initialized with pre-trained word embeddings. For regularization and addressing overfitting issues, strategically placed dropout layers are incorporated. The training process utilizes categorical cross-entropy loss and the Adam optimizer.

The model showcased proficiency in precisely attributing emotions to individual utterances, showcasing its capability to decipher intricate emotional expressions in a multilingual context. From a quantitative standpoint, our system achieved an accuracy of 0.378 in sentiment analysis and secured the 23rd position among the competing teams. These findings not only provide insights into the model's strengths and areas for improvement but also highlight the importance of specialized mechanisms for complicated emotional connections in multilingual communication such as expanding datasets to encompass a broader range of linguistic and cultural contexts, as well as areas for future research

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 763–769

2 Background

The task at hand focuses on comprehending and categorizing emotions presented in code-mixed Hindi-English interactions. In this context, the input comprises dialogues where individuals communicate in both Hindi and English. The primary aim is to analyze each segment of these interactions and assign a precise emotion from a predefined set to capture nuanced sentiments. For example, throughout a conversation, people may display a variety of emotions at different points, such as joy, sorrow, or rage.

The task comprises two datasets centered around Multi-modal Sarcasm Detection and Humor Classification (MaSac) for sub-tasks 1 and 2, and Multimodal Emotion Lines (MELD) for subtask 3, but this paper majorly focuses on sub-task 1. The datasets for this task consist of code-mixed conversations, reflecting the real-world scenario where individuals seamlessly blend Hindi and English while communicating. The genre of the conversations may vary, encompassing diverse topics and contexts to ensure a comprehensive understanding of emotion dynamics in code-mixed language interactions. The size of the datasets is not explicitly mentioned, but it likely involves a substantial amount of annotated dialogues to train and evaluate emotion recognition models effectively. The dataset consisted of four parameters the episode name, the speakers list, the utterances, and the emotions mapped to the respective utterances. The emotions mapped to the utterances provided a standard for assessing models' performance in recognizing emotional expressions. For example, the utterance "ok, chalo rosesh chalo bahar" was mapped to the emotion "Contempt".

3 Related Work

Arora et al. (Arora et al., 2016) explores the capabilities of deep neural networks (DNN) using rectified linear units (ReLU). It introduces an algorithm for training a ReLU DNN with one hidden layer to global optimality with polynomial runtime in data size. The paper also improves lower bounds for approximating ReLU deep net functions and provides gap theorems for smoothly parametrized families of "hard" functions. Notably, it demonstrates the existence of functions requiring k^3 total nodes in a ReLU DNN with k^2 hidden layers, shedding light on the network's complexity.

Anshul Wadhawan and Akshita Aggarwal et al. (Wadhawan and Aggarwal, 2021) presents a Transformer-based approach for detecting emotions in code-mixed tweets. They introduce a Hinglish dataset, use bilingual word embeddings, and experiment with various models, including CNNs, LSTMs, and transformers like BERT. The BERT model achieves the best accuracy at 71.43%. The paper highlights the importance of emotion detection in social media and multilingual contexts, providing a valuable annotated dataset for future research.

Shivani Kumar et al. (Kumar et al., 2023a; Bedi et al., 2021) delved into Emotion Flip Reasoning (EFR) in multiparty conversations, showcasing state-of-the-art performance against baselines. Their research highlights the significance of EFR in enhancing empathetic response generation and understanding emotional dynamics in conversational settings, thus addressing the gap and providing insights into how specific remarks or expressions affect listeners.

Deepanshu Vijay et al. (Vijay et al., 2018) addresses emotion prediction in Hindi-English code-mixed social media text. They introduce a corpus from Twitter annotated with emotions and source languages. The paper proposes a supervised classification system using machine learning techniques and diverse features for emotion detection, contributing to resources for Hindi-English code-mixed text analysis in multilingual contexts.

In a parallel domain, a study focused on emotion analysis in low resource language Tamil is done by Varsini et al. (S et al., 2022). They have employed a lexicon-based approach and transformer models, utilizing dictionaries of words labeled with emotions. This research specifically addresses the challenges of extracting emotions from low resource texts in social media contexts, offering valuable insights.

Contextual emotion detection is executed using gaussian model and ensemble model by Angel Deborah et al. (Deborah et al., 2022; Angel Deborah et al., 2020). The challenge of contextual emotion detection in natural language processing has been addressed, emphasizing the difficulty for both machines and humans to accurately detect emotions like sadness or disgust in a sentence without sufficient context. The study underscores the growing importance of providing sensible responses in text messaging applications, where digital agents play a prominent role. The research showcases the efficacy of a Gaussian process for detecting contextual

emotions within sentences, comparing its performance with Decision Tree and ensemble models, including Random Forest, AdaBoost, and Gradient Boost.

Emotion recognition in Hindi-English code-mixed data, as explored in relevant papers, employs models like BERT, RoBERTa, CNNs, and LSTMs. The challenges highlighted align with our work, emphasizing the importance of addressing code-mixing complexities and the scarcity of annotated datasets. Similarly, in corpus creation for emotion prediction, the focus on a Twitter-based annotated corpus resonates with our efforts. The shared emphasis on overcoming linguistic diversity and cultural nuances underscores the mutual pursuit of enhanced accuracy in emotion recognition, urging continued research in these aspects.

4 System Overview

To optimise efficiency, we methodically integrated numerous critical algorithms and modelling decisions into our sentiment analysis model.

4.1 Data Preprocessing

4.1.1 Text Cleaning and Tokenization

The initial phase of our sentiment analysis model required thorough dataset preprocessing. The dialogue data (Kumar et al., 2023b, 2024) includes annotations for various emotions expressed by the speakers. These utterances are in both Hindi and English. We used Python's regular expressions and popular natural language processing packages to apply text cleaning techniques. Special characters, numerals, and unnecessary spaces were deleted. The cleaned text was then tokenized with TensorFlow Keras and (Arora, 2020) Indic NLP packages as It provides language-specific tokenization and other preprocessing functionalities tailored to languages spoken in the Indian subcontinent, improving the model's understanding of linguistic nuances.

4.1.2 Language-specific Tokenization

The dataset's multilingual composition necessitated the use of a complex tokenization technique. English utterances were tokenized with (Loper and Bird, 2002) NLTK's word tokenizer which breaks the text into individual words while preserving English language semantics, whereas Hindi text was tokenized with the Indic NLP package. It generates tokens by separating the text into its constituent words or tokens based on the identified boundaries. The goal of this multilingual tokenization technique was to identify and record language-specific patterns that were present across the dataset. The model is able to absorb and comprehend the unique linguistic aspects of both languages in the dataset because of this bilingual tokenization technique.

4.1.3 Stop Word Removal

In order to enhance the model's attention towards meaningful content, we systematically removed stopwords from both Hindi and English text. This important preprocessing step allowed for a more detailed understanding of the underlying sentiment by removing unnecessary noise and refining the raw data. In addition, we consistently converted all text to lowercase for uniformity and better generalization. This approach to preprocessing contributes to the model's robust performance in capturing the intricacies of emotion in code-mixed interactions.

4.1.4 Data Splitting:

The preprocessed data was divided into two parts: the training and the testing sets using the `train_test_split` function from the `scikit-learn` library. This ensures that the model's performance can be evaluated on unseen data, facilitating a thorough assessment of its generalization ability. In this approach, we could closely examine the extent to which our model could process novel, unseen data and see whether it could apply the knowledge it gained to a wider context.

4.2 Model Architecture

4.2.1 Embedding Layer

At the center of our sentiment analysis model is the Embedding layer. It takes tokenized words and transforms them into smart vectors. This layer, configured with an input dimension of `max_words`, an output dimension of 128, and an input length of `max_len`, converts tokenized input sequences into dense vectors that capture semantic associations between words. This layer essentially helps the model understand the deep connections and meanings between words in the input sequences.

4.2.2 Bidirectional LSTM

To capture the sequential dependencies in language effectively, we incorporated a Bidirectional Long Short-Term Memory (LSTM) layer (Staudemeyer and Morris, 2019). With 64 units, this bidirectional architecture facilitates the model in understanding

contextual relationships in both forward and backward directions.

4.2.3 Dense and Dropout Layers

A dense layer of 64 units was inserted sequentially, followed by Rectified Linear Unit (ReLU) activation (Arora et al., 2016). This layer, along with a dropout layer with a rate of 0.5, dramatically improved the model's ability to recognize complicated patterns while reducing overfitting. This is also adds a moderation in the learning process.

4.2.4 Output Layer

Using the softmax activation function (Sharma et al., 2017), the model's output layer successfully classified emotions into distinct categories as it converts the raw output scores of the model into probabilities, indicating the correct classification for the input. This categorical method enabled a more sophisticated comprehension of the diverse attitudes exhibited in the dataset.

In the final act, our model showcased its classification prowess through the output layer. With a touch of softmax activation function (Sharma et al., 2017), it skillfully categorized emotions into distinct categories. This categorical wizardry allowed our model to attain a nuanced understanding of the diverse attitudes presented in the dataset.

4.3 Model Training

4.3.1 Loss Function and Optimizer

The model was built using categorical cross entropy loss function and the Adam optimizer (Zhang and Sabuncu, 2018), known for its efficiency in handling sparse gradients. The rationale behind selecting the categorical crossentropy loss function and the Adam optimizer lies in their proven track record of effectiveness in sentiment analysis endeavors. Categorical cross-entropy performs well in circumstances with several classes, precisely meeting the requirements of sentiment classification with distinct emotion labels. By making the model allocate higher probabilities to the correct class, this loss function fosters more accurate sentiment predictions. This combination was intended to successfully optimize the model's weights, resulting in a robust learning process during training.

4.3.2 Training Parameters

A batch size of 32 and five epochs were used in the training procedure. This configuration produced the ideal training length by striking a balance between model convergence and processing efficiency.

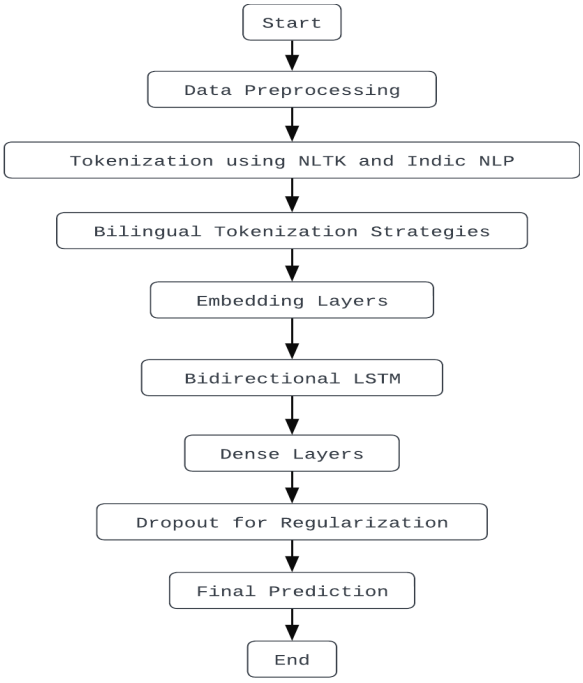

Figure 1: Model Process

4.4 Model Evaluation

4.4.1 Perfomance Metrics

The model's performance was evaluated using metrics including accuracy, loss, and weighted F1 score after training. These metrics provided a comprehensive understanding of how well the model identified emotions in textual input.

4.4.2 Prediction on the Test Set

Emotions on a test set were predicted using the trained model. This step consisted of applying the model to the preprocessed test data and decoding the predicted labels for further examination. The overall process of working is shown in Figure 1.

5 Experimental Setup

The data split used in the given code divides the dataset into training and testing sets. The split ratio is 80% for training data and 20% for testing data, as stated by the code's `test_size` argument of 0.2 to prevent overfitting and perform better on new data.

The learning rate is a crucial hyperparameter that determines the step size during the optimization

process.The learning rate, a key factor in the optimization process, was explored with values such as 0.01, 0.001, and 0.0001. To mitigate overfitting, dropout rates were varied, including options like 0.2 and 0.5

The number of LSTM units in the Bidirectional LSTM layer, a crucial aspect of model capacity, was adjusted with values like 32, 64, and 128. Additionally, the impact of different batch sizes (16, 32, 64) on convergence and computational efficiency was systematically explored.

In our experimental setup, we harnessed the power of scikit-learn for seamless implementation of various machine learning algorithms, handling data preprocessing tasks, and evaluating performance using diverse metrics. The NLTK library, an essential component, efficiently managed critical natural language processing functions, including tokenization, stopwords removal, and stemming.

To ensure model persistence and flexibility, we adopted joblib, a tool adept at saving and loading trained models. Moreover, our approach integrated external tools like NLTK Indic NLP, Scikit-Learn, and TensorFlow to elevate specific components of our sentiment analysis model. This encompassed optimizing tokenization, refining data splitting techniques, streamlining preprocessing steps, and conducting rigorous model evaluations, all contributing to the robustness and effectiveness of our experimental framework.

6 Results

The task is evaluated using the following performance metrics: precision, recall, accuracy and F1-score.

Recall indicates the classifier's ability to identify positive instances accurately and accuracy is defined as the ratio of the correctly predicted instances to the total number of instances in a dataset. It acts as a straightforward for the model's correctness while precision is a measure of how accurate the positive predictions are.

$$Precision = \frac{\text{TP}}{TP + \text{FP}} \quad (1)$$

$$Recall = \frac{\text{TP}}{TP + \text{FN}} \quad (2)$$

$$Accuracy = \frac{\text{TP + TN}}{TP + \text{TN} + \text{FP} + \text{FN}} \quad (3)$$

Approach	Accuracy
Word GloVe	0.35
Dist-Bert	0.30
LSTM Model	0.378

Table 1: Comparison of Accuracy for Different Approaches

$$F1\ Score = \frac{2 \times Precision \times Recall}{Precision + Recall} \quad (4)$$

$$Weighted\ F1\ Score = \sum_{i=1}^{N} W_i \cdot F1\ Score_i \quad (5)$$

The sentiment analysis model demonstrated the performance on the training dataset, achieving an accuracy of 0.39 and weighted F1 score of 0.38. The classification report is shown in Figure 2. On the test set, the model maintained the performance with an accuracy of approximately 0.378 and a weighted F1 score of 0.34 In the competition results, the model secured 23rd position. With LSTM approach, our model achieved an accuracy of 0.378 and secured the 23th position on the rankings. The comparison of various developed models are listed in Table 1.

We used a variety of approaches to improve the accuracy of sentiment analysis. One important approach was using pre-trained word embeddings, such as Word Glove (Rezaeinia et al., 2019), which captures semantic associations between words. The use of Word GloVe embeddings enabled a decent comprehension of contextual nuances, which contributed to increased sentiment analysis results with a F1 Score of about 0.35. While we initially explored the use of Word GloVe embeddings, we found that other methodologies yielded better results for our specific task. Therefore, we transitioned away from Word GloVe embeddings and pursued alternative approaches that demonstrated improved performance in managing the challenges associated with dual tokenization in mixed-language conversations. We also attempted to develop DistBERT, a transformer model, but faced a difficult case in which its integration resulted in an underwhelming F1 score of 0.30. This unexpected outcome spurred a rethinking of the implementation, prompting us to investigate alternate tactics and optimisations to improve the model's effectiveness.

	precision	recall	f1-score	support
anger	0.21	0.21	0.21	168
contempt	0.15	0.14	0.15	119
disgust	0.00	0.00	0.00	28
fear	0.14	0.11	0.12	83
joy	0.35	0.36	0.35	313
neutral	0.53	0.58	0.55	801
sadness	0.12	0.11	0.11	107
surprise	0.31	0.23	0.26	83
accuracy			0.39	1702
macro avg	0.23	0.22	0.22	1702
weighted avg	0.38	0.39	0.38	1702

Figure 2: Classification Report

Owing to the model's training on the restricted quantity of available data, it exhibits a bias towards specific emotions. "Okay chaliye dad, mein aapko bahar fenk kar aata hun!" is an example of a statement that should be predicted as "Joy," instead it is predicted as "neutral." The reason for the model's behaviour is that a lot of utterances are mapped to the neutral emotion; as a result, when a model is trained on this kind of data, it naturally becomes biased towards such emotion types.

In addition, a thorough analysis of the classification reports shed additional light on the theory on how class imbalances affect the model's functionality. As can be seen from the performance measures that were previously addressed, there are significant differences in the weighted and macro F1-scores, even if the classifiers' accuracy is the same for all datasets that were used. In particular, the sentiment analysis model performs noticeably better on the Hindi-English code-mixed dataset than on the Hindi and English monolingual datasets, highlighting the difficulties caused by the imbalances in the latter. This limitation is particularly notable for emotions with limited representation in the training data, emphasizing the need for strategies to address imbalances and improve the models' robustness across diverse linguistic scenarios.

7 Conclusion

We lay out a sentiment analysis system that can handle Hindi-English talks with mixed codes. Recognising and rationalising emotions in a bilingual environment was the main goal. The results show that the participants performed competitively in terms of emotion perception and reasoning, especially when there was frequent language change. The model using LSTM layers, NLTK Indic NLP provided the best result of 0.36 F1 score. Subtle emotional cues and particular code-mixing patterns continue to provide difficulties, nevertheless. Our method is noteworthy for its hybrid approach, which makes use of sentiment analysis, contextual embedding techniques, and language models that have already been trained and refined using code-mixed datasets.

It is still imperative to address specifics in low-resource languages in future development. Techniques like compiling lists of language-specific stop words have shown to be effective. Moreover, the effect of class disparities on the model's functionality is recognized. Furthermore, the effect of class imbalances on the performance of the model is recognized. Subsequent research could investigate customized approaches, including data enrichment or clustering techniques, to address these imbalances and improve the model's flexibility in a variety of language circumstances unique to our code.

Abstract

The goal of Emotion Cause Pair Extraction (ECPE) is to explore the causes of emotion changes and what causes a certain emotion. This paper proposes a three-step learning approach for the task of Textual Emotion-Cause Pair Extraction in Conversations in SemEval-2024 Task 3, named ECSP. We firstly perform data preprocessing operations on the original dataset to construct negative samples. Secondly, we use a pre-trained model to construct token sequence representations with contextual information to obtain emotion prediction. Thirdly, we regard the textual emotion-cause pair extraction task as a machine reading comprehension task, and fine-tune two pre-trained models, RoBERTa and SpanBERT. Our results have achieved good results in the official rankings, ranking 3rd under the strict match with the *Strict F1-score* of 15.18%, which further shows that our system has a robust performance.

1 Introduction

Emotions are innate to humans and significantly affect people's social interactions, decision-making, and cognition. People are becoming more interested in developing human-like reactions as social media evolves. Therefore, the recognition of emotions in the text is an important topic in natural language processing and its applications (Zhao et al., 2016). In addition to emotion recognition, the research on the cause behind emotions in conversation scenarios is more complex, such as customer support, mental health care, human-computer interaction, etc (Wang et al., 2023b). Thus, it is important to recognize the potential cause behind an individual's emotional state, i.e., Emotion Cause Analysis (ECA). [1]

In recent research, Xia and Ding (2019) proposed the Emotion Cause Pair Extraction (ECPE) task, which is used to automatically predict emotions in documents and recognize the corresponding causes of those emotions. This task has attracted attention from a number of academics (Ding et al., 2020; Wei et al., 2020; Chen et al., 2020). However, the ECPE task studies the emotion-cause relationship of specific events in the document, while in the conversational scene, due to the interaction of multiple speakers, the dialogue contains more diverse and richer emotional expressions, which makes the conversation continue to advance as the conversation progresses. Emotions are also constantly changing, and the emotion of one utterance may be caused by multiple utterances.

In this paper, we propose a three-step learning approach, **E**motion-**C**ause-**S**pan **P**air Extraction in Conversation (**ECSP**), for Subtask 1 of SemEval-2024 Task 3: Textual Emotion-Cause Pair Extraction in Conversations. ECSP consists of three modules: the data preprocessing module, the emotion classification module, and the textual emotion-cause pair extraction module. We first preprocessed the dataset to obtain a large number of negative examples. Then, the pre-trained model BERT is used to construct token sequence representations with contextual information that are fed into a feed-forward neural network layer for emotion prediction. In the textual emotion-cause pair extraction module, in order to obtain causal span, we fine-tuned pre-trained models such as RoBERTa and SpanBERT to make it a machine reading comprehension (MRC) task (Poria et al., 2021).

In the official ranking, our team ranked 3rd under the strict match with the *Strict F1-score* of 15.18%, and ranked 7th under the Proportional match with the *Proportional F1-score* of 19.63%.

[1] Description of the task by the organizer of SemEval-2024 Task 3

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 770–776

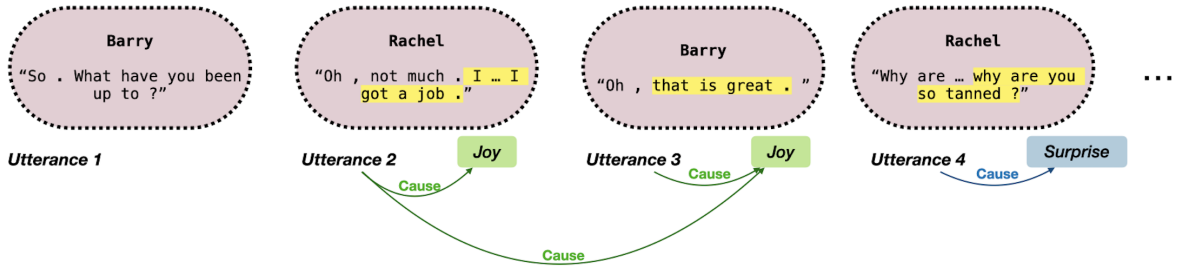

Figure 1: Description of the task of textual emotion-cause pair extraction in conversations.

2 Background

2.1 Task Definition

As shown in Figure 1, the task of textual emotion-cause pair extraction in conversations aims to extract all emotion-cause pairs in a given conversation based entirely on text and mark the specific causal span of the emotion cause (Wang et al., 2024).

Input: A conversation containing the speaker and the text of each utterance. Represented as the content in the pink rectangular box in Figure 1.

Output: All predicted emotion-cause pairs, where each pair contains an emotion utterance along with its emotion category and the textual cause span in a specific cause utterance. The utterance pointed by the curve to the emotion in the Figure 1 is the cause utterance of the emotion, and the yellow background text fragment is a specific textual cause span.

2.2 Related Work

Emotions always play a vital role in information exchange, from the communication between human individuals in the real world to the human-computer interaction in the virtual world. Recognizing emotion categories in text is an essential task in NLP and its applications (Zhao et al., 2016). In addition, the causes of emotions play a key role in human-computer interaction and customer service systems, which can provide important information on the reason for any emotion changes.

The aim of Emotion Cause Extraction (ECE) is to explore the causes of emotion changes and what causes a certain emotion (Chen et al., 2010). Xia and Ding (2019) reformed ECE into ECPE (Emotion-Cause Pair Extraction), aiming to extract potential emotions and corresponding causes from documents simultaneously.

Since ECPE does not fully consider the correlation between emotional utterances and causal utterances and the limited availability of background, Shan and Zhu (2020) proposed an Inter-EC model with self-attention, which optimized the interactive multi-task network model. Cheng et al. (2021) reconstructed the emotion-cause pair extraction task into the classification problem of candidate sentence pairs and proposed a goal-oriented, unified sequence-to-sequence model. Poria et al. (2021) constructed a dialogue-level dataset RECCON and introduced a task highly relevant for (explainable) emotion-aware to address causal span extraction and causal emotion entailment.

3 System Overview

In order to implement the task of textual emotion-cause pair extraction in conversations, we have designed the ECSP approach, which contains three main modules, namely data preprocessing, emotion classification, and textual emotion-cause pair extraction.

Firstly, in the data preprocessing module, the dataset is preprocessed to obtain a large number of negative samples. Then the pre-trained model BERT is used to convert token sequences with contextual information in the conversation into semantic representations and predict emotions in the emotion classification module. Finally, textual emotion-cause pairs are extracted based on the predicted emotions in the textual emotion-cause pair extraction module.

The overall architecture of ECSP system is shown in Figure 2, and the detailed description for each part is presented as follows.

3.1 Data Preprocessing Module

Since the original dataset only contains positive examples, i.e., utterances containing emotions, which are annotated using causal spans extracted from the historical context of the conversation, we designed the data preprocessing module to provide a large

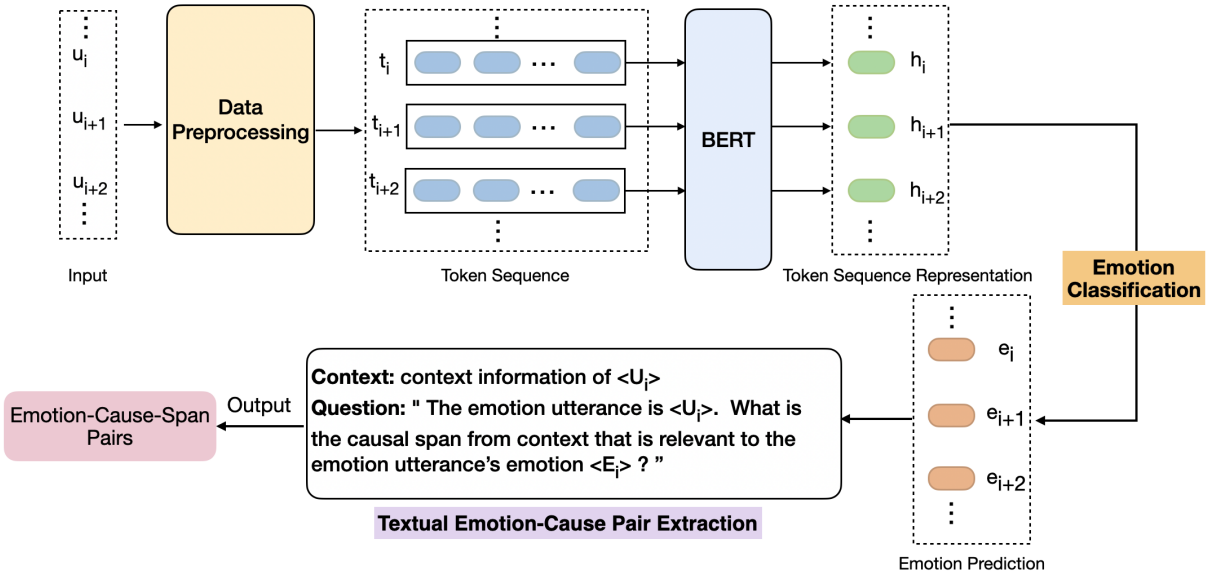

Figure 2: The overall architecture of ECSP consists of three parts: data preprocessing, emotion classification, and textual emotion-cause pair extraction. After preprocessing the origin dataset, BERT is utilized to transform the token sequence with contextual information in the conversation into a semantic representation and predict emotions. Then, extract textual emotion-cause pairs.

Dataset	Train	Val	Test
Positive Samples	7093	900	900
Negative Samples	36778	4247	4247

Table 1: Statistics of the preprocessed dataset, including positive and negative samples.

number of negative examples in which the cause is not expressed in order to better train the model to recognize emotional causes in conversation tasks.

Considering dialogue D and an emotion utterance U_i in D, we construct the complete set of negative examples as $\{U_{Neg}|U_{Neg} \in H(U_i) \setminus C(U_i)\}$, where $H(U_i)$ is the conversational history and $C(U_i)$ is the set of cause utterances for U_i.

Table 1 shows the statistics of the preprocessed dataset.

3.2 Emotion Classification Module

Without the loss of generality, the input can be represented by several utterances, $D = \{U_1, ..., U_i, ...U_n\}$. In our system, BERT is used to build the token sequence representations. Each token sequence is enveloped by predefined special tokens ($[CLS]$, $[SEP]$), $t_i^{'} = \{[CLS], w_{i1}, ..., w_{ik}, [SEP]\}$, where w_{ik} is the k-th token in the i-th utterance's token sequence. The [CLS] token is used for generating representations for classification tasks. The [SEP] token is used to denote the end of a sentence. The utterance's representation h_i is acquired through BERT, which is the final hidden state of [CLS].

$$h_i = BERT(t_i^{'}) \tag{1}$$

The token sequence representation h_i is fed into the Feed-Forward Neural Network (FFNN) layer to obtain the emotion prediction E_i.

$$E_i = Softmax(W^e h_i + b^e) \tag{2}$$

where W^e is a weight and b^e is a bias of the emotion classification layer, respectively.

3.3 Textual Emotion-Cause Pair Extraction Module

In order to implement the extraction of textual span in the ECPE task, we regard this module as a machine reading comprehension (MRC) task. The specific task is defined as follows:

Context: *Context* is the context information $U_j (j \in [1, i])$ of emotion utterance U_i, which is the traversal of all utterances in U_i's conversation history $H(U_i)$.

Question: The *Question* is framed as follows: *" The emotion utterance is $< U_i >$. What is the causal span from the context that causes the emotion $< E_i >$ of the emotion utterance? "*

Answer: The causal span $S \in CS(U_i)$ appearing in U_j if $U_j \in C(U_i)$. For negative examples, S is assigned an empty string.

Among them, emotion utterance U_i is the i-th utterance in dialogue D. $H(Ui)$ is the conversation history set of U_i, a set of all utterances from the beginning of the conversation till the utterance U_i, including U_i. $U_j \in H(U_i)$ is the context of U_i. $C(U_i)$ is the set of cause utterances of U_i, $C(U_i) \in H(U_i)$. $CS(U_i)$ is the cause span set of U_i.

3.4 Loss Function

Loss function is used to evaluate the extent to which the predicted and true values of the model are not the same. For different models and different tasks, the choice of loss function has a great impact on the performance of the model. In this task, the focal loss function is used to better alleviate the problem of unbalanced number of sample categories.

The goal of Focal Loss (Lin et al., 2017) is to address the issue where traditional cross-entropy loss contributes less to the loss of positive samples when there are a large number of easily classified negative samples. The adoption of the focal loss alleviates this issue by balancing the weight assigned to minority classes, facilitating the learning process (Wang et al., 2022).

$$BCEloss(o,t) = -\frac{1}{n}\sum_{i}\Big(t[i]\log(o[i]) + (1-t[i])\log(1-o[i])\Big) \quad (3)$$

As shown in formula 3, we use balance factor to deal with data imbalance in Balance Cross Entropy loss(BCEloss).

$$FL(p_t) = -\alpha_t(1-p_t)^{\gamma}\log(p_t) \quad (4)$$

Focal loss reduces the loss weight of easily distinguishable negative samples and increases the dynamic adjustment factor based on BCEloss to achieve the effect of mining difficult samples. We make the model more focused on hard-to-learn samples by setting γ value as 2 in the formula 4, thus the network will not be biased by too many negative examples.

4 Experiments

4.1 Dataset

The SemEval-2024 Task 3 dataset is ECF (Wang et al., 2023a), which contains 1,344 conversations and 13,509 utterances. As shown in Table 2, 55.73% of utterances are labeled with emotion categories, 91.34% of emotions are labeled with corresponding cause, and the same emotion may be caused by multiple cause utterances (the number of emotion-cause pairs is greater than the number of emotion with cause).

Filed	Number
No. of conversations	1,344
No. of utterances	13,509
No. of emotion (utterances)	7,528
No. of emotion (utterances) with cause	6,876
No. of emotion-cause (utterance) pairs	9,272

Table 2: Statistics of ECF dataset.

For each emotion category, the proportion of emotion utterances with reason annotations is shown in Figure 3.

We split the original dataset into 80% train set, 10% valid set, and 10% test set.

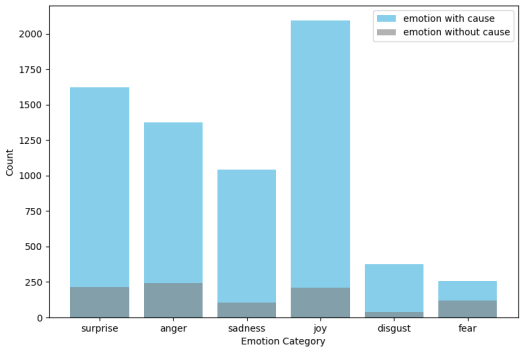

Figure 3: The distribution of emotions (with/ without cause) in different categories.

4.2 Baselines

In our experimental setup, we assume that emotion-cause pairs have two settings:

- Only non-neutral emotional utterances are recognized.
- The cause of emotion only exists in previous or current utterances because speakers cannot predict future utterances in conversational scenarios.

As to the emotion classification module, we used the pre-trained model BERT to obtain the semantic embedding of the input utterance.

BERT: BERT is a deep pre-trained language model based on the Transformer architecture. Devlin et al. (2018) used the Masked Language Model (MLM) to learn rich language representations and achieve SOTA performance in various downstream

Model		Strict			Proportional		
		P(%)	R(%)	F1(%)	P(%)	R(%)	F1(%)
w/o context	RoBERTa	16.30	12.19	13.57	21.17	17.49	18.42
	SpanBERT	15.03	13.92	13.72	19.33	20.33	18.71
with context	RoBERTa	**18.35**	12.63	14.63	**22.34**	17.51	19.06
	SpanBERT	17.56	**14.41**	**15.18** (3/16)	20.94	**20.20**	**19.63** (7/16)

Table 3: Experimental results of textual emotion-cause pair extraction task. Shown in ( ) is the official ranking.

tasks. In the emotion classification task, we added contextual information to each utterance such that each utterance contains all its previous utterances as context, then used the BERT tokenizer to generate the input tensor of the emotion classification model, encoded it by BERT, and used a linear layer to predict emotions.

As to the textual emotion-cause pair extraction module, we fine-tuned two pre-trained models: RoBERTa and SpanBERT.

RoBERTa: RoBERTa (Liu et al., 2019) is an improved version of the BERT model, adopting more model parameters, more training data, and larger batch sizes. We used a Roberta-base model and added a linear layer on top of the hidden state to calculate the start and end logic of the span.

SpanBERT: SpanBERT (Joshi et al., 2020) is based on BERT, has made specific optimizations in the pre-training stage for the task of predicting spans of text, and has excellent performance in question and answer tasks. We used the SpanBERT-base model fine-tuned on the SQuAD 2.0 dataset as the second baseline model for the textual emotion-cause pair extraction task.

We utilized the PyTorch library (Paszke et al., 2019) and the HuggingFace library (Wolf et al., 2020) on our models and trained and tested them on the Nvidia A800-40G.

4.3 Evaluation Metrics

Since the task of textual emotion-cause pair extraction involves the textual cause span, the organizers of SemEval-2024 Task 3[2] adopted two strategies to determine whether the span is extracted correctly (Wang et al., 2024):

- **Strict Match**: The predicted span should be exactly the same as the annotated span.
- **Proportional Match**: Considering the overlap proportion between the predict span and the annotated one.

[2]https://github.com/NUSTM/SemEval-2024_ECAC

For the **Strict Match**, we firstly evaluate the emotion-cause pairs of each emotion category separately and then further calculate a weighted average of Strict F1-scores across the six emotion categories.

$$\text{Strict}F1 = \sum_{j=1}^{6} w^j \text{Strict}F1^j \tag{5}$$

Where w_j denotes the proportion of the annotated pairs with emotion category j, $j \in \{anger, disgust, fear, joy, sadness, surprise\}$.

For the **Proportional Match**, match each predicted pair with one of the annotated pairs that has the maximum overlap proportion in terms of the cause span (if the predicted span overlaps with multiple annotated spans):

$$overlap_i = \begin{cases} len(ps_i \cap as_k) & [eu_i, ec_i, cu_i] \\ & \text{are correct and} \\ & ps_i \cap as_k \neq \phi, \\ 0 & \text{otherwise,} \end{cases} \tag{6}$$

$$k = \arg\max_t \frac{len(ps_i \cap as_t)}{len(as_t)} \tag{7}$$

where $len(*)$ denotes the number of textual tokens, ps_i and as_k represent the cause span in the predicted pair pp_i and the annotated pair ap_k respectively. Then the proportional F1-score is calculated based on the overlap length between the predicted span and the annotated span, and a weighted average of the six emotion categories is also calculated.

$$\text{Proportional}F1 = \sum_{j=1}^{6} w^j \text{Proportional}F1^j \tag{8}$$

In the SemEval-2024 Task 3, the organizers initially selected the *Strict F1-score* as the main ranking metric. Due to poor overall results, they eventually switched to using the *Proportional F1-score* as

the main ranking indicator. This also shows that it is very difficult to extract the accurate textual cause span of emotion utterances.

4.4 Results

The experimental results of our work are given in Table 3. As shown in the table, we conducted experiments based on whether to add contextual information to the emotion classification module and gave the performance of two baseline models for the textual emotion-cause extraction task under strict match and proportional match, respectively. Among them, the SpanBERT model using the contextual information emotion prediction module achieved the best performance, with the *Strict F1-score* of 15.18% and the *Proportional F1-score* of 19.63%.

In addition, we draw the following observations:

- Firstly, the context of whole dialogue is curcial for the prediction of causal spans. When contextual information is added to the input utterances in the emotion classification module, the overall performance of the model will be improved to a certain extent. In the RoBERTa model, after adding contextual information, the *Proportional F1-score* increased by 1.36%, and the *Strict F1-score* increased by 1.06%. In the SpanBERT model, the *Proportional F1-score* increased by 0.92%, and the *Strict F1-score* increased by 1.46%.

- Secondly, it can be seen from the experimental results that the SpanBERT model always achieved good performance compared with the RoBERTa model in the textual emotion-cause pair extraction task. When there is no context information in the emotion extraction module, the *Strict F1-score* of the SpanBERT model is 0.12% higher than the RoBERTa model, and the *Proportional F1-score* is 0.29% higher. When there is context information in the emotion extraction module, the *Strict F1-score* of the SpanBERT model is 0.55% higher than the RoBERTa model, and the *Proportional F1-score* is 0.57% higher.

In the official ranking, our team used the three-step learning approach ECSP, which consists of an emotion classification module with contextual information and a textual emotion-cause pair extraction module with SpanBERT as the baseline. The ranking obtained is shown in Table 3. Among them, our team ranked 3rd under the strict match with the *Strict F1-score* of 15.18%, and ranked 7th under the Proportional match with the *Proportional F1-score* of 19.63%.

5 Conclusion

In this paper, we introduce the system implementation of SemEval-2024 Task 3: Textual Emotion-Cause Pair Extraction in Conversations. We propose an integrated system named Emotion-Cause-Span Pair Extraction in Conversation (ECSP), which was implemented in three modules: preprocessing data, emotion classification with contextual information input, and textual emotion-cause pair extraction, and it performed well in the official rankings. In the future, we will utilize this dataset to investigate if the *Speaker* attribute affects the extraction task of emotion-cause pairs, as well as to implement methods such as external knowledge bases to improve our system's recognition performance on ECPE tasks.

Abstract

This paper describes the application of fine-tuning pre-trained models for SemEval-2024 Task 10: Emotion Discovery and Reasoning its Flip in Conversation (EDiReF), which requires the prediction of emotions for each utterance in a conversation and the identification of sentences where an emotional flip occurs. This model is built on the DeBERTa transformer model and enhanced for emotion detection and flip reasoning in conversations. It employs specific separators for utterance processing and utilizes specific padding to handle variable-length inputs. Methods such as R-drop, back translation, and focal loss are also employed in the training of my model. The model achieved specific results on the competition's official leaderboard. The code of this paper is available at https://github.com/jiaowoobjiuhao/SemEval-2024-task10.

1 Introduction

Navigating the complexities of emotional dynamics within conversations presents a formidable challenge in natural language processing (NLP). Human interactions are characterized by rapid emotional shifts, influenced by context and subtle linguistic nuances, requiring sophisticated models for accurate capture and interpretation. Thus, understanding and precisely identifying emotions, especially within conversations marked by emotional transitions, is a significant and challenging endeavor in NLP research.

The SemEval-2024 competition introduces the Emotion Discovery and Reasoning its Flip in Conversations (EDiReF) task (Kumar et al., 2024), divided into three subtasks designed to explore the nuanced landscape of emotional dynamics within dialogues:

- Subtask 1: Identify and classify the emotional states expressed in each utterance within a conversation (Kumar et al., 2023a). As shown in Table 1, the emotion of each utterance is identified through the first two columns.
- Subtask 2: Identify specific utterances that mark an emotional transition within Hindi-English code-mixed dialogues (Kumar et al., 2022, 2023b). As shown in Table 1, the triggers of emotions are identified through the first three columns.
- Subtask 3: Identify specific utterances that mark an emotional transition within English conversations (Kumar et al., 2022, 2023b). The first three columns in Table 1 identify emotional reversal triggers.

In the previous sentiment analysis work, various hand-crafted features and sentiment lexicons were utilized to construct solution systems. These systems were developed by integrating traditional methods such as Naive Bayes, Support Vector Machines (SVM) (Mohammad et al., 2013), and Decision Trees (Blake, 2007). Following the advent of deep learning, Convolutional Neural Networks (CNNs) (Kim, 2014), based on Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997)architectures, were employed for sentence classification tasks. Additionally, GloVe (Pennington et al., 2014) was utilized for learning sentence features, and Bidirectional Long Short-Term Memory (Bi-LSTM) (Kong et al., 2020; Zhang et al., 2018) models were applied to sentence classification to enhance performance. However, these methods encountered challenges in effectively capturing the contextual information of longer texts. With the progression toward larger models, BERT-based large-scale pre-training models marked a significant breakthrough in sentiment analysis (Zheng et al., 2022)

This study proposes a deep learning system for Task 10 in SemEval-2024. We use a

Table 1: Examples of EDiReF

decoding-enhanced bert with disentangled attention(DeBERTa) (He et al., 2020)sequence classification model as the base model. Our enhancement to the DeBERTa model introduces a pivotal integration of specialized mechanisms for processing [SEP] tokens and handling label padding with -1, along with the innovative incorporation of a KL divergence (Wu et al., 2021) loss function, known as R-drop. This strategic amalgamation ensures that each utterance within a conversation is precisely mapped to its corresponding emotional state, facilitating a more accurate representation of emotional dynamics. Introducing R-drop is critical in preventing overfitting by enforcing consistency between the model's outputs for various data sub-samples, thus enhancing the model's generalization ability across different conversational contexts. The contributions of this study are as follows.

- We introduce a foundational model utilizing a pre-trained Deberta sequence classification model for the label sequence classification issue.
- Incorporation of KL Divergence Loss (R-drop) for Overfitting Prevention and adoption of focal loss to address data imbalance issues.
- The model employs [SEP] tokens and -1 padding to align utterances with their corresponding labels and grasp the context within conversations.

The remainder of this paper is organized as follows: Section 2 provides an overview of our proposed model and system. Section 3 conducted the experiments to analyze the effectiveness of the proposed method. The paper concludes with a summary and reflections in Section 4.

2 System Description

This section delves into the architecture of the proposed model, detailing its essential components:

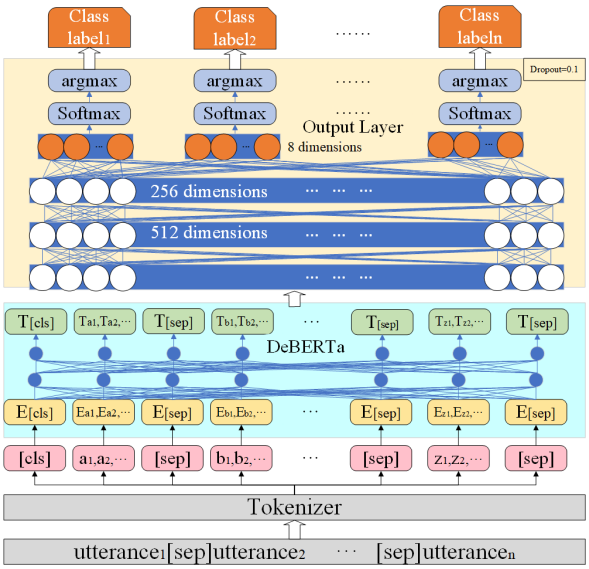

Figure 1: Multi-emotion label sequence classification model

the tokenizer, the pre-trained Deberta model, and the implementation of Regularized Dropout and Focal loss for Neural Networks. Specifically, the model tailored for Task 1, which addresses the multi-label sequence classification problem, is illustrated in Figure 1. Meanwhile, the models designed for Tasks 2 and 3, focusing on binary sequence classification issues, are depicted in Figure 2.

2.1 Tokenizer

Transforming raw text into a machine-readable format is a preliminary step for many NLP tasks. To achieve this, a tokenizer is utilized, segmenting the text into discrete elements and encoding them uniquely. In our model, the DeBERTa tokenizer, mainly designed for handling long texts in sequence classification challenges, is employed to process the text for NLP tasks. Input texts are segmented to accommodate the extensive length of dialogues in subtasks 1 and 2 using a 2048 token cutoff, ensuring comprehensive coverage of conversa-

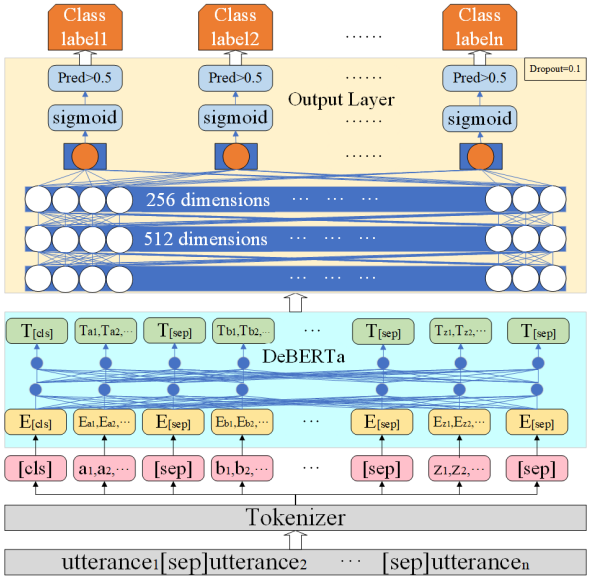

Figure 2: Binary label sequence classification model

tions without truncating critical emotional context in later utterances. For subtask 3, a 1024 token limit is applied, optimizing for shorter textual inputs. The final output X of the tokenizer is denoted as:

$$X = [CLS]\, a_1 \cdots a_n\, [SEP]\, b_1 \cdots b_m\, [SEP] \cdots z_1 \cdots z_p\, [SEP] \tag{1}$$

where n, m, and p denote the lengths of distinct utterances within the dialogue. With [CLS] marking the start and [SEP] serving as a delimiter between utterances, it ensures the model recognizes dialogue flow. For subtasks 1 and 2, sequences shorter than 2048 tokens are padded with zeros, and longer ones are truncated to maintain this limit, optimizing for more extended dialogues. Conversely, subtask 3 employs a 1024 token threshold, adjusting for its specific data structure and requirements.

2.2 DeBERTa Model

DeBERTa enhances BERT's (Devlin et al., 2019) architecture by introducing disentangled attention and an enhanced mask decoder, making it highly suitable for complex dialogue tasks requiring a detailed understanding of context and word positions. Like BERT, DeBERTa comprises two core components: an Embedding block for initial word vector representation and a Transformer Encoder block for deep contextual processing. Additionally, DeBERTa introduces a third major component, the Enhanced Mask Decoder (EMD).

Following the tokenizer's segmentation of input texts and incorporation of special tokens ([CLS] and [SEP]), these tokens are embedded, capturing the nuances of words as vectors that signify their meanings and relationships. The Transformer Encoder further processes these vectors by employing disentangled attention to analyze dialogues' contextual relationships and depth intricately. The EMD, leveraging content and positional information, refines the model's ability to predict and understand masked language elements, thoroughly comprehending dialogue intricacies. Consequently, the final layer's hidden state representation, denoted as H_L, is passed to the output layer, where L represents the number of layers in the Transformer.

2.3 Output Layer

Subtask1. This subtask involves multi-sequence sentiment classification, with the model designed to recognize [sep] and label padding of -1. This setup allows for processing the DeBERTa model's sequence output through a custom classifier, generating logits for each utterance to predict labels, detailed in section 3. The layer initially maps the data dimensions from L to 512 dimensions, then applies the ReLU activation function and dropout to refine and classify the data further, followed by mapping from 512 to 256 dimensions, adding ReLU and Dropout again, and finally mapping to the label dimension (8 dimensions) to obtain logits. After obtaining the classification probability distribution P , calculate the loss with the real classification label y and learn the model weight. The calculation formula of the probability distribution is as follows.

$$P = softmax\left(W_0 H_0 + b_0\right) \tag{2}$$

where W_0 is the weight matrix of the final linear layer, with dimensions of $R^{8\times256}$, H_0 is the feature vector input to this linear layer, with a dimensionality of 256; and b_0 is the bias term, with a dimensionality of 8.

Subtask2&subtask3. These two subtasks involve binary sequence classification, where the main difference in the output layer from subtask 1 is the transformation of the model's output logits into probabilistic classifications through a sigmoid layer. The calculation formula of the probability distribution is as follows.

$$P = sigmoid\left(W_1 H_1 + b_1\right) \tag{3}$$

where W_1 is the weight matrix of the final linear layer, with dimensions of $R^{1\times256}$, H_1 is the feature vector input to this linear layer, with a dimensionality of 256, and b_1 is the bias term, with a dimensionality of 8.

2.4 Methods

Regularized Dropout. Due to the existence of dropout, the same model with identical inputs will produce two distinct distributions, effectively treating them as two different network models. Denoted as $P_\theta(y|x)$ and $P_\theta^{'}(y|x)$, these distributions represent the output probabilities of the model under dropout conditions. The primary objective of R-Drop is to minimize the KL Divergence between these two distributions throughout the training process. Given the asymmetry of KL divergence, a globally symmetric version is indirectly employed by interchanging the positions of these distributions, a concept known as bidirectional KL divergence. Furthermore, the model is trained on both distributions' negative log-likelihood (NLL) loss terms. Given (x_i, y_i) as training set input ,The final loss is as follows:

$$\begin{aligned} L_{KL}^i &= \alpha \Big[D_{KL}\left(P_\theta(y_i|x_i)||P_\theta^{'}(y_i|x_i)\right) \\ &\quad + D_{KL}\left(P_\theta^{'}(y_i|x_i)||P_\theta(y_i|x_i)\right)\Big] \\ L_{NLL}^i &= -\log P_\theta(y_i|x_i) - \log P_\theta^{'}(y_i|x_i) \\ L_{R-drop}^i &= L_{KL} + L_{NLL} \end{aligned} \tag{4}$$

Focal Loss. Focal Loss (Lin et al., 2017) is utilized in our model as the primary loss function, specifically designed to mitigate the impact of class imbalance by dynamically adjusting the importance of each class and the difficulty of each sample. Two parameters α and γ are introduced to modulate each class's loss contribution and focus more on challenging, misclassified samples rather than those easily classified. P_t represents the probability of class t output by softmax or sigmoid function and α_t is a training parameter. The formula is listed as follows.

$$FL\left(P_t\right) = -\alpha_t(1-P_t)^\gamma \log\left(P_t\right) \tag{5}$$

3 Experimental Results

3.1 Datasets

The training sets for these three subtasks are derived from dialogues in various scenarios within TV dramas. In subtask 1, 343 training sets are provided, including four columns: episode, speakers, emotions, and utterances, with eight types of emotions contained within the emotions column. For subtasks 2 and 3, 4893 and 4000 training sets are provided, each with an additional column named triggers compared to subtask 1.

3.2 Evaluation Metrics

The evaluation tools employed for these three subtasks are Precision, Recall, and Micro-F1, with their formulas categorized as follows:

$$\begin{aligned} Precision &= \frac{TP}{TP+FP} \\ Recall &= \frac{TP}{TP+FN} \\ F1 &= \frac{2\times Precision \times Recall}{Precision + Recall} \end{aligned} \tag{6}$$

3.3 Implementation Details

Training Set Preprocessing. To align each utterance with its label throughout an entire dialogue and to learn the relationships within the dialogue, each dialogue is separated by [sep]. The label data are filled with -1 to match the maximum number of utterances in the training and validation sets, and a mask is incorporated into the model. This approach ensures that labels marked as -1 are excluded from loss calculation, allowing the model to handle dialogues of varying lengths. Specifically, the maximum number of utterances for subtasks 1 and 2 is 106, while for subtask 3, it is 24. The labels for subtask 1 are emotions, with eight types: anger, contempt, disgust, fear, joy, neutral, sadness, and surprise. These are mapped to data values 0-7, facilitating correct processing by the model. For subtasks 2 and 3, initially in string format as 0 and 1, the label data are converted to floating-point numbers 0.0 and 1.0. Given the limited training dataset for subtask 1, data cleaning and normalization are first performed using ekphrasis, which improves the model's learning from dialogues. Text augmentation is then conducted through back-translation (Edunov et al., 2018) and synonym replacement; Hindi dialogues are translated into English and then back, while the process is reversed for English dialogues. Synonym replacement involves exchanging words with the same meaning for different expressions. Finally, subtask 1 is expanded to 1029 training sets.

Imbalanced Data Handling. Due to the predominant proportion of neutral and joy labels in subtask

contempt	542
disgust	127
fear	514
joy	1596
neutral	3909
sadness	558
surprise	441

Table 2: Occurrences of Emotional Labels in Subtask

1, as illustrated by the quantities in Table 2, as well as the prevalence of the 0.0 label in subtasks 2 and 3, focal loss and oversampling methods (Chawla et al., 2002) have been utilized. This approach enables the model to learn more effectively from samples that appear less frequently, thereby enhancing the model's performance.

Prediction Challenges. When tokenizing text inputs, lengths of 2048 were selected for truncation in subtasks 1 and 2, while 1024 was chosen for subtask 3. However, during the prediction phase for subtask 2, the number of labels predicted fell short of the expected count. This shortfall could be attributed to dialogues in the test set that exceed the maximum length of 2048. The constraints posed by GPU capabilities also resulted in our model's inability to fully perform the prediction task for subtask 2. We hope to try using Longformer (Beltagy et al., 2020) to address the issue of long dialogues in the future.

Model Comparison. For all tasks, `bert-base-cased`, `bert-large-cased`, `deberta-base`, and `debertav2-xlarge` were compared. When employing the `debertav2-xlarge` model, the AdaLoRA (Zhang et al., 2023) model was used for fine-tuning to prevent exceeding the GPU memory limits.

Optimizer and Loss Parameter Configuration. The AdamW (Loshchilov and Hutter, 2017) optimization was employed to train the model across all subtasks, with a batch size of 1. To achieve the expected results, we experimented with different learning rates and epochs to observe their impact on the F1 score for Subtask 1 using the deberta-base model. Figures 3 and 4 are presented below. For subtask 1, the learning rate for AdamW was set at 5e-6, while for subtasks 2 and 3, it was established at 5e-5. Focal loss parameters for subtask 1 were defined as alpha=0.1 and gamma=0.3, while for subtasks 2 and 3, the parameters were set to

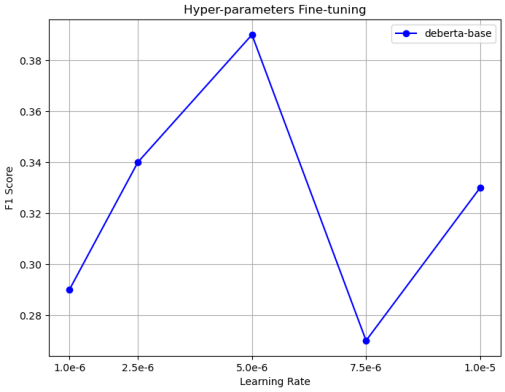

Figure 3: The impact of different learning rates on the F1 score for Subtask 1

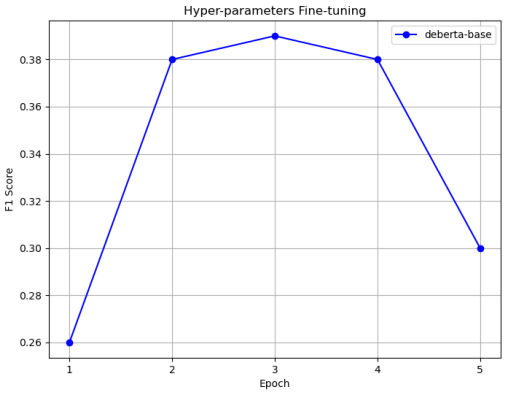

Figure 4: The impact of different learning rates on the F1 score for Subtask 1

alpha=1 and gamma=5.

3.4 Results and Analysis

Subtask1. Validation set results for different models for the multi-label sequence classification task are presented in Table 4. Performance increases from the bert to the DeBERTa phase, yet a significant decline occurs at the `debertav2-xlarge` model phase. This decline may be attributed to the large parameter size of the `debertav2-xlarge` model and the small dataset size, making it challenging for the model to learn features from a small dataset. The overall low scores for the model could be due to the approach of predicting the entire dialogue segment and calculating loss against actual values rather than calculating loss for each utterance individually. This approach might have contributed to the suboptimal performance of our model. Another potential reason could be the selection of 2048 as the trunca-

Speaker	Utterance	Predicted label	True label

Table 6: Validation Set Results for Subtask 2

tion value. Although this ensures that a few longer dialogue texts are fully captured, it may hinder the model's ability to learn information from long-distance texts for most shorter dialogues, leading to poor learning outcomes. There is a keen interest in attempting to segment longer texts in the future to mitigate the adverse effects on learning caused by long texts.

As indicated, the model `deberta-base` outperforms others on the validation set. Subsequent experiments will explore the impact of different methods on the model's performance based on `deberta-base`. The results are presented in Table 5, which reveals that the baseline model, not utilizing focal loss or r-drop, and instead using CrossEntropyLoss as the loss function, achieves an F1 score of only 0.25. Introducing either focal loss or r-drop results in improved scores, reaching 0.36 and 0.35, respectively. Combining these two methods and applying them to the `deberta-base` model on the validation set increases the F1 score to 0.39, outperforming the previous three configurations. The experiments demonstrate that both rdrop and focal loss contribute to enhancements in model performance.

The model `deberta-base-focalloss-rdrop` was employed to make predictions on the test set, with the results presented in Table 7, which indicates that the predictions for shorter sentences are not very accurate, which may be due to the model's insufficient learning of brief phrases. Another reason could be that the pre-trained model, `deberta-base`, was primarily trained in English, resulting in inadequate learning for languages like Hindi. Applying a multilingual model might yield better results, and further experiments are hoped to be conducted.

Subtask2. Validation Set Results for the Binary Label Sequence Task are shown in Table 6.When the `debertav2-xlarge` model was attempted for prediction, 2048 was selected as the truncation length for tokenizing the test set dialogues. It was found that the number of predicted labels did not meet the expected count, possibly due to dialogues exceeding the length of 2048, leading to this shortfall. Given the GPU constraints, our model could not effectively predict the test set.

Subtask3. Validation Set Results are presented in Table 8.It was observed that the values of precision and recall are identical across all tasks, which

Speaker	Utterance	Emotion	Predicted trigger	True trigger
Mark	why do all your coffee mugs have numbers on the bottom	surprise	0.0	0.0
Rachel	oh. that is so Monica can keep track. That way if one of them is missing, she can be like, where is number <number>?! <repeated>	anger	0.0	0.0
Rachel	y ' know what ?	neutral	0.0	0.0

Table 7: Model's prediction results on the test set for Subtask 3

Model	Dev set		
	P	R	F1
DeBERTa-base	0.82	0.82	0.82
DeBERTaV2-xlarge	0.82	0.82	0.82
Bert-base	0.82	0.82	0.82
Bert-large	0.82	0.82	0.82

Table 8: Validation set results for different models for Subtask 3

may be attributed to using micro-F1 as the evaluation metric and calculating loss based on entire dialogue segments rather than extracting individual utterances. This approach resulted in identical calculated values. The prevalence of 0.0 labels in every dialogue segment possibly made it challenging for the model to learn and perform well on the test set. The aspiration is to learn more practical models in the future to address this issue. The results obtained from predicting the test set using the `debertav2-xlarge` model are shown in Table 7, which shows that the model performs well in identifying non-emotional triggers. Based on my overall prediction results, the model's ability to predict triggers is unsatisfactory, which is an area I should aim to improve in the future.

4 Conclusions

This paper proposes a deep learning model for sentence sequence classification tasks, utilizing the DeBERTa sentence sequence classification model as the foundation. Achievements have been made in the final submission for SemEval-2024 Task10. However, there remains significant room for improvement in both the model and its parameters. Therefore, in future studies, enhancements will be made to the model to achieve better results.

Abstract

This paper describes the system for the YNU-HPCC team for SemEval2024 Task 2, focusing on Safe Biomedical Natural Language Inference for Clinical Trials. The core challenge of this task lies in discerning the textual entailment relationship between Clinical Trial Reports (CTR) and statements annotated by expert annotators, including the necessity to infer the relationships in texts subjected to semantic interventions accurately. Our approach leverages a fine-tuned DeBERTa-v3-large model augmented with supervised contrastive learning and back-translation techniques. Supervised contrastive learning aims to bolster classification ac-curacy while back-translation enriches the diversity and quality of our training corpus. Our method achieves a decent F1 score. However, the results also indicate a need for further en-hancements in the system's capacity for deep semantic comprehension, highlighting areas for future refinement. The code of this paper is available at: https://github.com/RGTnuw/RG_YNU-HPCC-at-Semeval2024-Task2.

1 Introduction

Clinical trials constitute a critical component of medical research, evaluating the safety and efficacy of new treatment methods, medications, or medical devices (Avis et al., 2006). A significant num-ber of Clinical Trial Reports (CTRs) are generated throughout clinical trials. These reports typically encompass information on research design, patient demographics, treatment protocols, outcomes (such as response rates and side effects), and overall conclusions. Such comprehensive and transparent reporting of trial results provides the scientific community and the public with valuable information, informing future research and clinical practice (Zhang et al., 2020). However, the challenge is compounded by over 400,000 Clinical Trial Reports (CTRs) and their rapidly accelerating publication rate. Conducting a comprehensive review of all pertinent literature when devising treatments is impractical (DeYoung et al., 2020).

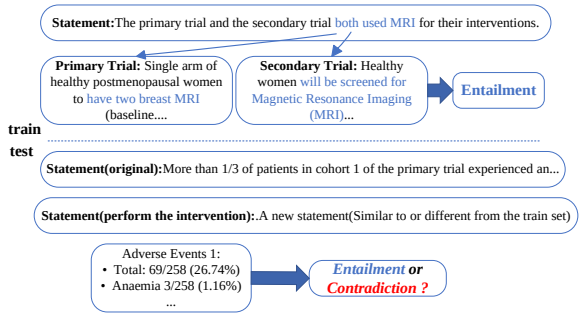

Figure 1: demonstrates textual entailment and contradiction between the medical statements and clinical trial records. Add interventions in the development and test sets.

In response to this challenge, Natural Language Inference (NLI) (Bowman et al., 2015; Devlin et al., 2019) presents a viable approach for the extensive interpretation and retrieval of medical evidence, facilitating enhanced precision and efficiency in personalized evidence-based care (Sutton et al., 2020). This task (Jullien et al., 2024) delineates the objective as classifying the inferential relationship between one or two CTR premises and a statement as either entailment or contradiction. Various interventions were applied to statements in the test and development sets, preserving or inverting entailment relations. It is imperative to ensure that inferred outcomes are justified, i.e., make correct predictions for the right reasons, and identical semantics yield consistent results, as shown in Figure 1 .

In the previous task (Jullien et al., 2023b), large language models (LLM) have achieved commendable performance(Zhou et al., 2023; Vladika and Matthes, 2023). However, the model's performance must improve when facing numerical reasoning, abbreviation, and other problems. DeBERTa-v3-large (He et al., 2023) maintained competitiveness

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 785–791

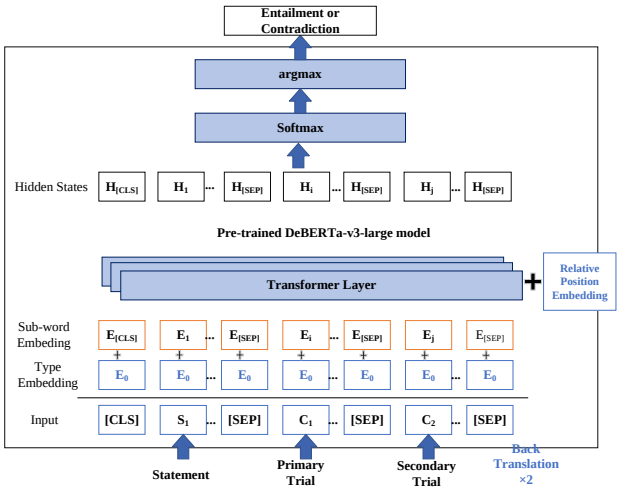

Figure 2: The structure of the system

with leading generative approaches, demonstrating that enhancements in model size correlate with performance improvements. Specifically, augmenting the model's scale directly boosts performance, significantly surpassing the gains from biomedical pre-training. Thus, validating the development set, we opted to submit results with higher experimental scores. Our approach involved fine-tuning the pre-trained DeBERTa-v3-large model, supplemented with supervised contrastive learning and back-translation techniques.

Comprehensive experiments showed that our system achieved a maximum F1 score of 0.77, securing the seventh position on the leaderboard. However, the model exhibited suboptimal performance in faithfulness and consistency metrics, indicating a weaker predictive capacity for data altered by interventions, highlighting areas for future enhancement.

The remainder of this paper is organized as follows. Section 2 describes the model and method used in our system, Section 3 discusses the results of the experiments, and finally, the conclusions are drawn in Section 4.

2 System Description

This section will describe the architecture of the proposed model in detail, including the data loader and back translation, the pre-trained model DeBERTa-v3-large, and supervised contrastive learning; the system model we proposed is shown in Figure 2.

2.1 Data preprocessing

Before feeding statements and CTRs into the model, preprocessing is performed. Initially, data augmentation is conducted through back-translation, a widely adopted technique involving translating text into another language and then back to the original language. This process, achieved via automatic translation systems, utilized Baidu's machine translation API[1] in this study, effectively doubling the training data. Given training data $\mathcal{D} = \{S, C, y\}$, y is the corresponding ground-true label, S is the medical hypothesis sentences, C is the corresponding CTR of the sentence, data loader is applied to transform training data as:

$$X = [CLS]s_1 s_2 \dots s_n[SEP]c_1 c_2 \dots c_m[SEP] \quad (1)$$

where s is the hypotheses with length n and c denotes the CTR reports with length m. [CLS] is a special mark indicating the beginning of the text sequence; [SEP] indicates the separator between text sequences. A similar process compares two CTRs, appending [SEP] and concluding similarly. Sequences exceeding 512 tokens are truncated, while shorter ones are padded.

2.2 Pre-trained DeBERTa-v3-large model

Given the commendable performance exhibited by the DeBERTa-v3 model (He et al., 2023) on this task (Jullien et al., 2023b) and the positive correlation between model parameter size and performance, the DeBERTa-v3-large model was selected as the baseline. Furthermore, an exploration was conducted with several DeBERTa-v3-large models fine-tuned on other NLI datasets available on the Hugging face[2] (Sileo, 2023; Laurer et al., 2023). The pre-trained datasets include MultiNLI, FeverNLI, ANLI, LingNLI, and WANLI. The DeBERTa-v3-large model has 24 layers and a hidden size of 1024. It has 304M backbone parameters with a vocabulary containing 128K tokens, which introduces 131M parameters in the Embedding layer.DeBERTa encodes the input text into the logits,

$$\mathbf{H} = \mathrm{Enc}(X; \theta) \quad (2)$$

where $\mathbf{H} \in \mathbb{R}^d$ is the logits with the dimensionality of d. The [CLS] token, positioned at the beginning of the input sequence, yields a hidden representation $\mathbf{H}_0$, signifying the sequence's initial contex-

[1] https://api.fanyi.baidu.com/
[2] https://huggingface.co/

tual semantic feature within the vector H. Following the acquisition of Following the acquisition of $\mathbf{H}_0$ the [CLS] representation, a fully connected layer leverages it to predict the corresponding label for the input text. The output is a softmax function,

$$\hat{\mathbf{y}} = \text{softmax}(W^0\mathbf{H}_0 + (h^0) \tag{3}$$

where $W^0 \in R^{d\times k}$ represents the weight of the fully connected layer, h^0 represents the offset of the fully connected layer, and k represents the number of classification labels.

2.3 Supervised Contrastive Learning Loss

Contrastive learning (Khosla et al., 2020)is a technique that learns to embed representations of similar samples closer together in the embedding space while pushing apart representations of dissimilar samples. In our model training, we employed this approach by incorporating a supervised contrastive loss alongside the cross-entropy loss. We hypothesized that this method would effectively handle interventions because it encourages the model to learn invariant features across different variations of the data introduced by such interventions (Feng et al., 2023). This invariance is critical for the model to generalize well to new, unseen data that might contain similar variations. Furthermore, we experimented with the R-drop technique R-drop(liang et al., 2021) to further enhance the model's generalization capabilities. However, results from Section 3 suggest that our implementation did not yield the expected improvements. This could be attributed to suboptimal parameter settings or the specific characteristics of our dataset and model size, which might have led to underfitting.

The cross-entropy loss is employed to guide the model towards accurate classification, which measures the discrepancy between the probability distribution predicted by the model and the actual distribution of the proper labels. The contrastive loss part h_i represents a feature vector, and h_{i+} is another feature vector within the same category. The dot product operation effectively calculates the cosine similarity between normalized feature vectors, τ which is the temperature parameter that modulates the model's ability to differentiate between pairs of samples. As the temperature parameter increases, the contrastive loss tends towards treating all sample pairs equally. In contrast, decreasing the temperature parameter focuses the model's attention on the most challenging negative samples. The indicator function ensures that a sample is not com-pared with itself. The SCL loss aims to bring samples of the same category closer together while pushing samples from different categories apart, thereby enhancing the discriminative power of the features. α and β hyperparameters are used to balance the contribution of each loss component. Ultimately, we formulated our loss function as follows to combine both losses effectively:

$$L_{CE} = -\sum_{i=1}^{N} y_i \log(\hat{y}_i) \tag{4}$$

$$L_{SCL} = -\frac{1}{N}\sum_{i=1}^{N} \log \frac{\exp(h_i \cdot h_{i+}/\tau)}{\sum_{j=1}^{N} 1_{[j+i]} \exp(h_i \cdot h_j/\tau)} \tag{5}$$

$$L = \alpha L_{CE} + \beta L_{SCL} \tag{6}$$

3 Experimental Results

Datasets. NLI4CT (Jullien et al., 2023a) is designed to assist in developing and benchmarking models for clinical NLI. Which consists of annotated Clinical Trial Reports (CTRs) focused on breast cancer research. Each CTR is meticulously structured into four key sections: (1)Eligibility Criteria: Specifies the prerequisites for patient inclusion in the clinical trial, detailing necessary conditions and characteristics. (2)Intervention: Describes the treatment regimen, including type, dosage, frequency, and duration of the administered treatments. (3)Results: Reports on the trial's participant count, outcome measures, metrics, and findings. (4)Adverse Events: Documents observed signs, symptoms, and any adverse effects encountered by patients during the clinical trial's course. The premises for NLI4CT are sourced from 1,000 publicly accessible Breast Cancer Clinical Trial Reports (CTRs) in English, published on ClinicalTrials.gov[3]. There are 999 breast cancer CTRs in the dataset. The datasets, which are divided into train, development, and test sets, contain a total of 2400 annotated statements. The distribution of labels be-tween the train and development sets is even. Upon employing back-translation, the volume of training data was effectively doubled. Notwithstanding, the test dataset substantially exceeds the size of the training dataset, a scenario that underscores the critical need for models to exhibit

Total	1700	200	3400	5667

Table 1: Data distribution

robust generalization capabilities. The distribution of the dacctaset is shown in Table 1.

Evaluation Metrics. The task has three metrics; the **Macro F1-score** is a foundational metric, offering a balanced measure of precision and recall across the dataset's categorial spectrum without any semantic interventions. **Faithfulness** quantifies a model's capacity to adjust its predictions for the right reasons, especially when confronted with semantic-altering interventions. This metric illuminates a model's understanding of the underlying semantics, rewarding models that exhibit agile adaptability to semantic nuances. **Consistency** gauges a model's reliability in producing uniform outputs for semantically equivalent stimuli, regardless of the correctness of the final prediction. This metric champions models that demonstrate robustness in semantic representation, ensuring that semantically similar inputs yield consistent predictions. The formula for the three indices is expressed as follows:

$$F1 = 2 \times \frac{Precision \times Recall}{Precision + Recall} \quad (7)$$

$$Faithfulness = \frac{1}{N} \sum_{i=1}^{N} |f(y_i) - f(x_i)| \quad (8)$$

where $x_i \in C$ with $\text{Label}(x_i) \neq \text{Label}(y_i)$ and $f(y_i) = \text{Label}(y_i)$.

$$Consistency = \frac{1}{N} \sum_{i=1}^{N} 1 - |f(y_i) - f(x_i)| \quad (9)$$

where $x_i \in C$ where $\text{Label}(x_i) = \text{Label}(y_i)$, N is the total number of sentences, x_i and $y_i$denote the modified and original statements, respectively. The F1 score primarily aims to evaluate the model's performance on data without interventions. At the same time, the other two metrics assess the ability to make correct judgments post-intervention, indicating the model's deeper and more logical understanding of semantic information.

Implementation Details. All compared models were downloaded from HuggingFace. We fine-tune these models on the training set. The models

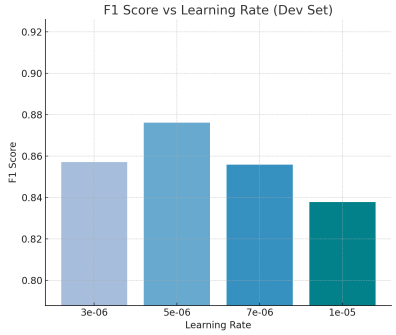

Figure 3: F1 scores on the development set for different learning rates, using the same pre-trained model and other parameters

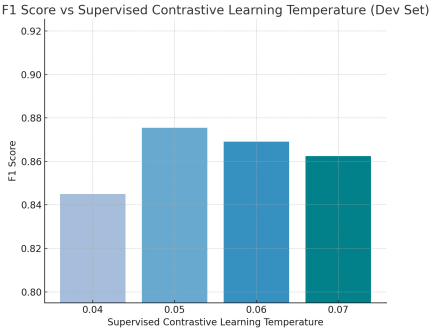

Figure 4: F1 scores on the development set for Supervised Contrastive Learning Temperature, using the same pre-trained model and other parameters

are evaluated on the validation every ten steps using precision, recall, and F1 scores. An Adam optimizer (Loshchilov and Hutter, 2019) updates the param-eters. The warmup strategy (He et al., 2016)is used to optimize the learning rate, and a fixed ran-dom seed is used.

Parameters Fine-tuning. Initially, manual adjustments were made to the hyperparameters, including the learning rate and the temperature for the contrastive loss function. Due to constraints imposed by GPU memory capacity, the batch size for training data was fixed at 4, with results illustrated in Figures 3 and 4. Upon identifying the approximate range of optimal parameters, the Optuna framework (Akiba et al., 2019) was employed for hyperparameter tuning. The parameters yielding the highest F1 score on the development set were selected for further training and model saving. The inference results were then uploaded to the platform.

Comparative Results and Discussion. Table 2 demonstrates that models pre-trained on additional datasets surpass the baseline model in performance on the development set. Nonetheless, it is shown

0.8834	0.75	0.73	0.74

Table 3: Optimal results of the test

that an excess of pre-training tasks yields minimal enhancements in model performance, such as the model that was fine-tuned with multi-task learning across over 600 tasks from the task source collection (Sileo, 2023; Laurer et al., 2023). It was also observed that R-drop might not be ideally suited for this task, potentially due to suboptimal parameter selection. It can be seen from Figure 3 and Figure 4 that the learning rate of the model is more suitable in the vicinity of 5e-6.

In contrast, the temperature of comparative learning is difficult to control, and the model performance is not linear, which needs further exploration. A degree of performance improvement was achieved through supervised contrastive learning. The highest F1 score of 0.8834 on the development set was achieved by combining supervised contrastive learning with the back-translation method. However, an F1 score of 0.75 was only achieved by this model on the test set, equating to the score of 11th place. Scores of 0.73 and 0.74 were reached on the other two metrics, comparable to the scores of the 17th and 9th places, respectively. Despite this, only the highest F1 scores are listed on the leaderboard. Another model of ours reached an F1 score of 0.77, placing it 9th, yet the scores on the other two metrics were not as high, placing 17th and 13th, respectively.

Such scores suggest that predictions are often not based on valid reasoning by the model. Accurate conclusions, when reached, may be derived from incorrect premises or misinterpretations of the input data, suggesting an insensitivity to semantic changes or an incapacity to reflect these changes accurately in its predictions. The reduction of this score indicates the model's prediction instability in the absence of significant semantic alterations, reflecting an excessive sensitivity to minor variations in input or a failure to capture and maintain the input's core semantic features accurately.

These findings reveal deficiencies in our system's ability to understand and process complex and subtle semantic changes despite adequate performance, as indicated by the F1 score. An overreliance on specific data distributions, a lack of generalizability, or challenges in explaining decisions in practical applications may result. To improve the model's Faithfulness and Consistency, it may be necessary for further research and improvements to be conducted on the model's internal representations and training processes or for additional mechanisms to be integrated for better processing of semantic information.

4 Conclusion

This paper introduces a system based on fine-tuning and pre-training Deberta-v3-large for SemEval2024 task 2, targeting safe biomedical NLI for clinical trials. Achieving seventh out of 32 with an F1 of 0.77 showcases the effectiveness of multi-task pre-training, supervised contrastive learning, and back-translation despite struggles with intervention data and deep semantic under-standing. Issues include truncated evidence from extended clinical trial premises (Kong et al., 2022)and insufficient model depth for causal reasoning. Future research should enhance semantic comprehension and causal reasoning and refine contrastive learning to improve the handling complex data and interventions, aiming to overcome current limitations in safe biomedical NLI.

YNU-HPCC at SemEval-2024 Task 1: Self-Instruction Learning with Black-box Optimization for Semantic Textual Relatedness

Weijie Li, Jin Wang and Xuejie Zhang
School of Information Science and Engineering
Yunnan University
Kunming, China
liweijie01@stu.ynu.edu.cn, {wangjin, xjzhang}@ynu.edu.cn

Abstract

This paper introduces a system designed for SemEval-2024 Task 1 that focuses on assessing Semantic Textual Relatedness (STR) between sentence pairs, including its multilingual version. STR, which evaluates the coherence of sentences, is distinct from Semantic Textual Similarity (STS). However, Large Language Models (LLMs) such as ERNIE-Bot-turbo, typically trained on STS data, often struggle to differentiate between the two concepts. To address this, we developed a self-instruction method that enhances their performance distinguishing STR, particularly in cases with high STS but low STR. Beginning with a task description, the system generates new task instructions refined through human feedback. It then iteratively enhances these instructions by comparing them to the original and evaluating the differences. Utilizing the Large Language Models' (LLMs) natural language comprehension abilities, the system aims to produce progressively optimized instructions based on the resulting scores. Through our optimized instructions, ERNIE-Bot-turbo exceeds the performance of conventional models in Track A,achieving a score enhancement of 4 to 7% on multilingual development datasets.

1 Introduction

SemEval-2024 Task 1(Ousidhoum et al., 2024) addresses the challenge of Semantic Textual Relatedness (STR), which goes beyond paraphrasing and entailment of Semantic Textual Similarity (STS)(Agirre et al., 2012, 2016; Cer et al., 2017; Xu et al., 2015) by considering topics and logical connections between sentence pairs. This task is particularly complex due to the nuanced context required for STR, a feature not fully captured by existing models trained predominantly on STS data. This gap can lead to black-box Large Language Models (LLMs) misinterpretations like ERNIE-Bot-turbo[1].

Our study introduces a self-instruction method to enhance the distinction between STS and STR in LLMs(Chen et al., 2023; Zhang et al., 2023; Hou et al., 2022; Wei et al., 2021). In our approach, back translation(Sennrich et al., 2016) converts low-resource language sentence pairs into English as inputs for LLMs. With a task description as the starting point, the black-box LLMs generate a new task instruction, which will be refined based on human feedback. The system iteratively refines the enhanced instruction by assessing it against the original and using the resulting score to produce increasingly optimized instructions. Our method improves how LLMs deal with tricky cases of similar but unrelated texts. Using our optimized instructions, ERNIE-Bot-turbo outperforms standard models and boosts scores by 4 to 7% on multilingual development datasets in Track A. The ranking of each Tack A's test dataset is as follows: English (36), Amharic (11), Algerian Arabic (24), Telugu (24), Spanish (24), Moroccan Arabic (24), Marathi (25), Kinyarwanda (20), and Hausa (20). The remainder of this paper is organized as follows. Section 2 describes the model and method used in our system, Section 3 discusses the results of the experiments, and finally, conclusions are drawn in Section 4.

2 Methodology

Figure 1 illustrates the overall framework of our self-instruction method. We employ back translation for datasets encompassing multiple languages to render sentence pairs into English as the input for LLMs. With a task description as the starting point, the black-box LLMs generates a new task instruction which will be refined based on human feedback. The enhanced instruction is subsequently assessed against the original, generat-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 792–799

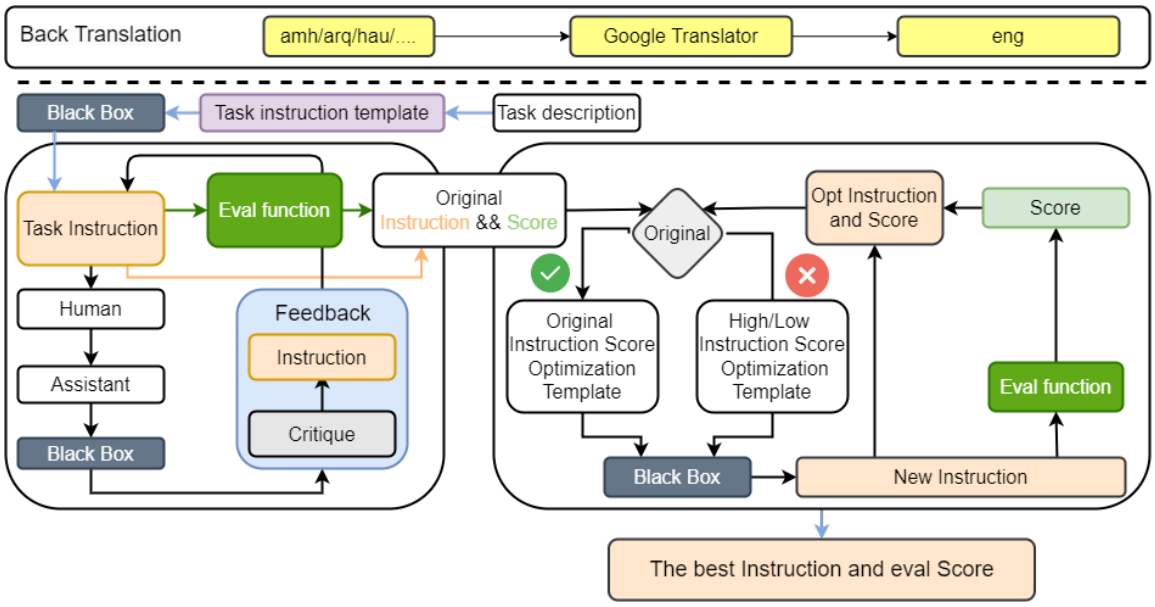

Figure 1: The framework of self-instruction method

ing a score that informs the optimization cycle. The system progressively refines the instructions in response to this score, resulting in progressively more optimized directives. The ensuing section will delve into a detailed analysis of this iterative optimization process.

2.1 Design of task instruction

Using sentences from the Amharic dataset as examples of hard sample with high Semantic Textual Similarity (STS) yet subtle Textual Relatedness (STR) for instance, What made him so certain? What contributed to his happiness? (original Amharic: "**ይህን ያህል እርግጠኛ እንዲሆን ያደረገው ምንድን ነው? ደስተኛ እንዲሆን አስተዋጽኦ ያደረገው ምንድን ነው?**"; goal label: 0.39) we underscore the significance of three components: instruction, the Chain of Thought (CoT)(Wei et al., 2022), and easily confused examples(Zhang et al., 2022; Li and Qiu, 2023). Human generated instructions aid LLMs in grasping the primary task but may not adequately explicate the concept of semantic textual relatedness (Figure 2.a) (Pred Score: 0.83). The CoT process facilitates LLMs in logical reasoning and analyzing sentence pairs, yet it encounters obstacles with complex samples prone to creating illusions (Figure 2.b) (Pred Score: 0.77). Easily confused examples are practical in dissecting hard samples but can skew the assessment of standard samples (Figure 2.c) (Pred Score: 0.67). Consequently, merging these approaches could provide more practical guidance for LLMs in discerning the relatedness of sentence pairs (Figure 2.d) (Prediction Score: 0.35). Detailed findings from the ablation study are discussed in Section 3.

2.2 Two fundamental components to generate the task instruction

Making use of natural language task description. LLMs excel in understanding natural language and simplifying the definition of optimization tasks. Capitalizing on this, we employ LLMs to convert the initial task description into detailed task instruction, guiding the LLMs to perform tasks such as STR analysis effectively, as indicated in Figure 3.a.

Refining task instruction through human feedback and evaluating their performance. While Large Language Models (LLMs) can generate task instructions from description, these instructions often fall short of being optimal and thus require human refinement and critical feedback. For instance, LLMs may overlook the significance of high and low relatedness (Figure 3.b). Subsequently, the improved instructions are evaluated, and their scores and instructions are integrated into the original framework, streamlining the subsequent optimization process (Figure 3.c).

2.3 LLMs as the black-box optimizer

After obtaining the original instruction-score (Figure 4.a), we utilize LLMs as the black-box optimizer to update and optimize the instructions iteratively. In each optimization step, the optimizer

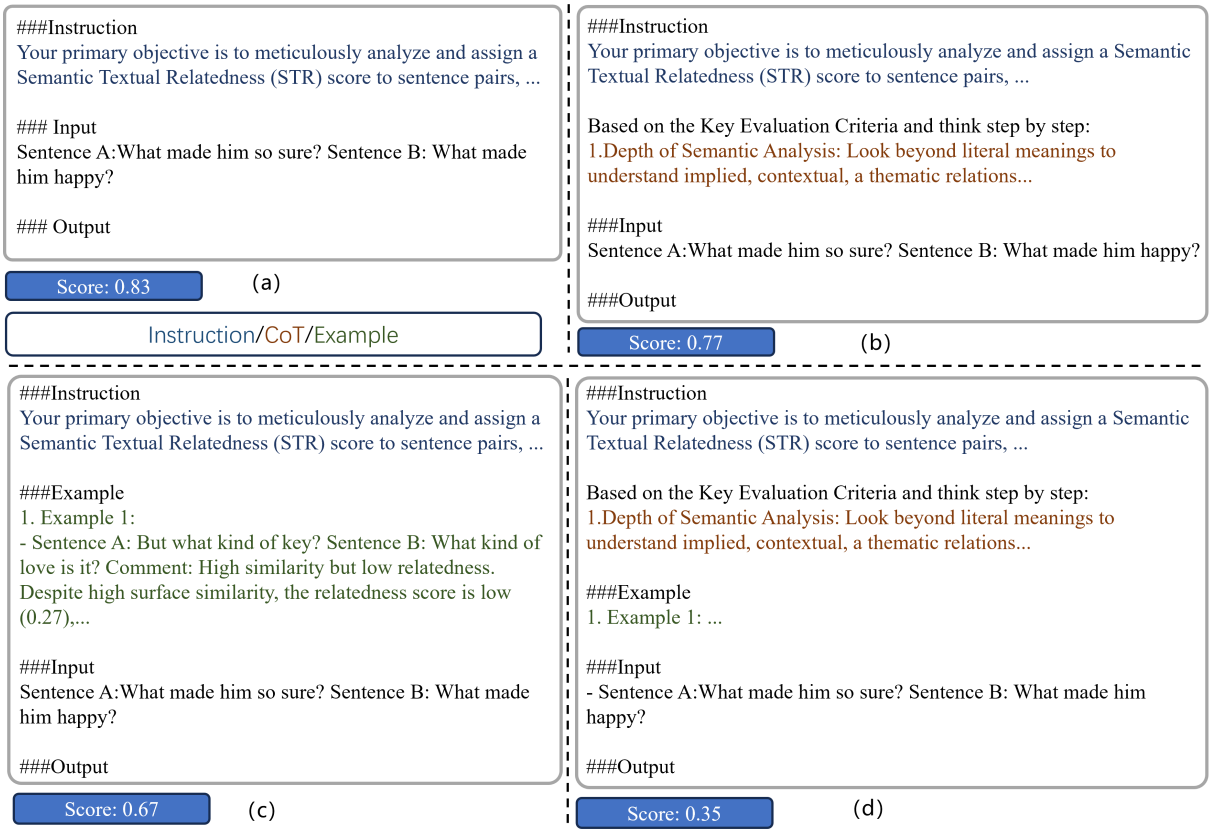

Figure 2: The process of task instruction design. (a)instruction(b)instruction + chain of thought(c)instruction + easily confused examples(d)instruction + chain of thought + easily confused examples

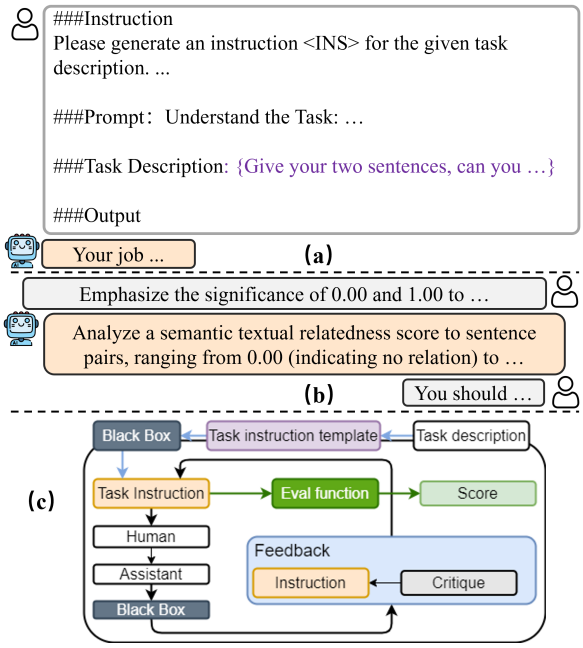

Figure 3: The process of original instruction optimization:(a)task instruction(b)task instruction optimization (c)overall process

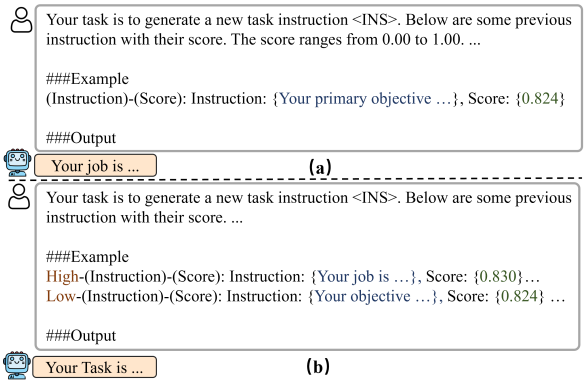

Figure 4: The process of utilizing LLM as the black-box optimizer

LLM generates candidate optimal instructions by analyzing the strengths of high-scoring and the weaknesses of low-scoring instructions (Figure 4.b). Subsequently, the new instruction is evaluated and added to the instruction-score list for sorting. From the instruction-score list, the top five high-scoring and the bottom five low-scoring instructions are selected and added to the instruction optimization template. The optimization process continues until the LLMs cannot propose new solutions with better optimization scores or the maximum number of optimization steps is reached.

