Introduction

The Semantic Evaluation (SemEval) workshops focus on the evaluation and comparison of systems that analyze diverse semantic phenomena in text, with the aim of extending the current state of the art in semantic analysis and creating high quality annotated datasets in a range of increasingly challenging problems in natural language semantics. SemEval provides an exciting forum for researchers to propose challenging research problems in semantics and to build systems/techniques to address such research problems.

SemEval-2024 is the eighteenth workshop in the series of International Workshops on Semantic Evaluation. The workshop began in 1998 and was originally known as SensEval and focused on word sense disambiguation.
In 2007, the workshop was renamed SemEval, and evolved to include semantic tasks beyond word sense disambiguation. Starting in 2012, SemEval has been organized every year. The tasks for the next iteration of the workshop, SemEval-2025 (https://semeval.github.io/SemEval2025/), are underway.

SemEval-2024 is co-located (hybrid) with the 2024 Annual Conference of the North American Chapter of the Association for Computational Linguistics (NAACL 2024). SemEval-2024 will be held in Mexico City, Mexico and it includes the following 10 tasks:

- Semantic Relations
  - Task 1: Semantic Textual Relatedness for African and Asian Languages
  - Task 2: Safe Biomedical Natural Language Inference for Clinical Trials
- Discourse and Argumentation
  - Task 3: The Competition of Multimodal Emotion Cause Analysis in Conversations
  - Task 4: Multilingual Detection of Persuasion Techniques in Memes
  - Task 5: Argument Reasoning in Civil Procedure
- LLM Capabilities
  - Task 6: SHROOM, a Shared-task on Hallucinations and Related Observable Overgeneration Mistakes
  - Task 7: NumEval: Numeral-Aware Language Understanding and Generation
  - Task 8: Multidomain, Multimodel and Multilingual Machine-Generated Text Detection
- Knowledge Representation and Reasoning
  - Task 9: BRAINTEASER: A Novel Task Defying Common Sense
  - Task 10: Emotion Discovery and Reasoning its Flip in Conversation

This volume contains both the task description papers (10), that describe each of the above tasks, and the system description papers (279) that present the systems that participated in the tasks.
In addition, SemEval-2024 features two awards, one for the organizers of a task and one for a team participating in a task. The Best Task award recognizes a task that stands out for making an important intellectual contribution to empirical computational semantics, as demonstrated by a creative, interesting, and scientifically rigorous dataset and evaluation design, and a well-written task overview paper. The three Best System Description Paper awards recognize a system description paper (written by a team participating in one of the tasks) that advances our understanding of a problem and available solutions with respect to a task. It does not need to be the highest scoring system in the task, but it should have a strong analysis component in the evaluation, as well as a clear and reproducible description of the problem, algorithms, and methodology.

We are grateful to the task organizers for their dedication in carrying out ten very successful tasks and to the large number of participants whose enthusiastic participation has made SemEval 2024 a successful event. We also appreciate the efforts of the task organizers and participants who reviewed the paper submissions. These proceedings have greatly benefited from their detailed and thoughtful feedback. Finally, we also thank the members of the program committee who reviewed the submitted task proposals and helped us to select this exciting set of tasks, the NAACL 2024 conference organizers for their support, and the ACL Special Interest Group on the Lexicon (SIGLEX) for sponsoring and supporting this event.

Keynote Talk: Beyond Single Scores: Transparent Evaluation through Fine-Grained Error Detection and Uncertainty Quantification

André F. T. Martins
Instituto Superior Tecnico, Senior Researcher at the Instituto de Telecomunicacoes, and VP of AI Research at Unbabel in Lisbon, Portugal

Abstract: Automatic evaluation metrics are key to drive progress in NLP. We use them to compare systems and decide which models to deploy, to understand the strengths and weaknesses of each model, and to help practitioners overcome existing failure modes. In this talk, I will discuss evaluation of machine translation quality. Today, lexical-based metrics (such as BLEU or ChrF) are being replaced by learned neural-based metrics, such as COMET and BLEURT, which exhibit much better correlation with human judgments. However, these metrics provide a single sentence-level score, offering little insight into translation errors (e.g., what are the errors and what is their severity). Can we do better? I will start by presenting xCOMET, an open-source learned metric which integrates both sentence-level evaluation and error span detection capabilities, exhibiting state-of-the-art performance across all types of evaluation (sentence-level, system-level, and error span detection). Moreover, it does so while highlighting and categorizing error spans, thus enriching the quality assessment. Then, I will discuss recent approaches that endow evaluation metrics with uncertainty quantification capabilities, using techniques such as Monte Carlo dropout, deep ensembles, heteroscedastic regression, quantile regression, and conformal prediction. Finally, I will present Tower, an open multilingual LLM for translation-related tasks. We perform continued pretraining on a multilingual mixture of monolingual and parallel data, creating TowerBase, followed by finetuning on instructions relevant for translation processes, creating TowerInstruct. The final model surpasses open alternatives on several tasks relevant to translation workflows and is competitive with general-purpose closed LLMs. To facilitate future research, we release the Tower models, our specialization dataset, an evaluation framework for LLMs focusing on the translation ecosystem, and a collection of model generations, including ours, on our benchmark.

Bio: André F. T. Martins is an Associate Professor at Instituto Superior Técnico, Senior Researcher at the Instituto de Telecomunicações, and VP of AI Research at Unbabel in Lisbon, Portugal. I also do scientific consulting for Priberam Labs. I work on natural language processing and machine learning.

Until 2012, André was a PhD student in the joint CMU-Portugal program in Language Technologies, at Carnegie Mellon University and Instituto Superior Técnico. His advisors were Mario Figueiredo, Noah Smith, Pedro Aguiar and Eric Xing.

Program

Thursday, June 20, 2024

09:10 - 09:25 *Welcome and Introduction to SemEval*

09:30 - 10:30 *Invited Talk 1, Shared with *SEM*

10:30 - 11:00 *Coffee Break*

11:00 - 12:30 *Oral Session-I*

SemEval Task 1: Semantic Textual Relatedness for African and Asian Languages
Nedjma Ousidhoum, Shamsuddeen Hassan Muhammad, Mohamed Abdalla, Idris Abdulmumin, Ibrahim Said Ahmad, Sanchit Ahuja, Alham Fikri Aji, Vladimir Araujo, Meriem Beloucif and Christine De Kock

SemEval-2024 Task 2: Safe Biomedical Natural Language Inference for Clinical Trials
Mael Jullien, Marco Valentino and André Freitas

SemEval-2024 Task 3: Multimodal Emotion Cause Analysis in Conversations
Fanfan Wang, Heqing Ma, Rui Xia, Jianfei Yu and Erik Cambria

SemEval-2024 Task 4: Multilingual Detection of Persuasion Techniques in Memes
Dimitar Dimitrov, Firoj Alam, Maram Hasanain, Abul Hasnat, Fabrizio Silvestri, Preslav Nakov and Giovanni Da San Martino

SemEval-2024 Task 5: Argument Reasoning in Civil Procedure
Lena Held and Ivan Habernal

SemEval-2024 Task 6: SHROOM, a Shared-task on Hallucinations and Related Observable Overgeneration Mistakes
Timothee Mickus, Elaine Zosa, Raul Vazquez, Teemu Vahtola, Jörg Tiedemann, Vincent Segonne, Alessandro Raganato and Marianna Apidianaki

12:30 - 14:00 *Lunch*

14:00 - 15:00 *Oral Session-II*

SemEval-2024 Task 7: Numeral-Aware Language Understanding and Generation
Chung-chi Chen, Jian-tao Huang, Hen-hsen Huang, Hiroya Takamura and Hsin-hsi Chen

Thursday, June 20, 2024 (continued)

SemEval-2024 Task 8: Multidomain, Multimodel and Multilingual Machine-Generated Text Detection
Yuxia Wang, Jonibek Mansurov, Petar Ivanov, Jinyan Su, Artem Shelmanov, Akim Tsvigun, Osama Mohammed Afzal, Tarek Mahmoud, Giovanni Puccetti and Thomas Arnold

SemEval-2024 Task 9: BRAINTEASER: A Novel Task Defying Common Sense
Yifan Jiang, Filip Ilievski and Kaixin Ma

SemEval 2024 - Task 10: Emotion Discovery and Reasoning its Flip in Conversation (EDiReF)
Shivani Kumar, Md. Shad Akhtar, Erik Cambria and Tanmoy Chakraborty

15:00 - 15:30 *Best System Paper's Presentations*

15:30 - 16:00 *Coffee Break*

16:00 - 17:30 *Poster Session I: System Description Papers (local and online)*

Friday, June 21, 2024

09:30 - 10:30 *Invited Talk: Beyond Single Scores: Transparent Evaluation through Fine-Grained Error Detection and Uncertainty Quantification (André F. T. Martins)*

10:30 - 11:00 *Coffee Break*

11:00 - 12:30 *Poster Session II: System Description Papers (online)*

12:30 - 14:00 *Lunch*

14:00 - 15:30 *Poster Session III: System Description Papers (in presence)*

15:30 - 16:00 *Coffee Break*

16:00 - 16:45 *Best Paper Awards and Concluding Remarks*

CUNLP at SemEval-2024 Task 8: Classify Human and AI Generated Text

Aggarwal Pranjal, Sachdeva Deepanshu

University of Colorado Boulder

(pranjal.aggarwal, deepanshu.sachdeva)@colorado.edu

Abstract

This task is a sub-part of SemEval-2024 competition which aims to classify AI vs Human Generated Text. In this paper we have experimented on an approach to automatically classify an artificially generated text and a human written text. With the advent of generative models like GPT-3.5 and GPT-4 it has become increasingly necessary to classify between the two texts due to various applications like detecting plagiarism and in tasks like fake news detection that can heavily impact real world problems, for instance stock manipulation through AI generated news articles. To achieve this, we start by using some basic models like Logistic Regression and move our way up to more complex models like transformers and GPTs for classification. This is a binary classification task where the label 1 represents AI generated text and 0 represents human generated text. The dataset was given in JSON style format which was converted to comma separated file (CSV) for better processing using the pandas library in Python as CSV files provides more readability than JSON format files. Approaches like Bagging Classifier and Voting classifier were also used.

1 Introduction

We perform Subtask A of the Task 8 [1] from the International Workshop on Semantic Evaluation: SemEval 2024[†] which stated - *Multidomain, Multimodal and Multilingual Machine-Generated Text Detection*. In this subtask we perform Monolingual (English in this case) classification for AI generated vs Human written texts.

This Binary classification task has utmost utility in real world scenarios like - content moderation on social media platforms, fake news detection that can impact organizations financially and people emotionally, detecting spam messages in email or communication channels like Slack.

Another application can be used in healthcare chatbots to make sure that a person is talking to a person as this kind of task needs human speciality. Product reviews classification - i.e., detecting whether an organization has human written reviews, or they had them generated through AI to rank their product higher up in the chain.

To perform this task, we use a series of techniques including manual feature engineering for supervised learning techniques like logistic regression and Bagging Classifier as well as more complex techniques like Neural Networks and attention mechanism with transformers. We used supervised learning as well like K-Nearest Neighbours. The best approach found was a combination of transformers [2] with hand engineered features like Coherence [3] of a text, Complexity, length and emoji count. The accuracy and performance of these experiments are discussed in the later sections.

In our experiments we found that some features were very influential like length of a text, vocabulary used in the text and coherence of a text. Other features like complexity of the text had less weightage and were thus, not used in all experiments. Even though transformers gave us the best accuracy we also used some other approaches that were competitive as well.

We also had some limitations in the usage of computing resources where one of our approaches that combines TF-IDF vector along with transformers uses over 50 GB of RAM that exceeds the amount of any available computing resource available to us.

2 Background

Dataset - The dataset that was used was provided by SemEval that is an extension of the M4 dataset [4]. which had approximately 133551 data points in the training set and the dev set contained 5000 samples. The dataset contained texts from various sources

[†] https://semeval.github.io/SemEval2024/tasks

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 1–6

including Wikipedia, Reddit, WikiHow, and PeerRead for English texts. The AI generated text was curated from Generative models like ChatGPT, Cohere, Dolly v-2 and Bloomz. After analysing the data, we found that the dev set data only included the data points from Bloomz and there were none of Bloomz model's generated texts in the training set. This was meant to test the real-life situation where a new generative model can come into picture when our model would not have seen that generative model's pattern.

An exploratory data analysis of the text, gave the following interesting observations:

1. The training set has a total vocabulary size of *2616365* in which there were around *328491* words that were only used by the AI generated texts..
2. The total number of unique words used by AI generated text was *581888* as compared to that used by Humans which was *2034477*. This data suggests that AI used a lot of repetitive words as compared to humans.
3. The average number of tokens used in a sentence generated by humans were - *283* as compared to AI which used only *155*.

Figure 1: AI Corpus Word Cloud

Key terms: Step, Part, Overall, S, One, Make

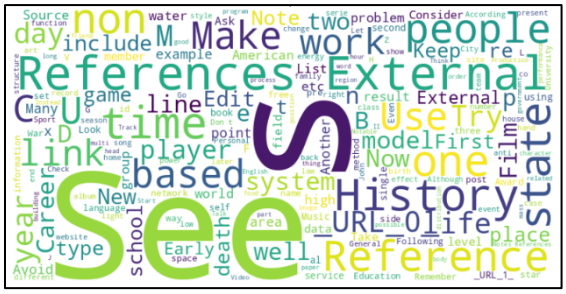

Figure 2: Human Corpus Word Cloud

Key terms: See, S, References, External, History

We also explored some aspects of sentence structure like coherence, complexity and length of the sentences. We used these features along with the TF-IDF vectors as an input to the Logistic Regression model, Bagging Classifier and K-Nearest Neighbours achieving a max training set accuracy score of *0.91* and *0.61* on dev set using Bagging Classifier. We also used a voting classifier which performed better, achieving an accuracy score of *0.68 on the dev set* using the above-mentioned models. Later we used transformers (BERT) with combination of the above-mentioned models in the Voting classifier. There were two more approaches where we tried topic modelling and feature repetition which yielded better results.

One thing to note here is that when a certain text is generated by AI it contains some sort of template or pattern around it. So, to use that we tried unsupervised learning to make possible clusters of the texts, to identify which class of template the text might belong to. This approach included the use of the K-means clustering method, which reported a dev set accuracy of 0.57

Heather et al. [5] mentions the use of simple machine learning techniques with great accuracy. Ahmed et al. [6] compared different methodologies and tools and how each of them perform on unseen data.

In any of the literature TF-IDF was not used along with any other features, and we experimented by including these features in our approach along with topic modelling setup that was novel.

3 System Overview

Text Classification even though an already accomplished task becomes challenging even for state-of-the-art models like Transformers. In this task the adaptability of GPT makes it even more challenging to differentiate between the two types of texts. Also, as AI progresses to understand human emotions [7] and behaviour it is expected from the model to generate texts i.e. convey its thought in a more human centric manner. We aim to tackle the same starting with the standard machine learning algorithms and then moving on to much more complex models like attention based transformer models, example - BERT [8], RoBERTa [9] among others.

We describe below in detail the specification used along with each approach and mention its accuracy and experimental setup.

For this task, we have used TF-IDF vectorization technique. Along with that we also analysed text structures and engineered 3 main features related to the task at hand. These were Complexity of the sentence, Coherence of a text and length of text (tokenization).

These features were used by the algorithms described below and are described in the next section in detail.

1. **Standard ML Algorithms with TF-IDF:** As this is a binary classification task, we start by using logistic regression. We used TF-IDF vectors as input to this. As discussed earlier, human text used a wide range of vocabulary with an average length of around 283 words, AI generated text used a smaller vocabulary set and the average sentence length was around 155 words. There were a lot of words that were not used in human Corpus (around 3.5 lakhs), so we used TF IDF Vector as the input to various machine learning models such as logistic regression, bagging classifier and unsupervised learning technique K-Nearest Neighbours.
2. **BERT:** BERT or Bidirectional Encoder Representations from Transformers uses an attention mechanism to capture the essential information for a given task. We used the BERT based uncased model as a baseline to compare the performance of our algorithms. Variations of BERT like RoBERTa, XLM-RoBERTa [10] were also used along with experimentation with our manually engineered features (with and without repetition) achieving a dev set accuracy of 0.66. Repetition of features is described in the experimental setup in more detail.
3. **Transformers with Features:** Features like Coherence and length of text were used in addition to the tokens that were passed in the transformer models. These were passed in the form of a list followed by tokens inputted into the transformers model. These features though could be imagined to be captured by the model itself but being complex features, it makes more sense to extract these features from the models specifically trained for this purpose. This helped us enhance the efficiency and performance of our models. Since these features were less in number, to increase their effect on the output, the features were repeated, and the repetition was treated as a hyperparameter, this value was randomly assigned in the range from 200 to 300.
4. **Transformers with TF-IDF and SVD:** Since TF-IDF is a feature that proves to be useful in trivial machine learning algorithms like logistic regression, we experimented to use it with much more complex models like state of the art - transformers. Since, using transformers itself is computationally expensive, along with TF-IDF the computational complexity increases exponentially, requiring over 50 GB of CPU memory to prepare the input tensor. Due to the lack of such computational resources, we relied on dimensionality reduction algorithms such as Singular Value Decomposition (SVD). After experimentation over 1 epoch, although requires more research, were appreciable.
5. **Topic Modelling with Transformers:** A common trait in a generative model is that the output follows from a particular prompt. That means that every text generated by the AI model can be segregated into a certain topic. So, we aim to use topic modelling as a feature to the input tensor while classifying AI and human generated text. As every human has a certain way of writing, similarly every AI model can be said to have a way of generating text. So here we approach this method by first using an unsupervised learning technique such as K-Means clustering that separates text into a certain number of clusters. This number again is a hyperparameter set to 100 in this experiment that can be set by the experimenter. After that, the output of this model i.e., the cluster number is fed into higher order models such as transformers to gain better results and an accuracy of 0.56 was achieved on the dev set.

4 Experimental Setup

Various experiments were performed on the given dataset. The train-test split for all the experiments was kept the same to the ratio of 80:20. This split comes from the training data itself and the dev set was kept unseen from the model during the training phase. The best results on the dev set after hyperparameter tuning are logged in the results section of the paper. In this section we discuss the following:

1. **Performance Metrics:** We used micro-F1 and macro-F1 scores as well as accuracy itself to measure the performance of the model across various algorithms. We also monitored precision and recall and observed lower recall rates across the models. This means that the algorithms are biased towards classifying the output as AI generated text. This recall was later used as a weightage in the voting classifier.
2. **Feature Engineering:** We used different features as input to models, like:
   a. Complexity of a Sentence: Using the 'textstat' module in python we calculated

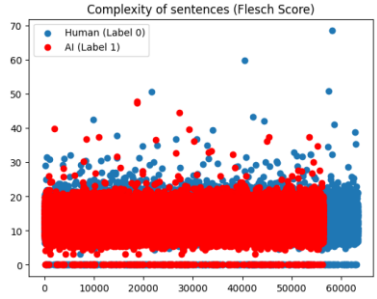

Figure 3: Complexity

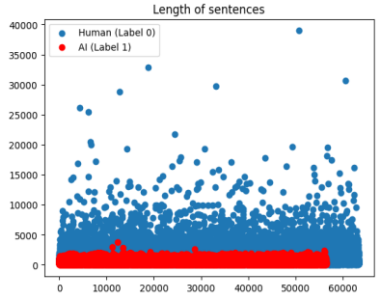

Figure 4: Length

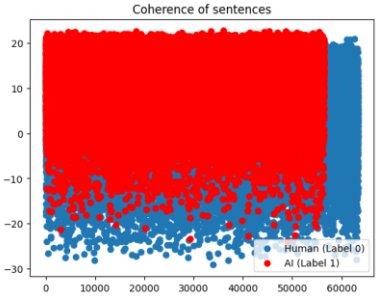

Figure 5: Coherence

the Flesch Score that indicates the readability of a sentence in the range of 0 to 100, with 0 being most confusing and 100 being very easy to understand.

b. Length of a Sentence: Observing the significant difference between the average length of text between AI generated text and Human Generated Text, we decided to use it as a feature to our ML algorithms. The average length of text in AI generated text was noted to be 155, however it was 283 for human generated text. The length of the sentence was calculated by first removing the stop words using the NLTK library, followed by lemmatization and then counting the number of tokens after the operation.

c. Coherence of Text: It is the measure of transitions in a text along with smoothness and logical flow. The coherence of text is an important feature, we observed that a human generated text was more coherent than AI generated. Coherence of the text was calculated using the SGNLP library in Python.

The comparison of AI generated text and human written text on the above features are shown in figures 3, 4, and 5, respectively. These features are referred as "sentence features" from now on in the paper.

3. **Loss Function:** The loss function used for logistic regression is the binary cross entropy loss. The same loss function has been used in Transformers as well.
4. **Optimizer:** Different optimization algorithms including Adam, AdaGrad and RMSProp were used during experimentation and the best performance was shown by Adam optimizer.
5. **Computational Resources:** Kaggle and Google Colab were used interchangeably for experimentation. However, since GPU was a requirement and the average time for experimentation for 1 epoch exceeded over 4 hours, multiple experiments were run on the Kaggle platform on a T4x2 GPU accelerator, this setup was exclusively used for transformers-based experiments. For experiments on machine learning algorithms, 12 GB CPU RAM was sufficient and hence Google Colab was used.
6. **Hyperparameter Tuning:** There were several hyper-parameters that required tuning over the course of this experiment, most of the hyper-parameter tuning was done in transformers with learning rate, weight decay, epochs and optimizer choice. Grid search was used to obtain the most optimal values of hyper-parameters. Other custom hyperparameters were also involved such as the number of repetition of features, d-dimensionality reduction in experimentation of TF-IDF with transformers and the number of topic models to be included as a feature in addition to transformers.

5 Results

We observed that the model combined with the attention mechanism of transformers with TF-IDF vectors provides is with the best results. However, it should be noted that the dimensionality of the vectors has been significantly reduced due to its computational complexity and thus is bound to affect the accuracy. The results mentioned in the below table (Table 1) are the optimal results obtained after repeated experimentation over different optimizers, epochs and weight decay rates. Some parameters have not been mentioned in the table, as the standard grid search can be reimplemented if there is a need for replication. As evident from the table, the best results were obtained when we used the XLM-RoBERTa model along with TF-IDF features and the sentence features (complexity, length and coherence).

Model	Accuracy	Epoch	Precision	F1
Logistic Regression	0.49	-	0.48	0.31
Bagging Classifier	0.57	-	0.55	0.42
Voting Classifier (LR, Bagging, KNN)	0.57	-	0.55	0.42
BERT (with Sentence Features)	0.72	1	0.94	0.71
RoBERTa (with Features)	0.77	2	0.96	0.73
XLM-RoBERTa (with TF-IDF and Sentence Features)	0.78	2	0.97	0.74

Table 1: Performance of different models

6 Conclusion

This Binary Classification task of predicting the mode of text generation is non-trivial in the aspect that as the generative models are largely trained on human generated text, they have learned to write more like humans and thus this becomes a challenging task. However, using proper means and computational methods, it is possible to segregate them using conventional feature extraction techniques combined with self-attention mechanism of transformers as seen in the experiments. We aim to use the topic modelling approach combined with TF-IDF and transformers further in the future that might yield promising results.

Abstract

In this system paper for SemEval-2024 Task 1 subtask A, we present our approach to evaluating the semantic relatedness of sentence pairs in nine languages. We use a mix of statistical methods combined with fine-tuned BERT transformer models for English and use the same model and machine-translated data for the other languages. This simplistic approach shows consistently reliable scores and achieves middle-of-the-pack ranks in most languages.

1 Introduction

SemEval 2024 Task 1 (Ousidhoum et al., 2024c) calls for assigning scores indicating semantic textual relatedness (STR) of sentence pairs in 14 different languages. We participate in Track A, which is the supervised subtask for systems that have been trained using the provided labeled datasets (Ousidhoum et al., 2024a). There are data in Algerian Arabic, Amharic, English, Hausa, Kinyarwanda, Marathi, Moroccan Arabic, Spanish, and Telugu for Track A and we provide a solution for all 9 languages. The labeled data has been manually annotated for relatedness using a comprehensive annotation framework (Abdalla et al., 2023).

A large portion of previous work in STR has been conducted for English-language data. This task does include English, but the focus is on lower-resourced languages (Hedderich et al., 2021; Marreddy et al., 2022). STR is a crucial component in information retrieval, summarization, and question answering, as well as in developing Large Language Models (LLMs). The lack of STR or similar NLP resources for low-resource languages means progress is often much slower in related research such as the development of LLMs too making the progress achieved through this task societally highly impactful by providing new tools and datasets for language where NLP resources are lacking (Vulić et al., 2020; Zhang et al., 2020).

Our methodology uses both traditional TF-IDF vectorization and transformer models like BERT (Devlin et al., 2018) fine-tuned for semantic relatedness tasks. We leverage the high availability of resources that exist for English to fine-tune a BERT model that we then use on machine-translated versions of the datasets for the other languages (except for Spanish where a multilingual BERT model yielded better results than with machine translating the data). This approach seems to capture both lexical patterns and deeper semantic relationships, making it effective for linguistically diverse datasets, and cost-effective because there is no need to manually annotate more than one dataset (language). It is therefore an alternative approach to creating language-specific models. Although our approach is simplistic, it has the upside of working reasonably well for any low-resource language that has some machine translation or parallel language data resources.

2 Background

In SemEval-2024 Task 1, the dataset was adapted from the STR-2022 dataset (Abdalla et al., 2023). The STR-2022 dataset contains 5,500 English sentence pairs that were manually annotated using a comparative annotation framework, yielding fine-grained scores ranging from 0 to 1 (maximally unrelated to maximally related). The dataset was constructed by sampling sentences from various sources to capture a wide range of text characteristics such as sentence structure, formality, and grammaticality. The sources include datasets on formality (Rao and Tetreault, 2018), book reviews (Wan and McAuley, 2018), paraphrases (Wieting and Gimpel, 2018), natural language inference (Bowman et al., 2015), semantic textual similarity (Cer et al., 2017), stance (Mohammad et al., 2016), and text simplification (Horn et al., 2014).

The corresponding datasets for the other languages are much smaller and consist of roughly

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 7–12

1000 sentence pairs each with minor variations in size.

Semantic **relatedness** and semantic **similarity** are closely related concepts in natural language processing (NLP), however, the terms are not interchangeable. Semantic similarity is a narrower definition that only takes term similarity into account (e.g. *fork* is similar to *knife*), whereas relatedness in addition to similarity can include terms or concepts that are related beyond hyponymic relationships such as *fork* being related to *eating*) (Asaadi et al., 2019; Batet and Sánchez, 2016). This task focuses on the broader concept of relatedness but utilizes more narrowly defined datasets based on similarity as well in the construction of the datasets.

In recent years the development of NLP resources for low-resource languages has been speeding up, but there are still large discrepancies in what types of tools, models, and resources exist for languages other than English (Hedderich et al., 2021). There are also significant differences in the resources available among low-resource languages and what being a low-resource language entails (Hämäläinen, 2021; Marreddy et al., 2022). For most of the languages in this task, there are at least some models and tools (see e.g Deode et al., 2023) but a handful of research groups working on a language is quite different from nearly all research groups in the world working on producing models and tools for a language (English). When there is a need for more data, often data augmentation methods are used to increase data points. Machine translation is an established method of data augmentation, particularly with low-resource languages where it might not be possible to use language-specific models (Amjad et al., 2020).

3 System overview

Our choice of methodology was shaped by pedagogical considerations as well as technical. As we participated in this task as part of an undergraduate senior research seminar in computational methods, we purposely started with the simplest most readily available tools progressing towards more advanced methods. Along the way, we compared the results and progress at each step in an attempt to better understand how each of the specific NLP tools worked and how accurate their output was when used on real projects such as this dataset.

The main strategy of our system is integrating classic NLP methods, such as the Dice Score and TF-IDF, with advanced deep learning techniques like BERT models, to determine semantic relatedness between sentence pairs. Firstly, our system imports a CSV dataset that contains pairs of English sentences (separated by "\n"), each paired with a relatedness score ranging from 0 to 1. Then, to assess semantic relatedness, the system adopts several basic NLP techniques, including Spacy's Linguistic Features for efficient text processing, TF-IDF for calculating word importance in sentences, Spacy Similarity and Cosine Similarity for measuring sentence similarity, and fine-tuned BERT Models for leveraging contextually rich semantic analysis (Devlin et al., 2018). These techniques collectively contribute to a robust evaluation of semantic relatedness against the given scores. We tried early on to adopt the same approach to the non-English languages with language-specific transformer-based similarity and relatedness models, but the language-specific models yielded much lower evaluation scores than what the English model achieved with machine-translated versions of the non-English datasets. We used the Google Translate API to translate the datasets into English to maintain consistency in analysis. Compared to other translation APIs such as DeepL, for this task, Google Translate seemed to produce better translations, perhaps because of how it favors more common words over context thus being more suited for STR and/or STS tasks (see e.g. Öhman, 2022).

Participating in the semantic relatedness task using the hybrid strategy allows for a comprehensive exploration of the system's performance and methodology. Through a detailed analysis, you can assess the effectiveness of traditional NLP methods, including TF-IDF and Spacy's Linguistic Features, in comparison to more advanced deep learning techniques like BERT. Evaluating the impact of contextual embeddings from fine-tuned BERT models provides insights into how well the model captures nuanced semantic relationships. The inclusion of Google Translate for non-English languages offers an opportunity to examine the system's ability to maintain consistency across languages. Assessing the generalization capability, scalability, and efficiency of the system provides a holistic understanding of its applicability to diverse datasets and real-world scenarios. Through this participation, we can uncover strengths, weaknesses, and potential areas for improvement, guiding future research directions and refining the hybrid strategy for en-

hanced semantic relatedness evaluation across languages and varied linguistic contexts. In particular, this approach shows that it is possible to achieve reasonable accuracies by leveraging the prevalence of tools and models designed for English with low-resource languages.