3 Experimental Result

Datasets. The STR task dataset comprises datasets in 14 distinct languages, including 9 languages specifically for Track A. Each language dataset contains pairs of sentences, where each pair in the training, development, and test sets is assigned a gold score. This score reflects the degree of STR between the two sentences, ranging from 0 to 1, as determined by manual annotation. Figure 5 below presents the composition of the training, test, and development sets for Track A.

Evaluation Metrics. The STR in Track A is evaluated using the spearman rank correlation coefficient(Sedgwick, 2014), which measures how well the system predicted rankings of test instances align with human judgment. The metric will be calculated as follows:

$$\rho = 1 - \frac{6\sum d_i^2}{n(n^2-1)} \quad (1)$$

where d_i represents the difference between the ranks of the i-th pair of sentences,n is the number of pairs of sentences,ρ is the spearman rank correlation.

3.1 Implementation Details

Our approach, addressing the scarcity of low-resource languages, uses back translation to convert their sentence pairs into English for (LLMs) inputs. This experiment prioritizes scoring on English datasets to select the most effective score model. We assess four baseline methods: BERT(Devlin et al., 2019; Sanh et al., 2019; He et al., 2020; Delobelle et al., 2020; Raffel et al., 2020; Chung et al., 2022), dual sentence encoding(Reimers and Gurevych, 2019; Ni et al., 2022), contrastive learning(Gao et al., 2021; Song et al., 2020; Wang et al., 2020; Chuang et al., 2022; Wu et al., 2022b,a) , and LLMs. These models were evaluated using the training set, with results presented in Table 1. Considering our experimental objective of analyzing hard samples and scoring sentence pair STR, ERNIE-Bot-turbo was chosen as the scoring model. The LLMs utilized as the optimizer and scorer are: (a)optimizer LLM: gpt-3.5-turbo and (b)scorer LLM: ERNIE-Bot-turbo.

3.2 Desigin of task instruction

At the experiment's outset, we performed adaptation tests on the English training dataset using four variations of instruction templates: (1) instruction only, (2) instruction with chain-of-thought, (3) instruction with easily confused examples, and (4) instruction with both chain-of-thought and easily confused examples. The experimental results in Figure 6 suggest that combining instruction, chain-of-thought, and easily confused examples significantly aids LLMs in semantic textual relatedness analysis.

3.3 Prompt optimization

The score LLM operates at a temperature of 0, ensuring deterministic decoding, whereas the optimizing LLM uses a temperature of 0.95 promoting creativity in instruction generation. Figure 7.a illustrates the accuracy fluctuations during the model's evaluation on the English training dataset. Figure 7.b presents the scores for Track A's development in three scenarios: without optimization, optimized (val-score: 0.8360) and further optimized (val-score: 0.8839). Figure 8 delves into the impact of these three optimization scenarios on hard samples. Consequently, our methodology effectively reduces the hallucinations of LLMs in STS and STR tasks. This leads to a more comprehensive analysis of hard samples and consistently

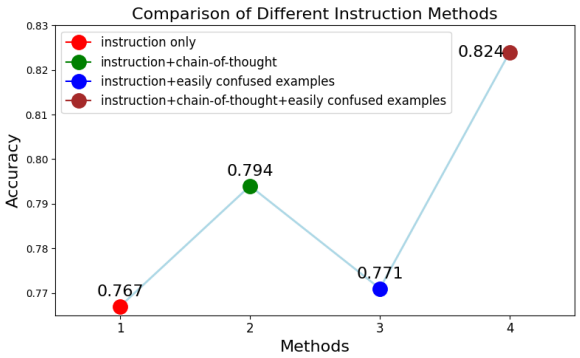

Figure 6: The ablation tests for four variations of instruction templates: 1.instruction 2. instruction + chain of thought 3.instruction + easily confused examples 4.instruction + chain of thought + easily confused examples

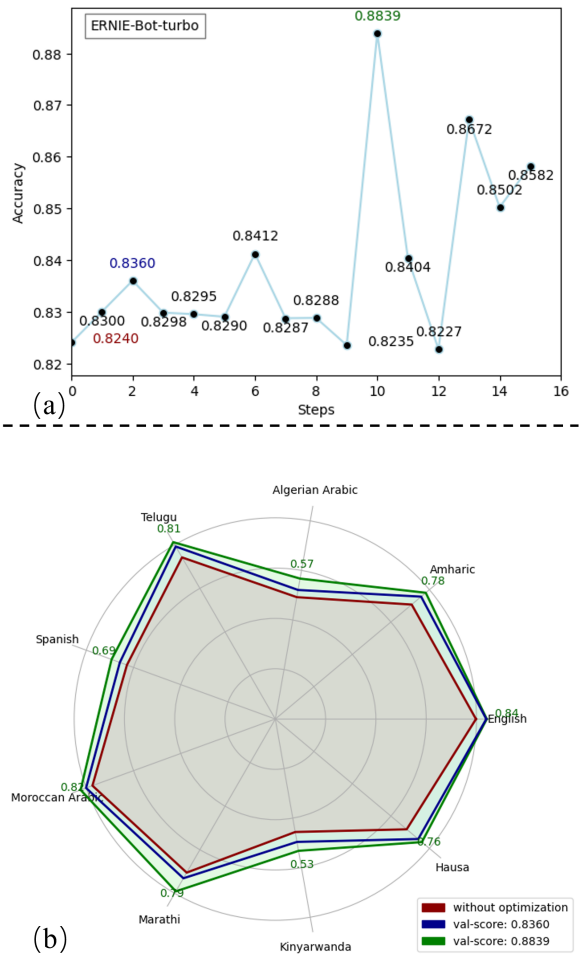

Figure 7: (a) shows changes in accuracy during evaluation on the English training dataset. (b) shows the development scores for Track A in scenarios: without optimization, optimized (val-score: 0.8360), and further optimized (val-score: 0.8839).

improves performance evaluations on the training dataset through an iterative process.

3.4 Result and Discussion

Results. Our final evaluation compared the 'no optimization' approach to 'optimization' across Track A's nine language development datasets using back translation, as shown in Figure 9.The outcomes indicate that optimized instructions significantly enhanced performance by 4 to 7% over the non-optimized approach.The ranking of each test dataset are as follows: English (36), Amharic (11), Algerian Arabic (24), Telugu (24), Spanish (24), Moroccan Arabic (24), Marathi (25), Kinyarwanda (20), and Hausa (20).

Discussion. The experimental results suggest the following:

- Our self-instruction method effectively reduces confusion between STS and STR in Large Language Models (LLMs), thereby improving accuracy and enhancing the LLMs's capability to analyze standard samples, particularly in examining hard sample.
- However, the experimental outcomes are somewhat modest due to the coarse granularity of the STR task and the considerable overlap between semantic textual similarity and relatedness.

...

###Input
SentenceA: What made him so sure? Sentence B： What made him happy?

###Output

(val-score: 0.8839)

Score: 0.42

Figure 8: It demonstrates how the scoring model assesses the impact of these three optimization scenarios on hard samples.(red: score, brown: chain-of-thought optimization,blue: example analysis optimization, purple: instruction optimization)

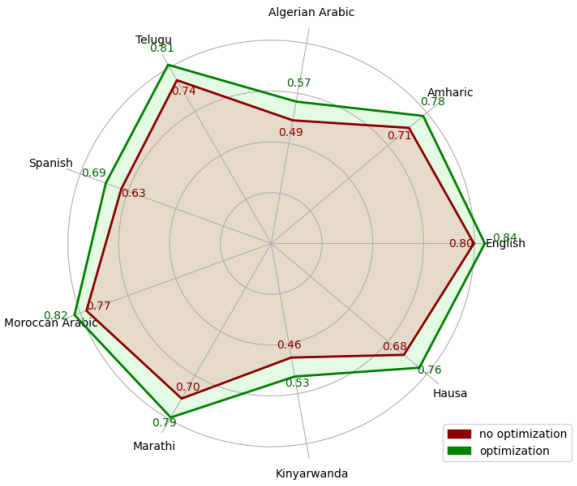

Figure 9: The performance of no optimization and optimization in development dataset.

- The back translation method encounters notable challenges when utilized with low-resource languages such as Arabic. This is primarily due to significant language biases between low-resource and high-resource languages like English within the semantic space, directly influencing the scoring model's judgment.

- The limitation of the score model is still an obstacle to performance. ERNIE-Bot-turbo (score model), trained on Chinese and English datasets corpus, demonstrates weaker proficiency in evaluating English sentence pairs.

4 Conclusion

In this paper, we developed a self-instruction method that enhances LLMs' ability to distinguish between Semantic Textual Similarity (STS) and Semantic Textual Relatedness (STR), particularly in hard samples(High STS but low STR).Through this method, ERNIE-Bot-turbo (score LLM) not only surpasses the performance of conventional models, achieving a score enhancement of 4 to 7 % on multilingual development datasets, but also effectively reduces confusion between STS and STR in Large Language Models (LLMs). Additionally, it achieved a commendable ranking in the final test evaluation. Our work demonstrates that optimized instructions, chain of thought, and easily confused examples enable LLMs to mitigate errors even in few-shot samples. Future research will aim to refine LLMs' capacity to grasp the overall semantic meaning of sentences further.

Abstract

This paper presents our system developed for the SemEval-2024 Task 1: Semantic Textual Relatedness for African and Asian Languages. The shared task aims at measuring the semantic textual relatedness between pairs of sentences, with a focus on a range of underrepresented languages. In this work, we propose using machine translation for data augmentation to address the low-resource challenge of limited training data. Moreover, we apply task-adaptive pre-training on unlabeled task data to bridge the gap between pre-training and task adaptation. For model training, we investigate both full fine-tuning and adapter-based tuning, and adopt the adapter framework for effective zero-shot cross-lingual transfer. We achieve competitive results in the shared task: our system performs the best among all ranked teams in both subtask A (supervised learning) and subtask C (cross-lingual transfer).[1]

1 Introduction

Semantic Textual Relatedness (STR) measures the closeness of meaning between two linguistic units, such as a pair of words or sentences (Budanitsky, 1999; Mohammad and Hirst, 2012). For example, one can easily tell that *"I like playing games"* is more semantically related to *"The game is fun"* rather than *"The weather is good"*, which largely depends on their lexical semantic relation and topic consistency. Semantic Textual Similarity (STS), a closely related concept, indicates whether two units have a paraphrasing relation. The difference between these two concepts is clarified in Abdalla et al. (2023): while similar pairs are also related, the reverse is not necessarily true.

In stark contrast to the extensive research on STS (Gao et al., 2021; Chuang et al., 2022; Zhang et al., 2022; Seonwoo et al., 2023), exploration of STR lags behind and predominantly focuses on English (Marelli et al., 2014; Abdalla et al., 2023), mainly due to the lack of datasets. To close this gap, the SemEval-2024 Task 1: Semantic Textual Relatedness (Ousidhoum et al., 2024b) is proposed to encourage STR research on 14 African and Asian languages. The shared task consists of 3 subtasks: supervised (subtask A), unsupervised (subtask B), and cross-lingual (subtask C).

In this paper, we present our system AAdaM (Augmentation and Adaptation for Multilingual STR) developed for subtask A and C. Our system adopts a cross-encoder architecture which takes the concatenation of a pair of sentences as input and predicts the relatedness score through a regression head (Devlin et al., 2019). As the provided task data for non-English languages is relatively limited, we perform data augmentation for these languages via machine translation. To better adapt a pre-trained model to the STR task, we apply task-adaptive pre-training (Gururangan et al., 2020) which has shown effectiveness on many tasks (Xue et al., 2021; Wang et al., 2023). For subtask A, we explore full fine-tuning and adapter-based tuning (Houlsby et al., 2019) combined with previously mentioned techniques. Additionally, we use the adapter framework MAD-X (Pfeiffer et al., 2020) for cross-lingual transfer in subtask C.

We select the best model based on the performance on development sets for the final submission, and our system achieves competitive results on both subtasks. In subtask A, our system ranks first out of 40 teams on average, and performs the best in Spanish. In subtask C, our system ranks first among 18 teams on average, and achieves the best performance in Indonesian and Punjabi.

2 SemRel Dataset

To encourage STR research in the multilingual context, Ousidhoum et al. (2024a) introduce SemRel, a new STR dataset annotated by native speakers, covering 14 languages from 5 distinct lan-

[1]Our code: https://github.com/uds-lsv/AAdaM

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 800–810

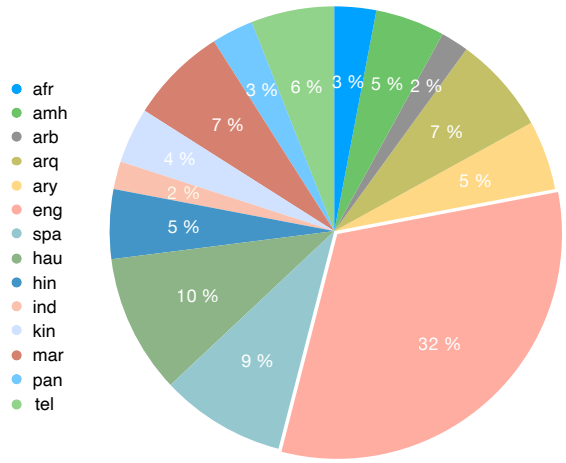

Figure 1: SemRel data distribution across languages.

guage families. These languages are mostly spoken in Africa and Asia, and many of them are under-represented in natural language processing resources. As shown in Figure 1, the data sizes vary widely from language to language constrained by the availability of resources. Notably, English data comprises 32% of the whole dataset and surpasses other languages by a large margin.

3 System Overview

Our system employs a *cross-encoder* architecture, which takes the concatenation of a pair of sentences as input and predicts the relatedness score through a regression head. Compared to bi-encoders (Reimers and Gurevych, 2019), which extract individual sentence representations and then compare them using cosine similarity, cross-encoders generally perform better, at the cost of increased inference latency (Humeau et al., 2020). We select cross-encoder because of its superior performance (see Appendix A), and leave the exploration of an efficient alternative as future work.

The core techniques underlying our system are (i) **data augmentation** using machine translation (§3.1), and (ii) **task-adaptive pre-training** on unlabeled task data (§3.2). We explore two training paradigms for supervised learning combined with the aforementioned techniques, i.e., **fine-tuning** and **adapter-based tuning** (§3.3), and the latter is also employed for cross-lingual transfer (§3.4).

3.1 Data Augmentation

Data augmentation (DA) serves as a widely used strategy to mitigate data scarcity in low-resource languages (Hedderich et al., 2021; Feng et al., 2021). Inspired by work on DA with machine translation (Hu et al., 2020; Amjad et al., 2020), we create additional training data for non-English languages by translating from various English sources, as illustrated below.

SemRel translation. As English data occupies a significant portion of the entire SemRel dataset, we perform augmentation by translating the English subset to other target languages.

STS-B translation. STS-B (Cer et al., 2017), a semantic similarity dataset, is highly relevant to STR, and we translate the STS-B training set in English to other target languages.

It worth noting that using translations as data augmentation yields a mixed data quality. For instance, the translation process may introduce artifacts that reduce data validity. Additionally, the concepts of "similarity" and "relatedness" are relevant but not equivalent, leading to a mismatch in their annotated scores. To leverage data in varied qualities, Zhu et al. (2023) shows that a two-phase approach is beneficial, in which the model is trained on noisy data first and then trained on clean data. Our training procedure follows this two-phase scheme: (i) training the model on augmented data as a *warmup*, and (ii) subsequently training the model on the original task data.

3.2 Task-Adaptive Pre-training

Pre-trained language models (PLMs) are trained on massive text corpora with self-supervision objectives for general purposes (Devlin et al., 2019; Liu et al., 2019). To better adapt PLMs to downstream tasks, Gururangan et al. (2020) propose task-adaptive pre-training (TAPT), i.e., continued pre-training on task-specific unlabeled data, and show that it can effectively improve downstream task performance. We integrate this strategy into our system, wherein we conduct masked language modeling (MLM) on unlabeled task data for a given target language before initiating any supervised training.

3.3 Fine-tuning vs. Adapter-based Tuning

Fine-tuning is the conventional approach to adapt general-purpose PLMs to downstream tasks. It updates all model parameters for each task, leading to inefficiency with the ever-increasing model scales and number of tasks. Recently, many works focus on introducing lightweight alternatives to improve parameter efficiency (Lester et al., 2021; Hu et al., 2022; He et al., 2022). For example, adapter-based

Model Tuning	TAPT	Warmup	arq	amh	eng	hau	kin	mar	ary	spa	tel

Table 1: Subtask A performance on development sets (Spearman's correlation $\times 100$). SemRel: warmup by training on SemRel translations; STS-B: warmup by training on STS-B translations. We underline the best performance of fine-tuning and adapter-based tuning, and **bold** the best performance across all variants.

tuning (Houlsby et al., 2019) only updates small modules known as adapters inserted between the layers of PLMs while keeping the remaining parameters frozen. In particular, it has shown impressive performance in cross-lingual transfer (Pfeiffer et al., 2020; Ansell et al., 2021; Pfeiffer et al., 2022).

We explore both fine-tuning and adapter-based tuning to compare their effectiveness on multilingual STR. For fine-tuning, we update all model parameters at each stage, namely the TAPT stage, the warmup stage and the final training stage using the original task data. For adapter-based tuning, we utilize the MAD-X framework (Pfeiffer et al., 2020) which consists of language-specific adapters and task-specific adapters. The language adapters are pre-trained with an MLM objective on unlabeled monolingual corpora. To this end, we collect open-source data from the Leipzig Corpus Collection (Goldhahn et al., 2012) for pre-training.[2] The task adapters are trained on labeled task-specific data (augmented or original), while keeping the language adapters fixed. Note that when applying TAPT, only language adapters are updated. In subtask A, we apply fine-tuning and adapter-based tuning in combination with TAPT and warmup techniques, and select the best model based on the performance on development sets.

3.4 Cross-lingual Transfer with Adapters

The high modularity of MAD-X enables efficient zero-shot cross-lingual transfer. During inference, we simply replace the source language adapter with the *target language adapter* while retaining the *source task adapter*. This task adapter has been trained on labeled data from the source language, without prior exposure to the target language.[3] A crucial challenge for cross-lingual transfer lies in source language selection, as improper sources may lead to negative results (Lange et al., 2021). To determine the best source language, we explore the following metrics to rank sources: (1) linguistic distance (Littell et al., 2017), (2) token overlap (Wu and Dredze, 2019), and (3) development set performance.[4] Results in Appendix C demonstrate that development set performance serves as the most reliable indicator of transfer performance. For subtask C, we select the optimal source from the adapters trained in subtask A based on their performance on development sets.

4 Experimental Setup

Model. Our backbone model is AfroXLMR-large-61L (Adelani et al., 2024), adapted from XLM-R (Conneau et al., 2020) through multilingual adaptive fine-tuning (Alabi et al., 2022). We use NLLB (`nllb-200-distilled-600M`) (Team et al., 2022) to translate from English resources to other languages as data augmentation.

Implementation. All experiments are conducted on a single NVIDIA A100 GPU with a batch size of 16. For MLM, we set the learning rate to 5e-5

[2]Details are provided in Appendix B.

[3]Note that when transferring from any other language to English, we ensure that the source task adapter has not been trained on augmented data translated from English resources, thereby eliminating the effect of data leakage.

[4]The existence of development sets is not realistic in the true zero-shot scenario, and we leave further discussion to the Limitations section.

and train models for 10 epochs. For fine-tuning, we conduct a grid-search of learning rate from {2e-5, 5e-5} on SemRel development sets and train models for 6 epochs. For adapter-based tuning, we select the optimal learning rate from {1e-4, 2e-4, 5e-5} and train adapters for 15 epochs.

5 Results and Analysis

5.1 Subtask A: Supervised Learning

In Table 1, we compare the performance on development sets using fine-tuning and adapter-based tuning along with various techniques. Fine-tuning achieves the best performance in most languages (6 out of 9), which is unsurprising as it optimizes the entire parameter space. Notably, adapter-based tuning demonstrates comparable performance to fine-tuning in Hausa (hau) and Telugu (tel), while even surpassing it in Kinyarwanda (kin), Marathi (mar) and Spanish (spa). Looking at the effectiveness of TAPT and warmup, we observe that they provide benefits in most cases compared to using no techniques at all. Nonetheless, the improvements are sometimes marginal, particularly in languages such as Amharic (amh), English (eng), and Moroccan Arabic (ary), where the baseline performances are already relatively strong compared to other languages.

In our final submission, we selected the best model for each language based on the performance of development sets. As shown in Table 2, our approach largely improves the baseline results (Ousidhoum et al., 2024a), especially for Algerian Arabic (arq), Kinyarwanda (kin), and Moroccan Arabic (ary). In comparison to several top-performing submitted systems, we achieve the best performance in Spanish (spa). There were a total of 40 final submissions in subtask A, and our system ranks first on average in the official leaderboard.[5]

5.2 Subtask C: Cross-lingual Transfer

In subtask C, we replace source language adapters from subtask A with target language adapters. We analyze two groups of language adapters: base language adapters trained only on Leipzig corpora and TAPT language adapters further trained on unlabeled task data. The cross-lingual transfer results

[5]PALI and king001 also achieved competitive performance; however, they are not ranked in the official leaderboard due to missing system descriptions.

Table 3: Subtask C performance on test sets (Spearman's correlation ×100). ♢: baseline results from Ousidhoum et al. (2024a). We **bold** the best performance across submitted systems.

on development sets are shown in Figure 2. We observe a discrepancy in the optimal source languages selected with two types of adapters, indicating a behavior shift after applying TAPT. Furthermore, the performance for target languages shows high sensitivity to the choice of source language. For example, using Spanish (spa) as the source language for Indonesian (ind) performs significantly better than using Kinyarwanda (kin), showcasing the importance of careful source language selection. When examining each target language, we find that in the case of Amharic (amh), the cross-lingual transfer performance is comparable to its supervised learning performance. However, it remains a challenge for a few languages, such as Indonesian (ind) and Punjabi (pan).

The results for test sets are shown in Table 3. Compared to LaBSE (Feng et al., 2022), a multilingual sentence embedding model, our cross-lingual transfer approach achieves better performance on most languages, especially for Algerian Arabic (arq), Hausa (hau), Moroccan Arabic (ary), and Punjabi (pan). However, our system is surpassed by the simple word overlap baseline in Indonesian (ind), Moroccan Arabic (ary) and Spanish (spa). This highlights the need for nuanced investigation of data distributions across various languages. Subtask C received 18 submissions in total, and we perform the best in the official leaderboard. In particular, we achieve the best performance in Indonesian (ind) and Punjabi (pan), which seem harder for other teams. For Punjabi (pan), where most teams get negative correlation scores, our method maintains its effectiveness.

5.3 Analysis

We partition ground-truth relatedness scores, ranging from 0 to 1, to different levels for fine-grained analysis. Figure 3 shows the detailed model performance for several under-performing languages.

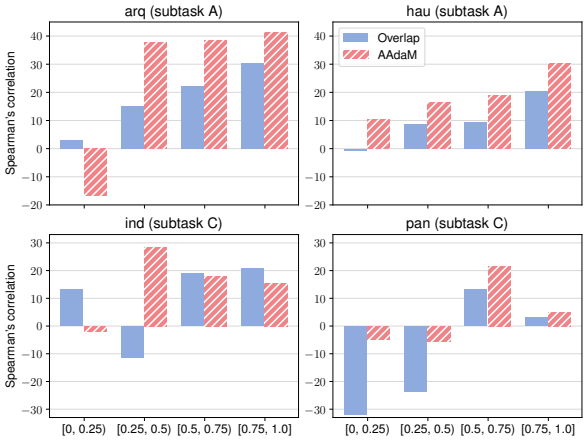

Figure 3: Performance on test sets (Spearman's correlation ×100) in different relatedness levels.

Although our evaluation scores on the entire test sets are all positive, some subsets exhibit negative correlations, particularly those with lower relatedness scores. Moreover, AAdaM largely lags behind the simple word overlap baseline for Algerian Arabic (arq) and Indonesian (ind) within the 0 to 0.25 range. These observations highlight the complexity of capturing nuanced relationships within specific categories, possibly affected by the data annotation procedure and unbalanced learning.

6 Conclusion

In this paper, we introduce our multilingual STR system, AAdaM, developed for the SemEval-2024 Task 1, which achieves competitive results in both subtask A and subtask C. We see noticeable improvements by using data augmentation and task-adaptive pre-training, and demonstrate that adapter-based tuning is an effective approach for supervised learning and cross-lingual transfer. Despite these strengths, our fine-grained analysis reveals that capturing nuanced semantic relationships remains a challenge, highlighting the need for further granular investigation and modeling improvements.

Limitations

Although our approach has demonstrated impressive performance, relying on development sets for source language selection undermines its practical value in the true zero-shot setting. While linguistic (dis)similarity (Littell et al., 2017) is a commonly used estimator for cross-lingual transfer performance, it alone does not explain many transfer results (Lauscher et al., 2020). Philippy et al. (2023) survey different factors that impact cross-lingual transfer performance, finding contradictory conclusions from previous studies. In future work, we plan to scrutinize the interplay among various factors, and select the optimal source language without relying on post-hoc evaluation.

A Model and Architecture Selection

In our preliminary study, we examine the capacity of different pre-trained models with or without any training. To assess their out-of-the-box effectiveness, we extract contextual embeddings for pairs of sentences from various multilingual models, and use the cosine similarity to predict the semantic relatedness score. The multilingual models include:

- **sentence transformers**: mpnet-base-v2[6] and LaBSE (Feng et al., 2022)
- **general-purpose models**: XLMR-large (Conneau et al., 2020), AfroXLMR-large (Alabi et al., 2022), AfriBERTa-large (Ogueji et al., 2021), AfroXLMR-large-61L and AfroXLMR-large-75L (Adelani et al., 2024)

Additionally, we add two simple baselines for comparison: word overlap[7] and fastText (Mikolov et al., 2018). For both fastText vectors and contextual embeddings, we employ mean pooling to get sentence embeddings.

In Table 4, we can see that sentence transformers achieve superior performance in most languages when no training is conducted. This observation is not unsurprising, as they have been trained for sentence embeddings that can better capture the semantic relationships. However, this trend shifts upon fine-tuning the models on task data with either bi-encoder or cross-encoder architecture. Notably, with the cross-encoder architecture, AfroXLMR-large-61L achieves comparable performance to LaBSE. To satisfy the requirement in subtask C, for which the pre-trained model should not be trained on any relatedness or similarity datasets, we adopt AfroXLMR-large-61L as our backbone model with the cross-encoder architecture for all our experiments.

[7] https://github.com/semantic-textual-relatedness/Semantic_Relatedness_SemEval2024/blob/main/STR_Baseline.ipynb

B Pre-training Data Collection

To pre-train language adapters, we collect open-source corpora from the Leipzig Corpus Collection and use the recent data derived from news and wikipedia domains. Data statistics are shown Table 5. As the SemRel data spans over diverse domains, there is a potential risk of domain mismatch between the pre-training data and task data, which needs a further investigation.

C Source Language Selection

To determine the best source language for cross-lingual transfer, we explore three metrics to estimate the transfer performance:

Linguistic distance. We use the average of six distances obtained from the URIEL Database (Littell et al., 2017) to measure the similarity between a pair of languages. These distances include syntactic, phonological, inventory, geographic, genetic, and featural distances. A lower distance indicates that the two languages are more similar, potentially facilitating more effective transfer.

Token overlap. We follow (Wu and Dredze, 2019) to measure how many tokens are shared in the source training set and the target test set. A higher token overlap indicates that more tokens were encountered during training in the source language, potentially transferring more supervision from the source to the target.

Development set performance. As small development sets are available in the shared task, we use their performance as an indicator of the transfer performance on test sets, assuming that they share a similar data distribution.[8]

In Figure 4, we show the metric values across different source languages, along with the best source languages identified by distinct metrics. After post-hoc evaluation following the release of test sets, we find that the performance of the development set indeed serves as the most reliable indicator, as the

[8] When training is allowed, it might be more advantageous to use small development sets for training directly rather than source selection, which needs to be further explored.

BITS Pilani at SemEval-2024 Task 10: Fine-tuning BERT and Llama 2 for Emotion Recognition in Conversation

Dilip Venkatesh[1], **Pasunti Prasanjith**[1], and **Yashvardhan Sharma**[1]

[1]Birla Institute of Technology and Science, Pilani, Rajasthan, India
Email: {f20201203, pasunti.prasanjith, yash}@pilani.bits-pilani.ac.in

Abstract

Emotion Recognition in Conversation **(ERC)** aims to assign an emotion to a dialogue in a conversation between people. The first subtask of EDiReF shared task aims to assign an emotions to a Hindi-English code mixed conversation. For this, our team proposes a system to identify the emotion based on fine-tuning large language models on the `MaSaC` dataset. For our study we have fine tuned 2 LLMs **BERT** and **Llama 2** to perform sequence classification to identify the emotion of the text.

1 Introduction

Emotion can be defined as a conscious mental reaction subjectively experienced as strong feeling usually directed toward a specific object and typically accompanied by physiological and behavioral changes in the body (Merriam-Webster, 2024). In recent times emotion recognition and sentiment analysis has become increasingly popular due to the research developments in natural language processing. Although similar to sentiment analysis, while sentiment analysis aims to classify text as `POSITIVE`, `NEGATIVE` and `NEUTRAL`, ERC aims to identify text as more in-depth emotions like joy, sadness, anger, contempt etc.

Emotion recognition has multiple use cases in the real world. Opinion mining of conversational data posted by users is done at a large scale at big tech companies. Poria et al. (2019) mentions that ERC has major potential to be used in healthcare systems for psychological analysis and education to understand student frustrations. It is important for language models and chat bots to understand the sentiment of an input text to respond accordingly and generate empathetic dialogue systems (Ma et al., 2020).

For the first subtask of the SemEval 2024 Task 10: *Emotion Discovery and Reasoning its Flip in Conversation (EDiReF)* (Kumar et al., 2024) on CodaLab (Pavao et al., 2023), we aim to conduct Emotion Recognition in Conversation on a Hindi-English code-mixed dataset. Our team proposes a system for this where we fine tune two large language models. Namely the transformer based BERT (Devlin et al., 2019) and Llama 2 (Touvron et al., 2023b).

All of our code can be found on GitHub at `github.com/dipsivenkatesh/SemEval-2024-Task-10`

2 Background

2.1 Task and Data Description

The EDiRef shared task[1] consists of three subtasks.

- Emotion Recognition in Conversation **(ERC)** in Hindi-English code-mixed conversations
- Emotion Flip Reasoning **(EFR)** in Hindi-English code-mixed conversations
- **EFR** in English conversations

In this paper we go through our team's system to solve the first sub task.

The first subtask is to perform ERC on the Hindi-English code-mixed `MaSaC` dataset proposed in Bedi et al. (2023). The dataset comprises of around 1,200 multi-party dialogues from the popular Indian TV show *'Sarabhai vs Sarabhai'*[2] and around 15,000 utterance exchanges (primarily in Hindi) between the speakers. The dataset consisted of the utterances by the speaker and the corresponding emotion label given to each utterance. The emotions were *anger, neutral, contempt, sadness, fear, disgust, joy* and *surprise*.

An example of Emotion recognition in conversation can be found in Table 1

[2]`https://www.imdb.com/title/tt1518542/`

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 811–815

Speaker	Utterance	Emotion
Sp1	Aaj to bhot awful day tha! (I had an awful day today!)	Sad
Sp2	Oh no! Kya hua? (Oh no! What happened?)	Sad
Sp1	Kisi ne mera sandwich kha liya! (Somebody ate my sandwich!)	Sad
Sp2	Me abhi tumhare liye new bana deti hun! (I can make you a new one right now!)	Joy
Sp1	Wo great hoga! Thanks! (That would be great! Thanks!)	Joy

Table 1: Hindi-English code-mixed conversation with emotions

2.2 Previous Work

Initially the naive Bayes algorithm was used for subject classification (Maron, 1961), specifically for sentiment analysis the variant, binary multinomial naive Bayes algorithm was proposed. More recently, the way to perform classification tasks in natural language processing is through supervised machine learning.

Hazarika et al. (2018b) proposes a conversational memory network (CMN), a method that uses memories to capture inter-speaker dependencies. This was further improved with Interactive Conversational memory Network (ICON) a multimodal method that models the self- and inter-speaker emotional influences into global memories (Hazarika et al., 2018a). The Interaction-Aware Attention Network (IANN) (Yeh et al., 2019) incorporates the contextual information through a novel attention mechanism. It works by by leveraging inter-speaker relation modeling, however it uses distinct memories for each speaker. This is solved with DialougeRNN (Majumder et al., 2019) a method based on RNNs that keeps track of the individual states of speakers throughout conversation. This is then used for emotion classification.

The discovery of Large Language Models (LLMs) have brought in a huge transformation to the field of natural language processing. This is due to to the reasoning and understanding capabilities of these powerful models such as GPT-3 (Brown et al., 2020), GPT-4 (OpenAI, 2023) and LLaMA (Touvron et al., 2023a). Fine tuning of these pre-trained LLMs have showed their versatility and effectiveness across a variety of tasks.

For this task we fine tune 2 models. BERT (Bidirectional Encoder Representations from Transformers) (Devlin et al., 2019), a model to pre-train bidirectional representations by jointly conditioning on both left and right context in all layers. Due to this, the model can be fine tuned with just one layer to achieve state of the art performance. We also use the Llama 2 7 billion parameter model (Touvron et al., 2023b). We choose the Llama 2 model due to it's state of the art performance on various NLP benchmarks. Due to the large size of Llama 2 we fine tune this model using Parameter Efficient Fine Tuning Methods (Mangrulkar et al., 2022). We do this with Low-Rank Adaptation of Large Language Models (LoRA) (Hu et al., 2021) which freezes the pre-trained model weights and injects trainable rank decomposition matrices into each layer of the Transformer architecture. This reduces the number of trainable parameters.

2.3 Evaluation Metrics

The systems used were evaluated with the weighted F1 score metric.

$$\text{Weighted F1} = \sum_{i=1}^{N} \left(\frac{\text{support}_i}{\text{total support}} \right) \cdot \text{F1}_i \quad (1)$$

$$\text{F1}_i = 2 \cdot \frac{\text{precision}_i \cdot \text{recall}_i}{\text{precision}_i + \text{recall}_i} \quad (2)$$

$$\text{where,} \quad \text{precision}_i = \frac{TP_i}{TP_i + FP_i} \quad (3)$$

$$\text{recall}_i = \frac{TP_i}{TP_i + FN_i} \quad (4)$$

and support_i is the number of true instances of class_i and total support is the total number of instances across all classes

3 System Overview

3.1 BERT

We fine-tune the BERT base model (cased) (Devlin et al., 2019) for the emotion classification task with 8 labels. We load the model and train it using the HuggingFace Transformers library (Wolf et al., 2020). The input text is tokenized with the *bert-based-case* tokenizer.

3.1.1 Model Architecture

The model uses the existing BERT base cased architecture. The final layer of the model (the output

layer) is altered to match the 8 classes in the classification task.

3.1.2 Loss Function

For this model we use the **Cross Entropy Loss** between the outputs of the model predictions and the actual labels to optimize the system.

3.2 Llama 2

We fine-tune the Llama 2, 7 billion parameter model (Touvron et al., 2023b) in a similar way in which we fine-tune BERT. We load the model and train it using the HuggingFace Transformers library (Wolf et al., 2020). The input text is tokenized with the *meta-llama/Llama-2-7b-hf* tokenizer.

3.2.1 Model Architecture

Llama 2 model architecture is similar in structure to its predecessor LLaMA (Touvron et al., 2023a) with a context length increase from 2048 to 4096 tokens and usage of Grouped-Query Attention instead of Multi-Query Attention. It is an auto-regressive language model that uses optimized transformer architecture.

3.2.2 Loss Function

We use custom loss function that combines the F1 score and Cross-Entropy Loss to form a single loss value that takes into account both the precision and recall, along with the class imbalances.

4 Experimental Setup

4.1 Dataset Splits

We load the `MaSaC` dataset (Kumar et al., 2023) train, validation and test splits provided to us by the EDiReF shared task organizers using huggingface datasets library (Lhoest et al., 2021). The train set consists of 8506 utterances along with their corresponding label (emotion). The validation set consists of 1354 utterances and the respective label. For final evaluation we are provided with an unlabeled test set of 1580 utterances, to which we must predict the emotion for submission.

4.2 Preprocessing data

Before we pass the inputs to the large language model, we must preprocess the data to an acceptable input format for the large language model, for this we tokenize the datasets.

- **BERT:** For the BERT model we use the pretrained BERT tokenizer *bert-base-cased*. This takes the text of the utterance and generates the *input ids*, *token type ids* and *attention mask*. To make sure all the input sequences have the same length we use maximum length padding. Longer sequences are truncated to the maximum allowable length of the BERT model.

- **Llama 2:** The text for the Llama model is tokenized with the *meta-llama/Llama-2-7b-hf* tokenizer. While tokenizing it is ensured that a space is added before the first token of a given text. The pad token and pad token id are set to the EOS[3] token and EOS token id. While tokenizing, we truncate the longer sequences to the maximum allowable length of the Llama model.

4.3 Training/Fine-tuning

We use the NVIDIA A100 GPUs available on Google Colab for fine-tuning the models.

We load the *bert-base-cased* on HuggingFace for fine-tuning. For the BERT model we use a data loader of batch size 32 while shuffling the data each epoch to not learn any unintended patterns. We use the AdamW optimizer for training (Loshchilov and Hutter, 2019). We set the initial learning rate to be 5×10^{-5} and use a linear learning rate scheduler across the entire duration of training. We then train the model for 4 epochs.

The Llama 2 model is available as *meta-llama/Llama-2-7b-hf* on HuggingFace. We load this model for fine-tuning. Similar to the BERT model, we use a data loader with shuffling for the Llama 2 model, but with a batch size of 16. The AdamW optimzer (Loshchilov and Hutter, 2019) is used while training. Due to the large size of the Llama 2 model, we fine tune the model with PEFT (Mangrulkar et al., 2022) and LoRA (Hu et al., 2021). The LoRA configuration we setup for parameter efficient fine-tuning is as follows. We set the task type as sequence classification, the rank of decompostion matrix (r) is set to 16, the alpha parameter to scale the learned weights (lora alpha) is set to 16 as advised by the LoRA paper. The dropout probability of the LoRA layers is set to 0.05. We do not add any bias term to LoRA layers. We apply LoRA to the projection layers for the query and value components in the attention mechanism of the transformer. We then fine-tune the model for 10 epochs with a learning rate of

[3]End of Speech

1×10^{-4}, warmup ratio of 0.1, maximum gradient norm of 0.3 and a weight decay of 0.001.

5 Results

For evaluation, the organizers rank the system based on weighted F1 score. This is due to the classes being highly imbalanced in the data distribution. The BERT model which was submitted to the leader board achieved a 0.42 weighted F1 score to get 14th place [4]. The performance of all the models can be found in Table 2

	Validation Set	Test Set
BERT	0.43	0.42
Llama 2	0.42	0.41

Table 2: Weighted F1 Scores

Acknowledgements

I would like to thank the organizers of the *EDiReF - SemEval 2024 Task 10* shared task for conducting this competition and organizing this task. I would also like to thank the faculty and research scholars at BITS Pilani for assisting me in my work.

BITS Pilani at SemEval-2024 Task 9: Prompt Engineering with GPT-4 for Solving Brainteasers

Dilip Venkatesh[1] and **Yashvardhan Sharma**[1]

[1]Birla Institute of Technology and Science, Pilani, Rajasthan, India
{f20201203, yash}@pilani.bits-pilani.ac.in

Abstract

Solving brainteasers is a task that requires complex reasoning prowess. The increase of research in natural language processing has lead to the development of massive large language models with billions (or trillions) of parameters that are able to solve difficult questions due to their advanced reasoning capabilities. The SemEval *BRAINTEASER* shared tasks consists of sentence and word puzzles along with options containing the answer for the puzzle. Our team uses **OpenAI's GPT-4** model along with **prompt engineering** to solve these brainteasers.

1 Introduction

There are two different types of thinking processes, vertical and lateral (Waks, 1997). Vertical thinking refers to the form of linear thinking thinking we are conditioned to. It is based on rationality and logic. Lateral thinking, or *"out-of-the-box"* thinking is a more creative way of thinking from different perspectives. This is contrary to first method.

The recent advancements of natural language processing models, more specifically large language models have achieved great progress in reasoning capabilities and therefore vertical thinking tasks (Talmor et al., 2019, Bisk et al., 2020).

This lateral, creative form of thinking has multiple use cases in the real world since rapid innovation and out of the box thinking are key functionalities of blooming institutions. Innovations are crucial to solve global scale problems like climate change and are very important to big tech companies to keep their consumers happy and engaged. Therefore an interesting part of language models are their abilities to show lateral thinking and defy default commonsense associations.

For the SemEval 2024 Task 9: *BRAINTEASER: A Novel Task Defying Common Sense* (Jiang et al., 2024) on CodaLab (Pavao et al., 2023), we aim to solve the brainteasers as a multiple-choice Question Answering (QA) tasks. Our team proposes a system for this where we use prompt engineering with GPT-4 to solve these brainteasers.

All of our code can be found on GitHub at https://github.com/dipsivenkatesh/SemEval-2024-Task-9

2 Background

2.1 Task and Data Description

The BRAINTEASER shared task[1] consists two different type of brainteasers/puzzles.

- **Sentence Puzzle**: Sentence-type brainteaser where the puzzle defying commonsense is centered on sentence snippets.
- **Word Puzzle**: Word-type brainteaser where the answer violates the default meaning of the word and focuses on the letter composition of the target question

We can find the examples of each puzzle in Table 1. In this paper we go through our team's system to solve both the sentence puzzle and word puzzle task.

The task requires us to to solve the brainteasers in the BRAINTEASER dataset (Jiang et al., 2023). The dataset was created by crawling the internet to find relevant puzzles. This is then filtered to remove irrelevant questions. The task is provided as a question-answering task in which for each puzzle we much select the correct answer from four options.

The task also consists of adversarial subsets to make sure that the approach is based on reasoning and not LLM memorization. The adversarial reconstructions are of two types.

[1]https://codalab.lisn.upsaclay.fr/competitions/15566

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 816–820

Question	Choices
Sentence Puzzle: A man shaves everyday, yet keeps his beard long	He is a barber. He wants to maintain his appearance. He wants his girlfriend to buy him a razor. None of the above.
Word Puzzle: What part of London is in France?	The letter N. The letter O. The letter L. None of the above.

Table 1: Sentence and Word puzzle examples.

- **Semantic Reconstruction** rephrases the original question without changing the correct answer and the distractors.
- **Context Reconstruction** keeps the original reasoning path but changes both the question and the answer to describe a new situational context.

We find instances of adversarial reconstructions in Table 2

2.2 Previous Work

The field of natural language processing has seen massive developments since the discovery of transformers (Vaswani et al., 2023). Initially used in machine translation, transformers found their way into other fields of natural language processing as well including large language models. These large language models like BERT (Devlin et al., 2019), LLaMA/Llama 2 (Touvron et al., 2023a, Touvron et al., 2023b) and OpenAI's GPT-3 (Brown et al., 2020) and GPT-4 (OpenAI, 2023) have powerful reasoning capabilities and can be applied on various tasks involving natural language.

Prompt engineering refers to structuring the input text for a large language model. Methods like prompt engineering and fine-tuning have tremendous efficacy on downstream tasks. If prompted on the role of the language model along with the input question and/or relevant data, language models do a good job on providing the correct output even in a zero-shot manner (Sanh et al., 2022).

There have been quite a few benchmarks for testing the creativity of automatic natural language systems. Identifying puns (Zou and Lu, 2019) and humour (Meaney et al., 2021) is an example of this. The shared task proposed in (Lin et al., 2021) tests the natural language understanding and creativity of it's systems by testing the systems on riddle style questions. This is pretty close to the `BRAINTEASERS` shared task that requires the system to automatically solve brainteasers. The commonsense reasoning ability of these language models are also tested with various benchmarks (Rajani et al., 2019, Ma et al., 2019, Lourie et al., 2021, Maharana and Bansal, 2022). These metrics provide a good analysis of the vertical thinking capabilities of the systems. However for the brainteaser task it is important to think in ways that go against common sense. It is also imperative for the model to understand the questions instead of just memorization as adversarial ways of forming the questions also exist in the task.

2.3 Evaluation Metrics

The systems will be evaluated on their accuracy in the question-accuracy tasks. The following two accuracy metrics are used.

- **Instance-based Accuracy**: where each question individual/adversarial are considered as a separate instance. The accuracy for the original question as well as both of the adversarial ways will be reported.
- **Group-based Accuracy**: This evaluates the accuracy of the original question along with its adversarial reconstructions combined. The value is only counted as correct if it gets all of these questions correct.

3 System Overview

3.1 GPT-4

We use the GPT-4 turbo as `gpt-4-1106-preview` model from the GPT-4 (OpenAI, 2023) family of models. We access the GPT-4 model using the OpenAI API. GPT-4 turbo has a 128,000 token context window and can solve difficult problems with

Adversarial Strategy	Question	Choice
Original	A man shaves everyday, yet keeps his beard long.	He is a barber. He wants to maintain his appearance. He wants his girlfriend to buy him a razor. None of the above.
Semantic Reconstruction	A man preserves a lengthy beard despite shaving every day.	He is a barber. He wants to maintain his appearance. He wants his girlfriend to buy him a razor. None of the above.
Context Reconstruction	Tom attends class every day but doesn't do any homework.	He is a teacher. He is a lazy person. His teacher will not let him fail. None of the above.

Table 2: Adversarial reconstructions of the brainteasers

greater accuracy than previous generation large language models. This is due to its broader general knowledge and advanced reasoning capabilities, its training data is up to the date of April 2023. We use the chat completions API in JSON mode to ensure that we get the correct option answer from the question passed to the model.

3.2 Prompts

We use prompt engineering with the roles of system prompts and user prompts to tell the model what to do and what instructions to follow.

- **Role Prompt**: You are an assistant that only responds in json. You solve riddles and brainteasers that require complex reasoning. Solve the riddle/brainteaser by selecting the correct option from the given option list. The response json should be in the format "optionindex": array index of the option selected from option list. this should be a zero-based index , "optionanswer": The answer selected from the given option list I only want the json output of this.

- **User Prompt**: Solve this brainteaser: (brainteaser question here) optionlist: (answer optionlist here)

With this we can see that we use one role prompt for the entire system, both sentences and word puzzles, and for the user prompt we specify the different questions and the options for the answer.

4 Experimental Setup

We load the BRAINTEASER test datasets (Jiang et al., 2023) provided to us by the BRAINTEASER shared task organizers using the HuggingFace datasets library (Lhoest et al., 2021). For the sentence puzzle we have 120 puzzles with 4 options corresponding to each puzzle and for the word puzzle we have 96 question s and for each question we have 4 options. The test set is unlabeled, it doesn't specify the correct option, and our systems must evaluate the correct option for each brainteaser.

We generate the prompts for each question with the methods specified above and pass them to the GPT-4 turbo chat completions API for solving the brainteasers.

5 Results

For evaluation, the organizers rank the system based on accuracy of the answers on the question-answering task. The GPT-4 with prompt engineering system that we have provided achieves 9th place on the leaderboard in the evaluation phase [2]. The performance of the system on all the different evaluation components can be found in Table 3 for the sentence puzzle and in Table 4 for the word puzzle.

Abstract

In the dynamic realm of digital media, headline generation stands as a critical force, bridging science and creativity to capture audience interest while ensuring accuracy. Current challenges in numerical integration impede precision, with extractive methods compromising accuracy and abstractive approaches struggling with coherence. Extractive methods, reliant on condensing sentences from source material, often fail to capture nuanced information accurately. Our study pioneers a novel two-step training approach, advancing NLP and emphasizing the crucial need for enhanced numerical reasoning in headline creation. Employing Masked Language Models like BERT and RoBERTa, known for nuanced understanding, and the T5 model's unique text-to-text processing for NLP tasks, our research showcases promising advancements. The Flan-T5 model, integrating external contributions and our dataset, enhances T5's capabilities. Through a rigorous comparative analysis, our study demonstrates the models' effectiveness in overcoming challenges related to numerical integration and headline generation.

1 Introduction

In the dynamic domain of digital media, the synthesis of scientific rigor and creative flair in headline generation is paramount for capturing audience interest while maintaining accuracy. Yet, a persistent challenge arises in integrating numerical data into these headlines with precision. Conventional methods often fall short, either by overlooking crucial numerical insights or sacrificing clarity.Consider the task of distilling information from source material, where existing techniques frequently neglect the nuances of numerical discourse—a critical shortfall, particularly in fields such as finance. This challenge extends to the domain of natural language processing (NLP), where computational systems strive to comprehend and generate human language seamlessly.Our research addresses this challenge through an innovative methodological approach. By leveraging advanced language models like BERT, RoBERTa, and T5, we aim to advance computational linguistics, particularly in reconciling textual narratives with numerical data.Furthermore, we introduce the Flan-T5 model, which integrates external contributions and proprietary datasets to enhance headline generation capabilities. Through systematic comparative analysis, our study validates the efficacy of our approach in overcoming challenges related to numerical integration and headline creation.

NEWS: The US is in the grip of the worst drought in more than 50 years, with almost 80% of the country either in drought or in abnormally dry conditions. The NOAA's latest report finds that 56% of the continental US is in drought, the sixth-highest percentage on record and the worst since 1956, reports the Washington Post. Topsoil has dried out and crops, pastures, and rangeland have deteriorated at a rate rarely seen in the last 18 years, the NOAA says. The Department of Agriculture has declared the drought the biggest disaster in its history, and forecasters expect little relief in the short term for the middle of the country, where corn and soybean crops have been devastated. I have never seen this type of weather before like this. A lot of old timers haven't either, a farmer in Kansas who has seen his corn crop wither and his cattle pastures dry up tells the AP. I just think we are seeing history in the making.

DistilRoBERTa :"Drought Reaches Unprecedented Levels in the US, Worst Since 1956 - NOAA Report"

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 821–828

FLAN T5: "Unprecedented Drought Grips US, Surpassing 1956 Record, NOAA Report Reveals"
T5: "NOAA: US Facing Worst Drought Since 1956, Agriculture Department Declares Historic Disaster"

Table 1: Sample Data for Headline Generatiion

In essence, our work underscores the importance of advancing computational methodologies to reconcile textual and numerical information. By doing so, we not only refine headline generation practices but also contribute to broader discussions on information dissemination in the digital era, fostering enhanced engagement and understanding among diverse audiences.

2 Related work

2.1 Graph-based Neural Networks

Shuzhi[1] proposed a paper on Fake News Detection through Graph-based Neural Networks provides a detailed examination of techniques, focusing primarily on graph-based methodologies.This system lacks a comprehensive comparative analysis with empirical validation across diverse approaches and datasets.

2.2 Seq2seq Model

Khairul[2] paper introduces a Multitasking-Based Seq2seq Model, SEQ2SEQ++, aiming to enhance chatbot performance. While comparing with two recent models, It lacks a comprehensive analysis against a wider range of existing techniques.

2.3 LaMini-LM

Abdul[3] paper proposes LaMini-LM, a technique to create smaller models from instruction-tuned large language models (LLMs) to address resource-intensive issues. LaMini-LM achieves comparable performance to strong baselines through meticulous fine-tuning and a diverse set of instructions. This approach optimizes resource utilization, making it suitable for resource-constrained environments.It lacks in generalizing the large models and different architectures due to less scalable performance and less applicability across settings.

2.4 NumNet:

Qiu Ran[10] paper introduces NumNet, a numerical machine reading comprehension (MRC) model employing a numerically-aware graph neural network for improved numerical reasoning. This models becomes complex for higher mathematical operations and computation costs are high during training.

3 Dataset Description

3.1 Subtask 1: Fill the Blank In News Headline

The NumHG dataset, consisting of 21,157 news stories from Newser, forms the basis for Subtask 1 by concealing numbers within masked headlines. The organized validation set of 2,572 articles follows a structured approach, featuring four columns: "News" (article content), "Masked Headline" (hiding numbers), "Calculation" (operations, copy, round, paraphrase, and conversion), and "Answer" (correct numerical values). This methodical structure serves as a robust foundation for constructing and evaluating models, facilitating the task of filling in blank news headlines with hidden numbers.

3.2 Subtask 2: Headline Generation

The dataset for Subtask 2 includes 2,365 validation and 21,157 training news articles. Differing from Subtask 1, this subset prioritizes headline creation over filling blank spaces, omitting the "calculation" column. The dataset structure is meticulously curated for cohesive training, sharing headlines with Subtask 1 articles for a unified approach. This strategic curation enhances overall dataset continuity and reliability for our study project.

4 Methodology

4.1 Proposed Models

4.1.1 Masked Language Model

Masked Language Models, exemplified by BERT, predict masked tokens in sentences like news headlines. RoBERTa, a more advanced version, improves upon BERT's design with enhanced linguistic pattern recognition. Trained on a dataset over 10 times larger than BERT, RoBERTa excels in discerning subtle nuances. Its dynamic masking strategy during training boosts its ability to acquire robust word representations.

DistilRoBERTa offers a streamlined, efficient alternative without sacrificing essential features.

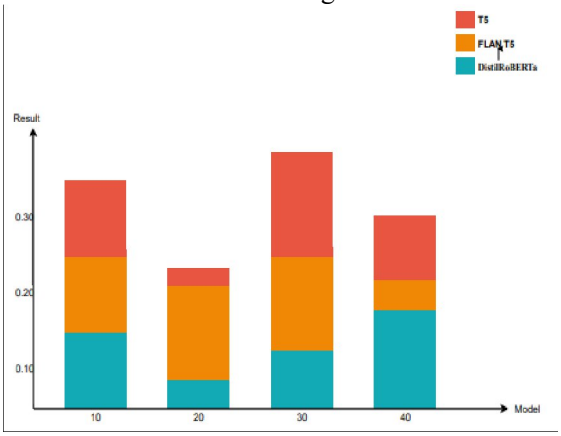

Figure 1:Result Vs Models for Subtask 1

4.1.2 T5 Language Model

The T5 model, or Text-to-Text Transfer Transformer, employs a unique approach in processing text input and generating corresponding text output for various NLP tasks. Unlike BERT, T5 utilizes a method introduced by Mishra in 2020, replacing consecutive tokens with a single "Mask" keyword. Specifically tailored for tasks like text summarization and headline generation, T5 diverges from BERT's focus on predicting individual words. In our research, we leverage external contributions, including Michal Pleban's training of the T5-base model on a dataset of 500k articles with headings, aimed at generating concise headlines (Pleban, 2020). Caleb Zearing's significant efforts in training T5 on a large collection of Medium articles for generating article titles also contribute to our research (Zearing, 2022). Building upon both Pleban's and Zearing's models, we enhance training with our proprietary dataset to advance NLP capabilities further.

4.1.3 Flan-T5 Model

The Text-to-Text Transfer Transformer (T5) offers a unique approach to handling text input and generating equivalent text output in various NLP applications. Unlike BERT, T5 utilizes a single "Mask" keyword to replace multiple consecutive tokens, as introduced by Mishra in 2020, enhancing its capability for tasks like text summarization and headline creation. Building upon T5's framework, we incorporate models trained for specific tasks by external researchers, such as T5-base-en-generate-headline (Pleban, 2020), designed for generating concise headlines from articles.

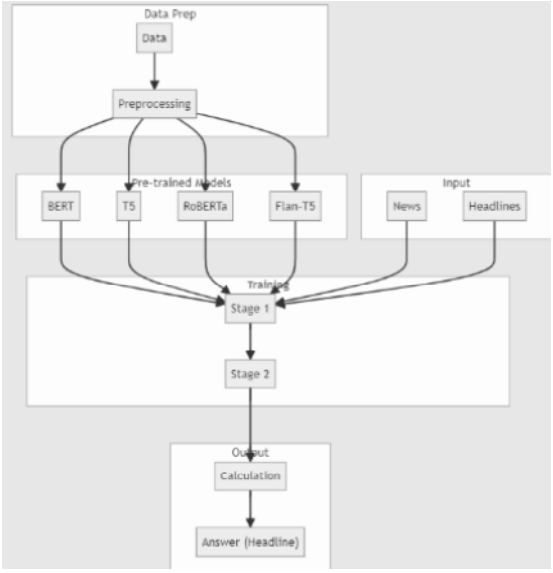

Figure 3: Proposed Architecture

Our research aims to leverage the valuable contributions of external researchers like Michal Pleban, expanding the understanding of T5's versatility in diverse applications.

4.2 Subtask 1

4.2.1 DistilRoBERTa

In order to prepare the dataset for DistilRoBERTa training, we combined pertinent columns and replaced underscores in the headlines with mask tokens. We used input-output pairs to train the model with a learning rate of 5e-5. To improve the model's predictive power, we gave the top 20 vocabulary tokens for numerical value extraction during training priority. Our objective was to improve DistilRoBERTa's numerical reasoning task performance by means of meticulous optimization and sophisticated training methods. This thorough method guarantees accurate and contextually relevant output, improving the model's usefulness in headline generation and other NLP tasks.

4.2.2 T5 & Flan-T5 Models - Train in One Step

We expanded training by including two additional T5-based models alongside Flan-T5. For masked headlines, we replaced underscores with a token and combined them with news columns as inputs, excluding the calculation column due to its

negative impact on performance. Flan-T5 was trained with a learning rate of 2e-5, while T5 models used 5e-5. A method to extract numerical values for blanks was implemented by finding the token index in each headline. Our aim was to enhance the models' accuracy in generating numerical values in headlines through iterative refinement of training settings, emphasizing the importance of adapting training approaches to optimize performance in tasks like numerical reasoning and headline generation.

4.2.3 T5 & Flan-T5 Models - Train Twice in Two Steps

The training procedure for T5 and Flan-T5 models involved two phases aimed at enhancing prediction accuracy and comprehension. Initially, the models were trained using news and masked headlines, with the calculation column as labels to understand the relationship between headlines, news content, and calculations.

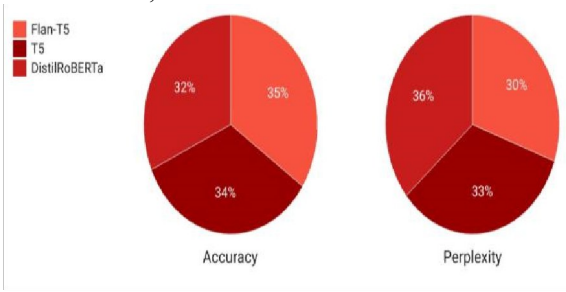

Figure 2: Accuracy Vs Perplexity for Subtask 1

In the second phase, the models were trained with the answer column as output and the calculation column as input to reinforce comprehension of calculation methods. This systematic approach ensured precise headline creation. Flan-T5, built upon the T5 architecture, revolutionizes text processing for NLP tasks by replacing successive tokens with a single "Mask" term, improving performance in tasks like text summarization and headline creation. By leveraging expertise from models like T5-base-en-generate-headline (Pleban, 2020), T5 becomes more versatile across applications, thanks to contributions from researchers like Michal Pleban.

4.3 Subtask 2

Based on T5 architecture, the Flan-T5 model transforms text production and handling for NLP applications. In contrast to BERT, it replaces successive tokens with a single "Mask" term, improving performance in tasks like text summary and headline creation. By incorporating models that are experts at creating succinct headlines, such as T5-base-en-generate-headline (Pleban, 2020), we increase the utility of T5. The excellent contributions of outside researchers such as Michal Pleban have allowed T5 to become more versatile in a wider range of applications.

5 Result

Subtask 1: Fill the Blank In News Headline

In our comprehensive assessment of seven distinct models—Czearing, Czearing with Two Steps, Lamini, Lamini with Two Steps, Michau, Michau with Two Steps, and DistilRoBERTa-based—our primary metric for evaluation was perplexity.

Model	***Accuracy (%)***	***Perplexity (Before)***	***Perplexity (After)***
Czearing (Single Step)	85.7	3.21	1.45
Czearing (Two Steps)	82.4	3.45	1.58
Flan-T5 (Single Step)	88.9	2.66	1.05
Flan-T5 (Two Steps)	90.2	2.18	0.92
Michau/t5-base	86.5	2.89	1.12
DistilRoBERTa-base	78.3	4.75	2.39

Table 2: Model Perplexity Before and After Training

The results showcased a notable enhancement in performance across all models post-training, indicating improved proficiency in numerical reasoning tasks.

Flan-T5 (Two Steps) emerged as the top performer in accuracy, boasting an impressive 90.2%. This model exhibited exceptional competence in arithmetic operations, decimal rounding, and handling complex mathematical operations.

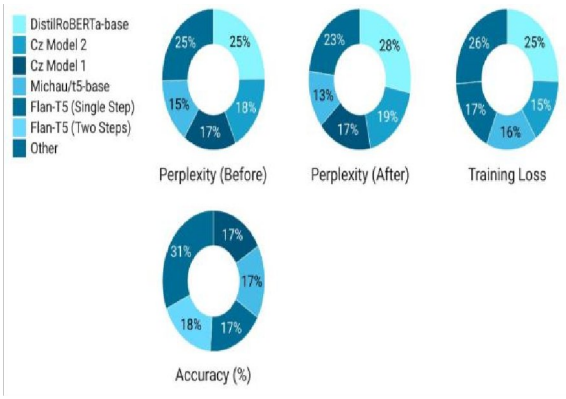

Figure 4:Performance Metrics for Subtask 1

A detailed analysis of error patterns revealed specific challenges encountered by the models, particularly in the domains of arithmetic operations, rounding decimal numbers, and combinations of various mathematical operations. These insights provide valuable guidance for refining the models and addressing their limitations.

The Czearing models demonstrated competitive performance, with the base Czearing achieving a training loss of 0.0250. Notably, Czearing with Two Steps exhibited comparable results, indicating the efficacy of the two-step approach.

Figure 5: Sample Data for Subtask 1 using Czearing (one step) model

MBZUAI/LaMini-Flan-T5-783M models showcased effective headline generation, achieving a training loss of 0.1411 and a validation loss of 0.1869 over four epochs. This performance underscores the model's proficiency in numerical reasoning tasks.

T5-based models, such as Michau/t5-base-en-generate-headline, demonstrated a significant reduction in perplexity from 2.66 to 1.05, showcasing enhanced numerical reasoning capabilities. The DistilRoBERTa-based model (distilroberta-base) also displayed successful adaptation to numerical reasoning, with perplexity decreasing from 6.23 to 3.68.

Our comparative analysis reveals that both T5-based and DistilRoBERTa-based models exhibit promising performance in numerical reasoning tasks. Particularly, the Flan-T5 model, especially in its Two Steps variant, stands out with superior accuracy in subtask 1. These findings provide valuable insights into the effectiveness and versatility of transformer-based models in addressing complex numerical reasoning applications. The observed improvements in perplexity post-training underscore the adaptability and learning capabilities of these models in handling diverse numerical challenges.

Error Type	***Examples***
Arithmetic Operations	Misinterpretation of mathematical symbols
Rounding Decimals	Incorrect rounding of numerical values
Combination of Operations	Challenges in handling complex expressions

Table 3: Error Patterns for Subtask 1

Subtask 2: Headline Generation

The first model, czearing/article-title-generator, harnessed the T5-base architecture during a 10-epoch training phase. This process yielded promising results with a training loss of 1.3876 and a validation loss of 1.6684. The tokenization methodology involved a maximum sequence length of 2024 for input and 128 for labels.

Figure 6: Comparision between T5 and Flan T5 Model for Subtask 2

Our evaluation process included a meticulous analysis of headline predictions using the ROUGE-L metric. The model demonstrated a proficiency in generating headlines that are not only contextually relevant but also exhibit a

nuanced understanding of numerals. To illustrate, when faced with the news snippet "US Soldier Held After Killing 5 at Baghdad Base," the model's prediction, "US Soldier Charged With Killing 5 at Stress Clinic," received a commendable ROUGE-L score of 0.74. A similar success was observed with the news piece "Nintendo Chief Dies at 55," where the model predicted "Nintendo President Dead at 55" with an impressive ROUGE-L score of 0.92.

Moving to the second model, michau/t5-base-en-generate-headline, which employed the T5-base-en-generate-headline architecture, underwent 7 epochs, achieving a training loss of 1.3329 and a validation loss of 1.6855. Tokenization parameters included a maximum sequence length of 2024 for input and 256 for labels.

In terms of predictions, this model also displayed competitive performance, albeit with a different focus. The ROUGE-L scores reflected the model's proficiency in numeral-aware headline generation. For instance, when presented with the news snippet "3 Killed in California Quarry Shooting Spree," the model predicted "3rd Victim Dead in Quarry Shooting; Manhunt St..." and obtained a ROUGE-L score of 0.38. Similarly, for the news piece "Dow Up 305 on Election Day," the predicted headline "Stocks Up 305 in Election Rally" garnered a ROUGE-L score of 0.50.

Both models exhibited noteworthy capabilities in capturing not only the essence of the news but also the specific nuances associated with numerals. The competitive ROUGE-L scores across different samples affirm the models' efficacy. These results suggest a potential application of these models in real-world scenarios where numeral-aware headline generation is crucial. The nuanced understanding of numerals showcased by these models positions them as valuable assets in the evolving landscape of natural language processing tasks.

5 Conclusion

Our research presents a significant stride in advancing numerical reasoning within the domain of news headline generation. The thorough evaluation of transformer models, including Flan-T5, DistilRoBERTa, and T5 variants, showcased remarkable improvements in accuracy for filling blank headlines with hidden numbers. Flan-T5 (Two Steps) particularly stood out with a commendable 90.2% accuracy, demonstrating exceptional competence in arithmetic operations and handling complex mathematical expressions. Additionally, the nuanced understanding of numerals displayed by T5 models in Subtask 2 underscores their efficacy in generating contextually relevant headlines. These findings collectively contribute valuable insights into the evolving landscape of natural language processing, especially in tasks involving numerical reasoning and headline creation.

TueSents at SemEval-2024 Task 8: Predicting the Shift from Human Authorship to Machine-generated Output in a Mixed Text

Valentin Pickard and Hoa Do
Seminar für Sprachwissenschaft
Eberhard Karls Universität Tübingen, Germany
{valentin.pickard, hoa.do}@student.uni-tuebingen.de

Abstract

This paper describes our approach and results for the SemEval 2024 task of identifying the token index in a mixed text where a switch from human authorship to machine-generated text occurs. We explore two BiLSTMs, one over sentence feature vectors to predict the index of the sentence containing such a change and another over character embeddings of the text. As sentence features, we compute token count, mean token length, standard deviation of token length, counts for punctuation and space characters, various readability scores, word frequency class and word part-of-speech class counts for each sentence. class counts. The evaluation is performed on mean absolute error (MAE) between predicted and actual boundary word index. While our competition results were notably below the baseline, there may still be useful aspects to our approach.

1 Introduction

With the rapid proliferation of Large Language Models (LLMs) that are able to produce fluent texts in response to user queries across a wide range of domains and topics, concerns are raised about the potential misuses of such powerful tools. In spite of their fluency, LLM-generated texts may contain factual errors, inadvertently spreading misinformation. Another common issue occurs in the education system, where students may attempt to pass off the responses of such an LLM as their own work, evading commonly used safeguards against plagiarism. Given the overwhelming volume of potentially machine-generated content, it is desirable to have automated means of detecting such texts to address the above-mentioned issues. In this task (Wang et al., 2024), we examine exclusively English mixed texts, where a switch from human authorship to LLM output occurs at most once in a text sample (some samples are entirely machine-generated). To us, this models a plausible use case, where a human user employs an LLM to finish their work for them. For each sample, the task is to predict the token index at which the authorship change occurs. We observe, that due to the structure of the samples, we can reformulate the task more generally as trying to detect an authorship change and its location within the sample texts, without explicitly trying to detect the presence of LLM-generated text. This allows us to adapt more traditional, computationally relatively inexpensive approaches to stylometry and authorship identification/attribution. While the task is formulated as prediction of a boundary word, we begin by identifying the boundary sentence in which the authorship change occurs. For each sentence, textual feature vectors are extracted and combined with character n-gram information, those sentence vectors are then fed into a Bidirectional LSTM network (Hochreiter and Schmidhuber, 1997) which is trained to predict the boundary sentence. We found that our approach performed reasonably well in-domain on the development set, in spite of inevitably introducing some token offset error by only making sentence level predictions and choosing the middle tokens, but failed out-of-domain on the test set, ranking at 26 out of 30 in the competition on subtask C.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 829–832

2 Background

In accordance with the task guidelines we do not use external data, but use the English subsets of larger data sets from subtask A and B to extract a character vocabulary. The subtask C dataset comprises a bit over 4000 texts with 505 pre-split into a dev set by the task authors, each text labeled with the index of the boundary word. The following table shows token and sentence counts for train and dev set, when tokenized by splitting on whitespace (U+0020) as in the task baseline model. Sentence splits are determined subsequently on the token lists by identifying sentence-final tokens using our detection regex, this is done to ensure matching the given boundary word labels.

	train	dev
texts	3,649	505
sentences	41,570	5,628
tokens (types)	864,153 (29,593)	116,221 (8,641)
chars	5,933,701	803,771
avg. sentences	11.4	11.1
avg. boundary	3.4	3.4

Table 1: Task data statistics

We observe that about half of the samples contain 4 - 11 sentences and sentence count per sample ranges from 1 to 76, with 24 samples containing just one sentence, like e.g. *"We have added a 2+ page* ***discussion*** *on the experimental results, highlighting the superiority of the ARC-based models and their impact on the field of deep learning."* (boundary word 'discussion' in bold). While on average the author switch occurs in the fourth sentence, in about 15-20% of the samples the switch occurs in the first sentence. Examining the boundary word position within their respective sentences we found an average offset of -1.6 (train set) or -1.8 (dev set) from the middle of the sentence, i.e. the switch occurs slightly before mid sentence on average.

An example text, split in sentences and tokens can be observed below, with the boundary word **"baseline"** at index 20 highlighted:

- Format: *label*: (*start token index*) [*tokens*]
- 0: (0) ['The', 'paper', 'proposes', 'a', 'method', 'to', 'recognize', 'time', 'expressions', 'from', 'text.']
- 1: (11) ['It', 'is', 'a\r\nsimple', 'rule-based', 'method,', 'which', 'is', 'a', 'strong', '**baseline**', 'for', 'time', 'expression', 'recognition.']
- 0: (25) ['The', 'authors', 'analyze', 'different', 'datasets', 'and', 'discover', 'that', 'only', 'a', 'small', 'set', 'of', 'words', 'are', 'consistently', 'used', 'to', 'convey', 'time', 'information.']
- remaining sentences omitted for brevity

Interestingly, by using the given tokenization method on whitespace only, we preserve linebreak characters such as in the third token of the second sentence, and obtain empty string tokens in between multiple whitespaces. We choose to include both this 'raw' text data as well as a normalized version in our system, since on the one hand, such typographic choices are indicative of authorship changes but on the other hand, we may not be able to rely on their presence in unseen data.

3 System overview

In our system, we at first sought to compare and combine more traditional textual features with task-specific learned character embeddings, as the former offer the benefit of cheap computation and greater transparency, whereas the latter should allow the system to capture more subtle patterns at the expense of transparency and at a higher computational cost. We choose a relatively straightforward basic architecture for our models, using a BiLSTM over sentence vectors to predict the boundary sentence at which the authorship change occurs. With regards to textual features, we compute for each sentence: token count, mean token length, standard deviation of token length, counts for punctuation and

space characters, various readability scores, word frequency class and word part-of-speech class counts. For our character model, we used another BiLSTM with embedding layer over the text characters, adjusting the token labels to the character level. As the character level model did not perform to our expectations on both normalized and raw text, we did not combine it with the textual feature model and decided to use the latter as a stand-alone model.

4 Experimental setup

We used the provided train/dev split to tune our models. We compared performances of a purely textual feature based model and a character-based model. We extracted the textual features offline, using the *spacy* (Honnibal and Montani, 2017) library for Python and its *textdescriptives* (Hansen et al., 2023) extension library. We used the *en_core_web_sm (v3.7.1)* pipeline for spacy. Hyperparameters were tuned manually, we settled on single-layer networks of hidden size 16, using Adam optimizer (Diederik, 2014) with learning rate 1e-5, training on batches of size 8 over 100 epochs. For the character-based network we choose an embedding size of 8. The task is evaluated on mean absolute error (MAE) between predicted and actual boundary word index. To translate our boundary sentence prediction into a token index, we selected the middle token index as default, rounding it down for sentences with an even token count. For the character model, we chose the token containing the predicted character index.

5 Results

On the development set our textual feature model showed somewhat promising results with regards to predicting the sentence containing the boundary word. It predicted the correct sentence in 69.9% of cases, the adjacent sentence in a further 21.4% with a sentence index MAE of 0.47. Translating these predictions into token level predictions using the sentence mid-point yielded a token MAE of 13.5, notably worse than the baseline model's. Our character embedding model did perform notably worse on the development set, with a token MAE of 48.9. We therefore did not pursue it further and abandoned our initial idea of combining it with the textual feature model. On the test set, for the competition, we submitted the predictions of our textual feature model, unfortunately not matching the performance on the development set. We only managed to predict 30% of boundary sentences correctly, with another 22.6% predictions of the adjacent sentence, resulting in a sentence MAE of 3.2 and a disappointing token MAE of 59, ranking 26 out of 30 among the participant models in subtask C. We suspect this drop in performance mainly be caused by introduction of a new text domain in the test set, while development and training samples are exclusively drawn from PeerRead (Kang et al., 2018) i.e. academic peer reviews, the test set introduces student essays from OUTFOX (Koike et al., 2023). This degradation of performance for stylistic textual features is in line with other findings, e.g. the comparisons performed on the M4 dataset (Wang et al., 2023) of which this competition's dataset is an extension.

6 Conclusion

While our model's performance leaves plenty of room for improvement, we can envision the use of simple textual features in a lightweight model, similar to ours as a basic tool in contexts where more powerful models are either unavailable or too expensive to run and the text domain is known in advance. Focusing on sentence level instead of token level predictions allows us to reduce computational effort and we consider it sufficient for many practical applications, where automated detection of LLM generated text is only a first step, such as e.g. examining student essays, where we would expect a teacher to follow up with affected students regarding suspicious spans of text individually.

Abstract

The increase in the popularity of code mixed languages has resulted in the need to engineer language models for the same . Unlike pure languages, code-mixed languages lack clear grammatical structures, leading to ambiguous sentence constructions. This ambiguity presents significant challenges for natural language processing tasks, including syntactic parsing, word sense disambiguation, and language identification. This paper focuses on emotion recognition of conversations in Hinglish, a mix of Hindi and English, as part of Task 10 of SemEval 2024. The proposed approach explores the usage of standard machine learning models like SVM, MNB and RF, and also BERT-based models for Hindi-English code-mixed data- namely, HingBERT, Hing mBERT and HingRoBERTa for subtask A.

1 Introduction

Code-mixed Hindi and English, also referred to as 'Hinglish', has gained widespread usage, especially in the realm of social media. With the increasing prevalence of code-mixed languages like Hinglish, there arises a necessity to analyze and understand this linguistic material. While language models designed for individual languages like English or Hindi (Ly, 2022) are quite robust and effective, they often struggle to perform well with code-mixed languages. This difficulty stems from the colloquial nature of the conversations in code-mixed dialogue, with no formal grammar rules.

Traditional machine learning models perform well on code-mixed data only when the nature of the classification task is simple, like in the form of sentiment analysis (classification into positive, neutral, and negative emotions). Task 10 of SemEval 2024 (Kumar et al., 2024) contains emotions from the extended Ekman model(Ekman, 1992), which contain emotions that are more complex to discern and distinguish between like contempt versus anger.

This paper explores the usage of both classical machine learning models as well as Transformer-based BERT models, specifically designed for Hinglish data.

2 Related Work

Thakur et al. (2020) delve into the current landscape of Hindi-English code-mixed natural language processing and their work meticulously surveys the progress made in sentiment analysis within this domain while also dissecting the inherent issues and challenges it encounters.

Sentiment analysis in code-mixed data is done in a plethora of ways, spanning from machine translation to corpus processing based on sentence structure. Jadhav et al. (2022) introduced a framework employing a pipeline for the conversion of Hinglish to English, offering a structured approach to the task. Similarly, Sinha and Thakur (2005) present a method for translating Hinglish to both English and Hindi, leveraging Hindi and English morphological analyzers and implementing cross-morphological analysis to achieve accurate conversion. Ensemble learning for identifying emotions in contextual texts was proposed by (Angel Deborah et al., 2020). Additionally, (S et al., 2022) proposed a lexicon-based solution for recognising emotions in Tamil texts.

Das and Singh (2023) embraced a deep learning paradigm, implementing convolutional neural networks (CNN), long short-term memory (LSTM), and bi-directional long short-term memory (Bi-LSTM) for sentiment analysis. Meanwhile, Ravi and Ravi (2016) conclusively identified a combination of TF-IDF vectorizer, gain ratio-based feature selection, and a Radial Basis Function Neural Network (RBFN) as the optimal pipeline for sentiment analysis of Hinglish data. Patwa et al. (2020) utilized M-BERT and the Transformers framework,

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 833–838

diverging from traditional methods. Singh (2021) employed diverse techniques for sentiment analysis of Hinglish, leveraging various embeddings such as count vectorizer and word2vec across different machine learning algorithms including SVM, KNN, and Decision Trees. A similar work by (Deborah et al., 2022) focused on recognizing emotions using Gaussian Process and decision trees.

However, the task of emotion classification poses a much greater challenge compared to the simpler task of sentiment analysis. It necessitates the utilization of specific techniques to process and balance data across a broader spectrum of classes. This paper attempts to utilize both traditional and Transformer based approaches for Hinglish emotion classification.

3 Dataset

The SemEval 2024 Task 10 dataset (Kumar et al., 2023) comprises 8056 samples, featuring fields such as ID, speaker, utterance, and emotion. The ID uniquely identifies each episode of the conversation, while the speaker field denotes the person speaking. The utterance field represents the dialogue, expressed in Hinglish, and the emotion field indicates the corresponding emotion conveyed in the utterance. Adding on, the validation dataset contains 1354 samples while the test dataset contains 1580 samples. Table 1 shows the distribution of labels in the dataset.

Emotion	Count
Anger	819
Contempt	542
Disgust	127
Fear	514
Joy	1596
Neutral	3909
Sadness	558
Surprise	441

Table 1: Distribution of emotions and their respective counts.

4 Data Preprocessing

In the domain of code-mixed emotion recognition, preprocessing the utterances is essential for effective model training. The emotion column, representing a spectrum of eight distinct emotions—'disgust', 'contempt', 'anger', 'neutral', 'sadness', 'fear', and 'surprise'—is encoded using a label encoder for standardized representation. Code-mixed data inherently presents spelling ambiguities, demanding robust normalization techniques. For example, the word 'friend' in Hindi could be spelled as 'dost', 'dhosth', 'dhost' etc. Spelling correction is done using a phonetic similarity assessment. For each word, a phonetic code is computed and identifies feasible correction candidates from a dynamically created phonetic dictionary. The Levenshtein distance metric is used to evaluate the dissimilarity between the input word and potential corrections. This procedure is applied to all the utterances, on each word. The resultant corrected words are subsequently merged to form a spell-corrected utterance. A dictionary of all the speakers is also created, and the speaker names present in the utterances are removed, along with numbers and symbols.

5 Proposed Methodology

5.1 Support Vector Machine, Multinomial Naive Bayes and Random Forest

To classify the utterances into one of the eight emotion classes, emotion labels were encoded using LabelEncoder. The CountVectorizer transformed text into numerical features. Initially, standard classification models like Support Vector Machines (SVM), Multinomial Naive Bayes (MNB), and Random Forest(RF) were utilized. These models were chosen based on their suitability for text classification tasks and their potential effectiveness in handling emotion classification within Hindi-English code-mixed data. These models were trained on the training set and evaluated on the validation set using accuracy and the weighted F1 score metrics. Table 2 and 3 shows the precision scores and other performance metrics of each of the standard machine learning models.

5.2 Long Short Term Memory (LSTM)

A Bidirectional LSTM model was then leveraged to address the challenges that could not be resolved by the SVM, MNB, and RF models. This model architecture is well-suited for sequential data processing tasks due to its inherent ability to capture long-range dependencies in text sequences. Figure 1 shows the architecture diagram of the Bidirectional LSTM model.

This bidirectional processing allows the model to effectively capture contextual information from

Emotion	SVM	MNB	RF
Anger	0.00	0.12	**0.19**
Contempt	**0.33**	0.00	0.17
Disgust	0.00	0.00	**1.00**
Fear	**0.33**	0.00	0.24
Joy	0.55	**0.58**	0.55
Neutral	0.43	0.43	**0.44**
Sadness	0.00	0.27	**0.28**
Surprise	0.22	**0.29**	0.27

Table 2: Precision scores of standard machine learning models

Metric	SVM	MNB	RF
Testing Accuracy	**0.44**	0.40	0.43
Testing Weighted F1	0.31	0.30	**0.33**

Table 3: Performance metrics of standard machine learning models

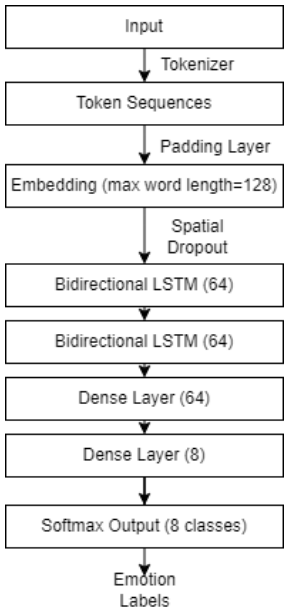

Figure 1: Architecture diagram of the Bidirectional LSTM model

preceding and succeeding words. The model architecture is described as follows:

Embedding Layer: This layer transforms input words into dense vectors of fixed size. It facilitates the representation of words in a continuous vector space, where similar words have similar representations.

Spatial Dropout1D Layer: This layer applies dropout to the input features with a dropout rate of 0.2. It helps prevent overfitting by randomly dropping input units during training.

Bidirectional LSTM Layers: The model consists of two Bidirectional LSTM layers. Each layer comprises 64 units and processes input sequences in both forward and backward directions.

Dense Layers: Two dense layers follow the LSTM layers. The first dense layer has 64 units and uses the ReLU activation function. The final dense layer has 8 units (equal to the number of emotion classes) and uses the softmax activation function for multi-class classification.

The training parameters are as follows:

Optimizer: The model is optimized using the Adam optimizer, a popular choice for training neural networks due to its adaptive learning rate.

Loss Function: Sparse categorical cross-entropy is used as the loss function, suitable for multi-class classification tasks with integer-encoded target labels.

Early Stopping: Training includes early stopping with a patience of 3 epochs. It monitors the loss metric and restores the best weights when no improvement is observed after the specified number of epochs.

Emotion	LSTM Precision Values
Anger	0.06
Contempt	0.08
Disgust	0.017
Fear	0.48
Joy	0.38
Neutral	0.12
Sadness	0.12
Surprise	0.21

Table 4: Precision scores of LSTM model

Batch Size: Training is performed with a batch size of 32.

Epochs: The model is trained for a maximum of 10 epochs.

The Bidirectional LSTM model achieves a test accuracy of **0.35** with a weighted F1 score of **0.43** on the testing set. Table 4 shows the precision scores of LSTM model.

5.3 Hindi-English Code Mixed BERT Models

The usage of BERT (Bidirectional Encoder Representations from Transformers) models tailored for Hindi-English code-mixed data can significantly enhance the accuracy and effectiveness of emotion classification tasks. These models are pre-trained on large corpora of code-mixed text and can be fine-tuned for specific classification tasks. In this

section, three models from the L3Cube Pune team (Nayak and Joshi, 2022), are utilized- namely HingBERT, Hing-mBERT, and HingRoBERTa.

5.3.1 HingBERT

HingBERT, akin to its BERT counterpart, comprises a stack of transformer blocks, typically 12 in number, with self-attention mechanisms and feed-forward neural networks. The model's architecture includes special tokens such as [CLS] and [SEP] to denote sentence boundaries and separation.

5.3.2 Hing mBERT

Hing mBERT inherits the architecture of BERT but is trained across a multitude of languages, including Hindi and English. Its architecture remains consistent with BERT's stack of transformer blocks, each equipped with self-attention mechanisms for capturing contextual information.

5.3.3 Hing RoBERTa

Hing RoBERTa, an extension of the RoBERTa architecture, delves into the intricacies of Hindi-English code-mixed text by integrating advanced architectural modifications. Built upon the foundation of RoBERTa's transformer-based architecture, Hing RoBERTa leverages deeper stacks of transformer layers, intricate attention mechanisms, and optimized weight initialization strategies to handle the nuances of bilingual conversations. With augmented batch sizes and increased learning rates, Hing RoBERTa optimizes gradient descent algorithms to navigate the vast parameter space effectively(Liu et al., 2019). Figure 2 shows the architecture diagram of the Transformer-based models.

5.3.4 Implementation

The implemented framework revolves around fine-tuning the HingBERT, Hing mBERT, and Hing RoBERTa Transformer-based models.

Architecture: The architecture is characterized by the transformer's ability to capture long-range dependencies and intricate contextual nuances within text sequences. Each model comprises a series of transformer blocks, with HingBERT and Hing mBERT featuring 12 transformer layers, while HingRoBERTa encompasses a more extensive architecture with 12 or more layers, as per its pre-defined configuration. Within each transformer block, self-attention mechanisms enable the model to dynamically weigh the importance of individual tokens based on their contextual relevance, facilitating effective feature extraction and representation learning.

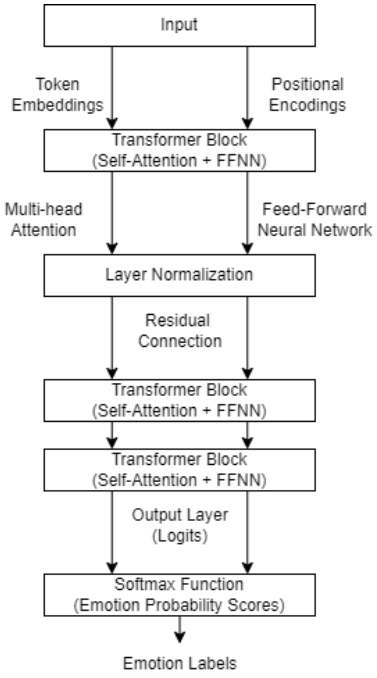

Figure 2: Architecture diagram of Transformer-based models

Multi-Head Attention Mechanism: The attention mechanism, a pivotal component of the transformer architecture, is augmented with multi-head attention, allowing the model to attend to different parts of the input sequence simultaneously.

Feed-Forward Neural Networks (FFNN): Following the self-attention mechanism, token representations are fed through feed-forward neural networks (FFNN) within each transformer block. FFNNs consist of multiple layers of linear transformations, interspersed with non-linear activation functions, such as the Rectified Linear Unit (ReLU), facilitating nonlinear transformations and feature extraction at each layer.

Gradient Clipping: Gradient clipping is employed during the backpropagation phase to alleviate the issue of exploding gradients, ensuring stable training dynamics and promoting convergence.

Embedding Layers: Token embeddings are employed to represent individual tokens within the input sequences, with dimensions determined by the pre-trained embedding matrices. Positional encodings are added to the token embeddings to convey positional information, allowing the model to differentiate between tokens based on their relative positions within the sequence.

Emotion	Hing BERT	Hing mBERT	Hing RoBERTa
Anger	0.28	0.27	**0.33**
Contempt	0.19	0.16	**0.26**
Disgust	**0.25**	0.20	0.20
Fear	0.24	0.23	**0.34**
Joy	0.45	0.49	**0.54**
Neutral	**0.52**	**0.52**	**0.52**
Sadness	0.35	0.28	**0.36**
Surprise	0.31	**0.34**	0.30

Table 5: Precision scores of BERT based models

	Hing BERT	Hing mBERT	Hing RoBERTa
Accuracy	0.45	0.44	**0.47**
Weighted F1	0.42	0.43	**0.45**

Table 6: Performance metrics of BERT based models

Activation Functions and Layer Normalization: Activation functions such as the GELU (Gaussian Error Linear Unit) are applied within the feed-forward neural networks to introduce non-linearity and enable the modeling of complex relationships within the data.

Tables 5 and 6 show the precision value across emotions and the accuracy and weighted F1-scores for the three Transformer-based models.

6 Results and Analysis

6.1 SVM, MNB and RF

The Support Vector Machine (SVM) classifier demonstrates varying performance across different emotions. Notably, it achieves relatively high precision for Contempt and Fear classes, scoring 0.33 for each. However, its precision is very low for Anger, Disgust, and Sadness, achieving 0.00 precision for these emotions. SVM's performance seems to struggle particularly with emotions characterized by intensity and subtlety. Multinomial Naive Bayes (MNB) exhibits competitive performance, particularly evident in its precision for Joy and Surprise emotions, achieving 0.58 and 0.29 respectively, which are among the highest precision values across all models.

Random Forest (RF) emerges as a robust performer across various emotions, demonstrating balanced precision values across the emotion spectrum. RF achieves perfect precision (1.00) for Disgust, indicating its capability to discern this emotion accurately within code-mixed text. Additionally, RF performs consistently well for Neutral and Sadness emotions.

While SVM and MNB show specific strengths for certain emotions, such as Fear and Joy respectively, RF emerges as a more balanced performer across the emotion spectrum, particularly excelling in capturing nuances associated with Disgust.

6.2 LSTM

The LSTM model's precision values exhibit notable variations across different emotions. While it achieves relatively high precision in classifying Fear (0.48) and Joy (0.38), its performance significantly diminishes in categorizing Disgust (0.017) and Anger (0.06). Despite its recurrent nature and ability to retain sequential information, the LSTM model appears to struggle with the contextual intricacies present in the emotion classification task. It achieves a weighted F1-score of 0.43.

6.3 Hindi-English Code-Mixed BERT Models

The BERT-based models showcase more consistent and generally higher precision values across various emotions. Specifically, Hing RoBERTa emerges as the top performer among the BERT-based models, achieving the highest precision scores in several emotional categories, including Contempt (0.26), Fear (0.34), Joy (0.54), and Sadness (0.36). Hing BERT and Hing mBERT also demonstrate competitive precision values, albeit slightly lower than Hing RoBERTa. HingRoBERTa achieves the highest weighted F1-score of 0.45. Table 5 and 6 shows the precision scores and other performance metrics of BERT-based models.

Our team, TechSSN1, placed 7th out of 39 participating teams in the shared subtask A.

7 Conclusion

The future scope of this work entails improving and enhancing the proposed models to handle a wider variety of data. The unstructured nature of Hinglish poses a challenge to the model's performance. By understanding the nuances, fine-tuning can be implemented to enhance the model's efficacy. Additionally, the work can be extended to encompass the classification of other types of emotions apart from the traditional Ekman model and refined to undertake tasks such as sarcasm or humor detection.

SHROOM-INDElab at SemEval-2024 Task 6: Zero- and Few-Shot LLM-Based Classification for Hallucination Detection

Bradley P. Allen, Fina Polat and **Paul Groth**
University of Amsterdam
Amsterdam, NL
{b.p.allen, f.yilmazpolat, p.t.groth}@uva.nl

Abstract

We describe the University of Amsterdam Intelligent Data Engineering Lab team's entry for the SemEval-2024 Task 6 competition. The SHROOM-INDElab system builds on previous work on using prompt programming and in-context learning with large language models (LLMs) to build classifiers for hallucination detection, and extends that work through the incorporation of context-specific definition of task, role, and target concept, and automated generation of examples for use in a few-shot prompting approach. The resulting system achieved fourth-best and sixth-best performance in the model-agnostic track and model-aware tracks for Task 6, respectively, and evaluation using the validation sets showed that the system's classification decisions were consistent with those of the crowd-sourced human labellers. We further found that a zero-shot approach provided better accuracy than a few-shot approach using automatically generated examples. Code for the system described in this paper is available on Github[1].

1 Introduction

Prompt engineering of large language models (LLMs) (Liu et al., 2023) has recently emerged as a viable approach to the automation of a wide range of natural language processing tasks. Recent work (Allen, 2023) has focused on the development of zero-shot chain-of-thought (Wei et al., 2022; Kojima et al., 2022) classifiers, where hallucination in generated rationales is a concern. Hallucination detection (Ji et al., 2023; Huang et al., 2023) is a way to determine whether the outputs of such systems are sensible, factually correct and faithful to the provided input. The SemEval-2024 Task 6 (Mickus et al., 2024) allows us to evaluate whether and how applying techniques we have developed in the above mentioned work and with related work on knowledge extraction (Polat et al., 2024) using zero- and few-shot classification can provide a means of addressing this concern. Previous systems that perform prompt engineering of LLMs as a means to implement hallucination detection include SelfCheckGPT (Manakul et al., 2023) and ChainPoll (Friel and Sanyal, 2023).

2 Data and Task

The challenge provides a dataset consisting of data points containing: the specific task that a given language model is to perform; an input given to the language model on which to perform that task; a target that is an example of an acceptable output, and the output produced by the language model. Table 1 shows an example of such a data point.

Task	Definition Modeling
Input text	"The Dutch would sometimes <define> inundate </define> the land to hinder the Spanish army ."
Target text	"To cover with large amounts of water; to flood."
Generated text	"(transitive) To fill with water."

Table 1: Example data point from the unlabeled training dataset for the model-agnostic task.

Hallucination detection is framed as a binary classification task, where the classifier assigns either 'Hallucination' or 'Not Hallucination' labels with associated probability estimates to data points. Classifier performance is evaluated by comparing these assignments and probabilities to human judgments and their probability estimates, using accuracy and Spearman's correlation coefficient (ρ) for assessment. Around 200 crowd-sourced human labellers each labeled about 20 data points. The competition features two tracks: model-agnostic, which uses the basic setup, and model-aware, adding a field for the Hugging Face model identifier of the model generating the text for each data point. Each track provides an unlabeled training dataset and labeled validation and test datasets.

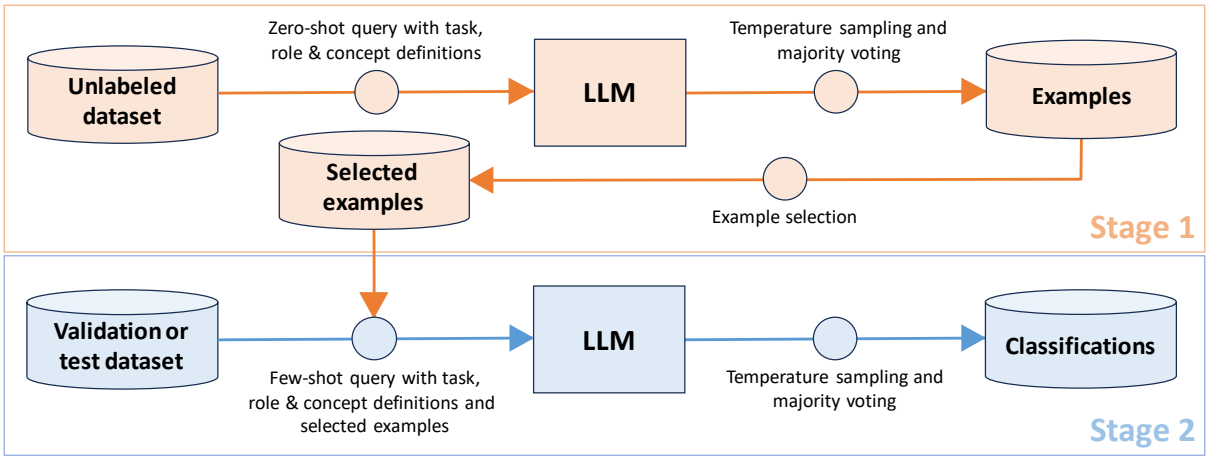

Figure 1: SHROOM-INDElab system workflow.

3 Approach

Our submission for the SHROOM task is a system that defines classifiers for hallucination detection using prompt engineering of an LLM. Figure 1 shows the two-stage workflow used to produce the classifier and evaluate it using the SHROOM datasets.

In Stage 1, we use in-context learning where we ask the LLM to perform the classification according to provided task, role, and concept definition in a zero-shot manner without providing any examples. These classified data points provide examples for a few-shot classifier used in Stage 2. We now proceed to describe the query design and processing steps in the workflow.

3.1 Zero- and few-shot query design

Figure 2 provides an example of the query used to prompt an LLM to produce a classification. The basic prompt template consists of instructions on how to evaluate the generated text according to a hallucination concept definition to answer the question if the generated text is a hallucination or not. Specific guidance is provided such that the form of the answer is in the labels needed to compare directly to the label test data.

The task associated with the data point determines the context for generating both the zero shot and the few shot query based on the prompt template, as illustrated in Figure 2. For the zero-shot query, no examples are included.

The elements involved in instantiating the template given a data point include the task definition performed by another LLM to produce the generated text, a role definition that we assign the classifier to perform, and the concept definition that frames hallucination phenomena and criteria to consider an output as hallucination. The use of role play with LLMs is described by (Shanahan et al., 2023) and its use in the context of zero-shot reasoning is described in (Kong et al., 2023). The role definition describes a persona that the LLM is instructed to assume in the context of making a classification decision. For example, for the Definition Modeling task, we instruct the LLM to assume the persona of a lexicographer. The task and role definitions for each task are shown in Table 2. We also provide a single concept definition for the notion of hallucination that is held constant across all of the tasks.

Task	Task definition	Role definition
Definition Modeling (DM)	The given task is Definition Modeling, meaning that the goal of the language model is to generate a definition for a specific term in the input text.	You are a lexicographer concerned that the generated text accurately captures the meaning of the term between the '<define>' and '</define>' delimiters in the input text.
Paraphrase Generation (PG)	The given task is Paraphrase Generation, meaning that the goal of the language model is to generate a paraphrase of the input text.	You are an author concerned that the generated text is an accurate paraphrase that does not distort the meaning of the input text.
Machine Translation (MT)	The given task is Machine Translation, meaning that the goal of the language model is to generate a natural language translation of the input text.	You are a translator concerned that the generated text is a good and accurate translation of the input text.
Text Simplification (TS)	The given task is Text Simplification, meaning that the goal of the language model is to generate a simplified version of the input text.	You are an editor concerned that the generated text is short, simple, and has the same meaning as the input text.

Table 2: Task and role definitions used for in-context learning.

3.2 Temperature sampling and majority voting

Part of the task involves producing an estimate of the probability that a data point exhibits hallucination. In the SHROOM-INDELab system, the estimated probability is calculated by performing temperature sampling (Ackley et al., 1985), query-

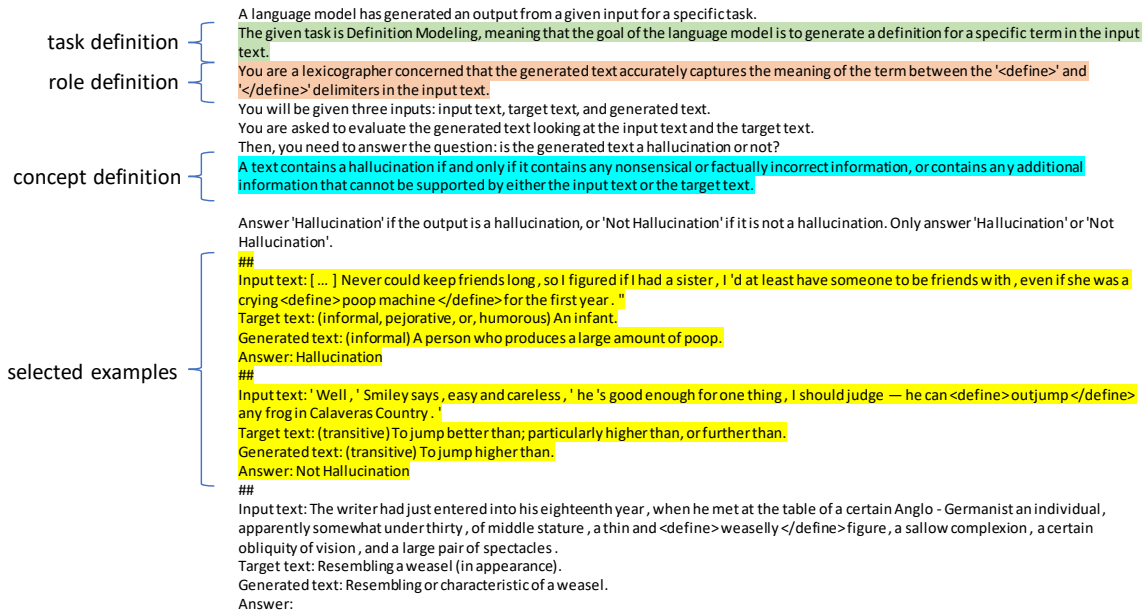

Figure 2: Example prompt for a Stage 2 classifier, given a Definition Modeling task data point from one of the SHROOM datasets, and using 1 example per label.

ing the LLM multiple times to generate a sample of classifications, and then dividing the number of positive classifications (i.e., where the generated label is 'Hallucination') by the total number of classifications in the sample. Temperature sampling is performed in producing both Stage 1 zero-shot and Stage 2 few-shot classifications.

3.3 Example selection

In Stage 1, the algorithm processes an unlabeled dataset to generate examples using a zero-shot query. Following the Self-Adaptive Prompting approach described in (Wan et al., 2023a,b), for each task type we sample 64 data points from the unlabelled dataset, and then use a zero-shot query to obtain a classification with estimated probability of hallucination. This information is combined with the data point to produce an example. We partition the examples per task type into two pools, one with positive examples where the label is 'Hallucination' and the other with negative examples where the label is 'Not Hallucination'.

The process used to select the examples to include in the prompt is shown in Algorithm 1. The first example chosen from each pool is the one with the maximum negative entropy of the classification probability, as defined in Equation 1:

$$F_0(p) = p * \log p + (1-p) * \log(1-p) \quad (1)$$

Algorithm 1 Select examples given a task and label

Require: P: generated examples for given task and label, K: number of selections
Ensure: S: selected examples

$S \leftarrow \emptyset$
$Pool \leftarrow P$
for $k \leftarrow 0$ **to** $K-1$ **do**
  if $k == 0$ **then**
    $s_k \leftarrow \arg\max_{p \in Pool} F_0(p)$
  else
    $s_k \leftarrow \arg\max_{p \in Pool} F(p, S)$
  end if
  $S \leftarrow S \cup \{s_k\}$
  $Pool \leftarrow Pool \setminus \{s_k\}$
end for

For each remaining selection $i \leq K$, the algorithm selects the example that maximizes a trade-off between the diversity of prompts and the consistency of the majority voting result, as defined in Equation 2:

$$F(p, S) = F_0(p) - \lambda \cdot \max_{s \in S}(1 - \text{sim}(\phi(p), \phi(s))) \quad (2)$$

ϕ is calculated for a given data point by concatenating its data into a string and then using an embedding model to produce a representation vector. This trade-off is quantified by subtracting a weighted maximum cosine similarity of the embeddings from the negative entropy, with the weight λ controlling the balance between diversity and consistency. In all of our experiments, in keeping with

(Wan et al., 2023b), λ is set to 0.2. The selected examples for both labels are then serialized and concatenated. This concatenated string is then used to augment the zero-shot query prompt given the task.

4 Experimental Setup and Results

The LLMs used in the evaluating the system were from OpenAI (`gpt-3.5-turbo`, `gpt-4-0125-preview`) and were invoked using the OpenAI API with the LangChain Python library. Stage 1 was performed once with $K = 5$ using `gpt-4-0125-preview` on 25 January 2024. The embedding model used in the calculation of ϕ was OpenAI `text-embedding-ada-002`. The Stage 2 run for our final submission during the evaluation period was conducted on 28 January 2024. Runs for the hyperparameter and ablation study results reported below were conducted between 17 February 2024 and 18 February 2024. Approximately $500 USD in OpenAI API charges were incurred during the above runs.

4.1 Classification performance

As shown in Table 3, using `gpt-4-0125-preview` and `gpt-3.5-turbo` as LLMs our approach showed a significant improvement in both accuracy and Spearman's ρ over the baseline reported for the model-agnostic and model-aware validation sets.[2]

Our best-performing submission to the competition used `gpt-4-0125-preview` as its LLM with 1 example provided per label, 20 samples for majority voting, and a temperature setting of 1.2. We compare it to the baseline system's performance on the test datasets together with that reported for each of the first ranked teams in the model-agnostic track (GroupCheckGPT) and the model-aware track (HaRMoNEE). The SHROOM-INDElab system ranked fourth and sixth in the tracks, respectively.

The values of ρ can be interpreted as showing a moderate to strong correlation between the estimated probability of hallucination provided by the system and that provided by the majority vote result of the human labellers.

[2]Although we submitted results for the model-aware track, our implementation of the approach is model agnostic and does not utilize the model field of the data point.

4.2 Hyperparameter study

The classifier has three hyperparameters; temperature, which is the parameter passed to the language model to indicate the level of stochasticity associated with its generation process; the number of examples per label provided for in-context learning; and the number of samples per query performed and used to calculate the estimated probability associated with the classification of the data point.

We investigated the impact of varying the values of the three hyperparameters of the classifier on the classifier's performance. We used `gpt-3.5-turbo` to conduct this investigation, computing values of accuracy and Spearman's ρ by executing three different passes over the model-agnostic validation dataset.

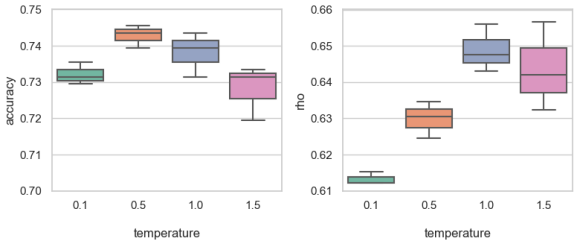

Figure 3: Classifier performance by temperature.

Figure 3 shows the best classifier accuracy is obtained with a temperature between 0.5 and 1.0, and that the best value for Spearman's ρ is obtained with a temperature between 0.5 and 1.5, given settings of 1 example per label and 5 samples per query.

Figure 4 shows that increasing the number of examples for few-shot classification beyond one per label led to an increase in accuracy with diminishing returns after 2 examples per label, but a decrease in Spearman's ρ, given settings of temperature of 1.0 and 5 samples per query.

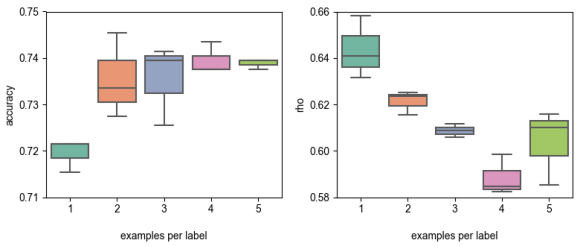

Figure 4: Classifier performance by examples per label.

Figure 5 shows that increasing the number of samples per query led to an increase in both accuracy and Spearman's ρ, given 1 example per label

Dataset	System	model-agnostic accuracy	model-agnostic ρ	model-aware accuracy	model-aware ρ
Validation	Baseline	0.649 (+0.000)	0.380 (+0.000)	0.707 (+0.000)	0.461 (+0.000)
	SHROOM-INDElab (`gpt-3.5-turbo`)	0.773 (+0.124)	0.652 (+0.272)	0.764 (+0.057)	0.605 (+0.144)
	SHROOM-INDElab (`gpt-4-0125-preview`)	**0.814** (+0.165)	**0.697** (+0.317)	**0.772** (+0.065)	**0.635** (+0.174)
Test	Baseline	0.697 (+0.000)	0.403 (+0.000)	0.745 (+0.000)	0.488 (+0.000)
	SHROOM-INDElab (`gpt-4-0125-preview`)	0.829 (+0.132)	0.652 (+0.249)	0.802 (+0.057)	0.605 (+0.117)
	HaRMoNEE	0.814 (+0.117)	0.626 (+0.223)	**0.813** (+0.068)	0.699 (+0.210)
	GroupCheckGPT	**0.847** (+0.150)	**0.769** (+0.366)	0.806 (+0.061)	**0.715** (+0.227)

Table 3: Classifier performance on SHROOM datasets. ρ = Spearman's correlation coefficient.

and a temperature of 1.0.

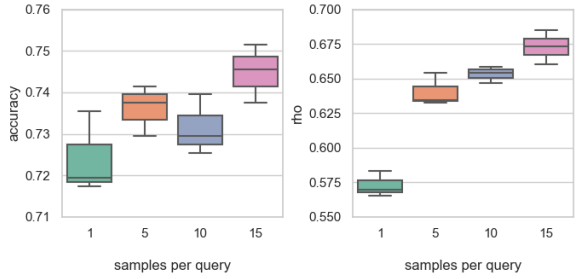

Figure 5: Classifier performance by samples per query.

4.3 Ablation study

Figure 6 shows the results of an ablation study to determine the contribution of the various elements of the prompt provided to the language models. We evaluated the contribution of each of the components of the Stage 2 classifier prompt by removing each in sequence, in the following order: the selected examples, the task definition, the role definition, and finally the concept definition. The ablation study was conducted using `gpt-3.5-turbo`, with 1 example per label, 5 samples per query, and a temperature of 1.0, again involving three different passes over the model-agnostic validation dataset.

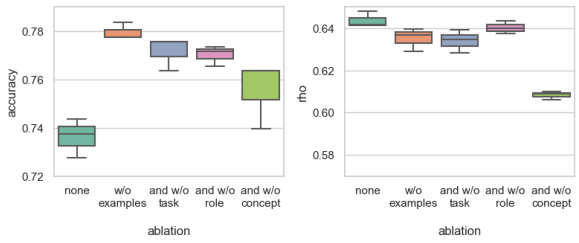

Figure 6: Ablation study using the model-agnostic validation dataset.

We interpret the results of the ablation study as indicating that the use of examples led to poorer accuracy but slightly better Spearman's ρ, that the contributions of the definitions of task and role towards classifier performance were minimal, but that the contribution of the definition of the concept of hallucination was significant.

4.4 Level of agreement with human labellers

We also investigated the degree of inter-annotator alignment exhibited with respect to the model-agnostic data set. Based on the human labeling data associated with each data point in the model-agnostic validation data set, we obtained a Fleiss' κ of 0.373, which can be interpreted as indicating a fair level of agreement among the human labellers, which in turn implies that the reliability of the human labeling might be reasonable, but is not highly consistent or unanimous. Adding the classifier's labeling yields an increase in Fleiss' κ to 0.405, closer to a moderate level of agreement, which implies that the classifier's decisions are consistent with those of the human labellers.

human consensus	N	accuracy	κ	ρ
low (2/3 split)	145	0.621	0.238	0.224
high (4/5 split)	171	0.854	0.701	0.734
unanimous	183	**0.929**	**0.856**	**0.885**
all	499	0.814	0.623	0.697

Table 4: Alignment between the system and human labellers.

We then proceeded to investigate the relationship between the degree of agreement between human labellers and system performance. Table 4 shows the level of agreement between the system and the human labellers, as measured by taking subsets of data points from the model-agnostic validation dataset filtered by the three degrees of consistency in human labeling and calculating the pairwise Cohen's κ between the system's labeling and the label provided by taking the majority vote of the human labellers. The results indicate that system agreement with human labeling increases as the certainty of the human labeling increases.

5 Discussion and Conclusion

In summary, the SHROOM-INDElab system was competitive with the other systems submitted for evaluation, and system labeling was consistent with that of human labellers.

The result in the ablation study that the exclusion of selected examples led to better accuracy suggests the need for further investigation with respect to how the way in which examples are selected and included in the classifier prompts impacts accuracy to determine the cause of the problem. The result that the exclusion of an explicit definition of hallucination leads to poorer accuracy and Spearman's ρ suggests the utility of including intentional definitions of concepts in prompts for LLM-based classifiers (Allen, 2023).

Given the above results, we plan to investigate the use of this approach to hallucination detection in future work on the evaluation of natural language rationale generation (Li et al., 2024) in the context of zero- and few-shot chain-of-thought classifiers for use in knowledge graph evaluation and refinement (Allen et al., 2023).

I2C-Huelva at SemEval-2024 Task 8: Boosting AI-Generated Text Detection with Multimodal Models and Optimized Ensembles

Alberto Rodero Peña, Jacinto Mata Vázquez, Victoria Pachón Álvarez
I2C Research Group, Universidad de Huelva

Abstract

With the rise of AI-based text generators, the need for effective detection mechanisms has become paramount. This paper presents new techniques for building robust models and optimizing training aspects for identifying synthetically produced texts across multiple generators and domains. The study, divided into binary and multilabel classification tasks, avoids overfitting through strategic training data limitation. A key innovation is the incorporation of multimodal models that blend numerical text features with conventional NLP approaches. The work also delves into optimizing ensemble model combinations via various voting methods, focusing on accuracy as the official metric. The optimized ensemble strategy demonstrates significant efficacy in both subtasks, highlighting the potential of multimodal and ensemble methods in enhancing the robustness of detection systems against emerging text generators. This strategy was applied to subtask A, monolingual classification, ranking 47th with an accuracy of 0.8079, and subtask B, multilabel classification, ranking 18th with an accuracy of 0.789.

1 Introduction

In the era of digital communication, AI-based text generators have become increasingly sophisticated, necessitating advanced detection methods to differentiate between human and machine-generated content (Radford et al., 2019; Brown et al., 2020). This paper addresses the challenge within the scope of English language texts, emphasizing the importance of reliable detection mechanisms in maintaining the integrity of digital discourse. The task at hand is crucial for various applications, including content moderation, misinformation prevention, and ensuring the authenticity of digital communication.

The core strategy of this system lies in its robustness and the optimization of model training. By limiting the size of the training dataset, the approach prevents models from overfitting to specific text generators, thereby enhancing their generalizability to novel content. Furthermore, the system leverages multimodal models that integrate traditional NLP techniques with numerical text features, such as lexical diversity and sentence structure, to enrich the detection capabilities. This is complemented by a rigorous exploration of ensemble methods and voting mechanisms to optimize model performance. Specifically, our conception of multimodal entails the strategic fusion of traditional, fine-tuned language models like RoBERTa with extracted numerical values from the text, such as number of grammatical errors and average sentence length, thereby enriching the language models with quantifiable text insights to enhance detection precision.

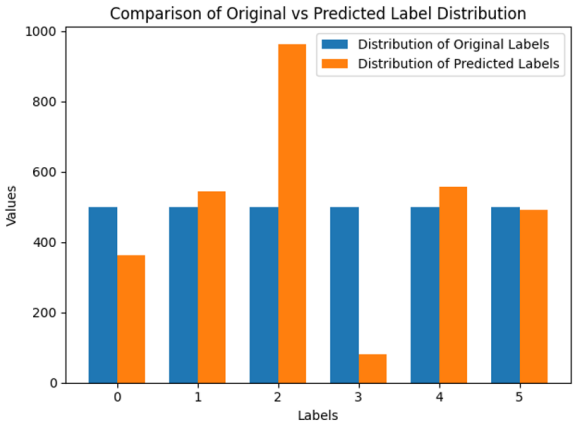

Figure 1: Comparison of Original vs Predicted Label Distribution Subtask B

Participation in this task led to the system ranking 47th in the monolingual subtask A with an accuracy of 0.8079 and 18th in the multilabel subtask B with an accuracy of 0.789 (Wang et al., 2024). These outcomes affirm the system's robustness in handling diverse generative models. However, the primary challenge encountered was distinguishing

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 845–852

between texts produced by similar generators. The system struggled to consistently differentiate between certain generators, often misattributing texts to one over another when faced with stylistically comparable outputs. This difficulty in discerning subtle variations between generator styles points to the need for further refinement in the detection algorithm, suggesting an area for future research to enhance the sensitivity and specificity of the model. As shown in Figure 1, the double bar graph compares the original label distribution and the predicted label distribution. The labels represent the model that generated each text of the samples, being 0 human, 1 chatGPT, 2 cohere, 3 davinci, 4 bloomz and 5 dolly.

2 Background

The task of detecting machine-generated text has garnered significant attention due to the rapid advancement and widespread use of AI-based text generators. The input for this task consists of textual content, with the output being a classification decision indicating whether the text is human or machine-generated in subtask A and which generator created the text in subtask B.

For this study, the dataset comprised English texts from diverse sources, including Wikipedia (March 2022 version), WikiHow, Reddit (ELI5), arXiv, and PeerRead (Koupaee and Wang, 2018; Kang et al., 2018). The machine-generated texts were produced using leading multilingual Large Language Models (LLMs) such as ChatGPT, textdavinci-003, LLaMa, FlanT5, Cohere, Dolly-v2, and BLOOMz. These models were prompted to create content resembling the human-written texts from the mentioned sources, ranging from Wikipedia articles to peer reviews and news briefs, ensuring a rich variety of genres and styles within the dataset. This richly varied dataset forms the foundation of the analysis, drawing on the comprehensive compilation of machine-generated texts as detailed in the work by Wang et al. (Wang et al., 2023). As shown in Figure 2, the training data distribution illustrates the sources and quantity of data used in the study.

This work focuses solely on the English portion of the dataset, engaging in the monolingual classification track. The choice of English allows for a concentrated examination of the nuances in detecting machine-generated texts in a language with extensive generative model research and development. The task setup and dataset composition are pivotal in understanding the challenges and innovations presented in this study.

This work builds upon foundational efforts in the field, such as "Machine-Generated Text Detection using Deep Learning" by Raghav Gaggar et al. (Gaggar et al., 2023), which emphasizes deep learning approaches for distinguishing AI-generated content. Gaggar's methodology leverages traditional neural network architectures, providing a critical basis for understanding how machine learning can be applied to text detection challenges. Similarly, "On the Possibilities of AI-Generated Text Detection" by Souradip Chakraborty et al. (Chakraborty et al., 2023) contributes to the discourse by establishing theoretical frameworks based on information theory, highlighting the nuanced differences between human and AI-generated texts and the implications for detection mechanisms. This paper underscores the importance of sample complexity and the robustness of detection systems to new and evolving text generators. "Ghostbuster: Detecting Text Ghostwritten by Large Language Models" by Vivek Verma et al. (Verma et al., 2023) methodology employs a series of weaker language models to compute token generation probabilities, offers a specialized perspective on model-agnostic detection. In contrast, this work extends the discourse by incorporating numerical text features alongside conventional NLP techniques within a multimodal framework, providing a more holistic analysis of text characteristics. This integration allows for a more nuanced distinction between human and AI-generated texts, addressing the challenges of style and generator diversity that single-model systems may struggle with.

3 System Overview

The system is designed to detect machine-generated text, combining an ensemble of finely-tuned transformer models such as RoBERTa ('FacebookAI/roberta-base') (Liu et al., 2019), ELECTRA ('google/electra-base-discriminator') (Clark et al., 2020), ALBERT (albert/albert-base-v2) (Lan et al., 2020), roberta-base-openai-detector ('roberta-base-openai-detector'), chatgpt-detector-roberta ('Hello-SimpleAI/chatgpt-detector-roberta') and BERT ('bert-base-uncased') (Devlin et al., 2018) with custom adaptations of RoBERTa including a one-vs-all system, that independently

Figure 2: Training Data Distribution

predicts each label's presence, treating each label as a separate binary classification problem, and multimodal models . A Random Forest classifier is used to analyze numerical text features. This ensemble integrates outputs from each model by aggregating predictions and confidence levels through various voting mechanisms. The process identifies the best combination of models and voting method, optimizing the ensemble to achieve the highest detection accuracy and robustness.

3.1 Training Sample Optimization for robustness

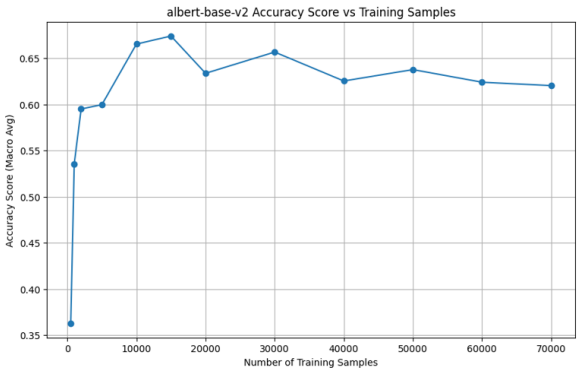

Figure 3: Accuracy by Training Sample Size

To optimize training samples for robustness, the number of samples used to train each model were systematically varied, aiming to find an optimal size that enhances robustness to new text generators while preventing overfitting. For instance, in the case of the ALBERT model, training began with 500 samples, then the model was reset and trained again with increasing sizes: 1000, 2000, 5000 samples, and so on. This process revealed that smaller sample sizes increased the model's robustness. It was determined that the ideal average number of samples for binary classification was 10,000, whereas multilabel classification required a larger average of 48,000 samples to maintain high predictive accuracy without compromising robustness to unseen generators in the evaluation dataset. As illustrated in Figure 3, the graph shows the relationship between model accuracy and training sample size.

3.2 Numerical Features

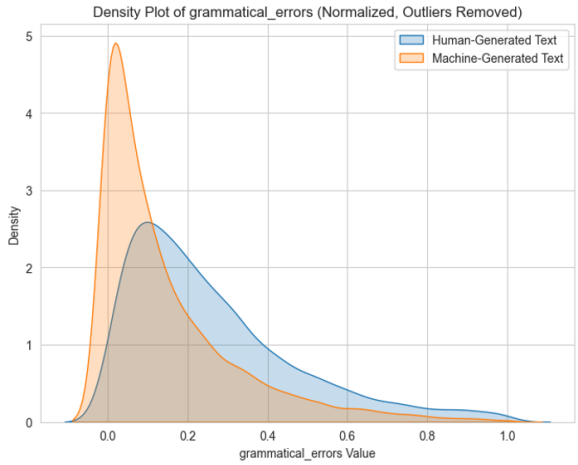

Figure 4: Human vs Machine Grammar Errors Density Plot

In addition to leveraging powerful transformer models, the system uniquely incorporates the extraction of numerical features from text to enhance its analytical depth. These features are: qord count, sentence count, lexical diversity, average sentence length, average word length, lexical density, flesch reading ease, gunning fog index, and grammatical errors in english, and they offer critical insights into the stylistic and structural elements of the text, which might be indicative of its origin. These features were obtained using methods from NLP libraries such as nltk. By analyzing these quantitative aspects, the system can identify subtle patterns and discrepancies that differentiate human-written texts from those generated by AI models, even when the linguistic content is convincingly human-like. This approach not only enriches the model's input but also helps in capturing the essence of text generation techniques used by various AI models, thereby contributing to a more robust detection

mechanism. The system's primary aim with numerical features was to supplement the multimodal model with additional information. For the numerical values, a Random Forest classifier was chosen as it is an easy out-of-the-box solution to be used with numerical values (Louppe, 2014). However, this aspect was not the main focus, and further experimentation was not pursued. Future work could explore the use of deep learning and other classification models like XGBoost to analyze these numerical features. As depicted in Figure 4, the density plot illustrates the distribution of grammar errors between human-written and machine-generated texts.

3.3 Multimodal Models

The system's architecture is notably enhanced by the inclusion of multimodal models, which not only utilize the capabilities of traditional NLP models like RoBERTa but also integrate numerical text features for a more comprehensive analysis. This approach, applicable to any large language model, involves extending the chosen LLM's architecture with a custom classification head that processes both the LLM's output and additional numerical features from the text. For this study, RoBERTa was selected due to its role in establishing the baseline performance, allowing for a direct comparison of the improvements attributed solely to the multimodal functionality. Two different multimodal models were used. The extended version includes all the numerical features extracted from the text, which performs better in binary classification but not as well in multimodal classification. The second model uses only the features that show a clear difference between texts written by humans and those generated by machines. This model does better in multilabel classification but doesn't do as well in binary classification. The numerical features used in the multimodal model are word count, average sentence length, average word length, gunning fog index and grammatical errors. The extended version also includes sentence count, lexical diversity, lexical density and flesch reading ease. It is also worth mentioning that the performance between multimodal versions is slight.

3.4 Optimization of Ensembles

The optimization of ensembles through various voting mechanisms stands as a testament to the system's strategic design. The system tested every combination of models to make sure each one added value to the ensemble and did not take away any useful information. Specifically, models are chosen for their complementary strengths and diverse natures, ensuring a broad coverage of the linguistic and stylistic features pertinent to text generation detection. It used the predictions and confidence scores from all included models along with the correct labels. Then, it applied different voting methods to see how they compared to the real labels. This way, it found the best mix of models and the best voting method. The voting methods tested included majority voting, majority score tie break voting (confidence based), rank voting, borda count voting and soft voting (Brownlee, 2020). In the binary classification task, a larger variety of models is employed to capture the nuanced differences between human and machine-generated texts, whereas for the multilabel task, only two models are needed, reflecting the different demands of each subtask. Notably, multimodal models, recognized for their high accuracy, are consistently selected across both subtasks, reinforcing the ensemble's performance. The chosen strategy ensures that the ensemble's collective judgment is both robust and sensitive to the nuances of text generation, significantly enhancing the system's overall accuracy and reliability.

As illustrated in Figure 5, the bar graph compares the accuracy of individual binary classification models, providing insights into their performance. The final ensemble model accuracy is also

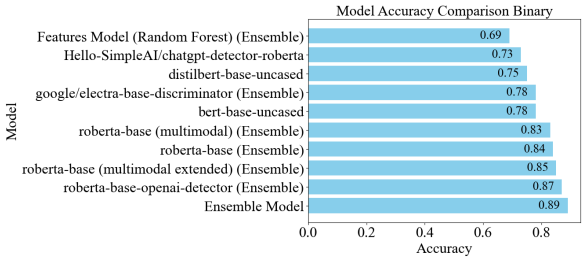

Figure 5: Substask A Models Accuracy in Training

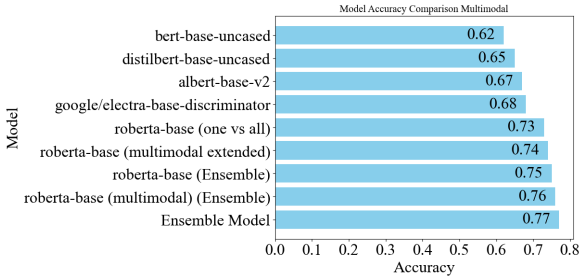

Figure 6: Subtask B Models Accuracy in Training

included. Similarly, Figure 6 presents a comparison of the accuracy of individual multilabel classification models. The figures illustrate the models that were ultimately chosen to be included in the ensemble using majority voting.

4 Experimental Setup

In this study, the optimization of the training sample size was a critical preliminary step before proceeding with the standard division of the dataset for model training and evaluation. The objective was to determine the most effective training sample size that would enable the models to learn sufficiently from the data without overfitting. This involved iterative testing of various sample sizes to identify the optimal balance that maximized model performance on unseen data. Once the ideal training sample size was established, it was then split following an 80-20 ratio, with 80% of the samples used for training and the remaining 20% for evaluation. The dev dataset served as the test set throughout the experiments, ensuring a consistent benchmark for evaluating the generalization ability of the models across different configurations and optimizations.

Fine-tuning the models was conducted with careful consideration of hyperparameters that directly influence model performance. The hyperparameters were determined by experimenting with a range of values and choosing those that led to better performance metrics. This approach aimed to enhance the model's ability to be robust to new text generators that were present in the evaluation dataset but not in the training dataset. The learning rate was set to 2e-5, a value chosen to ensure steady yet effective model updates without causing large fluctuations in model weights that could hinder learning. The batch size for both training and evaluation phases was maintained at 16, balancing computational efficiency with the need for granularity in gradient updates. The models underwent training for 3 epochs, a decision underpinned by the desire to minimize overfitting while allowing sufficient iterations for the models to converge to an optimal state. Weight decay was applied at 0.01 to regularize the model and further mitigate overfitting. The training process incorporated an epoch-based evaluation and save strategy, enabling continuous monitoring of model performance and retention of the best-performing model state at each epoch's conclusion, as determined by evaluation metrics.

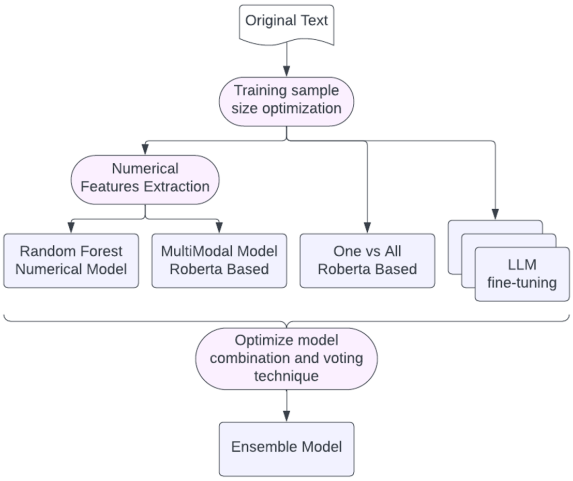

Figure 7: Experimental Setup for Training

The experimental framework utilized PyTorch for implementing the transformer-based models, specifically leveraging the RoBERTa-base model from the Hugging Face Transformers library for both the multimodal models and the one-vs-all classification approach in the multilabel subtask. For numerical feature extraction from text, the NLTK library was employed, enriching the model inputs with linguistic features that provide additional context and depth to the analysis. The numerical model, built using a Random Forest classifier, was optimized using the scikit-learn library, demonstrating the integration of traditional machine learning techniques with advanced NLP models for enhanced predictive performance. As depicted in Figure 7, the diagram illustrates the experimental setup for training, showcasing the steps and pipelines involved in the process.

5 Results

The system demonstrated commendable performance in the task, adhering to the official evaluation metric of accuracy. In Subtask A (monolingual classification), the system attained an accuracy of 0.8079, placing it at the 47th position in the competition. This ranking underscores the system's capability to effectively distinguish between human and machine-generated texts in a monolingual setting. For Subtask B (multilabel classification), the system achieved an accuracy of 0.789, ranking 18th out of the total number of participants. This notable performance highlights the system's robustness and effectiveness in handling more complex multilabel scenarios, despite the inherently

Table 2: Results obtained for Subtask B

challenging nature of distinguishing between multiple generators. These metrics were obtained after applying the ensemble model for each task.

In a comprehensive evaluation using the evaluation dataset, tables comparing model performances shed light on the system's effectiveness. For Subtask A, comparisons between various models in binary classification, and specifically between the RoBERTa-base model and its multimodal extensions, reveal the somewhat superior performance of the multimodal models. These models, incorporating key numerical features, mostly outperformed other fine tuned classificators. A similar trend was observed in Subtask B's multilabel classification, where multimodal models again demonstrated some enhanced accuracy. This data, while not from the final test set, underscores the potential of multimodal approaches in effectively distinguishing between human and machine-generated texts across different classification scenarios.

Table 1 provides a comprehensive metrics comparison for binary classification including multimodal models. It highlights the performance of fine-tuned LLMs for binary classification, including a Features only model built with a Random Forest classifier, and the performance evolution from base model RoBERTa-base to advanced multimodal models that integrate numerical features. The ensemble model is also included in this table, showcasing its role in the collective modeling approach. Table 2 provides a similar comparison but for multilabel classification scenarios.

5.1 Quantitative Analysis

A series of studies and comparative analyses were conducted to dissect the impact of various design decisions, such as the optimization of training sample sizes, the integration of numerical features, and the selection of models within the ensemble. The dev dataset served as the primary test bed for these analyses, ensuring consistency in evaluating the system's modifications and optimizations.

- A notable finding was the system's increased performance when numerical features were integrated, suggesting the significant value these features add to understanding text beyond mere semantic analysis.

- The ensemble's optimized combination of models, including transformer-based and numerical models, was pivotal in enhancing accuracy. The binary classification required a more diverse set of models to capture the nuances of different text generators, whereas the multilabel task achieved high performance with just two, indicating the strategic importance of model selection based on the task's nature.

5.2 Error Analysis

The examination of errors, particularly for Subtask B, shed light on the complexity of multilabel classification. The system was tasked with identifying multiple generator labels within the same text, a challenge compounded by the nuanced differences between generators' styles. As depicted in Figure 8, the confusion matrix heatmap provides insights into the errors made by the system in multilabel classification.

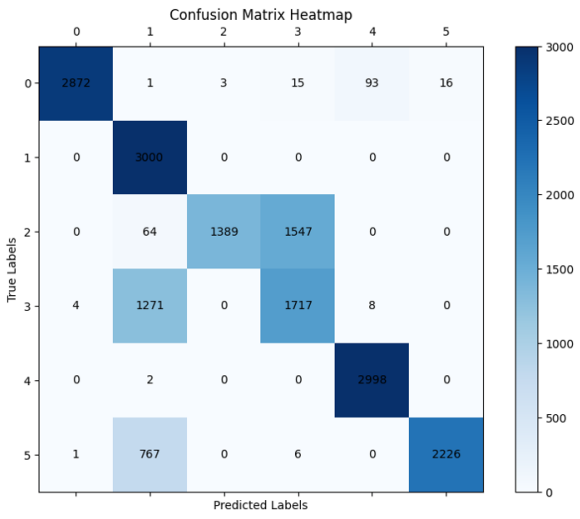

Figure 8: Confusion Matrix Heatmap Multilabel Subtask B

6 Conclusions

This study showcased innovative techniques aimed at enhancing model robustness in the task of detecting machine-generated text, notably through the careful optimization of training sample size, the strategic assembly of diverse models into optimized ensembles, and the deployment of multimodal models. These methodologies collectively facilitated a system that adeptly navigates the challenges of monolingual and multilabel classifications.

The exploration of training sample sizes revealed a delicate balance between sufficient model training and the avoidance of overfitting, highlighting the importance of dataset optimization. The ensemble model's success, derived from combining models with varying strengths, emphasizes the value of diversity in model architecture for robust performance. Moreover, the integration of multimodal models, blending traditional NLP techniques with numerical text features, showcased a sophisticated approach to capturing the nuanced distinctions between human and machine-generated texts.

Looking ahead, the focus will be on refining these novel techniques to further bolster model robustness. Future work will explore more granular adjustments to training sample sizes and investigate the potential of dynamic ensemble configurations responsive to the nature of the text being analyzed. Additionally, the extension of multimodal model frameworks to incorporate emerging linguistic and semantic features presents a promising avenue for enhancing detection capabilities. Applying these advanced methodologies to other areas of model building could advance the landscape of machine learning, offering a blueprint for developing systems that are not only robust but also universally applicable across various NLP tasks and challenges.

Abstract

This paper introduces an approach developed for multimodal meme analysis, specifically targeting the identification of persuasion techniques embedded within memes. Our methodology integrates Large Language Models (LLMs) and contrastive learning image encoders to discern the presence of persuasive elements in memes across diverse platforms. By capitalizing on the contextual understanding facilitated by LLMs and the discriminative power of contrastive learning for image encoding, our framework provides a robust solution for detecting and classifying memes with persuasion techniques. The system was used in Task 4 of Semeval 2024, precisely for Substask 2b (binary classification of presence of persuasion techniques). It showed promising results overall, achieving a Macro-$F_1 = 0.7986$ on the English test data (i.e., the language the system was trained on) and Macro-$F_1 = 0.66777/0.47917/0.5554$, respectively, on the other three "surprise" languages proposed by the task organizers, i.e., Bulgarian, North Macedonian and Arabic. The paper provides an overview of the system, along with a discussion of the results obtained and its main limitations.

1 Introduction

In recent years, the natural language processing (NLP) community has witnessed an ever-growing number of contributions aimed at identifying and analyzing various forms of harmful language found on the Web, including offensive language (Zampieri et al., 2020), hate speech (Basile et al., 2019; Röttger et al., 2022)—also comprising misogyny and transphobia (Nozza et al., 2022; Kirk et al., 2023), and propaganda techniques (Da San Martino et al., 2019). These linguistic phenomena not only harm civil debate but can also fuel the polarization and radicalization of users' opinions.

In an increasingly multimodal context, particular attention has also been paid to memes (Dimitrov et al., 2021), which, due to their virality and communicative immediacy, can easily become key tools in online disinformation campaigns. Therefore, the development of techniques to effectively classify possible nuances of information manipulation within these forms of content sharing assumes a central role in online disinformation research.

This motivated our participation in the SemEval 2024 Task 4[1] (Dimitrov et al., 2024), which focuses on "Multilingual Detection of Persuasion Techniques in Memes". The task aims to develop models capable of identifying rhetorical and psychological techniques employed in memes to influence users' opinions. Our team participated in Substask 2b, consisting of a binary classification problem to determine whether a meme contains at least one persuasion technique among the predefined set of 22 techniques. The dataset released to participants is made up of memes with textual content in English. However, to assess the robustness of the systems during the evaluation phase, the organizers made test sets available in three other languages besides English, i.e., Arabic, Bulgarian, and North Macedonian.

For the purpose of this task, we developed a system that combines Large Language Models (LLMs) and contrastive learning image encoders to discern the presence of persuasive elements in memes across diverse platforms. The following sections will thus describe the system architecture and its deployment in the task. A discussion of the results obtained and of some most recurring errors will also be proposed, aiming to highlight possible research paths for the further improvement of the approach.

2 System Overview

The proposed method, named "Themis", is a modular neural network architecture designed to analyze multimodal data, specifically targeting memes that often contain both textual and visual elements.

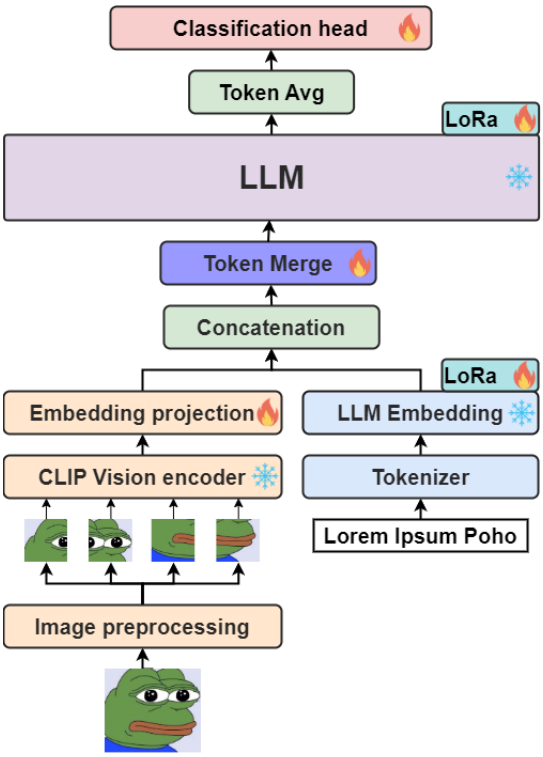

Figure 1: Themis model architecture.

2.1 Model Composition

Our Themis model comprises various interoperating components, as outlined in Figure 1. In this section, we shall examine their respective roles within the architecture.

Image Preprocessing. The meme image initially undergoes processing through the image processor of the Image Embedding Model, which standardizes and resizes it to conform to the model's specifications. Subsequently, the image is segmented into uniform patches of predetermined dimensions for subsequent processing. This preprocessing step guarantees that the image is adequately prepared for further analysis and feature extraction by the Image Embedding Model.

Image Embedding Model. Themis integrates an image embedding model for the extraction of features from meme images. This model is responsible for processing pixel values and extracting significant representations from the images.

Image Embedding Projection. An image embedding projection is applied to the features extracted from the image embedding model. This projection serves as a method to project image features in LLM-compatible size.

Large Language Model. Themis uses a language model to handle textual and visual inputs associated with memes. The LLM serves as the core of our model sequentially aligning tokens to an embedding space related to the persuasion detection task.

Token Merger Module. Themis employs a Token Merger module to merge tokens representing both image and textual features, enabling the model to attend to pertinent information within the images. This functionality allows the model to focus on salient aspects during meme processing. While drawing inspiration from the Patch Merger module (Renggli et al., 2022), our approach distinguishes itself by integrating both modalities. The Token merger learns a weight matrix that computes token scores based on representations and normalizes them using softmax. Subsequently, these weights are used to reduce the number of tokens through matrix multiplication. Ideally, this module aggregates similar tokens together, regardless of their original position. To address scale mismatches, layer normalization is applied post-merging, facilitating rapid adaptation through fine-tuning.

Token Average. We employ the token averaging technique, which involves extracting tokens from the LLM, to derive our final prediction. This strategy is designed to generate a single, semantically dense embedding, facilitating seamless processing by a classification head for obtaining the class prediction.

Classification Head. Themis incorporates a classification head to predict whether a meme contains specific persuasion techniques. This head takes the fused multimodal features and generates predictions based on the learned LLM representations.

2.2 Model Freezing and Low-Rank Adaptation (LoRA) Weights

The Themis model uses freezing techniques to control the training of certain parameters. Specifically, both the image embedding model and the language model are frozen during training. This ensures that

the pre-trained weights of these models are not updated, preserving the learned representations.

Additionally, Themis employs LoRA (Hu et al., 2022) weights to enhance its capabilities. LoRA weights are incorporated into the Image Embedding Projection layer and LLM model to introduce long-range interactions between tokens and patches, facilitating the capture of global context and improving overall performance in meme analysis tasks.

3 Experiment Setup

The experiments were executed on a workstation featuring an Intel Core i7-12700 @ 2.1GHz CPU, 32 GB RAM, and an NVIDIA RTX3060 GPU with 12GB of memory. Among the different experiments, one main issue is denoted by the limited availability of VRAM; this issue not only limited our approach to smaller LLM and Image encoders but also limited batch size. Our experiments aim to enable efficient prediction even in such low-end system requirements. As a result, we opted for a pre-trained Contrastive Language-Image Pre-Training (CLIP) (Radford et al., 2021) encoder as our main image encoder. Specifically, we used both CLIP Base[2] and CLIP Large[3] in our experiments. For the textual part, instead, we used TinyLlama[4] (Zhang et al., 2024), Phi-1.5[5] (Li et al., 2023) and Phi-2[6]. Table 1 depicts the full set of selected Image encoders and LLMs that suited our requirements.

Tipology	Model	# Params (B)
Image Encoder	CLIP Base 32	0.15
	CLIP Large 14	0.42
LLM	Phi-1.5	1.3
	Phi-2	2.7
	TinyLlama	1.1

Table 1: List of LLMs and Image Encoders used for our experiments.

For each combination of image and text models, the system was trained for 20 epochs, using a batch of 2 and a learning rate of $1e-4$, AdamW as the optimizer, and Binary Cross Entropy as the loss function.

To train the model we solely relied on the training data provided by the organizers. For Subtask 2b, this dataset comprised 1200 instances, each consisting of a meme image paired with its corresponding text. The validation set contained 150 instances, while the development set included 300 instances. The final test sets encompassed 600 memes in English, 100 memes each in Bulgarian and North Macedonian, and 160 memes in Arabic. The distribution of labels across the training, validation, and development sets is presented in Table 2[7].

Label	Train	Val	Dev
propagandistic	800	100	200
non-propagandistic	400	50	100

Table 2: Label distribution on the training, validation, and development set for Subtask 2b.

All results were evaluated using the official classification measure adopted by the task organizers for Subtask 2b, i.e., Macro-F_1.

To select our best model, we performed a search over the best set of hyperparameters. Specifically, we varied the rank of the LoRA weight matrices (LoRA R), their alpha regularization factor (LoRA Alpha), the dropout rate of the LoRA weights (LoRA Dropout), and most importantly, we controlled the number of tokens by a Token Merging strategy (see Section 2.1).

4 Results

The task was organized into two main evaluation phases: a development phase, during which only training and unlabeled development data were accessible, and a test phase, wherein the gold labels for the development set were disclosed alongside the unlabeled test sets in four languages: English, Arabic, Bulgarian, and North Macedonian. In this section, we outline the results obtained by our experiments in both phases.

Development phase. In this phase, we conducted tests on the unlabeled development set, employing various combinations of image encoders and LLMs. For each combination, we set LoRA R and LoRA

[6] https://huggingface.co/microsoft/phi-2

[7] For a comprehensive understanding of the dataset development and composition for each subtask, readers are encouraged to refer to the primary report of the task (Dimitrov et al., 2024).

Alpha to 8 and LoRA Dropout to 0.2. Notably, we omitted token merging during this phase based on preliminary results from the validation set, which indicated no significant performance enhancements with this setting. The results presented in Table 3 demonstrate that using larger Image Encoders, such as CLIP Large, yields an average increase of 0.7% in terms of Macro-F_1 performance. This enhancement may be attributed to higher-dimensional embeddings compared to their Base counterparts, even though it also produces a larger number of tokens due to a smaller patch size.

Image Encoder	LLM	Macro-F_1
CLIP Base	Phi-1.5	80.6
	Phi-2	80.6
	TinyLlama	80.8
CLIP Large	Phi-1.5	80.9
	Phi-2	81.6
	TinyLlama	81.6

Table 3: Macro-F_1 results on the development set of Subtask 2b across selected Image encoders and Large Language Models (for greater readability, F_1 scores are reported in percentage in all tables).

Among the various LLMs, both TinyLlama and Phi-2 exhibited identical performance. Consequently, we opted for TinyLlama and CLIP Large as the preferred models for further examination of model performance, using slightly adjusted hyperparameter settings. Specifically, we explored different numbers of tokens, LoRA ranks of 8, 16, and 32, and LoRA dropout values of 0.2, 0.3, and 0.4.

The results show that strong token merging strategies improve the model stability but limit its performance. The increase of the LoRA R greatly increases model instability due to the improved overfitting risk, while the increase in LoRA dropout greatly improves model performance, reaching the best Macro-F_1 result of 0.83487.[8] Our ablation study is depicted in Table 4.

Test phase. During the final evaluation phase of the campaign, we thus applied the best-performing setting described above on the test sets released by the task organizers. The results obtained are shown in Table 5. Overall, our team achieved reasonably good performance across both English and, albeit with a predictable decrease, in the zero-shot setting, where notable differences are observed. Upon comparing our performance with each top-ranked system in this subtask, we observe that the absolute difference between our system and the best-performing system in English (i.e., LMEME, which also ranks as the top system for Bulgarian) is 0.012, indicating that Themis achieved results very close to the top performer. For Bulgarian, the absolute difference is even smaller, at 0.003, suggesting that both systems exhibit very similar performance in this language. Conversely, for Arabic and North Macedonian, the difference is more pronounced, at 0.059 and 0.207, respectively, underscoring the limitations of our system in these languages.

5 Discussion and Error Analysis

Despite achieving promising results, in terms of Macro-F_1 scores, our model still occasionally misclassifies instances, particularly in cases involving the propagandistic nature of memes. Although the labeled test set was not made available by the organizers, we were still able to inspect more in detail the results obtained on the development set. Figures 3 and 4 illustrate examples of false positive and false negative predictions, respectively. In both

instances, we can formulate hypotheses regarding why and when our model generates errors. The false positive example may be misconstrued as employing a "Slogan" based persuasion technique, possibly due to text present in the sign. The false negative could stem from the model's inability to recognize inherent sarcasm due to limited sarcastic examples, further train with a larger dataset could mitigate this issue. The confusion matrix depicted in Figure 2 reveals an uneven distribution of errors across both classes, indicating a bias towards the propagandistic class. This bias could be attributed to the imbalance in the training set.

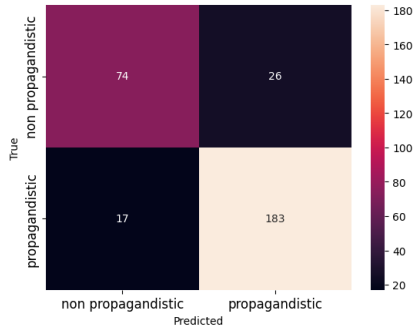

Figure 2: Confusion matrix of Themis predictions on the development set.

Figure 3: Example of false positive.

6 Conclusions

In this study, we introduced Themis, a novel model for analyzing multimodal memes by integrating LLMs and contrastive learning image encoders. Through comprehensive experiments, Themis demonstrated remarkable efficacy in detecting persuasion techniques within memes, achieving a notable F1 score of up to 83.4%. Our findings

Figure 4: Example of false negative.

underscore the critical role of meticulous model architecture design and hyperparameter optimization in meme analysis tasks. Notably, Themis presents a robust solution to combat societal challenges posed by biased content online, offering a promising avenue for mitigating the spread of misinformation and promoting digital discourse integrity.

Abstract

Predicting semantic textual relatedness (STR) is one of the most challenging tasks in the field of natural language processing. Semantic relatedness prediction has real-life practical applications while developing search engines and modern text generation systems. A shared task on semantic textual relatedness has been organized by SemEval 2024, where the organizer has proposed a dataset on semantic textual relatedness in the English language under Shared Task 1 (Track A3). In this work, we have developed models to predict semantic textual relatedness between pairs of English sentences by training and evaluating various transformer-based model architectures, deep learning, and machine learning methods using the shared dataset. Moreover, we have utilized existing semantic textual relatedness datasets such as the stsb multilingual benchmark dataset, the SemEval 2014 Task 1 dataset, and the SemEval 2015 Task 2 dataset. Our findings show that in the SemEval 2024 Shared Task 1 (Track A3), the fine-tuned-STS-BERT model performed the best, scoring 0.8103 on the test set and placing 25th out of all participants.

1 Introduction

Nowadays, there have been notable advancements in understanding and measuring pairwise semantic relatedness between texts within the domain of natural language processing. Predicting semantic relatedness plays a significant role in improving search engines, question-answering systems, text summarization tools, and machine translation.

However, previous works in natural language processing have mainly dealt with semantic similarity, a smaller aspect of relatedness, mainly due to the limited availability of relatedness datasets. Besides, dealing with ambiguous words or phrases that have multiple meanings can make semantic relatedness difficult. Understanding cultural context in language has been complex, and existing models have struggled to capture these variations. As language evolves, models struggle to adapt quickly to new linguistic patterns and expressions. To bridge these gaps, we need improved models that understand not just words but also context, cultural differences, and how language changes over time.

Semantic relatedness models have been developed using various transformer-based, deep learning, and machine learning techniques. Traditional machine learning methods (Buscaldi et al., 2015) have relied on predefined rules and features and offered moderate results. These approaches have often struggled with complex semantic relationships. Deep learning-based (Wang et al., 2018) approaches have surpassed traditional machine learning models in capturing complex relationships, particularly in tasks requiring a deep understanding of context. However, transformer-based approaches (Devlin et al., 2019) have outperformed others when it comes to capturing semantic relationships, particularly in understanding context, managing long-range dependencies, and handling contextual embeddings.

SemEval has arranged a shared task named SemEval 2024 Task 1: Semantic Textual Relatedness (STR) (Ousidhoum et al., 2024b), introducing a novel dataset called Shared Task 1 (Track A3) (Ousidhoum et al., 2024a) for determining the level of pairwise semantic relatedness between sentences based on the similarity score that ranges from 0.0 to 1.0.

The primary goal of this task is to build a robust and accurate model to predict the semantic relatedness between pairs of English sentences.

To accomplish this goal, we have used a variety of models, incorporating machine learning models (Linear Regression, Random Forest, XGBoost), models of deep learning (LSTM, BiLSTM), and pre-trained models based on transformer (RoBERTa, bert-base-uncased). We have named our approach of using the bert-base-uncased

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 859–864

model as STS-BERT.

By training and assessing every model, we have carried out a comparison analysis on the Semeval 2024 Task 1 (Track A3) dataset (Ousidhoum et al., 2024a), STSB multilingual dataset (May, 2021), SemEval 2014 Task 2 dataset (Marelli et al., 2014) and dataset provided for Task 1 in SemEval 2015 (Agirre et al., 2015) and have finally come to a conclusion that the STS-BERT model has demonstrated better performance compared to others boasting an impressive Spearman correlation coefficient of 0.81033 on the test dataset.

Key contributions of our research work are listed below -

- We have developed a fine-tuned-STS-BERT model that significantly helps in accurately predicting semantic textual relatedness across diverse sentence pairs.
- We have evaluated the model's performance through various tests conducted using the dataset and subsequently performed an in-depth evaluation of the outcomes.

The GitHub repository that follows has the implementation details available - https://github.com/Fired-from-NLP/SemEval-2024-task-1-track-A-eng.

2 Related Works

The associated works on semantic textual similarity can be generally categorized into three parts, approaches focused on machine learning, deep learning, and attention-based mechanism (transformer).

Among machine learning models, the Support Vector Regression model has been applied for calculating the semantic relationship between two short sentences (Sultan et al., 2013). In this system, three distinct measures, namely overlap in word n-gram, overlap in character n-gram, and semantic overlap, have been used for predicting similarity. In (Buscaldi et al., 2015), a Random forest-based approach has been utilized to find the semantic sentence similarity. The approach has relied on various similarity measures such as WordNet-based conceptual similarity, IC-based similarity, syntactic dependencies, and information retrieval-based similarity.

Traditional deep learning methods have depended on single or multiple granularity representations for detecting similarity. Apart from that, a different architecture that has focused on multiple positional sentence representations has been proposed (Wang et al., 2018). It has used Bi-LSTM for generating representations that enable the model to capture better context understanding. Another architecture has introduced a Siamese adaptation of LSTM (Mueller and Thyagarajan, 2016). Using a fixed-sized vector and a simple Manhattan metric, the model transforms sentence representation that represents semantic relationships. Another paper has described an architecture that has been built using deep learning paradigms (Zhao et al., 2015). This architecture has been trained using a combination of features like features based on a string, features based on a corpus, and features based on syntactic similarity, as well as newer matrices derived from distributed word embedding.

Transformer-based approaches have surpassed both machine learning and deep learning models in calculating semantic sentence relationships. Unlabeled text can be used to pre-train deep bidirectional representations using BERT (Devlin et al., 2019). BERT can be fine-tuned to do various NLP-related tasks like semantic analysis. A replication of BERT called RoBERTa (Liu et al., 2019), has focused on hyperparameters and training data size to improve model performance.

In this shared task, we have used BERT-based pre-trained models as they have been proven to be superior to other models available.

3 Dataset

We have employed the dataset made available as part of Shared Task 1 (Track A3) of the SemEval 2024: Semantic Textual Relatedness (STR) which contains 5500 samples in the training dataset and 250 samples in the dev dataset. Besides, the stsb multilingual benchmark dataset (May, 2021), the SemEval 2014 Task 1 dataset (Marelli et al., 2014) and the Semeval 2015 Task 2 dataset (Agirre et al., 2015) have been used.

Task	Sentence Pairs		
	Train	Validation	Test
SemEval 2014	4500	500	4928
SemEval 2015	2997	750	6729
stsb-multi-mt	5749	1500	1379

Table 1: Data sizes for external datasets

Table 1 shows the distribution of samples that we have used from external datasets. These datasets have been merged to get a total of 32508 samples

and then divided further into two sets: train and validation comprising 25676 and 6732 samples respectively. We have replaced the similarity score of duplicate sentence pairs with the average value to avoid labeling biases among different datasets. For the test dataset, The dataset made available as part of Shared Task 1 (Track A3), which consists of 2600 samples, has been used. These datasets

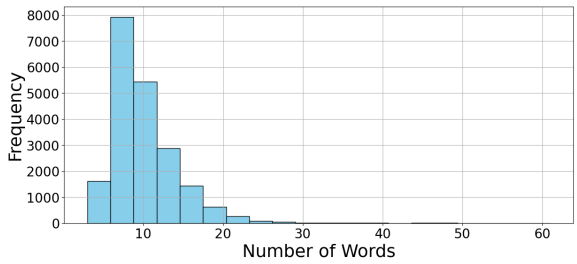

Figure 1: Word distribution of sentence1

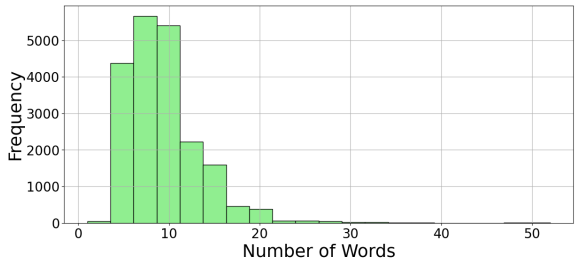

Figure 2: Word distribution of sentence2

contain a pair of sentences in each row, which we have split into two separate sentences namely sentence1 and sentence2. Figure 1 and Figure 2 show that sentence1 contains an average of 6-12 words, while sentence2 contains 3-12 words.

4 System Overview

In this section, we have outlined our methodology to develop models for determining sentence relatedness. First, we have used various extraction strategies to extract characteristics and then utilized a variety of machine learning and deep learning algorithms. Moreover, we have employed different transformer models to develop the system. Figure 3 provides a summary of our working methods.

4.1 Machine Learning-based Approaches

For determining sentence relatedness, we have applied traditional Machine learning-based methods such as Linear Regression and Random Forest. Moreover, To increase the performance, we have employed an ensemble classifier called XGBoost.

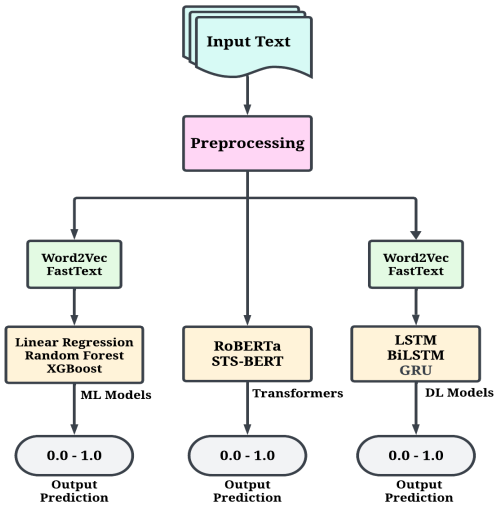

Figure 3: An outline of our approach

Here, we have tokenized the dataset using NLTKTokenizer, and then have we used Word2Vec to extract features. We also have used FastText for feature extraction as it not only captures semantic meaning like Word2Vec but also encodes subword information, allowing it to handle out-of-vocabulary words and morphologically rich languages more effectively. We have set the number of decision trees or boosting rounds to n_estimators for the ensemble approach at 100.

4.2 Deep Learning-based Approaches

Deep learning-based models have been utilized for determining sentence relatedness. We have implemented both models based on LSTM and Bi-LSTM. Two LSTM layers with various numbers of LSTM cells have been applied to the LSTM model. Each of the two directional layers has 50 or 100 LSTM cells in it. We have employed two Bi-LSTM layers, each with 100 and 50 Bi-LSTM cells, in the Bi-LSTM model.

4.3 Transformer-based Approaches

Methods based on transformers are now widely employed in many different contexts. We have employed STS-BERT (Devlin et al., 2019) and RoBERTa to tackle this task. As the sentences can be diverse, having a single representation and better understanding of the sentences is very important. For this reason, we have used the feature vector of the pooling layer as shown in Figure 4.

In our approach, we have first split the pair of sentences in the dataset into two. We have used two bert-based-uncased (Devlin et al., 2019) for

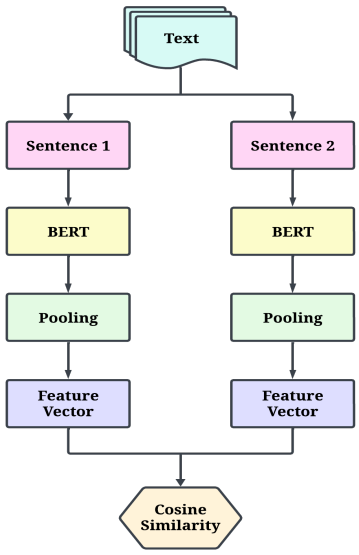

Figure 4: STS-BERT: Transformer-based model architecture for predicting semantic textual relatedness

two sentences. We have obtained the feature vector from the pooling layer of these two Bert models. After obtaining the pooled embeddings, we feed them to the cosine similarity for performing the relatedness task and compare them with the ground truth relatedness score. Then, we compute the loss using MSE (Mean Squared Error) based on the predicted relatedness and the actual relatedness. After the loss is calculated to improve the performance and minimize the loss, we have updated the model parameters using gradient descent.

5 Experimental Setup

This section gives a summary of our experimental setup while training and evaluating our model architectures for semantic textual relatedness.

5.1 Environment Setting

The simulation was executed on a personal computer featuring an Intel Core i7-9700 CPU clocked at 3.00 GHz and an NVIDIA GeForce GTX 2060 GPU. Additionally, to ensure ample processing capability, a Kaggle Notebook equipped with a P100 GPU was utilized.

5.2 Data Preparation

Besides the dataset provided in this competition, we have used three external datasets. We have used the stsb multilingual benchmark dataset (May, 2021), the SemEval-2014 Task 1 dataset (Marelli et al., 2014), and the SemEval-2015 Task 2 dataset (Agirre et al., 2015). We have combined all three datasets. The similarity score of external datasets ranges from 0.0 to 5.0. However, the provided dataset for this competition holds the relatedness between sentences ranging from 0.0 to 1.0. We multiplied the relatedness score of the dataset offered in the competition by 5.0 to match the similarity score in the combined dataset. We have replaced the similarity score of duplicate sentence pairs with the average value. Then, we have split the combined dataset into the training dataset and the validation dataset. The final size of the training dataset is 25676, whereas the overall size of the validation dataset is 6732. We have used the test dataset provided in the competition. The test set contains 2600 samples.

5.3 Parameter Settings

Table 2 shows the parameter settings used in LSTM. BiLSTM, and RoBERTa models.

Model	lr	optim	bs	epoch
LSTM	$1e^{-6}$	Adam	32	10
BiLSTM	$1e^{-6}$	Adam	32	10
RoBERTa	$1e^{-6}$	Adam	32	12

Table 2: Parameter configurations for various models

In Table 2, learning rate, optimizer, batch size, and number of epochs are represented by the variables lr, optim, bs, and epoch, in that order.

Table 3 summarizes the parameter settings used in our proposed STS-BERT model.

Parameter	Value
Learning Rate	1×10^{-6}
Optimizer	AdamW
Batch Size	8
Number of Epochs	12
Loss Function	Mean Squared Error (MSE)
Pooling	Mean Pooling

Table 3: Model parameter settings.

5.4 Evaluation Metrics

The instruction of Shared Task 1 of SemEval 2024 has been to use the Spearman correlation to evaluate the performance of our model using the test dataset. The mathematical representation of the Spearman correlation is provided in equation 1. Besides, we have used Cosine similarity in our model

to predict similarity between sentences. Equation 1 presents the mathematical representation for Cosime similarity.

$$\rho = 1 - \frac{6 \sum d_i^2}{n(n^2 - 1)} \quad (1)$$

In this context, ρ denotes the Spearman correlation coefficient. d_i represents the difference between the ranks of corresponding observations in the two variables, while n indicates the total number of observations.

$$\text{cos\_sim}(A, B) = \frac{\sum_{i=1}^{n} A_i \cdot B_i}{\sqrt{\sum_{i=1}^{n} A_i^2} \cdot \sqrt{\sum_{i=1}^{n} B_i^2}} \quad (2)$$

Where, $\text{cos\_sim}(A, B)$ is the cosine similarity between vectors A and B. A_i and B_i denote the components of vectors of A and B respectively. n indicates the dimensionality of the vectors.

6 Experimental Results

In this section, we have showcased the experimental findings obtained during the training and evaluation stages of the proposed model for semantic textual relatedness prediction.

Table 4 presents a comparative analysis of different types of models, evaluating their performance using the Spearman correlation coefficient on the test dataset.

Category	Model	Embedding	Score
ML	Linear Regression	word2vec	0.0507
		fasttext	0.0507

		fasttext	0.420
	BiLSTM	word2vec	0.4990
		fasttext	0.429
BERT	RoBERTa	-	0.749
	STS-BERT	-	**0.810**

Table 4: Results of different models on the test dataset

Among the machine learning models, we have found that the XGBoost model with word2vec embedding has achieved the highest score of 0.3178. In the deep learning category, we have seen better performance as both LSTM and BiLSTM models have higher scores than the machine learning models. The BiLSTM model achieved a score of 0.499, slightly outperforming the LSTM model, which obtained a score of 0.445.

In some cases, Fasttext word embedding has obtained the best results compared to word2vec (Meden, 2022). Therefore, we have also tested the performance of the model using Fasttext embedding. However, the transformer-based models have clearly outperformed other models based on machine learning and deep learning. For instance, the RoBERTa model achieved a score of 0.749, while our proposed STS-BERT model demonstrated exceptional performance with an impressive score of 0.810.

7 Error Analysis

In the development phase external datasets, SemEval 2014 Task 1 (Marelli et al., 2014), SemEval 2015 Task 2 (Agirre et al., 2015) and multilingual benchmark dataset (May, 2021) along with the competition dataset have been utilized. Hence the training set becomes more diverse and our model fails to learn about the relatedness between the sentences. The similarity scores of the external datasets ranged between 0.0 to 5.0. To make all the scores similar we have multiplied the scores of the competition dataset by 5.0 and normalized the whole training set by dividing all the scores by 5.0. Due to multiple conversions of the range of scores, precision loss has occurred. Sentence transformation has been another key reason for the poor performance of the model. When the second sentence is the transformation of the first sentence, our model can not detect it. For example, if the first sentence is in simple form and the second sentence is in the complex form of the first sentence, the model shows poor performance in that case. As a result, the overall performance of our proposed system has degraded.

8 Conclusion

In this research, we have conducted a comparative performance analysis, assessing a range of machine learning, deep learning, and transformer-based models to predict the semantic textual relatedness between pairs of English sentences. We have utilized the Task 1 (Track A3) dataset provided in the shared task, along with additional external datasets, for training various models. Our results indicate that the STS-BERT model has outper-

formed all other models, achieving an impressive score of 0.810. However, after analyzing errors, we have discovered that the slight score decrease is due to the integration of large external STS datasets with varying output ranges. To address this in future work, we plan to implement alternative strategies. Moreover, we will work on Task 1 (Track B and C) to have more comprehensive findings.

9 Ethical Considerations

To advance semantic text relatedness, we commit to emphasizing privacy through informed consent, reducing biases, as well as transparent modeling. Our ethical position prioritizes responsibility, accessibility, and privacy to build a positive and open technology environment.

BITS Pilani at SemEval-2024 Task 1: Using text-embedding-3-large and LaBSE embeddings for Semantic Textual Relatedness

Dilip Venkatesh[1] and **Sundaresan Raman**[1]

[1]Birla Institute of Technology and Science, Pilani, Rajasthan, India
{f20201203, sundaresan.raman}@pilani.bits-pilani.ac.in

Abstract

Semantic Relatedness of a pair of text (sentences or words) is the degree to which their meanings are close. The Track A of the Semantic Textual Relatedness shared task aims to find the semantic relatedness for the English language along with multiple other low resource languages with the use of pretrained language models. We propose a system to find the Spearman coefficient of a textual pair using pretrained embedding models like **text-embedding-3-large** and **LaBSE**.

1 Introduction

Semantic relatedness is defined as the degree of closeness of textual units (sentences, words, paragraphs) (Mohammad, 2008, Mohammad and Hirst, 2012). This makes semantic relatedness an important metric to understand the meaning of text. A paragraph is a string of multiple related sentences and similar paragraphs in a sequential manner form passages or documents which provides valuable information. Understanding this cohesion among sentences (Bernhardt, 1980) and passages is critical for understanding meaning and therefore generating more powerful natural language processing systems. We consider text to be semantically close if there is some sort of similar meaning. We can see an example of textual relatedness in Table 1

We make an important differentiation between **Semantic relatedness** and **Semantic Similarity**. Semantic similarity is when two textual units are synonymous, hyponymous, antonymous, or troponymous relation between them (Abdalla et al., 2023). Semantic relatedness consists of when there is a lexical relation between two units of text *conductor-orchestra, teacher-book*.

Since semantic relatedness is crucial to understanding meaning, it has many use cases in various NLP tasks such as question answering and text generation to produce coherent statements (Abdalla et al., 2023). Other natural language challenges like machine translation or information retrieval can be reduced to a semantic distance problem. It is also a key factor for text summarization, the relation between sentences in text will allow for more accurate summaries without too much loss of context.

For Track A of the SemEval 2024 Task 1: *Semantic Textual Relatedness **(STR)*** (Ousidhoum et al., 2024b) on Codalab (Pavao et al., 2023), we aim to create a system to automatically detect the degree of semantic relatedness between pairs of sentences with the OpenAI *text-embedding-3-large* and LaBSE text embedding models. This is for languages like English, as well as multiple low resource languages like *Algerian Arabic, Amharic, Hausa, Kinyarwanda, Marathi, Moroccan Arabic, Spanish, Telugu*.

Our code can be found on GitHub at `https://github.com/dipsivenkatesh/SemEval-2024-Task-1`

2 Background

2.1 Task and Data Description

The Semantic Textual Relatedness shared task [1] consists of three tracks.

- **Track A**: Supervised
- **Track B**: Unsupervised
- **Track C**: Cross-lingual

In this paper we go through our team's system to solve the track A of the challenge.

For the first track, we must develop a system to automatically find the closeness of meanings (semantic relatedness) between two sentences. We need to generate a relatedness score between 0

June 20-21, 2024

PAIRS	SENTENCE 1	SENTENCE 2
1	There was a lemon tree next to the house.	The boy enjoyed reading under the lemon tree.
2	There was a lemon tree next to the house.	The boy was an excellent football player.

Table 1: Sentence relatedness: We can see that the sentences in pair 1 are more related than the sentences in pair 2

(completely unrelated) and 1 (maximum relations). For this track teams are allowed to submit systems that use the given datasets or any external datasets. The use of pre-trained language models are also allowed.

The datasets for training consisted of a pair of sentences and the 0 to 1 semantic relatedness scores graded through manual annotation. A comparative annotation approach was used for generating these gold label scores thereby avoiding biases of traditional rating and guaranteeing a high reliability.

2.2 Previous Work

In recent times the standard way to represent word meanings is as **vector semantics**. This comes from two major ideas, the idea to represent a word in three dimensional vector space (Osgood et al., 1957) and defining a word by the distribution of words around it (Harris, 1954 and Joos, 1950). Representing text as embeddings is an example of representation learning (Bengio et al., 2013).

The combination of term frequency (Luhn, 1957) and inverse document (Sparck Jones, 1972) frequency led to the use of **tf-idf** for representing word embeddings. Tf-idf had many faults, it did not represent contextual word relationships or word co-occurrence. This is fixed with in **Pointwise Mutual Information** (PMI) (Fano and Wintringham, 1961) a measure of how frequent two events occur, compared their occurrence if they were independent. The problem with tf-idf and PMI embeddings is that they are sparse vectors. Instead methods like **word2vec** (Mikolov et al., 2013) and **GloVe** (Pennington et al., 2014) produce dense vectors for word embeddings. Language models have gained a lot of traction due to their understanding of natural language. Language models like BERT have the ability to generate contextual embeddings. Contextual embeddings are used to represent the word in the context that it is used.

More recently, state of the art embedding models use pre-trained transformers by fine tuning the to a certain task. This is used in text embdding models like **Sentence-BERT** (SBERT) (Reimers and Gurevych, 2019) that uses BERT along with siamese and triplet network structures to generate sentence embeddings.

For the Semantic Textual Relatedness shared task track A our system, uses OpenAI's text-embedding-3-large to generate text embeddings. We also use the Language-agnostic BERT Sentence Embedding model (LaBSE) (Feng et al., 2022) to generate embeddings for the other languages as this model generates better representations for these languages.

2.3 Evaluation Metrics

There are multiple ways to evaluate relatedness using the vector embeddings of the text, dot product is one such metric. However it favors longer vectors, therefore normalized dot product or the cosine of the angle between the two vectors is used

The evaluation metric for this challenge was the Spearman rank coefficient which compares the the sentence relatedness predictions of the system against the gold truth human judgements. The Spearman rank coefficient (ρ) can be calculated as:

$$\rho = 1 - \frac{6 \sum_{i=1}^{n} d_i^2}{n(n^2 - 1)}$$

where:

- d_i is the difference between the ranks of corresponding variables x_i and y_i,
- n is the number of observations.

3 System Overview

3.1 text-embedding-3-large

We use OpenAI's latest large text embedding model **text-embedding-3-large**[2] to generate embeddings. The state of the art *text-embedding-3-large* creates embeddings of 3072 dimensions. The embedding model achieves a score of 54.9% MIRACL benchmark (Zhang et al., 2023) and 64.6% on the MTEB benchmark (Muennighoff et al., 2022).

Model / Language	amh	arq	ary	eng	esp	hau	kin	mar	tel
LaBSE	0.79	0.46	0.41	N/A	0.72	0.48	0.50	0.80	0.78
text-embedding-3-large	0.68	0.56	0.45	0.86	0.70	0.47	0.52	0.78	0.74

Table 2: Performance comparison of sentence-transformers/LaBSE and text-embedding-3-large on training set

3.2 LaBSE

We use the **Language-agnostic BERT Sentence Embedding** (LaBSE) model (Feng et al., 2022) to generate the embeddings for most of the non-English languages. We use the model for inferencing using the HuggingFace Transformers library (Wolf et al., 2020).

3.2.1 Model Architecture

The model architecture of LaBSE is similar to BERT (Devlin et al., 2019) and uses self attention to process input text. This is then pre-trained on a large corpus that of multiple languages. After this pre-training the model can generate fixed length sentence embeddings. These embeddings are designed to be language-agnostic.

4 Experimental Setup

4.1 Dataset

We use the *SemRel* datasets (Ousidhoum et al., 2024a), a semantic relatedness dataset annotated by native accross 14 languages 14 languages: *Afrikaans, Algerian Arabic, Amharic, English, Hausa, Hindi, Indonesian, Kinyarwanda, Marathi, Moroccan Arabic, Modern Standard Arabic, Punjabi, Spanish* and *Telugu*. These datasets consists of multiple records of sentence pairs along with their manually annotated relatedness score. All the languages of Track A of the dataset consist of a train-test split.

4.2 Embedding

We propose a system where we take a zero-shot approach to the test set with the pre-trained embedding models. We don't train or fine-tune the models used on the training data. We use the training data for evaluation of model performance on the languages in this track. We can find the evaluation of the models on the training set in table 2. Based on this performance we use text-embedding-3-large for Algerian Arabic, Moroccan Arabic, English, and Kinyarwanda and LaBSE for Amharic, Spanish, Hausa, Marathi and Telugu.

5 Results

For evaluation, the organizers rank the system based on Spearman rank correlation coefficient with the golden labels. The performance of the models on all the languages can be found in Table 3. Our system to identify the relatedness scores uses a zero shot method and achieves scores similar to the baseline scores. The score for English surpasses the baseline score.

6 Conclusions and Limitations

In our paper for the SemEval Task 1: Semantic Textual Relatedness we propose a zero-shot approach for relatedness using the text-embedding-3-large and LaBSE embedding models. It is importand to consider that text-embedding-3-large is not an open-source model and that these models may contain inherent biases in them.

A Spearman Correlation on test dataset

Language	Our scores
Algerian Arabic (arq)	0.5097117963
Amharic (amh)	0.8000962937
English (eng)	0.8323738277
Hausa (hau)	0.5083993463
Kinyarwanda (kin)	0.5183340316
Marathi (mar)	0.8415291711
Moroccan Arabic (ary)	0.4441887719
Spanish (esp)	0.6557116114
Telugu (tel)	0.814199637

Abstract

In this paper, we present our novel systems developed for the SemEval-2024 hallucination detection task. Our investigation spans a range of strategies to compare model predictions with reference standards, encompassing diverse baselines, the refinement of pre-trained encoders through supervised learning, and an ensemble approaches utilizing several high-performing models. Through these explorations, we introduce three distinct methods that exhibit strong performance metrics. To amplify our training data, we generate additional training samples from unlabelled training subset. Furthermore, we provide a detailed comparative analysis of our approaches. Notably, our premier method achieved a commendable 9th place in the competition's model-agnostic track and 17th place in model-aware track, highlighting its effectiveness and potential.

1 Introduction

Large language models are proficient in generating human-like text across various styles. However, even the most advanced models can produce hallucinations, leading users to question their reliability. There are two primary types of hallucinations: factuality hallucinations, which involve the generation of content that deviates from actual facts, and faithfulness hallucinations, when the model fails to solve tasks correctly following specific instructions (Huang et al., 2023).

The SemEval 2024 Shared-task on Hallucinations and Related Observable Overgeneration Mistakes (Mickus et al., 2024) has integrated both types into three tasks. The Definition Modeling task (DM) focused on fact-related hallucinations by challenging models to generate contextually relevant word definitions. Both the Machine Translation (MT) and Paraphrase Generation (PG) tasks included faithfulness hallucinations, with models asked to produce translations or paraphrases for given sentences. Evaluation labelled datasets for these tasks were provided and the training dataset consisted only of source sentences and model generations, without corresponding labels.

Motivated by the lack of annotated resources and the efficacy of other language models trained on synthetic data, we developed two synthetic datasets that replicate the targeted domain. First, we collected data through a proprietary GPT-4 model (OpenAI, 2023), but our methods trained on the achieved data did not yield the desired results as prompt engineering made maintaining the domain challenging. As a second approach, we trained LLaMA2-7b (Touvron et al., 2023) adapters using a small set of annotated examples and applied them to the unlabeled training data. This method proved to be a more effective form of in-domain data augmentation.

While the competition was run on two tracks, we focus mainly on the model-agnostic track. In our methods we utilized the most effective models with varied sizes and architectures, which we had evaluated beforehand. Our experiments involved fine-tuning a pre-trained embedding model, repurposing it to function as a binary classifier across a number of open-source datasets, including our synthetic sets. We also experimented with a promising method for evaluating paraphrases by modifying its design and fine-tuning the model on different data. Finally, we tested different combinations of the highest-performing approaches in an ensemble setting. Generated synthetic data and code published on GitHub[1].

2 Related work

In the field of text representation, the E5 (Wang et al., 2022) family represents a group of cutting-edge sentence embedding models trained through

[1]https://github.com/s-nlp/shroom

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 869–880
June 20-21, 2024

contrastive methods. The E5-Mistral[2] model, a powerful embedding model that has been fine-tuned on a selection of annotated data, is currently recognized as the leading open-source model by the Multitask Text Embedding Benchmark (Muennighoff et al., 2023).

Vectara's *hallucination_detection_model*[3] is a fine-tuned DeBERTa focused on summarization datasets that includes annotations for factual consistency. TrueTeacher (Gekhman et al., 2023) is a family of models and an associated dataset designed for evaluating factual consistency. The dataset was created by first fine-tuning various-sized T5 models on summarization tasks. These models were then employed to generate hypotheses, which were subsequently automatically annotated using a 540B Large Language Model (LLM). This annotated dataset was then utilized to train multiple models to assess factual consistency.

The Mutual Implication Score (MIS) (Babakov et al., 2022) is a metric devised for evaluating the quality of text style transfer and paraphrasing systems, grounding its assessment on content similarity between the prediction and the reference text. It leverages a RoBERTa-NLI (Nie et al., 2020) model that has been fine-tuned and incorporates it into an architecture that processes two input texts sequentially in both forward and reverse directions. The final hidden states from these two passes are merged and forwarded to a classification head to determine the MIS score. Initially, the MIS metric was trained using the Quora Question Pairs dataset (QQP) (Sharma et al., 2019).

SimCSE (Similarity-based Contrastive Self-supervised Learning) (Gao et al., 2021) is a self-supervised learning method for text embeddings. It is used for creating embeddings of text data that are semantically meaningful and can be used in various downstream tasks. It involves training a neural network to maximize the similarity between embeddings of similar sentences and minimize the similarity between embeddings of dissimilar sentences. LaBSE (Language-agnostic BERT Sentence Embedding) (Feng et al., 2022) is a method for generating multilingual sentence embeddings using the BERT architecture.

Other metrics for evaluating content preservation, such as BLEU (Bilingual Evaluation Understudy) (Papineni et al., 2002), CHRF (Character n-gram F-score) (Popović, 2015), METEOR (Metric for Evaluation of Translation with Explicit ORdering) (Banerjee and Lavie, 2005), and BLEURT (Bilingual Evaluation Understudy for Ranking and Tuning) (Sellam et al., 2020), also stand out. BLEU utilizes a modified unigram precision score, CHRF evaluates the quality of machine translation by comparing character n-grams in candidate translations against reference translations to compute an F-score, METEOR calculates the harmonic mean of precision and recall at the single-word level, and BLEURT employs a fine-tuned BERT model in a cross-encoder setup, using synthetic data to assess semantic similarity.

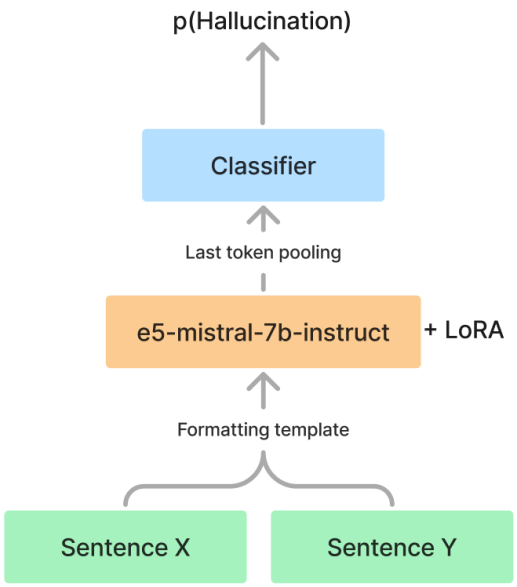

Figure 1: Classifier architecture when using synthetic data.

3 Data

3.1 Existing datasets

The QQP dataset consists of pairs of questions from the Quora forum. For each pair, it is indicated whether the questions are paraphrases, i.e. they ask about the same thing. PAWS (Zhang et al., 2019) is a paraphrase detection dataset that contains complex cases with both paraphrase and non-paraphrase samples that have high lexical overlap.

We postulated that other pre-existing datasets, such as QQP and PAWS, might exhibit particular biases due to their distinct task domains (for instance, QQP dataset includes only questions). To mitigate this potential issue, we generated synthetic

[3] https://huggingface.co/vectara/hallucination_evaluation_model

	DM	MT	PG
Not Hallucination	188	211	132
Hallucination	175	179	132
Total	363	390	264

Table 1: Adapter train sample sizes.

data taking unlabeled training samples as starting points.

Our experimentation with synthetic data creation was divided into two main approaches: the first involved training LoRA (Hu et al., 2022) adapters for the LLaMA2-7b model using the annotated data derived from the validation set. The second approach involved the generation of both correct and incorrect hypotheses by employing GPT-4 and specific prompts.

All tasks were distilled down to the paraphrase evaluation task. Consequently, we only used targets (sources for paraphrase generation) and hypotheses as inputs for the models.

3.2 LLaMA2-7b adapter

We trained 6 LoRA adapters, pairing them to specialize in either generating hallucinations or producing correct responses for each task. Due to the limited amount of labeled data, we made use of model's ability of in-context learning by prepending samples with instructions: *Paraphrase* for non-hallucinations and *Provide an incorrect paraphrase* for hallucinations. The number of samples for each adapter is shown in Table 1.