Our code is available on GitHub [1].

4 Experimental setup

At the beginning stage of the experiment, we undertook an examination of several readily implementable models on the English baseline dataset and compared the predicted scores with human-labeled scores through Pearson correlation scores.

In the initial English baseline model, we included the SpaCy similarity model[4], cosine vector similarity, and fine-tuned-BERT models[5]. For the SpaCy similarity, we directly applied it to the training dataset, yielding a result of 0.34 (Pearson). In the case of cosine similarity, we tried out two methods of word embedding:

1. **Binary occurrence vectors**: This approach involves creating set-based word vectors using binary occurrence, combining them into a joint space, and comparing them using cosine similarity to quantify the relatedness between the original sets in vectorized forms.

2. **TF-IDF transformer-based vectors**: Using the TF-IDF vectorizer from the sklearn (Pedregosa et al., 2011) library, we obtained TF-IDF weights for each word. The TF-IDF weight is proportional to the word's frequency in the document but is offset by its frequency in the corpus.

Upon comparing these two word-embedding methods, the Pearson correlation results did not reveal a significant difference. Therefore, we selected the Binary occurrence method as the cosine vector similarity, which achieved a score of 0.61 as indicated in Table 1. We use Pearson as opposed to Spearman rank correlation simply because that is what the original task description uses (Ousidhoum et al., 2024a,b).

The final component of the English baseline is the application of the fine-tuned BERT model to compute semantic relatedness with the (unfine-tuned) ClinicalBertSimilarity[5] and WebBertSimilarity[5] models and a batch size of 10 for both. The creators of the model claim that the "project contains an interface to fine-tuned, BERT-based semantic text similarity models. It modifies pytorch-transformers by abstracting away all the research benchmarking code for ease of real-world applicability"[5]. This proved to be the most successful approach with a result of 0.8 for English. Although the task in question is about semantic relatedness, since many of the datasets involved in the creation of the datasets come from similarity data. Additionally, as similarity can be considered a subtype of relatedness, the use of similarity models seemed logical due to their wider availability compared to relatedness models.

After establishing the English baseline, we evaluated several multilingual and language-specific BERT-based similarity models to assess textual relatedness (or similarity) across other language training datasets including the SBERT model for Telugu (Joshi et al., 2022), Sentence-BERT (Reimers and Gurevych, 2019), BioLORD-2023(Remy et al., 2023), etc. However, the results were suboptimal, which is surprising since previous work has shown that sentence transformers show significant improvements to semantic similarity tasks, particularly cross-lingual tasks (Hämmerl et al., 2023). Given the significantly better performance of the English baseline, we decided to translate all language datasets into English before applying the relatedness prediction models. In the case of Spanish we found that using distiluse-base-multilingual-cased-v1(Reimers and Gurevych, 2019) produced higher accuracies than the translation approach, and thus Spanish is the only language we did not translate to English.

When introducing the translation tools, we explored two approaches: utilizing a translation model (Machine Translation) and implementing Google Translate.

1. **Machine Translation**: In the Machine Translation method, we applied M2M100 (Fan et al., 2020) as the translation model. The model can directly translate between the 9,900 directions of 100 languages.

2. **Google Translate**: For the machine translations, we utilized the deep-translator library[6],

Table 1: Task scores for different methods

a versatile tool that facilitates simple language translation using multiple translators.

Despite the relatively high performance claimed by the M2M100 model as described by Fan et al. (2020), the results after the translation process are less than 0.5 for all languages except Spanish, where it achieved a result of 0.67. In contrast, the Google Translate API demonstrated better performance during the training process with the English baseline model (detailed results are listed in Table 1).

Our multilayered approach mirrors that of Jeyaraj and Kasthurirathna (2021) although ours is a much simpler setup.

5 Results

Our rankings show that our approach is nowhere near the state-of-the-art, but it is still a reliable option when more language-specific approaches are unavailable as is often the case with moderately low-resource languages. Out team ranked in the middle of the pack for most languages, but in the top third for English, Marathi, and Spanish, and the bottom for both Arabic dialects, which was expected. The rankings, scores, and models used for each submission can be seen in table 1. We analyze the results in the conclusions section.

6 Conclusions

To sum up, we first focused on English to have a good solution with fine-tuned BERT, and then we applied that solution to other languages by translating the sentences into English using machine translation. Since our English solution is reasonably good (rank 10/34, official score of .81), the application of the solution worked much better than using multilingual models in many languages including Amharic, Marathi, and Telugu for which there exist language-specific semantic similarity models. We speculate that the reason the *MT+English model* worked better than the language-specific relatedness models is due to the higher quality and more diverse training data for the English model(s) as well as machine translation simplifying words to the most commonly used ones, artificially making similar sentences more similar.

The importance of an accurate machine translation can be seen in the failure of our approach with the Arabic dialects in particular. Google Translate does not have specific translators for Moroccan or Algerian Arabic, instead, we had to rely on general Arabic. This likely produced much lower quality translations obfuscating the semantic links between the sentence pairs making it difficult for the English model to accurately judge relatedness. This issue was further exacerbated by the fact that no one on our team speaks any of the languages in the task besides English, which made manual evaluations of the MT output difficult.

Darja and Darija are the names for Algerian and Moroccan Arabic respectively, and they are collectively known as Maghrebi Arabic. Due to its roots in Berber languages, there are notable distinctions between Maghrebi Arabic and Standard Arabic, and using the latter for these two dialects may yield a suboptimal result.

Curiously, a similar issue occurred with Spanish. Spanish is much more closely related to English than the other languages in subtask A, and therefore we expected our approach to get a fairly high score similar to English, especially considering the current state of machine translation between English

[6] https://deep-translator.readthedocs.io/en/latest/README.html#id1

and Spanish. However, it seems that translation of Spanish into English affects the semantic relations of the original sentences, which might be one of the main reasons causing the very low scores and making us choose the multilingual model for Spanish rather than the machine-translated one.

We hypothesize that one of the reasons that Google Translate worked so well on the low-resource languages most dissimilar from English might be because smaller training datasets for MT would force the translation to use less context and instead increase the reliance on individual lexical items leading to sentence pairs with high relatedness becoming more similar via translation. For languages with better MT models, it is conceivable that the better translations work against this approach as it might make the sentence pairs less similar as reflected by the higher scores for Spanish using multilingual models, and the very low scores for both Arabic dialects. In future work, it might be worthwhile to use mixed methods starting with language-specific models and then expanding to incorporate machine translation and larger models developed for, e.g., English.

Abstract

This paper summarizes the participation of the L3i laboratory of La Rochelle University (L3i++) in *SemEval-2024 Task 8: Multigenerator, Multidomain, and Multilingual Black-Box Machine-Generated Text Detection*. In this task, we aim to solve two over three Subtasks: (1) Monolingual and Multilingual Binary Human-Written vs. Machine-Generated Text Classification; and (2) Multi-Way Machine-Generated Text Classification. We propose a comparative study among three groups of methods to trigger the detection: (1) Using metric-based models; (2) Using a fine-tuned sequence-labeling language model (LM); and (3) Using a fine-tuned large-scale language model (LLM). Our findings show that LLM surpassed the performance of traditional sequence-labeling LM as the benchmark and metric-based approaches. We ranked $5^{th}/62$ in Multilingual Binary Human-Written vs. Machine-Generated Text Classification and $6^{th}/70$ Multi-Way Machine-Generated Text Classification on the leaderboard. Our code is publicly available at https://github.com/honghanhh/semeval8.

1 Introduction

The rise of large language models (LLMs) has led to a significant step forward in producing remarkably controllable, fluent, and grammatical text, triggering a surge in machine-generated content across diverse platforms such as news, social media, question-answering forums, educational, and even academic contexts. Notably, recent LLMs like ChatGPT[1] and GPT-4 (OpenAI, 2023) exhibit a remarkable ability to generate coherent and contextually appropriate responses to a wide array of user queries.

Unfortunately, use and abuse come hand in hand. Although the fluency of these generated texts positions LLMs as potential candidates for replacing human labor in numerous applications, this has also raised concerns about their potential for misuse, particularly in spreading misinformation and causing disruptions within the education system. Given that humans struggle to distinguish between machine-generated and human-written text, it becomes imperative to develop automated systems capable of identifying machine-generated text to curb the risks associated with its misuse.

In this paper, as the participants in *SemEval-2024 Task 8: Multigenerator, Multidomain, and Multilingual Black-Box Machine-Generated Text Detection* (Wang et al., 2024), we investigate the feasibility of training a classifier that can reliably differentiate between text generated by humans and text that appears human-like but is generated by machines in two paradigms:

- Subtask A: Given a full text, determine whether it is human-written or machine-generated in monolingual (only English sources) and multilingual versions.
- Subtask B: Given a full text, determine who generated it (human-written or generated by a specific language model).

To address these problems, we explore the performance of diverse methodologies, which can be divided into three categories, including:

- Five different metric-based methods: Log-Likelihood, Rank, Log-Rank, Entropy, and DetectGPT (He et al., 2023).
- Two traditional sequence-labeling language models: monolingual RoBERTa$_{large}$[2] (Liu et al., 2019) and multilingual XLM-R$_{large}$[3] (Conneau et al., 2020).
- A large language model (LLM): $LLaMA-2-7b-hf$[4] (LLaMA-2) (Touvron et al., 2023).

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 13–21

This paper is organized as follows. We present related work in Section 2, followed by Section 3, where we introduce the data used to solve this challenge. Our proposed methods are described in Section 4 before we present our findings and an error analysis in Section 5. Finally, in Section 6 we present our conclusions, and future work and discuss the limitations of the proposed methods.

2 Related Work

The success of LLMs in various downstream NLP tasks (Perez et al., 2021; Vilar et al., 2022; Hegselmann et al., 2023) leads to the overuse and abuse of the information generated by LLMs. However, it is essential to acknowledge that the outputs generated by LLMs are not always accurate, giving rise to the issue of hallucination (Azamfirei et al., 2023). Consequently, there is a need for clear differentiation in addressing this concern.

To address these issues, researchers have developed several automatic detection methods (Badaskar et al., 2008; Zellers et al., 2019; Ippolito et al., 2020; Uchendu et al., 2021) that can identify the machine-generated text from the human-written text, which initially can be divided into two categories, i.e., metric-based methods and model-based methods.

2.1 Metric-based methods

Metric-based methods leverage pre-trained LLMs to process the text and extract distinguishable features from it, e.g., the rank or entropy of each word in a text conditioned on the previous context. Then, predicted distribution entropy determines whether a text belongs to machine-generated or human-written texts. Some metric-based detection methods include Log-Likelihood, Rank, Entropy, GLTR, Log-Rank, and DetectGPT (He et al., 2023), to cite a few.

2.2 Model-based methods

In the model-based methods (Zellers et al., 2019; Habibzadeh, 2023; Guo et al., 2023), the classification models are trained using a corpus that contains both machine-generated or human-written texts to make predictions, for example, ChatGPT Detector (Guo et al., 2023), GPTZero (Habibzadeh, 2023), LM Detector (Ippolito et al., 2020), to mention a few.

Regarding *SemEval-2024 Task 8: Multigenerator, Multidomain, and Multilingual Black-Box Machine-Generated Text Detection* (Wang et al., 2024), RoBERTa (Liu et al., 2019) and XLM-R (Conneau et al., 2020) are two language models that can be considered as the baseline for these specific tasks.

2.3 Challenges

Yet, there is currently no existing framework capable of automatically distinguishing between human-written and machine-generated texts at both binary and multi-way paradigms outlined in the described tasks as well as no existing free available architecture taking advantage of recent open-sourced LLMs to tackle the issue.

3 Data

We work on two datasets provided by *SemEval-2024 Task 8: Multigenerator, Multidomain, and Multilingual Black-Box Machine-Generated Text Detection* (Wang et al., 2024), whose statistics covering the number of examples for each source and each label are presented in Tables 1 and 2 for Subtask A and B, respectively.

Table 1: Subtask A

In Subtask A of the monolingual version, both the training and development sets are sourced from the same data group for both labels. However, in the multilingual version of Subtask A and Subtask B, the development set is sourced from different places compared to the training set.

For both versions of Subtask A, data were collected from diverse sources, leading to label imbalances. For example, in the monolingual Subtask A training set, there is a notable scarcity of samples from *peerread* compared to the other sources. Conversely, in Subtask B, the dataset is balanced.

4 Methodology

This section tackles the problem by formulating it as supervised classification tasks. We then introduce our proposed solution architecture for each task, covering the models used, and present how we fine-tuned them with hyperparameter configurations, and how we assessed their performance.

4.1 Problem Statements

4.1.1 Subtask A

We formulate the problem at hand as a binary supervised classification task, whose objective is to learn a mapping between a representation of the text and a binary variable, which is 1 if the text is machine-generated, and 0 otherwise. Mathematically, we learn a function f that, given an input text t_i, represented as a set of features $[f_1^i, ..., f_k^i]$, outputs an estimated label $\hat{l}_i \in \{0, 1\}$, i.e., $\hat{l}_i = f(t_i)$. Note that Subtask A covers two versions: monolingual and multilingual versions.

4.1.2 Subtask B

Similarly, we consider the task as a supervised classification where we aim to learn a function f that, given an input text t_i, represented as a set of features $[f_1^i, ..., f_k^i]$, outputs an estimated label $\hat{l}_i \in \{0, 1, 2, 3, 4, 5\}$, i.e., $\hat{l}_i = f(t_i)$ where 0 refers to the human-written texts and the rests are those generated by different machines, including 1-*ChatGPT*, 2-*cohere*, 3-*davinci*, 4-*bloomz*, and 5-*dolly*, respectively.

Furthermore, we are interested in gaining insights from the classifier's predictions that allow us to understand which features contribute positively to detecting machine-generated text.

4.2 Our architecture

The overall architecture of our proposed approach is demonstrated in Figure 1. The general idea is to use a machine learning model trained to discriminate between text samples generated by a human and text samples generated by LLMs. Different directions could be pursued to extract useful features from a text and perform text classification.

4.2.1 Metric-based models

Inspired the works from He et al. (2023) and Spiegel and Macko (2023), we capture the local information from the texts using the following methods: (1) *Log-Likelihood*, (2) *Rank*, (3) *Log-Rank*, (4) *Entropy*, and (5) *MFDMetric*.

- *Log-Likelihood*: Given a text, we average the token-wise log probability of each word generated from a language model to generate a score for this text.
- *Rank*: For each word in a text, given its previous context, we calculate the absolute rank of this word. Then, for a given text, we compute the score of the text by averaging the rank value of each word.
- *Log-Rank*: Slightly different from the Rank metric that uses the absolute rank, the Log-Rank score is calculated by first applying the log function to the rank value of each word.
- *Entropy*: Similar to the Rank score, the Entropy score of a text is calculated by averaging the entropy value of each word conditioned with its previous context.
- *Multi-Feature Detection Metric* or *MFDMetric*: This is a two-step zero-shot method that (1) considers four distributional information (*Log-Likelihood*, *Log-Rank*, *Entropy*), and statistical information (*LLM-Deviation*) as input features; and (2) classify the text using neural networks.

In *Log-Likelihood*, a larger score denotes the text is more likely to be machine-generated. Meanwhile, in *Rank* and *Log-Rank*, a smaller score denotes the text is more likely to be machine-generated. Similarly, the machine-generated text is more likely to have a lower *Entropy* score. Note that metric-based methods are only applied to Subtask A.

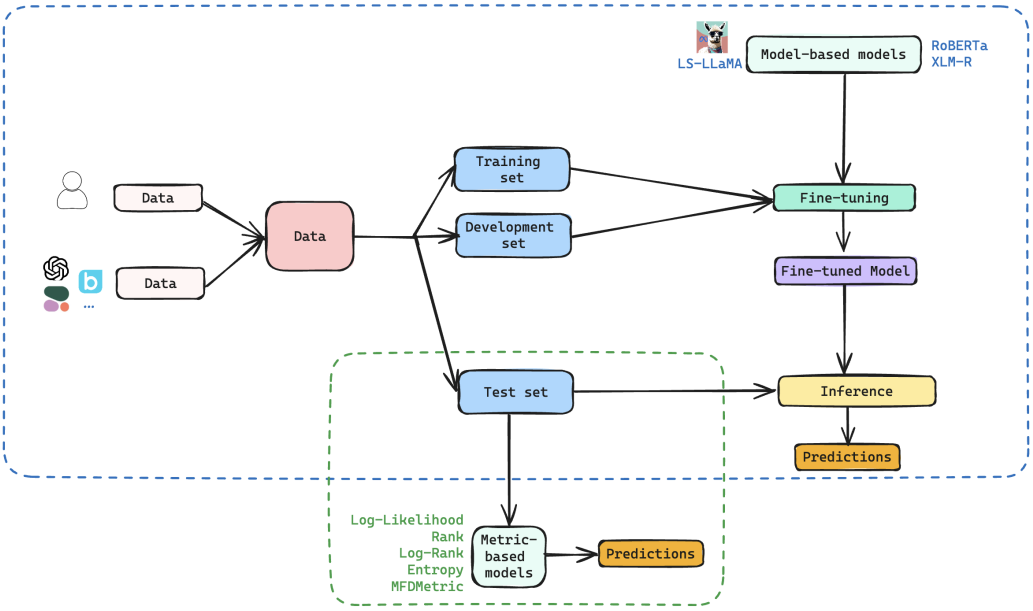

Figure 1: Our general architecture for Subtask A (both blue and green boxes) and Subtask B (only blue box).

4.2.2 Model-based models

LMs Two Transformer-based models have been fine-tuned as sequence classifiers, namely RoBERTa (Liu et al., 2019) and XLM-R (Conneau et al., 2020). RoBERTa is a Transformers model pretrained on a large corpus of English data in a self-supervised fashion using a masked language modeling (MLM) objective. Meanwhile, XLM-R is a multilingual version of RoBERTa that was pre-trained on 2.5TB of filtered CommonCrawl data containing 100 languages. These models are also suggested as the baseline methods from *SemEval-2024 Task 8* organizers.

LLMs Given the recent success of the LLMs architectures for solving downstream NLP tasks, we decided to follow the same vein to build our classifier. As such, we start with LLaMA-2 (Touvron et al., 2023), an LLM model pre-trained for the sequence classification task, using its corresponding tokenizer to preprocess data. We then fine-tune the model on the training subset of collected data. Consequently, the fine-tuned model is used for inference on the testing subset. Finally, the obtained classification scores are evaluated against the ground truth.

4.3 Hyperparameters

Metric-based models We took advantage of IMGTB[5] framework with default parameter settings suggested from He et al. (2023) and Spiegel and Macko (2023).

LMs We fine-tuned 2 LMs, namely RoBERTa and XLM-R, using HuggingFace Transformers Pytorch Trainer with the following configuration: batch size = 16, learning rate = 1e-5, weight decay = 0.01, number of epoch = 10.

LLaMA-2 To make the comparison comparable, we fine-tuned LS-LLaMA[6] (version: *LLaMA-2-7b-hf*) using the HuggingFace Transformers PyTorch Trainer class with the same configuration: batch size = 16, learning rate = 1e-5, and the number of epochs = 10 with max length = 256 and Lora = 12.

All the experiments were implemented on an NVIDIA RTX A6000 with CUDA Version of 12.0 and 49140MiB.

4.4 Evaluation metrics

For both Subtasks, we use *Accuracy*, *macro-F1*, and *micro-F1* as the evaluation metrics to measure our classifiers' performance. These are also the standard metrics in *SemEval-2024 Task 8*, which makes our works more comparable with other participants. We assess the performance of the development sets first and apply the best models to the test set. The final leaderboard reported results only for *Accuracy*.

Our ranking	**25**/125	**5**/62	**6**/70

Table 4: Our performance in *Accuracy* on the test set with the same train-validation-test split of *SemEval Task8*.

5.1 General Observations

We first present different experiment results on the development set in Table 3. We observed that overall, LLM-based methods, such as LS-LLaMA$_{2-7b-hf}$, tend to outperform other approaches across all sequence classification tasks, suggesting the effectiveness of leveraging large pre-trained language models for these tasks. Meanwhile, metric-based methods have varying performance, with *Rank* showing some competitiveness, but generally, they are outperformed by LLM and LM-based methods. Regarding LM-based approaches, XLM-R tends to surpass the performance of RoBERTa in the monolingual version of Subtask A despite RoBERTa being specifically designed for English only.

Based on the performance of the development set, we applied LS-LLaMA$_{2-7b-hf}$, which yields superior performance in these Subtasks compared to other methods, to the test set. As shown in Table 4, despite not surpassing the baseline of Subtask A's monolingual version, our models significantly outperform the baseline of Subtask A's multilingual version and Subtask B with approximately 10% gain on average. While we ranked only 25^{st} over 125 participants in the monolingual version of Subtask A, we demonstrate competitive performance to be ranked 5^{th} over 62 and 6^{th} over 70 participants in the multilingual version of Subtask A and Subtask B, respectively.

We conducted several analyses to investigate how different factors would affect the detection performance of our best classifier.

5.2 Effect of Text Length

We first present the distribution of the number of words (*#. words*) for predicted human-generated and machine-generated texts (*Predictions*) and their ground truth (*GT*) in the dataset in each Subtask (shown in Figure 2).

On ground-truth levels, Figure 2 highlights discrepancies in word distribution between human-written texts and those generated by different LLMs. This is evident in Subtask A by the difference in word count distribution between human and machine-generated labels and in Subtask B by the varying generated performance of individual LLMs compared to human-written ones. For instance, *davinci* can generate long-context answers (more than 2500 words) while others respond in more concise ways (less than 1500 words).

Despite these discrepancies, compared predictions against ground truth, our classifier effectively captures the distribution of generated texts per

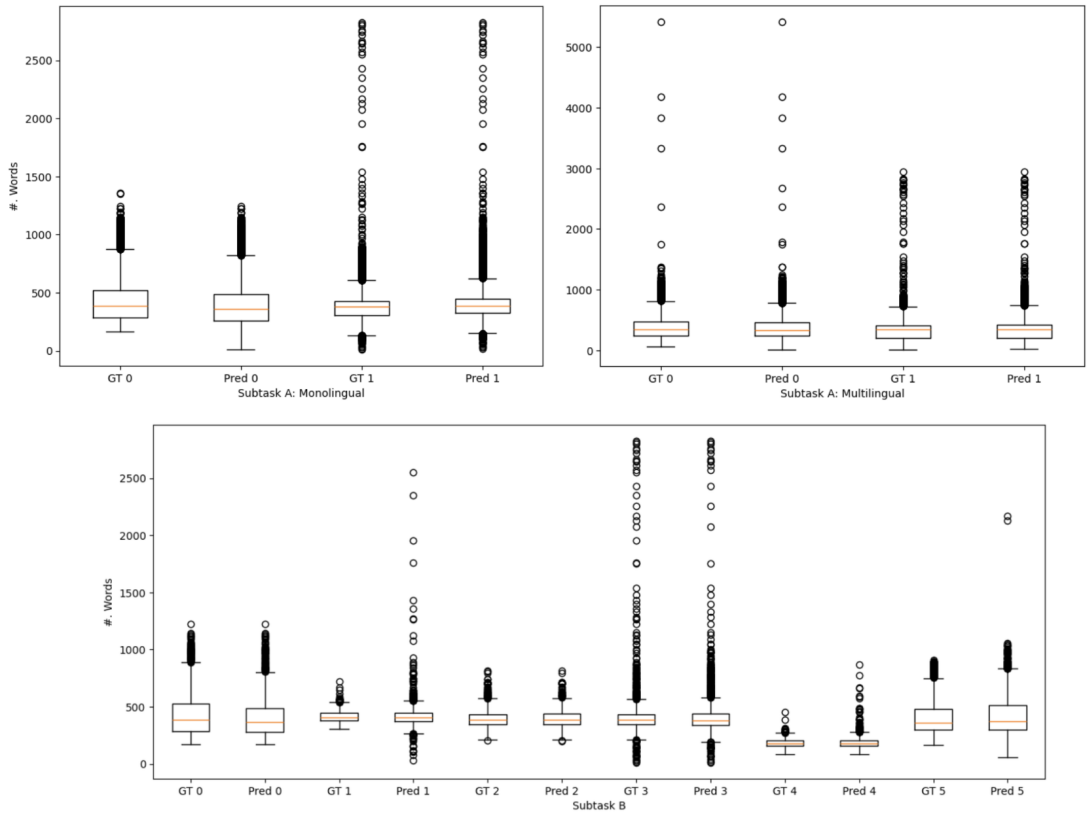

Figure 2: The distribution of words (*#. words*) for human-written and machine-generated texts of our predictions (*Pred*) and the ground truth (*GT*) on different datasets of different tasks (Subtask A: 0-*Human*, 1-*Machine*; Subtask B: 0-*Human*, 1-*ChatGPT*, 2-*cohere*, 3-*davinci*, 4-*bloomz*, and 5-*dolly*).

class, resulting in comparable word distributions between predictions and ground truth except in *ChatGPT* and *dolly* where most of the examples we misclassified are outliers.

5.3 Class-wise Performance

To better investigate the detection performance of different classes, we visualize the normalized confusion matrix of different tasks when we used our LLaMA-2 classifier as shown in Figure 3.

On one hand, in terms of Accuracy, unlike the multilingual version of Subtask A where all the classes can be well detected with up to 94% in Accuracy, the monolingual version suffers significantly from misclassifying human-written texts into machine-generated ones, which reduces the performance of the overall classifier (the accuracy of the human-written class falls into around 76%). Most of the misclassified texts are human-written that our classifier mistakenly took for the machine-generated ones.

On the other hand, when it comes to multi-way machine-generated text classification as Subtask B, the predictive performance of our classifier varies depending on the type of LLMs used to generate texts. Although LLaMA-2 has a good performance in identifying human-written and machine-generated texts generated by *ChatGPT*, *bloomz*, and *dolly*, the performance in attributing machine-generated texts from other LLMs (e.g., *cohere*, and *davinci*) is largely limited. For example, the prediction accuracy of *ChatGPT*, *bloomz* is almost perfect (99.53% and 99.70%, respectively). Meanwhile, that of *cohere* is just above the average (around 60%) and its texts are often misclassified as machine-generated texts from *davinci*, followed by *ChatGPT*. This is expected due to potential overlap in the distribution of the metric among various LLMs, which introduces extra challenges in attribution.

Broadly speaking, our findings suggest that the fine-tuned LLMs (e.g., LLaMA-2) excel in detecting machine-generated multilingual texts and accurately classifying machine-generated texts within a specific category, (e.g., *ChatGPT*, *bloomz*, *dolly*). However, they do exhibit challenges in detecting

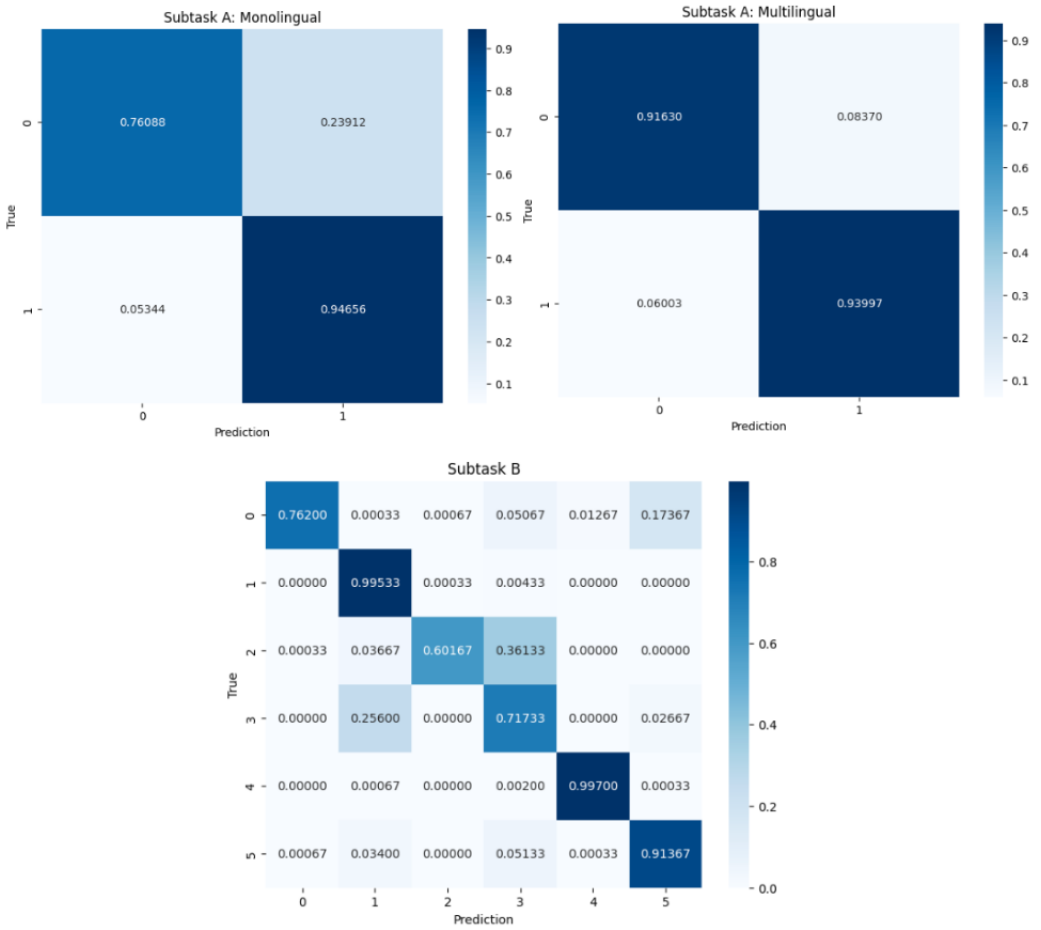

Figure 3: Normalized confusion matrix of LLaMA-2 methods on different tasks. Note that the values in the diagonal represent the class-wise accuracy (Subtask A: 0-*Human*, 1-*Machine*; Subtask B: 0-*Human*, 1-*ChatGPT*, 2-*cohere*, 3-*davinci*, 4-*bloomz*, and 5-*dolly*).

them in other categories (e.g., *cohere*, and *davinci*). Further studies are needed to improve the lower-performing classes.