Training and generation hyperparameters are displayed in Table 2. For each task and label we manually selected the best epoch by analyzing a small set of generated samples. These checkpoints were further employed to synthesize hypotheses for their task's training set. A small sample of the generated data using LLaMA2-7b adapter is provided in the Appendix C.

3.3 GPT-4 prompting

In addition, we created two distinct prompts for the PG task. In these prompts, we directed GPT-4 to generate a paraphrase of a source sentence extracted from an unlabeled training sample. The nature of the paraphrase, whether it should contain hallucinations and overgeneration errors or not, was determined by the specific prompt we used.

We enriched the prompt structure for few-shot learning purposes, incorporating several illustrative

Stage	Hyperparameter	Value
Training	lr	4e-4
	warmup_steps	1
	optimizer	AdamW
	scheduler	linear
	LoRA alpha	16
	LoRA dropout	0.05
	LoRA r	16
	batch size	32
Inference	num_beams	3
	do_sample	true
	repetition_penalty	1.2
	top_k	50
	max_new_tokens	512

Table 2: Training and inference hyperparameters for LoRA adapters.

examples drawn from both the validation and trial data splits. Alongside each *incorrect* example, we included an explanation to clarify why the provided hypothesis did not meet the criteria.

Moreover, we tasked GPT-4 to execute its reasoning step-by-step: to iterate through several examples with accompanying explanations, and, by leveraging those explanations, to discern and select the most suitable paraphrase.

We utilized the *gpt-4-1106-preview* model, adhering to the default generation parameters stipulated by the OpenAI API service.

3.4 Data filtration

In the process of evaluating the synthetic data we generated, we encountered multiple issues that necessitated an extra layer of filtering:

- A number of the samples produced by the LLaMA2-7B model were excessively lengthy, containing up to 1024 tokens.
- The labeling of samples by the LLaMA2-7B as *Hallucination* was frequently incorrect. Samples designated as hallucinations were often devoid of any such content, and conversely, non-hallucination samples sometimes contained hallucinations.
- A peculiar pattern was observed in the DM task generations from LLaMA2-7B, where more than 9,000 samples started with the word *any* or *anything* denoting a biased starting point which may impact the diversity and neutrality required for effective training.
- In the subsets of synthetic data generated by GPT-4 and labeled as *Not Hallucination* the resulting examples were deemed too straightforward, potentially leading to a training dataset

that cannot robustly challenge and thereby improve the model's discriminatory capabilities.

To tackle the identified issues with the synthetic data, we adopted a systematic filtering methodology. We began by eliminating any hypothesis that exceeded a length of 200 tokens, ensuring the data remained succinct. For the samples that started with *any* or *anything*, we decided to limit the number to 500 to minimize bias.

With the aim of refining the data quality, we then annotated all the synthetic samples using MIS. We set specific thresholds for these MIS scores to filter the data further. In the subset containing hallucinations, we removed samples that had a score lower than 0.1 or higher than 0.5. For non-hallucinated samples, we only retained those with a score between 0.7 and 0.9. These score ranges were established empirically to ensure a balance between discernibility and ambiguity in both the hallucinated and non-hallucinated examples.

The number of samples generated using both synthetic methods, before and after the filtering stage, is given in Table 3. After generating the synthetic data, we performed several experiments with different combinations of synthetic data.

4 Methods

4.1 Black-box baselines

First, we started with an assessment of various baseline models that are detailed in Section 2, including a new addition, GPT-4. These baseline models were utilized as-is, in a *black-box* fashion, without any further fine-tuning specifically for our tasks.

For all models other than GPT-4, we employed the inference code available on the official HuggingFace Hub pages. For GPT-4, we created specific prompts for each task. Within these prompts, we instructed GPT-4 to methodically process the information and ascertain the presence of hallucinations within the sample. We provided all pertinent data (source, hypothesis, and, when available, target) within the prompt. It is important to note that the collection and evaluation of predictions were conducted strictly within the model-aware track. The prompt is available in Appendix A.

4.2 SFT E5-Mistral

The obtained synthetic data was used to fine-tune the E5-Mistral model on our domain. In our experiments, we adjusted the data inputs by adding or omitting certain subsets of synthetic data to create the final blend used for training. The choice of the E5-Mistral model as the foundation for our work was based on its superior performance compared to other models.

The design of our classifier is depicted in Figure 1. In simple terms, we prepare two sample sentences with a specific format and input them into an model with LoRA. Afterwards, we obtain the embedding of the last token and pass it to the classification head.

4.3 Mutual Implication Score

In this setup we experimented with some improvements to the original Mutual Implication Score model architecture. Even though MIS was already trained on a large amount of paraphrase detection data, QQP dataset biased to the questions. Therefore, we thought that we can fine-tune it to decrease this bias.

In Table 4 we present default training hyperparameters used for experiments with MIS. Unless stated otherwise, we chose to train with the RoBERTa encoder, classifier and QQP dataset from original MIS study.

We tried various experiment configurations, ranging from the use of new datasets to alterations in architecture and training methods. We will describe all the modifications presented:

1. **MIS**: Vanilla MIS from HuggingFace Hub without any fine-tuning.
2. **MIS trained with LoRA**: Add LoRA adapters instead of partially unfreezing layers.
3. **MIS with Vectara**: Replace the original RoBERTa encoder with Vectara's model.
4. **MIS with one encoder**: Change MIS two-folded architecture with a single one.
5. **MIS trained on the PAWS**: Add 108,463 human-labeled paraphrase adversaries from PAWS.
6. **MIS trained on our synthetic data**: Add our synthetic data obtained previously.

4.4 Content Preservation Measures

We conducted a separate analysis on several NLP techniques as examined in the original MIS study. This exploration aimed to assess their suitability for the task of hallucination detection, considering the inherent connection between style transformation, paraphrase generation, and hallucination detection. A well-executed paraphrase should retain the essence of the original text without introducing

Source method	Task	Label	# before filtering	# after filtering
LLaMA2-7B	MT	Hallucination	18 093	7 758
		Not Hallucination	17 056	3 572
	PG	Hallucination	13 961	2 839
		Not Hallucination	14 928	3 952
	DM	Hallucination	19 224	5 939
		Not Hallucination	20 000	12 032
GPT-4	PG	Hallucination	7 439	-
		Not Hallucination	6 279	-

Table 3: The number of samples in the synthetic datasets. No filtering was performed for GPT-4.

Hyperparameter	Value
lr	1e-4
lr scheduler	constant
optimizer	AdamW
batch size	32

Table 4: Training hyperparameters for MIS experiments.

extraneous elements, which is particularly crucial given that one of the competition's subtasks involved paraphrasing. Specifically, our investigation involved LaBSE, SimCSE, and the metrics for evaluating content preservation described in Section 2.

4.5 Ensembling

To enhance the performance of different pre-trained models, we combined them into an ensemble. The final decision on the presence of hallucinations is based on the predictions of multiple independent models.

The predictions of separate models were normalized so that the decision boundary was the same for all models. Thus, differences in the scale of the threshold value did not introduce bias into the final decision.

We have chosen the best set of models for the ensemble from the possible options: E5-Mistral, fine-tuned E5-Mistral, Vectara, TrueTeacher, *all-mpnet-base-v2*[§] and also Mutual Implication Score. We calculated cosine between the encoded representations of the model's hypothesis and the target sentence. To obtain a prediction, this score was compared with a descision boundary. For each model we select the optimal classification threshold on validation subset for each track and task. For Vectara we used a threshold of 0.5.

[§]https://huggingface.co/sentence-transformers/all-mpnet-base-v2

We employed different strategies on aggregating individual hallucination scores: Normalized averaging and Voting.

4.5.1 Normalized averaging

The predictions of separate models were normalized so that the decision boundary was the same for all models. Thus, differences in the scale of the threshold value did not introduce bias into the final decision.

Individual model scores are normalized as follows:

$$\hat{p} = \begin{cases} kp + b, & p \geq \text{thr} \\ \frac{p}{2\text{thr}}, & p < \text{thr} \end{cases}$$

where $k = \frac{1}{2(1-\text{thr})}$, $b = 1 - k$ and thr is the optimal decision boundary on validation.

This transformation allows to keep the score within $[0, 1]$, at the same time, the decision boundary for all models becomes 0.5.

4.5.2 Voting

Another strategy is to aggregate the binary predictions of the models in an ensemble. The presence of hallucinations was determined by voting models, depending on the number of votes in favor. At the verification stage, we determine the minimum number of model votes required to acknowledge the pair of sentences, model hypothesis and ground truth, as a paraphrase, for example, at least one, two or three models voted in favor. That is, we predicted a hallucination if an insufficient number of models compared to the optimal validation threshold classified the sample as a paraphrase.

5 Results

The comparative analysis of the performance across all baselines, our proposed methods, and the leading approaches derived from the official rankings is collated in Table 5.

Method	val		test

	MIS + all-mpnet + Vectara + TrueTeacher	0.81	0.81	0.81	**0.79**

Table 6: Ensembling results. Accuracy is observed as evaluation score.

5.1 Ensembling

According to the results, the Voting approach we developed surpasses all baselines as well as other methods we devised. Nevertheless, the performance narrowly trails the foremost methods from the model-agnostic track in the official rankings by a minimal margin of 0.01. In regards to the application of Ensembling methods, a detailed evaluation delineating the constituent models employed is documented in Table 6. It was discerned that the incorporation of our SFT E5-Mistral model enhances overall performance metrics.

5.2 MIS

Succeeding in performance ranking is the MIS model, refined through training on the PAWS dataset. As previously elucidated, an assortment of configurations was examined, the details of which are exhaustively represented in Table 7. It is observed that the original MIS model's performance was not substantially uplifted; modifications yielded no marked increment in accuracy. Nonetheless, it is notable that the integration of the PAWS dataset into the training process marginally amplified accuracy for both tracks. Simultaneously, a minor enhancement on the aware track was observed upon the deployment of the Vectara encoder in place of the RoBERTa model.

5.3 SFT E5-Mistral

The next approach by performance is our SFT E5-Mistral. The accuracy for different configurations in our synthetic data experiments can be found in Table 8. The combination of PG and DM synthetic data achieves the best results. Unexpectedly, the use of synthetic data from GPT-4 does not yield as good outcomes. This suggests that GPT-4's synthetic data may contain some inherent biases.

Method	val		test	
	agnostic	aware	agnostic	aware
MIS (original)	0.80	0.78	0.77	**0.80**
+ LoRA	0.79	0.79	0.78	**0.80**
+ Vectara	0.79	0.81	**0.81**	0.77
+ Single fold	0.78	0.77	0.75	0.78
+ PAWS	**0.82**	**0.82**	**0.81**	0.78
+ Synthetic data	0.79	0.77	0.77	0.74

Table 7: MIS ablation study results. Accuracy is observed as evaluation score.

Source	Subset	agnostic	aware
GPT	PG	0.76	0.72
LLaMA	PG	0.81	0.75
	DM	0.63	0.51
	MT	0.79	0.71
	PG + DM	**0.83**	**0.77**
	PG + MT	0.81	0.76
	MT + DM	0.75	0.71
	All	0.77	0.71
GPT + LLaMA	All	0.77	0.73

Table 8: Synthetic data ablation study on E5-Mistral. Accuracy is observed as evaluation score.

We carried out a detailed evaluation of a particular subset and identified probable causes for bias:

- For texts generated without hallucinations, they tend to be overly formal and intricate.
- In cases with hallucinations, numerous instances are exceedingly convoluted, sometimes to the extent that the sentences convey the opposite meaning. Our investigation revealed that such hallucinations might not be readily detectable.

It is also clear that relying solely on DM synthetic data does not sufficiently address other tasks. By contrast, a model checkpoint trained with PG synthetic data shows promising performance. Just like the MIS approach, it appears that having PG data is sufficient to address hallucinations in other tasks, provided that the target is accessible.

5.4 Black-box baselines

All our advanced methods outperform black-box baselines on model-agnostic track. Even though, we observe that the E5-Mistral and MIS methods sets a solid baseline on model-agnostic track, maintaining a high level of performance even without any fine-tuning. Considering model-aware track, all baseline models except of GPT-4 show similar performance. The GPT-4 model does not do as well as the others in terms of the average score with our specific prompts. Finally, there is the official baseline that our approaches outperform.

5.5 Content Preservation Measures

Across preservation measures, SimCSE demonstrates the most notable results. In the model-agnostic track, it performs at the same level as more sophisticated approaches such as TrueTeacher, Vectara, or E5 Mistral, without any fine-tuning. However, other preservation measures do not perform as well. Most of them, with the exception of BLEURT, perform even worse than the official baseline in the model-agnostic track.

6 Conclusion

We conducted a comparative analysis involving six baseline models (MIS, E5-Mistral, Vectara, TrueTeacher, GPT-4, and the official baseline from the participant kit) alongside four sophisticated approaches (Voting and Normalized Averaging in Ensembling, as well as the refined MIS and SFT E5-Mistral). Of all methods evaluated, Ensembling demonstrated the highest performance. Nonetheless, the refined MIS and the SFT E5-Mistral exhibited only a minor shortfall in performance when compared to these leading methodologies.

Indeed, there appear to be several avenues for enhancing our synthetic data to potentially exceed the performance of other methods:

- Instead of training separate adapters for each task, centralized training with one adapter across multiple tasks could enrich the learning context and expand the size of the training dataset.
- Exploring a range of other models, such as Mistral-7b (Jiang et al., 2023), Mixtral-8x7b[¶], or LLaMA models of various larger sizes (LLaMA-13b, LLaMA-30b), could identify more efficient architectures or models that are better suited to handle the synthetic data effectively.
- For improving the quality of GPT-generated synthetic data, incorporating a more extensive range of examples within few-shot prompts and providing detailed explanations for the *correct* samples could help in mitigating bias and increasing the fidelity of the generated

[¶] https://huggingface.co/mistralai/Mixtral-8x7B-v0.1

data.

The potential use of our adapters to generate both positive and negative samples aimed at a specific target is indeed promising. By assembling datasets that offer these contrasting examples, we could refine the training process through contrastive fine-tuning. Such a method is hypothesized to yield superior performance by facilitating the model's ability to discern and learn from the nuanced differences between correct and incorrect instances.

A GPT-4 prompt for PG task evaluation

```
Read the source sentence and the paraphrased hypothesis and answer whether there are any hallucinations
or related observable overgeneration errors for the paraphrasing task.
Before answering, think step by step and write why you chose the answer you did.
Answer the last string with 'The hypothesis is correct' if there are no hallucinations or misgenerations.
Otherwise, answer with 'The hypothesis is false'.

Example 1:
Source sentence: "The European Parliament does not approve the budget."
Paraphrased hypothesis: "The budget cannot be adopted against the will of the European Parliament."
The hypothesis is false

Example 2:
Source sentence: "Everyone is capable of enjoying a good education in a society."
Paraphrased hypothesis: "We must create a society where everyone is able to enjoy a good education."
The hypothesis is correct
```

Figure 2: Prompt for GPT-4 evaluation on PG task.

B GPT-4 prompt for synthetic paraphrased data generation with hallucinations

```
Your aim is to produce an incorrectly paraphrased sentence that contains a hallucination for the given source sentence. Hallucinations in a paraphrase can add new information that wasn't present in the source sentence, or exclude some important information, or reverse the meaning of the source sentence. Remember that reversing source sentence has the lowest level of priority, so use it only if there is no other way to make a hallucination. Usually it's much better to misrepresent some information, add new or exclude something important. If there is some quantitative information in the source, feel free to change them slightly. Complete the task using the examples below. The examples also show the correct paraphrase for the source sentences. Note that there are no hallucinations in the correct paraphrase, whereas your aim is to corrupt the source and produce a false paraphrase.

Examples:
Source: "I have a permit."
The correct paraphrase: "Uh, I'm validated."
The incorrect paraphrase: "I have a permit to carry it."
Explanation: The incorrect paraphrase adds information that is not present in the source sentence ("to carry it")

Source: "Easy, easy."
The correct paraphrase: "Watch it now."
The incorrect paraphrase: "The process is easy."
Explanation: The incorrect paraphrase introduces additional information ("The process is")

Source: "A five, six, seven, eight."
The correct paraphrase: "And 5, 6, 7, 8."
The incorrect paraphrase: "A number between five and eight."
Explanation: While the source sentence is a rhythmic count or sequence of specific numbers, the incorrect paraphrase generalizes it to "a number between five and eight".

Source: "A lot safer that way."
The correct paraphrase: "Because it's safer."
The incorrect paraphrase: "That is a safer way to travel."
Explanation: The major hallucination lies in the addition of "That is," which wasn't present in the original source sentence. This introduces a new element and changes the focus from the general concept of safety to a specific way of travel

Source: "You're a scam artist."
The correct paraphrase: "You are an imposter."
The incorrect paraphrase: "You're not a good scam artist."
Explanation: While the source sentence simply states "You're a scam artist," the incorrect paraphrase implies a judgment on the person's skill as a scam artist

Don't answer now, read the source and think step by step how to make a false paraphrase for the source sentence. Before answering, provide several examples with explanations and choose the best one. Answer starting with 'The incorrect paraphrase:
```

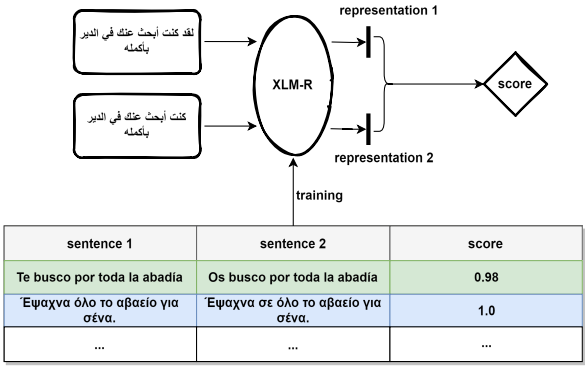
Abstract

Cross-lingual semantic textual relatedness task is an important research task that addresses challenges in cross-lingual communication and text understanding. It helps establish semantic connections between different languages, crucial for downstream tasks like machine translation, multilingual information retrieval, and cross-lingual text understanding. Based on extensive comparative experiments, we choose the $XLM\text{-}R_{base}$ as our base model and use pre-trained sentence representations based on whitening to reduce anisotropy. Additionally, for the given training data, we design a delicate data filtering method to alleviate the curse of multilingualism. With our approach, we achieve a **2nd** score in Spanish, a **3rd** in Indonesian, and multiple entries in the top ten results in the competition's track C. We further do a comprehensive analysis to inspire future research aimed at improving performance on cross-lingual tasks.

1 Introduction

Semantic textual relatedness (STR) encompasses a broader concept that takes into account various commonalities between two sentences. This includes factors such as being on the same topic, expressing the same viewpoint, originating from the same period, one sentence elaborating on or following from the other, and more. SemEval is an international workshop on semantic evaluation. In track C of SemEval-2024 task 1: Cross-lingual (Ousidhoum et al., 2024b), participants are to submit systems,which are developed without the use of any labeled semantic similarity or semantic relatedness datasets in the target language and with the use of labeled datasets (Ousidhoum et al., 2024a) from at least one other language.

Various methods were proposed to address the task of textual relatedness. One common approach



sentence 1	sentence 2	score
Te busco por toda la abadía	Os busco por toda la abadía	0.98
Έψαχνα όλο το αβαείο για σένα.	Έψαχνα σε όλο το αβαείο για σένα.	1.0
...	...	...

Figure 1: The description of cross-lingual semantic textual relatedness task.

is based on feature engineering, where the syntactic, semantic, and structural features of text, such as word frequency, TF-IDF, and word embeddings, are extracted. Machine learning algorithms are then employed for relatedness determination. Another popular approach is based on deep learning methods, such as Convolutional Neural Networks (LeCun et al., 1989), Recurrent Neural Networks (Graves and Graves, 2012) , and self-attention mechanisms (Vaswani et al., 2017). These methods can capture semantic relationships and contextual information within the text, and they are trained on large-scale datasets to enhance model performance and generalization ability.

However, there are two challenges in track C of SemEval-2024 task 1:

- Compared with static word representation such as Word2Vec (Mikolov et al., 2013) and Glove (Pennington et al., 2014), the pre-trained language models (PLM) can obtain sentence representation for different sentence in different contexts, thereby solving different problems. However, the vectors of BERT-based PLM models have limitations: **BERT-based models always induces a non-smooth anisotropic semantic space of sentences,**

[*] Equal contribution and shared co-first authorship.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 881–887

which harms its performance of semantic similarity (Gao et al., 2019; Li et al., 2020), which can lead to a challenge that sentences are strikingly similar while using the cosine similarity metric.

- Participants are not allowed to utilize labeled datasets in the target language for training. Instead, they must use labeled data in different languages as the training set to train the model and provide predictions in the target language. However, **multilingual pre-trained models suffer from the curse of multilingualism** (Conneau et al., 2020), that is, the overall performance of both monolingual and cross-lingual baselines declines when adding more languages to training data over a certain point. Hence, it is essential to investigate which additional languages would be inefficient as the training dataset for the target language.

In this paper, we used whitening techniques (Su et al., 2021), which maps vectors to standard orthogonal bases, to transform the word vector representations from anisotropic to isotropic, and surprisingly, we found that whitening significantly improves the accuracy of judging semantic similarity. Given the absence of labeled data in the target language, it is difficult to determine which other language would yield better prediction results when used as training data. Therefore, we proposed that removing certain language categories from the training data for a specific target language contributed to improving performance.

We conducted extensive experiments to demonstrate the effectiveness of the method we employed. As a result, our submitted outcomes achieved a **2nd** score in Spanish and a **3rd** score in Indonesian in track C of SemEval-2024's task 1. Additionally, we obtained multiple top-ten rankings in the competition.

2 Background

The task of semantic text relatedness covers several specific subtasks, including semantic similarity, semantic matching, textual entailment, semantic relation classification, and text pair ranking. Previous work has proposed various methods for these specific tasks, such as: Lexical and syntactic-based methods (Gamallo et al., 2001; Pakray et al., 2011): These methods rely on lexical and syntactic rules, such as word vector matching, lexical overlap, and syntactic tree matching. However, these methods often fail to capture higher-level semantic relationships. Feature engineering-based machine learning methods (Chia et al., 2021; Fan et al., 2019): These methods involve using manually designed features, such as bag-of-words models (Zhang et al., 2010), tf-idf weights, and syntactic features, followed by using machine learning algorithms like support vector machines and random forests for prediction.

While these methods have improved performance to some extent, they still have limitations in capturing complex semantic relationships. Neural network-based models: These models use neural networks to learn representations of text and capture semantic relationships between texts through training data. This includes methods that fine-tune pre-trained language models (e.g., BERT (Kenton and Toutanova, 2019) and GPT2 (Radford et al., 2019) etc.), as well as approaches that employ Siamese networks, LSTM, CNN, and other architectures for text encoding and matching. Transfer learning and multi-task learning (Pilault et al., 2020; Wu et al., 2020): These methods leverage knowledge from pre-trained models on related tasks to improve the performance of semantic textual relatedness tasks through transfer learning (Koroleva et al., 2019). Multi-task learning combines multiple related tasks in training to enhance the model's generalization ability and effectiveness. Application of external knowledge resources: Researchers have also attempted to incorporate external knowledge resources such as word embeddings, semantic knowledge graphs, and multilingual data to enhance the model's understanding of semantic relationships.

For cross-lingual semantic similarity tasks, mapping texts from different languages into a shared semantic space for similarity calculation is necessary. To address this, researchers have proposed various cross-lingual representation learning methods. Among them, unsupervised alignment methods like unsupervised machine translation (Lample et al., 2017) and cross-lingual pre-training models (Liang et al., 2020) can learn the correspondences between multiple languages and map texts to a shared vector space.

However, (Conneau and Lample, 2019) and (Wang et al.) mentioned that vector representations based on the Transformer models exhibit anisotropy, which means that the vectors are unevenly distributed and clustered in a narrow cone-shaped space. Therefore, both Bert-flow (Li et al.,

2020) and Bert-whitening (Su et al., 2021) aim to address the same issue, which is the anisotropy and uneven distribution of sentence embeddings.

3 System Overview

3.1 Framework Overview

In this section, we will introduce our proposed method for STR task which has three main modules.

- **PLM Encoder** We adopted the pretrained language model XLM-RoBERTa-base ($XLM\text{-}R_{base}$) (Conneau et al., 2020) for initial sentence encoding, which combines two powerful models: Transformer and RoBERTa. $XLM\text{-}R_{base}$ demonstrates strong multilingual capabilities and a deep understanding of semantics, surpassing some monolingual pre-training models. After conducting a series of tests on mBERT (Pires et al., 2019), XLM (Conneau and Lample, 2019), and $XLM\text{-}R_{base/large}$, we selected $XLM\text{-}R_{base}$ as the encoder due to its superior performance.

- **Whitening Module** After obtaining the sentence vectors of two utterances using $XLM\text{-}R_{base}$, we could have directly calculated the cosine similarity between the two vectors, but the sentence vectors after $XLM\text{-}R_{base}$ show anisotropy between them and are distributed in a conical space, resulting in a high cosine similarity. Therefore, we introduce the Whitening module to change the distribution of the sentence vector space so that its distribution has various anisotropies, amplifying the differences between the vectors and stimulating the performance of $XLM\text{-}R_{base}$ on the semantic text similarity reading task.

- **Data Filtering** The authors of (Conneau et al., 2020) mention the curse of multilingualism, where adding more languages leads to an improvement in cross-lingual performance for low-resource languages up to a certain point, after which the overall performance of both monolingual and cross-lingual baselines declines. In the task of cross-lingual semantic text similarity, to maximize the exploration of the positive impact of other languages on the target language, we propose a new dataset selection method. As the influence between languages is mutual, we utilize the unlabeled data of the target language to detect the impact of each language in track A, excluding the target language, and infer its influence on the target language. This allows us to select the training dataset optimally. This approach helps eliminate interference from certain languages on the target language and avoids the curse of multilingualism.

3.2 PLM Encoder

Through a simple test and comparative analysis of different multilingual pre-training models, we found that $XLM\text{-}R_{base}$ outperforms mBERT. $XLM\text{-}R_{base}$ is a cross-lingual pre-training model based on the BERT architecture, an improvement and extension of the original XLM model. The goal of $XLM\text{-}R_{base}$ is to enhance the performance and effectiveness of multilingual text processing. $XLM\text{-}R_{base}$ utilizes larger-scale pre-training data and more sophisticated training methods to enhance the model's representation capabilities. It undergoes deep learning on a large amount of unsupervised data using RoBERT (Liu et al., 2019) technology. This enables $XLM\text{-}R_{base}$ to better understand and capture the semantic and grammatical features between different languages. Compared to the original XLM, $XLM\text{-}R_{base}$ has made several improvements. Firstly, it introduces a dynamic masking mechanism that allows the model to better perceive contextual information. Secondly, $XLM\text{-}R_{base}$ emphasizes cross-lingual consistency learning through adversarial training, enabling better alignment and sharing of model parameters. This enables $XLM\text{-}R_{base}$ to provide more accurate representations of texts in cross-lingual tasks. Compared to mBERT, $XLM\text{-}R_{base}$ employs larger-scale pre-training data, covers more languages, and incorporates improvements through RoBERTa technology. This enables $XLM\text{-}R_{base}$ to better learn and capture the semantic and grammatical features between different languages, thereby enhancing the model's representation capabilities and performance.

3.3 Whitening Module

Due to the existence of anisotropy among the vectors obtained from the initial encoding by $XLM\text{-}R_{base}$, cosine similarity cannot accurately measure the semantic similarity between sentences. Therefore, we chose to use whitening to map the original vector space to an isotropic space, where the vectors are transformed into vectors in a standard

orthogonal bases. The principle is as follows:

Suppose we have a set of sentence vectors $S = \{s_1, s_2, \ldots, s_n\}$, the set of vectors can be transformed into a set of vectors with isotropy (i.e., zero mean and a covariance matrix of the identity matrix) through the following transformation $\tilde{S} = \{\tilde{s}_1, \tilde{s}_2, \ldots, \tilde{s}_n\}$.

$$\tilde{s}_i = (x_i - \mu)\mathbf{W} \tag{1}$$

If we want to make the set $\tilde{S}$ have a zero mean, we need to:

$$\mu = \frac{1}{n}\sum_{i=1}^{n} s_i \tag{2}$$

The next step is to calculate $\mathbf{W}$. The covariance matrix of S:

$$\Sigma = \frac{1}{n}\sum_{i=1}^{n} (\mathbf{s_i} - \mu)^\top (s_i - \mu) \tag{3}$$

The covariance matrix of $\tilde{S}$:

$$\tilde{\Sigma} = \mathbf{W}^\top \Sigma \mathbf{W} \tag{4}$$

If we want to transform $\tilde{\Sigma}$ into the identity matrix I, we need to:

$$\tilde{\Sigma} = \mathbf{W}^\top \Sigma \mathbf{W} = \mathbf{I} \tag{5}$$

Then:

$$\Sigma = (\mathbf{W}^\top)^{-1}\mathbf{W}^{-1} = (\mathbf{W^{-1}})^\top \mathbf{W}^{-1} \tag{6}$$

Since Σ is a positive definite symmetric matrix as the covariance matrix, it can be decomposed using Singular Value Decomposition (SVD), yielding:

$$\Sigma = \mathbf{U}\Lambda\mathbf{U}^\top \tag{7}$$

By combining equations (6) and (7), we obtain:

$$(\mathbf{W^{-1}})^\top \mathbf{W}^{-1} = \mathbf{U}\Lambda\mathbf{U}^\top = \mathbf{U}\sqrt{\Lambda}\sqrt{\Lambda}\mathbf{U}^\top \tag{8}$$

Then:

$$(\mathbf{W^{-1}})^\top \mathbf{W}^{-1} = (\sqrt{\Lambda}\mathbf{U}^\top)^\top \sqrt{\Lambda}\mathbf{U}^\top \tag{9}$$

Therefore, we can obtain $\mathbf{W^{-1}} = \sqrt{\Lambda}\mathbf{U}$, and finally obtain $\mathbf{W}$ as follows:

$$\mathbf{W} = \mathbf{U}\sqrt{\Lambda^{-1}} \tag{10}$$

3.4 Data Filtering

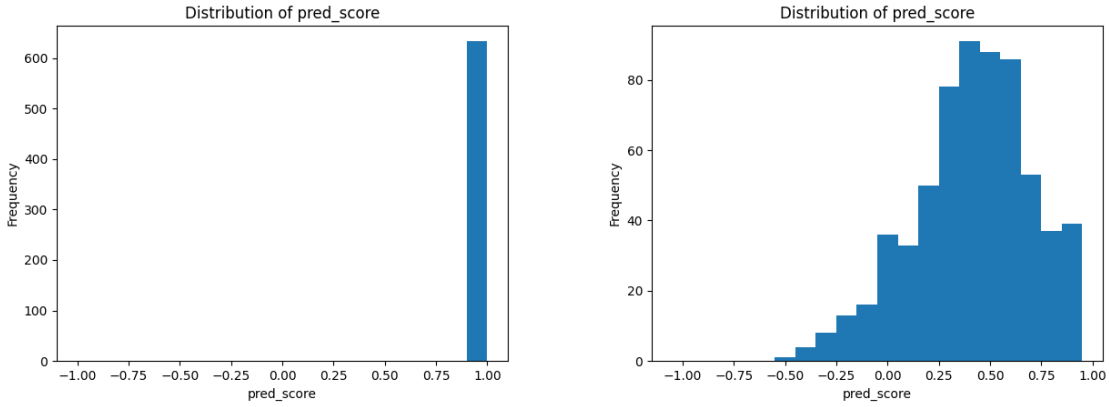
Our experiments have shown that when selecting training data for the target language, using a mixture of multiple languages often yields better results than using a single language. The authors of the $XLM\text{-}R_{base}$ paper mentioned that incorporating more languages improves the cross-lingual performance of low-resource languages up to a certain point. Beyond that point, the overall performance of both monolingual and cross-lingual benchmarks starts to decline. Additionally, we believe that there is interdependence between languages. For example, if including text from language A in training set to compute whitening parameters leads to a decrease in the prediction performance for language B, we expect that the opposite would hold true as well.

Therefore, inspired by this insight, we used the text in the target language as the dataset and individually tested the labeled training data provided in track A for different languages. For example, if the target language is identified by T, we use the text of T for whitening, and test the performance on language $Test_A$, $Test_B$, $Test_C$, $Test_D$,... one by one. If the prediction performance of $Test_A$ decreases after using T compared to not using T (measured by the Spearman correlation (Myers and Sirois, 2004) between the gold labels and predicted labels obtained using language $Test_A$), then $Test_A$ is excluded from target language's training set.

In the case of the Spanish, using the training set without data filtering (1,000 each of all data except Spanish) resulted in a final spearman coefficient of 0.6375; using the training set with data filtering (1000 each of kin and ind) resulted in a final spearman coefficient of 0.6886. Although the training data for about ten languages were reduced, the results were are significantly improved.

4 Experimental Setup

We use the 12 labeled training data from (Ousidhoum et al., 2024a) as training data and the test data from track C as test data. We observe that the amount of data for each language is concentrated around 1,000, so we take 1,000 as the boundary, use oversampling to make up for less than 1,000, and use randomization to take out 1,000 for more than 1,000 to ensure that sentence pairs of different similarities are involved. In finding the training set combinations for the target languages, we compute



(a) without whitening (b) with whitening

Figure 2: The results of model without whitening and with whitening.

the μ and $\mathbf{W}$ of whitening using the text data of the target languages in track C. We predict the training data one by one for each language, and compute the spearman coefficients using the gold labels and the predicted labels of the training data, and compare the results with the data without any whitening (i.e., the prediction result of the base model) to evaluate whether the target language enhances a certain language in the training data or not, and if it does not, it is excluded from the train data. Eventually, the remaining language data is used as a training set to predict the target language.

The hyperparameters are set as follows: we choose to freeze the pretrained model $XLM\text{-}R_{base}$ while setting the topk parameter of whitening to 256. The rubric we used was the spearman coefficient, calculated using the methodology provided by the competition officials.

5 Results

The official competition used the spearman coefficients to evaluate the results, and Table 1 gives the results of the spearman coefficients for both Indonesian (ind) and Spanish (esp) languages throughout the experiment. There is a big difference in the multilingual ability of different model bases. We chose $XLM\text{-}R_{base}$, which performs better, and we can see that the overall results are improved after using the whitening module to transform the vector space; $XLM\text{-}R_{base}$ with whitening is better than baseline, and we got a good ranking in track C of SemEval-2024 task 1, in which we ranked second in esp and third in ind.

As can be seen from Table 1, the whitening module improves the STR task more significantly,the

	ind-test	**esp-test**
Baseline	0.4700	0.6200
mBERT	0.4390	0.5971
$XLM\text{-}R_{base}$	0.4390	0.5907
$XLM\text{-}R_{large}$	0.4267	0.6003
mBERT-whitening	0.4471	0.6411
$XLM\text{-}R_{base}$-whitening	0.4746	**0.6886**
$XLM\text{-}R_{large}$-whitening	**0.4845**	0.6648

Table 1: The spearman coefficient of different models and baseline.

baseline is given by (Ousidhoum et al., 2024a). In order to further verify whether whitening works, we counted the cosine similarity distribution statistics of the data without whitening processing and after whitening. Figure 2 gives two cosine similarity statistics. The left side is the cosine similarity statistics without whitening. The cosine similarity of all utterance pairs is concentrated between 0.9 and 1.0, indicating that the vector space is anisotropic. In contrast, after adding whitening, the whole distribution tends to be normal, which indicates that whitening plays a role in mapping the vectors to an isotropic space, amplifying the differences between statements.

6 Conclusion

We use $XLM\text{-}R_{base}$ with whitening and propose a dataset filtering method that exploits the positive correlation of linguistic interactions, achieving good rankings in SemEval-2024 task 1 track C. We verifies that whitening performs well on utterance characterization as well as STR task. Besides, the proposed dataset filtering method is more efficient

and can alleviate the multilingual curse problem in cross-language problems to some extent.

In the future, we will further study this positive correlation of language interactions, and we hope that this correlation can become more detailed, not only in terms of inter-language correlations but also in terms of the domain of the text. We also hope that this correlation can be better utilized in dataset preprocessing, not only to eliminate poorly performing languages but to further improve the combination of datasets that can be directly selected to correspond to the optimal solution.

Acknowledgments

We want to express gratitude to the anonymous reviewers for their hard work and kind comments, which will further improve our work in the future. This work is funded by national key research and development program under grant 2021YFC3300500-02.

GreyBox at SemEval-2024 Task 4: Progressive Fine-tuning (for Multilingual Detection of Propaganda Techniques)

Nathan Roll
University of California, Santa Barbara
nroll@ucsb.edu

Calbert Graham
University of Cambridge
crg29@cam.ac.uk

Abstract

We introduce a novel fine-tuning approach that effectively primes transformer-based language models to detect rhetorical and psychological techniques within internet memes. Our end-to-end system retains multilingual and task-general capacities from pretraining stages while adapting to domain intricacies using an increasingly targeted set of examples– achieving competitive rankings across English, Bulgarian, and North Macedonian. We find that our monolingual post-training regimen is sufficient to improve task performance in 17 language varieties beyond equivalent zero-shot capabilities despite English-only data. To promote further research, we release our code publicly on GitHub: github.com/Nathan-Roll1/GreyBox.

1 Introduction & Background

The digital age has radically transformed the nature of propaganda and disinformation, requiring innovative detection mechanisms attuned to these shifts (DeCook, 2018; Macdonald, 2006; Sparkes-Vian, 2019).

Previous work on propaganda detection (Li et al., 2019) leveraged a logistic regression model to determine whether or not a given passage was propagandistic using vectors based on Linguistic Inquiry and Word Count (LIWC), TF-IDF, BERT, and sentence features. These researchers have reported an F1 score of 66.16%, which significantly outperformed their baseline model. Oliinyk et al. (2020) used a similar architecture on the task, achieving improved performance by replacing manual feature selection with induced sentence-level and article-level vectors. Elhadad et al. (2020) used a variety of machine learning models, including logistic regression, to create an ensemble classifier for COVID-19 misinformation. More recently, there has been an emergence of work focusing on detection of propaganda in memes, with Dimitrov et al. (2021) releasing a corpus of memes, hand-labeled with one of 22 propaganda techniques, and utilizing a fusion of large language models (LLMs) to successfully identify labels for a shared task: "Multilingual Detection of Persuasion Techniques in Memes" (*SemEval 2024 Task 4*).

The purpose of the shared task is to foster the development of systems which detect rhetorical and psychological devices, often propagandistic in nature, from memes (a more comprehensive explanation is available in Dimitrov et al., 2024). It contains the following subtasks:

- *Subtask 1*: Given exclusively the text extracted from a given meme, identify the specific persuasion technique(s) utilized (if any).
- *Subtask 2*: Given both the text and image of a meme, identify the specific technique(s) being utilized (*Subtask 2a*), and whether or not the meme contains any propagandistic techniques (*Subtask 2b*).

Our system primarily tackles *Subtask 1*, using the text of a given meme to identify which, if any, of the devices are present. Our approach builds on Dimitrov et al. (2021), in tackling the challenge by leveraging the comprehensive pretraining of large language models (LLMs) and fine-tuning it with human-annotated examples.

The multilingual and multi-task capabilities of LLMs have been well established, however low-resource languages and tasks often require additional data to meet or exceed human level performance. Given that fine-tuning generally degrades baseline model capabilities (Zhai et al., 2023), this reality presents obstacles when available language data does not extend to desired task contexts or vice-versa. Through interative refinement, we discover that successive fine-tuning rounds – encompassing increasing task-specific data – result in models which better adapt to our specific task while

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 888–893

also retaining sufficient multilingual capabilities. Our approach to split the post-training regimen into multiple steps finds support in prior research. Xu et al. (2021) found that multi-stage fine-tuning has downstream benefits, particularly in low-resource settings. ValizadehAslani et al. (2022) examined the challenge of class imbalance by introducing a two-stage fine-tuning strategy in which they initially adjusted the model with a class-balanced 'reweighting' loss to ensure that underrepresented classes are not overlooked.

Our system makes use of the provided English meme data, manually labeled according to the requirements of the corresponding task. A total of 18,650 training examples generated from 11,111 unique memes were provided across the training, development, and validation splits.

This paper describes our system and explores how progressive fine-tuning learns the syntactic and semantic properties of memes, with potential future applications in a variety of tasks. For more details, please see the task paper Dimitrov et al. (2024).

2 System Overview

Our system leverages a novel, multi-stage fine-tuning process which progressively adapts a pre-trained LLM (GPT 3.5-Turbo[1]) to the task of identifying persuasion techniques in memes. This process consists of two distinct fine-tuning steps (see figure 1):

1. **Priming for meaning**: Expose the LLM to all released data in the train and validation splits to understand the context, intention, and implied meanings in memes.

2. **Structural adaptation**: Undergo an additional fine-tuning round on only *Subtask 1* data to align to the specific structural requirements of the output.

2.1 Data preparation

Each of the provided `.json` files were parsed into Python dictionaries, and reformatted into chat-like training examples with the text of the meme as the "user" and the label(s) as the "assistant"[2]. Memes which appeared in multiple subtask train/validation sets (based on the `id` field) were filtered to only include a single instance of each. The reformatted chat examples were saved as `.jsonl` files and programmatically uploaded to the OpenAI fine-tuning API[3] for usage.

Language	Rank	F_h	Pr_h	Rec_h
English	5/32	0.670	0.652	0.688
Bulgarian	7/19	0.476	0.438	0.521
N. Macedonian	8/19	0.434	0.440	0.430

Table 1: Official performance on *Subtask 1* languages.

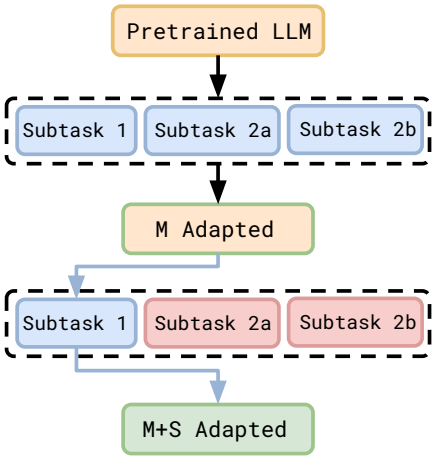

Figure 1: Our implementation of progressive fine-tuning on the *SemEval 2024 Task 4* data. Meaning-based (M) fine-tuning on broader data precedes a more targeted structural (S) fine-tuning step.

2.2 Fine-tuning

2.2.1 Step 1: Priming for Meaning

The priming stage of our fine-tuning process leveraged the train and validation splits across all subtasks. Given that each subtask has a distinct labeling methodology, the purpose of the priming stage is to impart task-specific knowledge (in terms of relevant tokens and their relationship to human-generated labels). Three epochs of fine-tuning were performed on GPT 3.5 Turbo with the training set, using the validation split to ensure that no overfitting was occurring during training. A total of 2.9M tokens were processed during the priming stage.

[1]For zero-shot evaluation, fine-tuning, and experiments we use the `gpt-3.5-turbo-1106` model with a context window of 16,385 tokens and a maximum output length of 4,096 tokens.

[2]We leave the system prompt blank in our fine-tuning pipeline to avoid excess costs from input redundancy.

[3]The GPT-3.5 family model weights can only be interacted with using OpenAI's API.

Table 2: Zero-shot performance on the *Subtask 1* development set varies by model and source language.

2.2.2 Step 2: Structural Adaptation

Model finalization involved an additional two epochs of fine-tuning on the pragmatically-primed model, using only data specific to *Subtask 1*. Two epochs of training were performed, however we encourage further study on the impact of hyperparameters on downstream performance.

2.3 Evaluation Metrics

To capture the hierarchical nature of propaganda techniques, we utilize three metrics which weight errors based on their similarity to each other via higher order categories: hierarchical precision (Pr_h), hierarchical recall (Rec_h), and hierarchical F1 score (Pr_h) (Silla and Freitas, 2011). While the official evaluation of the task does not require leaf-node predictions, our system is not designed to output broader categories in cases of ambiguity. Further justification for the usage of these metrics, along with the exact hierarchy, is provided in Dimitrov et al. (2024).

2.3.1 Hierarchical Precision

Hierarchical precision (Pr_h) measures, in aggregate, the quality of each prediction. This metric is defined as the weighted sum of the predicted classes and their ancestors in the hierarchy, normalized by the total weight of the predicted classes across all test examples. It is given by:

$$Pr_h = \frac{\sum_i |P_i \cap T_i|}{\sum_i |P_i|}$$

Where P_i is the set consisting of the most classes predicted for each test example i, and all of its ancestor classes; T_i is the set consisting of the true most specific class(es) of test example i, and all ancestor classes.

2.3.2 Hierarchical Recall

Similar to hierarchical precision, hierarchical recall (Rec_h) measures the total capture of correct predictions. It is expressed as:

$$Rec_h = \frac{\sum_i |P_i \cap T_i|}{\sum_i |T_i|}$$

2.3.3 Hierarchical F1 Score

The hierarchical F-1 score (F_h) combines both hierarchical precision and recall (using a harmonic mean) to provide a single measure of model performance. It is computed as:

$$F_h = \frac{2 * Pr_h * Rec_h}{Pr_h + Rec_h}$$

This is also the official evaluation metric used to rank performance in *Subtask 1* and *Subtask 2a*.

3 Analysis

We benchmark the performance of our progressively fine-tuned model, and its intermediates, on the Subtask 1 development set. To further explore multilingual capabilities across post-training steps, we create 16 translated versions[5] of the held-out data encompassing a wide variety of languages.

[5]Translation was performed by the Google Translate API: `cloud.google.com/translate`

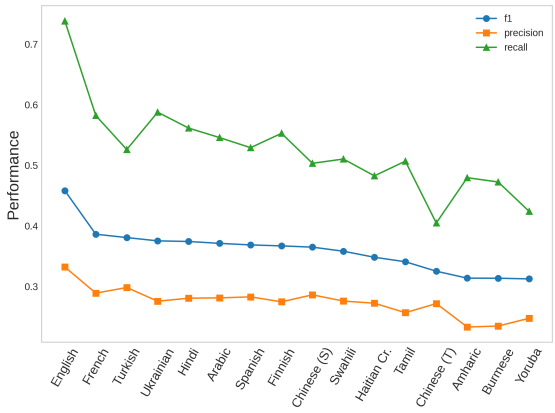

Figure 2: **Primed model (intermediate)**: Recall remains higher than precision in the intermediate model, generally indicating over-prediction. We also find that the relative performance of language varieties shift substantially.

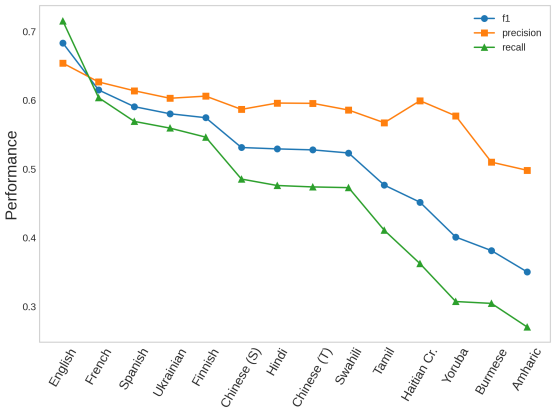

Figure 3: **Final Model**: The structure-tuned model exhibits the highest performance for most languages, included English.

3.1 Zero-Shot

We evaluate the capabilities of three popular out-of-the-box LLMs: OpenAI's GPT 3.5 Turbo, Meta's Llama 2 70B Chat model, and Mistral AI's Mixtral 8x7B instruct mixture of experts (MoE) model. Despite some variation in training data and architecture (see table 2), our tests reveal a consistent bias towards more-common languages (or those closely related to common languages). Furthermore, we find that multilingual capabilities do extend, at least in part, to the propaganda detection task.

3.2 Intermediate Model

After the first fine-tuning step (see section 2.2.1), we again evaluate how the 'meaning-primed' LLM performs in a multilingual setting in fig. 2. Despite English-only fine-tuning data, we find within-language performance improvements in nearly all settings. Our results also indicate that this step also improved some languages more than others, however these shifts do not have any clear syntactic, orthographic, or morphological basis.

3.3 Final Model

After the structural fine-tuning step described in section 2.2.2 , hierarchical F1, precision, and recall demonstrate further gains (see fig. 3). Again, despite English-only data, most languages[6] outperform zero-shot and intermediate counterparts. This is the version of the model which produced our official submissions for *Subtask 1*.

3.4 Multilingual Gains

In addition to producing the highest overall scores (likely a consequence of English-dominant pre-training and fine-tuning data), English also demonstrated the highest gain from additional data, as summarized in fig. 4. While both the priming and structural adaptation phases contributed positively, our results show that the latter was generally more impactful. We hypothesize that labeling differences across related subtask data prevented further performance increases between zero-shot and intermediate evaluation contexts. However, the minor modifications to the evaluation function which allowed for non-exact Python syntax and technique capitalization in the intermediate step would likely only serve to boost reported metrics.

4 Conclusion

Our work highlights the challenges inherent in adapting language models to tasks where relevant information deviates in format and/or linguistic scope from that of the desired output. Our results indicate that progressive fine-tuning offers a promising method for bridging this gap. By tailoring a standard LLM to effectively identify persuasion techniques within multilingual memes, we demonstrate the potential for decoupling syntactic requirements from task-specific 'understanding'. Although monolingual in post-training, this method yielded performance gains across all evaluated lan-

[6]Due to orthographic complications, we were unable to perform a final analysis on Arabic and Turkish.

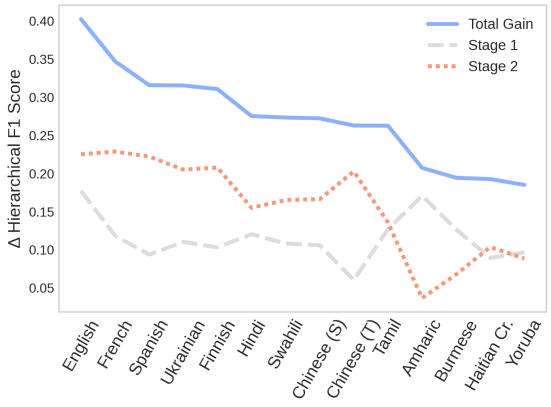

Figure 4: **Relative Performance**: English produced the highest overall increase between zero-shot and final performance, with the highest delta (in percentage points) coming from Stage 2 of the fine-tuning process.

guages compared to zero-shot settings, implying similar capabilities across a wide variety of use cases.

Nevertheless, this work prompts further questions regarding the interplay between pre-training corpora, post-training regimes, and the nature of evaluation data. Our results also call for further work in understanding how the data integration process impacts downstream performance– specifically in comparing our progressive fine-tuning approach to more common single-stage methods. Crucially, our findings reinforce the urgent need to investigate and mitigate biases in LLMs (Lai et al., 2023; Navigli et al., 2023) that impact their performance across varied language communities and use cases.

5 Acknowledgments

We thank Simon Todd for his input and suggestions. We also acknowledge the task organizers for designing such a topical and valuable challenge.

NLU-STR at SemEval-2024 Task 1: Generative-based Augmentation and Encoder-based Scoring for Semantic Textual Relatedness

Sanad Malaysha, Mustafa Jarrar, Mohammed Khalilia
Birzeit University, Palestine
{smalaysha, mjarrar, mkhalilia}@birzeit.edu

Abstract

Semantic textual relatedness is a broader concept of semantic similarity. It measures the extent to which two chunks of text convey similar meaning or topics, or share related concepts or contexts. This notion of relatedness can be applied in various applications, such as document clustering and summarizing. SemRel-2024, a shared task in SemEval-2024, aims at reducing the gap in the semantic relatedness task by providing datasets for fourteen languages and dialects including Arabic. This paper reports on our participation in Track A (Algerian and Moroccan dialects) and Track B (Modern Standard Arabic). A BERT-based model is augmented and fine-tuned for regression scoring in supervised track (A), while BERT-based cosine similarity is employed for unsupervised track (B). Our system ranked 1st in SemRel-2024 for MSA with a Spearman correlation score of 0.49. We ranked 5th for Moroccan and 12th for Algerian with scores of 0.83 and 0.53, respectively.

1 Introduction

The literature commonly examines semantic similarity, where the focus is on whether two linguistic units (words, phrases, sentences, etc.) share similar meanings (Bentivogli et al., 2016). However, semantic textual relatedness (STR) is less explored due to its complexity and the scarcity of datasets (Abdalla et al., 2023; Darwish et al., 2021). While the former task checks for the presence of similar meaning or paraphrase, STR takes a more comprehensive approach, evaluating relatedness across multiple dimensions, spanning topical similarity, conceptual overlap, contextual coherence, pragmatic connection, themes, scopes, ideas, stylistic conditions, ontological relations, entailment, temporal relation, as well as semantic similarity itself (Miller and Charles, 1991; Halliday and Hasan, 2014; Jarrar, 2021, 2011). For example, consider the two sentences (*The Earth orbits the sun at a speed of ~110,000 km/h.*) and (*Earth rotates at ~1670 km/h around its axis.*). They hold semantic relatedness through the shared topic of Earth's speeds. In contrast, both sentences are not semantically similar as they possess distinct meanings. This illustrates the broader range of STR as described by Abdalla et al. (2023), which ranges from highly relevant sentences, expressing the same idea with different wording, to entirely unrelated sentences, discussing unrelated topics.

Semantic relatedness has proven to be useful in evaluating sentence representations generated by language models (Asaadi et al., 2019), in addition to question answering (Tsatsaronis et al., 2014), machine translation (Mi and Xie, 2024), plagiarism detection (Sabir et al., 2019), word-sense disambiguation (Al-Hajj and Jarrar, 2021a; Malaysha et al., 2023), among others. Exploring the relatedness and similar tasks in languages other than English is hindered by the lack of data (Jarrar et al., 2023b; Al-Hajj and Jarrar, 2021b). The SemRel-2024 shared task (Ousidhoum et al., 2024a) provided datasets in fourteen languages and offered three tracks. In the supervised track (A), training and testing are performed on the same language. In the unsupervised track (B), the use of labeled data for training is prohibited; and in the cross-lingual track (C), testing is conducted on a different language than the one used for training.

This paper presents our contribution to track A and track B. In track A, we fine-tuned BERT models using the Algerian and Moroccan sentence pairs to produce similarity scores. To enrich the data, we augmented the SemRel-2024 dataset (Ousidhoum et al., 2024a) by generating additional sentence pairs from Google Gemini [1], a generative model, using a predefined prompt template. These generated pairs imitated the style and meaning of the existing pairs, and we assigned them

[1] https://gemini.google.com/

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 894–901

scores corresponding to the originals. We used the same datasets provided by the Shared Task in addition to a ~760 augmented Moroccan pairs to fine-tune BERT models, AraBERTv2 (Antoun et al., 2020) and ArBERTv2 (Abdul-Mageed et al., 2021), which resulted in a performance enhancement of 0.05 points. In track B, as training on labeled data is not allowed, we used cosine similarity using average pooling embedding (Zhao et al., 2022) on top of each model. Our approaches achieved Spearman scores (Tsatsaronis et al., 2014) of 0.49 for MSA (ranked first), 0.83 for Moroccan (ranked fifth), and 0.53 for Algerian (ranked twelfth).

2 Related Work

Semantic textual relatedness (STR) has proven to be a valuable task in numerous NLP applications, including the evaluation of LLMs (Asaadi et al., 2019; Naseem et al., 2021). Determining the degree of relatedness in STR, however, remains a challenging task in computational semantics. That is because STR encompasses a broader range of commonalities beyond just meaning, including shared viewpoint, topic, and period, demanding a deeper understanding than semantic similarity alone (Asaadi et al., 2019; Abdalla et al., 2023). For example, consider reading these two sentences (*He heard the waves crashing gently*) and (*Making him feel calm and peaceful*). While humans easily recognize their strong relatedness and shared description of the same view (a beach scene), machines require advanced lexical and statistical methods to achieve the same level of understanding. STR techniques mainly come from four approaches: lexical similarity (Chen et al., 2018; Jarrar and Amayreh, 2019; Alhafi et al., 2019), semantic similarity (Hasan et al., 2020; Ghanem et al., 2023), deep learning (Zhang and Moldovan, 2019), and LLMs (Li et al., 2021).

Recently, Abdalla et al. (2023) introduced their STR-2022 dataset, which uses fine-grained scores ranging from 0 (least related) to 1 (completely related). Their dataset consists of 5,500 scored English sentence pairs. They framed the task as supervised regression, where they fine-tuned two language models, BERT-base (Kenton and Toutanova, 2019) and RoBERTa-base (Liu et al., 2019), and applied average pooling on top of the final embedding layer. Their testing of these models on the STR-2022 dataset yielded an average Spearman correlation of 0.82 for BERT-base and 0.83 for RoBERTa-base. On the other hand, their unsupervised experiments using Word2Vec (Mikolov et al., 2013) achieved a correlation score of 0.60, outperforming both BERT-base (0.58) and RoBERTa-base (0.48) by 0.02 and 0.12 points, respectively.

Asaadi et al. (2019) created the Bi-gram Semantic Relatedness Dataset (BiRD) for examining semantic composition. To avoid inconsistencies and biases from traditional 1-5 rating scales, they employed fine-grained scoring of bi-gram pairs (0-1) using the best-worst scaling (BWS) annotation technique (Kiritchenko and Mohammad, 2017). The dataset consists of 3,345 scored English term pairs. They utilised three models to generate word representations: GloVe (Pennington et al., 2014), FastText (Grave et al., 2018), and a word-context co-occurrence matrix (Turney et al., 2011). To calculate relatedness scores between pairs, they employed cosine similarity between the generated addition-pooled vectors. The FastText model achieved the highest performance with a Pearson correlation of 0.60.

The semantic relatedness between noun-pairs was studied using contextual similarity by Miller and Charles (1991). They attempted to understand distinctions between nouns in contextual discourse and how the similarity can be broader than just the meaning. Additional ideas could rely on extracting named entities (Liqreina et al., 2023; Jarrar et al., 2022) to measure the relatedness (Ghosh et al., 2023). However, the task evolved, leading to the creation of the up-to-date dataset presented by the SemRel-2024 shared task (Ousidhoum et al., 2024b). Their dataset annotation scores are at the level of sentence pairs. They shared baseline results for fourteen languages and dialects using Spearman correlation score. Since our focus is on Arabic, we have chosen its results to show. For example, their baseline is 0.42 for MSA in track B using multilingual BERT (mBERT) (Kenton and Toutanova, 2019), 0.60 for Algerian and 0.77 for Moroccan in track A using Label Agnostic BERT Sentence embeddings (LaBSE) (Feng et al., 2022). Specifically, their Algerian Arabic dataset offers 1,261 training and 583 test instances, Moroccan Arabic dataset includes 924 training and 425 test instances, and MSA Arabic dataset has 595 instances for testing.

Many efforts have been made to understand Arabic dialects, such as dialect identification, intent detection, and morphological annotations (Haff et al., 2022; Nayouf et al., 2023; Jarrar et al., 2023c, 2017, 2023a), but none studied STR between dialects.

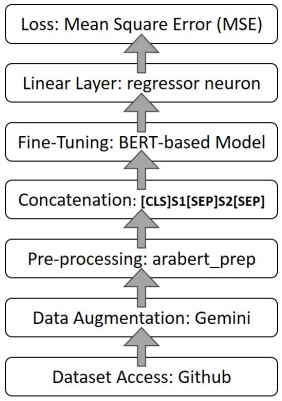

Figure 1: BERT-based Supervised Architecture (A).

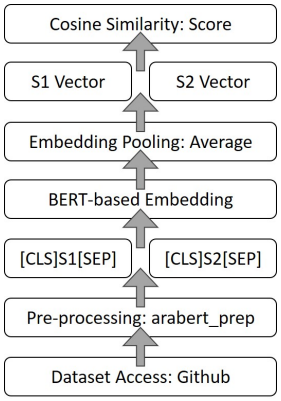

Figure 2: BERT-based Unsupervised Architecture (B).

3 System Overview

This section presents the techniques, datasets, and the augmentation we employed in tracks A and B.

3.1 Supervised Track (A)

Since the datasets use continuous scoring values, we tackled STR as a regression problem. We fine-tuned BERT with Mean Squared Error (MSE) objective. The model uses a regressor output layer, represented by a single neuron to predict the scores of the sentence-pairs. The data was pre-processed using the technique presented in (Antoun et al., 2020) to achieve standardized word forms. Before supplying the sentence pairs to the model, each was concatenated using the special tokens of the model input in this format:`[CLS]Sentence1[SEP]Sentence2[SEP]`. Figure 1 depicts our method architecture for the supervised track (A). Since we focused on the Algerian and Moroccan dialects in this track, we investigated various model parameters including learning rates, number of epochs, and pre-trained models to understand which model is better suited for each dialect. We found that both models, AraBERTv2 [2] and ArBERTv2 [3], best fits the Moroccan dialect more than Algerian. Nonetheless, we used same models for the Algerian dataset.

3.2 Unsupervised Track (B)

The STR using MSA is covered in track B (unsupervised learning), where training (or fine-tuning) on labeled data is not permitted. We employed cosine similarity (Reimers and Gurevych, 2019) as an unsupervised technique to calculate the sentence-pair scores. Figure 2 illustrates our architecture. We conducted initial experiments using the same aforementioned models, ArBERTv2 and AraBERTv2, for generating sentence representations. Various pooling options (CLS, average, max, and min) (Zhao et al., 2022) were applied on the final embedding layer in each (frozen) model, and found that AraBERTv2 with average-pooling is better suited for MSA in this track. The same data pre-processing used in track A is applied in B.

3.3 Datasets

The datasets provided by the SemRel-2024 shared task cover fourteen languages and dialects. In the paper, we used three Arabic datasets (Algerian, Moroccan, and MSA). Table 1 presents their data splits, including train, development, and testing. MSA has no labeled train data as it is included in Track B. However, for the other two dialects, we employed BERT-based models, that requires large train data (Bevilacqua et al., 2021).

	MSA	Algerian	Moroccan
Train			
Original	–	1,261	924
Augments	–	–	757
Total	–	1,261	1,681
Dev.	32	97	70
Test	595	583	425

Table 1: The original and augmented datasets splits.

Different methods can be used for data augmentation, such as back-translation (Lin and Giambi, 2021) and generative models (Saidi et al., 2022). The back-translation technique was tested by (Malaysha et al., 2023) and showed minor improvement in performance. The availability of high-

Original Sentence 1	Original Sentence 2	Score
كورونا..12 تقاسو بالفيروس فجهة العيون الساقية الحمراء	كورونا: 99 تقاسو بالفيروس فجهة العيون الساقية الحمراء	0.79
Original Sentence 1	**Augmented Sentence 2**	
كورونا..12 تقاسو بالفيروس فجهة العيون الساقية الحمراء	باقة تاخدات فالفيروس فلعيون الساقية الحمراء. 99 حالة بزاف	0.79
Augmented Sentence 1	**Original Sentence 2**	
فـ جهة العيون الساقية الحمراء، 12 تصاوبو بكورونا	كورونا: 99 تقاسو بالفيروس فجهة العيون الساقية الحمراء	0.79

Figure 3: Example of the augmented sentence-pairs.

quality generative models, such as ChatGPT [4] and Google Gemini, encouraged us to employ them in automatic augmentation. We employed in-context learning (Min et al., 2022) by prompting both models with the request depicted in Figure 4.

Prompt

Augment the following Arabic sentence using Moroccan dialect. Please generate Moroccan sentence similar in meaning to the one I provide you, and use average number of words close to the length of the provided sentence. You have to format the augmented sentence between pair of box brackets []. Do not add any explanations, I just need the reply same the format I provided without any additional texts or confirmations. I will repeat this request hundreds of times using different sentences, so do not change the format of your reply. The sentence is in Moroccan dialect:
كورونا..12 تقاسو بالفيروس فجهة العيون الساقية الحمراء

Reply: [فـ جهة العيون الساقية الحمراء، 12 تصاوبو بكورونا]

Figure 4: The prompt template employed for Gemini.

The initial manual reviews and tests for twenty prompts of Moroccan and Algerian sentences showed that both models are weak in Algerian comprehension. ChatGPT is also weak in the Moroccan, while Gemini demonstrated a high understanding of the Moroccan. Therefore, we decided to employ Gemini to augment the Moroccan train split. From every sentence-pair, we took each sentence and prompted it using the template in Figure 4. We mapped the augmented (new) sentence from the model with the other sentence in the same pair using the same score of the pair, as illustrated in Figure 3. By manually reviewing all the model replies, we found cases that were not valid (wrong content), and accordingly, we defined filters to exclude the not applicable data per the following rules:

- The model admits in the reply that it is just a language model and cannot fulfill the request. The model reply in such case has common format to rely on for the filter comparison.
- The case when the reply goes far from the original meaning. This option is achieved by manually reviewing the paraphrased contents.
- When the model rejects augmentation because the requested sentence contains information that breaks the model policy, i.e., talking about public figures or sensitive discussions. Similar to first rule, it has common reply format to automatically compare with.

Finally, after filtering the invalid augmentations, we reached 757 accepted sentences which we added to the Moroccan training set (See Table 1), reaching a total of 1,681 instances.

4 Experimental Setup

Our experiments fine-tuned two language models for Algerian and Moroccan, where we used the following pre-trained models: maubmindlab/bert-base-arabertv02 (Antoun et al., 2020) and UBC-NLP/ARBERTv2 (Abdul-Mageed et al., 2021). We employed the training data provided by the shared task, in addition to the data generated by our augmentation technique, when applied. The development data is excluded from either training or testing in the official evaluation phase, and testing is done on the shared task test set (See Table 1). The data pairs were concatenated using special tokens (`[CLS]` and `[SEP]`), as depicted in Figure 1, and digested by the models. The fine-tuning was done as a regression task using one neuron in the output layer, optimized using MSE as the loss function, and we used R-squared (Miles, 2005) to measure the improvement. The final hyper-parameters in the fine-tuning process were: 10 epochs for training, 4 epochs for early stopping, a batch size of 16,

Development Phase	Track A			Track B
	Algerian	Moroccan	Augmented Moroccan	MSA
ArBERTv2	0.55	0.82	0.88↑	0.42
AraBERTv2	0.69	0.84	0.79↓	0.58

Table 2: Our results on the development phase (i.e., on development split).

TEST Phase	Track A			Track B
	Algerian	Moroccan	Augmented Moroccan	MSA
Baseline (Ousidhoum et al., 2024a)	0.60	0.77	0.77	0.42
ArBERTv2	0.42↓	0.78↑	**0.83**↑	0.34↓
AraBERTv2	**0.53**↓	0.79↑	0.77↑	**0.49**↑

Table 3: The evaluation results on the test data. Our official ranked scores are in bold.

512 is the maximum sequence length, a learning rate of $2e^{-5}$, 50 evaluation steps, a seed of 42, and train ($\pm$ augmented data) split.

In the experiments of B track for the MSA, no supervised fine-tuning is needed. Therefore, we neither used labeled data nor augmentation. We employed average-pooling on the embeddings of the sentence tokens from the final layer in each model. Then, we calculated the cosine similarity between the average embeddings of the sentences in each pair. This was done to estimate the fine-grained scores for the test (or development) data provided by the shared task. The shared task considers Spearman correlation score to evaluate the submitted predictions against their ground truth.

5 Results

Our approaches have achieved competitive ranks in the SemRel-2024 shared task. The official results of the tracks we participated in, as well as the baselines that were introduced by Ousidhoum et al. (2024a), are shown in Table 3. Additionally, our results on the development data are presented in Table 2. In the test evaluation, we ranked first in Track B for the MSA, with a Spearman correlation score of 0.49 using the AraBERTv2 model, outperforming the baseline by 0.07 points. However, ArBERTv2 did not perform well in Track B for MSA on both test and development splits. In contrast, ArBERTv2 achieved a high score in Track A for the Moroccan dialect when fine-tuned on both the train split and augmentation data, outperforming the baseline by 0.06 points on test split, ranking 5th among the submitted systems. Nonetheless, neither of the models, ArBERTv2 or AraBERTv2, surpassed the baseline for the Algerian dialect in Track A, where our rank is 12. Similarly, both models achieved low performance on the Algerian development split. It is possible that if we were able to augment the Algerian data as well, it could have performed better, similar to the improvement achieved in the Moroccan dataset. It is worth noting that AraBERTv2 outperformed both the baseline and ArBERTv2 on the original training data of the Moroccan dataset. However, its performance degraded on both test and development splits once the augmentation was included in the fine-tuning, unlike what happened with the ArBERTv2 model, on both splits. This could be due to the nature of the data utilized in the pre-training phase of the model. Due to the anisotropy problem (Baggetto and Fresno, 2022) inherent in BERT-based pre-trained models, we noted that computing cosine similarity directly between sentence representations is insufficient for discerning relatedness.

6 Conclusion

We presented our contributions to the SemRel-2024 shared task. We targeted three Arabic dialects covered by the shared task datasets, including MSA, Algerian, and Moroccan. Our approaches employed supervised and unsupervised techniques using commonly known language models, namely ArBERT and AraBERT. We augmented the training data using generative models, which enhanced the models' performance. Our system ranked first (MSA), fifth (Moroccan), and twelfth (Algerian) across the different tracks. We plan to augment additional data of Moroccan and Algerian using other models than what we used in this work. We will use the augmentations to experiment with both Arabic mono-dialect and cross-dialect fine-tuning.

scaLAR SemEval-2024 Task 1: Semantic Textual Relatednes for English

M Hemanth Kumar and **Anand Kumar M**
Artificial Intelligence, Department of Information Technology
National Institute of Technology Karnataka
Surathkal, India
mogilipalemhemanthkumar@gmail.com,m_anandkumar@nitk.edu.in

Abstract

This study investigates Semantic Textual Related- ness (STR) within Natural Language Processing (NLP) through experiments conducted on a dataset from the SemEval-2024 STR task. The dataset comprises train instances with three features (PairID, Text, and Score) and test instances with two features (PairID and Text), where sentence pairs are separated by '/n' in the Text column. Using BERT(sentence transformers pipeline), we explore two approaches: one with fine-tuning (Track A: Supervised) and another without fine-tuning (Track B: UnSupervised). Fine-tuning the BERT pipeline yielded a Spearman correlation coefficient of 0.803, while without fine-tuning, a coefficient of 0.693 was attained using cosine similarity. The study concludes by emphasizing the significance of STR in NLP tasks, highlighting the role of pre-trained language models like BERT and Sentence Transformers in enhancing semantic relatedness assessments.

1 Introduction

Semantic Textual Relatedness (STR) is a crucial concept in natural language processing (NLP), focusing on determining the degree of similarity between linguistic units like words or sentences based on their meaning. This measure plays a vital role in evaluating the effectiveness of Large Language Models (LLMs) and aids in various NLP tasks. At its core, STR delves into understanding the closeness in meaning between two pieces of text. It examines different dimensions of relatedness, including sharing the same viewpoint, originating from the same context, or complementing each other's content. For instance, if two sentences convey similar ideas through paraphrasing or entailment, they might be considered semantically similar. However, relatedness en- compasses all possible commonalities between them. In NLP, researchers and practitioners leverage STR to enhance textual coherence, refine narrative structures, and tackle diverse language understanding challenges. By quantifying semantic relatedness, NLP systems can better comprehend and generate human-like responses, ultimately advancing the capabilities of language models.

The concept of semantic relatedness between language units has been recognized as foundational in understanding meaning. The automatic determination of relatedness has found numerous applications, including the evaluation of sentence representation methods, question answering, and summarization. Semantically similar sentences are those that exhibit either a paraphrasal or entailment relationship. In contrast, relatedness encompasses a broader spectrum of commonalities between two sentences. This includes considerations such as whether they pertain to the same topic, convey the same perspective, emerge from the same temporal context, or if one sentence elaborates on or logically follows from the other. Despite the significance of relatedness, much of the prior work in natural language processing has predominantly fo- cused on semantic similarity, particularly within the context of English.

We Explored SBERT. Sentence-BERT(Reimers and Gurevych, 2019) builds upon the architecture of BERT (Bidirectional Encoder Representations from Transformers)(Devlin et al., 2018), leveraging transformer-based models to encode contextual information from input sentences. Unlike BERT, which focuses on token-level representations, Sentence-BERT aims to generate fixed-size representations for entire sentences. To achieve this, Sentence-BERT employs siamese or triplet network architectures, which are trained on sentence pairs or triplets with similar or dissimilar semantic meanings. Through contrastive loss functions, Sentence-BERT learns to map semantically similar sentences closer together in the embedding space while pushing dissimilar sentences farther

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 902–906

apart.

2 Background

The exploration of semantic relatedness in language finds its roots in seminal works by (Halliday and Hasan, 1976) and (Miller and Charles, 1991), which laid early foundations for understanding the subtleties of meaning in text. Initially, these efforts primarily focused on semantic similarity, assessing the likeness between linguistic units through techniques like paraphrasing or entailment. However, as research progressed, scholars began recognizing the necessity of considering a broader array of connections between text segments, thereby giving rise to the concept of semantic relatedness.

Semantic similarity denotes the extent of resemblance in meaning between two linguistic units, while semantic relatedness encompasses a wider spectrum of connections, encompassing elements such as topical relevance, viewpoint alignment, temporal coherence, and logical sequence. While semantic similarity often relies on paraphrasing or entailment, relatedness factors in various nuances contributing to the overall coherence and cohesion of text.

Traditional methodologies for measuring semantic relatedness relied on lexical and syntactic features, including word overlap, syntactic parse trees, and semantic networks. However, the emergence of deep learning techniques has ushered in a paradigm shift towards leveraging neural embeddings and transformer-based models to capture richer semantic representations. These modern approaches have demonstrated superior performance across various Semantic Textual Relatedness (STR) tasks, such as semantic similarity estimation and semantic textual entailment.

In the field of natural language processing (NLP), assessing the relatedness between pairs of sentences is a fundamental task. The paper(Hany et al., 2023) addresses this challenge by proposing an innovative approach that combines two key techniques. First, the authors leverage embedding similarity techniques, utilizing seven different transformers to generate sentence vectors. These vectors capture the semantic content of sentences, allowing for more accurate relatedness assessment. Second, a classical machine learning regressor is trained on these sentence vectors. By integrating these methods, the study achieved impressive results on the SICK dataset. Specifically, the mean square error is reduced to 0.0481, and high Pearson's and Spearman's correlations of 0.978 and 0.9696, respectively, demonstrate the effectiveness of this approach. Overall, this research highlights the potential of combining embedding similarity techniques with machine learning for improving relatedness score assessment and advancing NLP algorithms. The zero-shot text classification (0SHOT-TC) has garnered significant attention. This task involves detecting classes that the model has never encountered during training. The emergence of pre-trained language models has transformed 0SHOT-TC into a binary classification problem, akin to textual entailment. Specifically, the model learns whether there is an entailment-relatedness (yes/no) between a given sentence (premise) and each category (hypothesis). However, existing approaches struggle with fully expressing the category space using labels or label descriptions. In contrast, humans can effortlessly extend a set of words to describe the categories to be classified. To bridge this gap, the paper(Liu et al., 2023) introduces a novel method called Semantically Extended Textual Entailment (SETE). Inspired by human knowledge extension, SETE enriches category representations using a combination of static knowledge (e.g., expert knowledge, knowledge graphs) and dynamic knowledge (e.g., language models).

Early methods, such as Bag of Words (BoW) and Term Frequency-Inverse Document Frequency (TF-IDF), fell short in capturing nuanced word meanings and context. To address this, the paper(Abdalla et al., 2021) surveys the evolution of semantic similarity techniques, categorizing them into knowledge-based, corpus-based, deep neural network-based, and hybrid approaches. By examining the strengths and limitations of each method, the survey provides a comprehensive overview for researchers navigating the complex landscape of semantic similarity research. Understanding the degree of semantic relatedness between two language units is fundamental. However, prior research has primarily focused on semantic similarity, a subset of relatedness, due to the scarcity of relatedness datasets. To address this gap, the authors(Chandrasekaran and Mago, 2021) introduce the Semantic Textual Relatedness (STR-2022) dataset, comprising 5,500 English sentence pairs manually annotated using a comparative annotation framework. Human intuition regarding sentence relatedness proves highly reliable, with a repeat annotation correlation of 0.84. The dataset not only

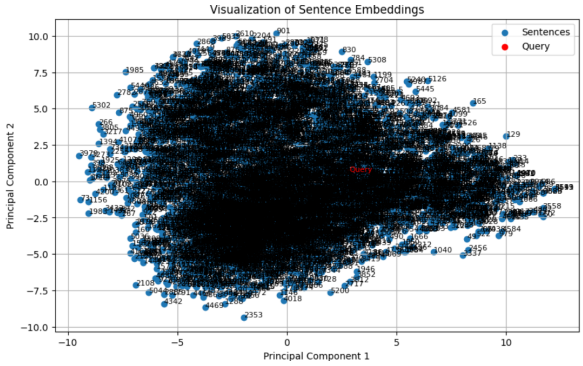

Figure 1: Visualization of Sentence Embeddings

facilitates exploration of what makes sentences semantically related but also serves as a valuable resource for evaluating automatic sentence representation methods and various downstream NLP tasks.

3 System Overview

A model in the Sentence-Transformers library is the bert-base-nli-mean-tokens collection. It is especially made for the purpose of Semantic Textual Similarity (STS). Sentences and paragraphs are mapped to a 768-dimensional dense vector space by this paradigm. The pre-training phase Bert-base-nli-mean-tokens are pre-trained using the conventional BERT architecture. This model is pretrained on the tasks of Modeling Masked Languages (MLM): Tokens in the training data are masked with a unique token [MASK] or randomly substituted with a small percentage, Bidirectional Contextualization: By analyzing both left and right context, BERT generates bidirectional contextualized embeddings as it learns to forecast masked tokens and Next Sentence Prediction (NSP): In the original text, BERT further forecasts if two sentences will come after one another. In learning sentence relationships, this aids the model. Fig -1 shows the visualization of Sentence embeddings from this model.

4 Experimental Setup

we considered the dataset(Ousidhoum et al., 2024a) from codalab SemEval-2024 STR task (Ousidhoum et al., 2024b). There are 5500 samples as train instances and three features namely PairID, Text ans Score . There are 250 samples as test instances and two features PairID and Text. In the Text column of the data, the pair of sentences are separated by '/n'. We conducted a couple of experiments

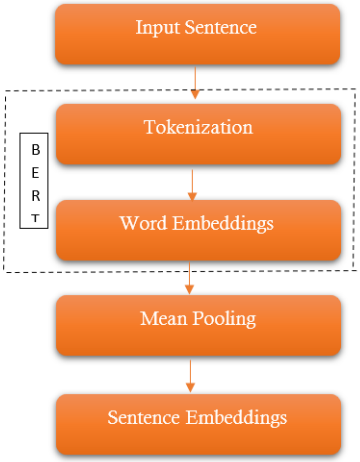

Figure 2: Methodology Used

for the Semantic Textual Relatedness on the above mentioned data using BERT. In our study, we utilized the bert-base-nli-mean-tokens model, a variant of the BERT architecture tailored for the Semantic Textual Similarity (STS) task. This model, an integral component of the Sentence Transformers (sbert) library, plays a pivotal role in assessing the semantic relatedness between pairs of text sentences. The designation 'base' signifies a medium-sized version of the BERT model, balancing computational efficiency with performance. Pre-trained on Natural Language Inference (NLI) tasks, the model captures intricate semantic relationships between text segments, essential for STS tasks. Additionally, employing mean pooling, it generates fixed-length sentence embeddings efficiently, providing a comprehensive representation of semantic content. Our utilization of bert-base-nli-mean-tokens in our research ensures robust and nuanced analysis of semantic similarity, contributing to advancements in natural language understanding and related fields.The fig- 2 shows the methodology we followed to extract sentence embeddings.

4.1 Without Fine Tuning

At First, we separated the two sentences by the delimited '/n'. we have the pair of sentences. Now, our task is to get the sentence embeddings for these sentences. We used Sentence Transformers pipeline, with the "bert-base-nli-mean-tokens" as the model.This particular model is based on the BERT (Bidirectional Encoder Representations from Transformers) architecture and is trained to generate sentence embeddings by taking the mean of the token embeddings.These sentence

embeddings are used to calculate Semantic Textual Relatedness by using custom defined Cosine Similarity function. The custom function computes the cosine similarity between two input vectors u and v(sentence Embeddings) . Utilizing NumPy's dot product and Euclidean norm functions, the function calculates the cosine similarity by dividing the dot product of the input vectors by the product of their Euclidean norms. Commonly employed in Natural Language Processing tasks, cosine similarity serves as a fundamental metric for comparing the semantic similarity between word embeddings or Sentence embeddings, facilitating various applications such as information retrieval and document clustering.
Every word in the text was mapped to a word embedding space using the model. The cosine distance between the two sentences was computed after the embeddings. Equation 1 illustrates how the cosine similarity between the two embedding vectors is computed.
$\cos(\theta) = \frac{A \cdot B}{\|A\|_2 \|B\|_2}$

The requested forecast for the two sentences under consideration was then given as the cosine similarity value.

4.2 Fine Tuning

Similar to the previous experiment, we separated the two sentences by the delimited '/n'. We used the same pipeline to generate sentence embeddings. But this time, instead of directly evaluating the performance of the model using cosine similarity. We first fine-tuned the model with the following parameters Table 1 and then we evaluated it's performance.

Table 1: Parameters Used

Parameter	Value
Batch size	16
Epochs	1
Loss	CosineSimilarityLoss
Optimizer	Adam

5 Results

On Google Colab, we put our approach into practice. Sentence Transformer was the library that we used. Pythorch7 (>=1.11.0) and Python 6 (>= 3.8) are required by the library. The Official Competition website provides the dataset that was provided for each phase. The Spearman rank correlation coefficient, which assesses how closely the rankings predicted by the system match human assessments, is the official evaluation statistic for this activity. The GitHub page8 dedicated to the competition has the assessment script for this common job, which offers a uniform process for rating the effectiveness of competing solutions. The Spearman correlation coefficient can be calculated using the formula found in
$\rho = 1 - \frac{6 \sum_{i=1}^{n} d_i^2}{n(n^2-1)}$

where n is the number of samples and d is the pairwise distances between the ranks of the variables xi and yi.

Table 2: Performance of Models Used

Model	BERT-BASE
Supervised	0.803
UnSupervised	0.693

Results for our experiments are shown in the table-2. It is important to remember that the bert-base-nli-mean-tokens model is no longer in use because of its poorer sentence embeddings.But In Supervised Approach, after finetuning the model with training data , the sentence embeddings are more meaningful as shown in fig-1. We were able to achieve better results than baseline in Unsupervised Approach using this model. In Supervised Approach , the baseline score is 0.830 and our proposed approach score is 0.803, with further improvements to our approach, we might achieve better results than baseline.

6 Conclusion

In order to address Task 1 at SemEval-2024, this paper presents the use of a BERT-BASE model embedding. For our submission, we chose a Supervised (finetuning) and unsupervised (not finetuning) approach, utilizing pre-trained Transformers that are already tailored to the domain. Based on this strategy, we used the contextual embeddings generated by the Sentence Transformer and used cosine similarity to measure the similarity between pairs of sentences, thereby quantifying the similarity between them. Although our method was successful, there is still room for improvement, as evi-

denced by the final ranking. Possible alternate approaches include utilizing the zeroshot capabilities of models like GPT , increasing the training data size by adding more datasets. There is some space for improvement in our straightforward method when compared to the top-performing models. It is noteworthy, nonetheless, that the assignment could be completed with a reasonable computational cost and no further pre-training thanks to Google Colab's free online tools.

Abstract

This paper presents our approach to SemEval-2024 Task 1: Semantic Textual Relatedness (STR). Out of the 14 languages provided, we specifically focused on English and Telugu. Our proposal employs advanced natural language processing techniques and leverages the Sentence Transformers library for sentence embeddings. For English, a Gradient Boosting Regressor trained on DistilBERT embeddings achieves competitive results, while for Telugu, a multilingual model coupled with hyperparameter tuning yields enhanced performance. The paper discusses the significance of semantic relatedness in various languages, highlighting the challenges and nuances encountered. Our findings contribute to the understanding of semantic textual relatedness across diverse linguistic landscapes, providing valuable insights for future research in multilingual natural language processing.

1 Introduction

Semantic Textual Relatedness (STR) is a pivotal aspect of natural language processing (NLP) that underlies the foundation of various language-related tasks (Ousidhoum et al., 2024a,b). This task takes this challenge to a global scale by encompassing 14 languages, including Afrikaans, Algerian Arabic, Amharic, English, Hausa, Hindi, Indonesian, Kinyarwanda, Marathi, Morrocan Arabic, Modern Standard Arabic, Punjabi, Spanish, and Telugu. This multilingual approach transcends linguistic boundaries, fostering collaboration and research within the NLP community. Exploring a diverse array of languages in this endeavor encourages the development of models adept at handling the distinct linguistic nuances inherent in each language. This progress fosters a more inclusive and universally applicable approach to natural language processing research.

SemEval-2024 Task 1 delves into the automated detection of semantic relatedness between pairs of sentences, a foundational aspect for unraveling meaning. The task's embrace of multiple languages is crucial, encompassing a spectrum of linguistic characteristics. This inclusivity fosters a collaborative atmosphere for researchers, pushing them to craft models adept at capturing semantic nuances across diverse linguistic landscapes. The task's importance extends to the assessment and benchmarking of sentence representation methods, pivotal for numerous NLP applications. STR evaluated through tasks, play a crucial role in areas such as question answering, summarization, and information retrieval. The task's outcomes serve as a benchmark, guiding the development and refinement of models that can effectively discern the relatedness of sentences, regardless of language.

When approaching this task, we concentrated on two languages: English and Telugu. Employing the Sentence Transformers library, we make use of the DistilBERT model for generating sentence embeddings in English and opt for a multilingual model for handling Telugu. The choice of state-of-the-art models and embedding techniques underscores our commitment to developing robust solutions capable of handling the linguistic diversity presented in this task.

Participating in this task has revealed crucial insights into the intricacies of semantic relatedness across languages. Our system demonstrated better performance, particularly in English, achieving noteworthy Spearman correlation coefficients on the test set. However, the challenges surfaced in capturing subtle nuances in semantic relations, especially in the context of Telugu. This highlights the necessity for specialized methodologies to address the complexities of multilingual semantic relatedness. As we explore the methodology, experiments, and results in the following sections, we delve deeper into the intricacies of our approach, providing a comprehensive understanding of how our model navigates the challenges posed by the

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 907–912

task.

2 Background

The task at hand revolves around Semantic Textual Relatedness (STR), focusing on evaluating the degree of semantic closeness between sentences in both English and Telugu. Unlike emotion recognition, this task delves into understanding the relationships between sentences rather than categorizing emotions in code-mixed interactions. In this scenario, the input comprises pairs of sentences in either English or Telugu, and the objective is to determine the relatedness score for each pair on a scale from 0 to 1.

For instance, consider the following English sentence pair:
Sentence 1: "The sun is setting over the horizon, casting a warm glow on the city."
Sentence 2: "As the day comes to an end, the sun sets, and the city is bathed in a warm glow."
Score Label: 0.85
In this example, the relatedness score of 0.85 indicates a high degree of semantic closeness between the two sentences, as they convey similar information about the sunset and the warm glow of the city.
Sentence 1: "The scientific method involves systematic observation and experimentation."
Sentence 2: "Bicycles are a popular mode of transportation in urban areas."
Score Label: 0.15

In this example, the relatedness score of 0.15 indicates a low degree of semantic closeness between the two sentences. Similarly, a dataset exists for Telugu.

The datasets used for this task include pairs of sentences in English and Telugu, capturing the real-world scenario of diverse linguistic interactions. These datasets are annotated with relatedness scores, providing a basis for training and evaluating models effectively. The input parameters consist of the sentence pairs, and the output involves predicting the relatedness score for each pair. The multilingual nature of the task fosters collaboration and research across linguistic boundaries, contributing to a more inclusive and globally applicable approach in the NLP community.

3 Related Work

Palakorn Achananuparp et. al.presents an evaluation of fourteen existing text similarity measures (Achananuparp et al., 2008). The ability to accurately judge the similarity between natural language sentences is crucial for various applications such as text mining, question answering, and text summarization. The evaluation encompasses three different datasets: TREC9 question variants, Microsoft Research paraphrase corpus, and the third recognizing textual entailment dataset. The study explores three classes of measures: word overlap, TF-IDF, and linguistic measures. The goal is to judge sentence pairs based on the notion that they have identical meanings, considering factors such as paraphrase or entailment. They address the challenges of computing sentence similarity, highlighting the importance of recognizing semantic equivalence beyond surface form comparisons.

Pantulkar Sravanthi and B. Srinivasu, address the challenge of measuring sentence similarity, emphasizing the importance of semantic similarity over syntactic measures (Sravanthi and Srinivasu, 2017). They introduce three semantic similarity approaches—cosine similarity, path-based (Wu–Palmer and shortest path), and feature-based. The feature-based approach incorporates WordNet, tagging, and lemmatization, showing superior performance in generating semantic scores. This study contributes valuable insights into semantic similarity measures and can enhance the understanding of feature-based approaches based on WordNet in sentence categorization.

Syed S. Akhtar et al. (Akhtar et al., 2017) address the need for word similarity datasets in Indian languages, specifically Urdu, Telugu, Marathi, Punjabi, Tamil, and Gujarati. They introduce manually annotated monolingual word similarity datasets for these languages, created through translation and re-annotation of English datasets. The paper presents baseline scores for word representation models using state-of-the-art techniques for Urdu, Telugu, and Marathi, evaluated on the newly created datasets. This work contributes valuable resources for evaluating word representations in Indian languages, fostering the development of techniques leveraging word similarity.

4 System Overview

To optimize efficiency, we methodically integrated numerous critical algorithms and modeling decisions into our semantic textual relatedness model.

4.1 Data Preprocessing

4.1.1 Text Cleaning

In the initial phase of our preprocessing pipeline, (Kadhim, 2018) we address the cleanliness of the textual data for both Telugu and English. For Telugu, we employ a language-specific approach, utilizing a tokenizing function tailored to the Telugu script. This ensures the proper segmentation of words while also excluding unwanted elements such as punctuation, special characters, and digits. Similarly, for English, we apply standard tokenization techniques to achieve a clean and well-structured representation, eliminating extraneous symbols and numerical values. This initial cleaning step lays the foundation for subsequent language-specific processing.

4.1.2 Language-specific Tokenization

Recognizing the distinct linguistic features of Telugu and English, we implement language-specific tokenization methods. In the case of Telugu, we adapt tokenization to the unique script and structural characteristics of the language. This approach ensures the accurate representation of Telugu text for downstream tasks. Conversely, for English, we rely on conventional tokenization techniques suited for the Latin script. By tailoring tokenization to the linguistic attributes of each language, we pave the way for more effective and contextually rich representations in subsequent stages of the preprocessing pipeline.

4.1.3 Stop Word Removal

Stopwords were removed from the combined tokens in order to enhance the model's focus on pertinent content. Through the removal of noise and refinement of the raw data, a deeper comprehension of the underlying sentiment was made possible.

4.1.4 Data Splitting

The `train_test_split` function from the `scikit-learn` library was used to split the preprocessed data into training and testing sets. This made it possible to thoroughly assess the model's capacity for generalization using data that had never been seen before.

4.2 Model Architecture

4.2.1 English

Embedding with DistilBERT: To capture semantic meanings, we utilized the DistilBERT model (version: distilbert-base-uncased) (Kici et al., 2021) from the Sentence Transformers library to generate sentence embeddings. DistilBERT is a distilled version of the BERT model, designed for faster inference while maintaining competitive performance. Sentences were encoded into embeddings using DistilBERT, facilitating the creation of robust representations. These embeddings served as the input features for subsequent relatedness score prediction.

Gradient Boosting Regressor Model:

To model the relatedness scores, we employed the Gradient Boosting Regressor algorithm. Specifically, we utilized the GradientBoostingRegressor class from the scikit-learn library (version: 0.24.2). The model was trained on the encoded sentences and evaluated on the test set.

In the process of hyperparameter tuning, the following parameters were optimized:
Learning rate: 0.05
Number of estimators: 200
Maximum depth of each estimator (max depth): 3
Subsample ratio of the training instances (subsample): 0.8

These hyperparameters were chosen based on a grid search conducted to maximize the model's effectiveness in predicting semantic textual relatedness for English sentences. Specifically, the learning rate controls the contribution of each tree in the ensemble, while the number of estimators determines the number of boosting stages. Additionally, the maximum depth of each tree and the subsample ratio influence the depth of the individual trees and the sampling strategy, respectively.

Model Persistence and Reporting: The trained Gradient Boosting Regressor model is saved for future use. Spearman correlation on the test set provides a quantitative measure of the model's ability to predict sentence relatedness. The model's performance, including the correlation coefficient, is printed for further analysis.

4.2.2 Telugu

Multilingual Sentence Embeddings: For Telugu, we opt for a pre-trained multilingual model (paraphrase-multilingual-MiniLM-L12-v2) to generate sentence embeddings. The Telugu dataset is encoded into embeddings using this multilingual model. The Telugu model is trained using a Gradient Boosting Regressor, and its performance is

evaluated on the test set using the Spearman correlation coefficient.

Advanced Model Tuning: We used an approach similar to one used for the English dataset where hyperparameter tuning is performed using a grid search for the Gradient Boosting Regressor on Telugu data. The best model is selected based on the optimal combination of hyperparameters, leading to improved performance. The chosen model is subsequently applied for prediction and evaluation.

4.3 Model Evaluation

4.3.1 Performance Metrics

To gauge the performance of the English-relatedness detection model, we utilized a comprehensive set of metrics, incorporating the Spearman correlation coefficient. These metrics collectively offered a well-rounded understanding of the model's accuracy, precision, and capacity to capture the subtleties of relatedness among English sentences. Following a similar evaluation approach for the Telugu-relatedness detection model, we subjected it to a thorough assessment using performance metrics. The Spearman correlation coefficient served as a valuable measure to assess the accuracy and precision of the model in capturing relatedness between Telugu sentences.

4.3.2 Prediction on the Test Set

We employed the trained model to predict textual relatedness on a test set. This involved passing the preprocessed test data through the model and deciphering the anticipated labels for subsequent analysis.

5 Experimental Setup

5.1 Data Preprocessing for Subtask 1a (English)

For the English dataset, we adopted a two-step preprocessing approach. Initially, sentences underwent precise tokenization using the Sentence Transformers library. This process harnessed the advanced capabilities of DistilBERT to encode sentences into dense embeddings, establishing the foundation for subsequent model training. The selected Gradient Boosting Regressor model underwent training on these embeddings, contributing to improved semantic textual relatedness.

5.2 Data Preprocessing for Subtask 1b (Telugu)

For Telugu, we implemented dedicated preprocessing, involving nuanced tokenization facilitated by the Natural Language Toolkit (NLTK). This process was complemented by a careful removal of stopwords, specifically tailored for Telugu text. Subsequently, the (Gillioz et al., 2020) Sentence Transformer's multilingual model came into play, encoding Telugu sentences into high-dimensional embeddings. These embeddings formed the basis for training a Gradient Boosting Regressor model. Importantly, hyperparameter tuning played a pivotal role in fine-tuning the model's performance specifically for Telugu.

5.3 Hyperparameter Tuning

For Subtask 1a, our focus on hyperparameter tuning aimed to optimize the performance of the Gradient Boosting Regressor model on the English dataset. The primary goal was to fine-tune the model for improved semantic textual relatedness prediction.

In Subtask 1b, specifically for Telugu, we conducted a thorough hyperparameter tuning process using GridSearchCV. Key hyperparameters such as estimators, learning rate, max-depth, and subsample were carefully explored to enhance the model's efficacy. This step was intended to fine-tune the Gradient Boosting Regressor model for optimal performance on the Telugu dataset.

5.4 External Tools / Libraries

External tools and libraries played a pivotal role in our experimentation. Sentence Transformers (v2.0.0) with its sophisticated capabilities was instrumental in encoding sentences into high-dimensional embeddings. NLTK (v3.6.3) facilitated precise tokenization and stopword removal, contributing to meticulous linguistic preprocessing. Scikit-Learn (v0.24.2) emerged as the preferred library for machine learning models and hyperparameter tuning, providing a standardized and comprehensive experimental framework.

5.5 Evaluation Metric

The evaluation metric of choice was the Spearman correlation coefficient. Renowned for its ability to discern the monotonic relationship between predicted scores and gold standard scores, this metric offered a nuanced assessment of semantic textual relatedness.

Approach	Accuracy
distilbert-base-uncased (English)	0.57
paraphrase-multilingual-MiniLM-L12-v2 (Telugu)	0.527

Table 1: Comparison of Accuracy for Different Approaches

6 Results

The system's performance was assessed using a regression model that predicts similarity scores between English sentences. The Spearman Correlation Coefficient is the major quantitative finding, measuring the monotonic relationship between expected and actual similarity scores. The Spearman correlation coefficient, often denoted as (rho), is a statistical measure used to assess the strength and direction of the monotonic relationship between two variables. Specifically, in the context of evaluating models, the Spearman coefficient is employed to quantify the association between predicted scores and actual scores.

$$\rho = 1 - \frac{6 \sum d_i^2}{n(n^2 - 1)} \quad (1)$$

Table 1 shows the Spearman score of the models used for English and Telugu. The English model, employing advanced natural language processing techniques and utilizing DistilBERT embeddings, demonstrated noteworthy performance on the test set. The Spearman correlation coefficient, a key indicator of the model's ability to predict relatedness between English sentences, was calculated. Our model achieved a Spearman correlation coefficient of 0.57 on the test set, showcasing its effectiveness in capturing semantic nuances and relationships within English sentence pairs.

The model's performance is influenced by the quality of the preprocessing applied to the text data. Any limitations or challenges encountered during the preprocessing stage, such as handling rare words or specific language nuances, should be discussed. The performance of our Telugu model in predicting semantic relatedness scores using a fine-tuned Gradient Boosting Regressor with hyperparameter tuning and embeddings from the Sentence Transformer model 'paraphrase-multilingual-MiniLM-L12-v2' is evaluated here. On the test set, our Telugu model achieved a Spearman correlation coefficient of 0.527. This result signifies a strong positive monotonic relationship between the predicted relatedness scores and the actual scores. The Spearman correlation coefficient is a crucial indicator of the model's ability to capture the underlying trends in sentence similarity within the Telugu language. The hyperparameter tuning process identified the following optimal hyperparameters for the Gradient Boosting Regressor on the Telugu dataset: learning rate : 0.05, max depth: 3, n_estimators: 200, subsample: 0.8 . These hyperparameters represent the configuration that maximizes the model's effectiveness in predicting relatedness scores for Telugu sentences.

7 Conclusion

Our system, anchored in the robust capabilities of Sentence Transformers and Gradient Boosting Regressor models, showcased a better performance in predicting semantic textual relatedness. The fusion of advanced tokenization, embeddings, and hyperparameter tuning resulted in a model finely attuned to the intricacies of the English and Telugu languages.

The results on the evaluation metrics, particularly the Spearman correlation coefficient, underscore the efficacy of our approach in capturing the nuances of semantic relatedness across diverse sentence pairs. The successful adaptation to multiple languages, as evident in the Telugu experiments, showcases the versatility of our system.

For future work, delving deeper into language-specific processing techniques and exploring more sophisticated models may unlock additional performance gains. Additionally, expanding the system's applicability to handle a broader array of languages and domains could further enhance its utility in real-world applications. Overall, our endeavors open avenues for continuous refinement and exploration in the realm of semantic textual relatedness prediction.

Abstract

Natural language processing (NLP) models have achieved remarkable progress in recent years, particularly in tasks related to semantic analysis. However, many existing benchmarks primarily focus on lexical and syntactic understanding, often overlooking the importance of numerical reasoning abilities. In this paper, we argue for the necessity of incorporating numeral-awareness into NLP evaluations and propose two distinct tasks to assess this capability: Numerical Reasoning and Headline Generation. We present datasets curated for each task and evaluate various approaches using both automatic and human evaluation metrics. Our results demonstrate the diverse strategies employed by participating teams and highlight the promising performance of emerging models like Mixtral 8x7b instruct. We discuss the implications of our findings and suggest avenues for future research in advancing numeral-aware language understanding and generation.

1 Introduction

Natural language processing (NLP) models have achieved impressive performance on a wide range of semantic analysis tasks in recent years. However, the majority of benchmarks used to evaluate these models, including past SemEval shared tasks, have focused predominantly on lexical and syntactic understanding, with little emphasis on numerical reasoning abilities. In this paper, we argue that comprehending and reasoning with numerical values expressed in text is vital for robust language understanding, and should be an integral part of NLP evaluations going forward (num).

We demonstrate across several application scenarios that a lack of numeracy can undermine model performance and result in erroneous output. As an illustration, fine-grained sentiment analysis, as explored in SemEval-2017 Task 5, relies heavily on distinguishing subtle differences in sentiment intensity. Anticipating a 30% stock price increase implies a markedly more positive outlook than a 3% rise. Without accounting for the differential impact of these numbers, sentiment analysis models may fail to capture such nuances.

Similarly, in legal judgment prediction settings like SemEval-2023 Task 6, sentencing decisions can hinge on numerical quantities - stealing $100,000 typically incurs harsher penalties than stealing $10. Clinical inference use cases such as SemEval-2023 Task 7 also require sensitivity to numbers like blood pressure readings, where contrasts between 121 mmHg and 119 mmHg could indicate notably different health outlooks (Devlin et al., 2019).

These examples highlight the limitations of current benchmarking paradigms in evaluating true language comprehension. Accordingly, we propose that new numerically-grounded NLP tasks be developed to test numerical reasoning capacities. Recent work has begun exploring this direction, but substantial efforts are still needed to build robust models that demonstrate human-like numeracy. We outline a potential experimental framework and novel dataset for this purpose in the following sections.

2 Dataset

Task 3 (Huang et al., 2023) of our study comprises two distinct subtasks: numerical reasoning and headline generation. We describe the dataset for each subtask separately below:

2.1 Subtask 1: Numerical Reasoning

For the numerical reasoning subtask, we curated a dataset consisting of news headlines with missing numerical values. Each instance in the dataset includes a news article along with a headline where a numerical value is replaced with a blank. An example of the format for each instance is as follows:

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 913–917

- **News Article**: [Insert news article text here]
- **Headline with Blank**: "Study predicts a [blank] increase in global temperatures by 2050."
- **Target Value**: The correct numerical value that should fill in the blank.

The dataset includes a diverse range of news articles covering various topics such as climate change, economics, healthcare, and more. Each instance is associated with a target value representing the correct numerical answer.

2.2 Subtask 2: Headline Generation

For the headline generation subtask, we compiled a dataset consisting of news articles without headlines. Each instance in this dataset includes a news article, and the task is to generate a headline based on the content of the article. An example instance is provided below:

- **News Article**: [Insert news article text here]
- **Target Headline**: The headline that should be generated based on the content of the news article.

Similar to the numerical reasoning dataset, the articles cover a wide range of topics to ensure diversity in the generated headlines.

The table below shows the number of data points in the validation, test, and train sets for the Numerical Reasoning task:

Dataset	Validation	Test	Train
Numerical Reasoning	2572	4921	21157

Table 1: Dataset Statistics for Numerical Reasoning

Similarly, the table below presents the number of data points in the validation, test, and train sets for the Headline Generation task:

Dataset	Validation	Test	Train
Headline Generation	2365	5227	21157

Table 2: Dataset Statistics for Headline Generation

3 Methods

Zero-shot prompting is an effective method for these news headline tasks because it allows the model to apply its generalized language understanding capabilities to novel tasks without extensive fine-tuning. The model can deduce the appropriate responses based solely on the instructions and examples provided in the prompt.

The prompts are carefully engineered to provide the model with clear guidelines and context. For the numerical reasoning task, the prompt poses the incomplete headline as a question and asks the model to fill in the blank with only a numerical value. This focuses the model on extracting and inferring the relevant number from the article text.

Similarly, the headline generation prompt provides the news article as context and directly instructs the model to generate a headline summarizing the key information. The simplicity of these prompts allows the model to use its innate language skills to produce fitting responses without needing gradient-based training on the specific tasks.

Furthermore, the varied topics and contexts in the dataset require the model to adapt its numerical and summarization strategies across different situations. This tests the model's ability to generalize based on the prompt instructions, rather than overfitting to biases in a narrow dataset. The broad applicability demonstrated through zero-shot prompting highlights the versatile reasoning capacity gained through the model's pretraining.

Overall, zero-shot prompting is an elegant and effective approach for this study, as it allows assessment of the model's intrinsic skills at numerical deduction and text summarization when provided suitable prompts. The prompt formulation is key to eliciting successful performance without task-specific fine-tuning.

3.1 Subtask 1: Numerical Reasoning

The prompt (Zamfirescu-Pereira et al., 2023) used for determining the value of the missing numerical variable is as follows:

```
message = "News: {News}.\n
Headline: {Headline}\n\n
What is the value of ___?
Only give a numerical Response: "

prompt = f"[INST] {message} [/INST]"
```

3.2 Subtask 2: Headline Generation

For the headline generation subtask, participants are required to generate a headline based on the provided news article. The prompt for headline generation is as follows:

Example 1: Numerical Reasoning

News: (Oct 1, 2009 3:30 PM CDT) Want to catch up on YouTube2019s greatest hits but don2019t have the time? No problem: Just watch a new 4-minute mash-up that brings 100 of the best (or worst, depending on your viewpoint) together. Clips include such classics as Keyboard Cat and David After Dentist, and stars range from Obama Girl to the Dr. Pepper Guys, Time reports. Watch it at left.
Masked Headline: Watch 100 YouTube Classics in ____ Minutes
Calculation: Copy(4)
Ans: 4

Example 2: Numerical Reasoning

News: (Nov 16, 2009 8:40 AM) A rocket attack intended for a French general instead killed three children and wounded 20 others in a busy market northeast of Kabul today. Insurgents fired into the marketplace hoping to hit a meeting between Brig. Gen. Marcel Druart and tribal elders from Tagab Valley, where France is in the midst of a major offensive. Neither Druart nor any of his troops were harmed.
Masked Headline: Afghan Rocket Misses French General, Kills ____ Kids
Calculation: Trans(three)
Ans: 3

Example 3: Numerical Reasoning

News: (Mar 12, 2009 3:19 PM CDT) Stocks rose steadily after a morning dip today, with the Dow closing back over 7,000 points, MarketWatch reports. Bank of America and General Motors shot up 18.2% and 14.5%, respectively, after each announced they don2019t expect to ask the government for more bailout cash. The Dow ended up 239.66 at 7,170.06. The Nasdaq rose 54.46, settling at 1,426.10; the S
P 500 closed up 29.38 at 750.74.
Masked Headline: Dow Up 240, Retakes ____K Mark
Calculation: Paraphrase(7,000,K)
Ans: 7

Example 4: Headline Generation

News: (Mar 25, 2009 12:30 PM CDT) What's Italian for leadfoot ?00a0A Milanese man going 168mph was busted on four separate highway cameras in less than hour, ANSA reports. He was driving for his employer, whose lawyers argue that he should be responsible for just one infraction. They said they also plan to cite a court ruling that says signs identifying cameras must be a certain distance from a speed trap, adding: Naturally, we do not condone such driving at all.
Headline: Italian Going 168mph Gets 4 Tickets in 1 Hour

Example 5: Headline Generation

News: (Apr 21, 2010 12:51 PM CDT) The $100 bill is getting a new look and two high-tech security features to curb counterfeiters, the AP reports. A 3D security ribbon on the front has images of bells and 100s that move as you tilt the bill. The note, which is out next February, also has a Liberty Bell that seems to disappear. The government has more details here, along with a video that borders on the cheesy side here.
Headline: $100 Bill Goes 3D

```
message = "News: {News}.
Generate a headline based on the provided
news article: "

prompt = f"[INST] {message} [/INST]"
```

4 Results

4.1 Numerical Reasoning

The table 3 presents the results for the Numerical Reasoning task:

Rank	Team	Score
1	CTYUN-AI	0.95
2	zhen qian	0.94
3	YNU-HPCC	0.94
4	NCL_NLP	0.94
5	NumDecoders	0.91
6	Infrrd.ai	0.90
7	hc	0.88
8	NLPFin	0.86
9	NP-Problem	0.86
10	AlRah	0.83
11	Noot Noot	0.77
12	GPT-3.5	0.74
13	Sina Alinejad	0.74
14	StFX-NLP	0.60

Table 3: Numerical Reasoning Results

In the domain of Numerical Reasoning, we showed a commendable performance, achieving a score of 0.77, marginally surpassing the baseline score attributed to the GPT-3.5 model, which stood at 0.74.

4.2 Headline Generation

4.2.1 Auto Evaluation

The table 4 presents the results for the Headline Generation task based on auto evaluation metrics.

We demonstrated notable proficiency in headline generation, attaining a ROUGE score of 38.4, a BERT score of 57.5, and a Mover's Accuracy score of 3.6 in the automated evaluation.

4.2.2 Human Evaluation

The table 5 presents the results for the Headline Generation task based on human evaluation metrics.

Human evaluators accorded the team a score of 1.68, indicating favorable reception of the generated headlines.

Team	Num Acc.	ROUGE	BERT Score	Mover Score
ClusterCore	38.2	51.6	13.9	33.5
Noot Noot	38.4	57.5	3.6	31.5
Infrrd.ai	65.8	68.4	61.3	46.8
np_problem	73.5	76.9	67.3	39.8
hinoki	62.4	66.3	55.2	43.1
Challenges	73.0	82.2	56.2	31.2
NCL_NLP	62.1	65.5	55.9	43.5
YNU-HPCC	69.0	73.0	61.8	48.9
NoNameTeam	55.7	57.7	52.1	40.7

Table 4: Auto Evaluation Results for Headline Generation

Team	Num Acc. (50 Headlines)	Recommendation(100 News)
ClusterCore	1.60	31
Noot Noot	1.68	11
Infrrd.ai	1.81	22
np_problem	1.57	14
hinoki	1.67	16
Challenges	1.70	10
NCL_NLP	1.73	16
YNU-HPCC	1.69	15
NoNameTeam	1.59	12

Table 5: Human Evaluation Results for Headline Generation

5 Conclusion

In this study, we explored the performance of various approaches for two distinct tasks: Numerical Reasoning and Headline Generation. Across both tasks, we observed a range of performances among the participating teams, indicating the diversity of techniques and strategies employed.

For Numerical Reasoning, the top-performing teams demonstrated high accuracy and effective reasoning capabilities, leveraging a combination of techniques to achieve superior results. Notably, the utilization of advanced models and fine-tuning methodologies played a crucial role in enhancing performance on this task.

In Headline Generation, both auto and human evaluations highlighted the effectiveness of certain teams in generating accurate and engaging headlines. Teams employing sophisticated natural language processing techniques, such as advanced neural models and feature engineering, exhibited superior performance in generating headlines that

resonated well with both automated evaluation metrics and human judges.

Furthermore, the introduction of Mixtral 8x7b instruct model showcased promising capabilities in both tasks. Despite not being fine-tuned specifically for the tasks at hand, the Mixtral model demonstrated competitive performance, particularly in Headline Generation. This suggests the robustness and versatility of the Mixtral 8x7b instruct model in understanding and generating natural language content across diverse domains and tasks.

Overall, our findings underscore the importance of leveraging state-of-the-art models and techniques in tackling complex natural language processing tasks. Additionally, the emergence of pretrained models like Mixtral 8x7b instruct offers promising avenues for future research and development, as they provide strong baselines and require minimal fine-tuning to achieve competitive performance across various NLP tasks.

Abstract

In this paper, we introduce a machine-generated text detection system designed to tackle the challenges posed by the proliferation of large language models (LLMs). With the rise of LLMs such as ChatGPT and GPT-4, there is a growing concern regarding the potential misuse of machine-generated content, including misinformation dissemination. Our system addresses this issue by automating the identification of machine-generated text across multiple subtasks: binary human-written vs. machine-generated text classification, multi-way machine-generated text classification, and human-machine mixed text detection. We employ the RoBERTa Base model and fine-tune it on a diverse dataset encompassing various domains, languages, and sources. Through rigorous evaluation, we demonstrate the effectiveness of our system in accurately detecting machine-generated text, contributing to efforts aimed at mitigating its potential misuse.

1 Introduction

Large language models (LLMs) are becoming mainstream and easily accessible, bringing in an explosion of machine-generated content over various channels, such as news, social media, question-answering forums, educational, and even academic contexts. Recent LLMs, such as ChatGPT and GPT-4, generate remarkably fluent responses to a wide variety of user queries. The articulate nature of such generated texts makes LLMs attractive for replacing human labor in many scenarios. However, this has also resulted in concerns regarding their potential misuse, such as spreading misinformation and causing disruptions in the education system. Since humans perform only slightly better than chance when classifying machine-generated vs. human-written text, there is a need to develop automatic systems to identify machine-generated text with the goal of mitigating its potential misuse.

The advent of sophisticated large language models (LLMs), including ChatGPT and GPT-4, has catalyzed a surge in artificially generated text across myriad domains, from news media to social platforms, educational resources, and scholarly publications. These neural network models exhibit an unprecedented capacity to produce natural language, enabling the automation of written content creation. However, the human-like fluency of LLM outputs has concurrently raised serious concerns surrounding potential misuse.

With syntactically coherent and topically relevant text, LLMs could plausibly disseminate misinformation, plagiarize or falsify documents, and automate persuasion-based attacks on a massive scale. The integration of models like ChatGPT into education has additionally ignited fierce debate; while proponents highlight opportunities for personalized instruction, critics argue LLMs enable academic dishonesty and undermine human knowledge acquisition. Amidst this controversy, institutions urgently seek policies to uphold academic integrity.

Alarmingly, humans perform only marginally better than random chance at distinguishing machine-generated versus human-authored text. Developing reliable technical systems to automatically detect AI content has therefore become a research priority. The goal is to provide educators, moderators, and end users tools to identify LLM outputs, thereby mitigating potential dangers from increasingly accessible, human-like models.

Constructing robust LLM detectors demands interdisciplinary collaboration, combining machine learning advances with insights from fields like ethics, media studies, and education. With judicious coordination across stakeholders, experts aim to actualize benefits of LLMs for automation while curtailing risks of misinformation, deception, and cheating.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 918–921

2 Dataset

The dataset provided by the organizers of this shared task (Wang et al., 2024a) comprises a diverse collection of texts encompassing various domains, languages, and sources. The dataset is structured to address the three subtasks outlined: binary human-written vs. machine-generated text classification (Subtask A), multi-way machine-generated text classification (Subtask B), and human-machine mixed text detection (Subtask C).

For Subtask A (Binary Classification), the dataset consists of a balanced corpus of human-written and machine-generated texts. The human-written texts are sourced from various publications, academic papers, forums, and social media platforms. The machine-generated texts are generated by state-of-the-art language models such as ChatGPT, GPT-4, cohere, davinci, bloomz, and Dolly. These texts cover a wide range of topics to ensure diversity and representativeness.

For Subtask B (Multi-Way Classification), the dataset includes texts generated by each of the six specified language models: ChatGPT, cohere, davinci, bloomz, Dolly, and human-written texts. The texts are annotated to indicate their respective sources, enabling the classification task to determine the origin of each text accurately.

For Subtask C (Human-Machine Mixed Text Detection), the dataset contains texts where the first part is human-written, and the subsequent part is machine-generated. Annotations demarcate the boundary where the transition from human to machine-generated text occurs. This allows for training and evaluating models on detecting the boundary between human and machine-generated segments within a single text.

The dataset is preprocessed to remove noise, standardize formatting, and ensure consistency across texts.

Subtask	Train	Dev
A (Monolingual)	119,757	5,000
A (Multilingual)	172,417	4,000
B	71,027	3,000
C	3,649	505

Table 1: Dataset Statistics for Each Subtask

3 Methods

We employed a fine-tuning approach using the XLM-RoBERTa Base model (Conneau et al., 2020) for the task of machine-generated text detection.

We chose Roberta-base as our base model for fine tuning as XLM-RoBERTa is a multilingual language model optimized for classification tasks. It is pretrained on massive multilingual data, and has a robust architecture and performance enable efficient fine-tuning across diverse text classification problems with state-of-the-art accuracy

The fine-tuning process involves initializing the RoBERTa Base model with pre-trained weights and then fine-tuning it on our specific dataset for the tasks of binary human-written vs. machine-generated text classification (Subtask A), multi-way machine-generated text classification (Subtask B), and human-machine mixed text detection (Subtask C).

During fine-tuning, we optimize the model's parameters using stochastic gradient descent (SGD) with backpropagation. We employ task-specific loss functions, such as cross-entropy loss for classification tasks and mean squared error (MSE) for mixed text detection. Additionally, we utilize techniques such as dropout regularization to prevent overfitting and gradient clipping to stabilize training.

The RoBERTa Base model is fine-tuned separately for each subtask, with hyperparameters tuned using grid search or random search techniques. We split the dataset into training, validation, and test sets to facilitate model training and evaluation, ensuring that the model generalizes well to unseen data.

4 Results

We present the performance metrics achieved by our machine-generated text detection system on each of the subtasks: binary human-written vs. machine-generated text classification (Subtask A), multi-way machine-generated text classification (Subtask B), and human-machine mixed text detection (Subtask C). The evaluation metrics include F1 score (macro and micro) and accuracy.

4.1 Subtask A: Binary Classification

Epoch	F1 Macro	F1 Micro	Accuracy
1	0.85431	0.85463	0.85463
2	0.81726	0.81918	0.81918
3	0.80595	0.80859	0.80859

Table 2: Performance Metrics for Subtask A (Monolingual)

Epoch	F1 Macro	F1 Micro	Accuracy
1	0.65693	0.69128	0.69128
2	0.71308	0.72564	0.72564
3	0.64664	0.68958	0.68958

Table 3: Performance Metrics for Subtask A (Multilingual)

From the tables of results of Subtask A, we can observe that in Monolingual case we get a better accuracy and F1-Score. The scores are in the range of 0.8 to 0.85, which decrease with the increase in number of epochs. Hence, the best score is observed in the model trained only for 1 epoch. This pattern indicates that the model can possibly be overfitting on the data.

In case of Multilingual, we observe the best scores in the model trained for 2 epochs.

4.2 Subtask B: Multi-Way Classification

Epoch	F1 Macro	F1 Micro	Accuracy
1	0.80686	0.8065	0.8065
2	0.85083	0.851	0.851
3	0.83146	0.83117	0.83117
4	0.84295	0.84328	0.84328
5	0.86936	0.86794	0.86794

Table 4: Performance Metrics for Subtask B

From the results of Subtask B, we can observe that the model trained for epoch 5 performs the best. Based on the Micro and Macro F1 scores in the table, we can observe that since the Macro F1 increasing over epochs indicates the model is improving at predicting each individual class correctly. The Micro F1 is also increasing which suggests that overall predictive capability on the aggregate data is improving. However, Micro F1 can be influenced by performance on majority classes.

4.3 Subtask C: Human-Machine Mixed Text Detection

Epoch	MSE
1	63.13998
2	33.09197
3	28.01411
4	30.04774
5	27.12254

Table 5: Performance Metrics for Subtask C

From the results of Subtask C, we can observe that the provided mean squared error (MSE) values indicate the model loss decreased with each epoch of training from an initial value of 63.13998 at epoch 1 to 27.12254 at epoch 5. The difference in MSE between epoch 1 and 2 implies that the model is overfitting on the training data. The lowest MSE score is observed in Epoch 5.

5 Conclusion

In this study, we proposed a machine-generated text detection system capable of addressing three subtasks: binary human-written vs. machine-generated text classification (Subtask A), multi-way machine-generated text classification (Subtask B), and human-machine mixed text detection (Subtask C).

Our system leverages the RoBERTa Base model, fine-tuned on a diverse dataset comprising texts from various domains, languages, and sources. Through extensive experimentation and evaluation, we achieved promising results (Wang et al., 2024b) across all subtasks.

For Subtask A, our system demonstrated robust performance in distinguishing between human-written and machine-generated texts, achieving high F1 scores and accuracy across multiple epochs. Similarly, in Subtask B, where the classification involves identifying the source language model among multiple candidates, our system achieved competitive performance, indicating its effectiveness in multi-way classification scenarios.

In Subtask C, where the objective is to detect boundaries between human-written and machine-generated segments within a single text, our system showed reasonable performance, albeit with some room for improvement. Future work could focus on refining the model architecture and exploring additional features to enhance the system's performance in this challenging task.

Overall, our study highlights the importance and feasibility of developing automatic systems for detecting machine-generated text, contributing to efforts aimed at mitigating the potential misuse of large language models in various contexts.

Iran University of Science and Technology
h_sabzevari@elec.iust.ac.ir, mo_rostamkhani97@comp.iust.ac.ir, sauleh@iust.ac.ir

Abstract

This study investigates the performance of the zero-shot method in classifying data using three large language models, alongside two models with large input token sizes and the two pre-trained models on legal data. Our main dataset comes from the domain of U.S. civil procedure. It includes summaries of legal cases, specific questions, potential answers, and detailed explanations for why each solution is relevant, all sourced from a book aimed at law students. By comparing different methods, we aimed to understand how effectively they handle the complexities found in legal datasets. Our findings show how well the zero-shot method of large language models can understand complicated data. We achieved our highest F_1 score of 64% in these experiments.

1 Introduction

Becoming skilled at presenting a legal case is essential for aspiring lawyers. It requires understanding not only the relevant legal areas but also using advanced reasoning tactics like making analogies and spotting hidden contradictions. (Chalkidis et al., 2022). Despite efforts to set standards for modern NLP models in legal language understanding, there still aren't complex tasks focusing on argumentation in legal matters.(Bongard et al., 2022)

The dataset utilized in this study was gathered from *The Glannon Guide To Civil Procedure* by Joseph Glannon (Glannon, 2018) in English. Each sample within the dataset comprises a question, a solution, and an introduction elaborating on the provided solution. The objective is to identify whether the given answer, derived from the introduction text, accurately addresses the question.

This paper explores various approaches to address the challenge of handling lengthy and intricate data, which can be challenging for human comprehension. Initially, we evaluated two models—Longformer (Beltagy et al., 2020) and Big Bird (Zaheer et al., 2021) —known for their effectiveness in classifying data with large input tokens. Subsequently, we assessed the performance of two pre-trained models, Legal-RoBERTa (Chalkidis* et al., 2023) and Legal-XLM-RoBERTa (Niklaus et al., 2023) for legal data using the original code. Finally, we compared the performance of three large language models —GPT 3.5, Gemini, and Copilot— using the zero-shot method on the test dataset.

We recognized the significant impact of leveraging the capabilities and extensive capacity of large language models on analyzing data, especially those focusing on specific topics or lengthy content. Looking ahead, our goal is to improve prompts further to achieve superior results not only for this task but also for similar works. Further details regarding the implementation can be found in this GitHub repository.

2 Background

2.1 Task Setup

As previously mentioned, the original dataset for this task is sourced from *The Glannon Guide To Civil Procedure*. Each sample within the dataset comprises the following components:

1. Question 2. Answer 3. Label 4. Analysis 5. Complete Analysis 6. Explanation

It's noteworthy that "Analysis" and "Complete Analysis" were absent in the test data. The data split involves allocating the initial 80% of questions from each chapter to the training set, the subsequent 10% to the validation set, and the final 10%—typically more challenging questions—to the test set. The final dataset consists of 848 entries.

In this task, the inputs to the model consist of the "Question," "Explanation," and "Answer" values, while the output of the model is represented by the "Label." If the model determines that the

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 922–926

answer provided for the question aligns with the explanation, the output label will be 1; otherwise, it will be 0. The objective of this task is to assess the model's reasoning capabilities, particularly its ability to analyze legal issues effectively.

2.2 Related Work

2.2.1 Pre-trained Legal Language Models

Numerous studies have been conducted in the realm of legal issues. Given the challenges posed by comprehending lengthy texts within this domain using existing models, pre-trained language models have been tailored to address this need. One such model is the Legal-BERT model (Chalkidis et al., 2020), which is also employed in this paper. This study introduces a specialized model aimed at facilitating NLP-based legal research by fine-tuning the original BERT model for legal applications. (Li et al., 2023) introduces SAILER, a novel pre-trained linguistic model with a unique architecture designed for legal case retrieval. Furthermore, (Cui et al., 2023b) provides a comprehensive survey of existing Legal Judgment Prediction (LJP) tasks, datasets, and models within the legal domain, encompassing an overview of 8 pre-trained models across 4 languages as part of the LJP. Moreover, an end-to-end methodology is introduced by (Louis et al., 2023) for generating long-form answers to statutory law questions, addressing limitations in existing Legal Question Answering (LQA) approaches.

2.2.2 Domain-Specific LLMs in Law

A Large Language Model (LLM), such as ChatGPT, is remarkable for its ability to handle general-purpose language generation and a variety of other NLP tasks. Domain-specific LLMs are versatile models optimized to excel at specific tasks defined by organizational standards. They further empower lawyers to expand their understanding and explore specialized legal domains. For instance, (Colombo et al., 2024) is the first LLM designed explicitly for legal text comprehension and generation with 7 billion parameters. To empower the legal field, (Cui et al., 2023a) presents ChatLaw, an open-source legal LLM built with a high-quality, domain-specific fine-tuning dataset. The focus of (Savelka et al., 2023) is evaluating GPT-4's effectiveness in generating explanations for legal terms – specifically, whether they are accurate, clear, and relevant to the surrounding legislation.

3 System Overview

3.1 Preprocessing Data

Our dataset comprises 666 samples for the training set, 84 samples for the validation set, and 98 samples for the test set. Initially, we excluded the columns "Analysis" and "Complete Analysis" from both the training and validation datasets as they were absent in the test data. Afterward, we analyzed to determine the distribution of class labels 0 and 1, revealing a notable class imbalance, with the number of instances belonging to class 0 nearly three times higher than those of class 1.

To address this issue, various approaches can be employed. In this study, we opted to mitigate the class imbalance using the focal loss function as our loss function. Our investigation demonstrates the efficacy of focal loss in rectifying class imbalance, enhancing the performance of classes with limited training samples, offering adaptability in adjusting the learning process, and attenuating the impact of noisy data.

3.2 Model

3.2.1 Pre-trained Models

In this study, we tackled the challenge of dealing with long sets of data. To overcome this, we looked into using two models designed to handle large inputs: the Longformer and Big Bird models. These models can handle up to 4096 tokens, which is much more than the BERT model. We also used two pre-trained models specifically trained for legal data: Legal-RoBERTa and Legal-XLM-RoBERTa. These models, like Legal-BERT (Chalkidis et al., 2020), were trained on various legal documents and cases.

Our aim is straightforward: to compare the performance of these models and understand how using pre-trained models with larger input sizes impacts their effectiveness. Through this analysis, we aim to gain insights into the optimal approaches for managing complex legal datasets.

To address the issue of unbalanced data, we implemented the focal loss function, a method that has shown promising outcomes in previous research (Lin et al., 2018) (Wang et al., 2022). The Focal Loss function formally incorporates a factor of $(1 - p_t)^\gamma$ into the standard cross-entropy criterion. This adjustment diminishes the relative loss for accurately classified examples ($p_t > 0.5$), thereby intensifying the focus on challenging instances that

are misclassified.

$$CE(p_t) = -log(p_t) \quad (1)$$

$$FL(p_t) = -(1-p_t)^{\gamma} log(p_t) \quad (2)$$

There is a tunable focusing parameter $\gamma \geq 0$. Figure 1 illustrates the varied impact of this parameter across a range of values.

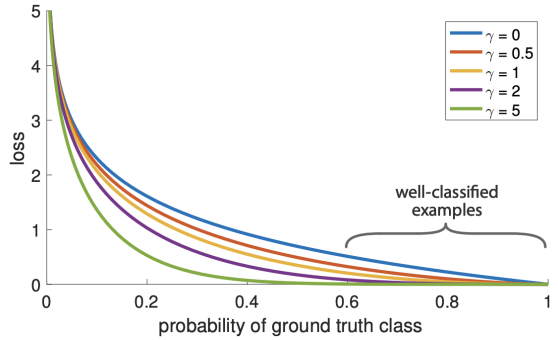

Figure 1: Comparison between cross entropy and focal loss

3.2.2 Large Language Models

In addition, we leveraged three popular large language models to assess their performance within the given task: OpenAI's GPT 3.5 model, Google's Gemini model, and Bing's Copilot model. Later, we formulated the task in the form of prompts, refined them through prompt engineering techniques, and presented them to the large language models. Our objective was to extract the desired answer (0 or 1) from the models' responses, thereby assessing their performance and capabilities in handling the task. We conducted extensive tests on numerous prompts to identify the most effective ones. Employing prompt engineering methodologies alongside large language models, we refined these prompts to enhance their performance and effectiveness in achieving our objectives.

4 Experimental setup

We utilized a dataset of 848 data points, dividing it into 80% for the training dataset, 10% for the validation dataset, and 10% for the test dataset. Our experimental approach involved exploring three main inquiries:

1. Exploration of Longformer and Big Bird models, tailored to effectively process lengthy data inputs.

2. Utilization of pre-trained models for legal contexts, including Legal-RoBERTa and Legal-XLM-RoBERTa, to ascertain their efficacy in legal text analysis.

Hyperparameter	Value
Optimizer	AdamW
Learning Rate	5e-5
Epochs	3
Batch Size	1
Loss Function	Focal Loss

Table 1: Hyperparameter values

Model	Accuracy	$\mathbf{F_1}$
Longformer	**0.79**	0.44
Big Bird	**0.79**	0.44
Legal-BERT	0.75	**0.58**
Legal-RoBERTa	**0.79**	0.44
Legal-XLM-RoBERTa	0.78	0.43

Table 2: Accuracy and macro F1-score of first and second parts' models on the validation set

3. Implementation of the Zero-shot methodology with prompt feeding across three distinct models: GPT 3.5[1], Gemini[2], and Copilot[3], aimed at exploring their adaptability and performance across diverse tasks.

In the initial phase, we employed the AdamW optimizer function with a learning rate set at 5e-5 for both models, conducting training over 3 epochs. The specific values chosen for each hyperparameter are listed in Table 1.

Then, in the second phase, we adapted the original code from the article with the necessary modifications.[4] The original code featured the utilization of Sliding Window Simple (SWS) and Sliding Window Complex (SWC) methods with the Legal-BERT model. We made adjustments to certain sections of the code to ensure compatibility with the test input data. Throughout our evaluation, we utilized the macro F_1 score as the primary evaluation metric.

In the final phase of our experiments, we used the API keys provided by OpenAI and Google. Unfortunately, despite our efforts, we encountered challenges locating the official API for Bing. Given its superior accuracy compared to other models, we decided to manually record the results of the test dataset. Throughout this phase, we employed a variety of prompts and iteratively refined them.

[2] https://gemini.google.com/app
[3] https://www.bing.com/chat
[4] https://github.com/trusthlt/legal-argument-reasoning-task

Model	Accuracy	F_1
GPT 3.5	**0.69**	0.59
Gemini	0.44	0.44
Copilot	0.67	**0.64**

Table 3: Macro F1-score of large language models on the test set

Our investigation revealed that incorporating terms such as "step by step" or asking for explanations of the inference steps to achieve the desired outcome positively impacted the model's performance. Furthermore, we encountered limitations in prompt completeness due to the token size constraints inherent in the input models. For instance, Bing's Copilot supported a maximum input size of 4000 characters, which proved insufficient for processing our long samples. Here is an example of an input prompt:

I will provide a question, an answer, and an explanation. Your task is to determine if the answer is correct based on the explanation provided. After reading the explanation, please respond with 'yes' if the answer is correct, or 'no' if it is incorrect.

Question: {question}
Proposed Answer: {answer}
Explanation: {explanation}

Is the proposed answer correct based on the explanation? (yes or no)
Please provide your detailed reason for your choice.
Then, reevaluate and check whether the selected answer is logical or not.
Please use the following format:
<selected_answer>: yes/no
<reason>: your reason for the initial choice
<reason for logical check>: your reason for reevaluation

5 Results

After completing the aforementioned three phases, our investigation revealed that despite fine-tuning, existing models struggled to effectively analyze lengthy data within challenging legal contexts, encountering training process issues and yielding suboptimal outputs. Moreover, the most promising result emerged from fine-tuning the Legal-BERT model, serving as the baseline. While we continue to analyze the underlying reasons for this outcome, initial observations suggest that the learning challenge may be linked to the specific characteristics of the dataset employed. Table 2 presents the performance metrics of the models from the initial two phases, evaluated on the validation dataset.

When it comes to evaluating the results of the zero-shot method, we identified its considerable potential and Bing's Copilot model emerged as the top performer, surpassing expectations. Following suit, the GPT 3.5 model presented moderate performance, while the Gemini model fell short of expected levels. The success of the Copilot model lies in its ability to address previous challenges associated with GPT models by leveraging real-time information accessible through the internet. Table 3 presents the results achieved from employing this method on the test dataset, representing the unofficial results submitted during the post-evaluation phase.

6 Conclusion

In this paper, we present methods designed for classifying lengthy legal cases. We divided our exploration into three main parts:

Firstly, we looked into models with large input token sizes such as Longformer and Big Bird. Secondly, we examined pre-trained models specifically fine-tuned for legal data, such as Legal-RoBERTa and Legal-XLM-RoBERTa. Lastly, we tested the zero-shot method across three major language models.

Among these methods, we found that the zero-shot technique and Bing's Copilot model showed the most promising performance. As for future works, we can explore techniques like data summarization, collaborative approaches such as the round table technique, trying various hyperparameters, and refine prompts to further enhance model performance. These efforts have the potential to advance the effectiveness of classification tasks in legal contexts.

As a future work, it would be valuable to explore additional large language models. These models offer extensive capabilities, especially in summarizing lengthy datasets, which could help evaluate various models' performance. However, it is necessary to note that during summarization, some important details might be overlooked.

Another avenue for future research involves testing the effectiveness of a multi-model approach.

(Chen et al., 2023) This method entails bringing together different large language model agents in a round table conference format. This setup encourages diverse perspectives and discussions to foster consensus. By adopting this approach, researchers can tap into the combined intelligence of multiple models, potentially enriching analysis across various tasks and domains. In this competition, our team achieved the 17th rank out of 21 groups. Our only submission during the evaluation phase utilized the basic prompt and the GPT model. However, significant improvements were made during the post-evaluation phase, resulting in a much higher level of accuracy.

Abstract

The Large Language Models (LLMs) exhibit remarkable ability to generate fluent content across a wide spectrum of user queries. However, this capability has raised concerns regarding misinformation and personal information leakage. In this paper, we present our methods for the SemEval2024 Task8, aiming to detect machine-generated text across various domains in both mono-lingual and multi-lingual contexts. Our study comprehensively analyzes various methods to detect machine-generated text, including statistical, neural, and pre-trained model approaches. We also detail our experimental setup and perform a in-depth error analysis to evaluate the effectiveness of these methods. Our methods obtain an accuracy of 86.9% on the test set of subtask-A mono and 83.7% for subtask-B. Furthermore, we also highlight the challenges and essential factors for consideration in future studies.

1 Introduction

Recent advancements in Large Language Models (LLMs) have facilitated a wide range of applications, notably in content generation (Chung et al., 2023). While LLMs offer creative and informative content generation capabilities, concerns such as misinformation, fake news, personal information leakage, legal and ethical issues have emerged (Chen and Shu, 2023; Li, 2023; Kim et al., 2023). Consequently, detecting machine-generated text has become a crucial task to address these aforementioned challenges.

The identification of machine-generated text is still an open challenge because of its overlapping similarities with human-written text. The current text generation models produce text that is strikingly similar to human language in terms of grammaticality, coherency, fluency, and utilization of real-world knowledge (Radford et al., 2019; Zellers et al., 2019; Brown et al., 2020). However, variations in sentence length, the presence of noisy data, and the generation of incomplete sentences are common indicators of machine-generated text.

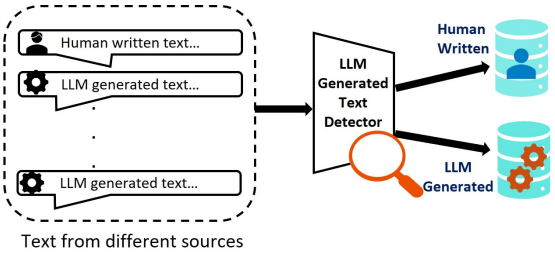

Figure 1: Block diagram for machine-generated text detection.

1.1 Essence of LLM generated text detection

LLMs' open-ended text generation techniques have sparked various concerns across domains (Jo et al., 2023). It has been demonstrated that LLMs have the potential to generate misinformation and fake news (Chen and Shu, 2023), which can be catastrophic in healthcare (Zhou et al., 2023), public safety, education, and finance. Moreover, LLMs can generate text without source attribution, raising the risk of plagiarism (Quidwai et al., 2023), and can include legal and ethical concerns too (Li, 2023).

Furthermore, when LLMs are used in enterprise applications there can be concerns of intellectual property rights infringement (Zhao et al., 2024) such as generated content might contain trademarks or branding elements (Ren et al., 2024). Lastly, LLMs can aggravate security concerns by generating phishing emails (Bethany et al., 2024), fake reviews (Adelani et al., 2020), hallucinations (Huang et al., 2023), biased content (Fang et al., 2023; Dai et al., 2024), and personal information leakage (Kim et al., 2023).

1.2 Tasks

The main objective of the competition is to differentiate text based on the source of its generation

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 927–934

method (see Figure 1), with specific importance given to machine-generated text and human-written texts (Wang et al., 2024a). The competition consists of three tasks Subtask A, Subtask B, and Subtask C. Our study focuses on Subtasks A and B.

Subtask A. Binary Human-Written vs. Machine-Generated Text Classification: This task aims to distinguish between human-written or machine-generated text. This task acts as a binary classification. Subtask A is again subdivided into the following two categories. *Mono-lingual:* The text is in the English language. *Multi-lingual:* The text is in English, Chinese, Russian, Urdu, Indonesian, Arabic, and Bulgarian languages.

Subtask B. Multi-Way Machine-Generated Text Classification: This task aims to classify the given text into six distinct classes, which are 'human', 'chatGPT', 'cohere', 'davinci', 'bloomz', 'dolly' with each class representing the source of its generation. This task acts as a multi-class classification.

The key contributions of this work include, 1) We present a comprehensive analysis of various machine-generated text detection techniques for multi-domain mono and multi-lingual data, 2) We provide a detailed experimental setup for statistical, neural, and pre-trained models along with corresponding error analysis, 3) We emphasize the discussions and future perspectives derived from the findings of the study.

2 Related Work

Recent works on LLM-generated[1] text detection has shown promising results. Statistical methods are used to detect the LLM-generated text by utilizing the entropy (Shen et al., 2023), and N-gram frequency (Tassopoulou et al., 2021). Some other studies uses the fact that language models assign high probability for the repeated sentences which is often AI model generated and ranks the AI model generated sentence Krishna et al. (2022). In a study, OpenAI has trained a classifier to detect LLM-generated text using the RoBERTa-based model (Solaiman et al., 2019).

Some of the widely-used methods adopted the GPT detectors such as OpenAI detection classifier[2], GPTZero[3], and ZeroGPT[4]. Another variant is DetectGPT (Mitchell et al., 2023), which works on the assumption of LLM-generated text lies in the negative curvature region of the log-likelihood. Using this approach, DetectGPT perturbs the input text using masked language models, such as BERT (Devlin et al., 2018), BART (Lewis et al., 2019), T5 (Raffel et al., 2019) and compare the log probability of the text and masked filled variants. Similarly, few works utilized the different decoding strategies including top-k, nucleus, and temperature sampling to generate the text from GPT2 and BERT based models employed to perform binary classification to label text as human-written or machine generated (Ippolito et al., 2020).

Recently, watermarking methods have been used in enterprises to protect the intellectual properties and fair use of the generation models. However these techniques simplify the detection of the LLM-generated output text by synonym replacement over generated outputs and text level posthoc lexical substitutions (Li et al., 2023; Sadasivan et al., 2023), and soft watermarking was introduced in (Kirchenbauer et al., 2023) using green and red token lists. Hidden space operations were also introduced by injecting secret signals into the probability vector of each target token (Zhao et al., 2023).
Bhattacharjee and Liu (2023) proposed a method which triggers when the text has common words randomly assembled as it is easier to find than identifying unique and rare tokens. Sadasivan et al. (2023) focused on zero-shot AI text detection by using two clusters depending on watermarked or not. Another study (Wang et al., 2024c), proposed a benchmark framework consists of an input module, a detection module and an evaluation module for machine generated text detection against human-written text. In contrast to existing works, this study presents the multi-domain multi-lingual machine generated text detection techniques.

3 Datasets

This section given an overview of the dataset utilized and the corresponding analysis.

3.1 Source and acquisition

The task organizers provided the dataset[5] for all the tasks (§1.2). The dataset is an extension of the M4 dataset (Wang et al., 2024b). The dataset provided for this task consists of machine-generated text and human-written text. The human-written text is gathered from various sources such as

[1]We interchangeably use the terms 'LLM-generated' or 'machine-generated'

Table 1: SemEval 2024 Task 8 data statistics.

Wikipedia, WikiHow (Koupaee and Wang, 2018), arXiv, and PeerRead (Kang et al., 2018), Reddit (Fan et al., 2019) for English, Baike and Web question answering (QA) for Chinese, news for Urdu, news for Indonesian and RuATD (Shamardina et al., 2022) for Russian. On the other hand, the machine-generated text is gathered by prompting different multi-lingual LLMs: ChatGPT (Achiam et al., 2023), BLOOMz (Muennighoff et al., 2023), textdavinci-003, FlanT5 (Chung et al., 2022), Cohere, Dolly-v2, and LLaMa (Touvron et al., 2023).

3.2 Exploratory data analysis

Preliminary analysis of data is a crucial step that is required to understand the dataset characteristics. We have observed that the number of sentences in each task data varies from 1 to a few hundred. Particularly, a few samples in the multi-lingual training data consist of empty samples as well. Another point to note is, that the number of sentences in the multi-lingual train and development varies a lot, which indicates the dataset obtained from different sources. There are a few cases, where some of the samples consist of more than 38k tokens in a single sample. With these observations, to experiment on cleaned data, we employ two types of pre-processing settings. The former (Version-1) applies heuristic-based pre-processing and sub-word removal, whereas the latter (Version-2) applies only heuristic-based pre-processing. We reported the detailed analysis of the dataset statistics in Table 1.

4 System Overview

This section offers various approaches employed to perform machine-generated text identification. Our approaches are categorized into 1) statistical, 2) neural, and 3) pre-trained models.

4.1 Methodology

4.1.1 Statistical methods

To understand the effectiveness of statistical models, we experimented with a wide range of statistical models and their variants including ensemble approaches. The statistical models including Logistic Regression (LR), SVM, MLP, LightGBM and some of the ensemble models detailed in Table 3.

4.1.2 Neural methods

Neural networks have demonstrated remarkable success in various domains, from image and speech recognition to natural language processing. We experiment with Convolutional Neural Networks (CNN), Recurrent Neural Networks (RNN), Long Short-term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) and their combinations. We utilize FastText [(Joulin et al., 2016), (Bojanowski et al., 2017)] embeddings to capture hierarchical patterns within the text data.

4.1.3 Pre-trained models

Self-supervised pre-trained models have been effective for the classification tasks. In this study, we experiment with a wide range of pre-trained models trained on either open-source or language model-generated data. The pretrained models including BERT (Devlin et al., 2018), RoBERTa (Liu et al., 2019), DistilRoBERTa base (Sanh et al., 2019), RoBERTa Base OpenAI Detector (Solaiman et al., 2019), XLM RoBERTa (Conneau et al., 2019).

4.2 Experimental setup

For all the experiments, we have utilized the default data splits provided by the task organizers. For all the statistical models, four types of embeddings were employed namely counter vectors,

Models	Subtask - A (Monolingual)				Subtask - A (Multilingual)				Subtask - B			
	Count	Word	N-gram	Character	Count	Word	N-gram	Character	Count	Word	N-gram	Character

word, n-gram, character-level TF-IDF vectors and spaCy embeddings. Moreover, we used the default configurations mentioned in the scikit-learn[6]. Whereas for pre-trained models the list of hyper-parameters details are listed in Table 6. We have not performed any hyperparameter-tuning for our experiments. We conduct most of our experiments using four Nvidia GeForce RTX 2080 Ti (11GB) GPUs. To evaluate all the models, we reported the 'Accuracy' scores.

5 Results and Analysis

This section provides a detailed analysis of the models utilized for subtasks A and B. Our experiments aim to showcase the effectiveness of several machine-generated text detection techniques.

5.1 Subtask A Mono-lingual

We experiment with the statistical and neural models to perform subtasks A and B. All the statistical and ensemble models experimental results on development data are mentioned in Table 2 and Table 3. The results on test data mentioned in Table 7. In the case of statistical models, Logistic Regression obtains the superior performance of 71.2% accuracy using n-gram level TF-IDF embeddings compared to other methods on the development dataset. Whereas in the case of the performance of the test set, our ensemble surpass all the remaining models. We built the ensemble model by creating a custom tokenizer by combining spaCy embedding and TF-IDF with n-gram level range of (3-5) embedding. Moreover, we trained an ensemble model with Naive Bayes, SGDClassifier[7], and LightGBM models which gave 86.9% accuracy on the test set. We experiment with a few neural models with fastText embeddings and out of them CNN+fastText outperforms the other models. We have listed results in Table 4. Moving ahead, we fine-tuned transformer-based pre-trained language models like RoBERTa Base OpenAI detector (Solaiman et al., 2019), which gave 76.6% accuracy on the development set and 78.7% accuracy on test set, BERT base model which gave 82.5% accuracy on the development set and 71.7 % accuracy on test set. The results are detailed in Table 5. Furthermore, we use the pre-processing steps discussed in Section 3.2.

[6] https://scikit-learn.org/stable/supervised_learning.html

[7] https://scikit-learn.org/stable/modules/generated/sklearn.linear_model.SGDClassifier.html

Model	Batch size	Epochs	Vocab size
BERT Base	16	10	30522
OpenAI Detector	16	10	50265
BERT Multilingual Base	8	3	30522
XLM-RoBERTa	8	5	250002
RoBERTa Large	4	2	50265
DistilRoBERTa Base	16	10	29409

Table 6: Experimental setup for pre-trained models. For all the models max source length set to 512 and learning rate $5e^{-5}$.

Fine-tuned the BERT base model with version-1's pre-processed data gave 80.7% on the development dataset and 71.7% on the test set. Then we fine-tuned the BERT base model with version-2 pre-processed data gave 81.3% on the development dataset and 69.7% on the test set. We secured 24^{th} rank out of 137 participants.

We observed that statistical models that performed modestly on the development set generalized effectively to the test set, whereas some pre-trained language models, despite performing well on the development set, struggled to generalize on test set. This discrepancy may stem from the differing sources of the training and development sets ('arxiv', 'reddit', 'wikihow', 'wikipedia', 'peerread') compared to the test set, potentially causing over-fitting of the pre-trained models on the training data and hindering their performance on the test set.

5.2 Subtask A Multi-lingual

For subtask A multi-lingual, we fine-tuned BERT Multilingual Base and XLM RoBERTa base models. BERT Multilingual Base along with version-2 pre-processed data resulted in 62.2% accuracy on the development set and 73.8% accuracy on the test set. Moreover, despite the decent performance of XLM-RoBERTa on the development set with 76.6% accuracy, the performance of on test set is sub-par. Furthermore, the BERT Multilingual base gave 62.2% accuracy on the development set and 73.1% accuracy on the test set. As mentioned in Section 3.2, we observed that, the multi-lingual data consists of empty samples. Hence, we fine-tuned the BERT Multilingual Base model on the version-2 of the pre-processed data, which helped in improving the accuracy of the test set even if we had the same accuracy on development set.

5.3 Subtask B

Subtask B deals with multi-class classification task. For this task, we have conducted experiments using the statistical models as well as the pre-trained language models. MLP model gave the best accuracy on the development set with 60.9% accuracy. Our ensemble approach obtains 70.8% accuracy on the development set and 65% accuracy on the test set. Moreover, we experimented with RoBERTa Base OpenAI Detector gave 75.3% on the development set and 83.7% accuracy on the test set. Whereas, the DistilRoBERTa base obtains 73.3% accuracy on the development set and 79.1% accuracy on the test set and secured 17^{th} rank out of 86 participants.

Task	Model	Accuracy
Subtask - A (Mono)	Baseline	0.74
	Naive bayes + SGDClassifier + LightGBM*	**0.869**
	RoBERTa Base OpenAI Detector	0.787
	BERT Base_v1	0.717
	BERT Base	0.715
	BERT Base_v2	0.697
Subtask - A (Multi)	Baseline	0.72
	BERT Multilingual Base_v2	**0.738**
	BERT Multilingual Base	0.731
	XLM-RoBERTa *	0.50
Subtask - B	Baseline	0.75
	RoBERTa Base OpenAI Detector	**0.837**
	DistilRoBERTa Base*	0.791
	Naive bayes + SGDClassifier+ LightGBM	0.650

Table 7: Test set accuracy results; *entries are the official submission models of the competition.

6 Conclusions

The study explores different methodologies for detecting machine-generation text, leveraging statistical, neural, and pre-trained models. We observe that the ensemble models are more effective in classifying the mono-lingual data (Subtask-A mono), while models trained on GPT2-text surpass other models in multi-class classification.

7 Limitations

In our study, due to computational constraints, we have not performed experiments with any large language models. Current evaluation has been limited to conventional ML and pre-tained language models. Some of our experimental methods perform better on development data, where as there is a significant drop on test data, this may result in lack of generalization.

Abstract

The central aim of this experiment is to establish a system proficient in predicting semantic relatedness between pairs of English texts. Additionally, the study seeks to delve into diverse features capable of enhancing the ability of models to identify semantic relatedness within given sentences. Several strategies have been used that combine TF-IDF, syntactic features, and similarity measures to train machine learning models to predict semantic relatedness between pairs of sentences. The results obtained were above the baseline with an approximate Spearman score of 0.84.

1 Introduction

The prediction of semantic relatedness between texts is a crucial task with applications in various natural language processing domains. In this study, our focus is on creating a system capable of predicting semantic relatedness across languages while investigating the features that contribute to this prediction. The development of such a system is not only beneficial for understanding semantic relationships within texts but also holds promise for enhancing deep learning models in tasks such as assessing sentence representation methods, question answering, and text summarization (Abdalla et al., 2023).

Despite the advancements in word representation techniques, especially using embeddings, the complexity of human languages presents persistent challenges in accurately capturing semantic relatedness. Our experiment primarily concentrates on the English language, acknowledging its significance as a widely used language in various applications. The inherent difficulty in identifying and quantifying the shared elements between two texts necessitates a thoughtful exploration of diverse features and methodologies.

In the subsequent sections, we describe the dataset used for this experiment, outline the methodology employed for predicting semantic relatedness, discuss the results obtained, and conclude with insights into the implications and potential future directions of this research. The research will delve into exploring features that enhance the prediction of semantic textual relatedness by developing several strategies concerning feature extractions and model training.

2 Literature Review

The complexity of machine-based human language modeling involves a nuanced understanding of various linguistic aspects, notably Pragmatics and Semantics (Abdalla et al., 2021; Miller, 1995). This research specifically emphasizes semantic modeling, with a focus on semantic relatedness, as opposed to the more commonly studied word similarity (Islam et al., 2012; Atoum and Otoom, 2016; Yum et al., 2021).

Traditionally, approaches like Bag of Words have been explored (Islam et al., 2012; Feng F. Jin, 2008), but they often fall short in achieving high performance for semantic relatedness tasks. WordNets models, while prioritized, face limitations in language coverage and comprehensive embedding of semantic relationships (Jordan J. Boyd-Graber, 2005).

A notable contribution by (Gomaa, 2019) introduced a model utilizing multiple similarity features, including cosine similarity and Jaccard. Their multi-layer architecture demonstrated that employing various similarity features collectively yields significantly better results than applying each measure in isolation. However, the approach did not add or consider syntactic features for the enhancement of the semantic prediction on textual data.

Recent advancements in deep learning models exhibit superior semantic similarity and relatedness performance. However, there remains a scarcity of research focusing on the distinctive features between Semantic Textual Similarity (STS) and Se-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 935–939

mantic Textual Relatedness (STR), and how models can better capture the nuances of semantic relatedness between words and sentences (Kolb, 2005).

3 Task Description

The primary objective of this experiment is to create a system that can predict the semantic relatedness between pairs of texts across various languages but also explore the different features that could help models identify semantic relatedness between given sentences. Although the current experiment is focused on English, the development of such a system holds the potential to enhance deep learning models for various tasks, including assessing sentence representation methods, question answering, and text summarization (Abdalla et al., 2023).

4 Data Description

SemEval 2024 Track 1 utilized data provided by organizers, featuring sentence pairs in training, development, and test sets. Each instance is annotated with a score indicating semantic textual relatedness, which ranges from 0 (unrelated) to 1 (related). Table 1 presents statistics about the dataset, while Figure 1 illustrates the distribution of scores, including the counts for scores of 1.0, 0.0, >0.80 and <0.50, in the training and development set.

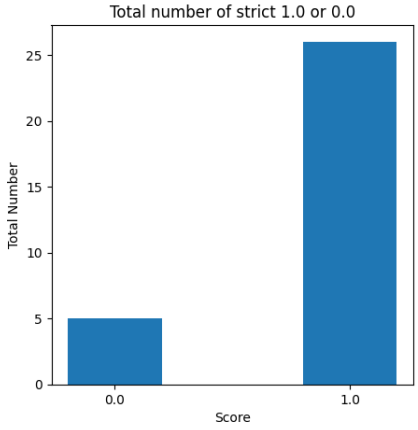
Table 1: Dataset Information

Dataset	Total Pairs	Pairs with Score 1.0	Pairs with Score 0.0
Training	5500	25	5
Development	250	7	123
Test	2600	-	-

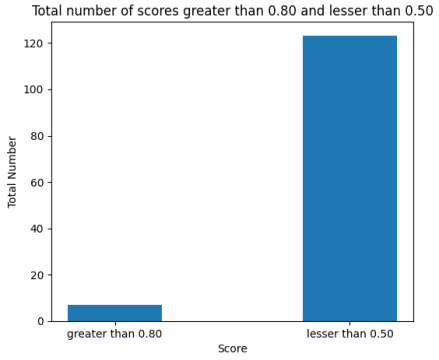
Table 2 displays sample instances, with additional details available in (Abdalla et al., 2021; Ousidhoum et al., 2024b,a).

Instance	Score
It that happens, just pull the plug. if that ever happens, just pull the plug.	1.0
The two little girls jump on the bed. A little girl is jumping down a sandy hill.	0.5
you're taking a sweater in a shop. to taking the life of Conor Greenleaf.	0.03

Table 2: Sample instances of data set



(a) Number of strict 1.0 and 0.0 in the Train set.



(b) Number of scores greater than 0.80 and lesser than 0.5 in the Dev set.

Figure 1: Train and dev scores comparison.

5 Methodology

In this study, our objective is to predict semantic textual relatedness between two texts. We made two key assumptions: firstly, we refrained from preprocessing the corpus to preserve sentence structure, essential for information retrieval and semantic identification (Hirst, 1987).

Secondly, we intentionally excluded Large Language Models (LLMs) from experiments, anticipating challenges in interpreting specific features contributing to semantic identification due to their contextual abilities and complexity (Turton et al., 2020). To extract diverse features, we employed various distance measures, including Jaccard distance, Cosine similarity, Levenshtein distance, and Word Mover's Distance (WMD) (Boubacar, 2014; Kusner et al., 2015; Su et al., 2008). These measures compute the similarity between text pairs based on common words, term vectors, and the minimum distance embedded words need to travel between documents. Feature extraction utilized the

bag-of-words (BoW) technique, specifically Term-Frequency Inverse Document Frequency (TF-IDF) (Hakim et al., 2014), and hidden vectors from a pre-trained SentenceBert model to compute cosine similarity (Reimers and Gurevych, 2019).

Additionally, syntactic features were extracted, parsing each sentence pair to identify words with the same dependency role. This approach resulted in three features: probability of exact word matching, probability of unique words, and probability of related words. The rationale was to explore the impact of words with common dependency roles on predicting semantic relatedness and assess the effect of their absence on the English corpus.

The reason behind using traditional models such as Gradient Boost is that this type of model can easily handle non-linear relationships in texts, which is crucial while capturing semantic relatedness but also can deal with imbalanced datasets (Natekin and Knoll, 2013).

A diagram of our methodology as well as the source code is freely available on GitHub. The link can be found in the Appendix section.

6 Results

The performance metrics of the different models submitted for semantic relatedness are presented. The evaluation metrics include solely the Spearman score. Even though the models submitted were Fasttext and Naive Bayes, during the training phase Linear Regression, XGradient Boost, Random Forest, and an ensemble of two traditional models were trained.

6.1 Train phase

During the training phase, several models were tested using different strategies, and in Table 3 we display the performance for each model. The main strategy that gave the results presented in this document has been explained earlier in the methodology section.

Model	Spearman
Linear Reg.	0.8512
Gradient Boost	**0.8527**
XGB	0.8467
Random Forest	0.8481
Ensemble Model	0.8521

Table 3: Training Model Performances

6.2 Development phase

At this stage of the experiment, the same models were tested on the development dataset which comprised of few number of samples, precisely 250 different instances. In Table 4 we display the performance over the development set.

Model	Spearman
Linear Reg.	0.8512
Gradient Boost	**0.8527**
XGB	0.8467
Random Forest	0.8481
Ensemble Model	0.8521

Table 4: Development Model Performances

6.3 Test phase

At the final stage of the experiments, the Gradient Boost model was chosen for the final tests on the testing dataset which comprised 5000 different instances. In Table 5, we display the results of the Gradient Boost models, compared to the baseline and the highest performance model in the same task.

Team	Spearman	Rank
PALI	0.8595	1
Pinealai	**0.8371**	10
SemRel-Baseline	0.8300	*

Table 5: Final Model Performance Metrics

7 Discussions

In the methodology section, our primary objective is to identify key features that enhance the capability of models in discerning semantic relatedness within textual data. We pursued two distinct approaches. First, we trained various models by employing Tfidf, Jaccard, or extracting specific syntactic features from the texts. This process does not take into account the internal structures of the texts which could give more insights about their meaning.

When exclusively utilizing syntactic features for model training, we achieved a maximum Spearman score of 0.32. Training models solely that used TF-IDF features to compute a cosine similarity and used the metric to predict yielded a separate score of 0.533. Incorporating features extracted from Sbert on top of the syntactic features resulted in a

notable score increase of 2, reaching approximately 0.70. Finally, combining all these strategies during the training phase produced a score of 0.85, with a corresponding score of 0.83 during the testing phase.

8 Conclusion

In conclusion, the study aimed to predict semantic relatedness in English, exploring diverse features and strategies. Limitations included the absence of word sense disambiguation algorithms, the exclusion of Transformer models for explainability, and the decision not to merge training and development sets. Despite these constraints, the models exhibited competitive performance, particularly the Gradient Boost model, which achieved a Spearman score of 0.8371. However, the experiment conducted can not help us derive a conclusion that the model can make a strict difference between semantic relatedness (STR) and semantic textual similarity (STS) in texts. The methodology highlighted the impact of syntactic features, TF-IDF representations, and SentenceBert embeddings. Moving forward, addressing limitations, incorporating advanced algorithms, and leveraging diverse datasets but also developing approaches that help models distinguish between STR and STS will contribute to a deeper understanding of semantic relations in textual data and further improvements in predictive capabilities.

Limitations

The study of semantic relatedness is a vast and tedious endeavor. The research conducted was very limited in many aspects. Firstly, the absence of algorithms specifically targeting direct word sense disambiguation represents a notable limitation. The incorporation of such algorithms could have potentially enhanced the models' effectiveness in this particular task. Also, the research did not explore the preprocessing techniques that could positively impact the semantic relatedness prediction.

Secondly, our study was confined to the training and testing of traditional machine learning models, excluding the exploration of Transformer models. While Transformers might have yielded superior results, their reduced explainability deterred their inclusion in our investigation.

Lastly, the decision not to merge the training and development sets for a final model training phase or add more datasets related to semantics relatedness or even semantic similarity represents another constraint. By solely transitioning to the testing phase with the models having learned solely from the training set given by the organizers, we may have missed opportunities for improvement. Combining both sets or augmenting the datasets through specific techniques in the final training phase could have potentially elevated the models' predictive capabilities, resulting in a more accurate score.

Ethics Statement

We affirm our commitment to ethical research practices and compliance with ACL guidelines in conducting and presenting our study. No ethical concerns or conflicts of interest arose during this research.

Abstract

We propose a training algorithm based on retrieval-augmented generation (RAG) to obtain the most similar training samples. The training samples obtained are used as a reference to perform contextual learning-based fine-tuning of large language models (LLMs). We use the proposed method to generate headlines and extract numerical values from unstructured text. Models are made aware of the presence of numbers in the unstructured text with extended markup language (XML) tags specifically designed to capture the numbers. The headlines of unstructured text are preprocessed to wrap the number and then presented to the model. A number of mathematical operations are also passed as references to cover the chain-of-thought (COT) approach. Therefore, the model can calculate the final value passed to a mathematical operation. We perform the validation of numbers as a post-processing step to verify whether the numerical value calculated by the model is correct or not. The automatic validation of numbers in the generated headline helped the model achieve the best results in human evaluation among the methods involved.

1 Introduction

In our busy lives, we barely have time to read the newspapers or an online article. Even a short period will not be enough to read all the latest news articles from different sources. The headline attached to the article attracts the reader only if it is interesting or provokes interest in the reader. A reader may have different interests and may not cover all areas. Some may be interested in movies, politics, science and technology, economy, environment, governance, sports, celebrities, weather, etc. The information fed to a reader is large and must be condensed and remembered. A unique headline condenses the unstructured text into a few words with some numbers. The numbers are presented to attract the reader's attention from the part of the unstructured text. These numbers can be based on positive or negative sentiments. A negative sentiment has a greater influence than a positive sentiment. A positive sentiment aims to create new information in the reader's mind. However, a negative sentiment harms the reader's mind by correcting and updating the information. Named entities, such as name, location, and number, are easier to remember for a long time than the rest of the text. The named entities are used more often by many people in several contexts with high-frequency usage. The narration in the text is constructed with the entities with a relationship. The occurrence of numbers in the relationship is more frequent than in other entities, especially in news articles.

We perform text summarization on unstructured text to obtain specific and highlighted information. It is helpful in many areas and reduces the time spent on unnecessary or irrelevant texts. Several events would occur in the process from the beginning to the end. All events may not be relevant or may appear as information overload. To reduce the list of events, we are using a text summary. Medical report summary, annual report summary, election results summary, movie reviews, product reviews, and sports reviews will highlight the main results of the research or the results of the conducted activities. A person must read the content to prepare a summary of the text. The likelihood is that many relevant points of the content should be included as part of the summary. Each person can prepare different lists of points using their previous knowledge and preferences. The main points of the different lists will be a central part of any summary. The core part can form a headline to attract readers to read the contents of the unstructured text.

Summary generation is a time-consuming process in which many people must contribute to preparing the highlights of the text content. In natural language processing (NLP), a model has to

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 940–951

process text content sequentially using a seq2seq model and generate these highlights. It reduces the time required to generate highlights, increases knowledge aggregation, and filters interesting content. A vast literature of text summarization tasks in NLP shows the required attributes of a machine. A summary is presented in plain text in most cases and may not always contain a number. In the generation of headlines, we need a few numbers to highlight the content. The numbers in a headline play an important role in attracting readers' attention. Here, the model must process the unstructured text sequentially and locate the numbers. All numbers in the text cannot be part of the headline. Only a few numbers can cover the complete information from the unstructured text. A model has to identify the numbers that cover the news content in order to generate the headline (Cai et al., 2023; Ding et al., 2023; Zhang et al., 2020).

The main contributions of the proposed method are as follows:

- Retrieval-augmented generation (RAG) of training samples to fine-tune a large language model (LLM).
- Chain-of-thought (COT) based generation of mathematical operations by the model.
- Verification of the computed value by the model to increase the confidence of the extracted numbers from the unstructured text.

2 Related Work

Large language models (LLMs) have started to demonstrate reasoning, calculation, knowledge acquisition, planning, and many more (LLAMA2; MISTRAL; OpenAI). At this point, we need to explore the potential capabilities of LLMs by proposing a wide range of problems that deal with a kind of artificial intelligence embedded in the model. In this paper, we study the numerical ability of a model.

EQUATE benchmark was prepared to make quantitative reasoning on different measures in the natural language inference (NLI) (Ravichander et al., 2019). The data set is prepared to understand whether a model can reason on the text. The results show that the models have the ability to reason and obtain an inference for the statements. The scale of the predicted number was done to understand whether a model can find the magnitude of the predicted numbers through an NLP (Chen et al., 2019). A language model does not explicitly distinguish numbers from words (Chen et al., 2023). The notation of a number cannot be clearly understood by the model. This can be due to a missing number in the training data. We cannot provide all numbers to the model by any means, so we need to use different symbols to express the numbers in the text so that the model can use the numbers to perform the reasoning tasks. However, there was scope to add additional challenges to the data set. The NumGLUE was proposed to identify the performance of LLMs through natural language understanding (NLU) (Mishra et al., 2022). There are eight different tasks based on common sense reasoning, arithmetic calculation, quantitative prediction, fill-in-the-blanks, and arithmetic word problems. Natural language optimization (NLOpt) is a competition to solve arithmetic word problems for linear programming problems (Ramamonjison et al., 2023). We proposed an ensemble approach to detect the named entities (NEs) in an unstructured text (He et al., 2022). The solution was generic and detected most of the entities in the text. Of all these tasks, the headline generation or summarization focused on numbers was missing.

The NumHG data set was prepared to cover the headline generation task by focusing on numbers (Chen et al., 2024, 2021; Huang et al., 2023). The NumEval competition is held to evaluate different models that can understand the numbers and generate the headline according to the ground truth specified (NumEval). The model can choose any random number from the text, which may not be relevant in many cases. The model is pushed to perform the calculation that provides the fill-in-the-blank task, where the model has to calculate the missing number from the headline or summary. A model must use mathematical operations to get the answer. The computational ability of the model is explored in this approach and is known as the task of 'numerical reasoning.' Several mathematical operations can be performed using a model. However, the news data set mainly covers the reproduction of the number, the conversion of a word into a number, and the rounding of the number. The distribution of mathematical operations is very narrow. We do not have sufficient samples for other types of mathematical operations, and the model may not be well suited for these types of operations even after fine-tuning. The data set is designed in such a way

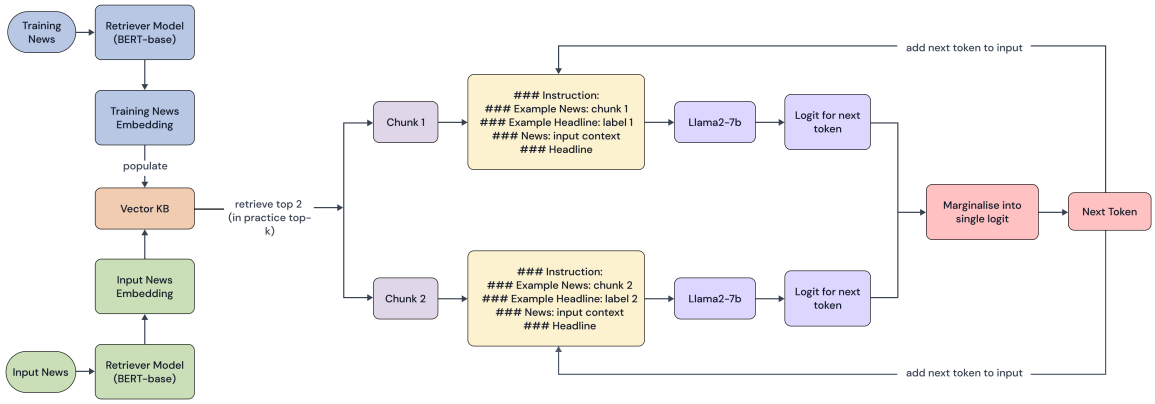

Figure 1: The retrieval-augmented generation (RAG) approach is used in the proposed method to generate headlines and numbers. A vector database is populated using the training news of the NumHG data set, and the training news is retrieved from the database during the inference. The prompted text is as follows: ### Instruction: Generate a Headline for the News and generate Numerical Reasoning for the numbers in the generated headline. Wrap the Numerical Reasoning with XML tags <NR> </NR>. Use the Example News and Example Headline as references. ### News: Input News. ### Headline: .

Table 1: The augmentation of headlines using the chain-of-thought (COT) approach. The NumHG data set provides arithmetic operations in the "calculation" field to be used for numerical reasoning tasks, which are fill-in-the-blanks tasks. The arithmetic operations from the numerical reasoning task are used as a reference to perform augmentation in the ground truth headline.

Ground truth headline	Guy Beat by Police Gets $1K, Lawyers Get $459K
Augmented headline	Guy Beat by Police Gets $1K <NR> paraphrase(1,000,K) </NR>, Lawyers Get $459K <NR> paraphrase(Add(100000,359000),K) </NR>

that the model must be aware of all the numbers presented in the text. Then, the model has to select a few numbers and make the calculation. The numbers are not known, and the mathematical operation is not known to the model in this NumEval task. The model must artificially identify the numbers and choose an appropriate mathematical operation to generate an answer.

3 Proposed method

A given LLM may not have full knowledge of the generation of headlines using a text. We need to provide some support to the model to excel in the task of headline generation. We propose a retrieval-augmented generation (RAG) model that is trained from end to end. The system consists of three modules: Knowledge Base, dense retrieval, and generation modules. Figure 1 shows the block diagram of the proposed approach.

The Knowledge Base (KB) was built using the training data provided. A pre-trained BERT base model is used to encode training news samples into vectors (Devlin et al., 2018). Then, these vectors are indexed using FAISS to enable the task of searching for vector-based similarity (Douze et al., 2024). The same BERT-based model is used during training and inference time. A given input text is encoded in a vector. Encoded vectors are used to search for dense vector similarity. Top-k similar news articles are retrieved by a dense retrieval module. Each result obtained will be added to the original input in a specific template to generate the headline. The purpose is to provide similar examples to generative models to help generate a better result. The prompt used in the experiment is shown in Figure 1. We use the LLAMA2-7b model to generate the output headline (Touvron et al., 2023; LLAMA2). We use the RAG token model (RAG) on the selected Top-k retrieved examples as shown in Figure 1. Each retrieved news is sent along with the input news to obtain two separate token predictions from the LLAMA2-7b model. These token predictions are marginalized, and the process is repeated until all tokens are generated.

Table 2: The ROUGE scores of different models using simple prompt to generate the headlines. The prompt is "Generate a headline for the following passage." The second row in the method name indicates the type of data set and the number of samples in the data set used for evaluation.

Method Name	ROUGE-1	ROUGE-2	ROUGE-L

Llama-2-7b-chat-hf_results The RAG examples were from the dry run set of 100 examples (Dev set - 2365)	40.19	16.42	35.62

$$p_{RAG-Token}(y|x) \approx \prod_i^N \sum_{z \in top-k(p(.|x))} p_\eta(z|x) p_\theta(y_i|x, z, y_{1:i-1}) \quad (1)$$

where input sequence x, retrieve documents z, target sequence y. A retriever $p_\eta(z|x)$ with parameter η (BERT-base model) and a generator $p_\theta(y_i|x, z, y_{1:i-1})$ with parameter θ (LLAMA2-7b model). The current token is generated using the previous $i-1$ tokens $y_{1:i-1}$.

3.1 Training

We trained the model from end to end to optimize both the retriever and the generative model together. Here, we aim to train a numerically literate model, which means that the model should be able to understand the numbers in the news and be able to perform mathematical operations on these numbers to arrive at a precise numerical value that will be used in the headline. We encapsulate the numbers in the headline of the news text with XML tags, as shown in the example in Table 1. The tags are an easier way to instruct the model to locate the numbers instead of the model itself looking for the numbers. The content within the XML tags is annotated in the training dataset of the NumHG data set under the numerical reasoning tasks as a "calculation" field. The headline generation task provides a headline as a ground truth. We introduce the information from the numerical reasoning task to the

Table 4: The ROUGE scores of different approaches used to improve the fine-tuned model. The details of number of samples used in the training set. The development set was used for evaluation. The performance improvements with the followed approaches is expressed mnemonically.

Method Name	ROUGE-1	ROUGE-2	ROUGE-L
Dev_Headline_Generation_RagEnd2End + Post_processing The number of training samples used are 14,720. All the numbers in the ground truth headlines are wrapped with XML tags for numerical reasoning task. BRIO generated outputs are used as post- processing step to replace problematic headlines. (Dev set - 2365)	48.08	23.06	43.32
Dev_Headline_Generation_RagEnd2End + XML tags The number of training samples used are 14,720. All the numbers in the ground truth headlines are wrapped with XML tags for numerical reasoning task. (Dev set - 2365)	48.01	23.03	43.32
Dev_Headline_Generation_RagEnd2End + 2nd Inference The number of training samples used are 14,720. All the numbers in the input news are wrapped with XML tags for numerical reasoning task. The second time inference is performed with retrieval using generated headline and news. (Dev set - 2365)	47.56	22.71	43.12
Dev_Headline_Generation_RagEnd2End The number of training samples used are 14,720. All the numbers in the input news are wrapped with XML tags for numerical reasoning task. (Dev set - 2365)	47.46	22.85	43.01
Dev_Headline_Generation_Bart-Large (3 epochs) (Dev set - 2365)	46.40	21.88	41.19
Dev_Headline_Generation_Brio (74 epochs) (Dev set - 2365)	46.08	21.14	40.53

headline generation task. In this respect, we use the "calculation" field in the data set to augment the headline of each training sample. By doing so, we explain the calculation of numbers with the Chain-of-thought (COT) generated in the headline (Wei et al., 2023). Table 1 shows the ground truth headline and the augmented headline.

3.2 Hyperparameters

The model was trained using both the training and the development set for the final submission. The model was trained for 3 epochs on a single A100 GPU with a batch size of 5. The number of documents retrieved is set to 3 for the training period and 5 for the inference period. The learning rate is set to 2e-4, and the linear decay warm-up scheduler is used as a learning rate scheduler with 30 warm-up steps. We use greedy search during inference time to speed up the execution.

We have used LORA (Hu et al., 2021) to fine-tune the LLAMA2-7b model. LORA reduces the number of trainable parameters and memory requirements. The LORA configuration used for the final submission of the headline generation task is as follows: "r": 8, "lora_alpha": 16, "lora_dropout": 0.05, "target_modules": ['gate_proj', 'up_proj', 'o_proj', 'v_proj', 'q_proj', 'k_proj', 'down_proj'].

4 Experiments

LLMs have shown the ability to perform well in unknown tasks even without training. Therefore, it is useful to check whether the model is well suited for the NumEval dataset.

4.1 Out of the box

We have tested several LLMs, and the results are presented in Table 2. Most models perform almost similarly in out-of-the-box scenarios. GPT4 used to take a long time to generate a response. Hence, we experimented on the dry run set provided by the NumEval competition. No examples were provided with inputs to the model. The model must depend on its internal knowledge to generate a headline. The ROUGE scores tabulated above show that the

Table 5: The accuracy of the different methods for the numerical reasoning task. The prompts used for the generation of answer may result in different score.

Method Name	Accuracy (%)
Out-of-the-box LLAMA2-7b	6.53
Out-of-the-box ChatGPT (gpt-3.5-turbo)	43.90
Fine-tuning LLAMA2-7b	86.31
Chain-of-thought (COT)	89.54
COT+under_sampling	82.85
COT+over_sampling	89.00
COT+minority_combined	91.44

model depends on its knowledge to generate a headline. The numerical reasoning task was performed using the fill-in-the-blanks task approach and the out-of-the-box results for LLAMA2 were very low compared to ChatGPT models. The results are summarized in Table 5.

4.2 In-context learning

We use the retrieval-augmented generation (RAG) approach to perform context-based learning. Here, we supplement the input with the retrieved examples. The model must understand the examples shown to generate a headline. The examples provided by the RAG approach are crucial. The number of samples in the knowledge base affects the performance of the model. We have tabulated the ROUGE scores for the RAG-based generation of headlines using different models. There is certainly an improvement from out-of-the-box to context learning. The difference is high in terms of the scores tabulated in Table 3.

4.3 Fine-tuning

The fine-tuning of the LLAMA2-7b model was performed using the RAG method from end to end. The other models were also fine-tuned using different sample sets in the knowledge base (KB). The score was not so much improved compared to LLAMA2-7b. In addition, the BRIO model was trained with different headlines generated by different models from Table 3. The fine-tuned BRIO model also provided performance closer to the best performance method (Liu et al., 2022). However, it was used in the post-processing stage to add the headline if the main model did not perform the mathematical operations correctly. The results of the fine-tuned models are presented in Table 4.

Table 6: The numerical accuracy of different competing methods on the test set.

Position	Team Name	Accuracy Private Leaderboard

14	StFX-NLP	0.60

4.4 Chain-of-thought (COT)

The numerical reasoning task requires the collection of the input text to perform the calculation. We provide a series of steps as instructions for the model. Suppose the model has to extract two numbers, say 19 and 16, and then perform addition to calculate the final score. We provide the model with a mathematical operation such as ADD(19,16) in the reasoning steps to get the final answer such as 35. The annotation of the input text to generate the instructions was simple in the NumEval data set. However, the model did not complete the calculations for some samples. Sometimes the model would not provide the final answer. The failure is unknown but based on the last step taken by the model. The last step was completed when the answer was empty. The COT-based reasoning improved the accuracy of the model compared to the LLAMA2-7b fine-tuned model. The results are tabulated in Table 5. The COT approach is superior compared to the fine-tuned model in the numerical reasoning task.

The results are tabulated in tables. 1-4 are based on experiments carried out on the development set. These experiments are conducted to identify the appropriate tools to help improve the performance of the model. The results show that current LLMs may not know completely how to generate a headline for a given text piece. The model needs the support of examples to generate headlines. The model also requires fine-tuning to reproduce answers closer to the ground truth.

5 Discussion and Results

The results of the test set based on the proposed method are presented in Tables 6, 7 and 8. The number of samples in the numerical reasoning task is 4921, and the number of samples in the headline generation task is 5227. The same proposed approach is used to estimate the results of the test set. The number of epochs used to train the model for the numerical reasoning task and the headline generation task are 1 and 3, respectively. Since LLMs consist of a large number of parameters, it is very difficult to make any internal changes. We could at least change some blocks that are connected to the LLMs either on the input or the output side. The changes to these blocks will be discussed in this section.

Table 8: Human evaluation of headline generation using reward points awarded by the human evaluator on the selected test set samples.

5.1 Numerical reasoning

The basic LLAMA2-7b model used in the out-of-the-box approach did not perform well in the fill-in-the-blank task. However, after fine-tuning the LLAMA2-7b model. The model was able to generate the answer for most of the samples correctly. However, there was still a gap in achieving higher numerical accuracy. The chain-of-thought (COT) approach is used to improve the model's accuracy. The improvement was marginal but observable in terms of numerical accuracy. The chain of thought forced the model to perform numerical reasoning in steps. The model would not complete some of the steps, but the answer was better than the simple fine-tuning approach. When the model fails to complete the last step, the answer is obtained through automated calculation. In addition to COT, we also conducted experiments for minor samples like undersampling and oversampling to train the model. The score was almost the same, and the changes were minimal. The higher the number of parameters (13b) in the model, the better the result than the smaller number of parameters (7b) in the model. Finally, we used the RAG-based approach to complete the fill-in-the-blank task. The combination of RAG and COT improved the model's ability to generate answers more accurately than the other approaches tested during the training period. Tables 5 and 6 show numerical accuracy on the development set and test set, respectively. We performed post-processing on the numerical value generated by the model by filling the empty values through understanding mathematical operations, but the numbers used by the model were not correct in most cases, leading to a wrong value and not improving the numerical accuracy.

5.2 Headline generation

We began to test the ability of LLMs to generate headlines using the out-of-the-box approach. The ROUGE scores were not satisfactory compared to the competition benchmarks (Huang et al., 2023). We used a context-based learning approach with which LLMs could understand the given examples and generate a much better headline. Even then, the ROUGE scores were below the benchmark. We

started fine-tuning the LLMs and got closer to the benchmark. We evaluated various types of models in the development set using all possible combinations. One interesting thing to identify is the numerically aware LLMs. Initially, we placed XML tags in the input text which provided a small improvement in the ROUGE scores in Table 4. We also performed inference for the second time using the first generated headline as part of RAG, which also provided a small improvement in the scores. Finally, we placed XML tags around the numerical values in the headlines to execute the COT approach. LLMs could understand that the answer should be selected from the input text and generate a mathematical operation that can complete the final answer. This gave the best score in the development set. Tables 7 and 8 show automated and human evaluation metrics for the submitted methods. The proposed method is second for most performance measures that are automatically calculated. In human assessment, the proposed method ranks first and second in terms of numerical accuracy and recommended headline, respectively.

5.2.1 Post-processing

We believe that the main contribution to numerical accuracy in Table 8 is verification. Verification is an important step in the process of finalizing the answer, which automatically improves confidence. One of the reasons for the verification is to select the numbers of the input text and compare them in the generated headline. There may be many numbers, but all of them cannot be used in the generation of headlines. Only a few numbers are used to complete the numerical calculation. Sometimes the model does not complete the calculation. We need to verify the steps followed by the model and fix some of the steps to improve the performance of the model in an automated way. The model generates the mathematical operations in an XML tag. The mathematical operations are processed with the numbers, which are part of the operation to verify that the number generated by the model is correct. We provide a few examples without errors in Appendix A.1 and with errors in Appendix A.2 in the verification stage. If the model fails to verify the generated numbers with the actual mathematical operation, a headline generated by the BRIO model is used to replace the headline generated by the main model (Liu et al., 2022). The number of samples with the replaced headlines is less than one percentage of the total number of samples in the test set. The percentage metric aligns with the top-2 reported results for the development set in Table 4. We were unable to fully explore the ensemble approach for LLMs but tried to combine the results of multiple models. A series of simple rules have been used to check and replace the headlines.

We instructed the model to generate a list of headlines, and then a new model was trained using reinforcement learning with human feedback (RLHF) (Böhm et al., 2019). The ROUGE scores from the RLHF-based model were better than a single headline generator but much less than the context-based learning approach. So, we have not reported the ROUGE scores for the RLHF approach. We are fine-tuning the model to confirm the ground truth, which may seem overfit for samples and deviate from the generalization capability of the model. Instead of a single ground truth headline, if we generate at least three headlines for the given input text similar to RLHF, that may help us understand whether the model falls into the category of generating the most common headline among the three. The performance measures will also change with multiple headlines as the ground truth. We speculate that a human factor would be added if several headlines were used as the ground truth rather than a single headline that is more like a robotic approach.