6 Conclusions

In conclusion, this paper outlines our contribution to the first two Subtasks of *SemEval-2024 Task 8: Multigenerator, Multidomain, and Multilingual Black-Box Machine-Generated Text Detection*, namely Monolingual and Multilingual Binary Human-Written vs. Machine-Generated Text Classification and Multi-Way Machine-Generated Text Classification. We conducted a comprehensive comparative study across three methodological groups: Five metric-based models (Log-Likelihood, Rank, Log-Rank, Entropy, and MFD-Metric), two fine-tuned sequence-labeling language models (RoBERTA and XLM-R); and a fine-tuned large-scale language model (LS-LLaMA).

Our findings suggest that our LLM outperformed both traditional sequence-labeling LM benchmarks and metric-based approaches. Furthermore, our fine-tuned classifier excelled in detecting machine-generated multilingual texts and accurately classifying machine-generated texts within a specific category, (e.g., *ChatGPT*, *bloomz*, *dolly*). However, they do exhibit challenges in detecting them in other categories (e.g., *cohere*, and *davinci*). This is due to potential overlap in the distribution of the metric among various LLMs. Overall, we ranked 6^{th} in both Multilingual Binary Human-Written vs. Machine-Generated Text Classification and Multi-Way Machine-Generated Text Classification on the leaderboard.

In future work, we would like to take a step further to evaluate whether our classifier is robust enough against adversarial attacks (e.g., paraphrasing, random spacing, adversarial perturbation) as

well as investigate how to make our model more interpretable and explainable, which is important, but insufficiently addressed when detecting machine-generated contents.

Limitations

Regarding specificity and domain dependence, our classifier might not effectively distinguish among different types of machine-generated texts, such as texts generated by different models, for different purposes, or in specific domains (which can be seen in the case of detecting texts generated by *cohere* and *davinci*).

nicolay-r at SemEval-2024 Task 3: Using Flan-T5 for Reasoning Emotion Cause in Conversations with Chain-of-Thought on Emotion States

Nicolay Rusnachenko
Newcastle Upon Tyne, England
rusnicolay@gmail.com

Huizhi Liang
Newcastle University
Newcastle Upon Tyne, England
huizhi.liang@ncl.ac.uk

Abstract

Emotion expression is one of the essential traits of conversations. It may be self-related or caused by another speaker. The variety of reasons may serve as a source of the further emotion causes: conversation history, speaker's emotional state, etc. Inspired by the most recent advances in Chain-of-Thought, in this work, we exploit the existing three-hop reasoning approach (THOR) to perform large language model instruction-tuning for answering: emotion states ($\text{THOR}_{\text{STATE}}$), and emotion caused by one speaker to the other ($\text{THOR}_{\text{CAUSE}}$). We equip $\text{THOR}_{\text{CAUSE}}$ with the reasoning revision (RR) for devising a reasoning path in fine-tuning. In particular, we rely on the annotated speaker emotion states to revise reasoning path. Our final submission, based on $\text{Flan-T5}_{\text{base}}$ (250M) and the rule-based span correction technique, preliminary tuned with $\text{THOR}_{\text{STATE}}$ and fine-tuned with $\text{THOR}_{\text{CAUSE-RR}}$ on competition training data, results in 3rd and 4th places ($F1_{\text{proportional}}$) and 5th place ($F1_{\text{strict}}$) among 15 participating teams. Our THOR implementation fork is publicly available: https://github.com/nicolay-r/THOR-ECAC

1 Task Overview

Extracting potential causes that lead to emotion expressions in text is the crucial aim of Emotion Cause Extraction (ECE) domain (Xia and Ding, 2019). In particular, the SemEval-2024 Task 3 (Wang et al., 2024) is aimed at emotion-cause pair analysis in conversations from the sitcom *Friends*. The conversations are organized into Emotion-Cause-in-Friends dataset (Wang et al., 2023) and includes the JSON-formatted training ($\text{TRAIN}_{\text{json}}$) and evaluation ($\text{TEST}_{\text{json}}$) parts. The authors propose 6 emotion classes to annotate: (i) speaker emotion states, and (ii) emotion caused by one utterance to the other. These classes are: $E = \{\text{SURPRISE, SADNESS, JOY, DISGUST, FEAR, ANGER}\}$, and NEUTRAL for absence of emotion. We denote $E' = E \cup \{\text{NEUTRAL}\}$ as a complete set.

Among the several subtasks of ECAC-2024, in this paper we focused on *Subtask 1*: textual emotion-cause pair extraction in conversations. In this subtask, each conversation represents a list of utterances. Every utterance (u) yields the following: utterance text (u_{text}), speaker name ($u_{speaker}$), emotion state ($u_{state} \in E'$), and ID (u_{id}). The annotation of the emotion cause pairs represents a list $P = [p_1 \dots p_{|P|}]$, in which each pair $p \in P$ is a labeled source-target[1] tuple $p = \langle u^{src}, u^{tgt}, e_c \rangle$, where $e_c \in E$.

We initiate our studies by analyzing the training data ($\text{TRAIN}_{\text{json}}$) for the subject of annotated emotion-cause pairs $\langle u^{src}, u^{tgt} \rangle$ in it, and report:

1. Quantitative statistics of the mentioned emotion-cause pairs (Table 1);
2. Distance statistics (in utterances) between u^{src} and u^{tgt} (Table 2);
3. Distribution statistics between speaker state (u_{state}) and emotion *speaker causes* ($e^{u \to *}$) (Table 3).

According to the Table 2, most emotion was found to be caused by such utterances u^{src} that are the same as or mentioned before u^{tgt} ($\delta \geq 0$). Therefore, given $\langle u^{src}, u^{tgt} \rangle$ we denote its context $X = \{u^1 \dots u^k\}$ as a *history* of the past $k-1$ utterances of u^{tgt}, where $u^{tgt} = u^k \in X$, $u^{src} \in X$.
Task definition: Given an emotion-causing utterance pair within context $\langle u^{src}, u^{tgt}, X \rangle$ answer the emotion $e_c \in E'$ caused by u^{src} towards u^{tgt}.

2 Methodology

We propose a two-stage training mechanism for performing instruction-tuning on large language models (LLMs), aimed at accurately inferring of

[1] Spans-prediction is beyond the scope of our methodology.

the task answers. Given triplet $\langle u^{src}, u^{tgt}, X \rangle$ of emotion-cause pair $\langle u^{src}, u^{tgt} \rangle$ in context X, the proposed mechanism aims at LLM instruction-tuning, in order to answer $e \in E'$ that refers to:

STAGE 1: emotion state u_{state}^{tgt};

STAGE 2: emotion cause by u^{src} to u^{tgt}.

Therefore, for emotion-cause pairs extraction we use the STAGE 2 towards the model tuned in STAGE 1 to infer $e_c \in E'$ caused by u^{src} towards u^{tgt}.

Instead of directly asking LLM the final result at each stage, we exploit the Chain-of-Thought (CoT) concept in the form of the Three-hop Reasoning (THOR) framework (Hao et al., 2023). We believe that LLM can infer the span that conveys emotion and opinion about it before answering $e \in E'$. Figure 1 illustrates the proposed training methodology, empowered by the CoT prompting. We refer to the instruction-tuning mechanisms of the STAGE 1 and STAGE 2 as THOR$_{\text{STATE}}$ and THOR$_{\text{CAUSE}}$ respectively.

2.1 Chain-of-Thought Prompting

We adopt the THOR framework (Hao et al., 2023) in LLM fine-tuning with the prompt templates adapted for emotion-cause pair analysis in conversations. We define the intermediate *span* (s) and latent *opinion* expression (o). With $C_i, i \in \overline{1..3}$ we denote the prompts that wrap the content in the input context. The construction of stages is as follows.

THOR$_{\text{STATE}}$ This is a STAGE 1 of the proposed training methodology, aimed at preliminary LLM instruction-tuning. Given $\langle u^{tgt}, X \rangle$, we apply the following three steps to infer $u_{state}^{tgt} = e'_1 \in E'$:

Step 1: s'_1 = [$C_1(X)$, which text spans are possibly causes emotion on u_{text}^{tgt}?]

Step 2: o'_1 = [$C_2(C_1, s'_1)$. Based on the common sense, what is the implicit opinion towards the mentioned text spans that causes emotion on u_{text}^{tgt}, and why?]

Step 3: e'_1 = [$C_3(C_2, o'_1)$. Based on such opinion, what is the emotion state of u_{text}^{tgt}?]

where s'_1 could be interpret as $s'_1 = argmax\ p(s_1|X, u_{text}^{tgt})$, latent opinion o'_1 as $o'_1 = argmax\ p(o_1|X, u_{text}^{tgt}, s'_1)$, and the final answer e'_1 noted as: $e'_1 = argmax\ p(e_1|X, u_{text}^{tgt}, s'_1, o'_1)$.

THOR$_{\text{CAUSE}}$ This is a STAGE 2 of the proposed methodology, based on emotions-cause pairs. We use this stage for (i) *fine-tuning* and (ii) task result *inferring* purposes. Given context $\langle u^{src}, u^{tgt}, X \rangle$ we omit[2] $u^{tgt} \in X$ from the input parameters by referring to it as «*end of the conversation*». We apply the following steps to infer $e'_2 \in E'$ caused by u^{src} to u^{tgt}:

Step 1: s'_2 = [$C_1(X)$, which specific text span of u_{text}^{src} is possibly causes emotion?]

Step 2: o'_2 = [$C_2(C_1, s'_2)$. Based on the common sense, what is the implicit opinion towards the cause of mentioned text span of u_{text}^{src}, and why?]

Step 3: e'_2 = [$C_3(C_2, o'_2)$. Based on such opinion, what is the emotion caused by source towards the last conversation utterance?]

[2]To reduce the problem statement to the one for which THOR was originally designed (Pontiki et al., 2016)

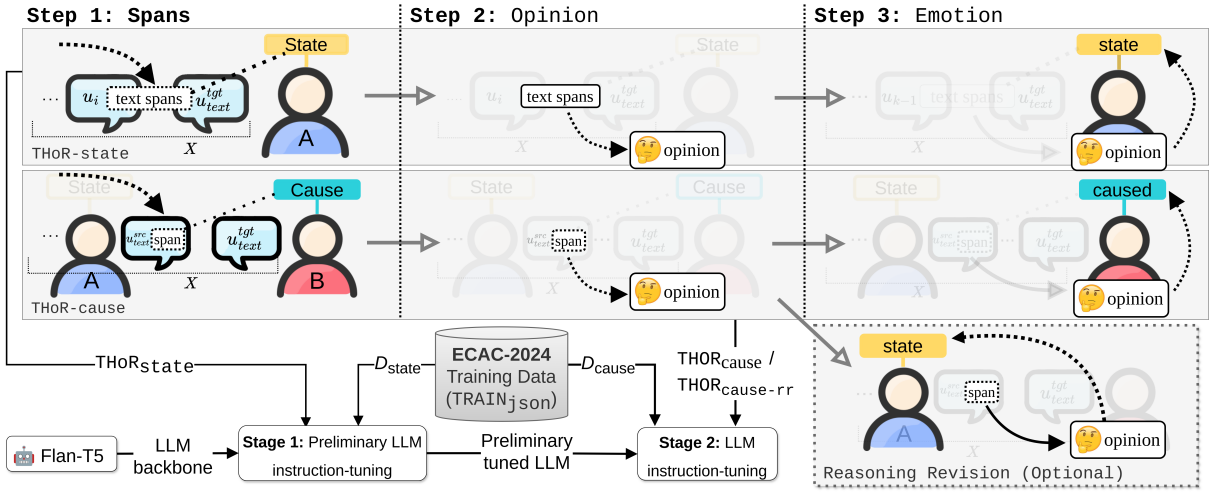

Figure 1: Two-stage LLM tuning methodology for inferring emotion caused by u^{src} towards u^{tgt} in context X by adapting THoR (Hao et al., 2023) to reason and answer: (i) u^{tgt}_{state} (THoR$_{\text{STATE}}$), and (ii) emotion caused by u^{src} towards u^{tgt} (THoR$_{\text{CAUSE}}$), optionally enhanced by Reasoning-Revision and by predicting u^{src}_{state} (THoR$_{\text{CAUSE-RR}}$).

where s'_2 could be interpret as $s'_2 = argmax\ p(s'_2|X, u^{src}_{text})$, opinion o' could be interpret as $o'_2 = argmax\ p(o_2|X, u^{src}_{text}, s'_2)$, and the final answer e'_2 noted as: $e'_2 = argmax\ p(e_2|X, u^{src}_{text}, s'_2, o'_2)$.

2.2 Reasoning Revision with Supervision

During the LLM instruction-tuning process with the THoR, it is possible to devise a reasoning path. Technically, at each step of the chain we have all the necessary information to query our model with the final answer. With the following approach, we believe in a better model alignment on state-cause dependency (Table 3): speakers are likely to cause an emotion, similar to their states[3]. To revise this knowledge, in this paper, we impute the following prompt to support our opinion O, obtained at the end of the THoR$_{\text{CAUSE}}$ step 2 (Fig. 1):

Step 3.1: u'^{src}_{state} =[$C_3(C_2, o'_2)$, Based on such opinion, what is the emotion state of u^{src}_{text}?]

Due to the definition of the task, we believe in the correctness of this knowledge within the emotion cause task. Once step 3.1 is embedded, the result answer $e'_2 \in E'$ in THoR$_{\text{CAUSE}}$ from the step 3 could be reinterpret as $e'_2 = argmax\ p(e_2|X, u^{src}_{text}, s'_2, o'_2, u'^{src}_{state})$. We refer to this setup as THoR$_{\text{CAUSE-RR}}$.

[3]Except NEUTRAL speaker state (Table 3)

3 Datasets and Experiential Setup

We adopt textual resources provided by the competition organizers (Wang et al., 2024): training (TRAIN$_{\text{json}}$) and evaluation (TEST$_{\text{json}}$) data. Within TRAIN$_{\text{json}}$, for each conversation, we rely on (i) speakers *emotion states*, and (ii) *emotion causes* annotation to compose the datasets D_{state} and D_{cause}, respectively. Each dataset represent a list of tuples $t = (u, X, L)$, where u is an utterance of the conversation context $X = \{u^1 \dots u^k\}$, and L is a list of emotion labels, defined as:

- $L = [u^k_{state}]$ in the case of D_{state} ($u^k_{state} \in E'$)
- $L = [u_{state}, e^u]$ in the case of D_{cause}, where e^u is emotion expressed by u towards u^k, or NEUTRAL otherwise ($e^u \in E'$)

D_{state} represent entries of all possible utterances in all conversations with their emotional states $u_{state} \in E$. For the particular utterance u, we consider its context as $X_u = \{u' : u_{id} - u'_{id} \leq k\}$.

D_{cause} includes all possible pairs $\langle u^{src}, u^{tgt} \rangle$, where $u^{src}_{id} \leq u^{tgt}_{id}$, and $u^{tgt}_{id} - u^{src}_{id} \leq k$. For the particular pair, we compose the related context (X') as follows: $X' = \{u' : u^{tgt}_{id} - u'_{id} \leq k\}$. For each pair, we assign $e \in E$ if the pair is present in conversation annotation and NEUTRAL otherwise. We rely on the analysis in Table 2 to limit the number of pairs, as well as the size of the context. We set $k = 3$ to cover 95.8% emotion-cause pairs. We also cover the case of emotions caused from within the same utterance (59.5%, see Table 1). As for emotions caused by the same speaker of

other utterance, we assess that excluding this type of pairs (12.83%, according to Table 1), results in $\approx 23\%$ pairs reduction of D_{cause} and hence reduces training time. Therefore, the result D_{cause} excludes pairs of this type in train, dev and test parts.

Table 4 lists the statistics of the composed resources. We use the 9:1 proportion for TRAIN$_{\text{json}}$ to compose train and dev, respectively. To represent $X \in t$, we concatenate its representation of utterances. For each utterance $u \in X$, we use the following formatting template: «$u_{speaker}$: u_{text}». To represent utterance $u \in t$, we refer to u_{text}. For each $l \in L$ formatting, we utilize its lowercase text value. The implementation details for the datasets preparation are publicly available.[4]

Setup. We follow the publicly available framework setups (Hao et al., 2023) and adopt encoder-decoder style instructive Flan-T5[5] as our backbone LLM for the proposed methodology. We experiment with a 250M (base) version. For evaluations on dev, we adopt the F1-measure for E', denoted as $F1(E')$. The evaluation on test assessed with the set of $F1$-metrics, provided by the competition organizers (details in Section 4). We consider the instruction-tuning of the Flan-T5 model with the following techniques: conventional PROMPT, THOR (Section 2.1), and THOR$_{\text{CAUSE}}$ with reasoning revision (Section 2.2). To conduct the experiment, we rent a server with a single NVIDIA A100 GPU (40GB). We set temperature 1.0, learning rate $2 \cdot 10^{-4}$, optimizer AdamW (Loshchilov and Hutter, 2017), BATCH-SIZE of 32.

For the PROMPT technique, we use the template «$C_1(X)$. $I(u)$. Choose from E'», where $I(u)$ corresponds to the instruction. For D_{cause} we use $I(u)$ = «What emotion causes u_{text} towards the last conversation utterance?»

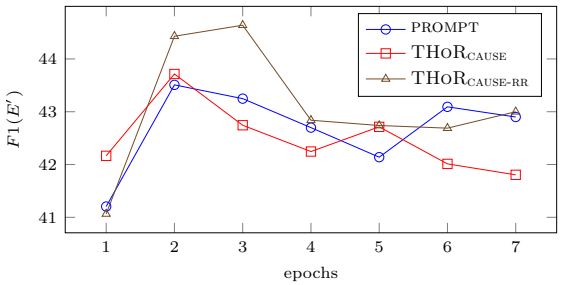

Figure 3: Flan-T5$_{\text{base}}$† fine-tuning results comparison by $F1(E')$ on D_{cause} dev part per each epoch across fine-tuning techniques: PROMPT, THOR$_{\text{CAUSE}}$, and THOR$_{\text{CAUSE-RR}}$.

4 Experiments

Stage 1. Figure 2 illustrates the analysis of the $F1$ on dev part during the preliminary tuning of Flan-T5$_{\text{base}}$ on D_{state}.[6] We investigate the overfitting after 2 epochs of training. The best state, obtained at the end of the epoch #2 with the $F1(E')$= 47.81 on the D_{state}-dev part, has been selected. In further, we refer to this model as Flan-T5$_{\text{base}}$†.

Stage 2 Figure 3 provides a comparative analysis of different fine-tuning techniques. As at the pre-training stage, we investigate the ability to learn task emotion states 2-3 training epoch, followed by overfitting. Switching from PROMPT to THOR$_{\text{CAUSE-RR}}$ technique, we investigate the improvement by 2.5% percent by $F1(E')$ on the dev

[6] We left the comparison with other pre-training techniques listed in 3 out of scope of this paper due to alignment with the CoT concept in STAGE 2.

part of the D_{state} dataset. We refer to the best fine-tuned versions as Flan-T5$_{\text{base}}$‡, separately per each fine-tuning technique in Table 5 (dev column).

The official evaluation includes the following $F1$ measures: (i) weighted averaged $F1^w_*$ / non-weighted ($F1_*$), and (ii) strict ($F1_s$) / not-strict ($F1_p$) towards predicted spans. To form the submissions for official evaluation, the following span corrections approaches were used: (i) punctuation terms[7] exclusion from utterance prefixes and suffixes (by default), and (ii) algorithm-based (Section 4.1). Table 5 (test columns) illustrate the available results of T5$_{\text{base}}$‡ in official evaluation. **Final submission** represents the results of Flan-T5$_{\text{base}}$‡ (THOR$_{\text{CAUSE-RR}}$ technique), and application of algorithm-based spans correction.

4.1 Algorithm-based Spans Correction

Our methodology (Section 2) is limited on utterance level emotion cause prediction.[8] We believe it is reflected in the relatively low results of $F1_s$ on the test dataset (see Table 5). Therefore, we analyze TRAIN$_{\text{json}}$ and adopt a placeholder solution, aimed at enhancing the results by $F1_s$.

We apply a *rule-based approach* based on differences between the original utterance texts and their span annotations in the training data. Using TRAIN$_{\text{json}}$, we compose *prefix-* (V_p) and *suffix-* (V_s) vocabularies. For vocabulary entries, we select those that satisfy all of the following criteria: (i) the length of entry does not exceed 5 words, (ii) entry starts (in the case of V_s), or ends (in the case of V_p) with the punctuation sign[7].