6 Conclusion

We proposed a RAG-based fine-tuning of LLMs to generate headlines and numerical values through reasoning. The model was trained from end to end to optimize the output of results. The model was trained for 3 epochs for headline generation and 1 epoch for numerical reasoning. We would like to train the model for a longer number of epochs in the future to confirm whether the model can improve performance. The verification step used to validate the generated numbers by the model is very useful to improve the confidence of the generated headline. There may be several numbers in the news, but the extraction and verification of numbers that can contribute to headline generation is a more concentrated approach. The additional verification stage helped the human evaluator select our proposed methodology as the most efficient among the competitors. We would like to explore further the rationale steps followed by the model in COT and improve the model performance by taking advantage of mathematical operations. We

would like to divide operations into a subset of operations. A combination of results from multiple models is attempted without fully exploring the ensemble approach. We would like to explore the possibility of combining models at different levels such as input, architecture, and so on.

A Appendices

We present a few examples from the verification stage. The examples provide insight into the verification stage followed in the proposed method.

A.1 Examples without errors in the verification stage

A.1.1 Example 1

News: (Jan 23, 2008 3:50 PM) A blast in the northern Iraqi city of Mosul claimed at least 15 lives and left 132 wounded today, Reuters reports. The explosion came after Iraqi troops detonated a roadside bomb near a building used as a munitions dump by militants, a US general said. At least 15 tons of explosives are estimated to have been stored in the building. Witnesses reported the resulting explosion was one of the biggest ever seen in Mosul, which, along with other areas of Nineveh province, has become a center for Sunni extremist fighters following their expulsion from Baghdad and the western Anbar province. A separate attack near Kirkuk, also in the north, killed 16 today, Reuters adds.

Pred_seq: Iraqi Blast Kills 15 <NR> Copy(15) </NR> in Mosul

Processed_headline: Iraqi Blast Kills 15 in Mosul

The method searches for any XML tag in the generated sequence. Here, the verification has found a tag. The method searches for the number '15' in the text because it is copied directly from the news section. The number '15' is found by the verification stage and removes the XML tag present in the generated headline.

A.1.2 Example 2

News:(Apr 22, 2009 9:11 AM CDT) Sick of waiting for a grand jury to act, Kathleen Savio's family has filed a wrongful death suit against husband Drew Peterson, the Chicago Tribune reports. The grand jury, which expires next month, has been investigating the death of Savio, Peterson's third wife, and the disappearance of fourth wife Stacy Peterson since November 2007. The Savios have hired John Kelly, the high-powered attorney who won the Brown family's civil suit against OJ Simpson, to represent them. We felt that the current grand jury is going to bring forward an indictment, or they'll be dismissed and we can proceed, said Kelly, who acknowledged it was unusual to file a civil case while a grand jury is still meeting. Defense attorneys will now be able to subpoena evidence from the criminal case for the civil one—but the state action will take precedence if the grand jury does return an indictment.

Pred_seq: Savio Family Files Wrongful Death Suit Against Drew Peterson

Processed_headline: Savio Family Files Wrongful Death Suit Against Drew Peterson

The method searches for any XML tag in the generated sequence. Here, the verification passes the generated headline without any changes due to the absence of XML tags.

A.1.3 Example 3

News: (Jul 31, 2012 3:13 AM CDT) The American Red Cross is facing a blood donation shortage serious enough that some people may have to cancel

elective surgeries. Donations are at their lowest in 15 years. In June, the organization came up 50,000 units short. July isn't looking good, either—a particular problem given the increased number of accidents typical in the summer, when people travel, a rep tells NBC News. Storms in the eastern and midwestern US both increased demand and cut supply, as the Red Cross was forced to cancel drives. With students, who account for 20% of donations, donating far less in the summer, the problem is compounded. We normally try to keep a three-day supply on hand locally, and we are down to a one—day supply, warns an Ohio Red Cross worker. And the need never, ever goes away, notes another representative.

Pred_seq: Red Cross Faces Worst Blood Shortage in 15 <NR> Copy(15) </NR> Years

Processed_headline: Red Cross Faces Worst Blood Shortage in 15 Years

The method searches for any XML tag in the generated sequence. Here, the verification has found a tag. The method searches for the number '15' in the text because it is copied directly from the news section. The number '15' is found by the verification stage and removes the XML tag present in the generated headline.

A.2 Examples with errors in the verification stage

A.2.1 Example 1

News: (Dec 20, 2016 5:40 PM) Forty-three days after the election, all the votes have finally been tallied and certified. History will show Hillary Clinton beating Donald Trump by a final count of nearly 3 million votes, the Hill reports. According to a tweet Tuesday from the nonpartisan Cook Report, Clinton received 65,844,610 votes (48.2%) to Trump's 62,979,636 (46.1%). However with the Electoral College officially making Trump the 45th US president on Monday, history will also show Clinton as the second Democrat in the past five elections to win the popular vote but lose the presidency. Meanwhile, the Huffington Post reports Trump had the third worst popular-vote performance by a winning candidate on record.

Pred_seq: 43 <NR> Subtract(43,1) </NR> Days After Election, All Votes Have Been Counted

Issues: Wrong Subtracted Value ('43', '<NR> Subtract(43,1) </NR>') | (43, 42), Value 43 not found in Snippet

Selected_headline: History Will Show Clinton Won Popular Vote by 3M Votes

The method searches for any XML tag in the generated sequence. Here, the verification has found a tag. When we search for the number '43', it is not found in the news section. We discard the generated headline and select the headline generated by the BRIO model as the generated headline.

A.2.2 Example 2

News: (Jul 12, 2014 4:20 PM CDT) Here's a dream come true for couch potatoes: You're not going to have to stop watching this movie for an entire month when it is ultimately released. Ambiancé, by Swedish director Anders Weberg, will be a full 720-hour film to be screened only once, starting on New Year's Eve in the year 2020, on every continent simultaneously, and then destroyed, reports The Verge. The filmmaker, who says this movie will be his last, has just released a teaser on Vimeo that is a short 72 minutes long, or roughly the length of a normal film. The short trailer, due out in two years, will be 7 hours and 20 minutes long (notice a theme?), reports Smithsonian magazine. The final trailer, out in 2018, will be 72 hours long. The film, a surreal dream-like journey beyond places, according to the film's site, is a sort of memoir that gives an abstract nonlinear narrative summary of the artist's time spent with the moving image. And it's expected to set the record as the longest film ever made. The teaser is only available until July 20. (Meanwhile, it's not too late to catch part of the world's longest concert.)

Pred_seq: World's Longest Film Will Be Destroyed After 1 <NR> Subtract(2020,2014) </NR> Screening

Issues: Wrong Subtracted Value ('1', '<NR> Subtract(2020,2014) </NR>') |(1,6), Subtraction operation is failed

Selected_headline: Longest Film Ever Made, 720-Hour Movie to Be Made, Destroyed

The method searches for any XML tag in the generated sequence. Here, the verification has found a tag. But, the model has failed to complete the subtraction operation. We discard the generated headline and select the headline generated by the BRIO model as the generated headline.

A.2.3 Example 3

News: (Dec 20, 2008 3:27 PM) The US could double the number of its troops in Afghanistan to about 60,000 by next summer, the highest such estimate to date, Reuters reports. American troops

currently number 31,000, but joint chiefs chairman Mike Mullen said today that an additional 20,000 to 30,000 will be needed by the spring or early summer. We're going to fill that requirement so it's not a matter of if, but when, he said. The majority will be deployed to the fragile south of the country, and Mullen was candid about the dangers. When we get additional troops here, I think the violence level is going to go up, he said. The fight will be tougher. Mullen also stressed that normalizing relations between Pakistan and India would ease violence in Afghanistan, and that any military progress must go hand in hand with economic development.

Pred_seq: US Could Double Troops in Afghanistan by Summer '09 <NR> Subtract(2009,2008) </NR>

Issues: Wrong Subtracted Value ('09', '<NR> Subtract(2009,2008) </NR>') |(09,1), Value 2009 not found in Snippet

Selected_headline: US Could Send 60K More Troops to Afghanistan

The method searches for any XML tag in the generated sequence. Here, the verification has found a tag. When we search for the number '2009', it is not found in the news section. We discard the generated headline and select the headline generated by the BRIO model as the generated headline.

Abstract

One major issue in natural language generation (NLG) models is detecting hallucinations (semantically inaccurate outputs). This study investigates a hallucination detection system designed for three distinct NLG tasks: definition modeling, paraphrase generation, and machine translation. The system uses feedforward neural networks for classification and SentenceTransformer models for similarity scores and sentence embeddings. Even though the SemEval-2024 benchmark is showing good results, there is still room for improvement. Promising paths towards improving performance include considering multi-task learning methods, including strategies for handling out-of-domain data and minimizing bias, and investigating sophisticated architectures.

1 Introduction

AI hallucination refers to a phenomenon where a Large Language Model (LLM) - usually Generative AI or a computer vision tool produces nonsensical and inaccurate outputs (Maleki et al., 2024). Thus, this leads to fluent but inaccurate generations. The term 'hallucination' is usually associated with human or animal brains but from the standpoint of machines, hallucinations refer to these inaccurately produced outputs.

Hallucinations in generative models may arise due to multiple factors such as overfitting during model training, complexity of the model, and bias in training data. According to multiple surveys (Huang et al., 2023), Hallucinations in natural language models may arise primarily due to two reasons - Hallucinations due to data and hallucinations during modeling.

Hallucinations in AI models may prove to be a threat in multiple scenarios such as healthcare where a model may not be able to predict the existence of the exact condition that needs to be treated. Hallucinations in fluent over generations may also lead to the spread of misinformation.

The most pressing problem in the modern-day natural language generation landscape is that the existing metrics (Bandi et al., 2023) can mostly detect fluency in generation rather than accuracy.

To deal with this issue, several studies have explored different techniques, such as Knowledge Graph Integration, Bias Detection, and Mitigation (Rawte et al., 2023). Building upon this prior research, our work proposes training tailor-made deep learning models and using Transformer (Vaswani et al., 2017) based architectures to identify cases of hallucinations.

To deal with this scenario, a task (Mickus et al., 2024) was proposed to build a system to detect instances of hallucinations in generated text.

2 Task

The primary task was to build a hallucination detection system capable of detecting outputs that are grammatically sound but are semantically inaccurate concerning the provided source input - both with or without access to the model used to generate the outputs. This is essentially a binary classification task and we were provided with two tracks - model agnostic and model aware. Model agnostic refers to the track where one would have no access to the model used to generate the outputs and model aware refers to the track where the model was provided in the dataset.

3 Related Work

Recent advances in natural language processing (NLP) have resulted in the development of Transformer based models such as BERT and its specialized variations that have introduced efficiency and accuracy in several NLP tasks.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 952–958
June 20-21, 2024

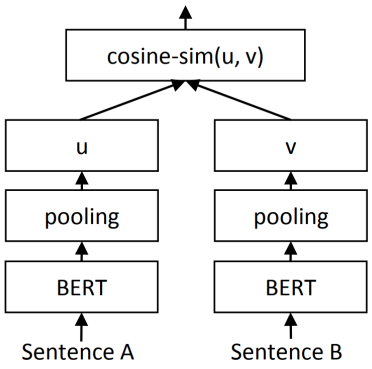

Figure 1: SBERT architecture to compute similarity scores

3.1 BERT

Bidirectional Encoder Representations from Transformers or BERT (Devlin et al., 2018), is an innovative machine learning technique for natural language processing (NLP). Researchers at Google AI Language created the adaptable BERT model in 2018, and it can perform more than 11 common NLP jobs, such as named entity recognition and sentiment analysis. Computers have never been very good at interpreting language. This requirement is attempted to be filled by NLP, a blend of languages, statistics, and machine learning. NLP activities required the usage of specialized models prior to BERT. With its cohesive approach and remarkable performance across a range of tasks, BERT transformed NLP.

3.2 SBERT

SBERT [1] or Sentence-Bert is a modified version of the BERT model which uses siamese [2] and triplet networks and is able to understand meaningful semantic embeddings in sentences. A common issue with BERT is, that the cross encoder setup of BERT takes up a lot of time and resources. To find the pair with the maximum similarity among n = 10,000 phrases, for example with BERT,

$$\frac{n(n-1)}{2} = 49{,}995{,}000$$

inference calculations are needed. This takes roughly sixty-five hours on a contemporary V100 GPU.

[1] http://arxiv.org/abs/1908.10084

[2] https://www.cs.cmu.edu/ rsalakhu/papers/oneshot1.pdf

4 Datasets

Since the task was divided into two tracks - model-aware and model-agnostic, we were provided with sets of two datasets. The model-aware dataset had a separate column for the generative model used to produce the outputs. The training dataset consisted of three natural language generation (NLG) tasks - Definition Modelling, Paraphrase Generation, and Machine Translation.

1. **Definition Modelling (DM)** - Clear and concise definition of concepts or terms generated by generative models.

2. **Paraphrase Generation (PG)** - Alternative wordings are generated that convey the same meaning as the input text.

3. **Machine Translation (MT)** - Translation of the text from one language to another while preserving fluency and meaning.

Each entry in the dataset comprises three text columns - hyp, src and tgt.

1. **hypothesis (hyp)** - Contains the generated text.

2. **source (src)** - The source text or the original text provided as input to the generative model for producing the hypothesis.

3. **target (tgt)** - Contains the correct generation output.

The trial dataset contains three columns dedicated to the labels. The 'labels' column contains the three most likely labels out of which the majority label is displayed in the 'label' column - which is either 'Hallucination' or 'Not Hallucination'. Finally, the 'p(Hallucination)' column comprises of probability values ranging from 0 to 1.

4.1 Trends in the dataset

The datasets provided include trial, validation (model-agnostic and model-aware), and test (model-agnostic and model-aware) sets, all represented by their respective figures (Figure 2, Figure 3, Figure 4, Figure 5, and Figure 6).

The datasets contain almost an even distribution of DM and PG tasks. However, the number of rows with the task 'MT' is considerably less.

Certain entries in the dataset had no probability values and to avoid difficulties in the training process, we have dropped the rows.

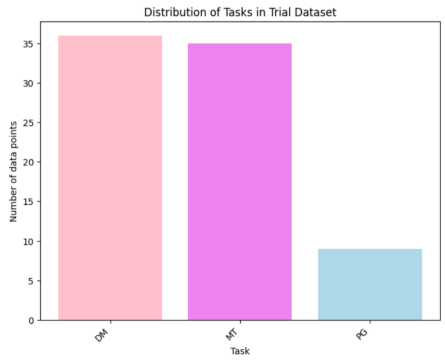

Figure 2: Trial Dataset

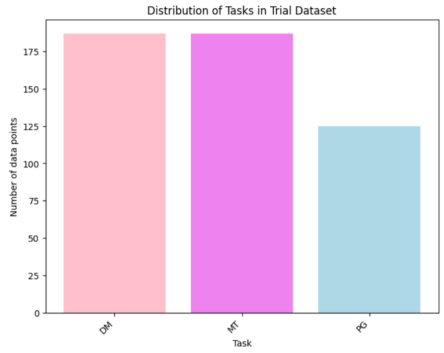

Figure 3: Validation Dataset (Model Agnostic)

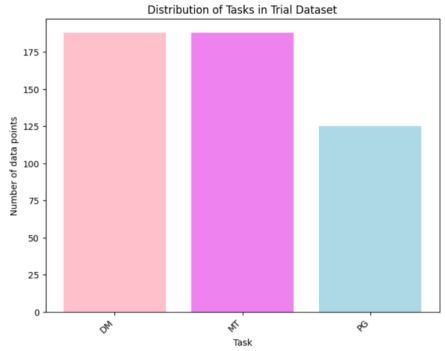

Figure 4: Validation Dataset (Model Aware)

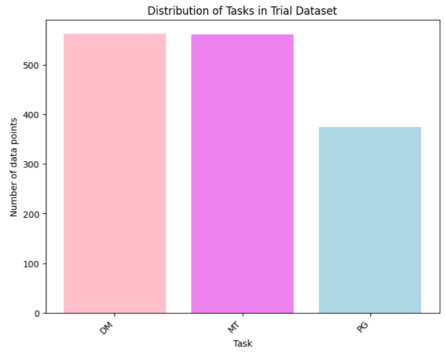

Figure 5: Test Dataset (Model Agnostic)

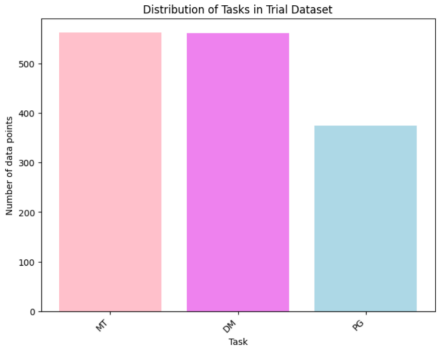

Figure 6: Test Dataset (Model Aware)

We determined that there was no viable utility for integrating the separate training dataset lacking annotations into our system. Furthermore, we were aware of the possible overfitting risk brought about by more unannotated data points. Consequently, we made the informed decision to refrain from its utilization.

5 Pre Processing

5.1 Data Cleaning

The text sections in the dataset have been processed by removing irrelevant elements in order to improve the efficiency of word embedding produced by the models used. The sentences under hyp, src, and tgt columns mainly contain prepositions and certain irrelevant expressions.

1. First the sentences are lowered by using Python's .lower() function.

2. In order to remove irrelevant expressions and prepositions, we have used Python's Regular Expression (re) library.

3. Finally, the sentences are stripped and split into individual words.

5.2 Labels

In order to make the training process more efficient, we converted the probability values in the 'p(Hallucination)' column into binary labels - if the probability value was more than or equal to 0.5, we converted it to 1 and otherwise it was labeled 0.

5.3 Tokenisation

We used 'all-mpnet-base-v2', a SentenceTransformer model to encode our sentences. The encoding process is comprised of three steps - tokenization, word embedding, and sentence embedding.

1. **Tokenization** - The sentence is split into individual tokens. This is done by the methods of stemming or lemmatization (Khyani and B S, 2021).

2. **Word Embedding** - Each token is then assigned a numerical vector. These are called word embeddings and they represent the semantic meaning of the word using information from a large text corpus.

3. **Sentence Embedding** - Finally the tokens are converted into a single vector representation for the entire sequence.

   Different models use different approaches to perform embedding.

   (a) **Mean pooling** - The average of all word embeddings is taken for the entire sentence. This method is useful in capturing the overall sentiment but may lead to a loss of semantic information.

   (b) **Weighted mean pooling** - Weights are assigned to the words using attention mechanisms to represent their importance in the sentence. This helps in prioritizing certain words and preserving semantic information.

   (c) **Transformers** - Transformer models consider the entire sentence and process the relationship between different words. Thus, contextualized embeddings capture the context more accurately.

6 Methodology

6.1 Experimental Setup

Since the generated texts have been divided into three tasks, we have divided the process into three branches.

For Definition modeling, we used 'all-mpnet-base-v2' [3] and for Paraphrase generation, we have used 'paraphrase-MiniLM-L6-v2' [4], both Sentence-Transformer models to encode the sentences and calculate two sets of cosine similarity values. One represents the similarity score between the hypothesis (hyp) and source (src) text and the other represents the similarity score between the source (src) and target (tgt) text. These similarity scores are converted into a numpy array using numpy's column stack for input into two sequential models respectively.

For Machine translation, we used 'all-MiniLM-L6-v2' [5], also a SentenceTransformers model to encode the sentences and produce embeddings. The Spearman correlation between the two sentences in the hypothesis and target columns is calculated. We chose these columns specifically as 'hyp' contains the English translation produced by the generative model and 'tgt' contains the correct translation. We used the SciPy library of Python for this metric. Finally, the correlation coefficients are pushed into a numpy array. In this case, we have used a different sequential model for training.

The input array is split into an 80:20 ratio for training and validation respectively and the test dataset was entirely used for producing the outputs. We have used a common pipeline for processing the entire dataset and then branched the input array according to the task label - if the task is 'DM' it was fed into the model prepared for definition modeling.

6.2 Model

We used three models for producing the outputs for the three tasks respectively.

6.2.1 Definition Modelling

Using the Tensorflow Keras framework, we created a deep-learning neural network. It has two densely concealed layers, each with 64 and 32 neurons. For the hidden layers, we employed ReLU activation functions, which give the model non-linearity (Kulathunga et al., 2021). This helps the model learn non-linear correlations and fortifies the neural network. To lessen overfitting, we have incorporated a dropout layer after each dense layer. Lastly, since this is a binary classification problem, we have utilized the sigmoid activation function for the output layer.

6.2.2 Paraphrase Generation

We designed a neural network architecture for the paraphrase generation type inputs comprising of an input layer accepting data with two features, followed by three hidden layers. The first layer consists of 128 neurons with ReLU activation, coupled with a dropout layer to mitigate overfitting. Subsequently, a 64-neuron layer employs ReLU

[3] https://huggingface.co/sentence-transformers/all-mpnet-base-v2

[4] https://huggingface.co/sentence-transformers/paraphrase-MiniLM-L6-v2

[5] https://huggingface.co/sentence-transformers/all-MiniLM-L6-v2

Task Specific Model	Accuracy
Definition Modelling	0.67
Paraphrase Generation	0.74
Machine Translation	0.83

Table 1: Evaluation of Individual Models

activation, batch normalization, and dropout regularization. Similarly, the third hidden layer integrates 32 neurons, ReLU activation, batch normalization, and dropout regularization. The outputs from the second and third layers are concatenated before feeding into a single-neuron output layer with sigmoid activation, typical for binary classification. This architecture is optimized using the Adam optimizer with a learning rate of 1e-4 and binary cross-entropy loss, while early stopping is applied during training to prevent overfitting. The model's configuration demonstrates a structured approach to feature extraction and classification, tailored for paraphrase generation types input data.

6.2.3 Machine Translation

The model for machine translation harnesses the formidable capabilities of the all-MiniLM-L6-v2 Sentence Transformer, designed to adeptly encode semantic nuances within input sentences into dense embeddings. These embeddings undergo meticulous examination through Spearman correlation (halo), discerning their intrinsic similarities. Post-normalization, they serve as inputs to a meticulously designed neural network architecture, capitalizing on ReLU activation functions for intricate feature extraction. Culminating in a sigmoid activation layer, the network adeptly estimates the probability of sentence hallucinations, embodying a rigorously scientific approach to classification.

6.2.4 Evaluation of Task Specific Models

This section presents an evaluation of three task-specific models trained for Definition Modelling (DM), Paraphrase Generation (PG), and Machine Translation (MT) tasks, respectively. Each model is assessed based on its training accuracy, providing insights into its performance on the training data.

6.3 Loss

We use binary cross-entropy (BCE) (Ruby and Yendapalli, 2020) as our loss function as it measures the difference between the predicted probability and the true binary label (0 or 1). BCE is not affected by class imbalance, which occurs when one class has noticeably fewer samples than the other, in contrast to Mean Squared Error (MSE). This guarantees that the model concentrates on efficiently learning both classes.

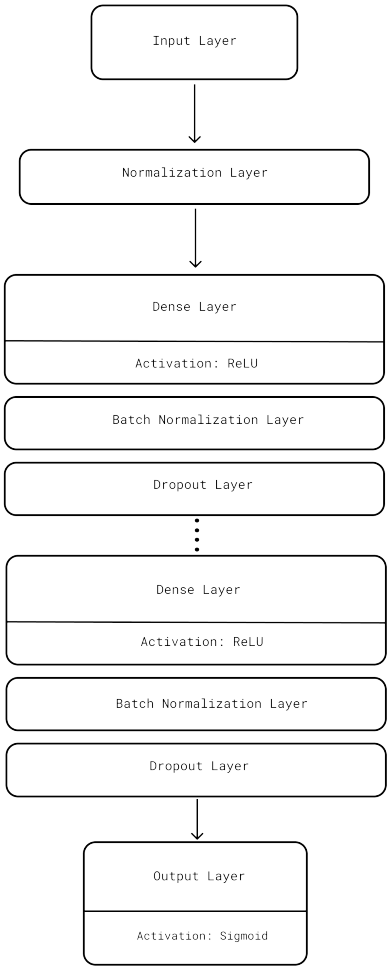

Figure 7: Generalised Architecture of the Model

6.4 Optimizer

We use the Adam (Kingma and Ba, 2017) optimizer for our neural networks as Adam is effective at traversing the loss landscape because it combines momentum and adjustable learning rates. It strikes a balance between exploration and exploitation, enabling the model to iteratively identify areas of high performance and improve its solutions.

A generalized representation of the model is visualized in Figure 7.

7 Evaluation

The predicted probability values generated by the model were translated into binary labels using a

Track	Accuracy	Rho
Model-Agnostic	0.654	0.294608108
Model-Aware	0.7113333333	0.4264291384

Table 2: Evaluation results

threshold approach. Data points with a predicted probability of 0.5 or higher were assigned the label "Hallucination," while those below 0.5 were labeled "Not Hallucination." These labels were then saved in a JSON file conforming to the specified format.

The SemEval-2024 task had two measures to evaluate the performance:

1. the accuracy that the system reached on the binary classification.

2. the Spearman correlation of the systems' output probabilities with the proportion of the annotators marking the item as overgenerating.

   It is given by:

$$\rho_s = 1 - \frac{6 \sum_{i=1}^{n} d_i^2}{n(n^2 - 1)}$$

   where d_i is the difference in ranks for item i and n is the total number of items.

Also, the submissions were divided into model agnostic and model aware tracks. Our model placed 31st out of all entries in the model-aware track and 41st out of all entries in the model-agnostic track.

8 Conclusion and Future Work

This paper explored detecting hallucinations in natural language generation (NLG) outputs using specialized models for definition modeling, paraphrase generation, and machine translation tasks - both while having access to the models used to generate the sentences and without. We used transformer-based models for calculating the similarity scores as they outperform other models such as Universal Sentence Encoder (USE) (Cer et al., 2018) and Doc2Vec (Lau and Baldwin, 2016).

While there have been previous studies on hallucination detection, our approach offers several key novelties that have contributed to its effectiveness.

- **Task-specific Models**: Instead of the one-size-fits-all approach, we built specific models for each task to better capture their unique characteristics. This customization aids in efficiently extracting features crucial for identifying hallucinations.

- **Transformer-based Similarity Scores**: To compute sentence similarity scores, we made use of SentenceTransformer, a Transformer based model. These models do better at capturing contextual information and fine-grained semantic relationships inside phrases than other models.

Several avenues exist for further development of our hallucination detection system. To enhance the performance of our model, we advise investigating data augmentation techniques, as transformer-based models have a large thirst for data. To increase the model's robustness and durability, we also suggest using adversarial training and exploring more advanced deep learning architectures.

This project has been possible due to the contributions of Sohan Choudhury, who developed the architecture for the definition modelling task, Priyam Saha, who created the paraphrase generation model, and Subharthi Ray, who built the machine translation model. We are also deeply grateful for the insightful guidance and mentorship provided by Shankha Shubhra Das and Dr. Dipankar Das throughout this journey.

Abstract

In this paper we present the system for Track A in the SemEval-2024 Task 1: Semantic Textual Relatedness for African and Asian Languages (STR). The proposed system integrates a Siamese Network architecture with pre-trained language models, including BERT, RoBERTa, and the Universal Sentence Encoder (USE). Through rigorous experimentation and analysis, we evaluate the performance of these models across multiple languages. Our findings reveal that the Universal Sentence Encoder excels in capturing semantic similarities, outperforming BERT and RoBERTa in most scenarios. Particularly notable is the USE's exceptional performance in English and Marathi. These results emphasize the importance of selecting appropriate pre-trained models based on linguistic considerations and task requirements.

1 Introduction

Semantic relatedness is a fundamental measure in natural language processing, providing a detailed assessment of how closely related two pieces of text are on a semantic level. This metric has wide-ranging significance in NLP tasks such as information retrieval, question answering, and text summarizing, contributing to the understanding of textual connections and improving algorithmic performance.

The importance of determining meaning through quantifying relatedness has been acknowledged within linguistic discussions for many years. Automating the determination of connected meanings holds significant value across diverse applications like evaluating sentence representation methods or supporting question-answering systems as well as summarizing processes.

However, the application of measuring relatedness to non-English languages presents substantial challenges due to disparities in linguistic resources and annotated datasets. In contrast to English many languages lack comprehensive lexical or syntactic resources which creates challenges in inaccurately capturing semantic subtleties and establishing cross-language associations. Additionally, variations across different languages such as morphological, syntactic, and semantic also add complexity to developing language-independent models for expressing relatedness Overcoming these obstacles requires extensive research and effective resource development tailored to different linguistic contexts ensuring that measures offered by the semantic similarity can be effectively applied across different languages. Here are some examples of the score of semantic relatedness of two sentences in three languages:

English: *"You figure this out all by yourself, did you?*
did you find all this on your own?" Score: 0.88

Spanish: *"Jean Hebb Swank es una astrofísica conocida por sus estudios sobre agujeros negros y estrellas de neutrones.*
Bajo la supervisión de Steve Frautschi, obtuvo su doctorado en física en 1967." Score: 0.52

Kinyarwanda: *"East Africa's Got Talent ku nshuro yayo ya mbere u Rwanda ni kimwe mu bihugu byemerewe kuyitabira aho rwahuriye n'ibindi birimo Uganda, Tanzania na Kenya.*
Iya mbere ni umubano mwiza uri hagati ya Mali n'u Rwanda, ndetse u Rwanda ni kimwe mu bihugu bifite abapolisi bagiye kugarura amahoro muri Mali." Score: 0.09

The rest of this paper is structured as follows: Section 2 introduces the problem statement and provides a summary of related works. Sections 3 and 4 detail the system description and experimental setup, respectively. The evaluation results are outlined in Section 5, followed by our conclusion

in Section 6.

2 Background

2.1 SemEval Task Description

We perform our experiments on data from the first subtask (supervised) of task 1 of SemEval-2024 (Ousidhoum et al., 2024b). We used 5,500 samples with 8 language pairs in the official training set (Ousidhoum et al., 2024a). The goal of the task is to predict the semantic textual relatedness between sentence pairs in different languages. The similarity score of pairs of articles in the provided dataset ranged from 0 to 1, with higher scores indicating higher semantic relatedness. To address the challenges of measuring semantic relatedness in non-English languages, research efforts need to focus on expanding resources and developing language-specific models.

2.2 Related work

Previous approaches to semantic relatedness have been categorized into knowledge-based and corpus-based methods. Knowledge-based methods use lexical resources like WordNet (Miller, 1995) to measure definitional overlap (Lesk, 1986), term distance within taxonomies, and term depth as specificity measures, among others. Knowledge-based methods are widely used in NLP applications, including word sense disambiguation and automatic summarization. The sources of knowledge utilized in these methods encompass various elements such as fuzzy logic, domain knowledge, Knowledge Graphs, ontologies, The Wikipedia among others. WordNet is an English language lexicon that arranges ideas into a conceptual structure. Its purpose is to represent the meaning of English words by categorizing synonyms and various relationships, both taxonomic and non-taxonomic. While semantic similarity quantifies specific likeness, relatedness provides a broader measure that encompasses connectedness as well.

On the other hand, corpus-based measures utilize probabilistic approaches such as Latent Semantic Analysis (Landauer et al., 1997), Explicit Semantic Analysis (Gabrilovich et al., 2007) and Salient Semantic Analysis (Hassan and Mihalcea, 2009), to decode word semantics based on contextual information observed in raw text. Corpus-based methods involve statistically analyzing large text corpora to quantify semantic similarities employing distributional semantics principles that capture contextual information within the text itself. Among these approaches is Latent Semantic Analysis, which uses a singular value decomposition technique to minimize word co-occurrence pattern matrix dimensionality within a corpus successfully applied among various natural language processing tasks including text classification and information retrieval. Another notable method utilizes random projection for mapping words onto high-dimensional spaces with cosine similarity vectors; termed Random Indexing, it outperforms LSA in particular tasks showing utility across diverse NLP applications like word sense disambiguation. In addition, researchers are exploring techniques leveraging the web as a corpus leading toward a branch known as web intelligence.

Neural networks have gained increasing significance in evaluating semantic relatedness due to their ability to comprehend intricate connections and subtleties in meaning from extensive data. Traditional approaches for assessing semantic relatedness often depend on manually crafted features or knowledge-based methods, which may have limitations in capturing the complete spectrum of semantic relationships between words and sentences. In contrast, neural networks can undergo training using large datasets to acquire contextualized representations of words and sentences. These representations capture the subtle meanings typically overlooked by traditional methods, enabling neural networks to achieve cutting-edge performance on tasks related to semantic relatedness. Furthermore, neural networks can be fine-tuned for specific purposes, enhancing their precision and efficiency. Furthermore, recent advancements in deep learning and

neural network technology have demonstrated encouraging outcomes when it comes to measuring semantic relatedness. For example, several pretrained language models like BERT (Devlin et al., 2018) and RoBERTa (Liu et al., 2019) have been tailored for semantic relatedness applications with state-of-the-art performance achieved on standard benchmark datasets.

Semantic relatedness in neural networks has been greatly impacted by the emergence of transformers, leading to a significant transformation in natural language processing (Gagliardi and Artese, 2023). Unlike traditional methods relying on manual features and statistical models, transformers utilize self-attention to dynamically allocate attention across input elements, effectively capturing long-term dependencies within language data. Current approaches for semantic relatedness mainly involve using powerful models like transformers to encode sentences into embeddings and then computing their similarity score using metrics such as cosine similarity. These advancements in deep learning and neural network technology have enabled the development of powerful models that can accurately measure semantic similarity and relatedness between sentences, surpassing the capabilities of traditional methods.

3 System Overview

The measurement of semantic relatedness involves assessing the connection or correlation between words or phrases, regardless of their meanings. Recently, deep learning models like convolutional neural networks and recurrent neural networks have garnered attention in measuring semantic relatedness. These models excel at capturing intricate patterns and interdependencies in textual data, thereby enhancing performance across a range of natural language processing tasks. For instance, Siamese networks make use of CNN or RNN structures to compare embeddings and gauge the relatedness between sentences or short texts. Attention mechanisms have also been integrated into these models to improve focus on crucial semantic elements (Sharma, 2023).

Siamese architectures are effective because they use the same model to handle similar inputs, and makes it easier to compare sentence pairs and reduces the number of parameters that need training, requiring less data and making them less susceptible to overfitting (Ranasinghe et al., 2019).

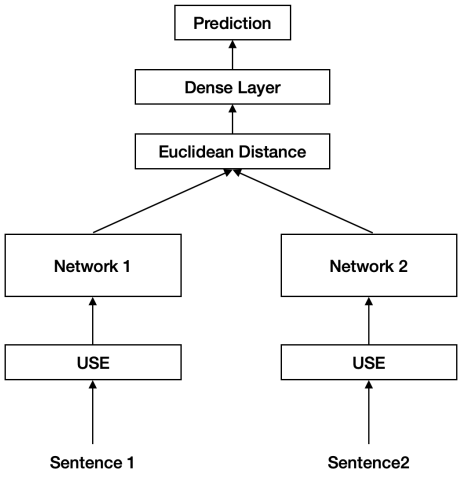

Figure 1: Basic structure of our system.

We implement a comprehensive system for evaluating sentence relatedness using a Siamese Network architecture coupled with Universal Sentence Encoder (USE) embeddings (Cer et al., 2018). The system comprises several distinct components, each contributing to the overall functionality and effectiveness of the model.

The Universal Sentence Encoder model is loaded from TensorFlow Hub [1], enabling the generation of high-quality embeddings for the input sentences. These embeddings capture semantic information, thereby facilitating the comparison and analysis of sentence similarity. Both the training and validation sentences are encoded into USE embeddings, which are then converted to NumPy arrays for seamless integration with the Siamese Network architecture.

The core of the system lies in the construction and training of the Siamese Network model (Figure 1). Utilizing TensorFlow's functional API, the model is designed to accept two input embeddings corresponding to pairs of sentences. It computes the Euclidean distance between these embeddings and passes the result through a Dense layer with sigmoid activation to predict the similarity score between the sentences. By employing Mean Squared Error (MSE) loss and the Adam optimizer, the model is trained on the training data, with performance monitored using the validation set.

Our code is available on GitHub [2]

[1] https://tfhub.dev/google/universal-sentence-encoder/4

[2] https://github.com/yasaminaali/Enhancing-Sentence-Relatedness-Assessment-using-Siamese-Networks

Models	English	Amharic	Alg Arabic	Spanish	Hausa	Kinyarwanda	Marathi	Telugu
USE	**0.75**	0.63	0.44	0.65	0.39	0.27	0.58	0.61
Bert	0.42	0.1	0.4	**0.5**	0.04	0.01	0.32	0.21
Roberta	0.38	0.2	0.31	0.46	0.01	0.1	**0.51**	0.24

Table 2: This table summarizes the key findings of the evaluation, highlighting the varied performances of different models across multiple languages. It specifically mentions the strengths of BERT in English and Spanish, RoBERTa's excellence in Marathi and Spanish, and the consistently exceptional results of the Universal Sentence Encoder across most languages in the training set.

4 Experimental Setup

4.1 Data Split

For all of our experiments, we split the task's training set using an 80/20 train/dev split, and we used the official development set as a test set.

4.2 Pre-processing

Pre-processing improves data quality, eliminates irrelevant information, and makes data more suitable for the calculation of the semantic relatedness score. This entails removing punctuation, numbers, and special characters such as # and $. Contractions are expanded to their full forms, and all text is converted to lowercase for consistency in processing.

4.3 Evaluation Metrics

The evaluation metric for task 1 is the Spearman Correlation between the predicted similarity scores and the human-annotated gold scores, with a range from 0 to 1 (from least to most correlated), which helps to determine how well the predicted scores align with human judgments.

5 Results

Our rankings show that in certain languages, our method closely matches the baseline performance. For example, in English, our rank is 0.82 compared to the baseline of 0.83, and in Spanish, our rank stands at 0.64 compared to the baseline of 0.7. Therefore, our method demonstrates significant effectiveness across different languages.

The evaluation of models across different languages showed varied performances. BERT demonstrated strong performance in English and Spanish, while RoBERTa excelled in Marathi and Spanish. However, the Universal Sentence Encoder consistently delivered exceptional results across most languages in the training set (Table 2).

Specifically, the USE model achieved the highest scores in English with 0.75 on the training set and 0.82 on the test set, indicating remarkable performance. The top overall score reached 0.86, showcasing its effectiveness in this task as well. Following English, Marathi exhibited the second-best performance at a score of 0.69 (Table 1).

5.1 Error Analysis

The model struggled with Kinyarwanda, Hausa and Algerian Arabic, hinting at relatively poor performance for this languages (Table 1).

To gain a deeper understanding of our model's performance, we compare its predictions with the test labels in English. Upon observation, it is evident that the model struggles when calculating the lowest semantic relatedness between sentences.

6 Conclusion

The system presented offers a strong framework for evaluating sentence similarity by integrating a Siamese Network architecture with Universal Sentence Encoder embeddings. A comprehensive overview of the system's components and processes, including data preprocessing, model construction, and training, demonstrates that the system effectively utilizes advanced techniques in natural language processing to make accurate similarity predictions. The evaluation results reveal the superior performance of the Universal Sentence Encoder across multiple languages, outperforming pre-trained models like BERT and RoBERTa in most scenarios. Notably, the system excelled in English and Marathi, demonstrating its versatility and effectiveness across diverse linguistic contexts. Further optimization and refinement of the system may enhance its performance in under-performing languages as well as broaden its applicability in real-world scenarios, ultimately advancing the field of natural language processing and facilitating a wide range of practical applications.

Abstract

Semantic hallucinations in neural language generation systems pose a significant challenge to the reliability and accuracy of natural language processing applications. Current neural models often produce fluent but incorrect outputs, undermining the usefulness of generated text. In this study, we address the task of detecting semantic hallucinations through the SHROOM (Semantic Hallucinations Real Or Mistakes) dataset, encompassing data from diverse NLG tasks such as definition modeling, machine translation, and paraphrase generation. We investigate three methodologies: fine-tuning on labelled training data, fine-tuning on labelled validation data, and a zero-shot approach using the Mixtral 8x7b instruct model. Our results demonstrate the effectiveness of these methodologies in identifying semantic hallucinations, with the zero-shot approach showing competitive performance without additional training. Our findings highlight the importance of robust detection mechanisms for ensuring the accuracy and reliability of neural language generation systems.

1 Introduction

The modern NLG landscape is plagued by two interlinked problems: On the one hand, our current neural models have a propensity to produce inaccurate but fluent outputs; on the other hand, our metrics are most apt at describing fluency, rather than correctness. This leads neural networks to "hallucinate", i.e., produce fluent but incorrect outputs that we currently struggle to detect automatically. For many NLG applications, the correctness of an output is however mission critical. For instance, producing a plausible-sounding translation that is inconsistent with the source text puts in jeopardy the usefulness of a machine translation pipeline. With our shared task, we hope to foster the growing interest in this topic in the community.

With SHROOM (Mickus et al., 2024) we adopt a post hoc setting, where models have already been trained and outputs already produced: participants will be asked to perform binary classification to identify cases of fluent overgeneration hallucinations in two different setups: model-aware and model-agnostic tracks. That is, participants must detect grammatically sound outputs which contain incorrect or unsupported semantic information, inconsistent with the source input, with or without having access to the model that produced the output. To that end, we will provide participants with a collection of checkpoints, inputs, references and outputs of systems covering three different NLG tasks: definition modeling (DM), machine translation (MT) and paraphrase generation (PG), trained with varying degrees of accuracy. The development set will provide binary annotations from at least five different annotators and a majority vote gold label.

2 Dataset

SHROOM (Semantic Hallucinations Real Or Mistakes) dataset, aimed at addressing the challenge of detecting semantic hallucinations in neural language generation systems. SHROOM encompasses data from three diverse NLG tasks: data modeling (DM), machine translation (MT), and paraphrase generation (PG). Each task presents unique nuances in identifying semantic inaccuracies within generated text.

2.1 Model Aware and Agnoustic Data

There were two types of data entries, one in which the model information was present, which was the model aware dataset and the other where the model information was absent, the model agnousitc dataset.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 964–968

Example 1: Definition Modeling (DM)
Source: The sides of the casket were covered with heavy black broadcloth, with velvet caps, presenting a deep contrast to the rich surmountings. What is the meaning of surmounting? **Target:** A decorative feature that sits on top of something. **Hypothesis:** A sloping top. **Model:** ltg/flan-t5-definition-en-base **Label:** Hallucination **Probability (Hallucination):** 0.6

Example 2: Definition Modeling (DM)
Source: And the mower whets his sithe, What is the meaning of whet? **Target:** To hone or rub on with some substance, as a piece of stone, for the purpose of sharpening – see whetstone. **Hypothesis:** To cause to whirl. **Model:** ltg/flan-t5-definition-en-base **Label:** Hallucination **Probability (Hallucination):** 1.0

Example 3: Definition Modeling (DM)
Source: The corporation was accused of unethical behavior for knowingly producing a product suspected of harming health. What is the meaning of unethical? **Target:** Not morally approvable; morally bad; not ethical. **Hypothesis:** Not ethical; not conforming to ethical principles. **Model:** ltg/flan-t5-definition-en-base **Label:** Not Hallucination **Probability (Hallucination):** 0.0

Example 4: Paraphrase Generation (PG)
Source: We must create a society where everyone is able to enjoy a good education. **Hypothesis:** Everyone is capable of enjoying a good education in a society. **Model:** tuner007/pegasus$_{p}araphrase$ **Label:** Hallucination **Probability (Hallucination):** 0.8

Example 5: Paraphrase Generation (PG)
Source: Schooling is a fundamental issue that we should today reaffirm. **Hypothesis:** We should reiterate the importance of schooling. **Model:** tuner007/pegasus$_{p}araphrase$ **Label:** Not Hallucination **Probability (Hallucination):** 0.2

Example 6: Machine Translation (MT)
Source: Malo osungilako asilikali ankhondo amaluso osiyanasiyana ku depatimenti ya zachitetezo yaku U.S. ikutsata ziduswa. **Target:** The United States Strategic Command of the U.S. Department of Defense office is tracking the debris. **Hypothesis:** The U.S. Department of Defense's military intelligence facility is tracking the targets. **Model:** facebook/nllb-200-distilled-600M **Label:** Hallucination **Probability (Hallucination):** 1.0

Table 1: Examples from SHROOM Val dataset

2.2 Data Analysis

The dataset compilation involved sourcing data from a variety of sources to ensure its robustness and generalizability. For DM, definitions were gathered from various domains, covering a wide range of topics. MT data consisted of parallel corpora from multiple language pairs to capture translation nuances effectively. Finally, for PG, a collection of sentences and corresponding paraphrases from various genres was curated to represent natural language variation comprehensively.

2.3 Annotation

Annotating the dataset for semantic hallucinations followed a binary scheme, where each instance was labeled by 5 annotators as either containing semantic hallucinations or being free of such errors. To ensure the reliability of annotations, each instance underwent assessment by at least five annotators, with a majority vote determining the gold label.

2.4 Dataset Statistics

The SHROOM dataset comprises of multiple instances across all tasks. The distribution of instances for each NLG task is summarized below:

NLG Task	Train Set	Test Set
Definition Modeling (DM)	10000	563
Machine Translation (MT)	10000	562
Paraphrase Generation (PG)	10000	375

Table 2: Distribution of Instances by Task

For the Model Agnostic Dataset and Model Aware Dataset, each has:

Validation Set (Labelled):

NLG Task	Instances
Data Modeling	187
Paraphrase	125
Machine Translation	187

Train Set (Unlabelled):

NLG Task	Instances
Data Modeling	10000
Paraphrase	10000
Machine Translation	10000

Test Set:

NLG Task	Instances
Data Modeling	563
Paraphrase	375
Machine Translation	562

2.5 Example Instances

Table 2 provides examples from the SHROOM dataset, showcasing instances with and without semantic hallucinations for each NLG task.

Our participation in this shared task involves leveraging the SHROOM dataset to develop and evaluate models for detecting semantic hallucinations in NLG systems. This dataset serves as a valuable resource for benchmarking and advancing research in this area.

3 Methodology

Our Methodology involved first Labelling the Training Data, fine tune a model on the test data then evaluating the model on test data. We chose Roberta-base as our base model for fine tuning as XLM-RoBERTa is a multilingual language model optimized for classification tasks. It is pretrained on massive multilingual data, and has a robust architecture and performance enable efficient fine-tuning across diverse text classification problems with state-of-the-art accuracy. For Labelling the Training Data, we used Mixtral 8x7B (Jiang et al., 2024), specifically mixtral-8x7b-instruct-v0.1.Q5_K_M.gguf

3.1 Labelling Training Dataset

The prompt (Zamfirescu-Pereira et al., 2023) used for Labelling Training Dataset using Mixtral-8x7b-instruct is:

```
if task == "PG":
    context = f"Context: {src}"
else: # i.e. task == "MT" or task == "DM":
    context = f"Context: {tgt}"

sentence = f"Sentence: {hyp}"
message = f"{context}\n{sentence}\nIs
the Sentence supported by the Context
above?
Answer using ONLY yes or no:"
```

```
prompt = f"[INST] {message} [/INST]"
```

3.2 Finetune Roberta-base on the Mixtral labelled train dataset

We chose to fine-tune Roberta-base on the Mixtral labeled train dataset to adapt the model specifically for the task of detecting semantic hallucinations. The Mixtral labeled training dataset provided binary labels indicating whether a given sentence exhibited semantic hallucinations or not. The probability label for hallucination ranged from 0 to 1, derived from the log probability of the Mixtral model output. Therefore, we formulated the task as a binary classification problem: distinguishing between sentences containing semantic hallucinations and those that do not.

During fine-tuning, we modified the last layer of Roberta-base to accommodate the binary classification task. We used techniques such as cross-entropy loss and gradient descent to update the model's parameters based on the labeled training data. By fine-tuning on the Mixtral labeled dataset, we aimed to enhance Roberta-base's ability to identify semantic hallucinations in natural language generation outputs.

3.3 Finetune Roberta-base on the Pre-Annotated Data

In addition to fine-tuning on the Mixtral labeled train dataset, we performed fine-tuning on preannotated data, specifically the development dataset. This dataset had been annotated by five annotators, and each instance was assigned a probability label for hallucination ranging from 0 to 1 in increments of 0.2. The probability labels were based on the consensus among the annotators.

To leverage the fine-grained annotations provided by multiple annotators, we formulated the task as a multi-class classification problem. We fine-tuned Roberta-base (Conneau et al., 2020) to classify instances into one of six categories corresponding to the six probability levels (0, 0.2, 0.4, 0.6, 0.8, or 1). This approach allowed the model to learn from the nuanced annotations provided by the annotators and make more nuanced predictions about the presence of semantic hallucinations.

By fine-tuning Roberta-base on both the Mixtral labeled train dataset and the preannotated development dataset, we aimed to create a robust model capable of accurately detecting semantic hallucinations across a range of natural language generation tasks and datasets.

4 Results

We present the results of our experiments using three different methodologies for detecting semantic hallucinations in neural language generation systems.

4.1 Methodology 1: Fine-tune on the labelled Training Data (2 Class)

We fine-tuned our model on the labelled training data, treating the task as a binary classification problem. The results over multiple epochs are summarized in Table 3. We observed an improvement in both agnostic and aware accuracy over epochs, with agnostic accuracy reaching 76.47% and aware accuracy reaching 61.27% by the third epoch. However, the Matthews correlation coefficient (rho) showed less consistent improvement, with agnostic rho peaking at 0.58 and aware rho at 0.38 in the second epoch.

Epoch	**Agnostic Acc.**	**Aware Acc.**
1	0.753	0.609
2	0.759	0.601
3	0.765	0.613
Epoch	**Agnostic ρ**	**Aware ρ**
1	0.568	0.346
2	0.580	0.381
3	0.584	0.355

Table 3: Results for Methodology 1: Fine-tune on labelled Training Data (2-Class)

4.2 Methodology 2: Fine-tune on the labelled Validation Data (6 Class)

In this methodology, we fine-tuned the model on the labelled validation data, treating the task as a six-class classification problem. Results are presented in Table 4. Agnostic accuracy fluctuated around 45-51% over different epochs, while aware accuracy showed similar fluctuations around 47-58%. Matthews correlation coefficient (rho) varied between 0.43 and 0.52 for agnostic classification and between 0.48 and 0.52 for aware classification.

4.3 Methodology 3: Zero-shot Mixtral 8x7b

For the zero-shot approach (Yue et al., 2023), where we directly applied the Mixtral 8x7b model without fine-tuning, results are shown in Table 5. Agnostic accuracy achieved 78.73%, while aware accuracy

Epoch	Agnostic Acc.	Aware Acc.
3	0.515	0.578
5	0.473	0.487
10	0.449	0.483
15	0.463	0.473
Epoch	**Agnostic ρ**	**Aware ρ**
3	0.477	0.490
5	0.477	0.490
10	0.502	0.524
15	0.434	0.512

Table 4: Results for Methodology 2: Fine-tune on labelled Validation Data (6-Class)

reached 77.73%. The Matthews correlation coefficient (rho) for agnostic classification was 0.50, and for aware classification, it was 0.48.

Overall, the zero-shot approach demonstrated competitive performance compared to fine-tuning on labelled data, indicating the effectiveness of the Mixtral 8x7b model in detecting semantic hallucinations without additional training.

Approach	Agnostic Acc.	Aware Acc.
Zero-shot	0.787	0.777
Approach	**Agnostic ρ**	**Aware ρ**
Zero-shot	0.499	0.485

Table 5: Results for Methodology 3: Zero-shot Mixtral 8x7b

5 Conclusion

In this study, we investigated three different methodologies for detecting semantic hallucinations in neural language generation systems. We fine-tuned a model using labelled training data, labelled validation data, and also explored a zero-shot approach using the Mixtral 8x7b instruct model.

Our results indicate that fine-tuning on labelled data, whether it is the training data or the validation data, led to improvements in both agnostic and aware accuracy over multiple epochs. However, the effectiveness of fine-tuning on validation data seemed to diminish as the number of epochs increased, suggesting potential overfitting.

Interestingly, the zero-shot approach using the Mixtral 8x7b instruct model achieved competitive performance compared to fine-tuning on labelled data. This indicates the robustness of the Mixtral model in detecting semantic hallucinations without additional training.

Overall, our findings suggest that while fine-tuning on labelled data can lead to improvements in detection accuracy, the zero-shot approach with pre-trained models like Mixtral 8x7b instruct provides a viable alternative, especially when labeled data is limited or unavailable. Future research could explore further optimization of fine-tuning strategies and investigate the generalizability of pre-trained models across different domains and tasks.

Transformers at SemEval-2024 Task 5: Legal Argument Reasoning Task in Civil Procedure using RoBERTa

Kriti Singhal[1], **Jatin Bedi**[2]
Computer Science and Engineering Department,
Thapar Institute of Engineering and Technology, India
[1]kritisinghal711@gmail.com, [2]jatin.bedi@thapar.edu

Abstract

Legal argument reasoning task in civil procedure is a new NLP task utilizing a dataset from the domain of the U.S. civil procedure. The task aims at identifying whether the solution to a question in the legal domain is correct or not. This paper describes the team "Transformers" submission to the Legal Argument Reasoning Task in Civil Procedure shared task at SemEval-2024 Task 5. We use a BERT-based architecture for the shared task. The highest F1-score score and accuracy achieved was 0.6172 and 0.6531 respectively. We secured the 13th rank in the Legal Argument Reasoning Task in Civil Procedure shared task.

1 Introduction

Mastering the art of arguing a legal case is essential for lawyers. This necessitates deep knowledge of the particular area of law along with advanced reasoning capabilities, including drawing similarities and differences. Researchers have made significant efforts towards setting the benchmark models for the new Natural Language Processing (NLP) problems in the domain of legal language understanding (Chalkidis et al., 2022).

The task, Legal Argument Reasoning Task in Civil Procedure[1] (Held and Habernal, 2024), organized at SemEval-2024 aimed at classifying the solution to a given problem as right or wrong.

Classifying an answer to a given question as correct or incorrect is a new NLP task. In particular, in the legal domain limited number of publicly available corpora exist. This contributes to added difficulty of this task (Fawei et al., 2016).

Recent advances in the field of NLP have addressed various issues, such as long texts and under-resourced domains. These include Long Short Term Memory (Hochreiter and Schmidhuber, 1997), and Gated Recurrent Units (Chung et al., 2014). But transformers (Vaswani et al., 2017) have taken the performance to new heights which were not possible earlier.

In the past, various efforts have been made to perform domain-specific adaption of different existing techniques and models. Some of these adaptions include SciBERT which was pre-trained for scientific texts, specifically in the bio-medical domain (Beltagy et al., 2019). Similarly, BioBERT was created with special emphasis on the bio-medical area (Lee et al., 2019).

In this paper, we discuss our use of a transformer-based model, RoBERTa, in the shared task of Legal Argument Reasoning Task in Civil Procedure at SemEval-2024.

2 Related Work

Researchers have used and explored various techniques in the past. In the work done by Beltagy et al. (2019); Lee et al. (2019), it was found that BERT-based architectures did not perform very well on problems that required specialized domain knowledge. Two possible solutions were found to address this issue. The first was to further pre-train BERT on domain-specific corpora, and the second possible solution was to pre-train BERT from scratch on domain-specific corpora (Chalkidis et al., 2020).

Lee et al. (2019) performed domain-adaption of BERT in the bio-medical domain. The experiment explored the effect of further pre-training BERT base for 470,000 steps on biomedical articles. The performance of the resulting model, BioBERT, was evaluated on biomedical datasets. This led to an improvement in performance when compared to BERT base.

Beltagy et al. (2019) proposed a family of BERT-based models, SciBERT, for scientific texts with a special focus on the bio-medical domain. Two approaches were followed for SciBERT, the first was further pre-training BERT base, and the second

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 969–972

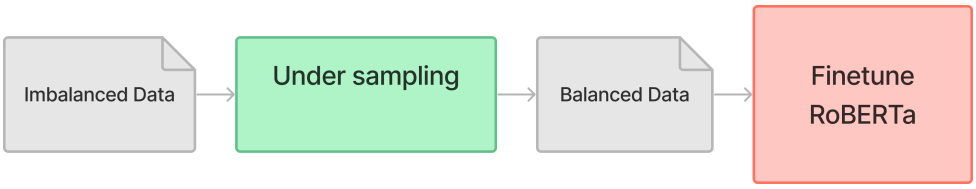

Figure 1: Proposed Methodology

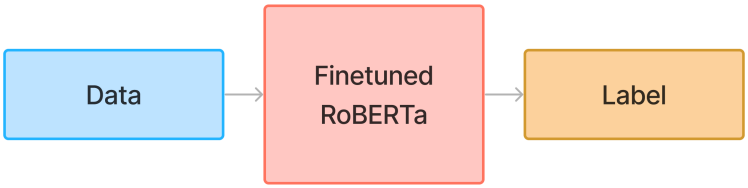

Figure 2: Label Generation for Unseen Data

approach was to pre-train BERT base on domain-specific corpora from scratch. In the second approach, random initialization of the model was performed, and a fresh new vocabulary was created. An improvement in performance was observed in the downstream tasks for both the approaches.

In the work carried out by Chalkidis et al. (2020), BERT domain adaption was performed for the legal domain. A systematic analysis was performed for the three available techniques. The first technique was to use BERT out of box, the second technique was to perform additional pre-training on BERT using domain-specific corpora, and the third approach was to perform pre-training from the start using domain-specific corpora.

3 Dataset Description

The dataset provided by the organizers was selected from the domain of the U.S. civil procedure and is based on a book aimed at law students.

In the training set, there are 666 instances, out of which 505 are labeled as 0 and 161 are labeled as 1. For each instance in the training data, there is a general introduction to a case, a question from that case, a possible argument solution along with a detailed analysis of why the argument is valid for that case. The test set, on the other hand, contains a question, answer and an explanation on the basis of which a label needs to be assigned to each instance. The assigned label will indicate whether or not the answer to the question is right or not.

4 Methodology

It was observed that in the dataset provided by the organizers, the number of instances in class 0 was 505, while the number of instances labeled as 1 was 161. Hence, in order to address the data imbalance, minority sampling was performed by randomly picking 161 instances from those labeled as class 0. This ensured that no bias existed in the trained model.

For identifying whether the answer to a given problem was correct or not, the RoBERTa Large model was employed. The RoBERTa model was designed by Facebook AI in 2019 (Liu et al., 2019). RoBERTa is a pre-trained transformer model which was trained in a self-supervised manner, i.e. only raw texts were used to train it without the involvement of human labeling.

While training the model, all the fields present in the training data, namely, question, answer, and analysis, were used to predict the provided label. The weighted Adam optimizer along with cross-entropy loss was used as the optimizer and the loss

Table 1: RoBERTa Performance Comparison

Model	F1-Score	Accuracy
RoBERTa Base	0.5511	0.6020
RoBERTa Large	0.6172	0.6531

function respectively. The learning of the optimizer was set at 1e-5. The RoBERTa model was trained for 100 epochs with the aforementioned parameters with a batch size of 8.

The training procedure has been summarised in Figure 1. The fine-tuned transformer was used to then predict the label for the unseen data as shown in Figure 2.

5 Results and Discussion

A BERT-based transformer, RoBERTa was discussed to perform categorization of an answer as right or wrong given a case, question, and a possible answer.

The data imbalance was handled by performing under sampling on the majority class instances in a random fashion. This was followed by fine-tuning the RoBERTa Large model for 100 epochs. After fine-tuning, the model achieved an F1 score of 0.5511 and an accuracy of 0.6020.

As shown in Table 1, the RoBERTa Base model performed better than RoBERTa Large, when fine-tuned for 100 epochs using the same methodology and hyper parameters. And it achieved an F1 score of 0.6172 and an accuracy of 0.6531.

Overall, we achieved the 13th rank in the Legal Argument Reasoning Task in Civil Procedure shared task at SemEval-2024 out of the 21 participating teams.

6 Conclusion and Future Work

Legal argument reasoning is a new NLP task, aimed at classifying a candidate answer as correct or incorrect given an introduction to the topic, a question and a candidate answer.

In this work, we describe our use of a BERT-based architecture, RoBERTa in the Legal Argument Reasoning Task in Civil Procedure shared task at SemEval-2024.

Ensembling techniques have shown promising results on various NLP tasks in different domains. Using an ensemble approach of different transformers may hence improve the performance. Transformers trained specifically with a focus on legal transformation such as Legal-BERT (Chalkidis et al., 2020) can improve the performance further.

YNU-HPCC at SemEval-2024 Task 7: Instruction Fine-tuning Models for Numerical Understanding and Generation

Kaiyuan Chen, Jin Wang and Xuejie Zhang
School of Information Science and Engineering
Yunnan University
Kunming, China
chenkaiyuan@stu.ynu.edu.cn, {wangjin, xjzhang}@ynu.edu.cn

Abstract

This paper presents our systems for Task 7, Numeral-Aware Language Understanding and Generation of SemEval 2024. As participants of Task 7, we engage in all subtasks and implement corresponding systems for each subtask. All subtasks cover three aspects: Quantitative understanding (English), Reading Comprehension of the Numbers in the text (Chinese), and Numeral-Aware Headline Generation (English). Our approach explores employing instruction-tuned models (Flan-T5) or text-to-text models (T5) to accomplish the respective subtasks. We implement the instruction fine-tuning with or without demonstrations and employ similarity-based retrieval or manual methods to construct demonstrations for each example in instruction fine-tuning. Moreover, we reformulate the model's output into a chain-of-thought format with calculation expressions to enhance its reasoning performance for reasoning subtasks. The competitive results in all subtasks demonstrate the effectiveness of our systems.[1]

1 Introduction

In numerous domains, precise numerical information within text is decisive in decision-making and planning. Understanding and generating text- numbers would be beneficial for improving the model's performance on specific tasks. However, it poses challenges for existing models. Also, previous research indicates that current models struggle to properly represent textual numbers (Chen et al., 2023), often leading to inaccuracies.

Therefore, Task 7 of SemEval (Chen et al., 2024) 2024 focuses on numerically-aware language comprehension and generation, which includes quantitative understanding (Chen et al., 2023), reading comprehension of the numerals in text (Chen et al., 2021), and numeral-aware headline generation (Huang et al., 2023).

[1]Our code is available at https://github.com/ChenKy23/semeval2024-Task7

We explored all the subtasks of Task 7 and designed corresponding systems for each subtask. Our work and contributions can be summarized as follows:

For Subtask 1, We adopt the paradigm of instruction tuning (Chung et al., 2022) to complete all subtasks and explore manually crafting instances. Our results demonstrate that the instruction tuning model (Flan-T5) (Chung et al., 2022) performs comparably to the BERT model (Devlin et al., 2019) on the Quantitative Understanding task.

For Subtask 2, we utilized the mT5 model (Xue et al., 2021) pre-trained on multilingual corpus and the Randeng-T5 (Wang et al., 2022) pre-trained on Chinese corpus to implement the respective systems, as this task involves Chinese. Consistent with Task 1, we designed an instruction template for inputs and employed instruction fine-tuning.

For Subtask 3, similar instances are retrieved and organized into the input-output format to further enhance model's performance in in-context learning. Specifically, we structured the model's output into the format of chain-of-thought (CoT) (Wei et al., 2022) and inserted calculation expressions to improve model's reasoning performance. Our system achieved the highest scores of ROUGE, BERTScore, and MoverScore in headline generation while ranking 3^{th} in numerical reasoning task.

The remainder of this paper is organized as follows. In Section 2, we describe the related work of our system. The system overview is presented in Section 3. The details of the experiments, main results, and a conclusion are drawn in Sections 4, 5, and 6, respectively.

2 Related Work

In-context Learning. As a novel paradigm, in-context learning (Brown et al., 2020; Chung et al., 2022) has proven to enable large language models to adapt to unseen tasks with instruction and a few

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 973–979
June 20-21, 2024

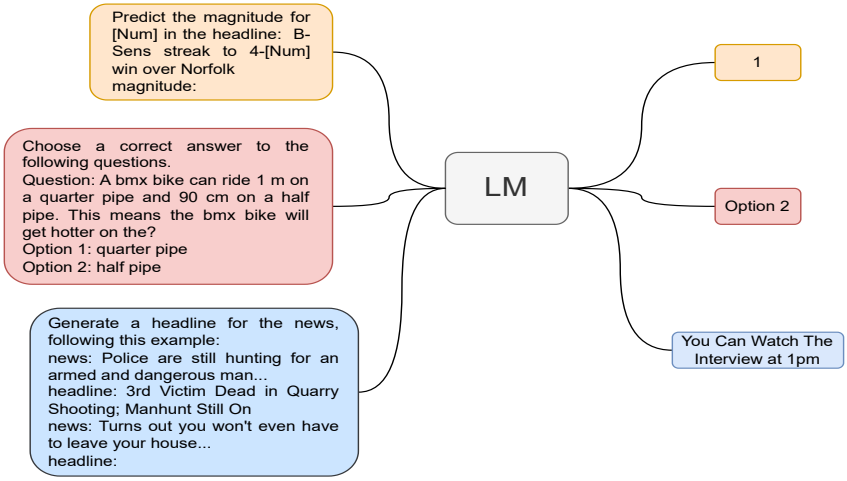

Figure 1: The application of instruction tuning across different tasks. In our system, LM represents either the Flan-T5 or T5 model. Different tasks employ different instruction templates, with or without demonstrations.

demonstrations, and it doesn't conduct any parameter updates. Furthermore, selecting semantically similar instances can further enhance the model's performance. (Liu et al., 2022; Rubin et al., 2022). Recent work has also applied in-context learning to fine-tuning small models (Fu et al., 2023).

Chain of Thoughts Prompt. CoT prompting (Wei et al., 2022; Kojima et al., 2022) is considered as a method to guide large language models (LLMs) in multi-step reasoning. In the numerical reasoning task of Subtask 3, the model's output can be reconstructed into a CoT format to enhance its reasoning performance. It's important to note that, unlike existing distillation methods (Fu et al., 2023), we don't use a LLMs to generate CoT rationales for each example. Instead, the original labels provided can be used to generate CoT rationales which is a more efficient way.

3 Overview of System

3.1 Instruction Tuning

The Instruction tuning models (Flan-T5 or T5) have developed strong generalization abilities through instruction fine-tuning across various tasks. Thus, appropriate instruction can lead to better model performance. While our system is not in a zero-shot setting, introducing instructions during the fine-tuning can enhance the model's performance. Therefore, we consider the input for all subtasks as the instruction template T concatenated with the query input x, i.e., $T + x$. In different tasks, T may have different meanings. The objective function

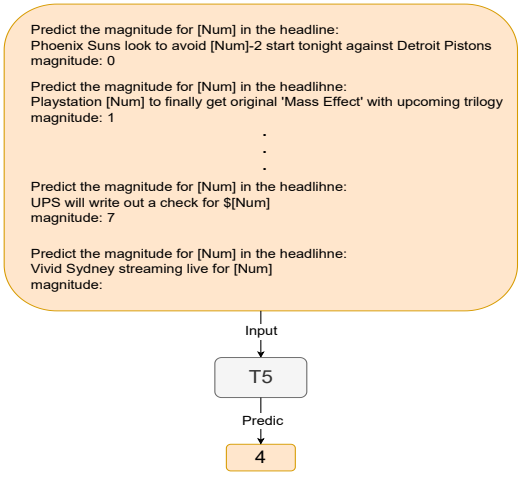

Figure 2: An example of instruction tuning with demonstrations from QP. According to different magnitudes, 8 instances can be selected manually.

for this process is as follows:

$$L_{instr} = \frac{1}{N}\sum_{i=1}^{N} CE\left(f\left(x_i, T\right), \widehat{y}_i\right) \quad (1)$$

where assume there are a total of N examples, x_i is i-th query input from the dataset, f is the output distribution function of models, CE represents the cross-entropy loss between predicted tokens and target tokens, and $\hat{y}_i$ denotes the tokens from the i-th gold label.

It's worth noting that the input-output formats vary for each subtask. We have designed distinct instruction formats for each task and employed instruction tuning to update the models across all tasks. Figure 1 illustrates how we employ instruction tuned models across various subtasks.

Operators	Expressions
$Copy(v)$	copy v from the news
$Trans(e)$	covert e into a number which represents v
$Paraphrase(v_0, n)$	paraphrase the form of v_0 to other representations in n «v_0/n=v_1»
$Round(v_0, v_1)$	hold v_0 digits after the decimal point of c, that is v_1
$Subtract(v_0, v_1)$	subtract v_0 from v_1 «v_0-v_1=v_2»
$Add(v_0, v_1)$	add v_0 and v_1 «v_0+v_1=v_2»;
$Span(s)$	select a span s from the article which represents 1;
$Divide(v_0, v_1)$	divide v_0 by v_1 «v_0/v_1=v_2»
$Multiply(v_0, v_1)$	multiply v_0 and v_1 «v_0*v_1=v_2»

Table 1: The 9 different operators can be translated into corresponding natural language expressions. Each expression might include an additional calculated number compared to the original operator.

3.2 Instruction Tuning with Demonstrations

The form of instruction tuning can be further expanded, where instructions can be subdivided into prompt P and a list of demonstrations D. P offers explicit guidance for the current task, while D provides the model with demonstrations of the input-output format. This paradigm has been recently referred to as in-context learning in related work (Brown et al., 2020; Chung et al., 2022). Therefore, the objective function for the extended instruction tuning can be expressed as follows:

$$L_{icl} = \frac{1}{N}\sum_{i=1}^{N} CE\left(f\left(x_i, P; D\right), \widehat{y}_i\right) \quad (2)$$

Based on the ways to select demonstrations, this method can be further categorized into manual and similarity-based instruction tuning.

Manual-based Instruction Tuning. This method is employed in Subtask 1 and 2. As subtask 1 involves various aspects, including QP, QNLI, QQA, the different demonstrations can be provided for each task. An example of how instruction is used for QP is shown in Figure 2. The manual selection of demonstrations are based on covering as many different results as possible.

Similarity-based Instruction Tuning. Using similarity-based retrieval for each input is more efficient and leads to better performance (Liu et al., 2022). We employed this method in the headline generation task for Subtask 3. First, pre-trained Sentence-BERT (Reimers and Gurevych, 2019) can be utilized as an encoder to map each news article x_i to a vector v_i. Then, with cosine similarity function F, the distances between v_i and all other vectors can be computed. Finally, the news article corresponding to the vector v_j, which has the closest distance, can be selected as a similar instance. The following function can represent this process:

$$v_i = S(x_i) \quad (3)$$

$$F(v_i, v_j) = \|v_i - v_j\|_2 (or \frac{v_i \cdot v_j}{\|v_i\|_2 \|v_j\|_2}) \quad (4)$$

$$v^i{}_{closest} = \underset{j \in \{1,2...N\} \cap j \neq i}{argmin} F(S(x_i), S(x_j)) \quad (5)$$

where N represents the total number of instances in the training set, S is the mapping function of Sentence-BERT, F denotes the cosine similarity function, and x_i represents a news article from the dataset.

3.3 Learning to Reasoning by CoT

As a part of Subtask 3, the numerical reasoning task requires deducing the numbers in masked headlines based on given news articles and approximately 20% of the questions involve reasoning and computation. Related operators can be categorized into 9 types, including $Copy$, Add, and others. Thus, directly predicting the numbers may be challenging. An example for NumHG (Huang et al., 2023) can be shown as follows:

Operations = Add(Subtract(5,3), Copy(3))

While this format of the execution process correctly deduces the results, it may not be very intuitive and does not provide the model with interpretable rationales. Therefore, it can be converted into a CoT format, which contains multiple immediate reasoning steps. The above example can be converted into the following CoT format:

First, subtract 3 from 5 «5-3=2»; Second, copy 3 from the news; Third, add 2 and 3 «2+3=5»;

We design corresponding natural language expressions for all 9 operators involved in the dataset and use the program to implement this process automatically. The complete correspondence between operators and natural language expressions

Table 3: The performance of different methods on the headline generation task of NumHG based on ROUGE, BERTScore, and Num Acc. The $direct$ indicates directly fine-tuning the model without instruction, and $truncate$ signifies truncating the input to a length of 512.

is shown in Table 1. Furthermore, expressions can be inserted for each computational operation. An external calculator (Cobbe et al., 2021) can be used for result correction. For the mentioned example, if the model output is *5-3=1*, the external calculator will correct it to the right result, which is *5-3=2*. Subsequently, string matching replaces the incorrect numerical values in the sequence.

4 Experiment Details

Datasets. Subtask 1 utilizes Quantitative 101 (Chen et al., 2023) as the dataset, encompassing three aspects: QP (Chen et al., 2019), QQA (Mishra et al., 2022), and QNLI (Ravichander et al., 2019); Subtask 2 utilizes NQuAD (Chen et al., 2021), which is a Chinese machine reading comprehension task; NumHG (Huang et al., 2023) is used in Subtask 3, which comprises over 27K annotated numeral-rich news articles and can be further divided into headline generation and numerical reasoning.

Model Selection. For Subtasks 1 and 3, Flan-T5 (Chung et al., 2022) is utilized. For Subtask 2, we employ mT5-Small (Xue et al., 2021) and Randeng-T5-77M (Wang et al., 2022). Specifically, for Subtask 3, we experimented with Flan-T5 models ranging from Base to XXL sizes. For Flan-T5-XL and Flan-T5-XXL, we applied 8-bit quantization (Dettmersλ et al., 2022) and performed parameter-efficient tuning using LoRA (Hu et al., 2022). The *all-mpnet-base-v2* [2] can be utilized as encoder to map the text to vector.

Hyper-Parameter Selection. Adamw (Loshchilov and Hutter, 2017) is employed as the optimizer. In Subtask 1, The learning rate for all four QNLI tasks and QQA is set to 5e-7. For the QP task, the learning rate is set to 3e-5. Unless specified, the learning rates, dropout and warm-up rates for remaining tasks are set to 5e-5, 1e-2 and 0.1, respectively. We also applie the PEFT[3] library for parameter-efficient tuning.

Evaluation Metrics. Quantitative-101 Score (Huang et al., 2023) is used for ranking the overall performance in Subtask 1, while Accuracy is used to evaluate Subtask 2 and the numerical reasoning task of Subtask 3. For the numerical reasoning task, based on whether the reasoning question involves calculation, they can be further categorized into *simple* and *complex*. ROUGE (Lin, 2004), BERTScore (Zhang et al., 2020), and MoverScore (Zhao et al., 2019) are used to evaluate the result of the headline generation task of Subtask 3 and nu-

merical accuracy in headlines is also considered.

5 Main Result and Analysis

Comparison Results on Quantitative 101 As results shown in Table 2, despite the distinct ways to handling queries, the instruction tuning Flan-T5 remains comparable to BERT. Notably, our system performs superior on QNLI and QQA, which have smaller datasets. The introduction of manual demonstrations (Sec 3.2) don't lead to improvement in instruction fine-tuning. This may be associated with the manual selection of examples and hyperparameters. Furthermore, in contrast to the *Digit-based* notations, utilizing the *Original* notation for numbers performs better.

Comparison Results on NQuAD As shown in Table 4, it can be observed that the T5 tuning by instruction outperformed the BERT significantly. Both mT5 and Randeng-T5 are pre-trained on multilingual or Chinese corpus, which can enhance their capability to address Chinese-related tasks effectively. Additionally, Randeng-T5, which is based on Chinese corpus, is superior to mT5. However, enlarging the model scale seemed to lead to decreased accuracy on this task.

Comparison Results on NumHG Tables 5 and 6 show that larger models perform better on both headline generation and numerical reasoning.

Table 3 shows that instruction fine-tuning indeed leads to better performance on text generation compared to direct fine-tuning, which means instructions providing proper guidance to Flan-T5. Interestingly, the introduction of similar demonstrations further enhances the model's performance on text generation evaluation metrics but comes at the cost of lower numerical accuracy, which can be observed both in the model of Base and XXL.

Method	Num Acc		
	Total	Simple	Complex
Flan-T5-Base$_{ans_only}$	88.691	94.205	61.125
Flan-T5-Base$_{operator}$	88.753	94.548	59.780
Flan-T5-Base$_{cot}$	88.509	94.279	59.658
Flan-T5-Base$_{cot+cal}$	88.936	94.279	62.225
Flan-T5-XXL$_{int8_LoRA+operator}$	93.704	97.164	76.406
Flan-T5-XXL$_{int8_LoRA+cot}$	94.010	**97.359**	77.262
Flan-T5-XXL$_{int8_LoRA+cot+cal}$	**94.173**	**97.359**	**78.240**

Table 6: The performance of different methods on the numerical reasoning task. The *cot* is the method proposed in Sec 3.3, and *cal* denotes using an external calculator (Cobbe et al., 2021) for result correction.

As for numerical reasoning, the CoT method leads to better performance on answering *Complex* questions compared to other methods and external calculator correction further amplifies this advantage, as shown in Table 6. For both Base and XXL models, the CoT method under external calculator correction achieved the best performance. However, due to the relatively limited capabilities of smaller models, the performance boost on *Complex* tasks don't contribute significantly to the overall performance for the Base model.

6 Conclusion

During Task 7 of SemEval2024, we participated in all the subtasks and implemented the corresponding systems by instruction fine-tuning. We utilized instruction fine-tuning with demonstrations to expand its format. We also reformulated the output in the form of a chain of thought to improve the model's reasoning abilities. Our approach proved to be highly effective by outstanding performance across all the subtasks. In future work, we plan to further explore the impact of varying instance quantities, instruction templates, and model sizes on the results.

Abstract

The explosive growth of online content demands robust Natural Language Processing (NLP) techniques that can capture nuanced meanings and cultural context across diverse languages. Semantic Textual Relatedness (STR) goes beyond superficial word overlap, considering linguistic elements and non-linguistic factors like topic, sentiment, and perspective. Despite its pivotal role, prior NLP research has predominantly focused on English, limiting its applicability across languages. Addressing this gap, our paper dives into capturing deeper connections between sentences beyond simple word overlap. Going beyond English-centric NLP research, we explore STR in Marathi, Hindi, Spanish, and English, unlocking the potential for information retrieval, machine translation, and more. Leveraging the SemEval-2024 shared task, we explore various language models across three learning paradigms: supervised, unsupervised, and cross-lingual. Our comprehensive methodology gains promising results, demonstrating the effectiveness of our approach. This work aims to not only showcase our achievements but also inspire further research in multilingual STR, particularly for low-resourced languages. (Ousidhoum et al., 2024b)

Keywords: Natural Language Processing, Semantic Textual Relatedness, Sentence Transformers, supervised learning, unsupervised learning, cross-lingual.

1 Introduction

The ever-increasing diversity of online content demands robust Natural Language Processing (NLP) techniques that can grasp the nuances of meaning across diverse languages. Semantic Textual Relatedness (STR) plays a crucial role in achieving this goal by delving beyond superficial lexical similarity and capturing the deeper connections between sentences. Unlike semantic similarity, which focuses solely on the taxonomic overlap of words, STR encompasses both linguistic elements and non-linguistic factors like the topic, point of view, and period. This richer understanding unlocks significant potential in various NLP tasks, regardless of the user's native language. Imagine searching for information online in your native language and receiving results that truly understand your intent, and not just match keywords. STR holds the key to unlocking this dream, bridging the language gap, and fostering true multilingual communication.

Despite the recognized importance of Semantic Textual Relatedness (STR) for multilingual communication, most prior NLP research has focused on semantic similarity within English due to limitations in labeled data for diverse languages (Abdalla et al., 2023). This narrow focus restricts the potential of STR applications like information retrieval across languages with different cultural contexts or machine translation that accurately captures nuances beyond direct word equivalents. Existing relatedness methods primarily target English (Hasan and Halliday, 1976), with limited exploration in languages like German, Chinese, and Japanese (Zesch et al., 2007) (Li et al., 2005) (De Saeger et al., 2010). This highlights a critical gap in Natural Language Processing (NLP): accurately measuring semantic relatedness across diverse languages.

The identified gap in multilingual STR research, with its limitations in diverse language applications, demands innovative solutions. This paper dives into the exciting realm of bridging this gap through multilingual Semantic Textual Relatedness (STR). Specifically, we explore methods to capture the semantic connections between texts in languages like English, Marathi, Hindi, and Spanish.

Our research focuses on the SemEval-2024 shared task, which provides three tracks to evaluate STR techniques:

1. Supervised Learning: This track focuses on building systems trained on the provided labeled datasets.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 980–985

2. Unsupervised Learning: Here, the challenge lies in developing systems that learn semantic relationships without relying on any labeled data.

3. Cross-lingual Learning: This track pushes the boundaries by requiring systems to leverage knowledge from labeled data in a source language (Track A) to address a target language with limited resources.

For each track, we present a comprehensive methodology, employing diverse language models and rigorously analyzing their performance. This allows us to identify the most effective approaches for each challenge. Notably, our submissions achieved promising scores on several tracks, demonstrating the strength and potential of our proposed methods.

Looking beyond our achievements, this work aims to inspire further exploration of multilingual STR, particularly for under-resourced languages. We believe that larger datasets and broader language coverage hold immense potential to benefit the NLP community, unlocking the true potential of language understanding and empowering communication across diverse cultures.

2 Related Work

Semantic textual relations (STR) play an important role in natural language processing (NLP), which aims to identify the degree of semantic similarity between text groups. It forms the backbone of various NLP tasks such as information retrieval, question answering, and paraphrase detection, necessitating the assessment of similarity between sentences, phrases, or documents.

Historically, detailed STR research from the 1900s through the 2000s relied heavily on statistical methods heavily dependent on lexical databases like WordNet. However, these methods suffered from a lack of real-world knowledge integration (Gabrilovich et al., 2007). Classified translation emerged with developments such as GloVe (Pennington et al., 2014), Word2Vec, and FastText, which enabled text to be converted into word input. The current methods require converting corpora into words or sentence-embedded forms and computing connectivity scores. Notably, large language models (LLMs) such as Sentence-BERT often use Cosine Similarity in embedded sentences to measure relatedness (Gunawan et al., 2018) (Reimers and Gurevych, 2019).

Previous methodologies have delved into both knowledge-based (ontology, classification) and corpus-based (unsupervised learning) approaches. For example, (Siblini and Kosseim, 2017) examined three approaches: semantic linkage, classification similarity, and hybrid approaches. Notably, the multilingual approach of (Hasan and Halliday, 1976), improved by 47%, confirming the potential of emphasis on the use of multilingual strategies. Furthermore, studies on less resourceful African languages highlight the need for different data types and methodologies (Delil and Kuyumcu, 2023).

A significant challenge in STR lies in the scarcity of huge-scale, promising datasets for education and assessment. Initiatives like SemEval play a pivotal role in addressing this gap through dedicated shared tasks focused on STR (Abdalla et al., 2023). These collaborative efforts foster the improvement and evaluation of STR models throughout diverse linguistic landscapes and domain names.

The current advent of the STR-2022 dataset by (Abdalla et al., 2023) marks a significant leap forward in STR studies. This annotated dataset, comprising sentence pairs with relatedness scores, serves as a precious aid for schooling and evaluating STR fashions. Covering various domains and languages, it displays the multilingual nature of STR studies (Abdalla et al., 2023).

Moreover, STR-2022 addresses biases and perceptions in relatedness judgments. Through meticulous curation, it aims to mitigate biases and ensure annotation quality, thereby fostering fair evaluations and robust model development. Additionally, the dataset highlights the relative nature of relatedness ratings, emphasizing the significance of context and assignment-precise thresholds in decoding similarity measures (Abdalla et al., 2023).

3 System Description

In this section, we aim to outline our system's components for assessing semantic textual relatedness across different datasets: a) labeled datasets using supervised learning, b) unlabeled datasets employing unsupervised learning, and c) cross-lingual datasets. We'll detail the utilized data, the models employed in each track, and the results obtained from training these models on respective datasets.

3.1 Data Collection

We utilized the SemRel2024 Dataset (Ousidhoum et al., 2024a) for training and evaluating our final results. This comprehensive dataset consists of semantic textual relatedness data across 14 diverse languages, including Afrikaans, Algerian Arabic, Amharic, English, Hausa, Hindi, Indonesian, Kinyarwanda, Marathi, Moroccan Arabic, Modern Standard Arabic, Punjabi, Spanish, and Telugu. From this array of languages, we focused on English, Hindi, Marathi, and Spanish datasets for our analysis.

Each entry in the dataset comprises a sentence pair along with its corresponding semantic similarity score. This score ranges from 0 to 1, where 0 signifies no similarity between the sentences, while 1 indicates complete similarity.

For the supervised track (Track A), we concentrated on English and Marathi datasets. In the unsupervised track (Track B), our attention was on English and Hindi datasets. Lastly, for Track C, we employed English and Hindi datasets, utilizing Spanish and English as their language training bases, respectively.

Language	Train	Dev	Test
English	5500	250	2500
Hindi	-	288	968
Marathi	1155	293	298
Spanish	1592	140	600

Table 1: Distribution of dataset for Training, Development, and Testing

3.2 Experiments

3.2.1 Track A:

The SemRel2024 English and Hindi datasets were initially trained on baseline models such as Support Vector Regression and XGBoost. However, we additionally adapted the sentence-transformer-based models, such as all-mpnet-base-v2 [1] and marathi-sentence-bert-nli [2] by L3Cube for English and Marathi respectively. This was done to compensate for the smaller size of the corpora available, as these sentence transformer models are trained on a larger data size initially, and this would be efficient to understand not only the n-gram sequences but also the context of the sentences that are being compared.

[1]https://huggingface.co/sentence-transformers/all-mpnet-base-v2

[2]https://huggingface.co/l3cube-pune/marathi-sentence-bert-nli

Preprocessing and Feature vectorization were done using Term-frequency and inverse-document-frequency (TF-IDF) to generate vectors and preprocess the models SVR and XGBoost. Term-frequency, Inverse-Document-Frequency (TF-IDF) is a numerical statistic that determines how important a word is in a given document or a piece of textual content. This is done by multiplying two metrics: How many times a word appears in a document Inverse document frequency of the word across a set of documents. This score for word in the document d from document D is calculated as follows:

$$tfidf(t, d, D) = tf(t, d).idf(t, D) \quad (1)$$

$$tf(t, d) = log(1 + freq(t, d)) \quad (2)$$

$$idf(t, D) = \log\left(\frac{N}{\text{count}(d \in D : t \in d)}\right) \quad (3)$$

(Chen et al., 2020).

Support vector regression (SVR) can be used for calculating semantic similarity scores between sentences. It's a supervised learning algorithm that can model the relationship between input features, (here in this case the sentences) and the output labels (semantic similarity scores in this case).

XGBoost can be used for semantic similarity score calculation between sentences as it is a powerful gradient-boosting algorithm, and it can be applied to various supervised learning tasks. This is capable of handling complex non-linear relationships between features and labels, and it's robust against overfitting.

All-mpnet-base-v2 (All- Massively Parallel Multilingual Transformer) is a sentence encoder model, given an input text, it gives a vector that collects the semantic information. The sentence vector is used for tasks such as clustering or sentence similarity tasks. This is a sentence-transformers model and it maps sentences & paragraphs to a 768-dimensional dense vector space. This is trained on the SemRel2024 dataset and additionally, it is capable of capturing long-range dependencies, and it leads to higher performance on text classification, NER, and question answering.

Marathi-Sentence-Bert-Nli (Joshi et al., 2022) is a Marathi sentence transformer model that has been trained on synthetic STS and NLI datasets. These are fine-tuned on MahaBERT, a BERT-based model that is fine-tuned on a large Marathi corpora.

3.2.2 Track B:

For track B, the unsupervised track, the SemRel2024 dev set, and the test set were used for testing the model selected. The languages were English and Hindi, for which Track-B dev and test sets were used. The models used for this were BERT-based uncased and Hindi-Bert v2 (Joshi, 2022) accordingly.

Hindi-BERT-v2 was roughly trained on 1.8 B tokens. Compared to general-purpose language models, this monolingual model is optimized to understand and process Hindi text effectively. Due to the larger corpus it has been trained upon this has been an accurate model to obtain results from.

BERT-based-uncased (Bidirectional Encoder Representations from Transformers) is trained on uncased text. BERT is based on the transformer architecture that relies on self-attention mechanisms to capture relationships between words in a sequence, enabling effective modeling of long-range dependencies in text data.

Algorithm:

1. The BERT model (English/Hindi) is initialized.
2. Sentence embeddings for sentence 1 are calculated.
3. Sentence embeddings for sentence 2 are calculated.
4. Calculate the cosine similarity scores of the embeddings.

3.2.3 Track C:

Cross-linguistic track: The English and Spanish SemRel2024 training datasets were used for training data in languages Hindi and English respectively. The dataset first underwent translation using the deep translation API. By translating the dataset from English to Hindi and Spanish to English, the training dataset for that language was available and was used for testing the development set and the test set of the SemRel 2024 dataset. The models used for training the dataset were the "all-mpnet-base-v2" sentence transformer and "hindi-sentence-bert-nli" [3] by L3cube. These 2 sentence transformers are discussed in Track A, above, however, this went through an additional translation pipeline before that.

[3]https://huggingface.co/l3cube-pune/hindi-sentence-similarity-sbert

1. Translate sentences from Language 1 to Language 2 using an appropriate translation service or tool.
2. Initialize the model for the task, such as sentence similarity or classification.
3. Encode Sentence1 into a numerical representation using the initialized model. This involves converting the text input into a format suitable for processing by the model, typically through tokenization and embedding.
4. Similarly, encode Sentence2 into a numerical representation using the same BERT model.
5. Train the initialized model on the provided dataset. This step involves feeding the encoded sentence pairs into the model and adjusting the model's parameters to minimize a predefined loss function, typically using techniques like backpropagation and gradient descent.
6. Evaluate the performance of the trained model on a separate evaluation dataset or through cross-validation. This step aims to assess the model's ability to generalize to unseen data and its overall effectiveness in the task of interest, such as sentence similarity or classification.
7. If necessary, repeat steps 3 to 6 for all pairs of sentences in the dataset. This process ensures that the model learns from a diverse range of examples and improves its performance across different input scenarios.

4 Experimental Setup

The dimensions of the dataset splits are summarized in Table 1, indicating the number of samples allocated for training, development, and testing across different languages. The experimental setup encompassed preprocessing procedures, leveraging Hugging Face Transformers for model access, NumPy for array operations, Pandas for data manipulation, Sentence Transformers for sentence embeddings, and NLTK for various NLP tasks. Evaluation measures such as the F1 score, accuracy, and recall were employed to comprehensively assess the performance of the models across correlation, classification accuracy, and retrieval quality aspects.

5 Results

Tables 2, 3, and 4 present the performance results for the three setups (supervised, unsupervised, and cross-lingual) in our experiments. Each table summarizes the F1 score, accuracy, and recall achieved by various models for each language.

Sr.No.	Language	Model Name	F1	Accuracy	Recall
1	English	BERT-base-nli	0.87	0.876	0.84
2	English	SVR	0.59	0.55	0.65
3	English	XG-Boost	0.79	0.82	0.76
4	Marathi	Marathi-NLI	0.83	0.81	0.90
5	Marathi	SVR	0.63	0.61	0.60
6	Marathi	XGBoost	0.66	0.67	0.70

Table 2: Performance Metrics for Track A

This table shows the performance of models in the supervised learning setup, where labeled data was available for training. BERT-based models ("BERT-nli" and "Marathi-nli") consistently outperform other models (SVR, XGBoost) in both English and Marathi, achieving significantly higher correlation scores (0.823 and 0.871, respectively). Interestingly, the Marathi-specific nli model even surpasses the multilingual BERT performance in Marathi, suggesting the benefit of language-specific models.