[7]We use string.punctuation preset in Python

[8]Technically it is possible to obtain spans (Section 2), however we could not investigate the practical valuty of the THOR$_{\text{CAUSE}}$-based Flan-T5$_{\text{base}}$‡ responses from step #1.

```

4.2 Final Submission Analysis

We report the following emotion-cause pairs $\langle u^{src}, u^{tgt} \rangle$ analysis results for the Flan-T5$_{\text{base}}$‡ (THOR$_{\text{CAUSE-RR}}$ technique, final submission):

1. Quantitative statistics of the extracted emotion-cause pairs (Table 6);
2. Distance statistics (in utterances) between u^{src} and u^{tgt} (Table 7);
3. Distribution statistics between speaker state (u_{state}) and the emotion *speaker causes* ($e^{u \to *}$) (Table 8);
4. Distribution statistics between speaker state (u_{state}) and emotion *caused on them* ($e^{* \to u}$) (Table 9).

According to the results in Table 8, we observe that the correlation between the state of the speaker u utterance (u_{state}) and the emotion it causes ($e^{u \to *}$) **is similar to** the related statistics on the competition training data (Table 3). We also investigate the alignment of the speaker states (u_{state}) with the emotion caused on them ($e^{* \to u}$) and the precision of the result varies between 80-97% (Table 9). The known source of misalignment is the case when emotion[10] $e^{* \to u} \in E$ caused on u with $u_{state} = \text{NEUTRAL}$ (bottom row, Table 9).

5 Conclusion

In this paper, we present a Chain-of-Thought (CoT) methodology aimed at fine-tuning LLM for emotion state and cause extraction. We consider the problem of *emotion cause analysis in conversations* as a context-based problem with the mentioned utterance that causes emotion towards the last utterance in context. We devise our CoT for emotion causes and propose a reasoning revision methodology aimed at imputing the speaker emotion to support the decision on caused emotion. Our CoT represent a Three-hop Reasoning approach priory known as THoR. We apply this approach to fine-tune LLM and predict: (i) emotion state of the mentioned utterance, and (ii) emotion caused by mentioned utterance towards the last utterance in context. We experiment with the Flan-T5$_{\text{base}}$ (250M) model fine-tuning using resources provided by task organizers. The application of CoT with reasoning revision allows us to improve the results by 2.5% (F1-measure) compared to prompt-based tuning. In further work, we expect to contribute with the: (i) analysis of larger models, and (ii) enhanced reasoning revision techniques, mentioned in the final submission analysis.

StFX-NLP at SemEval-2024 *Task* 9: BRAINTEASER: Three Unsupervised Riddle-Solvers

Ethan Heavey, James Hughes, Milton King
St. Francis Xavier University
{eheavey, jhughes, mking}@stfx.ca

Abstract

In this paper, we explore three unsupervised learning models that we applied to *Task* 9: BRAINTEASER of SemEval 2024. Two of these models incorporate word sense disambiguation and part-of-speech tagging, specifically leveraging SensEmBERT and the Stanford log-linear part-of-speech tagger. Our third model relies on a more traditional language modelling approach. The best performing model, a bag-of-words model leveraging word sense disambiguation and part-of-speech tagging, secured the 10^{th} spot out of 11 places on both the sentence puzzle and word puzzle subtasks.

1 Introduction

Riddles often exploit the commonsense of the solver to lead them astray, subverting expectations with it's answer. For example, the riddle "A young girl fell off of a 20 foot ladder but wasn't hurt. How? *She fell off of the bottom rung.*" leads the solver astray by including the height of the ladder in the initial question, tricking one into latching onto misleading information. *Task* 9: BRAINTEASER (Jiang et al., 2024) presents riddles to a predictive model and asks the model to choose one of four answers to the riddle, in the hopes of bridging the gap between vertical and lateral thinking (Waks, 1997) within language models. The data provided for the *Task* is written in English and was obtained from public websites by utilizing web crawlers (Jiang et al., 2023).

The three models we employ to solve this task all apply an unsupervised learning approach, with two of the three models leveraging word senses and part-of-speech tagging to aid in their predictive capabilities. We wanted to leverage the senses of the nouns in the question and in each possible answer as we hypothesized that the senses present in the question and each answer may aid our models in piercing the proverbial commonsense veil that makes brainteasers and riddles difficult to begin with.

Our best approach, the bag-of-words model, landed us in 10^{th} place out of 11 places in the "overall" results of both subtasks. While 13 teams competed, two teams tied for both 2^{nd} and 4^{th} place in the sentence subtask, two teams also tied for both 1^{st} and 11^{th} place in the word subtask results.

Our code can be found on Github[1].

2 Background

BRAINTEASER places emphasis on the ability of a predictive model to use vertical and lateral thinking. Vertical thinking leverages logic and rationality to perform a sequential analysis of a problem, whereas lateral thinking (or "thinking outside the box") leverages creativity to solve problems. The *Task* is divided into two subtasks — sentence puzzles and word puzzles. We applied our models to both, with each subtask requiring vertical and lateral thinking to solve. Figure 1 breaks down how sentence and word puzzles can be solved with lateral thinking. The train of thought labeled with a red "X" demonstrates logical thinking based on the information available at the time, whereas the alternate thought process — the line of thinking that allows the solution to be derived — displays how lateral thinking can affect the answer to a riddle as more context is provided.

The dataset associated with the *Task* presents each sample as a question and four possible answers. Table 1 shows an example of both a sentence puzzle question and its possible answers, and a word puzzle question and its possible answers. Each sample also has two variants; a semantic reconstruction and a context reconstruction. These reconstructions are designed to further test a model's reasoning ability.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 28–33

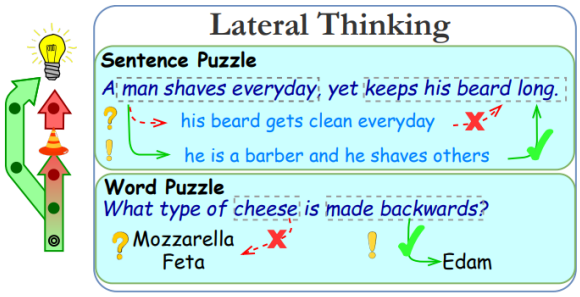

Figure 1: An example of how lateral thinking can be used to solve sentence and word puzzles. Figure taken from BRAINTEASER system paper (Jiang et al., 2023).

Whilst the training and development sets contain extra information regarding the correct answer, our unsupervised approaches only required the test set. Not using the labeled training and validation data, while limiting our models, allows them to be more versatile in situations where labeled data is not available.

Word Sense Disambiguation (WSD) is a natural language processing (NLP) task that involves determining the correct meaning or sense of a word within a given context (Navigli, 2009). Many words in natural language have multiple senses, and WSD aims to identify the intended sense of a word in a specific sentence or context. This is used in various language processing applications, such as machine translation, information retrieval, and text summarization. We employ WSD by leveraging SensEmBERT (Scarlini et al., 2020), coupled with WordNet (Fellbaum, 1998) to disambiguate the sense of a token in a particular context.

SensEmBERT is a knowledge-based approach to WSD that produces high-quality sense embeddings. WordNet is a large lexical database that organizes words and their meanings into sets of interlinked synonyms called synsets.

We leverage part-of-speech (POS) tagging in order to determine which tokens in each question and answer are nouns we can determine the sense of. We employ the English version of the Stanford Log-Linear POS Tagger[2] (Toutanova et al., 2003) — which leverages dependency networks to aid in tagging tokens — in this work. For the purposes of our work, we only work with nouns — tokens whose tag begins with "NN".

[2] https://nlp.stanford.edu/software/tagger.shtml

3 System Overview

The following is a description of each approach we took in an attempt to solve the *Task*. We implemented a bag-of-words, language modelling, and a sense comparison approach. The language model at the core of all three of our approaches is `bert-large-cased` (Devlin et al., 2018), the same model leveraged by Scarlini et al. (2020) in the creation of SensEmBERT.

3.1 Bag of Words with WSD Approach

Our bag-of-words (BOW-WSD) model combines POS tagging with WSD to create a bag of words for the question and each possible answer. When presented with a question (q), the model creates a list containing the most prevalent sense for each noun in the question — q_senses — by leveraging Algorithm 1. Note; in this algorithm, it is necessary to concatenate the embedding of each noun to itself in order to match the format of the WordNet senses, allowing said WordNet senses to be compared to and leveraged. From q_senses, we create q_bag by removing all stop and duplicate words. Token order and context is preserved during the generation of q_senses but not for the creation of q_bag.

The process used to create q_bag is then repeated four times — once for each possible answer — creating five bags of words in total, one q_bag and an $answer\_bag$ for each of the four answers. Each $answer\_bag$ is compared to q_bag through an overlap calculation — the number of common tokens across both bags — shown in Equation 1. For example, if q_bag is "[hair, shave, beard, cut, trade]" and one of the $answer_bag$s is "[trade, cut, hair, someone]", the overlap score would be 0.667 — three overlapping tokens of nine possible tokens. The $answer\_bag$ with the highest overlap score is predicted to be the correct answer.

$$\text{avg\_overlap} = \frac{2 \cdot (|\text{bag1} \cap \text{bag2}|)}{(|\text{bag1}| + |\text{bag2}|)} \quad (1)$$

3.2 Language Modelling Approach

In the example shown in Table 1, the correct answer can be read as a natural continuation of the question — contrary to the other possible answers which do not make logical sense if appended onto the end of the question. We explore this intuition with our language modelling approach, which takes each answer, concatenates it to the end of the question, and calculate the probability of the text from

Question	Choices
Sentence Puzzle Example	
A man shaves everyday, yet keeps his beard long.	*He is a barber.* He wants to maintain his appearance. He wants his girlfriend to buy him a razor. None of the above.
Word Puzzle Example	
What part of London is in France?	*The letter N.* The letter O. The letter L. None of the above.

Table 1: An example of a sentence puzzle and a word puzzle from the BRAINTEASER dataset. The correct answer for each puzzle is in italics.

Algorithm 1: WordNet Sense Extraction

Input: Input sentence
Output: WordNet senses of nouns in the sentence
`bert-large-cased` tokenizes input
Perform POS tagging on tokenized input
$filtered\_nouns \leftarrow$ nouns from the POS tagging results
$final\_senses \leftarrow []$
for n *in* $filtered\_nouns$ **do**
    Concatenate the noun's token embedding to itself /* This format matches that of WordNet, permitting querying */
    Search WordNet for the most similar sense key using cosine similarity
    Use sense key to retrieve WordNet sense of n
    Append n_sense to $final\_senses$
Return $final\_senses$

each answer following the question using BERT (`bert-large-cased`)[3]. The predicted answer is the one associated with the largest probability.

3.3 Sense Comparison Approach

In this approach we leverage an unsupervised WSD model that makes predictions by comparing the senses of nouns. Once the primary sense of each noun in the question is identified, we utilize the `bert-large-cased` model to retrieve the embedding of the `[CLS]` token for each identified sense. This procedure is replicated for every potential answer, and the cosine similarity is employed to compute a similarity score for each pairing of `[CLS]` tokens between the senses of the question and those of each individual answer. Subsequently, these similarity scores are aggregated and averaged based on the number of senses being assessed in the current computations, both for the question and the answer. The predicted answer is the one with the highest average similarity score. Algorithm 2 outlines the steps this approach takes in further detail.

Beyond the data provided by the *Task* organizers, we leveraged the English stop words available through the NLTK Python library[4] (Bird et al., 2009), and the senses provided by WordNet[5] (Fellbaum, 1998).

4 Experimental Setup

As previously mentioned, we only use the test set in our experiments. Due to the unsupervised nature of

Algorithm 2: Sense Comparison

Input: question, list of four possible answers
Output: Predicted answer
$q\_senses \leftarrow$ WORDNETSENSEEXTRACTION(*question*)
$q\_CLS \leftarrow$ [embedding for $sense$ in q_senses] `// calculated by bert-large-cased`
$answers \leftarrow [choice_1, choice_2, choice_3, choice_4]$
$answer\_similarity \leftarrow []$
for a *in* $answers$ **do**
    $a\_senses \leftarrow$ WORDNETSENSEEXTRACTION(a)
    $a\_CLS \leftarrow$ [embedding for $sense$ in a_senses] `// calculated by bert-large-cased`
    $total\_similarity \leftarrow 0$;
    for $q\_CLS\_embedding$ *in* q_CLS **do**
        for $a\_CLS\_embedding$ *in* a_CLS **do**
            $similarity\_score \leftarrow$ COS_SIM$(q_CLS_embedding, a_CLS_embedding)$;
            $total\_similarity \leftarrow total\_similarity + similarity\_score$;
    $answer\_similarity[i] \leftarrow \frac{total\_similarity}{len(q\_CLS) \cdot len(a\_CLS)}$
$max\_index \leftarrow$ index of max element in answer_similarity
Return answers[max_index]

our approaches, the labels are not required to train our models as none of them had hyperparameters to tune.

4.1 Libraries used

Table 3 shows the Python libraries and their versions used for this *Task*. Python version 3.10.11 was used. The full `requirements.txt` file is available in our GitHub repository[6] for the project.

4.2 Evaluation Measures

The *Task* uses six metrics for both the sentence and word puzzles — 12 total — of metrics to evaluate a model's ability to solve brainteasers. The three different types of questions (original, semantic reconstruction, context reconstruction) were evaluated individually and in two groups. For a model to predict a sample in one of the groups (original and semantic reconstruction, original and semantic reconstruction and context reconstruction) correctly, all of the samples in said group must be predicted correctly.

5 Results

The performances of our models, the provided baseline models, and the best performing models submitted to this *Task* are found in Table 2.

Our BOW-WSD model (Section 3.1), the best performing of our three approaches, was able to surpass the RoBERTa-L baseline in 2 of 6 of the sentence puzzle categories, and outperforms the same baseline on 5 of 6 of the word puzzle categories. BOW-WSD outperforms or comes very close to outperforming the RoBERTa-L baseline in both "Overall" categories. The performance of our unsupervised models didn't approach the ChatGPT or Human baselines in any category. The closest our models got to the ChatGPT baseline was in the original word puzzle category with a difference of 0.155, whereas the closest our models got to the Human baseline was in the context sentence puzzle category with a difference of 0.469. The numbers achieved by our BOW-WSD model netted us 10^{th} place overall in the sentence puzzle subtask.

We suspect the relationship between the tokens in the question senses and the tokens in the correct answer's senses allowed our BOW-WSD model to outperform our other approaches. Using the sentence puzzle in Table 1 as an example, the WordNet sense of the noun "barber" (available below) from the correct answer has two tokens that overlap with the question, leading to this answer achieving a higher score than other nouns that don't overlap.

> a hairdresser who cuts hair and shaves beards as a trade

Our language modelling approach outperformed the RoBERTa-L baseline in 4 of 6 of the word puzzle categories, but did not perform well in any of

SC	.175	.200	.350	.175	.125	.242	.156	.063	.219	.063	.031	.146

Table 2: The accuracy scores achieved by our models (Bag-of-Words, Language Model, and Sense Comparison) on each sub-category of the test dataset. Approaches in gray are shown for comparison: the best scoring participant model for each individual category; the participant model that performed best in both the sentence and word puzzle subtasks; and the organizer's ChatGPT, RoBERTa-L, and Human baselines.

the sentence puzzle categories. We suspect that the way the word puzzles are structured lends more to the language modelling approach than the sentence puzzle structure as all the word puzzles in the test set are structured as questions — adding each answer to the end of the question can provide the language modelling approach with enough context to choose the correct answer. We believe the more succinct nature of the word puzzle problems allowed our language modelling technique to outperform our BOW-WSD model on 4 of 6 word puzzle categories, netting us 10^{th} place in the word puzzle subtask too.

Our sense comparison model unfortunately performed worse than all our models and the *Task* organizers' baselines. Our idea to leverage the senses of nouns in the sentences did not perform well when applied to this *Task*.

6 Conclusion

Whilst the best of our unsupervised models surpassed only one of the established baselines, we have been able to show that word sense disambiguation may have a place in riddle-solving models. Our BOW-WSD model performed better on the sentence puzzles, but our language modelling approach performed better on the word puzzle subtask. The inherent logical reasoning large language models obtain through the copious amount of training data they're trained on can be led astray by the information provided by a riddle. Leveraging word sense disambiguation we attempt to isolate the meaning of each noun and compare and contrast said meanings to those present in each possible answer.

In the future, we will explore other means of incorporating WSD models within our riddle-answering model along with an ensemble method. While our unsupervised approaches didn't perform well compared to other submitted models on the *Task* leaderboard, the senses of the nouns in each question and answer held information valuable enough to allow our models to surpass one of the three proposed baselines. Regarding our bag-of-words model, we will add a metric that penalizes an answer if the senses it displays are wildly different to those of the initial question. This penalty could reduce the impact red herrings typically found in riddles have on the BOW-WSD model's predictive abilities.

hinoki at SemEval-2024 Task 7: Numeral-Aware Headline Generation (English)

Hinoki Crum and **Steven Bethard**
School of Information
University of Arizona
{hinokicrum,bethard}@arizona.edu

Abstract

Numerical reasoning is challenging even for large pre-trained language models. We show that while T5 models are capable of generating relevant headlines with proper numerical values, they can also make mistakes in reading comprehension and miscalculate numerical values. To overcome these issues, we propose a two-step training process: first train models to read text and generate formal representations of calculations, then train models to read calculations and generate numerical values. On the SemEval 2024 Task 7 headline fill-in-the-blank task, our two-stage Flan-T5-based approach achieved 88% accuracy. On the headline generation task, our T5-based approach achieved RougeL of 0.390, BERT F1 Score of 0.453, and MoverScore of 0.587.

1 Introduction

Comprehension of numerical values can significantly enhance performance in certain tasks as numbers provide important information in words. Numerical values are particularly important in accounting and finance fields as the majority of data is in monetary terms. While words can be ambiguous, numbers provide clear and precise information. They not only represent exact numerical values, but can also indicate a magnitude of the subject matter, which can be critical to fully understand a text.

Despite the significance of numerical values, much natural language processing work has treated numerical words in the same manner as all other words, without any direct understanding of the values they represent. As a result, numerical reasoning is still challenging for natural language processing models, even the pre-trained language models that have been so successful on other natural language processing tasks.

NumEval (Chen et al., 2024) provides shared tasks that encourage research systems to generate headlines with accurate numeral information. We fine-tuned pre-trained models for two sub-tasks. In the first, models are required to compute the correct number to fill the blank in a news headline given the corresponding news article. In the second, models are required to construct an entire headline (including its numerical information) based on the provided news article.

2 Related Work

A Math Word Problem (MWP) consists of a short natural language narrative describing a state of the world and poses a question about some unknown quantities Patel et al. (2021). The MWP task is a type of semantic parsing task where given an MWP the goal is to generate an equation, which can then be evaluated to get the answer. The task is challenging because a machine needs to extract relevant information from natural language text as well as perform mathematical reasoning to solve it. Patel et al. (2021) proved in their paper that the existing models can rely on superficial patterns present in the narrative of the MWP and achieve high accuracy without even looking at the question.

Ran et al. (2019) proposed a numerical Machine Reading Comprehension model named NumNet, which utilizes a numerically-aware graph neural network to make numerical comparison and performs numerical reasoning over numbers in the question and passage. Their NumNet model achieved some numerical reasoning ability with Exact Match (EM) of 64.56 and numerically-focused F1 score of 67.97 on the test data. However, NumNet is not applicable when an intermediate number has to be derived in the reasoning process such as from arithmetic operation.

Geva et al. (2020) proposed a general method for injecting additional skills into Language Models, assuming automatic data generation is possible. They applied their approach to the task of numerical reasoning over text, using a general-purpose

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 34–39

model called GENBERT, and a simple framework for generating large amounts of synthetic examples. Their experiments demonstrated the effectiveness of their method, showing that GENBERT successfully learns the numerical skills, and performs on par with similarly sized state-of-the-art numerical reasoning over text models.

Petrak et al. (2023) proposed arithmetic-based pre-training that combines contrastive learning to improve the number representation, and a novel inferable number pre-training objective to improve numeracy. Their experiments showed performance improvements due to better numeracy in three different state-of-the-art pre-trained language models, BART, T5, and Flan-T5, across various tasks and domains, including reading comprehension, inference-on-tables, and table-to-text generation.

Peng et al. (2021) proposed a novel pre-trained model, namely MathBERT, which is the first pre-trained model for mathematical formula understanding. MathBERT was jointly trained with mathematical formulas and their corresponding contexts to evaluate three downstreamtasks, including mathematical information retrieval, formula topic classification and formula headline generation. Formula headline generation is a summarization task aiming to generate a concise math headline from a detailed math question which contains math formulas and descriptions. In addition, in order to further capture the semantic-level structural features of formulas, a new pre-training task is designed to predict the masked formula sub-structures extracted from the Operator Tree (OPT), which is the semantic structural representation of formulas.

3 Data

3.1 Subtask 1: Headline Fill-in-the-Blank

The training dataset (Huang et al., 2023) consists of 21,157 news articles with masked headlines and the validation dataset consists of 2,572 news articles with masked headlines. Both the training and validation datasets have four columns consisting of "news", "masked headline", "calculation" and "answer" as shown in Table 1. The numerical values which should be predicted in the masked headline are shown in underscores. The calculation column shows the operations required to get to the answers, such as copy, round, paraphrase, convert number words to numbers, and arithmetic operations. The calculation may also be a combination of multiple operations.

The test set consists of 4,921 news articles with masked headlines without the calculation and answer columns.

3.2 Subtask 2: Headline Generation

The training dataset consists of 21,157 news articles with unmasked headlines and the validation dataset consists of 2,365 news articles with headlines. The datasets for subtask 2 do not have the calculation column. The test dataset consists of 5,227 news articles.

4 Methodology

4.1 Models

We employed several different types of neural network models for these tasks.

DistilRoBERTa RoBERTa (Liu et al., 2019) is transformer network trained on 16GB of text with a masked language modeling objective, making it appropriate for fill-in-the-blank tasks like Subtask 1. RoBERTa follows the standard transformer formulation, using self-attention to process an input sequence and generate contextualized representations as the output sequence. DistilRoBERTa (Sanh et al., 2019) is a distilled version of the RoBERTa-base model.

T5-Headline-Pleban The Text-to-Text-Transfer-Transformer (T5) model is a transformer network trained on 750GB of text with a language modeling objective where multiple consecutive tokens are masked and the output is a sequence. Because T5 models are designed to produce a sequence, they are suitable for headline generation tasks like Subtask 2. T5-Headline-Pleban (Pleban, 2020) is a T5-base model that was further fine-tuned to predict headlines from articles using a collection of 500k articles.

T5-Title-Zearing (Zearing, 2022) is a T5-base model that was further fine-tuned to predict titles from articels using a collection of Medium articles.

Flan-T5-LaMini Flan-T5 is an enhanced version of T5 that has been finetuned on a mixture of tasks (Chung et al., 2022). LaMini-Flan-T5-783M is a fine-tuned version of google/flan-t5-large on the LaMini-instruction dataset that

news	masked headline	calculation	answer
(Apr 18, 2016 1:02 PM CDT) Ingrid Lyne, the Seattle mom allegedly murdered while on a date, left behind three daughters—and a GoFundMe campaign set up to help the girls has raised more than $222,000 so far, Us reports. A friend of the family set up the campaign, and says that all the money raised will go into a trust for the girls, who are ages 12, 10, and 7. Lyne's date was charged with her murder last week.	$____K Raised for Kids of Mom Dismembered on Date	Paraphrase(222,000,K)	222

Table 1: Sample Data for Subtask 1

contains 2.58M samples for instruction fine-tuning (Wu et al., 2023).

4.2 Subtask 1: Headline Fill-in-the-Blank

We trained three types of models for subtask 1.

4.2.1 DistilRoBERTa

To construct the input for DistilRoBERTa, we concatenated the news text, masked headline, and calculation columns. The underscores we replaced with DistilRoBERTa's mask token, and time stamps were removed. We then trained DistilRoBERTa to predict the answer given this input, using a learning rate of 5e-5. At prediction time, we took the top 20 highest probability vocabulary tokens predicted by the model for the mask token, and returned the first numerical value.

4.2.2 T5 One-Step

To construct the input for our one-step T5 and Flan-T5 models, we replaced the underscores in the masked headline with the token <extra_id_0> and concatenated it to the news text. Unlike DistilRoBERTa, we did not include the calculation in the input as we found it deteriorated model performance. We trained the two T5 models with a learning rate of 5e-5, and the Flan-T5 model with a learning rate of 2e-5. At prediction time, we found the index of the extra token in the model output and used that to extract the numerical value.

4.2.3 T5 Two-Step

As Patel et al. (2021) demonstrated, if models rely on shallow heuristics to solve the majority of math problems without word-order information or question text, instead of training the models to have them directly predict numerical values from question texts, it might be more beneficial to train them

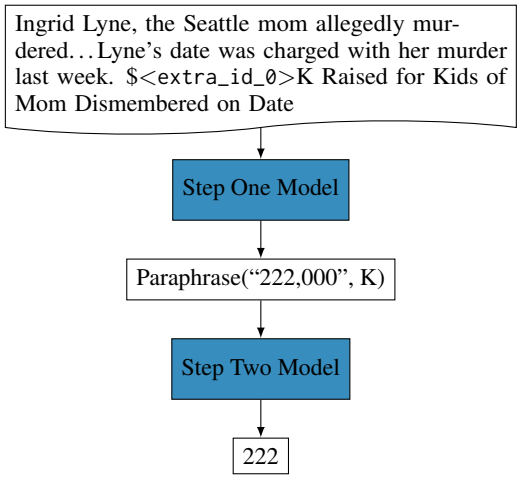

Figure 1: Two-step prediction for the headline fill-in-the-blank task.

to predict numerical values from formulas or calculation methods. Accordingly, we propose two-step models in which we constructed two training sets. For step one, we concatenated the news text and the masked headline as input, and used the calculation as output. For step two, we used the calculation as input, and the answer as output. We then trained two models, one on each dataset. At prediction time, we applied the step-one model to the concatenation of the news text and masked headline, then passed the output of the step-one model as the input to the step-two model, which then predicted the final answer. We used the same extra token processing and learning rates as in the T5 One-Step approach. This process is shown diagrammatically in Figure 1.

4.3 Subtask 2: Headline Generation

We trained T5 models with the news text as input and the headline as output. We prefixed the input

Data	Model	Before	After
Val	DistilRoBERTa	6.23	3.68
Val	T5-Headline-Pleban	2.66	1.05
Val	T5-Title-Zearing	2.14	1.05

Test	Flan-T5-LaMini	-	0.88
Test	GPT-3.5 baseline		0.74
Test	Best system		0.95

Table 3: Accuracy of models on the Headline Fill-in-the-Blank validation and test data

with a prompt "headline: " so T5 knows this is a headline generation task. Both T5 models were trained with the learning rate of 5e-5. We also tried Flan-T5, but results were similar to the other T5 models, so we focused our analysis on the headlines generated by the T5 models only.

5 Results and Evaluation

5.1 Subtask 1: Headline Fill-in-the Blank

One measure of the quality of a model is perplexity, defined as the exponential of the cross-entropy loss over the probabilities the model assigns to the next word in all the sentences of the test set. As shown on Table 2, perplexity decreased significantly for all models after training.

A more direct measure of the models in the headline fill-in-the-blank task is accuracy, counting the fraction of times that the model's prediction of a numeric value exactly matched the expected numeric value in the data. Table 3 shows accuracy of the different models on the validation data. Training in two steps did not improve the performance of T5-Headline-Pleban or T5-Title-Zearing, but did slightly improve performance of Flan-T5-LaMini. The final row of Table 3 shows that the best model, two-step Flan-T5-LaMini, achieved 88% accuracy on the test data.

We manually analyzed the errors of the models on the validation data. Errors often revolve around

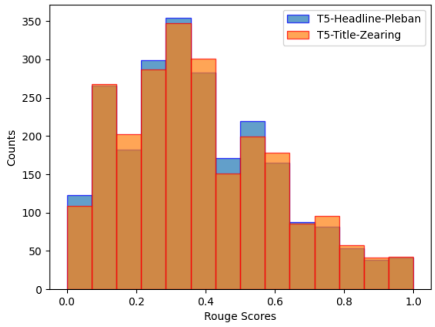

Figure 2: Rouge Scores of models on the Headline Generation validation data

arithmetic operations, rounding of decimal numbers, and the combination of operations. Table 4 shows examples of such errors.

While Patel et al. (2021) achieved about 65% accuracy from their best model, we achieved on the validation dataset the accuracy of 82% on predicting correct formulas while 88% on predicting correct numerical values from those formulas. We also noted that the accuracy on predicting right answers from correctly predicted formulas is 96%. This indicates that the models have no problem with making predictions from simple heuristics, which agrees with the findings by Patel et al.

5.2 Subtask 2: Headline Generation

We evaluated headline generation models based on how well their generated headlines matched the headlines in the data. We used two metrics, Recall-Oriented Understudy for Gisting Evaluation (ROUGE) and BERTScore. Both of these metrics measure the similarity between the predicted headlines and actual headlines, with the former relying on word n-grams and the latter relying on cosine similarity over contextualized embeddings derived from BERT (Mansuy, 2023). Figures 2 and 3 show the distribution of scores of the different T5 models over the validation data. The models are similar in terms of ROUGE score, but T5-Headline-Pleban performs slightly better than T5-Title-Zearing in terms of BERTScore.

We also used the official scoring script, producing the results shown in the first two rows of Table 5, where we see that T5-Title-Zearing is slightly better than T5-Headline-Pleban on the validation data for most measures. We thus submitted T5-Title-Zearing on the test set. The last row of Table 5 shows that it acheived 62.3% numerical accuracy

Actual	Predicted
Round(Divide(268,30),0)	Copy(9)
Round(1.29,0)	Span(a trillion)
Subtract(Sep 5,July 8)	Subtract(30,7)
Add(22,Trans(four))	Add(Trans(four),22)
Subtract(2014,1974)	Subtract(2018,1974)
Multiply(Trans(one-quarter),100)	Multiply(Divide(Trans(one-quarter),100)

Table 4: Examples of incorrect calculations generated by Flan-T5-LaMini on the Headline Fill-in-the-Blank data

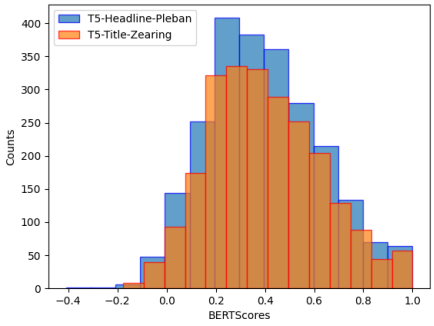

Figure 3: BERTScores of models on the Headline Generation validation data

on the test set with F1 scores of R1 of 43.1, R2 of 19.7 and RL of 40.0. MathBERT which trained with source texts, formulas and OPTs, achieved F1 scores of R1 of 61.25, R2 of 48.06 and RL of 57.72 on formula headline generation, which indicates that training the models with OPTs as inputs help improving the results.

We manually analyzed some of the errors of the models on the validation data. Table 6 shows examples of the headlines generated by T5 models. Items 1 and 2 show that both models properly included the numerical values and captured the meanings, but the expressions of the numerical values and the wordings are different. Several headlines were perfectly generated by T5-Headline-Pleban but not by T5-Title-Zearing, as in item 3, and vice versa, as in item 4. Item 5 is an example of perfect generations by both models. In item 6, a woman who offered a $25K reward for information on her husband's killer was arrested as the killer after 13 years. T5-Headline-Pleban properly captured the $25K reward, but failed to mention that she was the one who got arrested, while T5-Title-Zearing did the opposite. The predictions for item 7 made by both models are close to the actual headline, but the actual headline is designed to better draw attention and drive curiosity. For items 8 and 9, both T5 models failed to capture the appropriate numerical values. Item 10 is an example that both models failed to include any numerical value in the headlines.

6 Conclusion

T5 language models seem capable of generating meaningful headlines including appropriate numerical values. Although the models can reasonably compute the correct numbers from the provided news to fill the blank in headlines, they sometimes failed reading comprehension and arithmetic operations. In hope of overcoming those limitations, we trained them to generate the calculation methods first and then trained again with those calculations as inputs to predict the numerical values to fill the blank in the news headlines, but it did not significantly improve the results. In the future, we plan to try larger pre-trained models, which might improve performance. Also, the training datasets that we used are relatively small. If we increase the data size by data augmentation, we may be able to obtain better results.

T5-Medical at SemEval-2024 Task 2: Using T5 Medical Embeddings for Natural Language Inference on Clinical Trial Data

Marco Siino
Department of Electrical, Electronic
and Computer Engineering
University of Catania
Italy
marco.siino@unipa.it

Abstract

In this work, we address the challenge of identifying the inference relation between a plain language statement and Clinical Trial Reports (CTRs) by using a T5-large model embedding. The task, hosted at SemEval-2024, involves the use of the NLI4CT dataset (Jullien et al., 2023a). Each instance in the dataset has one or two CTRs, along with an annotation from domain experts, a section marker, a statement, and an entailment/contradiction label. The goal is to determine if a statement entails or contradicts the given information within a trial description. Our submission consists of a T5-large model pre-trained on the medical domain. Then, the pre-trained model embedding output provides the embedding representation of the text. Eventually, after a fine-tuning phase, the provided embeddings are used to determine the CTRs' and the statements' cosine similarity to perform the classification. On the official test set, our submitted approach is able to reach an F1 score of 0.63, and a faithfulness and consistency score of 0.30 and 0.50 respectively.

1 Introduction

In experimental medicine, clinical trials are essential because they verify the effectiveness and safety of novel treatments (Giaccone, 2002). Clinical Trial Reports (CTRs) are documents that describe the design and outcomes of a clinical trial and are used to direct patient interventions that are specific to them. But with over 400,000 published CTRs and more coming out each year (Bastian et al., 2010), it is not feasible to manually conduct thorough reviews of all the pertinent literature while developing new treatment procedures. For these reasons, the requirement for technologies that can automatically extract and classify information is always expanding.

With the development of machine and deep learning architectures in recent years, there has been a surge in interest in natural language processing, or NLP. Many efforts have gone into creating algorithms that can automatically identify and categorize text information that is accessible on the internet. In the literature, to perform text classification tasks, several strategies have already been proposed. In the last fifteen years, some of the most successful ones have been based on SVM (Colas and Brazdil, 2006; Croce et al., 2022), on Convolutional Neural Network (CNN) (Kim, 2014; Siino et al., 2021), on Graph Neural Network (GNN) (Lomonaco et al., 2022), on ensemble models (Miri et al., 2022; Siino et al., 2022) and, recently, on Transformers (Vaswani et al., 2017; Siino et al., 2022b).

For example, to address the CTR proposed task, and to enable a higher degree of accuracy and efficiency in individualized evidence-based treatment, Natural Language Inference (NLI) (MacCartney, 2009) provides a viable solution for the large-scale interpretation and retrieval of medical evidence (Sutton et al., 2020). SemEval-2024 Task 2 – Multi-Evidence Natural Language Inference for Clinical Trial Data (NLI4CT) (Jullien et al., 2024) – relies on the NLI4CT dataset[1]. The task is to determine the inference relation between a natural language statement, and a CTR. Inference chains in this drop-off range have to be constructed for a significant fraction of the NLI4CT dataset instances. Furthermore, inference on NLI4CT requires quantitative and numerical reasoning. Research has demonstrated that transformer-based models rely on flimsy heuristics for predictions instead of consistently applying this kind of reasoning (Helwe et al., 2021).