Sr. No.	Language	Model Name	F1	Accuracy	Recall
1	English	sentence-t5	0.66	0.49	0.49
2	English	BERT based uncased	0.85	0.86	0.80
3	Hindi	Indic-BERT	0.66	0.50	0.50
4	Hindi	hindi-bert-v2	0.66	0.74	0.50

Table 3: Performance Metrics for Track B

This table presents the results for the unsupervised learning setup, where models were trained without relying on labeled data. In English, the BERT-based model ("BERT-base-uncased" [4]) outperforms the pre-trained Sentence-T5 [5] model, possibly due to its larger size and fine-tuning on relevant NLP tasks. In Hindi, while both Indic-BERT(Kakwani et al., 2020) and hindi-bert-v2 (Joshi et al., 2022) have similar F1 scores (around 66%), the latter achieves a significantly higher correlation coefficient (0.796). This indicates that hindi-bert-v2 [6] captures semantic relatedness more effectively despite similar overall accuracy.

[4]https://huggingface.co/google-bert/bert-base-uncased

[5]https://huggingface.co/sentence-transformers/sentence-t5-base

[6]https://huggingface.co/l3cube-pune/hindi-bert-v2

Sr. No.	Language	Model Name	F1	Accuracy	Recall
1	Spanish to English	all-mpnet-base-v2	0.82	0.82	0.81
2	English to Hindi	hindi-sentence-bert-nli	0.71	0.77	0.92

Table 4: Performance Metrics for Track C

This table shows the performance of models in the cross-lingual learning setup, where the goal was to assess semantic relatedness across different languages. Both models used ("all-mpnet-base-v2" for Spanish-to-English and "hindi-sentence-bert-nli" for English-to-Hindi) achieve worthy correlation scores (0.786 and 0.809, respectively) demonstrating the potential of cross-lingual approaches.

Table 5 represents the results of the development phase.

Track	Language	Sp. Corr Coeff
A	English	0.812
	Marathi	0.855
B	Hindi	0.819
	English	0.825
C	Hindi	0.825
	Englsih	0.790

Table 5: Development Phase Results

6 Conclusion

In this paper, we presented a comparative analysis of systems for the Semantic Textual Relatedness (STR) task at SemEval-2024 Task 1. Our approaches, primarily based on language-specific transformer models, achieved top scores on several tracks, including 1st place in Unsupervised Learning for Hindi. Notably, we did not utilize any external datasets, highlighting the effectiveness of our approach despite potential variations in pre-trained model training data.

Prior research in STR has largely focused on English due to limited labeled data for diverse languages. This restricts the true prospect of STR applications like multilingual information retrieval and machine translation. We addressed this gap by exploring solutions for STR in English, Marathi, Hindi, and Spanish. We aim to inspire further research on multilingual STR, particularly for low-resourced languages. We believe larger datasets and broader language coverage hold immense potential for multilingual NLP, unlocking a deeper understanding and empowering cross-cultural communication.

Abstract

This paper describes our submission to Task 2 of SemEval-2024: Safe Biomedical Natural Language Inference for Clinical Trials. The Multi-evidence Natural Language Inference for Clinical Trial Data (NLI4CT) consists of a Textual Entailment (TE) task focused on the evaluation of the consistency and faithfulness of Natural Language Inference (NLI) models applied to Clinical Trial Reports (CTR). We test 2 distinct approaches, one based on finetuning and ensembling Masked Language Models and the other based on prompting Large Language Models using templates, in particular, using Chain-Of-Thought and Contrastive Chain-Of-Thought. Prompting Flan-T5-large in a 2-shot setting leads to our best system that achieves 0.57 F1 score, 0.64 Faithfulness, and 0.56 Consistency.

1 Introduction

The digitization of medical documents allows the development of tools using various NLP techniques. In the case of Clinical Trial Reports (CTR), these tools can facilitate recruiting patients to participate in a trial or help researchers keep up to date with the literature. Natural Language Inference (NLI) is particularly useful in detecting the relationship between a CTR and a statement. For instance, it can be used for patient-trial matching.

Task 2 of SemEval 2024 defines a Textual Entailment (TE) task applied to English breast cancer CTRs. A submitted system must perform a binary classification based on a CTR and a given statement, using the labels *entailment* or *contradiction*. In addition to the traditional F1-measure for Textual Entailment, the submitted systems are evaluated on 2 strong metrics: Faithfulness and Consistency.

In this paper, we first introduce the task and some related work in Sec. 2. Sec. 3 describes our proposed approaches, while Sec. 4 gives further details about the experimental setup. Sec. 5 presents the results and comparative analysis of methods, and Sec. 6 sums up our work done and provides ideas for future work.

2 Background

2.1 Corpus and task description

The NLI4CT (Jullien et al., 2024) corpus consists of a collection of breast cancer Clinical Trial Reports (CTR) taken from clinicaltrials.gov. The documents are exclusively written in English. These CTRs are structured with the following sections: *Intervention* section describes what treatment is going to be applied during the trial. *Eligibility* section consists of a set of inclusion and exclusion criteria that a test subject must comply with. *Results* section displays the outcome measures. Finally, *Adverse Events* section describes the side effects and symptoms observed during the trial. In NLI4CT there are two types of instances: *single*, where only 1 CTR is involved to perform the inference, and *comparison* where 2 CTRs need to be compared.

The task's objective is to perform Natural Language Inference on these clinical trials. A premise consists of a section of a CTR (or two CTRs if it is a comparison), and a statement is a single sentence. The model should predict whether the premise entails or contradicts the statement. To tackle the NLI4CT task, the model must perform several kinds of inference, such as quantitative, common-sense, and medical reasoning (see Fig. 2). The inference relationship can be predicted using the evidence, sentences where clues are contained, that are in one of the sections of a CTR. Evidence is provided only in the development and training sets. The dataset is balanced with half of the instances labeled as *entailment* and the other half as *contradiction* in the train and development subsets.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 986–996

2.2 Related work

A previous edition of the NLI4CT task was run as SemEval 2023 Task 7 (Jullien et al., 2023a). It was composed of 2 subtasks: an NLI classification task and an information retrieval task of evidence selection to support the predicted label. The training and development sets were the same as the present edition. For the first subtask, the task overview paper (Jullien et al., 2023b) reports both generative and discriminative approaches for the submitted systems. Over the past few years, we have seen the fast-paced development of Large Language Models (LLMs) and their increased capabilities in addressing both generative and discriminative tasks. Even general-domain LLMs like Flan-T5-xxl in Kanakarajan and Sankarasubbu (2023) and GPT-3.5 in Pahwa and Pahwa (2023) have been achieving competitive performance on domain-specific tasks for the 2023 edition of the NLI4CT task.

3 System overview

To address the NLI4CT task, we tested 2 main approaches: the first uses Pretrained Masked Language Models (MLM), and the second uses generative Large Language Models. We wanted to compare the ability of these two kinds of architectures to solve the same task, in particular in terms of consistency and faithfulness.

3.1 Finetuning pretrained masked language models

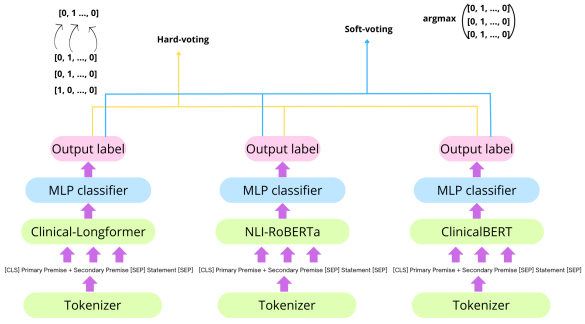

Figure 1: MLM ensemble architecture overview.

Our first system is based on finetuning and ensembling multiple MLMs on the task data (see an example in Fig. 1). We first finetune each model using the train and development splits of NLI4CT. We evaluate each finetuned model on the test set. We perform experiments with two ensembling methods: hard-voting and soft-voting. The hard-voting method consists of selecting the label y that gets the majority of votes across the predictions of each model j, defined as follows:

$$\tilde{y} = \underset{y}{\text{argmax}} \sum_{j=1}^{N} \mathbb{1}(\tilde{y}_j = y)$$

Soft-voting is computed by using the argmax of probabilities P_j from each model j for a given label y:

$$\tilde{y} = \underset{y}{\text{argmax}} \sum_{j=1}^{N} P_j(y)$$

3.2 Prompting generative large language models

We designed a set of prompts that rely on the following techniques:

1. A simple prompt instructing the model to perform Textual Entailment, giving the statement and a premise composed of the whole section where the evidence comes from. We took inspiration from the instruction templates found in the Flan-Muffin dataset[1] that (Lou et al., 2024) used to instruction-tune the Flan-T5 models (Chung et al., 2022). The template starts with optional demonstrations that instantiate this prompt with n training or development examples in n-shot settings:

[Demonstrations] [Premise] [Statement] Based on this premise, is the hypothesis true? OPTIONS: -'Yes' -'No'

2. Using the concept of Chain-Of-Thought (Wei et al., 2022) that decomposes the reasoning behind a given example; we insert the premise sentences that are the actual evidence used to infer an entailment or a contradiction in the demonstrations. See C.2 for a detailed example.

3. We tested the related Contrastive Chain-Of-Thought (CCOT) (Chia et al., 2023) technique that gives both one correct and one incorrect explanation in addition to the original template. In our case, we inserted premise sentences that were not actual evidence. See C.3 for an example. CCOT is inspired by how humans learn from positive and negative examples and aims to reduce reasoning errors by indicating what mistakes to avoid.

For the demonstrations, we tried three few-shot settings: zero-shot (ZS: no demonstration, only for the first template), 1-shot, and 2-shot. See Appendix C for detailed examples of the prompts.

[1] https://huggingface.co/datasets/causal-lm/flan-muffin

4 Experimental setup

4.1 Data pre-processing

We used the NLI4CT train and development splits published by BigBio on HuggingFace[2] and enriched them with new columns: primary and secondary evidence and premises from the JSON files provided by the organizers. We used this dataset to build our prompts (see Sec. 3.2). We shuffled the train and dev sets and selected random instances to include as demonstrations in our 1 and 2-shot settings.

4.1.1 Ensembling MLMs

We used Masked Language Models that are pretrained on general domain data or clinical data. For the general domain, we selected NLI-RoBERTa[3] (Reimers and Gurevych, 2019) from Sentence Transformers, which has been previously finetuned for NLI using SICK (Marelli et al., 2014) and STS benchmark (Cer et al., 2017). For the clinical pretrained models we use Clinical-Longformer[4] (Li et al., 2023), which can handle a context window up to 4096 tokens, and ClinicalBERT[5] (Wang et al., 2023) which has been pretrained on Electronic Health Records. We used Optuna (Akiba et al., 2019) for hyperparameter search and set our final configuration with a learning rate of $5e^{-5}$ using the AdamW (Loshchilov and Hutter, 2017) optimizer, a batch size of 64 and finetuned the models for 4 epochs. Ensembles of the same model used a different random seed when training each instance. We used 4 NVIDIA Tesla V100 with 32 GB of RAM with a training and inference time varying from 3 to 6.5 hours. A more detailed analysis of the training cost can be found in Appendix 6.

4.1.2 Prompting generative LLMs

We tested several Large Language Models (see Appendix F). We eventually chose Flan-T5-large[6] (Chung et al., 2022) for its ability to output answers that are easier to parse than the longer and more challenging answers that could be provided by Llama-2 (Touvron et al., 2023) or Mistral (Jiang et al., 2023). Flan-T5 has been pretrained on a mixture of 473 datasets covering 1,836 tasks. However, it has no biomedical or clinical pertaining. We rely on the HuggingFace framework for all experiments. We used the same computing setup as in the previous set of experiments. The codebase for all of our experiments is freely available.[7]

4.2 Evaluation

We evaluate our models using the following metrics. The F1 score of the *Entailment* class is measured on a control set of the gold test set which is the same as the NLI4CT 2023's test data. Faithfulness measures whether a model changes predictions when an 'entailing' statement is changed into a 'contradicting' statement. Consistency measures whether a model keeps its predictions when a statement is changed while preserving its relation to the premise. Both metrics are computed on a contrast set of the gold test set that has undergone perturbations (more details in Jullien et al. (2024)).

5 Results

5.1 Quantitative analysis

Under the username *math_agr*, our team ranked 27th for an F1 score of 0.57, 18th for Faithfulness of 0.64, and 25th for Consistency of 0.56. Tables 1–6 report the results of our experiments on the test set.

Single system	F1	Faithfulness	Consistency
Majority class	0.67	0.00	0.38
tf.idf (Jullien et al., 2024)	0.41	0.47	0.47
FZI-WIM	0.80	0.90	0.73
rezazzr	0.06	0.95	0.60
NYCU-NLP	0.78	0.92	0.81
a: NLI-RoBERTa	0.56	0.58	0.57
b: ClinicalBERT	0.00	**1.00**	**0.62**
c: Clinical-Longformer	**0.67**	0.00	0.38
Ensemble	s/h	s/h	s/h

[7] https://github.com/MathildeAguiar/SemEval-2024-Task-2

Each model has different strengths and weaknesses across the three metrics in the MLM experiments. The single NLI-RoBERTa seems to be the most stable baseline despite its lack of pretraining on biomedical data. It has already been finetuned on general-domain NLI, and its sentence-level representation seems to boost its performance. The ensemble of 3 NLI-RoBERTa does not add enough diversity to improve its results. The single ClinicalBERT obtains an F1-score of 0.00: we observed that it always predicts the label *Contradiction*, which causes a precision and recall of 0.00. Faithfulness yields 1.00 because it is computed on instances of the contrast test set that are all labeled as *Contradiction*. The ensemble of 3 ClinicalBERT does not have this issue: some seeds led to better models. The single Clinical-Longformer obtains the best results in terms of F1-score but the worst on the other two metrics, especially on Faithfulness. It predicts almost exclusively *Entailment*, which leads to Faithfulness and Consistency complementary to ClinicalBERT's. The ensemble keeps the same issues. An ensemble (d) of the three single models could not improve the single NLI-RoBERTa. Adding Flan-T5's 2-shot predictions to the ensemble increased Faithfulness by 0.24 points but did not yield better F1. This did not improve either over Flan-T5 alone (see row 2S in Tab. 2).

Prompt	F1	Faithfulness	Consistency
ZS	0.56	0.57	0.55
1S	0.53	0.63	**0.57**
2S	**0.57**	0.64	0.56
1SCOT	0.39	0.70	0.53
2SCOT	0.43	0.69	0.51
1SCCOT	0.28	**0.85**	**0.57**
2SCCOT	0.24	0.81	0.56

Table 2: F1 score, Faithfulness, and Consistency for the LLM approach, using Flan-T5-large.

Prompting Flan-T5-large in few-shot mode performs as well as the fine-tuned NLI-RoBERTa. Increasing the number of demonstrations tends to improve the scores. This illustrates the usual trade-off between fine-tuning a smaller model or prompting a larger model without fine-tuning it. The Chain-Of-Thought method makes it more difficult to recognize *Entailment* relations and leads to lower F1. As seen above, this mechanically increases Faithfulness. Contrastive Chain-Of-Thought further reduces the number of predicted *Entailment* relations, with an associated increase in Faithfulness. All systems achieve similar Consistency.

The tf-idf baseline was provided by the task organizers. Some of our proposed systems scored below the baseline in some metrics. For instance, Clinical-Longformer obtained a much lower Faithfulness and Consistency, ClinicalBERT, CCOT, and 1SCOT prompts obtained lower F1 scores.

According to the leaderboard, the top scores were 0.80 for the F1 score, 0.95 for Faithfulness, and 0.81 for Consistency, achieved by 3 different teams. We do not have information regarding the approaches these teams chose at the time of writing. Using last year's results on the F1 score, the approach of Kanakarajan and Sankarasubbu (2023), using Flan-T5-xxl, achieved an F1 score of 0.83. Their approach differs from ours by not only prompting Flan-T5 but by finetuning it beforehand using single- and multiple-instruction templates. This approach leads to a boost in performance compared to our simpler approach. Takehana et al. (2023) also performed ensembling and voting of MLMs and achieved an F1 score of 0.66. They performed what we called 'hard voting,' using 10 models for their ensemble and performing data augmentation on the original task dataset. Their result is comparable to our approach using an ensemble of 3 ClinicalBERT or 3 Clinical-Longformer.

5.2 Error analysis

In this section, we analyze our models in more depth by breaking down their results according to gold labels, whether a comparison of CTRs is involved, the types of inference to perform, CTR sections, and examine the F1 score per intervention type. For simplicity, we focus our analysis only on the two best-performing systems of each approach.

Accuracy per gold label From the accuracy displayed in Tab. 3, we observe that our LLM methods, especially CCOT, handle the Contradiction examples better. This label is the most frequent in the test set (67% of instances labeled as Contradiction and 33% as Entailment). MLMs, in contrast, have similar accuracy across both labels.

Comparison versus Single The *Comparison* of 2 CTRs implies longer input sequences and possibly an increased complexity since the model needs to confront the elements of two separate documents. Surprisingly, as reported in Tab. 4, we observe that all models perform similarly for *Comparison* and

System	Entailment	Contradict.
3 NLI-RoBERTa	**55**	56
(d) + Flan-T5-large	**55**	48
2S	44	64
1SCCOT	20	**82**

Table 3: Accuracy (in %) per label: *Entailment* and *Contradiction* (Contradict.). Systems: ensemble of 3 NLI-RoBERTa; ensemble of all MLM baselines (d) + Flan-T5-large (2S); Flan-T5-large in 2-shot (2S) and 1-shot contrastive chain-of-thought (1SCCOT) settings.

Single. We can hypothesize that the models are able to find more clues with 2 documents instead of 1 and predict more accurate labels.

System	Single	Comparison
3 NLI-RoBERTa	56	56
(d) + Flan-T5-large	49	51
2S	59	56
1SCCOT	**61**	**61**

Table 4: Accuracy (in %) per CTR type: *Single* and *Comparison*. Systems: see Tab. 3.

CTR sections From the accuracy displayed in Tab. 5, we observe no performance distinction between the models for different sections.

System	AE	Int.	Elig.	Res.
3 NLI-RoBERTa	60	59	52	52
(d) + Flan-T5-large	43	46	55	57
2S	55	58	**61**	54
1SCCOT	**62**	**63**	58	**60**

Table 5: Accuracy (in %) per CTR section: *Adverse events* (AE), *Intervention* (Int.), *Eligibility* (Elig.), and *Results* (Res.). Systems: see Tab. 3.

Types of 'intervention' Tab. 6 results were obtained directly from the task organizers' evaluation script. Once again NLI-RoBERTa is stable across *Paraphrase* and *Definition* interventions and achieves the best performance. NLI-RoBERTa seems to be less sensitive to semantic change when it comes to paraphrasing. Its score for *Definition* shows that it can capture the relevant information better when more details are provided. Contrastive Chain-Of-Thought does not increase the model's resistance to semantic change (as shown by the results on *Paraphrase*), its ability to perform numerical inference (see results on Numerical paraphrase) or to focus on relevant information (see results on *Definition*). For the latter, the model might struggle to focus on relevant information because of the long length of the input prompts (see Tab. 11).

System	Def.	NP	Para.
3 NLI-RoBERTa	**0.57**	**0.51**	**0.56**
(d) + Flan-T5-large	0.39	0.46	0.54
2S	0.39	0.46	0.54
1SCCOT	0.31	0.26	0.25

Table 6: F1 score per intervention type: *Definition* (Def.), *Numerical Paraphrase* (NP), or *Paraphrase* (Para.) interventions. Systems: see Tab. 3.

6 Conclusion and future work

This paper describes the two systems proposed by the SEME team for the SemEval 2024 Task 2 NLI4CT. Our first approach is based on the finetuning and ensembling of Masked Language Models, using only the challenge's data. Our second approach consists of a pipeline to prompt Large Language Models, using prompt engineering techniques, such as Chain-Of-Thought and Contrastive Chain-of-Thought, in Zero-shot, 1-shot, and 2-shot manners. Our two best-reported results are 0.57 F1 score, 0.64 Faithfulness, and 0.56 Consistency, with prompting Flan-T5-large in a 2-shot manner, ranking 27th out of 32 submissions for F1, 18th for Faithfulness and 25th for Consistency. We obtain the same scores for the MLM system using an ensemble composed of a finetuned NLI-RoBERTa + Clinical-Longformer + ClinicalBERT + the predictions of Flan-T5-large, that is 0.57 for F1 score, 0.64 for Faithfulness, and 0.56 for Consistency.

Some future work could include the continuation of the Masked Language Models pretraining on unlabeled clinical trials, before performing a similar finetuning as presented in the paper. We could also apply this approach to medical Large Language Models like MEDITRON (Chen et al., 2023), by performing instruction-tuning using clinically oriented instructions and then prompting the resulting model on the task data. Another possible approach, similar to (Conceição et al., 2023), would be to incorporate domain ontologies (like UMLS) into the finetuning of Masked Language

Models to provide definitions and supplementary knowledge.

Ethical statement

The NLI4CT task uses clinical data extracted and processed from https://clinicaltrials.gov/. This resource is freely available, provided by the National Library of Medicine, and is an official U.S. Department of Health and Human Services website.

Carbon emissions

Another arguable ethical aspect of our approach is the carbon emissions generated by our models' training and inference. Our experiments used 4 Tesla V100 GPUs paired with 2 Intel Xeon Gold 6148 20 cores and 384 GB of RAM. Depending on the approach chosen, the running time can be up to 10 times longer. For instance, we observe an execution time of 3 hours for the training and inference of an ensemble of 3 ClinicalBERT models. For the inference of Flan-T5-large on a 2-shot Contrastive Chain-Of-Thought, we achieve up to 30 hours of running time to get the predictions for all instances of the test set. Globally, we can say that the MLM approach is computationally more efficient, with running times varying from 3 to 6.5 hours (for the ensemble of ClinicalBERT, NLI-RoBERTa, and Clinical-Longformer). For the LLM approach, we observe running times ranging from 10.5 hours (in Zero-shot) to 38 hours (in 1-shot Chain-Of-Thought).

We used Green Algorithms[8] (Lannelongue et al., 2021) to estimate carbon emissions, taking into consideration our aforementioned computational configuration. The MLM approach produces up to 831g of CO_2 with the 3 models ensembling approach. For the LLM approach, the emissions vary from 1.34 kg of CO_2 for zero, 1, and 2-shot experiments to 4.86kg for Contrastive Chain-Of-Thought experiments.

Considering the little gain in performance of LLMs compared to MLMs using our approach and the CO_2 overconsumption of the LLMs, it would be more reasonable to use the MLM approach in our case. The MLM approach also provides faster predictions, which can be much more convenient.

Abstract

Large language models (LLMs) have recently obtained strong performance on complex reasoning tasks. However, their capabilities in specialized domains like law remain relatively unexplored. We present CLUEDO, a system to tackle a novel legal reasoning task that involves determining if a provided answer correctly addresses a legal question derived from U.S. civil procedure cases. CLUEDO utilizes multiple collaborator models that are trained using multiple-choice prompting to choose the right label and generate explanations. These collaborators are overseen by a final "detective" model that identifies the most accurate answer in a zero-shot manner. Our approach achieves an F1 macro score of 0.74 on the development set and 0.76 on the test set, outperforming individual models. Unlike the powerful GPT-4, CLUEDO provides more stable predictions thanks to the ensemble approach. Our results showcase the promise of tailored frameworks to enhance legal reasoning capabilities in LLMs.

1 Introduction

Recent improvements in large language models are leading to a rethinking of legal practices, particularly in the United States (Frankenreiter and Nyarko, 2022; Hoffman and Arbel, 2023; Glaze et al., 2021). This can potentially transform time-consuming tasks such as brief writing and corporate compliance (Guha et al., 2023; Benedetto et al., 2023a). This could also contribute to alleviating the access-to-justice crisis (Corporation, 2017; Tito, 2017). The unique properties of LLMs, including their ability to learn from limited labeled data and proficiency in complex reasoning tasks, make them appealing for legal applications (Zheng et al., 2021; Guha et al., 2023; Benedetto et al., 2023b, 2024).

However, enthusiasm is tempered by concerns about the risks associated with LLMs, such as generating offensive, misleading, or factually incorrect content (Engstrom and Gelbach, 2020; Bender et al., 2021). These issues could have significant consequences, particularly affecting marginalized or under-resourced populations (Surden, 2020; Volokh, 2023; Koudounas et al., 2023, 2024).

To address safety implications, there is a pressing need to evolve and enhance legal reasoning capabilities in LLMs. Despite this urgency, practitioners face challenges in assessing LLMs' legal reasoning capabilities, as existing legal benchmarks are limited and often fail to capture the diverse aspects of legal tasks (Guha et al., 2023).

In this direction, the organizers of SemEval-2024 Task 5 introduce a novel Natural Language Processing (NLP) task and dataset derived from the U.S. civil procedure domain (Bongard et al., 2022). Each dataset instance comprises a case introduction, a specific question, and a potential solution argument, along with an in-depth analysis justifying the argument's applicability to the case. When provided with a topic introduction, a question, and a potential answer, the objective of the proposed task is to determine whether the given answer is accurate or not.

To tackle this task, we initially transform the dataset into a multiple-choice question answering problem using the multiple-choice prompting (MCP) approach (Robinson et al., 2023). We experimented with various open-source language models on this modified dataset, including Flan T5 XXL (Wei et al., 2021; Chung et al., 2022), LLama 7B and 13B (Touvron et al., 2023), Zephyr 7B (Touvron et al., 2023), and Mistral 7B (Jiang et al., 2023). Specifically, we trained these models to solve legal problems while also providing an explanation for the predicted outcome, leveraging the analysis provided. We thus introduce the *CLUEDO* approach, which stands for "**C**hoosing **L**egal o**U**tcome by **E**xplaining **D**ecisions through **O**versight". This framework utilizes multiple collaborative models to synthesize the final outcome based on each model's predictions. Each individual

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 997–1005

model is trained to predict the label of the correct candidate answer and generate an explanation accordingly. The final *"detective"* model operates in a zero-shot manner, relying upon the outputs of the collaborators. The model processes the answers and the explanations of all collaborators and deduces the ultimate answer.

The results on the challenge dataset demonstrate that our proposed methodology surpasses the performance of single models trained with standard fine-tuning. Furthermore, our approach achieved the second-place position in the public competition, achieving a final test F1 macro score of 0.77[1].

Research Questions. We investigate the following research questions (RQs):

- **RQ1.** Is the multiple-choice setting more effective than the single-choice one?
- **RQ2.** Does including the analysis in the training and generation process improve performance?
- **RQ3.** Is our detective model CLUEDO more effective than individual collaborators in a zero-shot setting? Are CLUEDO results more stable?

2 Related Work

In the legal domain, the advent of Legal LLMs has reshaped how legal professionals approach case analysis, decision-making, and document generation processes (Lai et al., 2023). LLMs possess logical reasoning capabilities that enable legal professionals to comprehend case processes, aid judges in decision-making, swiftly identify similar cases through language comprehension, analyze and condense essential case details, and utilize automated content generation to draft repetitive legal documents (Guha et al., 2023). Researchers have recently started exploring whether large language models have the capability to carry out legal reasoning. Unlike BERT-based models, LLMs are evaluated on their ability to learn tasks in-context, primarily through prompting (Liu et al., 2022). Studies have explored the role of prompt-engineering for Legal Judgment Prediction (Jiang and Yang, 2023), statutory reasoning (Blair-Stanek et al., 2023) legal exams (Yu et al., 2023). Several case studies (Nay et al., 2023; Drápal et al., 2023; Savelka, 2023; Savelka et al., 2023; Westermann et al., 2023) highlight the potential and the limitations of GPT models in real use cases. However, to the best of our knowledge, limited effort has been devoted to analyzing the effectiveness of smaller and open-source language models (e.g., Llama 2 (Touvron et al., 2023)) in this domain (Guha et al., 2023), and how they can effectively be employed in conjunction with closed-source foundational models, such as GPT-4 (OpenAI et al., 2023).

3 Dataset and Task Description

Bongard et al. (2022) present a new dataset from the U.S. civil procedure domain. This dataset is derived from a book intended for law students, suggesting its complexity and suitability for benchmarking modern legal language models. Each instance of the dataset consists of:

- *General introduction to the case*: an overview of the case to set the context.
- *Particular question*: a specific legal question related to the case is presented.
- *Possible solution argument*: a potential answer associated with the question is provided.
- *Annotated label*: it defines if the possible solution is correct (1) or not (0).
- *Detailed analysis*: Accompanying each solution argument is a thorough analysis explaining why the argument applies to the case in question.

The task is structured as a binary classification task where the goal is to predict the correctness of the answer provided, i.e., the label provided together with the textual information. The analysis and the labels are not available during test time.

4 System Overview

This section provides a comprehensive overview of the proposed methodology. Firstly, we outline the approach to the multiple-choice question-answering problem and how we adapt it to our scenario. Secondly, we introduce the *CLUEDO* framework, along with details about the competitors incorporated into our study.

[1]Code available at https://github.com/irenebenedetto/PoliToHFI-SemEval2024-Task5

Table 1: **Zero-shot** models on dev set. The best performance (in terms of F1 macro) for each model family is in bold. The multiple-choice approach leads to higher performance in five out of six cases.

Model	Classification task	Prec	Rec	F1	Acc
Flan T5 XXL	Multiple choice	0.60	0.67	**0.59**	0.64
Flan T5 XXL	Single choice	0.54	0.53	0.32	0.32
GPT-4	Multiple choice	0.66	0.73	**0.66**	0.57
GPT-4	Single choice	0.40	0.50	0.44	0.80
Llama 2 13B	Multiple choice	0.64	0.58	**0.59**	0.79
Llama 2 13B	Single choice	0.55	0.58	0.54	0.61
Llama 2 7B	Multiple choice	0.51	0.51	0.51	0.74
Llama 2 7B	Single choice	0.53	0.52	**0.52**	0.73
Mistral v0.1 7B	Multiple choice	0.55	0.59	**0.54**	0.61
Mistral v0.1 7B	Single choice	0.55	0.58	0.52	0.57
Zephyr beta 7B	Multiple choice	0.54	0.56	**0.50**	0.69
Zephyr beta 7B	Single choice	0.40	0.50	0.44	0.80

Table 2: **Trained** models performance on dev set. All models are trained to generate both labels and analysis, following the multiple-choice setting.

Model	Prec	Rec	F1	Acc
Llama 2 7B	0.57	0.60	0.56	0.64
Mistral v0.1 7B	0.61	0.63	0.62	0.73
Zephyr beta 7B	0.62	0.65	0.63	0.73
Llama 2 13B	0.65	0.69	**0.66**	0.75

Multiple-choice. Following the intuition of Robinson et al. (2023), we convert the dataset into a multiple-choice question answering problem and adopt multiple choice prompting (MCP) (Robinson et al., 2023). In MCP, the language model is presented not only with the question but also with a set of candidate answers, akin to a multiple-choice test. Each answer is linked to a symbol such as *"A," "B,"* or *"C."* This approach enables the model to compare answer choices explicitly and diminishes computational expenses for a generation. In cases where there is only one candidate answer, the system automatically generates the alternative *"None of the above is true"*. These additional answers are not accounted in the test and validation metrics.

In our experiments, we evaluate whether the multi-choice approach is indeed more effective than a single-choice approach. In the single-choice setting, we prompt a single choice, and the model should directly predict whether it is correct.

CLUEDO. To tackle the task of the challenge, we introduce the *CLUEDO* framework, which stands for "Choosing Legal Outcome by Explaining Decisions through Oversight." In a nutshell, multiple collaborative models are trained to predict the correct label for a candidate answer that addresses the legal question. These models generate their analysis as part of their training. The final model, operating in a zero-shot manner, utilizes the responses and explanations from the set of collaborators to identify the most accurate final answer, considering their collective performance. More in detail, the *CLUEDO* system is structured as follows:

- *N collaborative models*: given the introduction, the legal question, and the candidate answers, these models are trained to predict the label of the candidate answer that correctly responds to the legal question and generate an explanation. We fix the number of collaborators equal to three. We select the collaborators based on their results on the dev set.

- *The final "detective" model*: this model is employed in a zero-shot manner. Based on the responses from the collaborators and their corresponding explanations, this model must identify the most accurate final answer, overseeing the collaborators' performance. The final model is also provided with the introduction, legal questions, and candidate answers.

Example of prompts for collaborative and detective models are reported in Table 3.

Competitors. To assess the strength of the proposed CLUEDO approach, we compare the results with a set of alternatives on the final test set: the best collaborator chosen based on the results achieved on the dev set (that we call *Best collaborator*), and the correction of collaborator models based on consensus (after named *Collaborators agreement*). The latter approach involves taking the predictions of the top-performing collaborator (on the dev set) and rectifying instances where both the second and third collaborators mutually confirm inaccuracies. We finally employ the zero-shot final model without any collaborators to test its generalization capabilities, namely *Zero-shot detective model*.

5 Experimental Setup

Models. We evaluated various open-source models, employing both zero-shot and fine-tuning methodologies. Our analysis covered Flan T5 XXL (Wei et al., 2021; Chung et al., 2022), LLama 7B (Touvron et al., 2023) and 13B, Zephyr 7B (Touvron et al., 2023), and Mistral 7B (Jiang et al., 2023), selected for their unique features and performance metrics. Furthermore, we integrated into our assessment GPT-4 (OpenAI et al., 2023) in a zero-shot context.

Training procedure. We employed a Supervised Fine-Tuning (SFT) approach, implementing precision enhancement with 8-bit quantization. The models were trained for three epochs utilizing Parameter-Efficient Fine-Tuning (PEFT) (Mangrulkar et al., 2022), with a batch size set at 4 and a learning rate of 5e-5. The sequences were processed with a context length of 4096, optimizing the model's ability to capture long-range dependencies in the data.

Hardware. We run the experiments on a machine equipped with Intel® Core™ i9-10980XE CPU, 1 × Nvidia® Tesla T4 GPU, 16 GB of RAM running Ubuntu 22.04 LTS.

6 Results

To illustrate the efficacy of the multiple-choice setting and model selection criteria, we conduct individual tests for each configuration and present the obtained results on the development set. The following paragraphs address the research questions previously presented.

RQ1: Impact of the multiple-choice setting. Table 1 shows the zero-shot models' performance on the development set. For each model family, the multiple-choice question-answering approach consistently outperforms the single-choice approach in terms of F1 Macro. There is variability in the performance of different models within the same family. In general, larger models tend to exhibit stronger generalization capabilities than smaller ones.

RQ2: Impact of analysis inclusion in model training. In Table 4, we highlight the impact of including the analysis in the models' training process. To examine outcomes across various model sizes and classification tasks, we fixed the model family (Llama 2 from Meta). In both the 7B and 13B models, including the analysis (✓) consistently leads to higher performance for multiple-choice tasks. In particular, including the analysis during training leads to more balanced precision and recall metrics, resulting in an overall improvement in the F1 Macro score. For both Llama 2 7B and Llama 2 13B, the F1 Macro scores in single-choice tasks do not show significant improvement with the inclusion of the analysis. This may indicate that these models are less sensitive to additional analysis in single-choice tasks.

Additionally, the training of Llama 2 13B with the analysis allows for an additional $+0.07$ F1 score compared to its zero-shot counterpart, while for the 7B models, the training deteriorates the performance.

RQ3: CLUEDO results. The selection of collaborative models is guided by the results obtained on the development set as shown in Table 2. All models are configured to generate both labels and analysis, following the multiple-choice setting. Among the models, Llama 2 13B stands out with the highest F1 Macro score, indicating robust performance across multiple evaluation metrics, followed by Mistral and Zephyr models. For the supervisor model, we choose GPT-4, the best performer in the zero-shot setting (see Table 1).

Results on the test set are summarized in Table 5. Applying corrections based on the consensus of the second and third collaborators (Mistral and Zephyr) slightly reduces the F1 Macro to 0.65 on both development and test sets. This suggests that the initial collaborator's predictions were already quite accurate. The zero-shot model without collaborators

Table 3: **Example of prompts** for collaborative models and our CLUEDO approach.

Approach	Example Prompt
Collaborative Models	<s>[INST] <<SYS>>Given the following explanation and the question, which of the candidate answers is correct? The correct answer is the one that is true according to the explanation. <</SYS>> <explanation>Although discovery usually extends to all evidence relevant to claims and defenses in the action, Rule 26(b)(1) expressly carves out one [...] </explanation> <question>4. Llama 2 7B	Single choice	✓	0.40	0.50	0.44	0.80
Llama 2 13B	Single choice	x	0.55	0.58	0.52	0.57
Llama 2 13B	Multiple choice	✓	0.65	0.69	**0.66**	0.75

Table 5: **Final Results** on dev and test sets: the best collaborator, collaborative agreements, and collaborators within CLUEDO are trained to generate the analysis along with the labels and adopt the MCP approach.

	Dev		Test	
Method	**F1**	**Acc**	**F1**	**Acc**
Best collaborator	0.66 (± 0.001)	0.75 (± 0.001)	0.69 (± 0.001)	0.75 (± 0.001)
Collaborators agreement	0.65 (± 0.001)	0.75 (± 0.001)	0.65 (± 0.001)	0.75 (± 0.001)
Zero-shot detective model	0.63 (± 0.038)	0.71 (± 0.024)	**0.77** (± 0.022)	0.83 (± 0.016)
CLUEDO	**0.74** (± 0.017)	0.78 (± 0.017)	**0.77** (± 0.017)	0.82 (± 0.013)

(GPT-4) performs well on the development set with an F1 score of 0.63. However, it surpasses all other methods on the test set with a notable F1 Macro of 0.77, showcasing its robust generalization capabilities. The CLUEDO model outperforms other methods with the highest F1 Macro on the development set (0.74) while achieving the second-highest score on test data. To assess the stability of predictions, we experimented five times on the validation set and test set and measured the performance of the models. Even with a greedy decoding strategy, small discrepancies regarding floating point operations lead to divergent generations, especially for larger models (Gawlikowski et al., 2021). It is known that this issue primarily concerns GPT-4[2]. Therefore, even though the temperature is set to 0 for all experiments, users have often reported significant variations in the output.

Although the predictions of trained models remained consistent, notable differences were observed in GPT-4 predictions, particularly when used without collaborators (the temperature is set to zero with no sampling). The results are presented in Table 5. With the proposed CLUEDO approach, the standard deviation is reduced by half. Additionally, the error estimate on the development set aligns with the one obtained on the test set. In conclusion, even though CLUEDO may not outperform others on test data, it ensures higher stability in predictions.

7 Conclusion

This paper presents a novel solution to the SemEval 2024 - Legal Reasoning Task, which introduced a challenge for evaluating contemporary legal language models. We transform the original dataset into a multiple-choice question-answering problem using the multiple-choice prompting approach and propose an original system, namely *CLUEDO*, that utilizes multiple collaborative LLMs and employs a final *"detective"* model to predict the outcome. Results show that our framework outperforms individual models in the public competition while returning more stable predictions, securing second place in the public competition.

[2]Here some discussion of the OpenAI community on models variability: https://community.openai.com/t/why-the-api-output-is-inconsistent-even-after-the-temperature-is-set-to-0/329541, https://community.openai.com/t/run-same-query-many-times-different-results/140588

Abstract

Our approach to detecting machine-generated text for the SemEval-2024 Task 8 combines a wide range of linguistic-stylistic features with pre-trained language models (PLM). Experiments using random forests and PLMs resulted in an augmented DistilBERT system for subtask A and B and an augmented Longformer for subtask C. These systems achieved accuracies of 0.63 and 0.77 for the mono- and multilingual tracks of subtask A, 0.64 for subtask B and a MAE of 26.07 for subtask C. Although lower than the task organizer's baselines, we demonstrate that linguistic-stylistic features are predictors for whether a text was authored by a model (and if so, which one).

1 Introduction

The SemEval-2024 Task 8 is aimed at the detection of machine-generated texts across different domains, languages, and generators. The challenge of distinguishing machine-generated from human written texts has become increasingly relevant with the rapid improvement and coinciding widespread usage of Large Language Models (LLMs) such as ChatGPT. Detection of machine-generated text can be important to uncover the purposeful spreading of misinformation on social media, or fraudulent articles and papers in the context of journalism and academics (Tang et al., 2023). To this end, the task organizers collect human data from Wikipedia, Reddit, Wikihow, PeerRead, and ArXiv abstracts in English, Chinese, Urdu, Russian, Indonesian, Arabic, and Bulgarian (Wang et al., 2023b). Consequently, Wang et al. (2023b) prompted 5 different generative LLMs to write the corresponding posts or abstracts based on the titles. The shared task consists of 3 subtasks. Subtask A is the task of classifying between human and machine-generated texts, subtask B pertains pointing out which LLM (or human) generated the text specifically, and lastly, subtask C is about determining the boundary where a text switches from human written to machine-generated.

The focus for our submission to the shared task is to investigate and compare the linguistic-stylistic characteristics of various LLMs, given that previous literature has shown that text produced by generative LLMs contain linguistic-stylistic anomalies (Tang et al., 2023). Additionally, we explore ways to combine features with the power of a pre-trained language model (PLM). Although a system inspired by linguistic-stylistic features may not achieve the greatest scores, it may perform well across domains and is highly interpretable. Additionally, the performance with linguistic-stylistic features may differ per LLM and per domain, for which they possibly yield interesting insights and contribute to scientific knowledge regarding what LLM-generated anomalies consist of.

Ultimately, our system yields passable results, coming in at 110 and 41 for subtask A mono- and multilingual respectively, and ranking at 46 for subtask B and 20 for subtask C. Contrary to expectations, the system appears to be relatively poor at generalizing between domains, but markedly better at dealing with multiple languages, as indicated by the increase in accuracy as well as ranking between the mono- and multilingual conditions in subtask A.

2 Background

To investigate which features contribute to the detection of machine-generated text, we collected 20 metrics from previous research which seem relevant. These features can be broadly divided into 6 categories, which will each be presented in this section.

2.1 Readability

Studies have shown that LLMs are capable of producing more readable text than human profession-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1006–1014

als when it comes to complex matters such as informed consent documentation (Decker et al., 2023). Pu and Demberg (2023) have also shown that, when it comes to producing summaries for layman or experts, ChatGPT tends to score very similar in both conditions, whereas human summarizers achieve lower scores for laymen, and higher in the expert condition. For this reason, we have selected 3 common, yet distinct readability formulas. The Flesch-Kincaid score for reading ease by taking the average sentence length, and the average number of sylables per word (Kincaid et al., 1975). Similarly, the Coleman-Liau index takes into account the average sentence and word lengths to compute a score (Coleman and Liau, 1975). Lastly, the Dale-Chall Readability Score is calculated using the average sentence length and the ratio of difficult words from a list to the total number of words (Chall and Dale, 1996).

2.2 Entity recognition

While previous research on using LLMs for Named Entity Recognition has shown promising results (Wang et al., 2023a), LLMs are still not as good as humans annotators. Therefore, we expect there may be a difference between human and machine-generated texts when it comes to entities. For this reason, we incorporate the ratio of entities to total words, as well as the ratio of unique to total number of entities as features.

2.3 Syntax

Syntax is concerned with the way words are put together to form proper sentences, often operationalized through dependency parsing where sentence constituents are labelled and linked to determine the syntactic structure of a sentence. Pu and Demberg (2023) used ChatGPT to transform texts from formal to informal and vice versa and found a clear difference between ChatGPT-generated and human-written text in the dependencies for both formal and informal sentences. Therefore, we include several metrics using dependency parsing. Firstly, we consider the average parse tree height (the length of the longest series of dependencies from the root constituent of a sentence). Additionally, we include the average number of noun phrases per sentence. Lastly we employ a measure of syntactic complexity, namely the Coh-Metrix SYNNP index (Graesser et al., 2004), which measures the mean number of modifiers per noun-phrase to compute complexity.

2.4 Semantics

Aside from syntactic features, previous research has also indicated differences on a semantic level. Firstly, machine-generated texts are less coherent than their human written counterparts (Tang et al., 2023). To make the concept of coherence measurable, we adopt the notion of lexical chains (Morris and Hirst, 1991), which refers to a series of related words that are linked by a common thread of meaning. The relevant features based on lexical chains are the total number, the average length and the span of lexical chains in a document. Furthermore, research has shown that ChatGPT produces less negative sentiment and offensive speech compared to human-authored texts (Tang et al., 2023), so we also include a score for controversy as a feature.

2.5 Text length statistics

As an extension of the readability metrics (see Section 2.1), which mostly combine different statistical features of texts to compute a score, we also take into account individual statistics of the document. Specifically, the average number of syllables per word, and the average sentence length.

2.6 Lexical Richness

LLMs work by selecting high-likelihood words to create coherent texts, making it likely for them to write using a lower diversity of words than humans. Previous research has shown that this is indeed the case (Guo et al., 2023). For this reason, we include a number of measures of lexical richness. Firstly, the type token ratio (TTR) and secondly, as an alternative to the TTR, which is sensitive to a steep drop-off in longer texts, the Measure of Lexical Diversity in Text (MLTD). To further study the lexical diversity put forth by LLMs, we consider the hapax richness of the document, which is the ratio of words in the text that occur only once. Lastly, we examine the ratio of function words to content words.

3 System overview

The backbone of our system is combining a feature-driven approach with the state-of-the-art in text classification, namely PLMs. To accomplish this, we tested three main system architectures for this shared task. Firstly, we augment DistilBERT with the feature set. Similarly, to achieve token-level classification, we perform the same for Longformer, and lastly, we use a Random Forest classifier with

DistilBERT embeddings in conjunction with the feature set. For comparison the features were also used separately and in combination with unigrams in a random forest classifier. The following sections will go into detail on each of these individually.

3.1 Augmented DistilBERT

For subtasks A and B, we augment `distilbert-base-cased` (Sanh et al., 2020) for the monolingual tasks and `distilbert-base-multilingual-cased` for the multilingual task with an additional layer for classification using features. The 20 features are run through a linear layer with ReLU activation. The output from this linear layer, which is equal in dimensions to DistilBERT's configured hidden size, is concatenated to the pooled output from DistilBERT's final hidden state. This results in a new tensor of 2*hidden size. This tensor is fed into another linear layer (2*hidden size, hidden size) with ReLU activation and dropout. The output from this is fed into the final classifier layer (hidden size, amount of labels).

3.2 Augmented Longformer

A challenge we ran into is the application of sentence-based features to token-level classification in subtask C. To address this problem, we use an augmented version of Longformer (Beltagy et al., 2020). The architecture of the Longformer is similar to the augmented DistilBERT, except that the output from the extra features is concatenated to the output state of each of the tokens separately. This essentially augments each token with contextual knowledge of the linguistic characteristics of the text that they occur in, enabling token-level classification.

3.3 DistilBERT-embedded Random Forest

Next to the augmented DistilBERT for subtasks A and B, we explore the use of a Random Forest classifier using `distilbert-base-cased` embeddings, instead of simpler one-hot encodings or TF-IDF embeddings, contatenated with our 20 linguistic-stylistic features. After tokenizing each text, we extract the DistilBERT embeddings for the first 512 sub-word tokens and average them using a concatenation of mean, max, sum and L2 (Euclidean norm) pooling. After retrieving the embeddings, we concatenate them with the feature vector composed of our 20 linguistic-stylistic features. We then use the concatenated embeddings with the features to fit a Random Forest classifier.

We experimented with different configurations which differed in the use of the layer (or hidden state) and pooling technique. We found the first hidden state layer (i.e., the layer after the input layer) using a concatenation of mean, max, sum and L2 pooling to produce the most satisfactory results. Similar to the augmented DistilBERT, we use `distilbert-base-multilingual-cased` in the multilingual track of subtask A.

4 Experimental setup

Much of the experimental setup is similar to the format dictated by shared task organizers (Wang et al., 2024). In particular, the provided train and dev sets were used as-is. However, some relevant aspects for our specific system will be presented in this section.

First and foremost, the features are extracted using a variety of external libraries, including SpaCy and fasttext, and subsequently put into JSON format. Furthermore, in the multilingual track, we recognize the language in question using Stanza and fasttext (how and why these models were used is explained in Appendix B.1), and apply language-specific feature extraction methods accordingly. Features that only work for English (e.g., Dale Chall) are not included in the multilingual track. These features were all assigned a value of -1. An overview of the features and how they were calculated can be found in Appendix B. To compare the features, we measured importance using Mean Decrease in Impurity (MDI), which computes the average change in homogeneity in Random Forest nodes for each feature. The systems will be evaluated using the official metrics of the task: accuracy for subtasks A an B and mean absolute error for subtask C.

5 Results

5.1 Development results

The results of our systems for subtasks A and B can be found in Table 1. For subtask A monolingual, augmented DistilBERT works best with an accuracy of 0.75, slightly better than the baseline of 0.74 from the organizers (Wang et al., 2024). Curiously, it performs worse than the default DistilBERT in the multilingual task. Where the default system had an accuracy of 0.71, the augmented version only had an accuracy of 0.67. Possible explanations are that not all features could be used multilingually

	Random Forest				DistilBERT	
	uni.	feat.	uni. + feat.	emb. + feat.	base	augm.
Subtask A monolingual						
Human	0.70	0.65	0.67	0.46		0.79
Machine	0.49	0.33	0.32	0.71		0.69
Accuracy	0.62	0.54	0.56	0.62	0.69	**0.75**
Subtask A multilingual						
Human	0.62	0.45	0.57	0.33		0.63
Machine	0.35	0.48	0.51	0.60		0.71
Accuracy	0.52	0.47	0.54	0.50	**0.71**	0.67
Subtask B						
Human	0.44	0.40	0.47	0.39		0.66
ChatGPT	0.74	0.57	0.73	0.59		0.77
Cohere	0.40	0.38	0.35	0.31		0.50
Davinci	0.58	0.11	0.40	0.24		0.29
Bloomz	0.93	0.89	0.89	0.83		0.95
Dolly	0.44	0.44	0.51	0.54		0.63
Accuracy	0.60	0.49	0.58	0.51	0.60	**0.64**

Table 1: F1-scores and accuracy for subtask A (monolingual and multilingual) and subtask B on the development sets for all our experiments: random forest with unigrams, features, unigrams + features and embeddings + features, and a base and augmented distilBERT model.

or that the quality of the multilingual features is worse than for the monolingual data, since not every language has the same quality parsing models available.

From the different implementations of the random forest model, the best accuracy on the monolingual task was achieved by both the unigram model and the model using DistilBERT embeddings and features with an accuracy of 0.62. There is a sizeable difference between the f1-scores of the 'human' and 'machine' labels. For the models using either unigrams, features or both, the 'human' label has an f1-score between 0.67 and 0.70, where the 'machine' label only scores between 0.32 and 0.49. Interestingly, adding the DistilBERT embeddings resulted in reversed scores. For this model the 'human' label only obtained an f1-score of 0.46 and the 'machine' label 0.71.

For the multilingual track the best random forest model was the one using unigrams and features which had an accuracy of 0.54. The model using only features performed worst with an accuracy of only 0.47. The reversal of the f1-scores of 'human' and 'machine' labels that occurred one the monolingual data is also present here but only when comparing the unigram model with the model using embeddings and features. The model using only features and unigrams and features both have similar scores for both labels.

Augmented DistilBERT also worked best for subtask B with an accuracy of 0.64. Of the random forest models, there was no model using features that outperformed the model using only unigrams. Of the different sources, davinci was the most difficult to predict with an f1-score of only 0.29 from augmented DistilBERT. The fact that the provided development set almost exclusively contains examples of Bloomz is clearly visible based on the comparatively high f1 scores for that class ranging between 0.83 and 0.95.

Since our features are document-based and subtask C is a token-level classification task, we only have have the results from our baseline Longformer and the augmented Longformer. The augmented system had a mean absolute error (MAE) of 5.29 on the development set. Much better than our non-augmented baseline system which had a MAE of 16.62, but still worse than the organiser's baseline of 3.53 (Wang et al., 2024).

5.1.1 Feature importance

Figure 1 shows the feature importances for subtasks A and B. Similar trends can be seen for both tasks, although there are some differences as well. Type-token ratio (and its extension, MTLD) and the amount and length of lexical chains are important for all tasks. The average number of syllables per word is very important for the monolingual track of subtask A, but not so much for subtask B. Unfortunately this feature could not be used for the multilingual track so a comparison is not possible. For further analysis, a correlation heatmap can be found in Appendix D.

5.2 Test results

The predictions of augmented DistilBERT were sent in for this task for both the monolingual and the multilingual track. For the monolingual track this resulted in an accuracy of 0.63, placing us at position 110 on the leaderboard. For the multilingual track of subtask A, the system performed better with an accuracy of 0.77, leading to position 41. Unfortunately both scores are lower than the organisers' baseline of 0.88 and 0.81 respectively.

For subtask B the same system was used as for subtask A: augmented DistilBERT. The accuracy on the test set was the same as on the development set, namely 0.64. This is lower than the organisers' baseline of 0.75 unfortunately. For this task it is interesting to look at a confusion matrix which is shown in Figure 2. It shows that there were a few

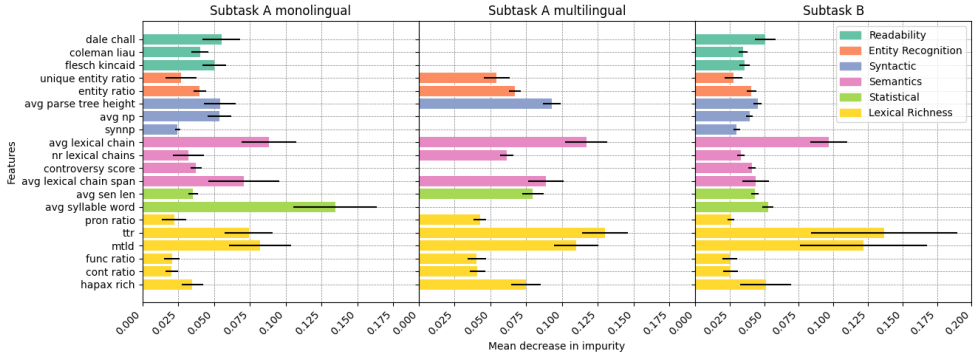

Figure 1: Feature importance (mean decrease in impurity from a random forest model using only our features) for subtasks A and B on the train set. The features are grouped by category.

generators that were problematic for the system. Cohere was almost never classified correctly and was mostly classified as ChatGPT. Dolly was often misclassified as davinci. Human written text was often classified as generated by either davinci or dolly, but almost never as the other three generators. For this subtask we obtained position 46 on the leaderboard.

We also evaluated the performance of our other main system for subtasks A and B, the random forest with embeddings and features, on the test set. This resulted in accuracies of 0.59 and 0.65 for subtask A (mono- and multilingual) and 0.39 for subtask B, also featured in Table 2. A possible explanation for the lower accuracies is that only the first 512 sub-word (BPE) tokens were taken into account. A lot of information gets lost during pooling and combing different strategies could not prevent a severe loss of information.

For subtask C the augmented Longformer achieved a MAE of 26.07, ranking us at position 20. Unfortunately this system also did not outperform the organiser's baseline of 21.54.

Subtask	Baseline	Augm. DistilBERT	Emb. RF
A mono	0.88	0.63	0.59
A multi	0.81	0.77	0.65
B	0.75	0.64	0.39

Table 2: Accuracy of the baseline, augmented DistilBERT and the embedded random forest on the test set for subtasks A and B.

6 Conclusion

Unfortunately none of our systems performed better than the baseline but our experiments did give some insight in how features can be used. Our final systems producing the most satisfactory results for the test set were: the augmented DistilBERT system for subtasks A and B, resulting in accuracies of 0.63 and 0.77 respectively, and the augmented Longformer for subtask C, obtaining a MAE of 26.07.

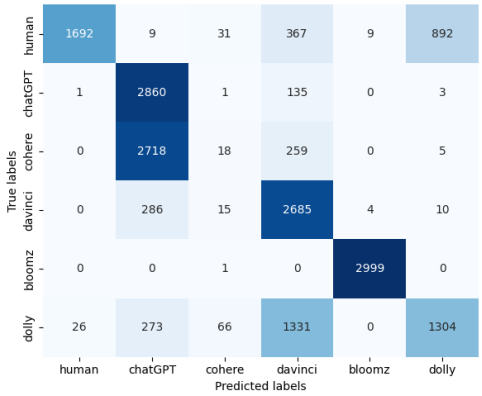

Figure 2: Confusion matrix from augmented DistilBERT for subtask B on the test set.

Contrary to the literature, it does not appear that the feature-based methods are better at generalizing. During our experiments we saw that when the unseen test data is from the same distribution (held from the training data), the feature-based approach performs far better in terms of accuracy (A mono: 0.88; A multi: 0.79; B: 0.71; for a full overview, see Appendix E). This is a clear indication that our proposed stylistic-linguistic features contain sufficient predictive power to distinguish human- from machine-written text. In particular, we find Type-token ratio, MTLD, the amount and length of lexical chains, and the average number of syllables per word to be noteworthy features for the given task. Future research into (different) features, especially for multilingual tasks could therefore be fruitful.

A Acknowledgements

This submission has been carried out as part of the 2023-2024 edition of the master course Shared Task Information Science (LIX026M05) at the University of Groningen, taught by Lukas Edman and Antonio Toral. We thank the Center for Information Technology of the University of Groningen for their support and for providing access to the Hábrók high performance computing cluster.

B Feature Extraction

In this section we describe how our features were calculated, what language models were used and how these models were selected. Version numbers of the specific libraries that were used can be found in appendix C.

B.1 Model selection

For the monolingual subtasks, we use the English `spacy_udpipe` model. This model is used to obtain POS-tags, noun chunks, syllable counts and parse trees. `en_core_news_sm`, also a spacy model, is used for named entity recognition.

For the multilingual task, the documents are first tagged with a language label by stanza's language identification model. This language label was then used to (try to) download the correct `spacy_udpipe` model and when this was not available, the correct stanza model. We did not use stanza models for all languages because they are quite large and slow.

For the NER tagger, the script first tries to download either `language_core_web_sm` or `language_core_news_sm`. When neither of these models is available, a universal model is used, namely `xx_ent_wiki_sm`.

For the fasttext embeddings the language of each document was first detected with ftlangdetect's `detect`. Because the spacy, stanza and fasttext models together take up quite some space, the data was processed per language. For this we chose the

stanza-identified language. For each language as it was identified by stanza, we chose the most occurring fasttext-detected language to download the correct fasttext model. It was not possible to use the stanza detected language for this as the language codes were not always identical and the languages supported by both are not the same.

B.2 Readability features

Flesch Kincaid

Note: this feature only works for English.
Calculated using `textstat`'s `flesch_reading_ease()`. The score is normalized by dividing the score by 100 (the maximum score) and subtracting this from 1 to invert the scale.

Coleman Liau

Note: this feature only works for English.
Calculated using `textstat`'s `coleman_liau_index()`. The score is normalized by dividing it by 30 (the maximum score).

Dale Chall

Note: this feature only works for English.
Calculated using `textstat`'s `dale_chall_readability_score()`. The score is normalized by dividing it by 20 (the maximum score).

B.3 Entity Recognition features

Entity Ratio

The number of entities divided by the number of words in a document.

Unique entity ratio

The number of unique entities divided by the total number of entities in a document.

B.4 Syntactic features

Average parse tree height

Average length of the longest series of dependencies from the root constituent of all sentences in the text.

Average number of noun phrases

Average number of noun chunks in a document.

SYNNP

Average number of tokens in a noun chunk in a document.

B.5 Semantic features

Lexical Chains

To create lexical chains only nouns were used. A chain is created by putting words together whose fasttext embedding have a cosine similarity (`sklearn`'s `cosine_similarity`) of more than 0.5. This feature is not used on its own, but to calculate the next three features.

Number of lexical chains

The sum of all lexical chains in a document. The score is normalized by dividing it by the number of words in a document.

Average lexical chain length

The average number of words in a lexical chain in the document. The score is normalized by dividing it by the number of words in a document.

Average lexical chain span length

The span is the number of words in the document between the first and last word of a lexical chain. Of this we take the average. The score is normalized by dividing it by the number of words in a document.

Controversy score

Note: this feature only works for English.
Calculated using `polarity_scores()` from `nltk`'s `SentimentIntensityAnalyzer()`.

B.6 Statistical features

Average number of syllables

Note: this feature only works for English.
Average number of syllables in a token.

Average sentence length

Average number of tokens per sentence (split by a period) in a document.

B.7 Lexical richness features

TTR

Calculated using `LexicalRichness().ttr` from `lexicalrichness`.

MTLD

Calculated using `LexicalRichness().mtld()` from `lexicalrichness`.

Hapax Richness

Calculated by getting `hapaxes()` from `nltk`'s `FreqDist()` and dividing it by the number of tokens in the document.

Content word ratio

The following POS-tags were used to select content words: "NOUN", "PROPN", "VERB", "ADJ", "ADV" and "NUM" from the universal POS tags and "CD", "JJ", JJR", "JJS", "POS", "PRP$", "RB", "RBR", "RBS", "WP$" and "WRB" from the Penn Treebank POS tags. The ratio is calculated by dividing the number of content words by the total number of words.

Function word ratio

Function words are all words that are not content words. The ratio is calculated by dividing the number of function words by the total number of words.

Pronoun ratio

Pronous are selected using the universal POS-tag "PRON" and the Penn Treebank POS-tags "PRP", "PRP$", "WP" and "WP$". The ratio is calculated by dividing the number of pronouns by the total number of words.

C Dependencies

The dependencies with version numbers that were used for both the feature extraction and the different system implementations.

Magnum JUCSE at SemEval-2024 Task 4: Multilingual Detection of Persuasion Techniques in Memes

Adnan Khurshid and **Dipankar Das**
Department of Computer Science and Engineering
Jadavpur University, Kolkata, 700032, India

Abstract

This paper explores the detection of persuasion techniques within meme text, emphasizing logical fallacies and emotional appeals. Using a multilingual dataset structured as a directed acyclic graph, the study employs a node-level hierarchical classification with Support Vector Machines and pretrained sentence embeddings. Results demonstrate effective capture of nuanced persuasion techniques, providing fine-grained and general labels. The paper acknowledges dataset imbalance and assesses threshold impact on classification. The work contributes to understanding memes as conduits for persuasive communication, paving the way for future integration of image information for comprehensive analysis.

1 Introduction

In the realm of digital communication and social media, memes have emerged as a powerful and widely shared form of content, known for their ability to convey messages in a succinct and often humorous manner. While memes are commonly associated with entertainment, their potential as a tool for persuasive communication, particularly in the context of textual content, has become increasingly evident. This paper focuses on the nuanced task of detecting persuasion techniques within meme text in multiple languages like English, North Macedonian, Arabic and Bulgarian, exploring the ways in which textual elements contribute to the dissemination of persuasive messages.

The main strategy of the system is to train a binary classifier for each node in the hierarchy and predict labels in a top down fashion by seeing the confidence value of the prediction at any node. For each unique label in the hierarchy, a dataset is created from the original dataset which is then used to train the binary classifier for that label.

This task (Dimitrov et al., 2024) helped in understanding the intricacies of Hierarchical classification as well as sentence transformers. Our team participated in subtask 1 and ranked 21 out of 34 in English Language whereas 4 out of 20 in Bulgarian, 3 out of 20 in North Macedonian and 11 out of 17 in Arabic.

1.1 Objectives

The main objectives in this task include achieving the accuracy in classification of the internal nodes and minimising the number of classifiers and to look for a global classifier approach which takes the whole hierarchy into account at once. One more challenge due to having multiple levels of classes is handling the problem of inconsistency in predictions at different levels which means that the system may give negative prediction for some class at a level and then gives positive prediction for its children nodes. Since there are multiple output labels, Instances may belong to multiple classes that are not mutually exclusive or have overlapping characteristics due to the hierarchy being in the form of Directed Acyclic Graph. Distinguishing between such classes becomes complex

1.2 Contribution

The work done aims to create a model which performs the task of hierarchical multilabel classification of Persuasion techniques in memes with maximum accuracy. The model not only predicts the leaf nodes but also is able to predict corresponding internal nodes if the confidence in prediction is lower than some specified threshold at some node. Thus solving the class parent-child inconsistency problem stated earlier and providing a more robust and comprehensive classification of persuasion techniques in memes, enabling a deeper understanding of the hierarchical structure and allowing for enhanced decision-making based on varying levels of confidence in the predicted labels.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1015–1018

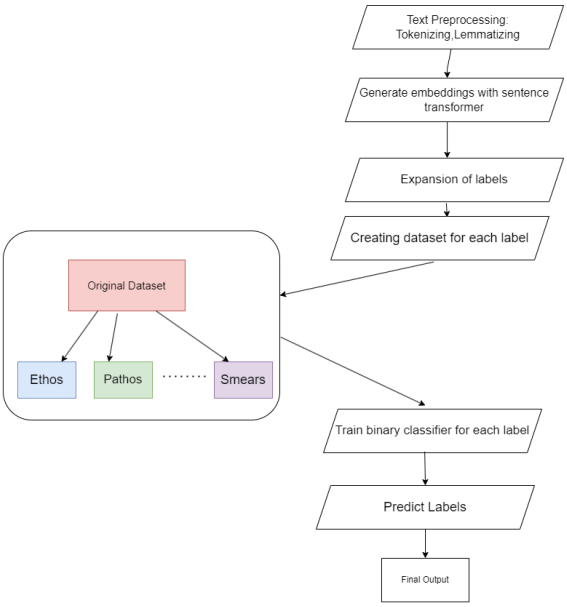

Figure 1: A diagram of the workflow.

2 Background

Our task involves the detection of persuasion techniques from memes. The data is provided in JSON format with string text and a list of string labels for each text. The labels are defined in a hierarchical manner in the form of a directed acyclic graph (DAG). A training set, a development or validation set, as well as a test set are available. The training and validation sets contain the labels while the test set only contains the text. In our dataset, 29 persuasion labels are defined.

The dataset is quite unbalanced, with some labels occurring many times, with others occurring much less. This can be partially attributed to the hierarchical nature of the data. Labels present neaerer to the root of the label DAG tend to appear much more frequently than the labels present nearer to the leaves of the DAG

3 System Overview

The step by step flow of the system is shown in the Figure [1] and explained in detail in the subsections which follow.

3.1 Overview

In this work, we use node level hierarchical classification. Our method consists of four major phases, data denoising, feature generation, node level classifier training and finally inference. Initially the data is cleaned and denoised, post this, features are generated for each of the sentences using a pre-trained sentence transformer. For classification, we consider a binary classifier at each node (Silla and Freitas, 2011) which predicts whether the example belongs to that node or not. We have employed the SVM (Support Vector Machine) as the classifier in our case.

Inference is done in a top-down fashion which the branch to be taken at each node is decided by the classifier at that node. This allows us to provide fine-grained as well as general labels. Fine grained labels are available toward the leaves of the tree and general labels are available towards the root. Based on the decision probabilities, we select the most suitable depth for the prediction results.

A final point worth mentioning is the identification of the threshold. Due to the imbalanced nature of the dataset , a threshold is determined using trial and error. The system works best with low threshold values for positive class because the training dataset for each unique label becomes highly skewed with negative examples.

3.2 Feature generation

Training a large language model from scratch on a corpus of strings requires very heavy computational resources, to which we did not have access. To circumvent this, we have utilized transfer learning, where the embeddings generated form a model on a general task is applied downstream effectively. This allows us to reuse previous work, if the task is sufficiently general, the pretrained model can produce very contextual and high quality embeddings.

For our current work, we have utilized the Sentence Transformer with Siamese BERT Embeddings as described in (Reimers and Gurevych, 2019). The authors of this paper have derived sentence embeddings in a contrastive manner utilizing similarity losses. Namely, they have utilized the triplet loss, which involves the creation of an anchor, a positive pair and a negative pair for embedding generation.

$$\mathcal{L}(A, P, N) = \max\left(d(A, P) - d(A, N) + \alpha, 0\right) \quad (1)$$

The goal of the Triplet Loss function is to minimize the distance between the anchor and the positive sample while simultaneously maximizing the distance between the anchor and the negative sample. A classification loss has also been utilized by the authors. Three labels have been considered, contradiction, neutral and entailment between

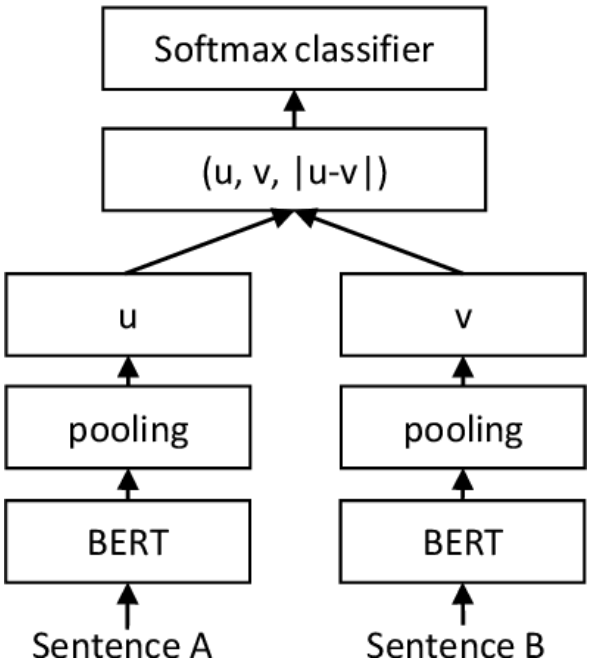

Figure 2: Architecture of the utilized sentence transformer.

pairs of sentences. The generated embeddings have length 768.

where:

- A represents the anchor sample,
- P represents the positive sample (same class as anchor),
- N represents the negative sample (different class from anchor),
- $d(A, P)$ denotes the distance between anchor and positive sample,
- $d(A, N)$ denotes the distance between anchor and negative sample,
- α is the margin, a hyperparameter that specifies the minimum difference between the distances.

3.3 Node Level Classifier

The data labels are represented in the form of a DAG. At each node, a SVM(support vector machine) is trained to predict whether the text instance belongs to that node or not. The node level classifiers are trained on the feature embeddings generated using the pretrained sentence transformer.

Support Vector Machines (SVMs) are powerful supervised learning models used for classification and regression tasks. The fundamental idea behind SVMs is to find the hyperplane that best separates the data points into different classes while maximizing the margin, which is the distance between the hyperplane and the nearest data points of each class.

SVMs can handle linearly separable as well as non-linearly separable data by employing the kernel trick, which maps the input data into a higher-dimensional space where it is easier to find a separating hyperplane. The optimization problem associated with SVM can be formulated as a convex optimization problem, typically solved using techniques such as quadratic programming.

4 Experimental Setup

4.1 Data Preprocessing

The input data is in the form of textual content for memes. There is a mix of capitalized, uncapitalized data as well as non-English words and gibberish. There is also the presence of arbitrary newlines in the dataset. To clean this data, firstly we have removed the unnecessary newlines in the data, replacing them with a single white-space , post this, we have removed all the punctuation. After this, we have lowercased the all the strings in the dataset, followed by stopword removal and lemmatization. This preprocessing improves the performance of the model as in general the dataset is very noisy and a model trained on it will not perform up to the mark.

4.2 Dataset Splitting

The original dataset is expanded by adding all the labels from root to leaf for a specific leaf label. So for example, if a row has label 'Slogans', then all the labels from root (Persusaion) to leaf (Slogans) are added, namely, Persuasion, Logos, Justification, Slogans and thus a dataset with expanded labels is formed. The dataset is then represented in One-Hot Encoding format for all the unique labels in the Hierarchy. So the dataset now contains 31 columns, 1 for the text, 1 for embeddings and 29 columns for the 29 labels in the hierarchy. So if a row has labels [Persuasion, Logos, Justification, Slogans] then the columns of these labels will have value 1 and others will have 0. Then a set of smaller datasets with the columns text,embeddings and the binary output for each label is created from the original dataset. These datasets are stored in a dictionary in key-value pairs where the key is the label and value

is a dataframe containing the dataset. Thus for the 29 unique labels in the hierarchy, 29 datasets are created.

4.3 Inference

The classification is done in two ways. First the text embedding is passed through all leaf node classifiers and the labels which give positive prediction with confidence greater than 0.7 are directly added to the output. Secondly, we then pass the embedding to a function which does the classification in a top down or depth first approach. We start from the root by pushing the children nodes of the node which has positive prediction confidence greater than the predefined threshold value to a stack. Then we pop from the stack and keep repeating until a leaf node is reached or the prediction confidence is very low at any particular node. The distinct labels from both these are then taken as the final output.

5 Results

We have provided the results of our method using some different thresholds. The result contains Hierarchical F1 Score, Hierarchical Precision as well as Hierarchical Recall. How the threshold is set is explained in the table [1]. A confusion matrix is shown for the prediction of leaf nodes in Figure [3] The test results for the languages Bulgarian and North Macedonian after final submission are also shown in tables [2] and [3]

Threshold	Hierarchical F1	Precision	Recall
For Depth = 0 : 0.3			
For Depth = 1 : 0.4			
For Depth $\geq$ 2 : 0.5	0.5624	0.6322	0.5065
All nodes : 0.24	0.6034	0.5465	0.6734

Table 1: Results for different threshold values at different depths of the hierarchy.

Threshold	Hierarchical F1	Precision	Recall
All nodes : 0.24	0.49986	0.47027	0.53342

Table 2: Final submission result on test data in Bulgarian Language.

Threshold	Hierarchical F1	Precision	Recall
All nodes : 0.24	0.48267	0.48568	0.47970

Table 3: Final submission result on test data in North Macedonian Language.

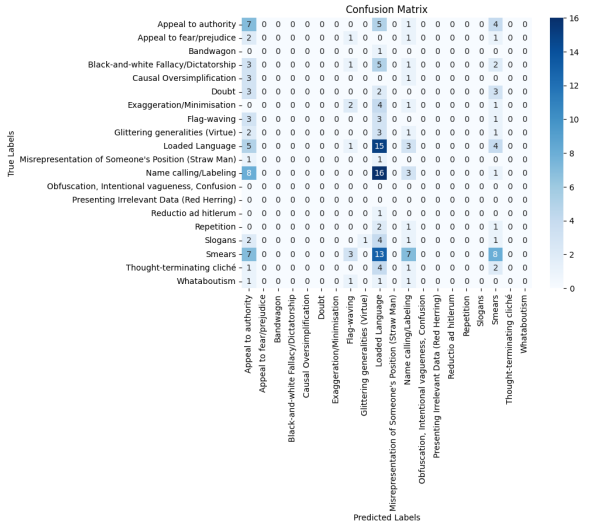

Figure 3: Confusion matrix for only leaf node predictions.

6 Conclusion and Future Work

The system gives satisfactory results on the validation dataset but more testing is required to measure the accuracy of the model. The accuracy of classifiers for some of the internal nodes is low because of a large variety of text sentences corresponding to the internal labels The leaf node classifiers generally have very high accuracy due to low number of example instances

This system only works with textual data, considering memes have rich image information as well, utilizing it in sync with the textual data to accurately predict persuasion techniques would be a natural continuation of this work.

Çağrı Çöltekin
University of Tübingen, Germany
cagri.coeltekin@uni-tuebingen.de

Abstract

The paper introduces our system for SemEval-2024 Task 1, which aims to predict the relatedness of sentence pairs. Operating under the hypothesis that semantic relatedness is a broader concept that extends beyond mere similarity of sentences, our approach seeks to identify useful features for relatedness estimation. We employ an ensemble approach integrating various systems, including statistical textual features and outputs of deep learning models to predict relatedness scores. The findings suggest that semantic relatedness can be inferred from various sources and ensemble models outperform many individual systems in estimating semantic relatedness.

1 Introduction

Identifying semantic relatedness is a 'related' task to many well-studied tasks of semantic similarity. According to Abdalla et al. (2023), two sentences are considered similar if they are paraphrases or share a relation of entailment. Semantic relatedness, however, is a broader concept than semantic similarity. Two expressions are considered related if they share any semantic association. For instance, 'teacher' and 'student' are related because they frequently occur within the same context or domain. Similarly, 'tasty' and 'unpalatable' are related, as both terms are used to describe food, albeit with opposite meanings.

SemEval-2024 Task 1 (Ousidhoum et al., 2024b) is designed to estimate the relatedness of sentence pairs. The task is based on a multilingual dataset of 14 languages and offers supervised, unsupervised and cross-lingual tracks. Our team participated in two tracks, and a subset of available languages: Track A (supervised learning) for English, and Track B (unsupervised learning) for English, Spanish, and Hindi.

We posit that semantic relatedness can be inferred from a multitude of sources and therefore propose an ensemble approach that integrates outcomes from diverse systems to estimate semantic relatedness. Our study explores features from textual statistical analysis, general large language models, word embedding models, and models trained on semantic labeled datasets, question-answering pairs, or title-passage pairs in estimating semantic relatedness, and we conducted ensemble experiments with these features.

2 Related Work

SemEval in previous years has introduced tasks focusing on semantic textual similarity to evaluate the degree of similarity between sentence pairs (Agirre et al., 2012; Manandhar and Yuret, 2013; Agirre et al., 2014; Cer et al., 2017). There tasks provided datasets with human labeled similarity scores, which have been extensively utilized for training sentence embedding models and conducting semantic evaluations (Wieting et al., 2015; Cer et al., 2018; Reimers and Gurevych, 2020; Feng et al., 2022).

2.1 Sentence Embeddings

Word embedding models such as BERT (Devlin et al., 2019), GloVe (Pennington et al., 2014), RoBERTa (Liu et al., 2019), and Word2Vec (Mikolov et al., 2013) are frequently employed to assess the semantic distance between words. Sentence embeddings with a fixed length are often generated via mean/max pooling of word embeddings or employing `CLS` embedding in BERT. The semantic distances are commonly measured using the cosine similarity of embeddings of two expressions.

Siamese or triplet network architectures are frequently employed in sentence embedding training. For example, models such as Sentence-BERT (Reimers and Gurevych, 2019, 2020) utilize a dual-encoder architecture with shared weights for

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1019–1025

predicting sentence relationships (e.g., semantic contradiction, entailment, or neutral labeling) or for similarity score prediction using regression objectives, e.g., the difference between human annotated similarity score (sim) of two sentences and the cosine of two sentence embeddings (v and u), illustrated in Equation (1).

$$\mathcal{L} = |\cos(v, u) - \text{sim}| \tag{1}$$

In triplet neural networks, an anchor sentence (u) can be trained along with a positive sample (a sentence with a similar meaning) and a negative sample (a sentence with a dissimilar meaning), with contrastive loss. InfoNCE (Noise-Contrastive Estimation) can be utilized as the objective function. A larger number of negative samples can also be integrated into neural networks through the application of InfoNCE, as demonstrated in Equation (2). Here, v^+ denotes positive samples. The negative sample size is denoted as K, and the total sample size (including one positive sample) as $K + 1$. This approach is adopted by the Jina embedding model (Günther et al., 2023), which is used in our ensemble system.

$$\mathcal{L} = -\mathbb{E}\left[\log \frac{f(v^+, u)}{\sum_{i=1}^{K+1} f(v_i, u)}\right] \tag{2}$$

2.2 Ensemble Learning

In previous studies, ensemble learning presents several advantages. The ensemble approach can reduce the errors from individual models by amalgamating results from multiple sources or can make the system more robust. In our study, using multiple pre-trained models can also save a substantial amount of computation while making use of information from the large data during pre-training. Previous research has demonstrated that ensemble learning can achieve remarkable success (Huang et al., 2023; Osika et al., 2018).

In our study, we aim to integrate multiple deep learning models to assess semantic relatedness. When models are trained on diverse datasets with different architectures, they may produce varied predictions on semantic relatedness, and combining them may improve overall performance.

We use sentence embeddings mainly from the following models. Sentence-BERT (Reimers and Gurevych, 2019) is trained on datasets involving SNLI (a collection of 570,000 sentence pairs) and MultiNLI (comprising 430,000 sentence pairs). The Jina Embedding model (Günther et al., 2023) utilizes 385 million sentence pairs and 927,000 triplets (comprising positive and negative samples of semantic similarity) after a filtering process. The T5 model is trained on approximately 7 TB of text data derived from Common Crawl, serving various text-to-text purposes (Raffel et al., 2020; Ni et al., 2021).

3 Methodology

In this study, we hypothesize that semantic relatedness covers a broader spectrum than semantic similarity in theory. Consequently, the integration of various systems and features should achieve superior results compared to individual systems.

3.1 Supervised Learning

For the supervised track[1], we first evaluated subsystems in an unsupervised manner and selected those with a higher Spearman's correlation with human annotations for ensemble learning. The selected results were then further fine-tuned using the training data (5,500 English sentence pairs labeled with relatedness scores provided by the shared task, Ousidhoum et al., 2024a) to achieve closer alignment with human annotations.

In the following subsections, we present the features and systems utilized for ensemble learning. The features can be classified into three categories: textual statistical features (Section 3.1.1), word embedding models (Section 3.1.2), and sentence embedding models (Section 3.1.3).

3.1.1 Textual Statistical Features

Our analysis began with surface-level textual statistical features, including word overlap and the Levenshtein distance measurement at the character level. These scores were then normalized into ratios to estimate their correlation with human-annotated relatedness. Specifically, we considered the following features:

- Character Distance Ratio: normalization of Levenshtein distance. Levenshtein distance (represented as $Dist$ in Equation (3)) or edit distance is a string metric for measuring the

[1] In the supervised track, we only participated English subtask, in which relatively more training data was provided. For this reason, our analysis of supervised learning is specific to English.

Statistic Features	Spearman *r*
Char Distance Ratio	0.513
Word Overlap Ratio	0.593
Content Words Overlap Ratio	0.604

Table 1: Correlation between human-annotated relatedness scores with ratios of textual statistical features.

difference or distance between two sequences at the character level. The character ratio we use in this study is defined as:

$$\frac{\text{len}(\text{Sent}_1) + \text{len}(\text{Sent}_2) - \text{Dist}}{\text{len}(\text{Sent}_1) + \text{len}(\text{Sent}_2)} \quad (3)$$

- Word Overlap Ratio: the count of overlapped words over the total word count in sentence pairs, expressed as:

$$\text{Ratio} = \frac{|\text{Words(A)} \cap \text{Words(B)}|}{|\text{Words(A)} \cup \text{Words(B)}|} \quad (4)$$

- Content Word Overlap Ratio: the overlap ratio with content word considered only. Content words and functional words are distinguished by analyzing their part-of-speech (POS) using `SpaCy` python package.

We found that the overlap ratio computed solely on content words shows a better correlation with the human judgment of relatedness (Table 1). Furthermore, we tested the correlation of the word overlap ratio with the other two scores: Spearman's *r* with content word overlap ratio is 0.77, and Spearman's *r* with character distance ratio is 0.78. This suggests that the combination of two or more results may improve the relatedness estimation.

3.1.2 Word Embedding Models

In this subsection, we evaluate the performance of word embedding models' potential to estimate semantic relatedness. Sentence embeddings are represented as the mean of the word embeddings of all words in the sentence. We explored static word embeddings (GloVe and first layer BERT embeddings) and contextual word embeddings (the last layer of BERT embeddings) in relatedness estimation. The performance of the following variations is presented in Table 2:

- PCA transformation of embeddings. By using the PCA technique, we do not intend to reduce the dimension of the sentence embeddings, but transform sentence embeddings onto a new coordinate system such that the principal components capture the largest variation in the data. In practice, the maximum dimension that fits the dataset is adopted: *min* (*embedding_length, sample_size*).

- Content word embeddings: the average of word embeddings of content words only.

- Noun embeddings: the average of word embeddings for nouns only.

- Tree-Based word embeddings: the mean of embeddings of words that are at the top three levels of dependency trees,[2] namely the root (main predicate), direct dependents of the root, and dependents with the dependency distance of 2 from the root.

Our preliminary analysis offers the following insights for further ensemble learning:

1. Excluding functional words (using content words only) can enhance the effectiveness of GloVe embedding.

2. Focusing on words closer to the sentence's 'root' in terms of dependency distance did not yield better results.

3. Contextualized BERT embeddings do not necessarily outperform uncontextualized embeddings in semantic relatedness estimation.

4. PCA-transformed embeddings show improved correlation with human annotation of relatedness.[3]

3.1.3 Models for Sentence Representations

For supervised learning, we also incorporate sentence representations from pre-trained language models into our ensemble system. This includes models known for their strong performance in sentence similarity tasks, involving Sentence-BERT (`mpnet-base`, Reimers and Gurevych, 2019) and Jina Embedding (`jina-v1`, Günther et al., 2023), as well as the general large language model, T5

[2]We use SpaCy to parse sentences and select the root and dependents

[3]Despite the better performance of PCA-transformed embeddings in Spearman's correlation when word embedding models are tested individually, it was not beneficial in later supervised training. Ultimately, $\text{GloVe}_{\text{Content}}$ word embedding was utilized in supervised and unsupervised ensemble learning for English.

Model	Spearman *r*
GloVe	0.460
$\text{GloVe}_{\text{PCA}}$	0.533
$\text{GloVe}_{\text{Content-words}}$	**0.554**
$\text{GloVe}_{\text{Tree-Based}}$	0.249
$\text{GloVe}_{\text{Noun}}$	0.430
$\text{BERT}_{\text{LastLayer}}$	0.399
$\text{BERT}_{\text{LastLayer/PCA}}$	0.446
$\text{BERT}_{\text{FirstLayer}}$	0.570
$\text{BERT}_{\text{FirstLayer/PCA}}$	**0.593**

Table 2: Spearman's correlation between human-annotated relatedness scores with the cosine similarity of average embeddings of all words, content words, all nouns or tree-based word selections within a sentence. PCA-transformed average embeddings of all words in a sentence are also presented.

encoder (Raffel and Chen, 2023; Ni et al., 2021). Among all models tested in this study for English (refer to Table 3), T5 demonstrates the highest performance, achieving a Spearman's correlation of approximately 0.82 with human annotation.

3.1.4 Ensemble Learning

We explored two approaches for ensemble learning. The first approach operated directly on sentence representations from multiple models. This included concatenating sentence embeddings from various models and applying transformation (e.g., PCA transformation) in the embedding space to achieve a better correlation with human judgment. Our analysis indicates that while concatenation and transformation operations can slightly improve Spearman's correlation, they are not as effective as incorporating more statistical features into supervised fine-tuning.

In the final system, we directly used the cosine similarity values from sentence embedding and word average embeddings as features (from models `mpnet-base`, `jina embedding`, `T5-base` and mean of content word embeddings from GloVe), along with textual statistic features (content word overlap ratio and character distance ratio) to estimate the relatedness of sentence pairs. These features are fed into Support Vector Machine (SVM) regression models (with RBF kernel) to predict human annotated relatedness.

3.2 Unsupervised Ensemble

In the unsupervised track, without utilizing labeled datasets for sentence similarity or relatedness and without employing models pre-trained on labeled datasets, we aim to evaluate whether models trained on other types of datasets intended for different purposes could generate representations suitable for estimating semantic relatedness.

In addition, we investigated whether integrating additional features, such as the cosine distance of average word embeddings and word overlap ratios, could enhance performance. We calculated the arithmetic mean of the cosine distances and ratios from textual statistics as the relatedness prediction of sentence pairs. Various feature combinations are tested with the provided validation dataset.

For the unsupervised task of English, we utilized two models to generate sentence representations: a model designed for semantic search (`multi-qa-MiniLM-L6-cos-v1`, Reimers and Gurevych, 2019), trained on 215 million question-answer pairs; and e5 (`e5-base-unsupervised`, Wang et al., 2022),[4] trained on question-answer pairs, post-comment pairs, and title-passage pairs. These models were further refined with an unsupervised transformation (PCA). Additionally, we incorporated two other features: PCA-transformed GloVe embeddings (average of content word embeddings within a sentence) and content word overlap ratios into the unsupervised ensemble system.

For the unsupervised tasks in Spanish and Hindi, we used a similar method for predicting relatedness, combining features involving the cosine distance of `multi-qa-MiniLM` model representations, word embedding model and word overlap ratios. For word embeddings, we employed multilingual BERT (`bert-base-multilingual-uncased`), utilizing both the first-layer (uncontextualized) and last-layer (contextualized) embeddings for relatedness estimation.

4 Results and Analysis

The shared task evaluates the participating systems based on Spearman's correlation (r) between the human-annotated scores, which ranges from 0 to 1. In Table 3, we compare the correlation scores for our systems and other popular models on the official test set.

[4]The e5 monolingual model is exclusively used for English, not for the other two languages: Spanish and Hindi

Models	English	Spanish	Hindi
Lexical Overlap	0.741	0.661	0.587
$\text{mBERT}_{\text{\_Ave}}$	0.640	0.655	0.566
mpnet-base[5]	0.809	0.590	**0.746**
T5 (base)	0.825	-	-
LaBSE[6]	0.818	0.651	0.709
multi-qa-Mini	0.793	0.638	0.466
$\text{Ensemble}_{\text{Sup}}$	**0.850**	-	-
$\text{Ensemble}_{\text{Unsup}}$	**0.837**	**0.705**	0.649

Table 3: Spearman correlation between human-annotated relatedness scores and system predicted scores on the test dataset.

Results presented in Table 3 suggest that the ensemble approach generally outperforms single models. Specifically, the ensemble system trained with true labels, for the supervised English task, achieved the best result among all listed systems, with an improvement in Spearman's correlation of 0.025 compared to the T5 base model.

The ensemble approach for English and Spanish unsupervised tasks also achieved relatively high scores, despite the absence of similarity or relatedness scores in learning. It suggests that semantic relatedness can be estimated without necessarily relying on human-annotated scores of semantic similarity or semantic relatedness. Other sources like question-answering pairs or statistical features of texts also play a role in relatedness estimation. Thus, the ensemble of statistical text features, word embedding models, and models trained on question-answer pairs can achieve good results.

Although the results for Hindi did not match the superior outcomes of other supervised models, such as `mpnet-base` and `LaBSE`, which were trained with semantic labels or similarity scores, the ensemble system's performance still surpasses that of the multilingual BERT embedding model and the `multi-qa` model, both of which were utilized for ensemble learning as base models.

4.1 Biased Performance

We also observe that the unsupervised results for Hindi are not comparable with those from Spanish and English though with the same ensemble approach. This discrepancy stems from the suboptimal performance of the sub-models used in the unsupervised ensemble. For example, the multi-qa-MiniLM model utilized for Hindi only achieves a correlation of 0.466, and the multilingual BERT for Hindi is also less effective compared to the other two languages.

Apart from Hindi, we also applied the same ensemble method to other non-Indo-European languages in the unsupervised track, yet the results scarcely surpassed 0.60 for the validation dataset, so results of other languages were ultimately not submitted.

The results indicate that some multilingual models are biased towards English and Indo-European languages, and perform less effectively for other languages. This bias may be attributed to imbalanced data during the models' pre-training phase.

5 Conclusion

Our system employs an ensemble approach to estimate semantic relatedness, integrating results from multiple systems: textual statistical features, word embedding models, and sentence representation models. Our findings suggest that semantic relatedness can be deduced from a variety of sources. Although some features (e.g., lexical overlap ratio) may not perform as strongly as models specifically designed to obtain sentence representations, the results demonstrate that these features, when used in a combined manner, can outperform many individual systems and collaboratively achieve a better correlation with human judgment on semantic relatedness.