To develop our model, we thought of a two-stage architecture. In the first stage, we used a Sentence Transformer specifically trained on the medical domain. On the generated embeddings, we evaluated a cosine similarity to predict the entailment or con-

[1] https://github.com/ai-systems/nli4ct

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 40–46

tradiction relationship between the two sentences analyzed.

The remainder of the paper is structured as follows. We give some background information on Task 2 hosted at SemEval-2024 in Section 2. Section 3 offers an explanation of the submitted approach. We describe the experimental setup to reproduce our work in Section 4. The outcomes of the formal assignment and certain debates are given in Section 5. We provide our conclusion and suggestions for further research in section 6.

We make all the code publicly available and reusable on GitHub[2].

Figure 1: A sample from the official webpage. Given two trials and a section description, a model has to predict if there is entailment or contradiction with regard to the statement provided.

2 Background

We give some background information on Task 2 hosted at SemEval-2024 in this section. The task is predicated on a set of CTRs, statements, labels, and explanations related to breast cancer that have been annotated by domain experts.

The gathered CTRs are compiled into four components for the textual entailment task:

- *Eligibility criteria* — A list of requirements that patients must meet in order to participate in the clinical trial;
- *Intervention* — Details about the type, strength, frequency, and length of the treatments under investigation;
- *Results* — Units, outcome measures, number of trial participants, and results;
- *Adverse events* — These are the symptoms and indicators that the patients had throughout the clinical study.

With an average length of 19.5 tokens, the annotated statements are sentences that make a claim regarding the data presented in one of the CTR premise's sections. The remarks could compare two CTRs or make assertions about a single CTR. Finding the inference relation (entailment vs. contradiction) between CTR is the problem at hand. The training set provided is identical to the training set used in previous tasks (Jullien et al., 2023b), however, the organizers have performed a variety of interventions on the test set and development set statements, either preserving or inverting the entailment relations. The technical details adopted to perform the interventions were not disclosed, to guarantee fair competition and in the interest of encouraging approaches that are robust and not simply designed to tackle these interventions.

An example is shown in the Figure 1 and is provided in the official task webpage available online[3].

Even if it has already been proved that the Transformers are not necessarily the best option for any text classification task (Siino et al., 2022a), depending on the goal some strategies like domain-specific fine-tuning (Sun et al., 2019; Van Thin et al., 2023), or data augmentation (Lomonaco et al., 2023; Mangione et al., 2022; Siino et al., 2024a) can be beneficial for the considered task.

The training and practice test sets were made available by the task organizers prior to the competition's official commencement. The gold labels were supplied for both sets. Participants could build and test their models during the first phase, called the *practice phase*, by uploading their predictions to CodaLab[4]. The second step, known as the *evaluation phase*, began with the release of the unlabeled test set.

3 System Overview

The rising use of Transformer-based architectures in the literature, has been supported also by several approaches presented at SemEval 2024. These approaches address very different tasks, obtaining interesting results. For example, in the case of the Task 1, where the semantic textual relatedness is evaluated using MPNet (Siino, 2024a), or in the case of the Task 4, where a Mistral 7B model is used for detecting persuasion techniques in meme

[2] https://github.com/marco-siino/SemEval2024/tree/main/Task%202

[3] https://sites.google.com/view/nli4ct/semeval-2024/dataset-description

[4] https://codalab.lisn.upsaclay.fr/competitions/16190

(Siino, 2024c), or, eventually, as in the case of the Task 8, where a DistilBERT model is employed to detect machine-generated text (Siino, 2024b). To develop our model, we also take advantage from a Transformer architecture, creating a two-stage pipeline. In the first stage, we used a *Sentence Transformer* specifically trained on the medical domain. This is a Python framework to create cutting-edge sentence, text, and image embeddings. The initial work is described in (Reimers and Gurevych, 2019). More than 100 languages have sentences and text embeddings that can be computed using this method. Sentences with a similar meaning can subsequently be found by comparing these embeddings, for example, using cosine-similarity. Semantic search, paraphrase mining, and semantic textual similarity can all benefit from this. The framework offers a huge selection of pre-trained models suited for different tasks and is built on PyTorch and Transformers. Moreover, fine-tuning models is also feasible.

The model used as Sentence transformer is T5-large-medical, and it is available on *Hugging Face*[5]. The base model is T5 (Raffel et al., 2020). Specifically, sentences and paragraphs are mapped to a dense vector space of 768 dimensions. PyTorch was used to convert the TensorFlow model st5-large-1 to this one. While the TFHub model and this PyTorch model can provide somewhat different embeddings, they yield the same results when applied to the same benchmarks.

The model was used to map all the words present in the text to the domain-specific embedding. Following the embeddings of the primary section and the statement, the cosine similarity between the two was calculated. In the case of presence of a secondary section, the operation was also carried out between the secondary section and the statement. The cosine similarity between the two embedding vectors is calculated as shown in the Equation 1.

$$\cos(\theta) = \frac{A \cdot B}{\|A\|_2 \|B\|_2} \tag{1}$$

In the first case, if the cosine similarity was greater than 0.5, the label of entailment was assigned, vice versa that of contradiction. In the second case, before calculating the cosine similarity, the average between the cosine similarity score between the two sections and the statement was calculated. Our code is available online together with the predictions generated and sent in relation to the test set.

As noted in the recent study by (Siino et al., 2024b), the contribution of preprocessing for text classification tasks is generally not impactful when using Transformers. More specifically, the best combination of preprocessing strategies does not provide relevant improvements compared to not performing any preprocessing when using Transformers. For these reasons, and to keep our system faster and computationally light, we have not performed any preprocessing on the text.

4 Experimental Setup

We implemented our model on Google Colab[6]. The library we used is Sentence Transformer. The library requires Python[7] (>= 3.8) and PyTorch[8] (>=1.11.0). The dataset provided for all the phases are available on the Official Competition page. On the basis of our preliminary experiments, we found beneficial to set the threshold value for the cosine similarity equal to 0.5. We did perform additional fine-tuning on the T5 embedding. To run the experiment, a T4 GPU from Google has been used. After the generation of the predictions, we exported the results on the JSON format required by the organizers. As already mentioned, all of our code is available on GitHub.

5 Results

For the task the official metric used were F1 (also known as balanced F-score or F-measure), Faithfulness and Consistency.

The F1 score can be described as the harmonic mean of the precision and recall, with a maximum score of 1 and a minimum score of 0. Recall and precision both contribute equally to the F1 score in terms of relative importance. Equation 2 shows the formula for the F1 score.

$$F1 = 2 * \frac{Precision * Recall}{Precision + Recall} \tag{2}$$

Faithfulness is a measure of the extent to which a given system arrives at the correct prediction for the correct reason. Intuitively, this is estimated by measuring the ability of a model to correctly change its predictions when exposed to a semantic-altering intervention. Given N statements x_i in the

[5] https://huggingface.co/sentence-transformers/sentence-t5-large

[6] https://colab.research.google.com/

[7] https://www.python.org/

[8] https://pytorch.org/

	F1	Faith	Const
T5-large-medical	0.63	0.30	0.50

Table 1: The suggested method's performance on the test set. In the table, the words *Faith* and *Const* stand out for *Faithfulness* and *Consistency*

contrast set (C), their respective original statements y_i, and model predictions *f()* faithfulness can be computed using Equation 3.

$$Faithfulness = \frac{1}{N}\sum_{n=1}^{N} |f(y_i) - f(x_i)| \quad (3)$$

Consistency is a measure of the extent to which a given system produces the same outputs for semantically equivalent problems. Therefore, consistency is measured as the ability of a system to predict the same label for original statements and contrast statements for semantic preserving interventions. That is, even if the final prediction is incorrect, the representation of the semantic phenomena is consistent across the statements. Given N statements x_i in the contrast set (C), their respective original statements y_i, and model predictions *f()* we compute consistency using Equation 4.

$$Consistency = \frac{1}{N}\sum_{n=1}^{N} 1 - |f(y_i) - f(x_i)| \quad (4)$$

In Table 1, the results obtained using the three metrics on the official test set are shown. Considered the very low effort required to run the proposed approach and to generate the predictions, the F1 score of 0.63 appears to be an interesting baseline, while consistency and faithfulness exhibit a very large room for improvements using the proposed approach. It is worth noticing that the approach is a Zero-Shot one with no prior knowledge on the specific task.

In the Table 2, the results obtained by the first three teams and by the last one, as showed on the official CodaLab page, are reported. Compared to the best performing models, our simple approach exhibits some room for improvements. However, it is worth notice that our proposed approach do not require any further pre-training and the computational cost to address the task is manageable with the free online resources offered by Google Colab. We performed few interventions to assess the setup

	F1	Faith	Const
dodoodo (1)	0.78	0.92	0.81
aryopg (2)	0.78	0.95	0.78
jvl (3)	0.78	0.80	0.77
MJ2301 (32)	0.47	0.44	0.47

Table 2: Comparing performance on the test set. In the table are shown the results obtained by the first three users and by the last one. In parentheses is reported the position in the official ranking.

of our approach. For example, we evaluated the number of the epochs to use for fine-tuning the Transformer embedding, the number of warm up steps and the train loss to use. All the details that led our model to reach its final performance, can be deducted from our code available on GitHub.

6 Conclusion

This paper presents the application of T5-large model embedding for addressing the Task 2 at SemEval-2024. For our submission we decided to follow an easy Zero-Shot learning approach, employing as-is, an in-domain pre-trained Transformer. After getting the contextual embedding provided by the Sentence Transformer, we made use of a cosine similarity to calculate the similarity between sentences and generate the entailment/contradiction labels. The task is challenging, and there is still opportunity for improvement, as can be noted looking at the final ranking. Possible alternative approaches include utilizing the zero-shot capabilities of models like GPT, increasing the size of the training set by using further data, or directly integrating ontology-based domain knowledge differently than what has been proposed in our work. To assess the effect of biomedical pre-training on MLMs, performance consistency between sections, generalization capacity of models trained on NLI4CT, performance comparability between numerical and biomedical cases and further error analysis is required. Furthermore, given the interesting results recently provided on a plethora of tasks, also few-shot learning (Wang et al., 2023; Maia et al., 2024; Siino et al., 2023; Meng et al., 2024) or data augmentation strategies (Muftie and Haris, 2023; Tapia-Téllez and Escalante, 2020; Siino and Tinnirello, 2023) could be employed to improve the performance. Eventually, an optimal threshold learnt from the validation dataset could be also employed in future works, in place of the

fixed one that we used in this study. Compared to the best performing models, our simple approach exhibits some room for improvements. However, it is worth to notice that the proposed approach required no further pre-training and the computational cost to address the task is manageable with the free online resources offered by Google Colab.

Abstract

Large language models (LLMs) have demonstrated remarkable capabilities in pushing the boundaries of natural language understanding. Nevertheless, the majority of existing open-source LLMs still fall short of meeting satisfactory standards when it comes to addressing numerical problems, especially as the enhancement of their numerical capabilities heavily relies on extensive data. To bridge the gap, we aim to improve the numerical understanding of LLMs by means of efficient data alignment, utilizing only a limited amount of necessary data. Specifically, we first use a data discovery strategy to obtain the most effective portion of numerical data from large datasets. Then, self-augment is performed to maximize the potential of the training samples. Thirdly, answers of all training samples are aligned based on some simple rules. Finally, our method achieves the first place in the competition, offering new insights and methodologies for numerical understanding research in LLMs.

1 Introduction

In recent years, the field of Natural Language Processing (NLP) has witnessed remarkable advancements, particularly with the advent of generative large language models (Jiang et al., 2023; Bai et al., 2023; Yang et al., 2023; Brown et al., 2020). These models have predominantly focused on textual data, demonstrating impressive capabilities in understanding and generating human-like text. However, an often-overlooked aspect of these developments is the nuanced role that numerical data plays in fully grasping the semantics of language. This oversight becomes particularly glaring in specialized fields such as stock market analysis, medical diagnostics, and legal decisions (Cortis et al., 2017; Modi et al., 2023; Jullien et al., 2023). In these domains, subtle numerical differences can have far-reaching implications, significantly affecting outcomes and decisions. Thus, the ability to understand and work with numbers, in these contexts underscores a critical gap in the semantic understanding capabilities of current language models.

Acknowledging this deficiency, there has been a growing interest within the NLP community towards enhancing the textual numeracy and computational abilities (Huang et al., 2023) of language models. This burgeoning interest has culminated in the introduction of SemEval2024's Shared Task 7. This innovative task is strategically designed to elevate the standards in the field by promoting the development of models that excel not only in literacy but also in computational skills. Such models promise to significantly boost usefulness and efficiency across a wide array of applications, ranging from automated financial analysis to predictive healthcare diagnostics and beyond.

However, the enhancement of numerical capabilities of LLMs heavily relies on the inclusion of a large amount of data, posing two significant challenges. On one hand, obtaining high-quality numerical annotated data is costly, as it requires significant economic costs and manual effort from professional annotators. On the other hand, the extensive use of as much data as possible to train the model can diminish the utility of high-value data and lead to increased computational consumption.

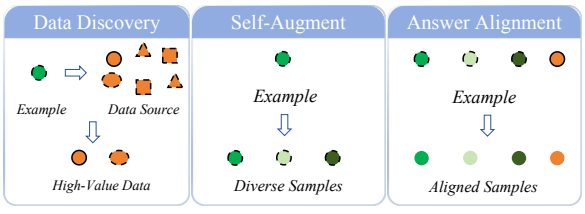

Figure 1: Pipeline of our system in this task.

As illustrated in Figure 1, this paper focuses on how to efficiently use a limited amount of data to

*Equal Contribution.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 47–52
June 20-21, 2024

improve the numerical capabilities of LLMs. Our goal is to enhance the model's performance in numeral while minimizing costs, such as data annotation expenses and computational requirements for model training. Our method propose effective data alignment by employing strategies of data discovery, self-augment and answer alignment. The contributions are summarized as follows:

- A strategy of data discovery is proposed to extract numerical training samples, obtaining the most effective portion of numerical data from datasets and minimizing training costs.
- We implement original self-augment to all the training samples to maximize their effectiveness in enhancing the numerical capabilities of LLM.
- We align answers of all training samples according some customized rules to improve LLM's numerical reasoning performance and shorten the reasoning path.

After conducting numerous experiments and iterating on our strategies, we are proud to announce that we have secured the championship title at the competition of SemEval-2024 Task 7. Detailed ablation study and analysis of our method are also provided in this paper to identify contributions from individual components and facilitate future research.

2 Background

GPT-3 (Brown et al., 2020) marked significant progress in large language models, enhancing few-shot learning and demonstrating robustness across diverse NLP datasets. Bai et al. (Bai et al., 2023) developed the qwen model, notable for its performance in various tasks, particularly its chat model refined through human feedback. However, these models largely focus on textual data, paying limited attention to the importance of numerical values in semantic understanding.

Addressing this, the NumHG (Huang et al., 2023) dataset was introduced, focusing on generating news headlines with numerical information. Evaluations of high-performing models indicated room for improvement in numerical accuracy, aiming to advance research in numerically-focused headline generation and improve task performance.

Additionally, learning Mathematical Reasoning for tasks like GSM8K (Cobbe et al., 2021) and MetaMATH (Yu et al., 2023) remains a significant challenge for LLMs. Enhancing LLM reasoning through augmented output sequences (Wei et al., 2022) has been explored, with methods like Complexity-based CoT (Fu et al., 2022) showing that increased in-context steps can improve performance. Self-Consistency approaches (Wang et al., 2022) use multiple reasoning paths and majority voting to select answers. Other works leverage closed-source LLMs (Brown et al., 2020) for knowledge distillation (Magister et al., 2022), while some apply rejection sampling for better reasoning (Yuan et al., 2023). Techniques like the reinforced evol-instruct method (Luo et al., 2023) and constraint alignment loss for calibration (Wang et al., 2023) also contribute to the advancement of LLMs in mathematical reasoning.

Building on these developments, our work introduces a novel approach to refine LLMs' numerical reasoning capability. We fine-tune our base model with a curated selection of numerically samples, focusing on diversity and efficiency to cover a broader range of mathematical concepts.

3 System Overview

In this section, we will introduce our proposed method from several aspects. We start with data analysis of SemEval-2024 Task 7. Then, we present the proposed data discovery, self-augment and alignment strategies.

3.1 Data Analysis

The competition dataset, NumHG, provided news articles with headlines, where the task involved identifying masked numerical values in the headlines and explaining the calculations behind these numbers. Each data sample from NumHG comprises four elements: News, masked headline, calculation, and answer. As shown in Table 1, we conducted an analysis of the mathematical processing utilized in each data sample, and discovered the following: (1) Most answers can be directly copied from the text, indicating that these numerical values are explicitly mentioned. (2) Additionally, a portion of the answers required converting textual descriptions into numerical forms, involving text understanding and translation. (3) Simple mathematical operations, such as basic arithmetic and rounding, are also involved in a small subset of the dataset, demanding LLM to perform context-based mathematical operations.

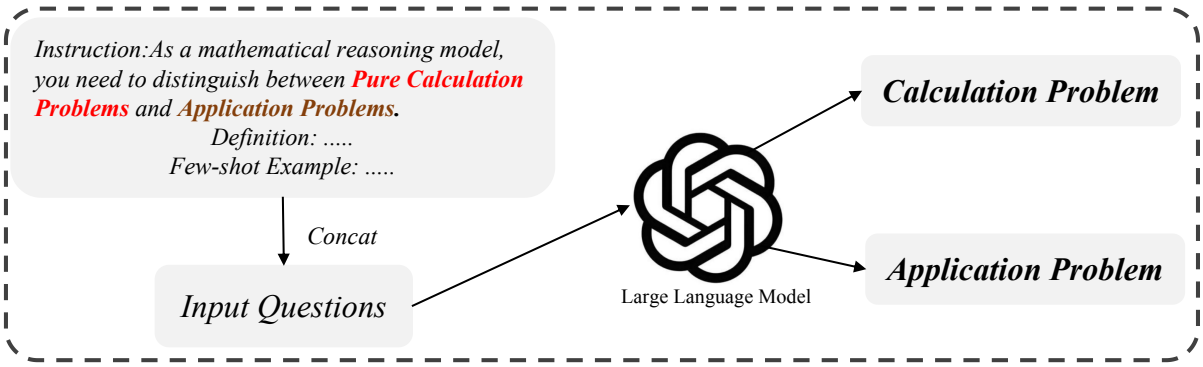

Figure 2: Data Discovery: Demonstrates the selection and integration of applicable problems from GSM8K and MetaMathQA datasets into the training set.

Example 3.1 Application Problem

At Rosa's Rose Shop, a bouquet containing a dozen roses costs $\$20$. If the price of a bouquet is directly proportional to the number of roses it contains, A bouquet of ____ roses will cost 65 dollars. What is the value of unknown variable ____?

Example 3.2 Pure Calculation Problem

Factor completely: $x^6 - 3x^4 + 3x^2 - ____$. The answer is 3. What is the value of unknown variable ____?

What is the value of ____ \times (7 - 5) - 5$? The answer is 1. What is the value of unknown variable ____?

Figure 3: Example of mathematical application problems and pure calculation problems in our dataset.

Table 1: Analysis on mathematical processing in the NumHG dataset.

Mathematical Processing Type	Count
Copy	15998
Trans	4111
Paraphrase	1727
Round	716
Subtract	496
Add	408
Span	104
Multiply	81
Divide	51
SRound	37

The above analysis reveals that the dataset and task possess distinct characteristics (e.g., emphasize understanding numbers within text rather than solving complex mathematical problems), suggesting that limited relevant data could potentially aid in enhancing performance. Furthermore, the high similarity among samples in this dataset underscores the importance of effective data augmentation and alignment strategies to maximize the utility of training samples.

To undertake the aforementioned investigation, we employed Qwen-Chat (Bai et al., 2023) as our base model, setting the input as a concatenation of news and masked headline, and output as a combination of calculation and answer to compile our training set. We crafted a preset prompt, *You are a numerical reasoning model. Please compute the correct number to fill the blank in a news headline.*, to utilize the inherent command-following ability of the LLM.

3.2 Data Discovery

As mentioned previously, we advocate for extracting a limited yet most effective subset of the dataset to enhance model performance. Specifically, we utilized the GSM8K and MetaMathQA datasets as the complementary source of external training data.

It is noted that, deviating from standard math tasks, the NumHG dataset focuses on understanding numerical semantics rather than complex calculations, primarily involving basic arithmetic and sourced from real news. Thus, we first integrated the GSM8K samples and selectively utilized MetaMathQA samples relevant to variable X to form a new collection of numerical samples, matching the competition's focus on masked numbers. Then, incorporating the analysis of both the NumHG dataset and general mathematical datasets (i.e., GSM8K and MetaMathQA), we have defined all mathematical samples into two categories: addressing mathematical application problems and pure

calculation problems. Specifically, we utilized a large language model's few-shot learning to classify the collected samples. We initially crafted several examples for each problem type as input to guide the mode, which covered a broad spectrum of scenarios to enrich the model's adaptability. Secondly, we instructed the model to distinguish between the given samples, categorizing them as either application or pure calculation problems, as illustrated in Figure 2.

Figure 3 shows examples of mathematical application problems and pure calculation problems. Ultimately, we rely on the model's output to determine the category of the input questions. We found that around 78% of GSM8K questions are application-based, versus 23% in MetaMathQA, aiding our understanding of each dataset's distribution and shaping our data Strategies. Finally, instead of using all external samples, we only retained the numerical-based and application problem samples as supplementary training data. This allows us to maximize the improvement in model performance using as little data as possible.

3.3 Data Self-Augment

Given the high similarity among samples in the NumHG dataset, we try to improve the diversity of samples and the difficulty of the task through data augmentation. Inspired by strategies from the visual domain (Jo and Yu, 2021), we introduced sentence-level random shuffling as a data self-augment strategy, as shown in figure 4. Our goal is to generate structurally diverse training samples while preserving the core information of texts. After reshuffling sentences within each training sample, the LLM continues to perform the original task of filling numerical values across structurally varied texts.

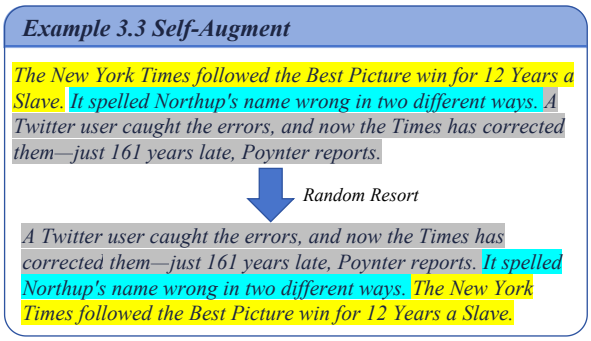

Figure 4: Self-Augment Strategy: sentence-level random shuffling to increase sample diversity while preserving key numerical information.

Although this strategy may disrupt the coherence between sentences within each sample, our experiments have found that it effectively improved the model's ability to handle mathematical problems in more complex contexts.

3.4 Answer Alignment

Adhering to the shared task submission system, the model's output should be a string convertible to a numerical value, devoid of computational methods and descriptive characters. Incorporating the requirements above, we further devised a strategy to simplify the model's output, enhancing model's numerical reasoning performance and shorten the reasoning path. Another reason for implementing this strategy was to ensure data consistency without compromising performance, given the unique characteristics of the competition's computational expressions such as 'Copy and Add'.

Hence, for all samples (i.e., from NumHG, GSM8K and MetaMathQA), we employed regular expressions to directly extract the numerical value as the output for training. Figure 5 shows some example from NumHG. Additionally, this strategy reduced cognitive inference time on 4,921 test instances by eliminating complex computational steps, offering a more direct feedback path.

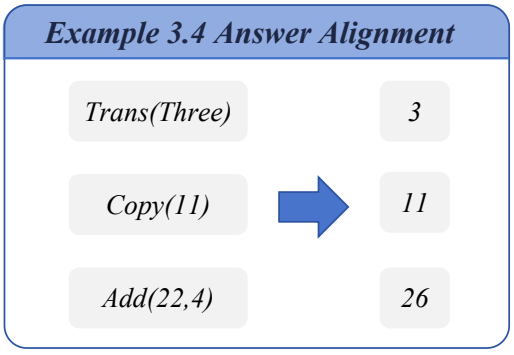

Figure 5: Examples of aligning answers in NumHG, simplifying the model's inference path.

4 Experimental Setup

We utilized the Qwen-72B-Chat model as our base model, on which we performed full parameter fine-tuning. The experiments were conducted on Nvidia A800 GPU with 80GB of memory. During training, we set the maximum token length to 2048, batch size to 8, and performed gradient accumulation every step. An initial learning rate of 5e-6 was set, employing a cosine decay strategy, for a total

of 3 epochs of training. All samples processed by our strategies were used as training data, while the validation set of NumHG were utilized for error analysis. For inference, we employed the default inference parameters.

5 Results

5.1 Final Result

Team	Private Score	Public Score
CTYUN-AI	0.95	0.94

Table 2: Competition results of our team.

At the NumEval-2024 Task 7, the public and private scores were derived from 20% and 80% of the test set data, respectively. In the final standings among all teams, we secured the first place with a private score of 0.95, as shown in Table 2.

This achievement highlights the effectiveness of our method, especially in the more heavily weighted portion of the test set.

5.2 Ablation Study

We took ablation studies to confirm each strategy's (i.e., Data Discovery, Self-Augment, and Answer Alignment) contribution to our final method's success. As shown in Table 3, data discovery, self-augment, and answer alignment brought performance gains of 2%, 4%, 2% separately. Finally, we achieved a 9% performance increase over the baseline in total, underscoring the significance of our approach against high benchmarks.

Method	Private Score	Public Score
Base Data	0.86	0.87
Base Data w/ Prompt	0.87	0.88
+ Data Discovery	0.89	0.88
+ Self-Augment	0.93	0.91
+ Answer Alignment	0.95	0.94

Table 3: Ablation study on our method.

Meanwhile, we evaluated the impact of using samples for mathematical application versus pure calculation problems during data discovery, as shown in Table 4. Findings show application-type problems improve model performance by enhancing real-world numerical understanding, while pure calculation samples negatively affect it due to their complexity leading to intricate computations.

Method Type	Method	Private Score	Public Score
Base Data	w/o Prompt	0.86	0.87
	w/ Prompt	0.87	0.88
w/ Data Discovery	Pure Calculation	0.87	0.87 (-0.01)
	Application	0.89 (+0.02)	0.88

Table 4: Ablation study on data discovery and fusion.

5.3 Error Analysis

In analyzing error cases, we discovered that rounding could lead to misunderstandings in numerical comprehension. For instance, one example states: *"...Nielsen numbers show that 31.1 million people,..."* hence the answer to the question *"____M Watched Jackson Memorial"* should be 31.1, yet the model predicted 31. This indicates that the model's rounding may lead to incorrect answers.

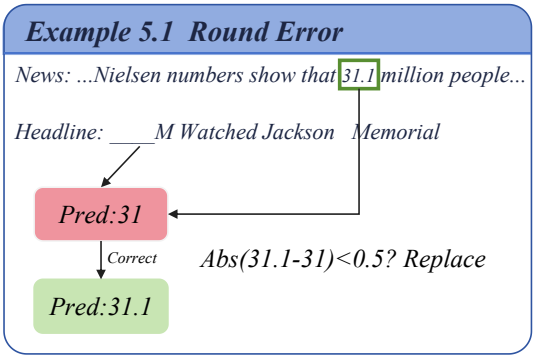

Figure 6: A rounding error case and we introduce a post-processing strategy for it.

As shown in Figure 6, we implemented a post-processing strategy to correct rounding errors. This involves extracting all numbers from the text, comparing them with the model's prediction, and adjusting predictions within a 0.5 difference to the nearest number. This method enhanced our test set performance to 0.95, although it was not included in the competition submission.

6 Conclusion

In this work, we have demonstrated an approach to enhance numerical understanding in large language models (LLMs) using limited data through effective data alignment. Our method integrated data discovery, self-augment, and answer alignment strategies, and significantly improved the model's performance on numerical reasoning tasks. Our success in SemEval-2024 Task 7 highlights the potential of our method in advancing natural language processing, particularly for enhancing the various basic capabilities of large language models.

McRock at SemEval-2024 Task 4: Mistral 7B for Multilingual Detection of Persuasion Techniques in Memes

Marco Siino
Department of Electrical, Electronic
and Computer Engineering
University of Catania
Italy
marco.siino@unipa.it

Abstract

One of the most widely used content types in internet misinformation campaigns is memes. Since they can readily reach a big number of users on social media sites, they are most successful there. Memes used in a disinformation campaign include a variety of rhetorical and psychological strategies, including smearing, name-calling, and causal oversimplification, to achieve their goal of influencing users. The shared task's objective is to develop models for recognizing these strategies solely in a meme's textual content (Subtask 1) and in a multimodal context where both the textual and visual material must be analysed simultaneously (Subtasks two and three). In this paper, we discuss the application of a Mistral 7B model to address the Subtask one in English about finding the persuasive strategy that a meme employs from a hierarchy of twenty based just on its textual content. Only a portion of the reward is awarded if the technique's ancestor node is chosen. This classification issue is multilabel hierarchical. Our approach based on the use of a Mistral 7B model obtains a Hierarchical F1 of 0.42 a Hierarchical Precision of 0.30 and a Hierarchical Recall of 0.71. Our selected approach is able to outperform the baseline provided for the competition.

1 Introduction

When information is intentionally crafted to serve a predetermined agenda, we often classify it as propaganda (Geissler et al., 2023). Propaganda employs various psychological and rhetorical strategies to achieve its goals (Çakmak, 2023). These methods encompass the utilization of logical fallacies and the manipulation of audience emotions (Soares et al., 2023). Logical fallacies can be particularly deceptive as they may initially appear sound and impartial, yet upon closer examination, it becomes evident that the conclusion cannot be logically derived from the premises. Another tactic involves employing emotionally charged language to sway the audience's opinion, bypassing rational analysis in favour of an emotional connection. Memes, typically comprising images overlaid with text, serve as a platform for propagandistic dissemination. Within deceptive memes, images either reinforce or complement textual techniques, or they themselves convey persuasive strategies.

To address these objectives, there is an ongoing demand for automated tools capable of extracting and categorizing data from online sources, facilitating the response to both established and emerging societal concerns. Recent advancements in machine and deep learning architectures have spurred heightened interest in Natural Language Processing (NLP). Substantial endeavours have been directed towards devising techniques for the automated identification and categorization of textual content accessible on the internet today. In the literature, to perform text classification tasks, several strategies have already been proposed. In the last fifteen years, some of the most successful strategies have been based on SVM (Colas and Brazdil, 2006; Croce et al., 2022), on Convolutional Neural Network (CNN) (Kim, 2014; Siino et al., 2021), on Graph Neural Network (GNN) (Lomonaco et al., 2022), on ensemble models (Miri et al., 2022; Siino et al., 2022) and, recently, on Transformers (Vaswani et al., 2017; Siino et al., 2022b).

The surge in the adoption of Transformer-based architectures within academic research has been further propelled by diverse methodologies showcased at SemEval 2024. These methodologies address a range of tasks and yield notable outcomes. For instance, in Task 2 (Jullien et al., 2024), T5 is utilized to confront the challenge of identifying the inference relation between plain language statements and Clinical Trial Reports (Siino, 2024b). In Task 10, a Mistral 7B model is employed to perform emotion Recognition in Conversation (ERC) within Hindi-English code-mixed conversations

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 53–59

(Siino, 2024c). Additionally, in Task 8 (Wang et al., 2024), a DistilBERT model is leveraged to identify machine-generated text (Siino, 2024a).

Finally, for the Task 4 at SemEval 2024 (Dimitrov et al., 2024) – Multilingual Detection of Persuasion Techniques in Memes – three Subtasks were proposed. As already stated, in a disinformation campaign, memes effectively manipulate users through various rhetorical and psychological strategies, including causal oversimplification, name-calling, and smear tactics. The objective of this shared task is to develop models capable of detecting these techniques within the textual content of memes alone (Subtask 1), as well as within a multimodal framework where both textual and visual elements are analysed jointly (Subtasks 2 and 3). To face with the first Subtask in English, we proposed a Transformer-based approach which made use of Mistral 7B (Jiang et al., 2023). We used the model in a particular few-shot way described in the rest of this paper. Specifically, we provided the definitions of the 20 techniques to the model to identify, given each sample, all the techniques detected. We opted for Mistral 7B because the comparative analysis between Mistral 7B and other leading models, namely Llama 2 and Llama 1, reveals noteworthy advancements in common NLP tasks. Across multiple benchmark evaluations, Mistral 7B consistently exhibits superior performance in comparison to Llama 2, a prominent open 13B model. Moreover, its efficacy extends beyond mere parity with, but rather exceeds, the achievements of Llama 1, a state-of-the-art 34B model, particularly in tasks pertaining to reasoning, mathematics, and code generation. These findings underscore Mistral 7B's substantive contributions to the advancement of NLP, suggesting its potential as a benchmark model in the field.

The rest of the paper is made as follows. In Section 2 we provide some background on the Task 4 hosted at SemEval 2024. In Section 3 we provide a description of the models presented. In Section 4 we provide details about the experimental setup to replicate our work. In Section 5, the results of the official task and some discussions are provided. In section 6 we present our conclusion and proposals for future works.

We make all the code publicly available and reusable on GitHub[1].

2 Background

This section furnishes background information regarding Task 4 (Subtask 1), held at SemEval 2024. The task entails identifying, based solely on the textual content of a meme, which of the 20 persuasion techniques, organized hierarchically, are employed. The selection of an ancestor node of a technique warrants only partial reward. The task thus presents a hierarchical, multilabel classification challenge. The hierarchical structure is illustrated in the official task's page, with 22 techniques depicted, although "Transfer" and "Appeal to Strong Emotion" are excluded from Subtask 1. For comprehensive details, please refer to provided resources.

For all Subtasks, the annotations from the PTC corpus, comprising over 20,000 sentences, were utilized where feasible. Although the corpus pertains to news articles, annotations adhere to identical guidelines, albeit with fewer techniques considered. As highlighted by the task coordinators, certain meme content may be deemed offensive or excessively potent by certain audiences. A similar multilingual corpus was also accessible during SemEval 2023 (Piskorski et al., 2023). Here again, the corpus revolves around news articles across nine languages, yet the number of techniques and annotation guidelines differ marginally. A training set for local system development was additionally provided. Furthermore, the organizers furnished a development set and a public leaderboard for real-time result sharing among task participants. Ultimately, the organizers supplied a test set devoid of annotations and an online submission platform to evaluate the system performance.

Subtask 1 relies on the textual content extracted from memes as input data. Training, development, and test sets for all Subtasks are disseminated as JSON files, with each Subtask having its own individual file. For Subtasks 2a and 2b, in addition to the meme's textual content, input data includes the meme's image. In the Figure 1, is reported a sample from the official competition website[2].

Given the Figure 1:

- *ID* consists of a unique identifier of the example across all the Subtasks;
- *text* represents the textual expression within the meme, formatted as a singular UTF-8

[2] https://propaganda.math.unipd.it/semeval2024task4/

Subtask 1

The entry for that example in the json file for subtask 1 is

```
{
        "id": "125",
        "text": "I HATE TRUMP\n\nMOST TERRORIST DO",
        "labels": [
                "Loaded Language",
                "Name calling/Labeling"
],
"link": "https://..."
},
```

Figure 1: An example from the dataset. In this case, two labels are assigned to the sample's text.

string. Initially, this text is automatically extracted from the meme, subsequently undergoing manual post-processing to rectify errors and arrange it such that each sentence occupies a distinct row. Furthermore, segments of text originating from distinct regions within the image are demarcated by blank rows. Notably, Task 1 qualifies as an NLP endeavour, given that image input is absent;

- *labels* denotes a compilation of permissible technique names identified within the text. These labels serve as the gold standard and will solely be furnished for the training set. In this particular instance, two techniques were identified: "Loaded Language" and "Name calling/Labelling."

3 System Overview

Even if it has already been proved that the Transformers are not necessarily the best option for any text classification task (Siino et al., 2022a), depending on the goal some strategies like domain-specific fine-tuning (Sun et al., 2019; Van Thin et al., 2023), or data augmentation (Lomonaco et al., 2023; Mangione et al., 2022) can be beneficial in several applications.

Our approach is a few-shot one (Littenberg-Tobias et al., 2022) and make use of the above-mentioned Mistral 7B. Mistral 7B, a language model equipped with 7 billion parameters, is designed to excel in both performance and efficiency. Compared to the leading open 13B model (Llama 2), Mistral 7B demonstrates superior performance across all evaluated benchmarks. Moreover, it outperforms the top released 34B model (Llama 1) in tasks related to reasoning, mathematics, and code generation. The model leverages grouped-query attention (GQA) to expedite inference, along with sliding window attention (SWA) to efficiently process sequences of varying lengths while minimizing inference costs. Additionally, a fine-tuned variant, Mistral 7B – Instruct, tailored for adhering to instructions, surpasses the Llama 2 13B – chat model across both human and automated benchmarks. The introduction of Mistral 7B Instruct underscores the ease with which the base model can be fine-tuned to achieve notable performance enhancements. Notably, this variant lacks any moderation mechanisms. The Mistral 7B Instruct variant requires a specific input format, as stated below:

> <s>[INST] Instruction [/INST] Model answer</s>[INST] Follow-up instruction [/INST]

Instruction, along with the following *Model answer*, can be a single sample with the related label or a set of sample/label pairs (realizing, in this case, a few-shot use of the model). Then, *Follow-up instruction* is the current sample for which the prediction has to be provided by the model. More specifically, given the 20 persuasion techniques in memes, we have prepared a text string containing the techniques and their definitions to provide context in the template ready. The definitions of the 20 techniques are provided by the task organizers[3]. At this point, the full text containing the twenty definitions plus the sample to be classified were provided as prompt to Mistral.

Then the question provided as prompt to mistral was: *"Given the above Definitions of the Persuasion Techniques, Identify the Persuasion Techniques used in the Sentence. Answer using ONLY one or more numbers in the range 1-20 separated by commas. No text nor other options are allowed."*.

To this request, the model replied with one or more techniques detected in the corresponding sample. So, as an example, to the sentence: "Happy April Fools Day - - Ooop I mean: March Fools day" the model replied to the prompt with the numbers 3 and 5. These two numbers correspond to the technique 3 (i.e., *Whataboutism*) and to the technique 5 (i.e., *Obfuscation, Intentional vagueness, Confusion*). It is important to mention that we also tried to use the model in a zero-shot configuration. In this case, we just asked the model to pick one or more categories given a meme. Unfortunately, the model did not report one or more correct categories, while developing discussions as answers.

Finally, we collected all the predictions provided

[3] https://propaganda.math.unipd.it/semeval2024task4/definitions.html

on the test set to into a JSON file with the required format to submit our predictions.

As noted in the recent study by (Siino et al., 2024b), the contribution of preprocessing for text classification tasks is generally not impactful when using Transformers. More specifically, the best combination of preprocessing strategies is not very different from performing no preprocessing at all in the case of Transformers. For these reasons, and to keep our system fast and computationally light, we have not performed any preprocessing on the text. The low impact of the best preprocessing techniques - or combinations of techniques - using Transformers, as reported in the study, is due to several factors like preserving the quantity and the quality of the original information available.

4 Experimental Setup

We implemented our model on Google Colab. The library we used comes from Hugging Face and as already mentioned is Mistral 7B[4]. We employed the v0.2 iteration of Mistral 7B, which represents an enhanced version of the Mistral-7B-Instruct-v0.1 model. To harness the capabilities of instruction fine-tuning, prompts must be enclosed within [INST] and [/INST] tokens. Additionally, the initial instruction should commence with a sentence identifier. The next instructions should not. The assistant generation will be ended by the end-of-sentence token ID. We also imported the Llama library (Touvron et al., 2023) from *llama_cpp*. The library is fully described on GitHub[5]. The dataset provided for all the phases are available on the Official Competition page. We did not perform any additional fine-tuning on the model. To run the experiment, a T4 GPU from Google has been used. After the generation of predictions, we exported the results on the format required by the organizers. As already mentioned, all of our code is available on GitHub.

5 Results

The evaluation was done by submitting to the leaderboard the predictions provided by the model. Subtask 1 and 2a are reliant on a hierarchical structure. The gold label consistently corresponds to a leaf node within the Directed Acyclic Graph (DAG). However, any node within the DAG can serve as a predicted label:

- If the prediction does not correspond to a leaf node and is an ancestor of the correct gold label, a partial reward is issued, with the reward magnitude contingent upon the distance between the two nodes. For instance, if the gold label is "Red Herring" and the predicted label is "Distraction" or "Appeal to Logic."

- If the prediction does not align with any ancestor node of the correct label, no reward is granted. For instance, if the gold label is "Red Herring" and the predicted label is "Black and White Fallacy" or "Appeal to Emotions." A graphical representation illustrating this concept is provided.

However, it's worth noting that the hierarchical structure can be disregarded by confining predictions solely to technique names. This approach renders the task analogous to SemEval 2023 Task 3 (Piskorski et al., 2023).

An illustrative example of the evaluation function can be accessed online[6]. In this case, the Subtask consists of a hierarchical multilabel classification task. Drawing from the aforementioned figure depicting the hierarchy, any node within the DAG can be designated as a predicted label. The gold label consistently corresponds to a leaf node within the DAG. Hierarchical-F1, detailed in (Kiritchenko et al., 2006), is employed as the official evaluation metric.

In the Table 1, the results obtained by the first three teams and by the last one, as showed on the official page[7], are reported. Compared to the best performing models, our simple approach exhibits some room for improvements, although it is able to outperform the baseline. However, it is worth notice that it required no further pre-training and the computational cost to address the task is manageable with the free online resources offered by Google Colab.

6 Conclusion

This paper presents the application of Mistral 7B-model for addressing the Task 4 at SemEval 2024.

Table 1: Comparing performance on the test set for Subtask 1 in English. In the table are shown the results obtained by the first three users and by the last one. Furthermore, is included the result of the baseline considered and of our approach making use of Mistral 7B. In parentheses is reported the position in the official final ranking.

For our submission, we decided to follow a few-shot learning approach, employing as-is, an in-domain pre-trained Transformer. After several experiments, we found beneficial to build a prompt containing the definitions of the techniques in memes. Then we provide, as a prompt, the definitions together with a sample. The model was asked to select all the techniques detected in the sentence. The task is challenging, and there is still opportunity for improvement, as can be noted looking at the final ranking. Possible alternative approaches include utilizing the zero-shot capabilities of other models like GPT and T5, increasing the size of the training set by using further data, or directly integrating ontology-based domain knowledge differently than what has been proposed in our work. Further improvements could be obtained with a fine-tuning and modelling the problem as a different text classification task. Furthermore, given the interesting results recently provided on a plethora of tasks, also other few-shot learning (Wang et al., 2023; Maia et al., 2024; Siino et al., 2023; Meng et al., 2024) or data augmentation strategies (Muftie and Haris, 2023; Siino et al., 2024a; Tapia-Téllez and Escalante, 2020; Siino and Tinnirello, 2023) could be employed to improve the results. Looking at the final ranking, our simple approach exhibits some room for improvements. However, it is worth notice that required no further pre-training and the computational cost to address the task is manageable with the free online resources offered by Google Colab. Also, thanks to the proposed approach, we have been able to outperform the baseline provided by the task organizers.

Acknowledgments

We extend our gratitude to the anonymous reviewers for their insightful comments and valuable suggestions, which have significantly enhanced the clarity and presentation of this paper.

Abstract

Within few-shot learning, in-context learning (ICL) has become a potential method for leveraging contextual information to improve model performance on small amounts of data or in resource-constrained environments where training models on large datasets is prohibitive. However, the quality of the selected sample in a few shots severely limits the usefulness of ICL. The primary goal of this paper is to enhance the performance of evaluation metrics for in-context learning by selecting high-quality samples in few-shot learning scenarios. We employ the chi-square test to identify high-quality samples and compare the results with those obtained using low-quality samples. Our findings demonstrate that utilizing high-quality samples leads to improved performance with respect to all evaluated metrics.

1 Introduction

The advent of large language models (LLMs) like GPT-3.5 has brought about transformative capabilities, seamlessly handling tasks like question answering, essay writing, and problem-solving (Aljanabi et al., 2023; Wu et al., 2023; Rasheed et al., 2023a). However, this technological advancement necessitates careful consideration of its associated challenges. Concerns regarding the potential impact on creativity and ethical implications, particularly concerning the generation of deepfakes (Tang et al., 2023), warrant careful attention (RAYMOND, 2023). Additionally, the limitations of LLMs, including the possibility of producing erroneous information, require rigorous evaluation and verification. The substantial energy consumption required for training LLMs on massive datasets raises environmental concerns, contributing to their carbon footprint. Moreover, plagiarism issues emerge as users may misuse the generated content, either inadvertently or intentionally (Hadi et al., 2023).

Various models have been introduced in recent years designed to distinguish text generated by humans from that created by machines(Mitchell et al., 2023). Examples include GPTZero(gpt), AI Content Detector(cop), and AI Content Detector by Writer (wri) among others. Some of these models are trained on specific datasets, while others are commercially available. Designing and implementing LLMs for classification tasks requires substantial resources and computational power, which are often only accessible to institutions and governments. Therefore, various optimization models, such as LoRA (Hu et al., 2021), distillation(Hsieh et al., 2023), quantization(Dettmers et al., 2022), and in-context learning (Liu et al., 2022), have been developed to reduce the resource requirements for LLM implementation. This paper focuses on In Context Learning (ICL) (Liu et al., 2022), which utilizes the capabilities of other models to enhance their ability to classify AI-generated text.

In Context Learning (ICL) is a Natural Language Processing (NLP) technique utilized to enable Large Language Models (LLMs) to learn new tasks based on minimal examples. This technique proves powerful in scenarios where training models on extensive datasets is impractical or when there are constraints on dataset availability for a specific task. ICL operates on the premise that humans can often acquire new tasks through analogy or by observing a few examples of task performance. It can be employed without any examples and is referred to as zero-shot learning. Alternatively, if the input includes one example, it is termed one-shot learning, and if it contains more than one, it is known as few-shot learning. This paper focuses on the application of few-shot learning within the context of ICL(Ahmed and Devanbu, 2022; Kang et al., 2023).

In this study, our focus lies exclusively on few-shot learning. We present a methodology that leverages the chi-square statistic (Rasheed et al., 2023b;

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 60–63

Lancaster and Seneta, 2005) to select samples for few-shot learning and evaluate its impact on the performance of a machine-generated text classification model. We work on task A English language only (Wang et al., 2024).

2 Dataset

The dataset employed for Task A comprises two main components. The first part, derived from human writing, was collected from diverse sources including WikiBidia, WikiHow, Reddit, ArXiv, and PeerRead. The second part consists of a machine-generated text produced by ChatGPT, Cohere, Dolly-v2, and BLOOMz(Muennighoff et al., 2023). For further details, please refer to the associated paper (Wang et al., 2023).

3 Chi-square

Chi-square is a statistical test used to assess the independence of two categorical variables. It calculates the difference between observed and expected frequencies of outcomes, and a larger chi-square value indicates a stronger rejection of independence. In text analysis, chi-square can be used to identify keywords that are more likely to occur in one category than another, making it useful for feature selection and text classification. We computed the chi-square values for each training sample and recorded the sample index with the highest and lowest chi-square values for both human-generated and machine-generated samples. Table I displays the index and corresponding chi-square values for each of these instances. We will use X^2 to refer to chi-square (Lancaster and Seneta, 2005).

Table 1: Indices and chi-square values for highest/lowest in human-generated and machine-generated text

Name	Index #	X^2 Value
Highest X^2 (Human)	70873	1351.59
Lowest X^2 (Human)	85726	1.21
Highest X^2 (Machine)	2426	1154.27
Lowest X^2 (Machine)	29111	0.8243

4 System overview

The system architecture is illustrated in Figure 1. The process starts with feeding the entire training dataset to a chi-square computation, where the chi-square value for each sample is calculated. Subsequently, the indices of the samples with the highest and lowest chi-square values are selected for both human-generated and machine-generated datasets using information from Table I. Next, context learning is prepared. Initially, multiple templates were tested, and the one presented in Figure 1 yielded the best results. This template is then fed with two samples: the first being the machine-generated sample with the highest chi-square value, and the second being the human-generated sample with the highest chi-square value. Due to context window size limitations, only the first 5000 characters of each sample are incorporated. This is applied to training samples exceeding 5000 characters to ensure the context learning size is not exceeded. Finally, the test sample is fed into the context-learning process. The Flan-T5 model large version is used. The results are then recorded and evaluated. The dev/test sample size was truncated to 3000. We also evaluated the system using samples with the lowest chi-square values and doing the same process.

5 Findings and Analysis

We employed the Flan-T5 Large model for both the development and testing datasets. We selected samples from both human-generated and machine-generated sources, with each sample limited to 5000 characters to avoid exceeding the token size limit. A total of four experiments were conducted. The first experiment utilized samples with high chi-square values from the development set. The second experiment focused on samples with the smallest chi-square values from the development set. The third experiment involved samples with high chi-square values from the test set. Finally, the fourth experiment utilized samples with low chi-square values from the test set. Table II presents all achieved results.

Based on the results presented in Table II, we can discuss several key points.

- The results highlight the crucial role of sample quality in the performance of in-context learning. By leveraging the chi-squared metric and prioritizing samples with high values, we essentially provide the Flan-T5 model with examples rich in diverse features. This choice enables the Flan-T5 model to learn more effectively, drawing substantial insights from the samples. Consequently, the model becomes more familiar with the provided data, ultimately enhancing its performance. In

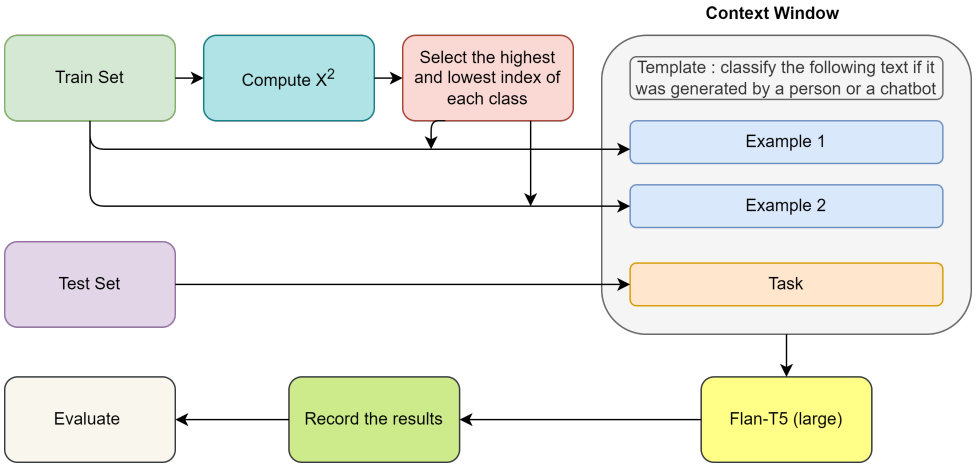

Figure 1: Proposed System Components

Dataset	Chi Type	Recall	Precision	F1-Score	Accuracy
Dev set	Lowest	46.92	46.90	46.84	46.92
	Highest	53.76	53.76	53.74	53.76
Test set	Lowest	55.04	55.07	55.03	55.27
	Highest	58.68	58.81	58.81	**55.99**

Table 2: Experiments results

contrast, selecting samples with lower quality leads to less optimal performance. This can be noticed for both the dev and test set. The main reason behind this is that words in the sample with high chi-square values contain the most distinctive features. This is because the chi-square test assigns high values to words that are frequent within a particular class but appear less frequently in other classes.Conversely, samples with lower chi-square values likely contain more random words that appear with similar frequency across all classes. In chi-square analysis, words that appear equally or approximately equally in each class receive lower scores.

- The classification of machine-generated text represents a novel frontier in machine learning, and the availability of datasets for this task is currently limited. The dataset used in this study was generated in 2023, marking it as a recent development and underscoring the lack of established benchmarks. Models that support in-context learning have not been trained extensively on such tasks, resulting in lower accuracy when applied. While examples with high-quality data can enhance model performance, it remain below the desired threshold. Hence, it is advisable to train the model directly on the dataset rather than relying on in-context learning.

- We have utilized the Flan-T5 model; however, other models can be employed to evaluate the performance of text classification machinery. We suggest considering alternatives such as bard, Jurassic-1 Jumbo, and ChatGPT.

6 Conclusion

This work presents a system for classifying human-generated and machine-generated text. The system leverages the combined strengths of in-context learning and Chi-square analysis. Chi-square is employed to select high-quality samples from the trainin dataset for few-shot learning in the in-context learning. We implement Flan-T5 model large version for in-context learning. Evaluation using accuracy, recall, precision, and F1-score demonstrates that selecting high-quality samples improves system performance for both dev and test. Furthermore, the results indicate that relying solely on in-context learning for new tasks like machine-generated text detection yields relatively low performance.

Pu'er University
{daojiaxu, lizhuoying, suyoubang, gongwensheng}@peu.edu.cn

Abstract

The paper summarizes our research on multilingual detection of persuasion techniques in memes for the SemEval-2024 Task 4. Our work focused on English-Subtask 1, implemented based on a roberta-large pre-trained model provided by the transforms tool that was fine-tuned into a corpus of social media posts. Our method significantly outperforms the officially released baseline method, and ranked 7th in English-Subtask 1 for the test set. This paper also compares the performances of different deep learning model architectures, such as BERT, ALBERT, and XLM-RoBERTa, on multilingual detection of persuasion techniques in memes. The experimental source code covered in the paper will later be sourced from Github.

1 Introduction

Memes has been steadily increasing as human behavior as social media platforms have become more prevalent. This type of content is known for its rapid spread, achieved through the manipulation of audience psychology and the blurring of logical relationships.

Memes are generally made up of stacked images and text. The essence of its expression in order to generate an emotional effect is actually the skillful role of three persuasive strategies (Davison, 2012) in rhetorical portions:

1) Ethos: This involves the strategic employment of statements from individuals endowed with authority or credibility, thereby persuading the audience of the veracity of the content and augmenting its perceived legitimacy.

2) Pathos: By sharing personal anecdotes or experiences, memes forge a connection with the audience, evoking emotional resonance and deepening the affective engagement with the content.

3) Logos: The application of logical arguments and reasoning enhances the structural integrity and coherence of the message, fortifying its persuasiveness.

If we further split these three categories of persuasion strategies into twenty-two, scientists are able to obtain textual and visual features from memes for analysis. For instance, it is feasible to efficiently decrease or prevent the spread of hate speech, racial discrimination, and deceptive information by analysing memes, then simultaneously preserving the peace and stability of social media.

Memes can assist merchants in quickly capturing market trends, allowing them to carry out advertising and marketing operations more effectively and raise brand influence. Memes helps media workers in understanding the concerns of their audiences. Memes in politics have the potential to help voters demonstrate their policy views. The goal of the task is to classify corpora of text in memes and assign them to relevant persuasive strategies. Our work in SemEval-2024 Task 4 focuses on subtask 1,and this is a multi label classification task.

Our contrbutions can be highlighted as follows:

1) We explored new possibilities by screening models for news texts and multilingual corpus models. Fine-tuning using the social media posts corpus on the roberta-large model, and the experiment obtained hierarchical F1 of 0.647 on the English - Subtask 1 the dev set.

2) In SemEval-2024 Task 4, our model has an hierarchical F1 result of 0.66 in the English - Subtask 1 the test set, and our model ranks 7th on the leaderboard.

language processing and multimodal analysis has been profound(Khare et al., 2021). BERT and its advanced derivatives, such as RoBERTa(Liu et al., 2019), XLM-RoBERTa(Xie et al., 2021), and ALBERT(Lan et al., 2019), have demonstrated their robust capabilities in a broad spectrum of applications, ranging from sentiment analysis to complex multimodal tasks that combine textual and visual data. Notably, RoBERTa has been recognized for its superior performance in accurately classifying sentiment(Liao et al., 2021), emotion(Kamath et al., 2022), and offensive content(Xu and Liu, 2023), highlighting the model's efficiency as a sophisticated text encoder.

The advent of these models has revolutionized the approach to analyzing diverse datasets and tasks, enabling nuanced understanding and processing of complex language patterns. This has been particularly evident in the domain of multimodal research, where BERT-based models have been instrumental in advancing the study of visual and textual data integration(Khan and Fu, 2021; He and Hu, 2021; Lee et al., 2021).

The success of these models in such a unique and culturally rich context exemplifies their broad applicability and the expanding frontiers of computational linguistics and content analysis. In conclusion, the inclusion of BERT and its variants in the analysis of persuasion techniques in memes marks a significant milestone in the field(Avvaru and Vobilisetty, 2020; Kougia and Pavlopoulos, 2021; Khedkar et al., 2022). It underscores the models' unparalleled flexibility and their emerging role in understanding the complexities of human communication in the digital age. As these models continue to evolve, their contribution to bridging the gap between textual and visual data analysis will undoubtedly pave the way for groundbreaking research and applications across diverse disciplines.

3 System Overview

3.1 Datasets

Our experiment employed four distinct datasets: the training set, validation set, development (dev) set, and test set, all formatted in JSON. The datasets feature a minimum sentence length of one. The training set comprises 7,000 entries, categorized into 20 distinct classes, showcasing an average sentence length of 19.94 and a maximum of 253. The validation set includes 500 entries, with an average sentence length of 18.85 and a maximum reaching 333. The development set, containing 1,000 samples, presents an average sentence length of 18.73 and a peak length of 145. Lastly, the test set encompasses 1,500 instances, with the sentences averaging 18 words in length.

Table 1 presents the sample dataset, illustrating the structured data used in our analysis.

Figure 1 sorts the distribution of categories in the training set in descending order of frequency, highlighting the frequency of each category. The term "None" denotes instances lacking specific classification. According to the depicted statistics, the category "Smear" constitutes the most significant portion of the dataset. In contrast, categories such as "Obfuscation", "Intentional vagueness" and "Confusion" represent the smallest proportions.

3.2 Pre-trained Model

The research team tends to choose from models related to news, tweets, and comments. The research team tested a number of models and deciding that Jochen Hartmann's sentiment-roberta-large-english-3-classes model (As shown in Table 2) while it received the best ratings. A comparison of outcomes from multiple models will be presented in the results section.

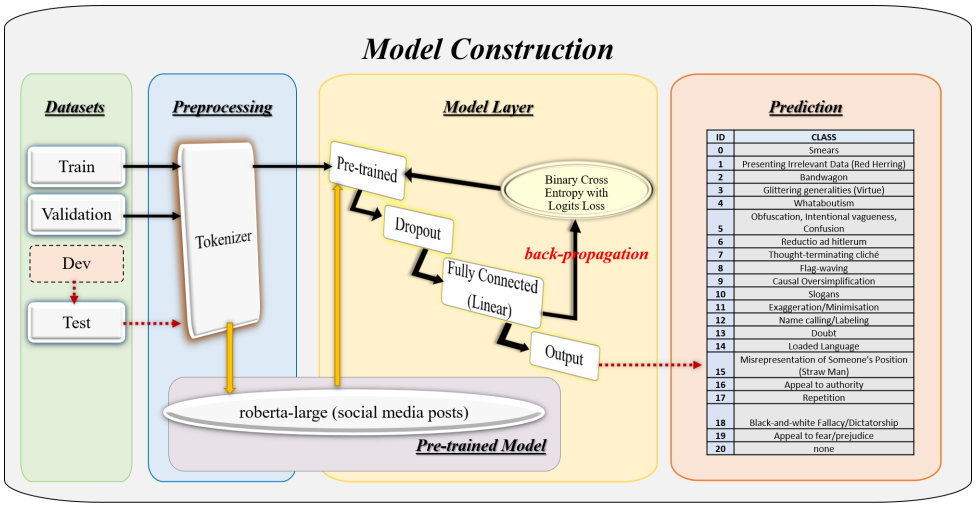

Figure 2: The architecture of model construction

ID	Model
1	bert-base-uncased
2	bert-base-multilingual-cased
3	albert-base
4	roberta-base
5	xlm-roberta-base
6	roberta-large
7	roberta-large(social media posts fine-tuned)

Table 2: Pre-trained Model

The sentiment-roberta-large-english-3-classes model (Hartmann et al., 2021) is trained based on tweets on social media platforms such as Twitter and Instagram, and includes text that is expected to include captions from the sender in the tweet image and comments from other observers. RoBERTa is used to construct the model. Achieving a hold out accuracy of 86.1 % , this model is used to evaluate user comments on posts and identify if the user is willing to buy a certain product. It demonstrates that the model has high robustness and a strong capacity to extract complicated text features.

3.3 Model Construction

In English-Subtask 1, to commence our experiment, we utilize the officially provided Train.json and Validation.json files as the training and validation datasets for supervised learning. Additionally, we assess subsequent results using the officially available dev dataset.

Secondly, we'll perform data preprocessing. The training and validation sets are fed into the Tokenizer, and the pre-trained model roberta-large(social media posts fine-tuned) is used for word segmentation and vectorization processing.

Following that, regarding model structure:

1) Input processing: Feed the pre-trained model with the processed token.

2) Dropout processing: Enter the dropout layer after model processing and set the inactivation probability to 0.1.

3) Linear fully connected layer: 1024 features are carried into the linear fully connected layer.

4) Loss function: For multi label classification jobs, Binary Cross Entropy With Logits Loss (Wang et al., 2022)serves as the loss function throughout the backpropagation gradient calculation procedure. BCEWithLogitsLoss comes with a sigmoid function that can convert predicted result values into probabilities, and can automatically handle numerical instability while preventing the sigmoid function from overflowing upwards or downwards (Yue et al., 2023).

Finally, the output layer is made up of 21 neurons, 20 of which are classified and one of which is none. The architecture of model construction is shown in Figure 2.

4 Experiment Setup

4.1 Evaluation Metrics

For English-Subtask 1, the participating systems are evaluated using standard evaluation metrics, including precision, recall, and hierarchical F1 scores.

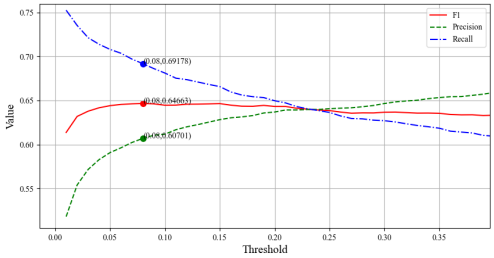

Figure 3: Impact of threshold on dev set

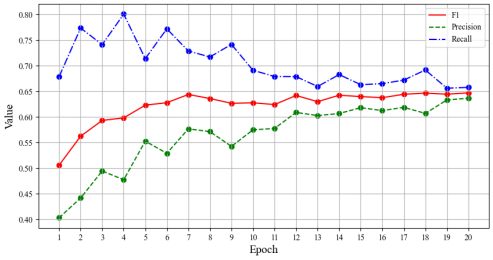

Figure 4: Impact of epoch on dev set

These metrics are calculated as follows:

$$Precision = \frac{TruePositives}{TruePositives + FalsePositives} \quad (1)$$

$$Recall = \frac{TruePositives}{TruePositives + FalseNegatives} \quad (2)$$

$$F1 = \frac{2 \cdot Precision \cdot Recall}{Precision + Recall} \quad (3)$$

The organizers provided baseline models for each subtask. For English - Subtask 1, the Hierarchical F1 scores for the baseline model were 0.358 on the development set and 0.369 on the test set.

4.2 Threshold Selection

The experimental results in training tasks will depend on the threshold selection. We select the most optimal hierarchical F1 value for determining the threshold, assuming that recall and precision are of identical significance. With a 0.01 interval, the experiment increased the threshold from 0 to 1.

The red dots on the hierarchical F1 value curve in Figure 3 represent the experimental results, which show that the most suitable threshold value for hierarchical F1 value is approximately 0.08. In our threshold parameter experimentation, we attained a recall rate of 0.69 and a precision of 0.60. Owing to the threshold being established at 0.08, Figure 3 incorporates merely a fraction of the experimental data. The hierarchical F1 scores start to decline as the threshold surpasses 0.4.

4.3 Epoch Selection

The epoch was raised in the experiment from 1 to 20 at intervals of 1. The Figure 4 illustrates that the Precision is low and unstable and the Recall value is high but swings continuously when the epoch is under seven. As a result of the Precision and hierarchical F1 values' continued continuous increase, the experimental model's instability will grow. The Recall steadily stabilizes as the epoch gets closer to 20, while the hierarchical F1 value also tends to stabilize.

In addition to the above parameters, other training parameters are set in Table 3 below.

Params	Value
num_train_epochs	20
per_device_train_batch_size	4
per_device_eval_batch_size	8
warmup_steps	500
weight_decay	0.01
logging_steps	100
save_strategy	epoch
evaluation_strategy	epoch
learning_rate	$1.5e^{-5}$
threshold	0.08

Table 3: Training Arguments

5 Results

As Table 4 shown, the model's performance on the development set revealed an hierarchical F1 score of 0.64, a precision of 0.63, and a recall of 0.65. The results indicate that our model achieves better results than other models. The performance of English-Subtask 1 on the test set yielded an hierarchical F1 score of 0.66, a precision of 0.65, and a recall of 0.67, ultimately securing the 7th position in the ranking.

6 Conclusion

In our participation in SemEval-2024 Task 4, specifically English-Subtask 1, we focused on addressing the challenge of multi-label text classification. Our study investigated the impact of various pre-trained models on experimental outcomes and the influence of different hyperparameters on

Model	F1	Precision	Recall
bert-base-uncased	0.59335	0.60017	0.58668
bert-base-multilingual-cased	0.58840	0.58235	0.59459
albert-base	0.59484	0.58081	0.60957
roberta-base	0.62268	0.60781	0.63829
xlm-roberta-base	0.58612	0.57927	0.59313
roberta-large	0.63679	0.61831	0.65640
roberta-large (social media posts fine-tuned)	0.64708	0.63666	0.65786

Table 4: Dev Set Results

model performance. Ultimately, the adoption of the roberta-large model fine-tuned on social media posts led to outstanding performance, achieving a hierarchical F1 score of 0.66 on the test set and securing a commendable 7th position among English-Subtask 1 participants.

In our experimentation, we did not pursue a finer-grained classification within the multi-label task. Moving forward, our future research direction will pivot towards fine-grained multi-label classification. This would entail optimizing the loss function or implementing multi-level classification techniques to enhance the model's generalization capabilities.

Puer at SemEval-2024 Task2: A BioLinkBERT Approach to Biomedical Natural Language Inference

Jiaxu Dao, Zhuoying Li, Xiuzhong Tang, Xiaoli Lan, Junde Wang
School of Technology
Pu'er University
{daojiaxu, lizhuoying, tangxiuzhong, lanxiaoli, wangjunde}@peu.edu.cn

Abstract

This paper delineates our investigation into the application of BioLinkBERT for enhancing clinical trials, presented at SemEval-2024 Task 2. Centering on the medical biomedical NLI task, our approach utilized the BioLinkBERT-large model, refined with a pioneering mixed loss function that amalgamates contrastive learning and cross-entropy loss. This methodology demonstrably surpassed the established benchmark, securing an impressive F1 score of 0.72 and positioning our work prominently in the field. Additionally, we conducted a comparative analysis of various deep learning architectures, including BERT, ALBERT, and XLM-RoBERTa, within the context of medical text mining. The findings not only showcase our method's superior performance but also chart a course for future research in biomedical data processing. Our experiment source code is available on GitHub at: https://github.com/daojiaxu/semeval2024_task2.

1 Introduction

Clinical Trial Reports (CTRs) play a crucial role in documenting the methods and results of clinical trials(Jullien et al., 2023a; Vladika and Matthes, 2023). It contains a detailed overview of participant circumstances, intervention experiment descriptions, experimental results, and adverse events that happened in the participants. Natural Language Inference is a valuable technique for analyzing experimental data in CTR and interpreting the results. Natural Language Inference is able to analyze logical linkages, consistency, and contradictions in a document. It can assist detect logical relationships in text automatically, identify potential conflict areas fast, and improve decision-making accuracy and efficiency. Researchers can better gather and analyze clinical trial data by using Natural Language Inference techniques, which promotes medical quality improvement(Jullien et al., 2023b).

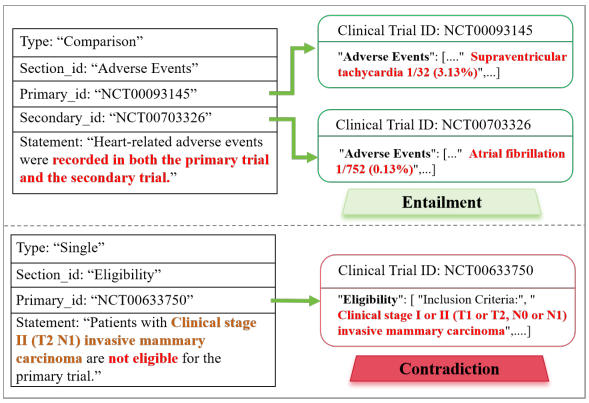

Figure 1: Dataset Example

The Figure 1 shows the example dataset used in this work. The dataset includes two forms of CTR: single and comparison. A single type CTR can retrieve relevant evidence using a Primary Id. To retrieve two relevant pieces of evidence using comparison type CTR, Primary Id and Secondary Id must be used simultaneously.

As an illustration, in the first instance, CTR represents "Heart-related adverse events were recorded in both the primary trial and the secondary trial." Searching for the matching components of the two pieces of evidence reveals that there are heart-related adverse effects, such as supraventricular tachycardia and atrial fibrosis. As a consequence, the first example is labeled as "Entailment"(Alsuhaibani, 2023). In a comparable way, in the second example, CTR believes that "Patients with clinical stage II (T2 N1) invasive breast cancer are not eligible for the primary trial." However, the participation conditions in the gathered evidence clearly show that individuals with clinical stage I or II (T1 or T2, N0 or N1) invasive mammary carcinoma match the criteria. As a result, the second case is labeled "Contradiction"(Liu et al., 2021; Zhou et al., 2023).

In the quest to push the frontiers of biomedical natural language understanding, SemEval-2024

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 70–75

Task 2 has emerged as a critical arena for testing the efficacy of AI models in parsing complex medical texts(Jullien et al., 2024). Engaging with this challenge, our work utilizes BioLinkBERT to set new benchmarks in the safety and accuracy of clinical trial inference(Ida et al., 2023; Karkera et al., 2023; Kanakarajan et al., 2022). This endeavor not only underscores the significance of developing robust NLI systems but also highlights our commitment to contributing meaningful innovations to the biomedical domain(Wang et al., 2023; Mahendra et al., 2023; Pahwa and Pahwa, 2023). Through this paper, we aim to share our methodologies, findings, and the implications they hold for the broader field of medical research, hoping to inspire further advancements and collaborative efforts in this vital area of study.

We created a number of attempts using the above dataset, and the following additions were contributed to our work:

1) We have designed a new loss function by combining the ideas of cross entropy and contrastive learning. This loss function can flexibly adjust parameters according to actual situations and has strong adaptability.

2) We have performed fine-tuning on the BioLinkBERT-large model and finally ranked 15th, achieving an F1 score of 0.72, a score of 0.59 in Faithfulness, and a score of 0.64 in Consistency.

2 System Description

2.1 Data Preprocessing

For this experiment, the training dataset was segmented into four distinct categories: Statement, Section, First Evidence, and Second Evidence. To facilitate precise identification of these text segments by the BioLinkBERT-large model, we employed the token "[SEP]" as a delineator for segment segmentation. This approach ensured that the model could accurately recognize and process the varied input text paragraphs, thereby enhancing its ability to understand and interpret the context and relationships within the data. This method of data preparation was crucial in optimizing the model's performance by providing clear structural demarcations within the training set.

More precisely, we create each input sample as shown in Figure 2.

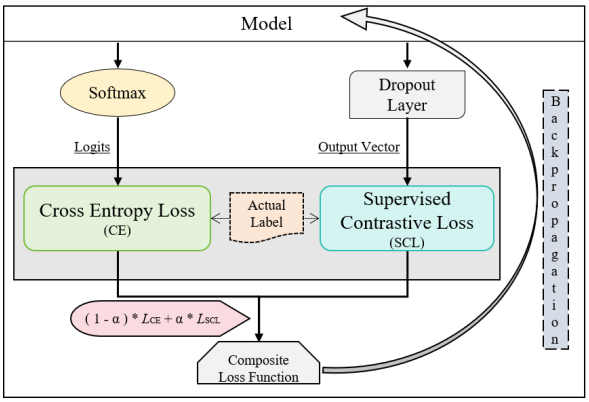

Figure 3: Composite Loss Function

Figure 2: The Architecture of Tokenizer

2.2 Model Construction

BioLinkBERT-large Model. In the domain of biological medicine, the BioLinkBERT model has been shown to be superior to the BERT model due to its ability to learn information across documents (Yasunaga et al., 2022). BioLinkBERT outperformed other models (BERT, BioMegatron, PubMedBERT, BioClinicalBERT, BioMedLM, BioGPT) in extracting the association between microorganisms and diseases from biomedical literature, with F1 precision and recall more than 0.8 (Karkera et al., 2023). The optimal accuracy was obtained in the histopathology image captioning challenge by integrating the BioLinkBERT target model with the image feature extractor ConvNexT Large (Elbedwehy et al., 2023). When compared to PubMedBERT and ChatGPT, the BioLinkBERT has demonstrated superior performance in all aspects in benchmark trials focused on biomedical text production and mining(Chen et al., 2023). The model we use is based on the BioLinkBERT large model that has been fine tuned from the MNLI and SNLI datasets.

Design of Loss Function. In the training phase, our loss function is bifurcated into two pivotal components. The initial segment utilizes the cross entropy loss function (`CrossEntropyLoss()`)(Zhang and Sabuncu, 2018), which first computes the predicted probability values via a softmax function. Subsequently, it leverages the cross entropy loss to quantify the deviation between these predicted probabilities and the actual labels, a process encapsulated by the symbol CE. The latter segment incorporates the supervised contrastive learning

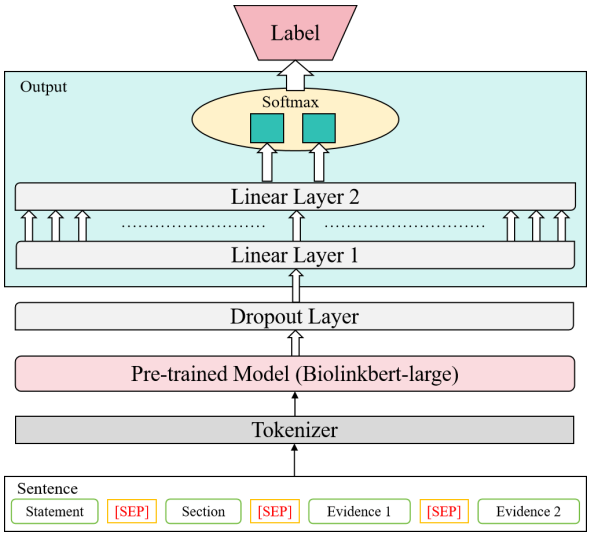

Figure 4: The Structure of System

loss function (`SupConLoss()`)(Khosla et al., 2020). Here, vectors generated post-processing by the pre-trained model are juxtaposed against the true labels to ascertain the contrastive learning loss, denoted as SCL.

Simultaneously, we have instituted a threshold parameter α to modulate the significance of each loss component. By amalgamating CE and SCL in accordance with this threshold, we obtain the composite loss. This loss is then subjected to back-propagation to minimize its magnitude, thereby aligning the predicted values more closely with the actual values. This methodology underscores our strategic approach to loss optimization, blending traditional and contrastive learning mechanisms to enhance model accuracy and performance.

$$L_{CE} = -\frac{1}{N}\sum_{i=1}^{N}\sum_{c=1}^{C} y_{i,c} \cdot \log P \tag{1}$$

$$L_{SCL} = \sum_{i=1}^{N} \frac{-1}{N_{y_i} - 1} \sum_{\substack{j=1 \\ j \neq i}}^{N} 1_{y_i = y_j} \cdot \log \left(\frac{\exp(\Phi(x_i) \cdot \Phi(x_j)/\tau)}{\sum_{\substack{k=1 \\ k \neq i}}^{N} \exp(\Phi(x_i) \cdot \Phi(x_k)/\tau)} \right) \tag{2}$$

$$Loss = (1 - \alpha) * L_{CE} + \alpha * L_{SCL} \tag{3}$$

The Supervised Contrastive Learning (SCL) loss, as delineated in Equation (2), plays a pivotal role in the model's learning process by promoting the aggregation of examples from the same class while concurrently driving apart examples from distinct classes. Within a given batch, examples are meticulously grouped based on their corresponding labels, ensuring that the learning process is finely attuned to the nuances of class similarity and diversity. This is achieved through the implementation of the indicator function $1_{y_i=y_j}$, which is designed to ensure that the loss calculation exclusively considers pairs of examples (i, j) that, while sharing the same label, are distinct entities $(i \neq j)$. This deliberate focus on fostering intra-class cohesion and inter-class distinction is fundamental to augmenting the model's discriminative capabilities. A critical aspect of this approach is the use of N_{y_i}, which denotes the count of examples within the batch that share the same label as example i. This count is instrumental in normalizing the contribution of positive pairs to the loss, thereby ensuring that the SCL loss effectively enhances the model's proficiency in distinguishing between classes. This proficiency is further reinforced by the SCL loss's capacity to adjust based on the relative distances of examples within the embedding space, taking into account both positive pairs (belonging to the same class) and negative pairs (belonging to different classes), with N_{y_i} playing a crucial role in normalizing these effects based on the representation of each class within the batch.

This design strategy excels in leveraging annotated data to its fullest potential, significantly enhancing the model's generalization capabilities and the discriminative power of its feature representations. The cross-entropy loss function plays a pivotal role in assessing model performance by quantifying the discrepancy between predicted outputs and actual labels. Concurrently, the supervised contrastive learning loss function is instrumental in refining the discriminative capacity of feature representations, thereby bolstering classification accuracy. This dual-faceted approach not only ensures a comprehensive evaluation of model quality but also fosters a more nuanced understanding and representation of data features, which is crucial for achieving high precision in predictive tasks.

Model Layer Description. The levels in our model are as follows:

1) Sentence Input Layer: The model feeds the tokenizer with the text that was described in 2.1 as the training set.

2) Pre-trained Model Layer: To process the to-

Model	Loss	F1	Precision	Recall	Faithfulness	Consistency
bert-base-uncased	ce	0.6556	**0.956**	0.4989	0.0335	0.396
	ce+scl	0.6474	0.944	0.4926	0.0486	0.3931
albert-base	ce	0.6127	0.788	0.5012	0.1805	0.44
	ce+scl	0.6447	0.784	0.5474	0.2361	0.4951
biolinkbert-large	ce	0.7042	0.824	0.6149	0.4629	0.5971
	ce+scl	**0.7166**	0.764	**0.6749**	**0.5914**	**0.638**

Table 1: Comparative results of experiments in the test set

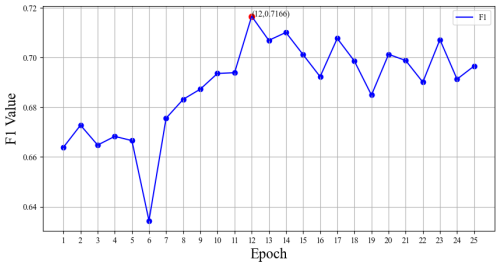

Figure 5: F1 Changes at Different Epochs on The Test Set

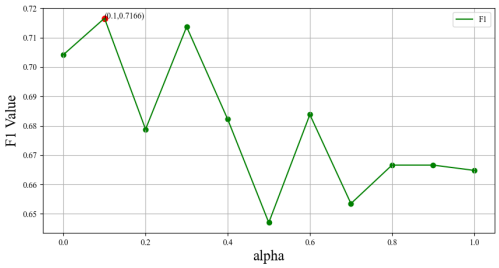

Figure 6: F1 Changes at Different Alpha on The Test Set

kenized text and produce the resultant vector representation of the text, the model makes use of the pre-trained model Biolinkbert-large.

3) Dropout layer: We implemented inactivation rate of 0.2 on the result vector to promote robustness and prevent overfitting of the model.

4) Linear Layer: To further process and transform vectors, the model employs two linear layers in the output module.

5) Softmax Function: Lastly, the model transforms the linear layer's output into a probability distribution by using the softmax function.

The loss function shown in Figure 3 was employed for backpropagation during the model training phase.The model's accuracy and real performance can be enhanced by adjusting the loss function parameter Alpha based on the current situation.

2.3 Hyper-parameters Fine-tuning

Epoch Selection. To ascertain the optimal F1 score, our experiment methodically adjusted the training duration, varying the epoch count from 1 to 20 in increments of one. At each epoch, we meticulously documented the corresponding F1 scores. As depicted by the blue line in Figure 5, a detailed analysis reveals that the F1 score peaks at epoch 12. This finding underscores the significance of epoch selection in maximizing model performance, illustrating that a carefully calibrated training period can significantly influence the effectiveness of the model's predictive accuracy.

Alpha Setting. Building upon this groundwork, we embarked on a series of experiments aimed at identifying the optimal value of alpha within the loss function, meticulously adjusting alpha from 0.1 to 1 in increments of 0.1. This systematic variation is represented by the green line in the accompanying graph. Through careful analysis, the ideal F1 score was observed when alpha was set to 0.1. This discovery not only highlights the critical role of alpha in tuning the loss function for enhanced model performance but also establishes a direct correlation between the fine-tuning of alpha and the achievement of peak predictive precision.

3 Experimental Results

In our methodology, we conducted two control trials by varying the loss function parameter Alpha, and selected three models(BERT-base-uncased(Devlin et al., 2018), ALBERT-base(Lan et al., 2019), and Biolinkbert-large)as outlined in

Table 1, aligning with the structure of our experiment. Subsequent to a rigorous examination of the experimental outcomes, it became evident that the experimental cohort employing the composite CE+SCL loss function surpassed the cohort utilizing the standalone CE loss function. This enhancement was observed across multiple metrics, including F1 score, recall, faithfulness, and consistency, specifically within the ALBERT-base and Biolinkbert-large models.

Upon comprehensive evaluation, the Biolinkbert-large model consistently demonstrates outstanding stability and superior performance. While the BERT-based-uncased model, employing the Cross-Entropy (CE) loss function, achieved the highest Precision score, it also registered relatively lower scores in terms of Faithfulness and Consistency. To encapsulate, the Biolinkbert-large model has exhibited exceptional proficiency in addressing this particular challenge.

4 Conclusion

This study has presented a comprehensive analysis of the effectiveness of BioLinkBERT in enhancing clinical trials. Our research has meticulously fine-tuned the BioLinkBERT-large model with a novel mixed loss function. The experimental results, particularly the achievement of an F1 score of 0.72, underscore the potential of leveraging advanced pre-trained language models in medical research. Our findings suggest that the integration of contrastive learning and cross-entropy loss functions significantly improves the model's performance, indicating a promising direction for future research in biomedical text mining.

Moreover, the success of this project opens new avenues for exploring the application of language models like BioLinkBERT in other domains of healthcare and medical research. Future work could focus on expanding the dataset, experimenting with different architectures, and exploring the impact of domain-specific adaptations on model performance. This could potentially lead to breakthroughs in how we process, understand, and derive insights from clinical trial reports, ultimately contributing to the advancement of medical science and patient care.

Abstract

This paper describes the system of the team NRK for Task A in the SemEval-2024 Task 1: Semantic Textual Relatedness (STR). We focus on exploring the performance of ensemble architectures based on the voting technique and different pre-trained transformer-based language models, including the multilingual and monolingual BERTology models. The experimental results show that our system has achieved competitive performance in some languages in Track A: Supervised, where our submissions rank in the Top 3 and Top 4 for Algerian Arabic and Amharic languages. Our source code is released on the GitHub site[1].

1 Introduction

The SemEval-2024 Task 1 (Ousidhoum et al., 2024b) aims at detecting the degree of semantic relatedness between pairs of sentences across 14 different languages, encompassing Afrikaans, Algerian Arabic, Amharic, English, Hausa, Hindi, Indonesian, Kinyarwanda, Marathi, Moroccan Arabic, Modern Standard Arabic, Punjabi, Spanish, and Telugu. This shared task has three main tasks, each focusing on different aspects of predicting semantic textual relatedness within sentence pairs.

Semantic Textual Relatedness (STR) is a task in Natural Language Processing (NLP) that aims to measure the degree of semantic relatedness between two text passages, typically sentences. STR plays a crucial role in various NLP applications, as it allows computers to understand the relationships between different pieces of text. As mentioned in (Abdalla et al., 2023), it is also employed in chatbots and dialogue systems to understand the user's intent and in question-answering systems to identify answer passages that are semantically related to the question. Additionally, STR finds applications in text summarization, where it helps identify the most important and semantically relevant sentences to create a concise summary of a longer document. STR also plays a role in text generation tasks, such as machine translation and dialogue systems, by guiding the model to generate text that is semantically related to the input or context. However, accurately measuring STR presents several challenges. One key challenge lies in capturing the nuances of language, such as synonyms, paraphrases, and ambiguity. Another challenge is dealing with different languages and cultural contexts, where semantic relationships might not be directly translatable.

Our team only focuses on addressing Track A in the shared task. Our approach is based on the domain adaption for different transformer-based models, and then we continue to fine-tune the pre-trained transformer-based models on the task-specific training data. Therefore, our system is able to leverage domain-specific knowledge to improve performance. Subsequently, we train a cross-encoder model on the adapted transformer-based models, harnessing its ability to capture semantic relatedness between sentence pairs effectively. To further enhance the robustness and performance of our predictions, we adopt a weighted voting technique to combine the outputs of multiple models.

2 Background

2.1 Problem Description

This study investigates the task of predicting Semantic Textual Relatedness (STR) between sentence pairs across 14 languages. Each sentence pair will be associated with a human-annotated relatedness score ranging from 0 (completely unrelated) to 1 (maximally related). There are three Tracks for participants, however, in our work, we only focus on Track A: The first task entails a supervised approach, wherein participants are tasked with developing systems that leverage labelled training

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 76–81

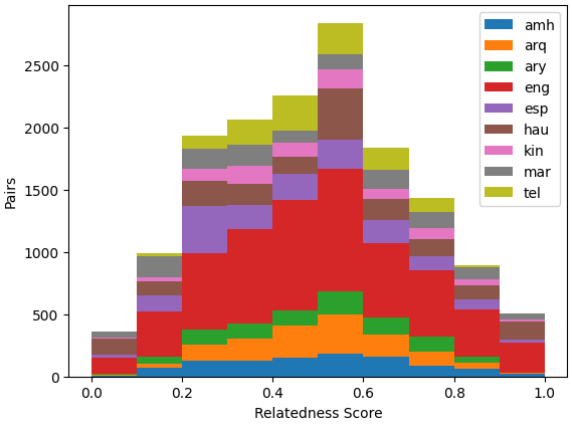

Figure 1: Relatedness Score distribution over languages on the training set.

datasets to infer the degree of semantic relatedness between sentence pairs.

2.2 Data Description

The dataset (Ousidhoum et al., 2024a) typically contains pairs of text along with their corresponding relatedness score, which indicates how semantically related the two fragments are.

Figure 1 shows the distribution of relatedness score over languages. Among the languages included in the dataset, English comprises the largest subset of sentence pairs. The remaining languages also contribute sentence pairs, albeit with varying degrees of representation. It is notable that while most languages exhibit relatedness score distributions spanning the entire range of 0 to 1, some languages demonstrate more limited distributions.

3 Related Work

STR is a fundamental concept which has been considered as an important role in language understanding tasks. Historically, many previous studies focused on semantic similarity, which aims to measure the likeness or resemblance between linguistic elements based on their meaning (Abdalla et al., 2023). Unlike semantic similarity, which often involves assessing the degree of overlap or similarity in meaning between words or phrases, STR involves determining the overall relatedness or closeness in meaning between pairs of sentences or longer textual units (Mohammad and Hirst, 2012). (Gabrilovich et al., 2007) proposed a novel method called Explicit Semantic Analysis (ESA) for fine-grained semantic representation of unrestricted natural language texts. The effectiveness of ESA is evaluated by automatically computing the degree of semantic relatedness between fragments of natural language text. Hussain et al. (2023) proposed a novel vector space model for computing semantic similarity and relatedness between concepts by aggregating taxonomic features from WordNet and Wikipedia.

With the emergence of deep learning models, Gu et al. (2023) introduced a novel Siamese Manhattan LSTM-SNP approach (SiMaLSTM-SNP) which combines Word2Vec and a 10-layer Attention strategy to represent and extract sentence pairs. The multi-head self-attention layer identifies text associations and redistributes hidden state weights. The last hidden state is extracted, and the relatedness score is calculated using the Manhattan distance. Hany et al. (2023) employed a two-layered approach. Firstly, embedding similarity techniques were utilized, leveraging seven different transformers to obtain vectors for each pair of sentences. Secondly, a classical machine learning regressor was trained on these seven vectors. This research highlights the potential of combining embedding similarity techniques with machine learning methods to enhance relatedness score assessment and other NLP tasks.

4 System Description

4.1 Approach

The diagram in Figure 2 illustrates our ensemble approach for Task A. The framework consists of two main layers: a layer of cross-encoder model, and a voting ensemble layer. Firstly, the input sentence pair is passed through a single encoder to produce a joint representation which captures the semantic relationship between the two sentences in the pair and produces a number ranging from 0 to 1. Following this, the predictions of chosen models are combined using the weighted voting technique with each weight determined by its performance in the development phase.

Our approach commences with domain adaptation on masked language modeling (MLM) task (3) which has been shown a powerful training strategy for learning sentence embeddings (Gururangan et al., 2020). To achieve this, we leverage each sentence in the sentence pairs of the training dataset to train MLM which is called In-domain corpus in Figure 2. This process involves masking certain tokens within the input sentences and training the model to predict the masked tokens based

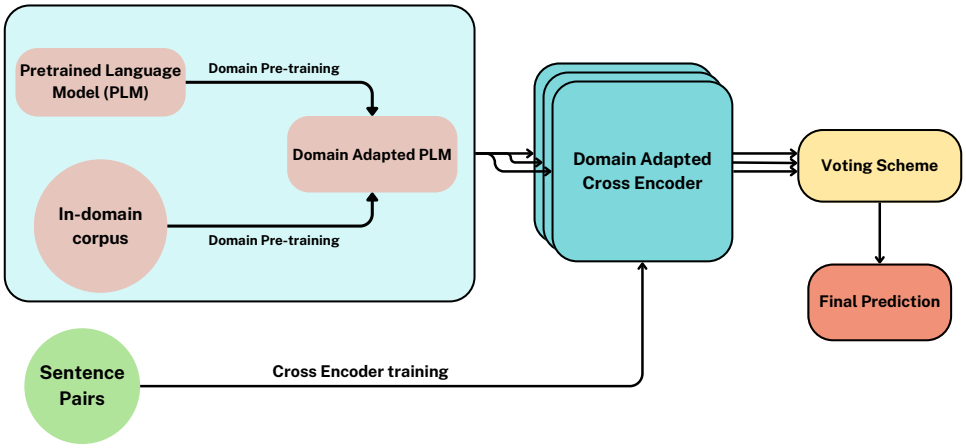

Figure 2: The overall framework of our system for the Track A: Supervised in the Semantic Textual Relatedness shared task.

on their context. In the next stage, we employ a cross-encoder architecture from Sentence-BERT (Reimers and Gurevych, 2019) which is a variant of the BERT model specifically designed for generating fixed-size sentence embeddings that capture semantic similarity between sentences. The cross-encoder architecture of SBERT processes sentence pairs jointly, encoding them into dense fixed-size vectors while considering their contextual information and semantic relationships. After obtaining the logits, we apply the sigmoid function to transform the logits into scores ranging from 0 to 1.

$$\sigma(x) = \frac{1}{1 + e^{-x}} \quad (1)$$

This transformation ensures that the output scores are normalized and represent the degree of semantic relatedness between sentence pairs. To optimize the model during training, we utilize Binary CrossEntropy loss function $\mathcal{L}$ as follows:

$$\mathcal{L} = -\frac{1}{N}\sum_{i=1}^{N}[y_i \log(p_i) + (1-y_i)\log(1-p_i)] \quad (2)$$

Fine-tuning Language Model: As can be seen in Figure 2, we utilize the power of pre-trained contextual language models, encompassing BERT-based models which are BERT (**?**), DeBERTa-V3 (He et al., 2022), XLM-RoBERTa (Conneau et al., 2019) and E5 (Wang et al., 2022). To fine-tune the language models, we followed

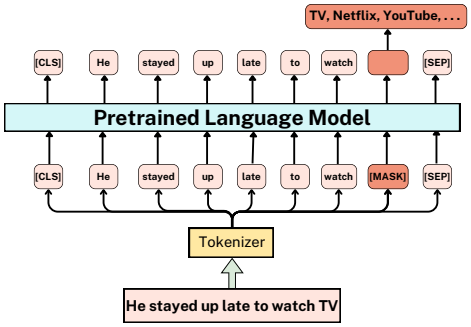

Figure 3: Masked language modelling task illustration for BERT-based models.

the approach of (Devlin et al., 2019), which is presented in detail below.

Voting Scheme: Our motivation for applying an ensemble approach is to take advantage of the performances of various models. Given predictions $\{\hat{y}_{\theta_1}, \hat{y}_{\theta_2}, .., \hat{y}_{\theta_n}\}$ of the n base regressors. We applied the weighted voting technique to merge the predictions of the base models. In our case, the individual regressors are treated based on their performance in the evaluation phase. We compute the weighted sum of the output of n regressors as the final prediction.

4.2 Pre-trained Contextual Language Models

We briefly explain the pre-trained language models used in this paper.

- **mBERT**: we use the multilingual version of BERT (Devlin et al., 2019) which is trained

on the top 104 languages with the largest Wikipedia using a masked language modelling (MLM) objective with case sensitivity.

- **XLM-R**: XLM-R (Conneau et al., 2020) is another multilingual language model. It is pre-trained on 2.5TB of filtered CommonCrawl data containing 100 languages.
- **mDeBERTa-V3**: a DeBERTa (He et al., 2020) version improved the efficiency of original DeBERTa using ELECTRA-Style pre-training with Gradient Disentangled Embedding Sharing (He et al., 2022). In our case, we choose the multilingual version of DeBERTa-V3 which was pre-trained only on the ConmmonCrawl dataset and other versions, which are fine-tuned on the XNLI dataset and multilingual-NLI-26lang-2mil7 dataset (Laurer et al., 2024), respectively.
- **E5**: E5 (Wang et al., 2022) is trained in a contrastive manner with weak supervision signals from our curated large-scale text pair dataset. We chose monolingual (which is trained only in English) and multilingual versions for our task.

5 Experimental Setup