6 Limitation and Future Work

Constrained by the size of the training data and the availability of pre-trained language models, it is regrettable that we did not offer insights into other Asian and African languages. In future research, studies on low-resource languages will be valuable, including tasks such as data collection, annotation, and pre-training models tailored to these languages.

{spulipa,srmhalgi,joelarso,skuebler}@iu.edu

Abstract

Since Large Language Models have reached a stage where it is becoming more and more difficult to distinguish between human and machine written text, there is an increasing need for automated systems to distinguish between them. As part of Sem-Eval Task 8, Subtask A: Binary Human-Written vs. Machine-Generated Text Classification, we explore a variety of machine learning classifiers, from traditional statistical methods, such as Naïve Bayes and Decision Trees, to finetuned transformer models, such as RoBERTa and ALBERT. Our findings show that using a finetuned RoBERTa model with optimized hyperparameters yields the best accuracy. However, the improvement does not translate to the test set because of the differences in distribution in the development and test sets.

1 Introduction

Large Language Models (LLMs) are becoming more and more accessible, which has resulted in an increase in machine-generated content across a wide variety of domains, including education, technology, and science. With this increase in machine generated texts from LLMs, and with the increase in the quality of LLM created texts, concerns regarding but not limited to fake product review generation (Adelani et al., 2019) spam/phishing (Weiss, 2019) and fake news generation (Zellers et al., 2019; Brown et al., 2020; Uchendu et al., 2020) have arisen. Weiss (2019) demonstrated that humans can only detect such misuses of LLMs at chance level, which demonstrates the clear need for automated systems to detect machine generated content. In this paper, we describe the IUCL submission to SemEval task 8 (Wang et al., 2024); we focused mostly on comparing traditional and neural models. Our best system ranked 70th out of 137 submissions.

2 Related Work

In terms of impressionistic differences between human generated text and LLM generated text, it has been observed that LLMs tend to be more focused (i.e. less diversion from the subject at hand), more objective, and highly formal. Human texts, on the other hand, are overall more emotional, subjective, and less formal. In terms of linguistic difference, humans use fewer nouns and conjunctions, while employing more punctuation and adverbs. Dependency relations are also shown to be shorter. Lastly, human texts have higher type/token ratios in texts of the same length (Guo et al., 2023) Current LLM models include GPT-2 (Radford et al., 2019), GPT-3 (Brown et al., 2020), CTRL (Keskar et al., 2019) and ChatGPT.

We will first begin by discussing statistical approaches to detecting machine-generated content, then using LLM technology itself to do so.

Solaiman et al. (2019) use a bag-of-words approach with TF-IDF feature vectors (both unigrams and bigrams) and a logistic regression model to differentiate between human-written web pages and text generated web pages from GPT2. They examine a different number of parameters of the LLM (117M, 345M, 762M and 1,542M) as well as different sampling methods (k-sampling, p-sampling and pure sampling). This is because an assumption that many researchers take is that language models sample from the head to generate natural looking text e.g. max sampling (Gu et al., 2017) and k-max sampling (Fan et al., 2018). Their findings are that the larger the LLM, the harder to detect how machine-like the generated text is and k samples are easier to detect than pure samples, probably due to the fact that k samples over-produce common words, which is easy to detect using statistical methods.

Gehrmann et al. (2019) use BERT and a group of statistical features: the probability of each word, ab-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1026–1031

solute rank of each word, and entropy of the distribution, and create a tool for users to see specifically what features are more likely to be machine generated over human generated. They clearly show that the model GPT-2 oversamples certain words; it is worth pointing out, however, that as LLMs grow more sophisticated, such methods may not work as well.

Solaiman et al. (2019) use finetuning on RoBERTa and find that it can detect text generated from GPT-2 with an accuracy of 95%. The RoBERTa detector has also been used in detecting fake news articles from several LLMs (Uchendu et al., 2020), Amazon product reviews (Adelani et al., 2019), and biomedical texts (Rodriguez et al., 2022).

3 Data

We used the M4 dataset (Wang et al., 2023) provided by the SemEval-2024 Task 8: Multigenerator, Multidomain, and Multilingual Black-Box Machine-Generated Text Detection. We used the English data provided for Subtask A, the Monolingual (English) binary classification task.

The dataset for this subtask consists of 119,757 samples of human-written and machine generated text. There are an additional 5,000 samples as a development set. The test set consists of 34,272 samples.

About 53% of the samples in the training set are machine generated while the rest are human written. The machine generated text was produced by a range of models: ChatGPT and DaVinci by OpenAI, Dolly by Databricks, Cohere. The sources from which the human texts are taken are Reddit, WikiHow, ArXiV, Wikipedia and PeerRead. In contrast, the development set consists of an equal ratio of human and machine generated samples. The machine generated samples are entirely from the Bloomz model. The human sources are also equally distributed between WikiHow, Wikipedia, Reddit, ArXiV and PeerRead. In the test set, 52.5% of the texts are machine generated with GPT4, Cohere, ChatGPT (GPT3.5), Bloomz, Dolly, and DaVinci as sources. Note that this means optimizing a system on development data is difficult since the test data are much closer to the training data than the development data.

Further details about the data and the task are available at the overview of the shared task (Wang et al., 2024).

We present a comparison of a range of classifiers (see below). For those experiments, we use the development set of 5,000 samples for benchmarking and finetuning the model performance.

4 Methods and Features

4.1 Features

Ratio features We started with extraction of features from the dataset that cannot be controlled consciously by authors: stopword ratio and average sentence length. We used the NLTK stopwords[1] (Bird et al., 2009) to calculate the stopword ratio for the dataset. The left graph in Figure 1 shows the distribution for the sentences generated from different sources. The median stopword ratio for humans and different models are around 0.40. It is difficult to distinguish human text from machine text as the distributions of the texts generated by machines are similar to those of the human generated texts. We then computed the average sentence length generated by different sources, see the right graph in Figure 1. The average number of the sentences generated in each of the category is around 21. Again, there is little difference between machine and human generated texts.

Textual features We also used TF-IDF and word unigram features.

4.2 Statistical Learning Methods

We used the ratio features to train Multinomial Naïve Bayes, Random Forest, XGBoost, Logistic Regression and SVC models on the data. For the textual features, we trained SVC, Decision Tree, Logistic Regression and Random Forest classifier models. For all models, we used the scikit-learn implementations (Pedregosa et al., 2011).

We chose the Naïve Bayes classifier because of its simplicity and the ability to handle missing data values. Support Vector Classifier is better at handling high dimensional spaces and is robust to overfitting. Random Forest is an ensemble learning method which is robust to overfitting and provides feature importance ranking, helping to identify the most influential features. Logistic Regression and Multinomial Naïve Bayes classifiers are easy to interpret and are computationally efficient. XGBoost provides a gateway to handle data in a highly efficient and scalable manner. Because of time constraints, we did not perform any hyperparameter

[1] https://gist.github.com/sebleier/554280

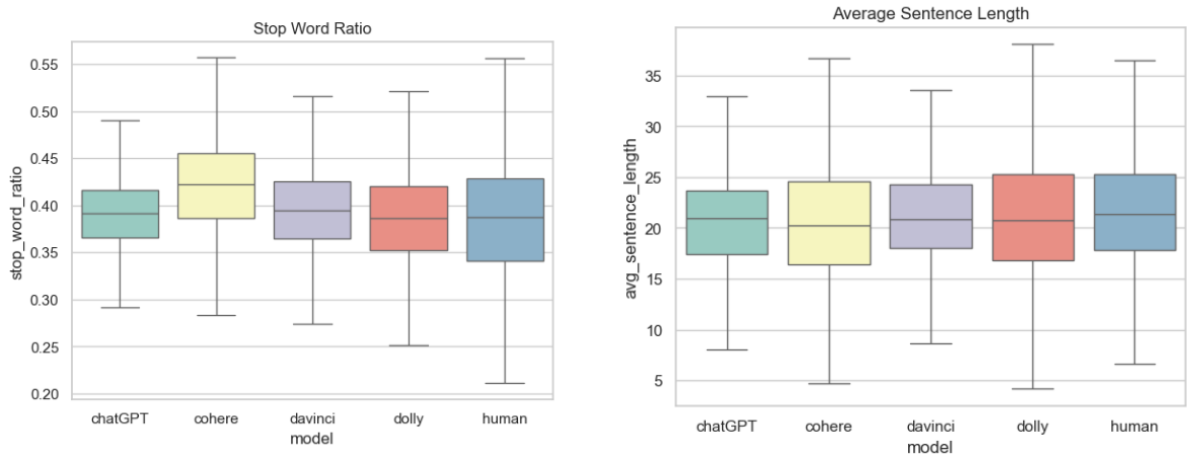

Figure 1: Stop word ratio (left) and average sentence ratio (right) generated by different models.

tuning, and used the default settings to train the models.

4.3 Deep Learning Methods

Fully connected DL model We used the same data preprocessing techniques described in Section 4.1 and trained a fully connected 2 layer neural network having 512 hidden units with ReLU activation. We used the Binary Crossentropy to calculate the loss and Adam optimizer to train our neural network on 100 epochs. We set the batch size to 2048, due to processing limitations and kept a learning rate of 0.001 with an early stopping mechanism in place.

Finetuned Language Models We also finetuned the following language models: BERT and its derivative models ROBERTa and ALBERT. We use the Hugging Face library (transformers) for this task.

BERT (Bidirectional Encoder Representations from Transformers) is a language model developed by Devlin et al. (2019). It is a bidirectional model that uses a transformer architecture. We use the BERT base model for our experiments.

RoBERTa is a variant of BERT developed by Liu et al. (2019). It is pre-trained on a larger corpus of texts. We use the RoBERTa base as well as large models for our experiments. The best performing model of our study is a RoBERTa base model. ALBERT is a smaller version of BERT developed by (Lan et al., 2020). The hyperparameters selected are shown in Table 1.

	RoBERTa	BERT	ALBERT
Learning Rate	5e-5	2e-5	2e-5
Batch Size	8	32	16
Nr. Epochs:	3	4	4
Grad. Acc. St.	4	2	2

Table 1: Hyperparameters for the neural models

5 Results

We will first discuss our results on the development data, then the official results of the shared task.

5.1 Results on the Development Set

The shared task provides a baseline accuracy of 74% using a RoBERTa model. Our aim is to investigate a range of models and features and incrementally improve models, starting out with traditional machine learning models and then moving on to deep learning models.

Table 2 shows the performance of the different combinations of models and features on the development set.

We first look at the statistical methods combined with the standard sparse features, bag of words, and TF-IDF weighted bag of words features. The results in the first block show that the TF-IDF weighted feature results in a lower accuracy than standard frequency counts (56.44% vs. 60.22%) for logistic regression. For this reason, we decided to concentrate on frequency counts. Among the different statistical classifiers, logistic regression reaches the highest results (60.22%), followed by XGBoost with 59.26%.

When we use the ratio features, i.e., stop word

Features	Model	Acc.
TF-IDF	Logistic Regression	56.44
words	Random Forest	58.86
	Naïve Bayes	50.54
	XGBoost	59.26
	Logistic Regression	60.22
Ratio features	Logistic Regression	67.14
BERT	Logistic Regression	63.48
	Fully connected NN	67.19
	Fully connected NN (optimized)	70.11
ALBERT	ALBERT	66.78
RoBERTa	RoBERTa BASELINE	*74.00*
	XLM-RoBERTa Large	77.67
	XLM-RoBERTa (10,000 training samples)	78.24
	XLM-RoBERTa Base Default	79.61
	XLM-RoBERTa Base (optimized)	**79.90**

Table 2: Model comparison with respect to features and accuracy for Dev Set

ratio and average sentence ratio, combined with logistic regression, we reach an accuracy of 67.14%, which is surprising in that this outperforms word features by almost 6% absolute, even though they did not show large differences in Figure 1.

Next, we investigate whether using BERT embeddings instead of sparse features improves results. When we use those features with logistic regression, results increase by 3% absolute to 63.48%, combining them with the fully connected neural network, we reach an accuracy of 70.11%, outperforming the ratio features, but not reaching the baseline provided by the shared task.

We then move on to use BERT and its variants. We start off with ALBERT, a smaller version of BERT. This model gives us an accuracy of 66.78%. This shows that we need a large scale model for good performance. We find that the XLM-RoBERTa model, a multilingual pre-trained model performs better than a RoBERTa model. An XLM-RoBERTa model with full data and default parameters gives us an accuracy of 79.61%. We add gradient accumulation to the finetuning process to speed up training and improve performance. We also reduce the batch size and adjust the learning rate, to get an incremental 0.3% improvement due to the hyperparameters. Optimizing hyperparameters tuning further increases accuracy to 79.90%. This is the best accuracy we have obtained in our experiments. When we compare those results to the XLM-RoBERTa large model with its higher number of parameters, accuracy drops to 77.67%, showing that simply increasing the number of parameters does not guarantee good performance.

A final experiment investigates the importance of the training set size. For this experiment, we reduce the training data to 10,000 samples. This model gives us an accuracy of 78.24%, showing that finetuning XLM-RoBERTa with even a small dataset reaches competitive results. Increasing the training set from 10,000 to about 120,000 results in an increase in accuracy of 1.66% absolute.

System	Score	Rank
Our submission	74.96	70
Baseline	88.46	–
safeai	96.88	1

Table 3: Official Results (accuracy).

5.2 Official Results

We generated our final predictions using the finetuned XLM-RoBERTa system. We show our results in comparison to the best system and the baseline in Table 3. Our submission had an accuracy of 74.96% on the test set and was ranked 70 out of 137 teams. The best ranking team had an accuracy of 96.88%. Note that while our system improved over the baseline for the development data, this is not the case for the test data. This is most likely a consequence of the different distributions between the development and test data.

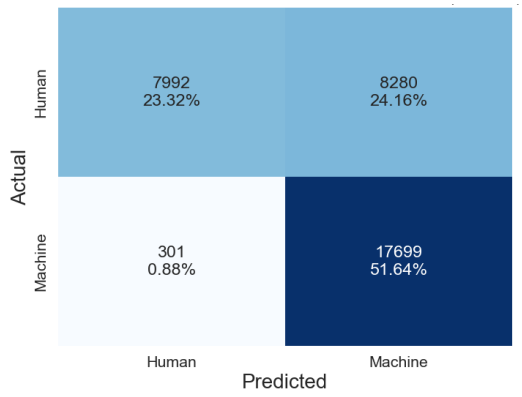

Figure 2: Confusion Matrix of the best model (Test Set)

5.3 Discussion

We had a closer look at the confusion matrix for the best performing model, the optimized XLM-RoBERTa model, on the test data, shown in Figure 2. We notice that the model has a tendency to incorrectly identify human samples as machine generated (false positives) in 8,280 cases, as opposed to just 301 cases of false negatives.

One of the limitations of our work is that we have not explored data processing and augmentation techniques that can help us improve the performance of the model.

6 Conclusion and Future Work

In this project, we have investigated the performance of various machine learning models. We found that our best performing model is a base XLM-RoBERTa model that is fine-tuned on the dataset. Using the smaller ALBERT or the large XLM-RoBERTa models resulted in decreases in accuracy. However, we also see that finetuning is very sensitive to underlying data characteristics, since the gains we saw on the development set did not translate to equivalent gains on the test set.

There is a significant scope for improvement in the performance of the models by working on further text preprocessing and feature engineering. Future work includes using ensemble methods that combines the finetuned models along with a model using ratio features.

RACAI at SemEval-2024 Task 10: Combining algorithms for code-mixed Emotion Recognition in Conversation

Sara Niță and **Vasile Păiș**

Research Institute for Artificial Intelligence "Mihai Drăgănescu", Romanian Academy

Bucharest, Romania

saramaria.nita9@gmail.com, vasile@racai.ro

Abstract

Code-mixed emotion recognition constitutes a challenge for NLP research due to the text's deviation from the traditional grammatical structure of the original languages. This paper describes the system submitted by the RACAI Team for the SemEval 2024 Task 10 - EDiReF subtasks 1: Emotion Recognition in Conversation (ERC) in Hindi-English code-mixed conversations. We propose a system that combines a transformer-based model with two simple neural networks.

1 Introduction

Emotion recognition in conversation (ERC) (Kumar et al., 2023) is a crucial task in conversational artificial intelligence research that aims to identify the emotion of each utterance in a conversation. ERC proves useful in applications such as opinion mining and empathetic dialog systems. However, many of the existing models and datasets for emotion recognition are single-language. But, proliferating mixed language interactions have boosted interest in code-mixed natural language processing (NLP) tasks.

The present work describes the system that participated in the shared task "Emotion Discovery and Reasoning its Flip in Conversation (EDiReF)", task 10, organized at SemEval 2024 (Kumar et al., 2024). The EDiReF shared task is made up of three subtasks: (i) Emotion Recognition in Conversation (ERC) in Hindi-English code-mixed conversations, (ii) Emotion Flip Reasoning (EFR) in Hindi-English code-mixed conversations, and (iii) EFR in English conversations. Out of these subtasks, our team participated only in sub-task (i).

Many current approaches for diverse NLP tasks, including ERC, relies on the application of large language models (LLMs) and fine-tuning them on a specific dataset. For this work we were interested in determining how existing language resources, such as emotion lexicons, could be used to complement and improve the predictions of LLM-based approaches. For this reason, our final system, as detailed in Section 4.2, is an ensemble of a BERT-based implementation and traditional feature-based approaches, employing an emotion lexicon. Apart from the emotion lexicon, we did not use any external datasets. Only the dataset provided by the task organisers was used as an emotion annotated dataset. We also took into account the requirement expressed by the task organizers, that no data from task 2 or task 3 can be used to train/evaluate task 1.

This paper is organized as follows: Section 2 provides related work, Section 3 briefly presents the task and describes the dataset, Section 4 gives an overview of the participating system, including pre-processing and architecture, Section 5 presents the results, and Section 6 gives conclusions.

2 Related work

Wang et al. (2020) recognizes the importance of ERC for developing empathetic machines in a variety of areas. The authors model the ERC task as sequence tagging where a Conditional Random Field (CRF) layer is leveraged to learn the emotional consistency in the conversation. Experiments are performed on three datasets: IEMOCAP (Busso et al., 2008), DailyDialogue (Li et al., 2017), and MELD (Poria et al., 2019). The authors ackowledge an imbalanced data distribution in some of the ERC datasets, similar to the distribution provided for the current task (as described in Section 3).

Ghosal et al. (2019) propose Dialogue Graph Convolutional Network (DialogueGCN), a graph neural network based approach to ERC. The authors test the approach on a number of datasets, including IEMOCAP and MELD, showing good results.

Song et al. (2022) employ a Supervised Prototypical Contrastive Learning (SPCL) loss for the ERC task. In this case, the SPCL aims to solve the imbal-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1032–1037

anced classification problem through contrastive learning. Their approach further improve results on the IEMOCAP and MELD datasets, achieving F1 scores of 69.74% and 67.25%, respectively.

De Bruyne et al. (2022) evaluate the language-dependence of an mBERT-based emotion detection model. Experiments included the Hindi and English languages. Their findings suggest that there could be evidence for the language-dependence of emotion detection performance.

Datasets and systems for emotion recognition have been proposed for other languages as well. For example, for the Romanian language, Ciobotaru and Dinu (2021) introduced the RED dataset for emotion detection in Romanian tweets. Colhon et al. (2016) showed that particular Romanian language words, such as negations, intensifiers and diminishers, affect the detected polarity of the sentiments described in natural language texts. Furthermore, Tăiatu et al. (2023) introduced RoBERTweet, a BERT-like LLM for Romanian language. The authors also describe a system using the RoBERTweet model for emotion detection outperforming previous general-domain Romanian and multilingual language models.

Laki and Yang (2023) explore sentiment analysis with neural models for the Hungarian language. The authors try to solve the class imbalance problem either by removing examples from the highly represented class (while keeping the same number of examples as the least represented class) or by duplicating examples from the least represented class. In addition they explore data augmentation by means of machine translation and cross-lingual transfer. Different Hungarian language LLMs, especially BERT-like LLMs, are considered for the experiments. Üveges and Ring (2023) introduce HunEmBERT, a fine-tuned BERT-like model for classifying sentiment and emotion in political communication in the Hungarian language.

Apart from neural network models and datasets, lexicons constitute another type of useful resources for sentiment analysis. This type of resources have been created for different languages. Lupea and Briciu (2019) introduced the Romanian Emotion Lexicon (RoEmoLex v.3). It contains associations between a series of words and eight basic emotions (Anger, Anticipation, Disgust, Fear, Joy, Sadness, Surprise, Trust) and two sentiment orientations (Positivity and Negativity). Initially translated from an English version, it now contains additional tags, including derived emotions, part-of-speech, additional polarity scores and conceptual category information. It was also expanded with synonyms of the original terms and new words and phrases.

Mohammad and Turney (2010, 2013) propose the NRC Word-Emotion Association Lexicon (EmoLex). It contains English words and their associations with eight basic emotions (anger, fear, anticipation, trust, surprise, sadness, joy, and disgust) and two sentiments (negative and positive). The annotations were manually done by crowdsourcing. The authors assess that despite some cultural differences, the majority of the affective norms are stable across languages. Thus, the lexicon is also provided in over 100 languages by automatic translating the English terms using Google Translate.

Various datasets for sentiment classification, including those mentioned in this section, suffer from a class imbalance problem. Frameworks for data augmentation, such as NL-Augmenter (Dhole et al., 2023), have been proposed, allowing automatic enrichment of less represented classes. Chawla et al. (2002) proposed SMOTE, a synthetic minority over-sampling technique. Their approach combines under-sampling of the majority class with a special form of over-sampling the minority class. The minority class is over-sampled by creating "synthetic" examples rather than by over-sampling with replacement, thus reducing the potential overfitting.

3 Dataset and task

The goal of the emotion recognition task is to classify a given sentence from a dialogue into one of eight emotion states: the seven universal human emotions as described by Dr. Paul Ekman (Ekman, 1992) ("anger", "surprise", "contempt", "disgust", "fear", "joy", "sadness") and "neutral". The dataset files, with splits for training, validation, and testing, were provided in JSON format. The records contain fields for the name of the episode the lines were taken from, a list of speakers, the actual dialogue (list of sentences called "utterances"), and a list with the emotions attributed to each line ("emotions" or "labels"). The utterances included some unrecognized characters that needed to be removed. The training dataset contains 343 entries (8,506 utterances), the validation dataset contains 46 entries (1,354 utterances), while the test dataset contains 57 entries (1,580 utterances).

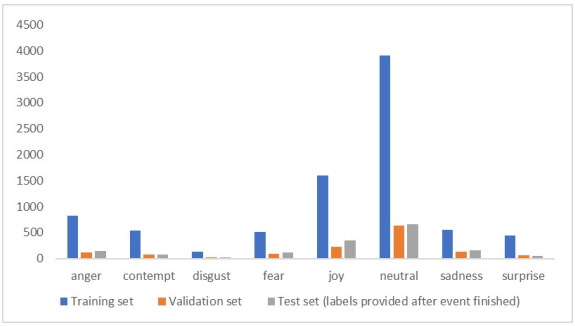

Figure 1: Emotion distribution for train, validation and test sets

The labels distribution for the train, validation and test splits is given in Figure 1. Similar to other emotion recognition datasets, such as IEMOCAP or MELD, as reported in Section 2, there is a class imbalance present in the task dataset as well. Many sentences are marked as being "neutral", while the next class, considering the number of samples, is "joy". The least represented class is "disgust".

4 Methodology

4.1 Pre-Processing

In the pre-processing stage, all blank characters, including new lines, tabs, and other unrecognized UTF-8 characters, were transformed into regular spaces. Dialogues were split into individual sentences and duplicates removed from the training set.

Given the observation of De Bruyne et al. (2022) regarding the possible language-dependence of emotion detection performance, combined with the existence of a large number of emotion lexicons in the English language, individual sentences were completely translated into English, removing any Hindi text (including roman script). For this purpose, we employed the GoogleTranslator from the deep_translator library.

4.2 Overall system architecture

The system is comprised of two parts: one being a multilingual BERT LLM and the other consisting of a Decision Tree and a Random Forest classification algorithms, employing additional features.The final result was obtained by running the three sets of predictions from the models through a voting system. If two or all three models predict the same emotion, then this becomes the final prediction, but if they each give different results, then the BERT prediction is chosen as the final prediction, because when taken separately, BERT has better results then either decision trees or random forest, as shown in in Table 1. A diagram of the entire system is given in Figure 2.

4.3 Decision Tree and Random Forest

To aid in feature construction, the text was lemmatized by employing the WordNet (Fellbaum, 1998) lemmatizer available in the NLTK library[1].

From the translated sentences a set of handcrafted features were produced, some of which were binary features associated with each one of the seven emotions. Through the use of an English lexicon, the NRC-Emotion-Lexicon-Wordlevel[2] (Mohammad and Turney, 2013), the feature was either marked as "1", if the emotion was the most commonly found one among the meanings of the words in a given sentence, or as "0". The lexicon unfortunately did not contain any data about the “contempt” value of words. As a unified resource for both Hindi and English was not successfully found, the translation previously performed was necessary. The other features were: length, the number of sentences in an utterance, punctuation (for full stop, question mark, exclamation mark and ellipsis), ratio of words from the lexicon that were predominantly positive or negative and the confidence of the lexicon. The confidence was computed based on the number of words belonging to different classes which were found in the lexicon for a given sample.

For the decision tree predictions only, new examples were synthesized using a SMOTE pipeline (Chawla et al., 2002) due to the imbalanced nature of the dataset.

4.4 BERT

The LLM used for training the system was bert-base-uncased. This was chosen due to our assumption that a smaller model may benefit more from additional resources, such as an emotion lexicon. The LLM classifier has two additional linear layers, with 2,048 and 1,024 cells respectively, employing ReLU and tanh activation functions respectively. These are followed by a final class prediction head. The model was trained for at least 5 epochs and a maximum of 20 epochs, with early stopping, when there was no improvement for 3 epochs. During the first 3 epochs, the LLM was frozen and only

[1] https://www.nltk.org/

[2] https://saifmohammad.com/WebPages/NRC-Emotion-Lexicon.htm

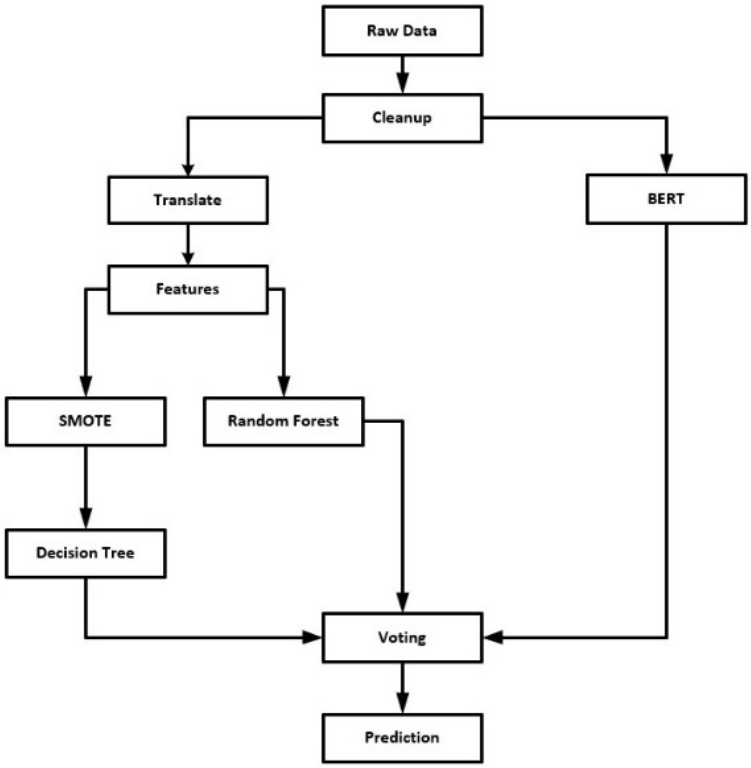

Figure 2: System architecture.

the last linear layers were actually trained. A batch size of 6 was used. The learning rates for the LLM and the other layers were kept separated. The best hyper-parameters were found to be encoder learning rate 1.0e-05, and linear layers learning rate 3.0e-05. The final model training lasted 18 epochs.

5 Results and discussion

Results are given in Table 1 for the test dataset, in terms of weighted precision, recall, and F1 scores. In this case, the weighted recall is equal to the accuracy measure. The baseline is computed on the assumption that all results are neutral. As expected, due to the class imbalance, this provides the best accuracy. Decision tree and random forest classifiers provide results worse than BERT alone and even worse than the baseline approach. This translates into words not being found in the lexicon or words that may mean different things in context, while the lexicon does not take into account the context. Even though the voting mechanism favors the BERT prediction, it seems it actually decreases all the metrics. It is however worth observing the precision score associated with the random forest classifier employing features generated based on the lexicon which is quite high (only 4% under the precision offered by the LLM predictor).

System	P	R	F1
BERT	**36.2**	37.6	**35.0**
DT	7.8	16.7	10.5
RF	0.326	16.7	18.2
Voting	35.2	33.9	30.9
Baseline	17.1	**0.42**	0.24

Table 1: Results on the test dataset.

6 Conclusion and future work

The proposed system tried to combine a lexicon approach with a LLM prediction, considering that a manually created emotion lexicon could complement the LLM predictions. Nevertheless, even though the precision given by the random forest classifier based on features derived using the lexicon is surprisingly good, the recall is significantly lower, thus resulting in an overall lower F1 score, even in the face of a LLM with a reduced number of parameters.

In accordance with open science principles, the code for the described system is made available

open source in its own GitHub repository[3].

The class imbalance problem was tackled only with the SMOTE technique. However, as mentioned in Section 2, different frameworks for data augmentation are available. Future work may include experiments with other data augmentation techniques for the minority classes.

As documented in Section 2, different authors have shown improvements using language-specific and domain-specific LLMs. For this work, we focused on a single BERT LLM. Other LLMs, with more specificity or a larger number of parameters, may provide better results. However, the question regarding the possible enhancement of predictions using additional resources, such as emotion lexicons, still remains valid.

Limitations

The current system implementation makes use of English-only emotion lexicons. The system architecture does not take into account long messages that surpass the direct capability of the LLMs used.

Ethics Statement

We do not foresee ethical concerns with the research presented in this paper. However, it is important to acknowledge that unintended bias might be present in the dataset and this could be reflected in the resulting models. Furthermore, since the emotion lexicons have been created by people they capture various human biases which may be reflected in the final system.

ROSHA at SemEval-2024 Task 9: BRAINTEASER A Novel Task Defying Common Sense

Mohammadmostafa Rostamkhani, Shayan Mousavinia, Sauleh Eetemadi
Iran University of Science and Technology
{mo_rostamkhani97, sh_mousavinia}@comp.iust.ac.ir, sauleh@iust.ac.ir

Abstract

In our exploration of SemEval 2024 Task 9, specifically the challenging BRAINTEASER: A Novel Task Defying Common Sense, we employed various strategies for the BRAINTEASER QA task, which encompasses both sentence and word puzzles. In the initial approach, we applied the XLM-RoBERTa model both to the original training dataset and concurrently to the original dataset alongside the BiRdQA dataset and the original dataset alongside RiddleSense for comprehensive model training. Another strategy involved expanding each word within our BiRdQA dataset into a full sentence. This unique perspective aimed to enhance the semantic impact of individual words in our training regimen for word puzzle (WP) riddles. Utilizing ChatGPT-3.5, we extended each word into an extensive sentence, applying this process to all options within each riddle. Furthermore, we explored the implementation of RECONCILE (Round-table conference) using three prominent large language models—ChatGPT, Gemini, and the Mixtral-8x7B Large Language Model (LLM). As a final approach, we leveraged GPT-4 results. Remarkably, our most successful experiment yielded noteworthy results, achieving a score of 0.900 for sentence puzzles (S_ori) and 0.906 for word puzzles (W_ori).

1 Introduction

Human reasoning involves two primary types of thinking: vertical and lateral. Vertical thinking, synonymous with linear, convergent, or logical thinking, follows a sequential analytical process based on rationality and rules. Conversely, lateral thinking, often referred to as "thinking outside the box," is a divergent and creative process that challenges preconceptions by approaching problems from new perspectives. Despite the success of language models in tasks requiring implicit and complex reasoning, there is a notable lack of attention to lateral thinking puzzles within the NLP community. To address this gap, the BRAINTEASER Question Answering task (Jiang et al., 2023) has been introduced, designed to evaluate a model's ability to exhibit lateral thinking and challenge default commonsense associations. SemEval 2024 Task 9, BRAINTEASER (Jiang et al., 2024b) comprises two subtasks, Sentence Puzzle and Word Puzzle, which require unconventional thinking to overcome commonsense "defaults" without violating hard constraints. An adversarial subset is included in both tasks, created by manually modifying original brain teasers without altering their underlying reasoning paths. In our initial series of experiments, our focus is on fine-tuning XLM-RoBERTa (Conneau et al., 2020) in three variations: once on the original training data, once alongside the BiRdQA dataset (Zhang and Wan, 2022), and once alongside the RiddleSense dataset (Lin et al., 2021). Additionally, we introduced an innovative approach involving the extension of each word in the BiRdQA dataset into a complete sentence. This method aims to enhance the contextual meaning of individual words during the training process for word puzzle (WP) riddles. To achieve this, we utilized ChatGPT-3.5 to expand each word into a comprehensive sentence, applying this transformation to all options within each riddle. Subsequently, our exploration extends to the application of RECONCILE (Round-table conference) (Chen et al., 2023), incorporating three substantial language models: GPT 3.5, Gemini, and the Mixtral-8x7B (Jiang et al., 2024a) Large Language Model (LLM), a pre-trained generative Sparse Mixture of Experts. Noteworthy is the superior performance of the Mixtral-8x7B model compared to Llama 2 70B across various benchmarks. In the third set of experiments, we assess the zero-shot performance of GPT-4 using the Copilot GUI. Our observations highlight a significant superiority of GPT-4 over alternative models and methods. Furthermore, our

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1038–1042

findings underscore the collaborative utilization of Large Language Models (LLMs) in a round-table format, showcasing substantial enhancements in overall performance. Evaluation metrics are based on two accuracy measures: Instance-based accuracy, treating each question (original/adversarial) as a distinct instance, and group-based accuracy, where each question and its associated adversarial instances form a group, and a system is awarded a score of 1 only if it correctly solves all questions within the group. Our submission to the evaluation phase comprised XLM-RoBERTa fine-tuned on the original training dataset and BiRdQA dataset. The resulting method ranked 25 out of 31 in sentence puzzles and 20 out of 23 in word puzzles. For a detailed implementation of our method, refer to our GitHub repository.

2 Background

The model's inputs consisted of the puzzle and its corresponding choices, provided as input to XLM-RoBERTa. For alternative methods, we employed a prompt, feeding both the puzzle and choices to the model. All puzzles were written in English. To enhance the training of XLM-RoBERTa, we augmented the primary training dataset with additional datasets, namely BiRdQA and RiddleSense. In the context of word puzzles, we further enriched each choice by transforming it into a complete sentence using ChatGPT. The output from all models and methods was expressed as a numerical representation, denoting the correct choice in a zero-based format.

3 System overview

3.1 Preprocessing

In the preprocessing stage, we employ the following steps for the XLM-RoBERTa model: Each choice is concatenated with the corresponding question and subsequently tokenized. In the case of the BiRdQA and RiddleSense datasets, each riddle initially contains 5 options. However, the standard format, based on data validation, necessitates 4 options. To handle this, we transform each riddle into two separate riddles. The approach involves first removing the correct answer from the set of 5 options, resulting in 4 shuffled options. We then create two new riddles from this set by selecting 3 options for each. Finally, we add the correct answer back to the list of labels for each of the new riddles. In an alternative approach, we endeavored to transform each word into a sentence for every option within the BiRdQA dataset. This strategy aimed to enhance the robustness of our model, facilitating a more comprehensive understanding of each option. The rationale behind this was rooted in the notion that comprehending a sentence is generally more straightforward than understanding an isolated word. To execute this transformation, we presented each option to ChatGPT-3.5 with the prompt: "What is the definition of "text"? Write in a sentence." This process generated an extensive file resembling a dictionary. Throughout our training procedure, instead of utilizing individual words, we incorporated the respective definitions created by ChatGPT into our model. For methods utilizing Large Language Models (LLMs), no specific preprocessing is applied. Instead, we use the data in the format of our prompt without any additional preprocessing steps.

Table 1: Values of hyperparameters

3.2 Dataset

To construct the dataset for the XLM-RoBERTa model, we store tokenized sentences for each choice, concatenated with the corresponding question, and include the corresponding label indicating the correct answer to the riddle. Additionally, we incorporate the BiRdQA dataset, designed for bilingual question answering on challenging riddles, and the RiddleSense dataset, alongside the original training dataset. The creation of new datasets from these sources is detailed in the preprocessing section. The original train and test datasets for sentence puzzles comprise 507 and 120 instances, respectively. For word puzzles, the train and test datasets consist of 396 and 96 instances, respectively. The original RiddleSense and BiRdQA datasets initially contain 3510 and 4093 instances, and after applying the transformations outlined in the preprocessing section, they expand to 7020 and 8186 instances, respectively.

DataSet	W_ori	W_sem	W_con	W_ori_sem	W_ori_sem_con	W_overall

Table 3: Results of Round-Table on sentence puzzle

3.3 Model

We opted for XLM-RoBERTa as our model for this problem due to its pre-training on 100 different languages, indicating a robust understanding of language. Our fine-tuning process involved updating all the model weights using gradient descent on datasets we created. The architecture includes a multiple-choice head with 4 choices over the XLM-RoBERTa model, and we apply Categorical Cross-Entropy loss. For implementing the RECONCILE method, we leverage GPT-3.5, Gemini, and the Mixtral-8x7B Large Language Model (LLM), with certain adaptations to the original method designed for binary classification. We modified it to suit multiple-choice questions and incorporated 4 rounds for our specific application. In each round, the model is prompted to think step by step (Zhou et al., 2023), generating the correct answer and providing a confidence level (0 to 100) along with a reasoning for the selected choice. The original authors suggested that 4 rounds are sufficient for convergence. The output of all models from the previous round serves as input for the next round, where the model evaluates its logical consistency. No fine-tuning is applied to this method. When utilizing GPT-4 with the Copilot interface, we prompt the model to think step by step and generate the correct option. The model provides the corresponding confidence level and a rationale for choosing that particular choice.

4 Experimental setup

We allocated 20% of the original dataset for our validation set, resulting in 80 samples for validation in the word puzzle (WP) domain and 102 samples for validation in the sentence puzzle (SP) domain. Notably, when incorporating additional datasets into our training data, we maintained consistency by retaining the original validation dataset throughout the training process. This decision was driven by the recognition that the supplementary data introduced distinct variations compared to the original training and testing data. Preserving the originality of the validation data aimed to uphold the quality and uniqueness of the final model.
For fine-tuning using XLM-RoBERTa, we utilized the Hugging Face platform and implemented a cosine annealing scheduler.

5 Results

Leveraging the BiRdQA and RiddleSense datasets led to enhancements across all the metrics utilized for evaluating our model, surpassing the performance observed with the original dataset.

The findings presented in table 3 and table

Round	Model	W_ori	W_sem	W_con	W_ori_sem	W_ori_sem_con	W_overall
Round 1	**ChatGPT**	0.375	0.313	0.438	0.219	0.125	0.375
	Gemini	**0.719**	0.594	**0.813**	0.500	**0.438**	**0.708**

Table 5: Comparison between copilot and XLM-RoBERTa results

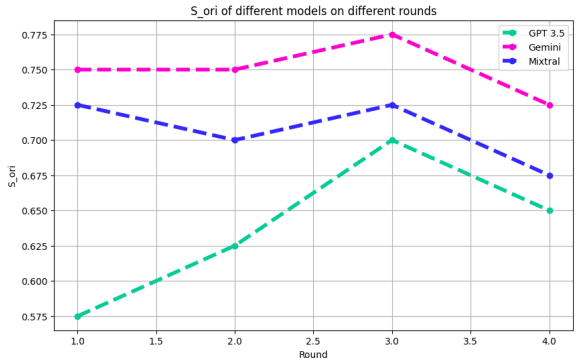

Figure 1: Visualization of Round-Table results for sentence puzzle

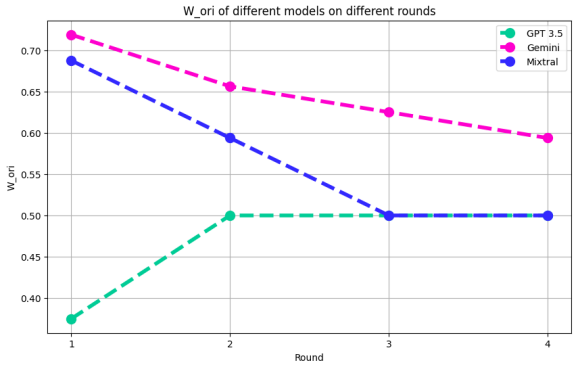

Figure 2: Visualization of Round-Table results for word puzzle

4 indicate that the incorporation of round-table discussions can enhance model performance in sentence puzzles, but conversely, it leads to a decrease in performance for word puzzles. This discrepancy may stem from the fact that, in solving sentence puzzles, some models can provide correct reasoning and influence others positively, whereas the complexity of reasoning in word puzzles may result in incorrect reasoning leading other models astray. Optimal results suggest that employing 3 rounds is most effective for sentence puzzles, while 1 round is preferable for word puzzles. Notably, Gemini consistently outperforms all other models across all rounds. Furthermore, this approach demonstrates its efficacy in boosting the performance of GPT 3.5 in both sentence and word puzzles.

GPT-4 consistently outperformed other models by a significant margin, demonstrating superior results across all metrics.

6 Conclusion

This study explores various methodologies for tackling SemEval 2024 Task 9: "BRAINTEASER: A Novel Task Defying Common Sense." To enhance our model's performance in word puzzles, we incorporate additional datasets for fine-tuning. Additionally, we introduce a modified round-table approach implemented over four rounds. We also evaluate the zero-shot performance of GPT-4 on this task,

Question	Options	BiRdQA	Orginal	RiddleSense	BiRdQA Word Extender	Correct
What kind of stock doesn't have shares?	Small-cap stock, Livestock, Growth stock, None of above	0	0	**1**	2	**1**
What kind of birds always make noise?	Humming bird, Hawk, Owl, None of above	**0**	2	2	1	**0**
What type of chase never involves running?	Escape chase, Paperchase, Risky chase, None of above	0	2	**1**	0	**1**
What kind of tree can you hold in your hands?	Oak, Pine, Palm, None of above	0	0	1	**2**	**2**
What species of geese engages in snake-fighting?	Canada goose, Snow goose, Mongoose, None of above	1	1	1	0	**2**

Table 6: Examples of predictions from different models

which demonstrates superior results across all metrics.

Abstract

Semantic Textual Relatedness holds significant relevance in Natural Language Processing, finding applications across various domains. Traditionally, approaches to STR have relied on knowledge-based and statistical methods. However, with the emergence of Large Language Models, there has been a paradigm shift, ushering in new methodologies. In this paper, we delve into the investigation of sentence-level STR within Track A (Supervised) by leveraging fine-tuning techniques on the RoBERTa transformer. Our study focuses on assessing the efficacy of this approach across different languages. Notably, our findings indicate promising advancements in STR performance, particularly in Latin languages. Specifically, our results demonstrate notable improvements in English, achieving a correlation of 0.82 and securing a commendable 19th rank. Similarly, in Spanish, we achieved a correlation of 0.67, securing the 15th position. However, our approach encounters challenges in languages like Arabic, where we observed a correlation of only 0.38, resulting in a 20th rank.

1 Introduction

STR delineates the meaningful association between linguistic units, showcasing conceptual proximity within a shared semantic frame (Taieb et al., 2019; Abdalla et al., 2021). For instance, "cup" and "coffee" are related in meaning, yet they are not synonymous (Jurafsky and Martin, 2009). Despite its crucial role in various NLP applications such as Spelling Correction, Word Sense Disambiguation, Plagiarism Detection, Opinion Mining, and Information Retrieval (Franco-Salvador et al., 2016; Chen et al., 2017; Taieb et al., 2019), STR has garnered less attention compared to Semantic Textual Similarity (STS) due to a scarcity of available datasets. Addressing this gap, Abdalla et al. (2021), and Ousidhoum et al. (2024a) contributed to the field by constructing the first sentence-level STR datasets. In this paper, we endeavor to tackle the STR problem within shared Task 1(Ousidhoum et al., 2024b), Track A, leveraging supervised data in English, Spanish, and Arabic languages provided by Ousidhoum et al. (2024a). Additionally, we briefly explore Track C and provide supplementary details in Appendix B as a secondary objective.

Building upon the findings of Abdalla et al. (2021), which underscore the superior performance of fine-tuning Transformer models in supervised tasks, our proposed system captures the relationship among sentences by fine-tuning the RoBERTa Transformer (Liu et al., 2019). At the core of our system, we employ a pre-trained RoBERTa model as a regression model and fine-tune it to generate a floating-point value for the input text. During the pre-training process of RoBERTa, the emphasis is placed on tasks related to NLU. This involves exposing the model to a diverse range of linguistic contexts and training it to comprehend the nuances of language. Furthermore, the integration of a Classifier Head enables sentence classification, a pivotal aspect of our system architecture elaborated upon in section 3.

Our experimental results showcase promising performance on English and Spanish datasets, achieving respective correlation rates of 0.82 and 0.67 on test data, surpassing the baseline correlation set by SemEval-2024 at Subtask A (Ousidhoum et al., 2024b). However, the model's performance on Arabic data falls short, yielding only a 38% correlation on development data. We attribute this discrepancy to differences in the underlying RoBERTa model and its training methodology across Latin and non-Latin languages, a topic further explored in section 5. To promote reproducibility and facilitate future research endeavors,

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1043–1052

the complete codebase of our project has been shared on GitHub[1].

2 Background

2.1 Dataset Overview

The SemEval-2024 Task 1 is structured into Tracks A, B, and C, each tailored to specific methodologies and objectives. Our focus lies on Track A (Supervised), which utilizes labeled data to train STR systems. The datasets for Task 1 encompass training, development, and test sets across 14 languages, each comprising sentence pairs (Ousidhoum et al., 2024a). Each sentence pair is annotated with a semantic relatedness score, ranging from 0 (indicating no relatedness) to 1 (suggesting strong relatedness). Participants are tasked with predicting the degree of semantic relatedness between sentence pairs, crucial for furthering research in NLP.

2.2 Related Work

The exploration of sentence-level STR has been hindered by the scarcity of available datasets (Abdalla et al., 2021). Existing datasets, such as those compiled by Finkelstein et al. (2002), Gurevych (2006), Panchenko et al. (2016), and Asaadi et al. (2019), predominantly focus on unigram and bigram STR. However, the seminal works of Abdalla et al. (2021), and Ousidhoum et al. (2024a) paved the way for further research by constructing the first sentence-level STR datasets. Traditionally, both STR and STS have been approached using knowledge-based and statistical methods (Sadr, 2020; Chandrasekaran and Mago, 2020). Notable efforts include the application of knowledge bases such as thesauri, ontologies, and dictionaries for STR, as surveyed by Salloum et al. (2020). Statistical methods, on the other hand, leverage features extracted from corpora, with prominent examples including Latent Dirichlet Allocation (LDA) by Blei et al. (2009) and Latent Semantic Analysis (LSA) by Landauer and Dumais (2008) for topic modeling.

In recent years, the application of deep learning methodologies has surpassed traditional approaches in STS tasks. Noteworthy advancements include the Tree-LSTM model proposed by Tai et al. (2015), which outperformed other neural network models in SemEval-2014. He and Lin (2016) introduced a hybrid architecture of Bi-LSTM and CNN, outperforming the Tree-LSTM model on the SICK dataset. Wang et al. (2016) achieved state-of-the-art results using the Word2Vec embeddings model in both the QASent and the WikiQA datasets, while Shao (2017) leveraged GloVe embeddings to achieve the third rank in SemEval-2017.

Several studies have demonstrated that fine-tuning transformer-based models achieves state-of-the-art in comprehending the semantics of textual data. The transformer model, first introduced by Vaswani et al. (2017), employs attention mechanisms to capture word semantics. Later on, Devlin et al. (2019) utilized it to create BERT word embeddings. Subsequently, XLNet, proposed by Yang et al. (2019), surpassed BERT in performance. Consequently, Lan et al. (2019) introduced ALBERT, which outperforms previous models. Additional transformer-based variations of BERT models include TinyBERT (Jiao et al., 2020), RoBERTa (Liu et al., 2019), and DistilBERT (Sanh et al., 2019). Also, Raffel et al. (2019) presented five distinct versions of the T5 transformer model, each varying in parameter size. Their work demonstrated that the performance of these pretrained models improves with larger datasets and enhanced computational resources.

Laskar et al. (2020) addressed sentence similarity modeling within an answer selection task. Through experiments conducted, they showed that fine-tuning RoBERTa model achieves state-of-the-art performance across datasets. Yang et al. (2020) showcased that the RoBERTa-based model achieved superior performance compared to the BERT and XLNET models in a clinical STS task, achieving a Pearson Correlation of 0.90. Similarly, Huang et al. (2021) conducted a comparison of TF-IDF combined with various models including ALBERT, BERT, and RoBERTa for word similarity detection in sentence pairs within Task 2 of SemEval-2021. Their experimental findings substantiated that RoBERTa yielded superior results by 0.846 on the test data. Nasib (2023) addressed reference validation task by employing BERT, SBERT, and RoBERTa. His study illustrated the efficacy of fine-tuning a RoBERTa-based model for text classification tasks, achieving state-of-the-art performance across multiple benchmark datasets. He emphasized that optimizing the model's performance involves activ-

[1] https://github.com/Sharif-SLPL/Sharif-STR

ities such as hyperparameter tuning, regularization, and data augmentation.

Abdalla et al. (2021) conducted an extensive investigation into semantic sentence representation methods, revealing that supervised methods utilizing contextual embeddings, particularly those fine-tuning BERT or RoBERTa, outperform other techniques, reaching a correlation of 0.83. Building upon these findings, we adopt fine-tuning RoBERTa as the primary strategy in this paper. Subsequent sections will detail our system architecture.

3 System Overview

In this section, we present a comprehensive overview of our system's architecture, outlining the key algorithms and modeling decisions that underpin our model.

3.1 Core Algorithms and System Architecture

Our system harnesses the Transformer architecture for its ability to capture long-range dependencies. At its core, we harness the power of a pre-trained RoBERTa model (Liu et al., 2019) for regression analysis, tailoring its parameters to accurately predict a floating-point value from the input text. While RoBERTa isn't explicitly trained for sentence relatedness scoring, its training encompasses an understanding of the relatedness of sentences within discourse, rendering it suitable for our task.

During the pre-training process of RoBERTa, the emphasis is placed on tasks related to NLU. This involves exposing the model to a diverse range of linguistic contexts and training it to comprehend the nuances of language. Our word embeddings utilize an embedding matrix with a dimensionality of 768. Position embeddings and token type embeddings further contribute to the model's comprehension of sequential and contextual information within the input data.

The RobertaEncoder comprises a stack of 12 identical RobertaLayers, each employing a multi-head self-attention mechanism. This mechanism enables the model to concurrently absorb different parts of the input sequence, showing promise in analyzing similarities between various inputs. Following the attention mechanism are intermediate sub-layers and output sub-layers. The intermediate sub-layer employs a fully connected feed-forward network with a GELU activation function, while the output sub-layer is responsible for proper transformation and normalization of features.

The classification head, positioned after the encoder, is tasked with generating the final output for sequence classification. It consists of a linear layer with 768 input features, followed by a dropout layer to prevent over-fitting. An additional linear layer featuring a solitary output neuron enables binary classification. By viewing the problem as a regression task, the classifier yields a linear output designed for a singular class, producing a probabilistic value indicative of the relatedness between input sentences.

3.2 Resources

For training our model, we relied on the dataset provided for SemEval-2024 Task 1 (Ousidhoum et al., 2024a). In addition to the primary dataset, we augmented our training dataset using the T5 model (Raffel et al., 2019). By leveraging T5's paraphrasing capabilities, we explored data augmentation techniques for Track A on the training sets of our dataset but failed to achieve consistent results across experiments. While some experiments showed an increase in model accuracy, in other cases, it did not alter the results. Data augmentation consistently worked well only on the English dataset. More details about data augmentation results and our secondary investigation on Track C are provided in Appendix A and B.

By incorporating both the SemEval-2024 Task 1 dataset (Ousidhoum et al., 2024a) and augmented training data generated by T5, our approach benefits from a comprehensive and diverse set of resources, enabling robust training and evaluation of our STR model across multiple languages and textual domains.

3.3 System Challenges

Augmenting the dataset for training set using T5 paraphrases posed several challenges. Firstly, while the primary dataset was labeled through collaborative human judgment, the augmented data lacked this human validation. This absence of human labeling for the augmented data may potentially impact its quality. Moreover, the augmentation process introduced alterations to the diversity of the data, presenting a challenge to maintaining the original data variety.

The decision to employ data augmentation exclusively for testing purposes raises concerns re-

garding its potential impact on model quality. Addressing these challenges associated with data augmentation is crucial for improving the efficacy of our model. Exploring solutions to mitigate these issues can enhance our approach to tackling the task at hand.

4 Experimental Setup

4.1 Dataset

The dataset statistics utilized for each language are presented in Table 1:

As shown in Table 1, approximately 0.8 of the Task 1 dataset is allocated for system training, while the remainder is reserved for evaluation. The limited availability of training data necessitates cautious consideration during testing, as the model's performance may be influenced by the scarcity of training instances. Additionally, the entire development set is utilized for model selection.

4.2 Pre-processing and Hyper-Parameter Tuning

A crucial aspect of our pre-processing involves converting the labels (scores) of each data instance to float values, ensuring compatibility with the model's expected input format. Furthermore, the input texts undergo tokenization using the RoBERTa-tokenizer both during training and inference.

Hyperparameter tuning plays a pivotal role in optimizing model performance. Our tuning process encompasses exploring various hyper-parameters, including learning rates in the range of [0.00001, 0.00003], dropout rates ranging from [0.1, 0.3], batch sizes spanning [4, 32], and token sizes from [32, 128]. Through iterative experimentation, we determined that a learning rate of 0.00003, a dropout rate of 0.1, a token size of 128, a batch size of 16, and a weight decay of 0.01 yield optimal results across all languages.

The selection of an appropriate token size is not solely based on computational considerations; rather, it is informed by dataset analysis. Upon examination, it became evident that the majority of data instances are predominantly short, aligning with our token size choice. Additionally, truncation during tokenization supports the chosen token size, ensuring efficient model training without sacrificing data representativeness.

4.2.1 Mean Squared Error (MSE)

Mean Squared Error quantifies the average of the squared differences between predicted and actual values. It is calculated using the formula:

$$MSE = \frac{1}{N}\sum_{i=1}^{N}(y_i - \hat{y}_i)^2 \quad (1)$$

Where N is the number of instances, y_i is the true label, and $\hat{y}_i$ is the predicted value.Additionally, Mean Absolute Error computes the average absolute differences between predicted and actual values.Moreover, the R-squared score assesses the proportion of variance in the dependent variable explained by the independent variable.

These evaluation measures collectively shed light on our regression model's performance in predicting the degree of relatedness between text samples. Using these metrics together enables the monitoring of the model's performance and, hence, facilitates decisions on hyper-parameters, model selection, etc. The evaluation method and hyper-parameter choices remain consistent across all models and languages. For the analysis of results presented in Section 5, the obtained scores were discretized and categorized into five distinct ranges to enhance visual understanding.

5 Results

5.1 Findings

A direct comparison with previous models and datasets similar to this task is challenging due to our specific focus on fine-tuning the RoBERTa model and utilizing the dataset provided by Ousidhoum et al. (2024a). Drawing from the insights of Raffel et al. (2019) working on the STS dataset, it is evident that the performance of transformer models improves with larger training corpora and enhanced computational resources. Raffel et al. (2019) demonstrated that the RoBERTa transformer-based model achieved a Pearson correlation of 0.922, surpassing ERNIE 2.0, DistilBERT, and TinyBERT on STS dataset benchmarks. Conversely, ALBERT, XLNet, and T5-11B outperformed RoBERTa on the same task, achieving a Pearson correlation of 0.925. Therefore, we recommend conducting a benchmark study of top-performing transformer models like RoBERTa, ALBERT, XLNet, and T5-11B in future research endeavors. Using the official metric of Spearman Correlation proposed in SemEval-2024 Task 1 (Ousidhoum et al., 2024b), our system achieves the following scores on different data splits and languages:

As shown in Table 2, Firstly, comparing the performance between English, Spanish, and Arabic

Language/Split	Dataset	Train	Testset	Devset
English	5752	4400	1101	251
Spanish	1702	1249	313	140
Arabic	1360	1009	252	97

Table 1: Dataset Statistics

Language/Split	Devset	Testset(Competition)
English	0.83	0.82
Spanish	0.71	0.67
Arabic	0.32	0.38

Table 2: Correlation Metric Scores

models, we observe varying degrees of success. The English model demonstrates the highest Spearman Correlation scores, both on the development and test sets, with scores of 0.83 and 0.82, respectively. This indicates that the English model performs relatively well in capturing the semantic relatedness between text pairs. Similarly, the Spanish model also achieves respectable scores, albeit slightly lower, with scores of 0.71 on the development set and 0.67 on the test set. However, the Arabic model lags significantly behind, exhibiting notably lower scores of 0.32 on the development set and 0.38 on the test set.

The disparity in performance between the Arabic model and the English and Spanish models could be attributed to several factors. One possible explanation is the availability and quality of training data. The Arabic dataset may suffer from a scarcity of labeled instances, resulting in a less robust model. Additionally, linguistic and structural differences between Arabic and Latin languages may pose challenges for the model in accurately capturing semantic relatedness. This discrepancy underscores the importance of adequately addressing language-specific characteristics and challenges in model development.

Furthermore, the analysis of the Arabic model's performance on the test set reveals a noteworthy observation. Despite achieving a relatively low Spearman Correlation score, the model appears to disproportionately classify most inputs as highly related. This discrepancy suggests a potential limitation in the model's ability to discern varying degrees of relatedness accurately. It implies that while the model may perform adequately in certain aspects, such as overall correlation with human annotations, it may struggle with nuanced interpretations of relatedness levels in real-world scenarios. The output of the model is provided in Appendix D.

The scatter plots depicted in Figure 1, respectively for English, Spanish, and Arabic, illustrate the correlation between the model predictions and human annotations. The English model closely aligns with human annotations, while the Spanish model exhibits an even closer alignment on certain inputs. However, the Arabic model's performance varies, indicating discrepancies between predicted and actual relatedness scores. These findings underscore the importance of dataset size and linguistic nuances in model performance across different languages. Further investigation is warranted to elucidate the factors influencing model behavior and to improve performance, particularly in languages with limited training data.

5.2 Error Analysis

While confusion matrices are less commonly utilized in regression problems, discretizing the model's scores allows us to glean insights into its performance. Confusion matrix plots for English, Spanish, and Arabic are provided in Figure 2, respectively. Upon examining the confusion matrix of the English dataset, it becomes apparent that the model performs well within certain score ranges. However, there are notable areas, particularly within the highly related range (0.6-1.0), where our model could benefit from improvement.

A similar observation holds true for the Spanish dataset, where the model demonstrates proficiency in predicting less related sentences but encounters challenges with highly related ones. Conversely, the Arabic dataset presents a markedly different scenario. While the majority of predictions fall within the mid-range of relatedness, they are predominantly incorrect.

Based on the histogram and extracted statistics from the fine-tuning data in Figure 3 in Appendix C, it appears that the majority of the training data has a distribution centered around the median (Spanish

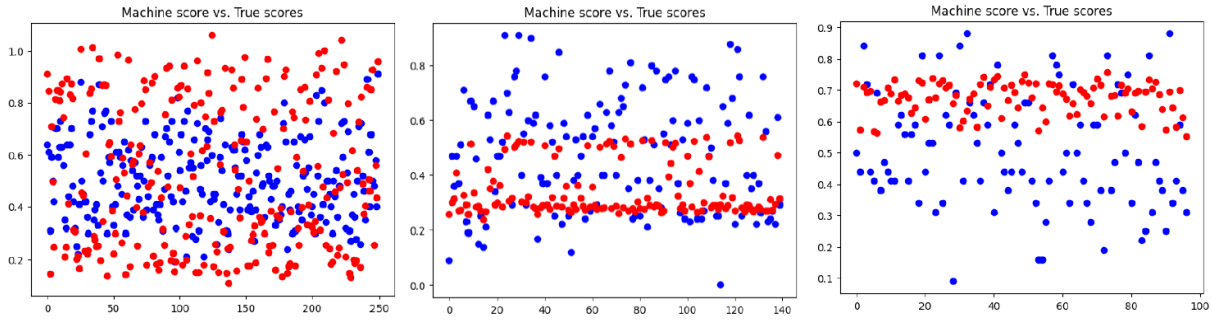

Figure 1: Scatter Plots of English, Arabic and Spanish Languages

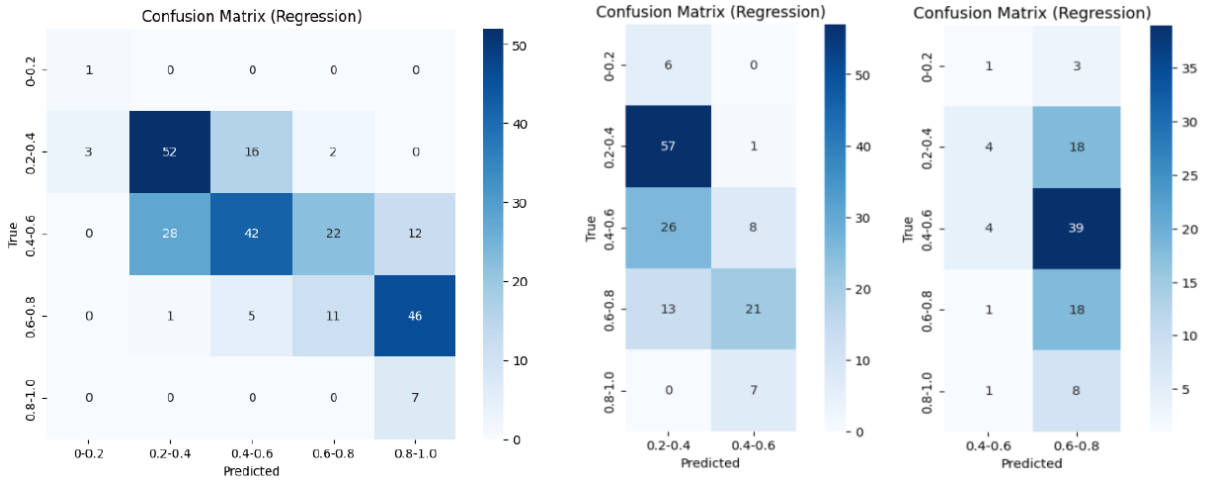

Figure 2: The Confusion Matrix Plot of English, Arabic and Spanish Languages

Mean Score: 0.43, Arabic Mean Score: 0.50). Consequently, finte-tuned Arabic and Spanish models seem to have less capability in understanding data on both ends of the spectrum.

These insights highlight the model's strengths and weaknesses across different datasets and underscore the need for further investigation into improving performance, particularly in accurately predicting highly related sentences across all languages. Further exploration of the factors contributing to model errors, such as dataset characteristics and linguistic nuances, is essential for refining the model's predictive capabilities.

6 Conclusion

In our investigation, we focused on fine-tuning RoBERTa for STR, primarily targeting Latin languages like English(0.82) and Spanish(0.67). While our approach showed promising results for these languages, particularly in achieving high correlation, the outlook was less favorable for Arabic(0.38). This echoes discussions in previous works, emphasizing the significant influence of the data on model performance. Our exploration into Track C, which is given in Appendix B, further enriched our understanding of the challenges and opportunities in STR system development. As a contribution to the field, we put forth several recommendations for enhancing STR systems. Firstly, we propose the development of additional Transformer models trained on diverse language families, focusing on languages that share similarities with Latin languages. Furthermore, a comprehensive benchmark of models on the STR dataset is essential, building on previous research that highlights the strong performance of models like ALBERT, XLNet, and T5-11B on the STS dataset. Moreover, the utilization of translation techniques and data augmentation methods could enhance model performance, particularly for languages with limited training data. In conclusion, our study sheds light on the nuances of STR system development and underscores the importance of considering language-specific factors and domain characteristics. By pursuing the avenues outlined in this paper, we aim to contribute to the advancement of STR research and facilitate the development of more robust and accurate models for NLU tasks.

Acknowledgments

We express our gratitude to the Speech and Language Processing Laboratory at Sharif University of Technology[2] for offering us the opportunity for collaborative work.

A Data Augmentation Results

As we describe data augmentation in section 3.2, we use T5 model to augment some training data and use them in training of model.So in this section we show results of data augmentation effect on Pearson Correlation for English language in Table 3.

Model hyper parameters		without data augmentation	with data augmentation
Learning rate	3e-5	0.79	0.81
Max length	128		
Batch size	16		
Epoch	4		

Table 3: Data Augmentation Affect on Pearson Correlation

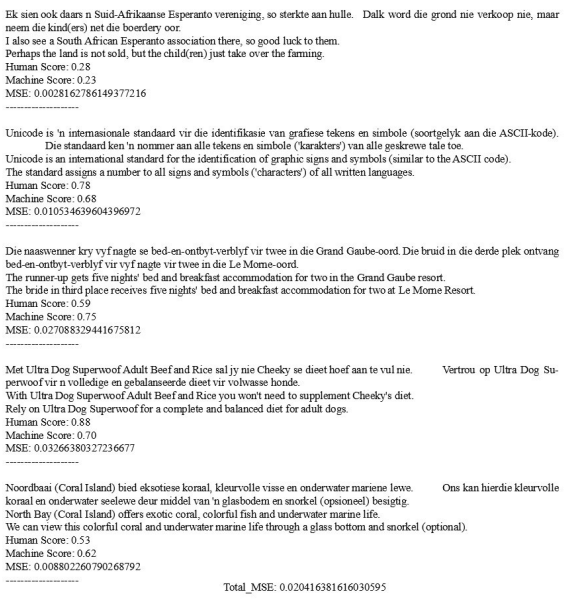

Figure 3: Output of Afrikaans

B Track C - Cross-Lingual

Using the translation method in Track C, we employed our Track A model trained on English language. The input sentences were first translated into English using the Google Translate API, followed by the utilization of the trained Track A model. The evaluation results demonstrate promising performance across some languages with this approach. However, errors might arise from either the Google Translate API or the model itself. Exploring alternative translation APIs could potentially enhance the overall performance. Figures 3, 4, and 5 display the outputs in Afrikaans, Amharic, and Modern Standard Arabic. Additionally, the high-quality output images are provided in our GitHub project.

Abstract

Text-generative models have proven to be good reasoners. Although reasoning abilities are mostly observed in larger language models, a number of strategies try to transfer this skill to smaller language models. This paper presents our approach to SemEval 2024 Task-5: The Legal Argument Reasoning Task in Civil Procedure. This shared task aims to develop a system that efficiently handles a multiple-choice question-answering task in the context of the US civil procedure domain. The dataset provides a human-generated rationale for each answer. Given the complexity of legal issues, this task certainly challenges the reasoning abilities of LLMs and AI systems in general. Our work explores fine-tuning an LLM as a correct/incorrect answer classifier. In this context, we are making use of multi-task learning to incorporate the rationales into the fine-tuning process.

1 Introduction

In recent years, Large Language Models (LLM) development has witnessed unprecedented advancements, with Large Language Models such as GPT-3 demonstrating remarkable capabilities in understanding and generating human-like text. However, the effectiveness of these models in reasoning tasks remains an area of ongoing exploration and enhancement. While LLMs excel in linguistic fluency and context understanding, their capacity for reasoning often falls short of human-level comprehension (Huang and Chang, 2022).

In this paper, we describe the DUTh participation in *SemEval 2024 Task 5: The Legal Argument Reasoning Task in Civil Procedure* (Bongard et al., 2022)[1], on leveraging the reasoning capabilities of Large Language Models for multiple-choice question-answering in the context of US civil procedure. The task can be formulated as follows: *given an introduction to a case, a question, and a candidate answer, classify if the given answer is correct or wrong*. The dataset is based on *The Glannon Guide To Civil Procedure* by Joseph Glannons (Glannon, 2023). The multiple-choice questions come from the book's exercises, which aim to test the reader.

The training set has a size of 666 entries, which is smaller compared to other similar datasets aiming to examine the capabilities of LLMs using human-generated rationales (Hancock et al., 2019). Although the complexity of legal domain text and the number of details engulfed in real legal cases are large. The cognitive skills required to understand and handle legal cases make this task an interesting challenge for LLMs' reasoning abilities.

Our proposed system is a LegalBERT (Chalkidis et al., 2020) classifier, fine-tuned on a downstream task incorporating rationales for each answer. Our code implementation builds on the organizers' and is publicly available.[2] Additionally, we experimented with a multi-task Flan-T5 model. This strategy involves a different way to use rationales in the training process. The model is trained to predict the correct labels and, at the same time, generate relevant rationales. Its performance is evaluated through a custom loss function that accounts for the loss of the label prediction task and the loss of the rationale generation task separately. Although it did not surpass the performance of the LegalBERT classifier, it is an interesting approach that can be further examined on the current task.

2 Background

2.1 Related Work

Large Language Models have demonstrated remarkable few-shot capabilities (Smith et al., 2022; Zhang et al., 2022). This models, having more than 100 billion parameters, prove to be difficult to be

[1] https://codalab.lisn.upsaclay.fr/competitions/14817

[2] https://github.com/DataMas/SemEval2024-Task5

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1053–1057

deployed for regular real-world applications. For this reason, a lot of effort is being made toward leveraging the reasoning capabilities of smaller language models.

Knowledge distillation is a fine-tuning strategy aiming to transfer knowledge from larger and more complex models into smaller and more practical models. The larger teacher model acts on a dataset to predict its labels, and then the smaller student model is trained on these generated labels. In fact, distillation can be performed on unlabeled or limited labeled data (Abbasi et al., 2021; Fu et al., 2023).

Based on this idea, rationales can also be used to supervise the fine-tuning process of a smaller model. Human-generated rationales have been used as auxiliary inputs to improve the model's performance (Fatema Rajani et al., 2019). Another approach involves using these rationales as labels in order to make a model generate similar explanations for its predictions(Eisenstein et al., 2022). Learning from LLM-generated rationales is a relatively new field of experimentation. Larger Language Models can explain their predictions by generating reasoning steps (Kojima et al., 2022). This reasoning steps can be used in the same way as human-generated rationales to improve the performance of smaller models (Pruthi et al., 2022).

Taking the previous ideas one step further, (Hsieh et al., 2023) proposed a multi-task fine-tuning framework. They essentially train a model on two separate tasks at the same time. The model is trained to not only predict the correct labels but also to generate accurate rationales explaining its predictions. They extract rationales from LLMs using Chain-of-Thought prompting. With their multi-task training, they are able to fine-tune smaller language models, which perform comparable to or better than larger models. They achieve not only to reduce the size of the final models but also the size of the needed data.

2.2 Dataset

The organizers provide a dataset from the US legal domain in English. It is essentially a multiple-choice question-answer dataset. It contains questions and possible answers regarding topics of US civil procedure. Every question concerns a legal case. Along with each question, a paragraph serving as a general introduction to the case is provided. Every possible answer is accompanied by an analysis of why its context is relevant to the case. Additionally, for every batch of possible answers corresponding to a question, a paragraph with general comments discussing all answers' rationales is given.

The training and development sets are compiled of all the features discussed above (introduction, question, answer, analysis, and explanation), while the test set excludes the features giving reasoning behind every answer. The train, development, and test sets consist of 666, 84, and 98 entries, respectively. Following, we can see the structure of the dataset clearly. The items without bold annotations are not included in the test set.

- **"introduction":** A paragraph regarding the context of the question.
- **"question":** The question regarding a legal case.
- **"answer":** A possible answer to the question.
- **"label":** A binary indicator for correct and wrong answer.
- "analysis": Reasoning on why each answer is right or wrong.
- "explanation": A paragraph discusing the reasoning of all possible answers to a question.

2.3 Evaluation Measures

Submissions are evaluated by two metrics:

- F1 score: The F1 score is defined as the harmonic mean of precision and recall, offering a single metric to asses a classifier's performance by considering both false positives and false negatives.
- Accuracy: Accuracy score is a measure used to evaluate the performance of a classification model. It is defined as the ratio of correctly predicted observations to the total observations.

Finally, participants are ranked based on the F1 score of their system.

3 System Overview

3.1 Data Pre-processing

Pre-trained Large Language Models are constrained by the maximum length of text input they can process. This limitation arises from the model's fixed-sized input layer, which can only accommodate a certain number of tokens (e.g., words or sub-words). We want to use the *introduction* and

analysis as context for the *question* and *answer* accordingly. This makes the final input exceed its token limit. The models we have used for our experiments have a limit of 512 tokens. Combining the *introduction, question, analysis* and *answer* creates input instances of length greater than 700 words on average.

In order to fit the constructed input instances, we have employed a sliding window mechanism. We use the same Sliding Window Complex (SWC) strategy proposed by the organizers (Bongard et al., 2022)[3]. This sliding window algorithm splits the inputs into chunks of specified length L, which is smaller than the limit length. In order for everything to fit, some features must be sliced. The specific details on how the features are sliced will be described later in the System architecture and Multi-task learning sub-sections. For example, one approach is to concatenate *explanation* and *answer* by keeping the whole *answer* to every chunk and pad the explanation until the limit of words is reached.

3.2 System Architecture

For our system, we utilize Legal-BERT to classify every chunk as wrong or correct. We also evaluated BERT (Devlin et al., 2018) and DistilBERT (Sanh et al., 2019), but they proved inferior. We fine-tune each model with constructed input instances. These instances are compiled by the *question*, *introduction*, *answer*, and *analysis*. The way these features are concatenated to form an input is to keep the whole *question*, *analysis*, and *answer*. The rest of the available space is filled with a part of the *introduction*.

Before the *question*, we add the distinctive feature *Q:*, while we also do the same thing before the *answer* with the distinctive feature *A:*. This way, we are making it clear to the model when a question and an answer begin. We have experimented with the learning rate and weight decay and used Optuna on the best performing model for hyperparameter optimization. Finally, training was terminated with early-stopping, with patience being set to 10.

3.3 Multi-task Learning

Based on the idea of *Distilling-step-by-step* (Hsieh et al., 2023)[4], we implement a similar system where we use the *analysis* feature provided in the dataset as rationale. During the training process, the model is trained to both predict the correct label and, at the same time, generate a comprehensive rationale for every input instance. This is done through the use of a custom loss function that accounts for the label prediction error and the rationale generation error.

$$L = (1 - w)L_{\text{label}} + wL_{\text{rationale}}$$

Adding the rationale generation loss to the training process helps the model better understand the logic behind why every answer is correct or wrong. The loss function is weighted with a factor w. Through w, we can control which task the model should focus on more during training. Choosing a $w = 0.5$ means that the model will try equally to learn both tasks. For values $w < 0.5$ the model places more importance on learning to predict labels correctly, and for values $w > 0.5$ the model is more focused on learning to generate accurate rationales.

We use the sliding window to create the input instances. These consist of an *introduction*, a *question*, and an *answer*. The distinctive features *Q:* and *A:* are also used here in the same way as described in the previous paragraph. In order to fit every instance into the limit of input tokens, every chunk has the complete *question* and *answer* and is padded with part of the *introduction*. In order to help the model distinguish between the two tasks, every instance is padded with another distinctive feature. For the label prediction task, we use the feature *Predict:* at the beginning of the instance. For the rationale generation task, we use the feature *Explain:*. This is done on our custom data collator function[5] and the result is two separate datasets.

In order to train the model in a multi-task manner, we created a custom trainer function. In this function, the model is prompted separately with the two task-specific datasets coming from the data collator. The answers of the model are evaluated, and the loss is computed through the custom function we described earlier. Finally, we define the prediction step of the model to produce answers for both tasks.

For this strategy, we utilize the small version of the Flan-T5 model (Chung et al., 2022). Because the model is trained to generate rationales, it must receive the labels as text. We transformed the labels of 0 to *Wrong* and the labels of 1 to *Correct*. Consequently, when the model is prompted to predict the

[3] github.com/trusthlt/legal-argument-reasoning-task
[4] github.com/google-research/distilling-step-by-step
[5] huggingface.co/docs/transformers/main_classes

labels of new data, it will respond with *Correct* or *Wrong*. For this reason, we have to convert the text responses to 1–0 accordingly in order to evaluate them and submit our results.

The final multi-task trained system receives a dataset and first preprocesses it. It concatenates the *introduction*, *question*, and *answer* and converts the labels to *Correct* - *Wrong* text. The model is prompted with the instances, and its responses are converted into 1–0.

Pre-trained model	F1-score	Accuracy
LegalBERT	0.5382	0.6837
BERT	0.5081	0.7245
DistilBERT	0.4269	0.7245
LegalBERT*	0.4827	0.7245
Multi-task Flan-T5	0.5324	0.6224

Table 1: Best performance of each model. *This is the score the best-performing model achieved during the evaluation phase. All the other scores have been achieved during the post-evaluation phase and are not counted for the leaderboard.

4 Experimental Setup

4.1 Chain of Thought

Before creating embeddings, we tried to fine-tune the models using a Chain of Thought strategy. During the sliding window process, we used auxiliary phrases to make the final input make more sense to the model. For example, we used the phrase *Based on the following* before adding the part of the *introduction*. After the *introduction* and before the question, we added the phrase *Answer the following question*. For the answer-analysis part, we used the phrases *The following answer* followed by the answer and *is correct/wrong because* followed by the analysis.

Although a widely used and promising technique, CoT did not prove to increase the performance of our models. At least based on the phrases and the arrangement we used. The task prefixes *Predict* and *Explain* that we used for the multi-task system can also be considered as a CoT approach. On this occasion, they were efficient in guiding the model to distinguish between the two tasks.

4.2 Experiments

Our experiments are mainly focused on fine-tuning different models under different hyperparameters. The hyperparameters we experimented on were the learning rate and the weight decay. We We came up with the best set of hyperparameters through optimization using the Optuna hyperparameter optimization framework. [6] In the first set of experiments regarding fine-tuning on a downstream classification task, we evaluated three pre-trained models: BERT, LegalBERT, and DistilBERT. The best-performing model proved to be the LegalBERT. For the second set of experiments regarding multi-task fine-tuning, we utilized the small version of the Flan-T5 model. The same hyperparameter optimization procedure was followed. We also experimented with the parameter w which controls the amount of focus on each task. A weight $w = 0.5$ proved to be slightly better.

5 Results

The comprehensive scores of our systems across the utilised models are presented on Table 1. The highest F1 score was 0.5324 achieved by LegalBERT, followed closely by the multi-task T5. According to accuracy, BERT and DistilBERT perform better with a score of 0.7245, and LegalBERT comes in second with 0.6837. LegalBERT . Although our models do not perform well, we can make some assumptions on why that is.

Firstly, regarding LegalBERT, it is possible that simply adding the rationale to the input along with the *introduction*, *question* and *answer* will not helping the model learn the logic behind justifying each answer. In fact, it makes the model perform worse compared to setups where only *introduction*, *question* and *answer* is used (Bongard et al., 2022). Additionally, our multi-task system, although incorporating a more complex training mechanism, it does not seem to be able to distinguish answers efficiently. The small version of Flan T5 is only of 80 million parameters. At this scale, it might be difficult for language models to grasp complex concepts laying on rationales. This, in fact, can be confirmed by prompting the multi-task model to generate rationales based on the input. The generated rationales barely makes any sense.

6 Conclusion

Through our experiments, we could not find a significantly performing system. Even the multi-task approach, which makes good use of the rationales to better establish a connection between input and

[6] https://github.com/optuna/optuna

label, could not perform well. But we demonstrated the possible limitations and difficulties of such tasks, where logical reasoning is needed in order for a model to perform well.

The primary benefit of multi-task learning lies in the use of rationales, enabling the model to perceive the reasons behind the correctness or incorrectness of every answer. In this work, our capabilities were constrained by hardware limitations, leading us to experiment with a smaller Language Model. However, this model's capacity to comprehend longer content is limited by its size.

Next steps could involve experimentation with bigger Language Models regarding the multi-task approach. We believe that a larger model could better grasp the context of the rationales and draw better associations between a question and possible answers. Another approach regarding the multi-task strategy is to incorporate rationales through a more efficient loss function. Another weighing strategy could be used, for example.

Abstract

In the intersection of language understanding and numerical reasoning, a formidable challenge arises in natural language processing (NLP). Our study delves into the realm of NumEval, focusing on numeral-aware language understanding and generation using the QP, QQA and QNLI datasets[1]. We harness the potential of the Orca2 model, Fine-tuning it in both normal and Chain-of-Thought modes with prompt tuning to enhance accuracy. Despite initial conjectures, our findings reveal intriguing disparities in model performance. While standard training methodologies yield commendable accuracy rates. The core contribution of this work lies in its elucidation of the intricate interplay between dataset sequencing and model performance. We expected to achieve a general model with the Fine Tuning model on the QP and QNLI datasets respectively, which has good accuracy in all three datasets. However, this goal was not achieved, and in order to achieve this goal, we introduce our structure 1.

1 Introduction

In the realm of natural language understanding (NLU), the quest for models capable of comprehending and reasoning with textual data has been a longstanding pursuit. The NumEval task, focusing on Numeral-Aware Language Understanding and Generation, stands at the frontier of this endeavor, challenging researchers to develop models adept at grasping numerical information embedded within linguistic contexts. In this study, we delve into the intricacies of fine-tuning methodologies and their impact on the performance of language models, particularly focusing on the QP, QQA and QNLI datasets. (num)

The primary challenge in NLU lies in imbuing models with the ability to interpret and reason with textual information akin to human cognition. Traditional approaches often face hurdles in capturing the nuances of language, especially when numerical data intertwines with linguistic expressions. One possible cause of this problem is that numerals can have various notations, some of which are difficult to understand from their subwords. While models like Orca2 (Mitra et al., 2023), an instance of Large Language Models (LLMs), exhibit remarkable capabilities, their performance nuances in understanding numeral-aware contexts warrant deeper exploration.

The QP, QQA and QNLI datasets(Chen et al., 2023a), (Chen et al., 2019), (Ravichander et al., 2019), (Mishra et al., 2022) serve as test for evaluating the efficacy of language models in understanding questions, question-answering and natural language inference, respectively. These datasets present a diverse array of linguistic challenges, including numeral-aware reasoning, prompting the need for sophisticated training strategies.

Our study uses the Orca2 model, an advanced LLM known for its language comprehension skills. Through meticulous fine-tuning and evaluation on the QP, QQA and QNLI datasets.

We aim to catalyze discourse and innovation in the field of NLU, steering towards more robust and nuanced language models capable of navigating the complexities of numeral-aware language understanding and generation in real-world scenarios.

However, the road to achieving robust language understanding is fraught with challenges, chief among them being the inherent ambiguity and variability present in natural language. Numerical information adds an additional layer of complexity, requiring models to not only parse linguistic constructs but also interpret and reason with numerical data embedded within textual contexts.

Conventional training methodologies, while effective to a certain extent, often fall short in encapsulating the intricate interplay between linguistic semantics and numerical reasoning. The advent of large-scale language models has undoubtedly propelled the field forward, but their performance on numeral-aware tasks remains an area ripe for exploration and refinement.

After conducting several experiments, we have determined that fine-tuning a model for a specific subtask yields significantly higher accuracy compared to fine-tuning a model across all subtasks. Our attempt to fine-tune a generalized model across all subtasks while maintaining accuracy proved unsuccessful. Upon reviewing the results, we recognized the effectiveness of the Orca 2 model utilizing the LORA method for each subtask. Consequently, we trained the model using QLORA, resulting in improved accuracy. To establish a robust framework for addressing a range of reasoning

subtasks, we propose a structured approach that employs an agent as a supervisor capable of categorizing subtasks. This agent determines which of our fine-tuned models should address each task.

2 Related Work

The intersection of Numerical Evaluation (NumEval) and Natural Language Processing (NLP) has witnessed a surge in research endeavors aimed at refining models' numerical comprehension and processing capabilities. Within this burgeoning field, a multitude of studies have delved into diverse methodologies and frameworks to deepen our understanding of numeracy in linguistic contexts.(Chen et al., 2023b)

A seminal study by (Chen et al., 2021) introduced the utilization of digit-based encoders to represent numerals, laying the groundwork for subsequent investigations into numerical representation methods. Expanding upon this, (Zhang et al., 2020) pioneered the exploration of scientific notation for numerical representation, shedding light on the efficacy of alternative numerical formats in quantitative skill tasks. These methodologies not only deepen our understanding of numerals' linguistic representation but also pave the way for novel approaches in numerical evaluation tasks.

Pretraining tasks have played a pivotal role in enhancing language models' capabilities in comprehending numerical language. (Devlin et al., 2019) revolutionized the field by introducing masked language model (MLM) and next sentence prediction (NSP) tasks, ushering in a new era of transformer-based NLP research. Building upon this foundation, (Yasunaga et al., 2022) proposed the document relation prediction (DRP) task, specifically designed to bolster models' performance in multi-hop reasoning and multi-document understanding tasks. These pretraining paradigms have significantly enriched models' numerical understanding capabilities, underscoring the pivotal role of pretraining in enhancing NLP models' numerical acumen.

In parallel, pre-finetuning strategies have emerged as a promising avenue for enhancing models' numerical comprehension. The Comparative Numbers Dataset (CND), introduced as a pre-finetuning resource, has garnered attention for its efficacy in enhancing models' numerical reasoning abilities. Experimental investigations leveraging BERT, RoBERTa, LinkBERT and FinBERT (Araci, 2019) have demonstrated notable improvements in models' performance across various numerical evaluation tasks, underscoring the potential of pre-finetuning methodologies in augmenting models' numerical understanding.(Chen et al., 2023b)

Generally, the landscape of NumEval research is characterized by a dynamic interplay of numerical representation methods, pretraining tasks and pre-finetuning strategies, each contributing to the advancement of language models' proficiency in numerical understanding and processing.(Chen et al., 2023b)

The results of our tests are very promising in this field and on the tested datasets, the accuracy is higher than the accuracy of the reference article.

3 Approach

Through our exploration with the Fine Tuning model, we discovered commendable accuracy in each sub-task individually. Upon scrutinizing the test outcomes, a noteworthy observation emerged: encoding numerical values within the text as statement-char significantly boosts accuracy in the QNLI task. However, a pertinent challenge persists: determining the appropriate agent for input assignment.

To address this challenge, we devised a framework. Initially, the input undergoes classification by an agent, ensuring its allocation to the most suitable model. In the case of the QNLI task, we preprocess words into statement-char format before directing them to the designated agent.

Furthermore, leveraging the Orca model's remarkable 100% accuracy in the QQA task, we opted to employ the base model as our agent. This strategic decision underscores our commitment to optimizing task performance and model efficacy.

3.1 Baseline Model:

The Orca2 model, a variant of the large language model (LLM), served as the cornerstone of our experiments. Built upon state-of-the-art architecture, Orca2 harnesses the power of deep neural networks to comprehend and generate human-like text responses. Leveraging its pre-trained weights, we fine-tuned Orca2 on the task-specific datasets to imbue it with numeral-aware capabilities.

3.2 Training Modes:

- Baseline Model Training: Initially, we evaluated the performance of the Orca2 model on each dataset section without any specific fine-tuning. This provided us with a baseline accuracy metric for comparison with subsequent experiments.

- Normal Fine Tuning: In this mode, we fine-tuned the Orca2 model on the respective datasets using conventional prompt tuning techniques. The model was trained to understand numeral-rich contexts and generated responses accordingly.

- Chain-of-Thoughts tuning Method: As an extension of traditional fine-tuning, we explored the Chain-of-Thoughts tuning method to train Orca2. This approach encourages the model to retain contextual information across sequential examples, enhancing its ability to grasp complex numeral-related nuances.

4 Experiments

4.1 Data

The four Used datasets (QP, QQA, QNLI [2] and AWPNLI [3]), are all related to natural language processing tasks and have been widely used in research and benchmarking for various NLP models, particularly those based on deep learning.

These datasets are often utilized to evaluate the performance of NLP models, particularly those designed for tasks like question answering, paraphrase detection and natural language inference. They provide standardized benchmarks for assessing the capabilities of different models and techniques in handling these tasks effectively.

4.2 Evaluation method

In evaluating the performance of the NumEval model across the QP, QQA and QNLI datasets, we employ a series of evaluation metrics tailored to the specific characteristics of each dataset and the different training modes applied to the Orca2 model.

4.2.1 Evaluation metrics:

Accuracy, F1-score and Recall serves as the primary evaluation metric across all experiments conducted on the QP, QQA, QNLI and AWPNLI datasets. It represents the proportion of correctly classified instances over the total number of instances in the datasets.

4.2.2 Experimental Modes:

Three experimental modes are considered in the evaluation:

- Basic Orca2 model without any fine-tuning.
- Orca2 model fine-tuned.
- Orca2 model fine-tuned using the Chain-of-Thought method.
- Sequential fine-tuning of Orca2 model using QP and QNLI datasets

Cross-dataset generalization is evaluated by training the Orca2 model on one dataset and subsequently fine-tuning it on another dataset to assess the model's ability to transfer knowledge across domains.

[3] https://drive.google.com/file/d/10JNRN6iI5u9ZbEJPUEq4LAksBPW3vzGG/view?usp=sharing

By employing these evaluation methods, we aim to comprehensively assess the effectiveness of the NumEval framework in numeral-aware language understanding and generation tasks across diverse datasets and training modes.

4.3 Experimental details

In our study, we conducted experiments utilizing the NumEval framework, focusing on the QP, QQA and QNLI datasets to assess the performance of the Orca2 model. Below, we outline the experimental details for each dataset and the various modes of training and testing conducted.

4.4 Results

In this section, we present the quantitative results obtained from our experiments across the QP, QNLI and QQA datasets. We compare our results against baselines established by various models, including BERT, CN-BERT, LinkBERT, CN-LinkBERT, RoBERTa and CN-RoBERTa, each evaluated on different data modes: original, Digit-based and ScientificNotation.

In table 1 presents the powers claimed in the article.

In the following, we present the quantitative results of our experiments conducted on the QP, QQA and QNLI datasets using the Orca2 model in various training modes including normal Fine tuning and Chain-of-Thoughts tuning in table 2. Additionally, we discuss the implications of these results in relation to our initial hypotheses and the effectiveness of our approach.

In a series of experiments, the model was Fine Tuned and tested on QNLI dataset which has scientific numbers or numbers that the decimal part is removed by multiplying by a large number with multiples of 10 units.

The quantitative results of our experiments reveal several noteworthy findings. Firstly, in the QP dataset experiments, we observed a substantial improvement in accuracy from the baseline when employing both Normal Fine-tuning and Chain-of-Thoughts tuning methods. Notably, the Chain-of-Thoughts tuning approach yielded the highest accuracy at 97.25%, demonstrating the effectiveness of sequential reasoning in improving model performance.

In contrast, the experiments conducted on the QNLI dataset showed similar trends, with both normal Fine Tuning and Chain-of-Thoughts tuning methods outperforming the baseline accuracy. The Chain-of-Thoughts tuning method again exhibited superior performance, underscoring its efficacy in capturing nuanced relationships within the data.