Data and Pre-processing: We utilized the official training set for training models. The development set was used to determine the weights for each model chosen to apply the voting technique based on their performance.

Configuration Settings: We implemented our models using the Trainer API from the Hugging Face library (Wolf et al., 2020) for the MLM task and employed the Cross Encoder architecture from SBERT (Reimers and Gurevych, 2019) for the Cross Encoder task.

- **MLM Task**: The maximum input length is set to 512 tokens, and the number of epochs is set to 10 with a batch size of 16 for all languages. During the training phase of the MLM, we set the MLM probability to 0.15, which means a token will be replaced with the [MASK] token in the input sequence with a probability of 0.15.
- **Cross Encoder Task**: The maximum input length is set to 512 tokens, and the number of epochs is set to 10 with a batch size of 16 for all languages.

We used the AdamW optimizer with a linear schedule warm-up technique for both the MLM task and the Cross Encoder task.

Submission Systems: We submitted the performance of the ensemble weighted voting model for all languages for both the development phase and evaluation phase and as mentioned above, the weights of each model based on its performance in the development phase and determined manually.

6 Results and Discussion

In this section, we present the official results of our final submission model for Track A in the SemEval

2024 Task 1, comparing them with the results of the two top-performing teams for each sub-track.

Table 1 showcases the performance of our ensemble model alongside that of the top two teams across nine tracks. Our system demonstrates competitive performance across four sub-tracks: Track A1 (Algerian Arabic), Track A2 (Amharic), Track A3 (English), and Track A7 (Moroccan Arabic). Additionally, we provide the results of both base models and ensemble systems on the development set. As indicated in Table 2, the ensemble gives better performance in most of the sub-tracks. Notably, we observe a decline in the performance of the ensemble on certain tracks (e.g., Track A1, Track A8) attributed to the presence of a base model that significantly outperforms the others and when this superior model is combined with the rest, it leads to a degradation in the overall performance of the ensemble that underscores the complexity of ensemble. In Track A2, the mBERT model was excluded from the ensemble due to its poor performance, the ensemble was thus formed using only the remaining models. Consequently, we opted for the ensemble model as the final submission system over the best model identified on the development set.

7 Conclusion

This paper introduces a straightforward yet effective ensemble architecture for Track A in the SemEval-2024 Task 1: Semantic Textual Relatedness. Our system leverages fine-tuning of pretrained transformer-based language models as base regressors, coupled with a weighted voting technique to amalgamate predictions from diverse base models. Experimental results demonstrate its competitive performance across select languages in Track A without any additional resources. For future works, we propose enhancing our system by integrating African transformer-based models and exploring data augmentation techniques to improve the overall performance.

BrainLlama at SemEval-2024 Task 6: Prompting Llama to detect hallucinations and related observable overgeneration mistakes

Marco Siino
Department of Electrical, Electronic
and Computer Engineering
University of Catania
Italy
marco.siino@unipa.it

Abstract

Participants in the SemEval-2024 Task 6 were tasked with executing binary classification aimed at discerning instances of fluent overgeneration hallucinations across two distinct setups: the model-aware and model-agnostic tracks. That is, participants must detect grammatically sound output which contains incorrect or unsupported semantic information, regardless of whether they had access to the model responsible for producing the output or not, within the model-aware and model-agnostic tracks. Two tracks were proposed for the task: a model-aware track, where organizers provided a checkpoint to a model publicly available on HuggingFace for every data point considered, and a model-agnostic track, where the organizers do not. In this paper, we discuss the application of a Llama model to address both the tracks. Our approach reaches an accuracy of 0.62 on the agnostic track and of 0.67 on the aware track.

1 Introduction

In the modern Natural Language Generated (NLG) domain, two interconnected challenges persist: neural models often produce linguistically fluent, yet inaccurate, output, while evaluation metrics primarily focus on fluency rather than accuracy. This situation leads to the phenomenon of "hallucinations," wherein neural networks generate output that sound plausible but deviate from the intended meaning, posing difficulties in automatic detection. However, in many NLG applications, the accuracy of output is paramount. For instance, generating translations that diverge from the source text undermines the effectiveness of machine translation systems. Also, as reported in recent survey papers, LLMs are prone to hallucinations, as proven in a variety of recent survey papers (Huang et al., 2023; Ji et al., 2023; Zhang et al., 2023). This LLMs drawback led to the proposal of SemEval-2024 Task 6 (Mickus et al., 2024), where participants were tasked with conducting detection of hallucinations across two subtracks: model-agnostic and model-aware. Put simply, participants were required to detect grammatically correct output containing incorrect or unsupported semantic information, regardless of access to the model responsible for generating them. In the literature, the task has been recently addressed with prompt engineering strategies that provide further context to the models to properly drive and control the models' output (Martino et al., 2023; Li et al., 2024).

To aid in this assignment, a dataset including references, inputs, checkpoints, and outputs from systems trained for three NLG tasks (definition, modeling, machine translation, and paraphrase generation) was provided. These systems were trained with varying levels of accuracy. The dataset included development and test sets annotated by a minimum of five annotators, with a majority vote establishing the gold label for binary annotations.

To address these objectives, there is an ongoing demand for automated tools capable of extracting and categorizing data, facilitating the classification of NLG content containing hallucinations. Recent advancements in machine and deep learning architectures have spurred heightened interest in Natural Language Processing (NLP). Substantial endeavors have been directed towards devising techniques for the automated identification and categorization of textual content accessible on the internet today. In the literature, to perform text classification tasks, several strategies have already been proposed (Kim, 2014; Siino et al., 2024a; Lomonaco et al., 2023).

To face with the task, we propose a Transformer-based approach which made use of Llama (Touvron et al., 2023). We used the model in a zero-shot setup described in the rest of this paper. Specifically, we prompted the latest pre-trained version of Llama with any sample in the dataset. Specifically, we provided a *context* and a *sentence*, asking the

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 82–87

model if the sentence was really supported by the context or was an example of hallucination.

The subsequent sections of the paper are structured as follows: Section 2 offers background information on Task 6, held at SemEval-2024. In Section 3, we outline the approach introduced in this study. Section 4 delves into the specifics of the experimental setup employed to reproduce our findings. The outcomes of the official task and relevant discussions are presented in Section 5. Finally, Section 6 concludes our study and suggests avenues for future research.

We make all the code publicly available and reusable on GitHub[1].

2 Background

This section furnishes background information regarding Task 6, held at SemEval-2024 (named, *SHROOM*). SHROOM participants are tasked with identifying grammatically correct output containing incorrect semantic information, regardless of their access to the model responsible for generating the output.

The data files are formatted as JSON lists, with each element representing a datapoint. Each datapoint corresponds to a different model production and includes the following details:

- Task (task): indicating the objective the model was optimized for.
- Source (src): the input provided to the models for the generation.
- Target (tgt): the intended reference "gold" text that the model should generate.
- Hypothesis (hyp): the actual output generated by the model.
- Annotator labels (labels): indicating whether each individual annotator considered this datapoint to be a hallucination or not.
- Majority-based gold label (label): based on the previous per-annotator labels.
- Probability of hallucination (p(Hallucination)): representing the proportion of annotators who deemed this specific datapoint to be a hallucination.
- Indicator of semantic reference (ref): specifying whether the target, source, or both contain the semantic information necessary to determine if a datapoint is a hallucination.

Furthermore, model-aware datapoints also identify the model used to produce each datapoint, represented by a Hugging Face identifier (model).

For each sample in the dataset, there is a source text, a target text and a hypothesis text. Depending on the task (DM, MT, PG) the goal is to determine if the Hypothesis contains any hallucination.

In the Table 1 there are three different samples from the official test set. Even if the labels are shown in the table along with the hallucination probabilities, during the evaluation phase of the competition, labels, and probabilities were hidden for the participants.

3 System Overview

Even if it has already been proved that the Transformers are not necessarily the best option for every text classification task (Siino et al., 2022), depending on the goal some strategies like domain-specific fine-tuning (Sun et al., 2019; Van Thin et al., 2023), or data augmentation (Lomonaco et al., 2023; Mangione et al., 2022; Siino et al., 2024a) can be beneficial for the considered task.

However, to address the task 6 hosted at SemEval-2024, we made use of a zero-shot learning approach (Chen et al., 2023; Wahidur et al., 2024), making use of the GPT Transformer named Llama 7B. This was dictated by our choice to bear in mind the computational efficiency without further feature engineering and/or heavy data preprocessing strategies.

Llama 2, a suite of large language models (LLMs), includes pretrained and fine-tuned models ranging from 7 to 70 billion parameters. Specifically tailored for dialogue applications, the fine-tuned LLMs are designated as Llama 2-Chat. The models demonstrate interesting performance when compared to open-source chat models across the majority of assessed benchmarks. Additionally, according to human evaluations focusing on helpfulness and safety, they could potentially serve as viable substitutes for closed-source models. Even if several others Open LLMs have proved to be able of outperforming Llama (Jiang et al., 2023), here we investigate the model's actual performance on this specific task. The authors of the model of-

Target Text	Hypothesis Text	Label	p(Hallucination)
"Would you be surprised if I told you my name isn't actually Tom?"	*"You're gonna be surprised if I say my real name isn't Tom?"*	Not Hallucination	0.0
"There will be plenty of food."	*"The food will be full."*	Hallucination	0.8
"The two brothers are pretty different."	*"There's a lot of friends."*	Hallucination	1.0

Table 1: Three samples from the official test set are provided. Together with the labels for each sample, is also reported the probability of hallucination.

fer a comprehensive account of the fine-tuning approach and safety enhancements for Llama 2-Chat, with the aim of facilitating community engagement and contributing to the responsible advancement of LLM technology.

The Llama 2 suite comprises:

- Llama 2: an enhanced iteration of Llama 1, trained on a revised assortment of publicly available data. Notable improvements include a 40% augmentation in the size of the pretraining corpus, a doubling of the model's context length, and the adoption of grouped-query attention. Variants of Llama 2 with 7 billion, 13 billion, and 70 billion parameters are being released. Additionally, authors have trained 34 billion parameter variants, detailed in their paper but not released to the public;
- Llama 2-Chat: a fine-tuned version of Llama 2 tailored for dialogue applications.

To develop the new Llama 2 model family, the authors commenced with the pretraining methodology outlined in Touvron et al. 2023, utilizing an optimized autoregressive transformer. However, the authors made several modifications to enhance performance. These included more rigorous data cleaning, updates to data mixtures, training on 40% more total tokens, doubling the context length, and implementing grouped-query attention (GQA) to enhance inference scalability, particularly for larger models.

More specifically, given the task hosted at SemEval-2024, we asked the model: *"Is the Sentence supported by the Context above? Answer using ONLY yes or no:"*. To this request, the model replied with one or more words — usually starting with *yes* or *no* — that we parsed to extract one of the two labels. For example, given the context:

> *"The East African Islands are in the Indian Ocean off the eastern coast of Africa"*

The sentence:

> *"The eastern islands of the Indian Ocean are located in the eastern part of the Indian Ocean"*

And our question:

> *Is the Sentence supported by the Context above? Answer using ONLY yes or no:*

The model replied with:

> *no, the sentence is not supported by the context provided*

that we mapped into the label *Hallucination*.

It is worth noting that we needed to post-process the model answers to extract only the first word of the reply (i.e., *yes* or *no*). The model barely replied with a single word, even if prompted with the specific request of limiting its answer.

In the literature, several prompt engineering strategies have already been introduced (Denny et al., 2023; Giray, 2023). However, also from this perspective, we opted for a straight interaction with the GPT model, without any further engineering of the process. Finally, we collected all the predictions provided on the test set to into a JSON file with the required format to submit our predictions.

As noted in the recent study by Siino et al. 2024b, the contribution of preprocessing for text classification tasks is generally not impactful when using Transformers. More specifically, the best combination of preprocessing strategies is not very different from doing no preprocessing at all in the case of Transformers. For these reasons, and to keep our system highly fast and computationally light, we have not performed any preprocessing on the text.

4 Experimental Setup

We implemented our model on Google Colab. The library we used come from HuggingFace and as already mentioned is Llama 2[2]. Llama 2 comprises a series of pretrained and fine-tuned generative text models with parameter ranges spanning from 7 billion to 70 billion. This repository specifically hosts the 7B fine-tuned model, tailored for dialogue applications and converted to the Hugging Face Transformers[3] format. We also imported the Llama library (Touvron et al., 2023) from *llama_cpp*. The library is fully described on GitHub[4]. The dataset provided for all the phases are available on the Official Competition page. We did not perform any additional fine-tuning on the model. To run the experiment, a T4 GPU from Google has been used. After the generation of predictions, we exported the results on the format required by the organizers. As already mentioned, all of our code is available on GitHub.

5 Results

Submissions were divided into two tracks: a model-aware track, where organizers provide a checkpoint to a model publically available on Hugging Face for every data point considered, and a model-agnostic track, where organizers do not. The organizers encouraged participants to make use of model checkpoints in creative ways. For both tracks, all participants' submissions were evaluated using two criteria: the accuracy that the system reached on the binary classification; and the Spearman correlation of the systems' output probabilities with the proportion of the annotators marking the item as overgenerating. The evaluation script was made available[5], along with baseline systems and format checkers.

In the Table 2 we report the results obtained by our approach. In the rows are reported the two tracks (i.e., model agnostic or model aware) while in the column are reported the results according to the output score provided on CodaLab. As can be noted from the Tables 3, 4 our proposed approach it is not able to outperform the baseline provided for the task (i.e., Mistral 7B).

In the Table 3 and in the Table 4, the results obtained by the first three teams and by the last one, as showed on the official task page, are reported. Compared to the best performing models, our simple approach exhibits some room for improvements. Furthermore, our proposed approach is not able to outperform the baseline provided for the task. For this reason, we are confident that no further investigations should be performed for this task making use of the Llama model. However, it is worth notice that it required no further pre-training and the computational cost to address the task is manageable with the free online resources offered by Google Colab.

	Acc	Rho
Agnostic	0.625	0.204
Aware	0.671	0.244

Table 2: The method's performance on the test set. In the table are reported the results obtained by our private area on CodaLab.

6 Conclusion

This paper presents the application of a Llama-model for addressing the Task 6 at SemEval-2024. For our submission, we decided to follow a zero-shot learning approach, employing as-is, an in-domain pre-trained Transformer. After several experiments, we found beneficial to build a prompt containing the question for the model. Then we provide as a prompt the target sentence and the hypothesis sentence. The model was asked to decide if the hypothesis sentence is supported by the content of the target sentence, or if it is just a hallucinated text. The task is challenging, and there is still opportunity for improvement, as can be noted looking at the final ranking. Possible alternative approaches include utilizing the few-shot capabilities or also the use of other models like GPT and T5, increasing the size of the training set by using further data, or directly integrating other samples from the training and from the development sets. Further improvements could be obtained with a fine-tuning and modelling the problem as a text classification task. Furthermore, given the interesting results recently provided on a plethora of tasks, also other few-shot learning (Wang et al., 2023; Maia et al., 2024; Siino et al., 2023; Meng et al., 2024) or data augmentation strategies (Muftie and Haris, 2023; Tapia-Téllez and Escalante, 2020; Siino and Tinnirello, 2023) could be employed to improve the

Abstract

Safe and reliable natural language inference is critical for extracting insights from clinical trial reports but poses challenges due to biases in large pre-trained language models. This paper presents a novel data augmentation technique to improve model robustness for biomedical natural language inference in clinical trials. By generating synthetic examples through semantic perturbations and domain-specific vocabulary replacement and adding a new task for numerical and quantitative reasoning, we introduce greater diversity and reduce shortcut learning. Our approach, combined with multi-task learning and the DeBERTa architecture, achieved significant performance gains on the NLI4CT 2024 benchmark compared to the original language models. Ablation studies validate the contribution of each augmentation method in improving robustness. Our best-performing model ranked 12th in terms of faithfulness and 8th in terms of consistency, respectively, out of the 32 participants.

1 Introduction

In the domain of clinical trial analysis, researchers and practitioners are overwhelmed with an ever-expanding corpus of clinical trial reports (CTRs). The current repository contains a vast number of documents and is rapidly growing, a trend that correlates with the increasing prevalence of cross-national, cross-ethnic, and multi-center clinical studies (Bastian et al., 2010). This growth necessitates a scalable approach to evaluate and interpret the massive amount of data in these reports (Goldberg et al., 2017; Li and Bergan, 2020).

Recent advances in Natural Language Processing (NLP) offer promising avenues for the automated analysis of CTRs. Such analyses include medical evidence understanding (Nye et al., 2021), information retrieval (Wang et al., 2023b), causal relationship identification (Cai et al., 2017), and the inference of underlying reasons for trial outcomes (Steinberg et al., 2023). Integrating natural language inference (NLI) with CTRs has the potential to revolutionize the large-scale, NLP-based examination of experimental medicine (Kim and Delen, 2018). Despite the progress in NLP, the application of large language models to this task presents several challenges, including susceptibility to shortcut learning, hallucination, and biases stemming from word distribution patterns within the training data (Huang et al., 2023).

To address these issues, we propose a novel method that leverages generative language models, such as GPT-3.5[1], and biomedical domain knowledge graphs to enhance data diversity. Our approach introduces three types of data augmentation: numeric question-answering data generation, semantic perturbations, and domain-tailored lexical substitutions for the biomedical field. By combining these data augmentation techniques with multi-task learning and the DeBERTa (He et al., 2021) architecture, we have achieved significant improvements in terms of faithfulness and consistency on the NLI4CT 2024 dataset. This paper outlines our approach, elaborates on the design of the perturbations and the multi-task learning process, and demonstrates the efficacy of our method through rigorous evaluation.

2 Background

In a crucial field like healthcare, where misinterpretations can have severe implications, NLI models must present precise predictions and reliable interpretations. This highlights the importance of accurate and trustworthy reasoning in these NLI models.

SemEval 2024 Task 2 (Jullien et al., 2024) provides multi-sentence textual data consisting of patient case histories and medical reports. The objec-

[1]https://openai.com/chatgpt

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 88–94

tive of this task is to predict the logical relationship between the CTR and a given statement, including entailment and contradiction. The evaluation emphasizes prediction accuracy as well as the robustness to the controlled interventions, helping increase healthcare practitioners' trust in the system's predictions.

Enhancing the robustness of NLI models for healthcare can be strategically achieved using data augmentation techniques. Synthetic data generation via techniques like conditional text generation can expand training data diversity and volume to improve model generalization capabilities (Liu et al., 2020; Puri et al., 2020; Bayer et al., 2023). Meanwhile, multi-task learning with auxiliary objectives related to logical reasoning and explanation generation can enhance faithful reasoning abilities (Li et al., 2022). Useful domain knowledge can be captured by training language models on domain-specific medical textual datasets (Singhal et al., 2023; Tian et al., 2024). Complementary data-centric methods can augment model architecture design to develop more capable, trustworthy, and clinical NLI systems.

3 System overview

In this section, we describe the proposed system to tackle the NLI problem and enhance the model's robustness against interventions spanning numerical, vocabulary, and semantic dimensions, as shown in Figure 1.

3.1 Data for Numerical Question Answering Task

A major limitation of many language models lies in their tendency to learn linguistic patterns and features from large-scale textual data while lacking capabilities for numerical and quantitative reasoning (Geva et al., 2020). Such capabilities are crucial for analyzing relationships between CTRs and corresponding claims. Although BERT-based models pre-trained on NLI tasks, i.e. DeBERTa, can conduct general linguistic inference, they remain vulnerable to numerical perturbations in statements.

Therefore, we propose to leverage GPT-3.5 to generate data tailored to the numerical question-answering task based on original entailed statements: The entailed statement, denoted as x, corresponding to a given CTR, is converted into a question q that requires numerical reasoning. Subsequently, three candidate choices c are enumerated, each accompanied by an answer a extracted from the original statements. The loss function employed for this task is binary cross-entropy and is expressed as follows:

$$\mathcal{L}_{NQA} = \begin{cases} -\log g_\theta\left(\text{CTR}, q, c;\right) & c = a \\ -\left[1 - \log g_\theta\left(\text{CTR}, q, c\right)\right] & c \neq a \end{cases}$$

where $g(\cdot)$ is the function to determine if the candidate choice is the correct answer, and θ is the corresponding parameters for the DeBERTa backbone network and the additional classifier.

This numerical question-answering task serves as an auxiliary task to enhance numerical reasoning abilities. The final loss function for the system combines the losses from this task and the main NLI task, i.e.

$$\mathcal{L} = \mathcal{L}_{NLI} + \lambda \mathcal{L}_{NQA}$$

where λ is the hyper-parameter to be tuned in the validation phase.

3.2 Semantic Perturbation

We utilize GPT-3.5 to generate perturbed statements based on the original entailed input, obtaining both semantic-altering variants labeled as "contradictions" and semantic-preserving variants labeled as "entailment". Specifically, to produce contradictory versions, guiding keywords such as "contradicted" and "minor changes" are injected into the input prompt to slightly modify the original statement while altering the semantics to create a contradiction. Conversely, to generate entailed versions, guiding phrases such as "paraphrase" are included in the prompt to rephrase the statement extensively while retaining semantic equivalence. This controlled semantic perturbation of the input statement via guided text generation allows us to efficiently augment the dataset with both contradicting and entailing variants of the original input.

3.3 Vocabulary Replacement

When we analyze textual data in the clinical domain, we need to pay attention to the vocabulary because it contains many terms that are specific to this domain (Wang et al., 2018). However, most NLI models are pre-trained on data from general domains, and they are unaware of the meaning or relevance of these terms (Wang et al., 2023a). To address this problem, we use a combination of biomedical knowledge graph embedding and statistical model, which can help us find the most important keyword to replace the term in the statement

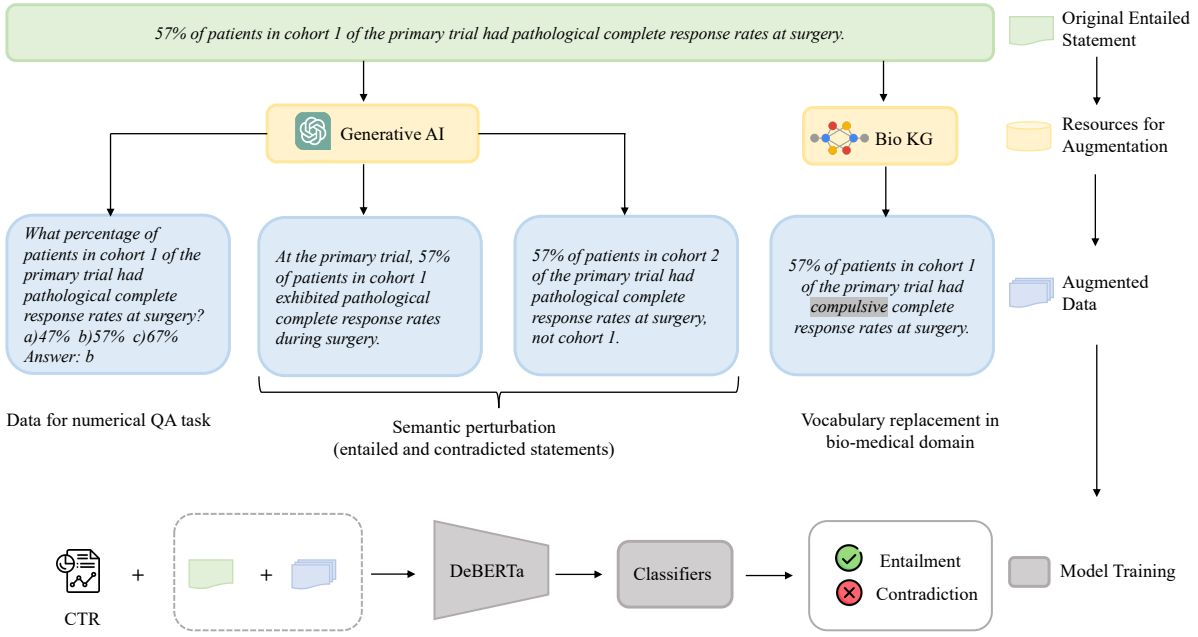

Figure 1: The overall demonstration of the proposed system. The upper part of the demonstration involves the application of data augmentation techniques to entailed statements extracted from the original NLI dataset, leveraging generative artificial intelligence (AI) and biomedical domain knowledge graphs. Specifically, we undertake the following procedures: 1) Transformation of statements into multiple-choice questions accompanied by corresponding answers; 2) Introduction of semantic perturbations to the original entailed statements; 3) Employing a statistical method to identify keywords within the original entailed statements, followed by their substitution with synonyms sourced from the biomedical knowledge graph. In the lower part of the demonstration, we incorporate the original entailed statements, augmented data, and CTRs as training data to develop a classifier based on the DeBERTa architecture.

and generate the augmented data to improve the vocabulary alignment. Specifically, given a statement x, consisting of n words, i.e. $x = \{w_1, w_2, ..., w_n\}$ and the set of all the statements, denoted as D, we first remove all the stop-words and apply Term-Frequency-Inverse Document Frequency (TF-IDF) to identify the most important term in the statement, i.e.

$$w^* = \arg\max_{w_i \in x} \text{TF}(w_i, x) \times \text{IDF}(w_i, D)$$

Subsequently, we locate a term in the biomedical embedding space that shares the same part-of-speech and has the highest similarity score with the chosen term, using it as the substitute, i.e.

$$\hat{w}^* = \arg\max_{w \in V} \{sim(w^*, w) \mid \text{PoS}(w) = \text{PoS}(w^*)\}$$

where V is the biomedical term vocabulary and $\text{PoS}(\cdot)$ is the part-of-speech of a word. In this way, we can substitute w^* in the original statement with $\hat{w}^*$ to generate a new adversarial sample to enhance the model robustness in the vocabulary aspect.

4 Experimental setup

4.1 Dataset

	Ent.	Con.	Alt.	Pres.	SUM
Train	850	850	-	-	1,700
Val.	100	100	1,606	336	2,142
Test	250	250	4,136	864	5,500

Table 1: Statistics of the validation and test set. "Ent." and "Con." stands for entailment and contradiction, while "Alt." and "Pres." stands for altering and preserving.

We conducted experiments on the NLI4CT 2024 dataset (Jullien et al., 2024), generated by clinical domain experts and sourced from a large database for clinical studies[2]. The statistic of this dataset is summarized in Table 1. The training data is the same as the NLI4CT 2023 dataset (Jullien et al., 2023) while there are perturbed samples in the validation and testing sets.

[2]https://ClinicalTrials.gov

4.2 Metrics

We first assessed the performance of the original statements without any perturbation and recorded the corresponding F1 score, precision, and recall. Then, we assessed the performance of the contrast set, consisting of interventions. Specifically, to evaluate the model's robustness to the semantic-preserving interventions, we used consistency as the metric, i.e.

$$Consistency = \frac{1}{N}\sum_{1}^{N} 1 - \left|f(x_i') - f(x_i)\right|$$
$$x_i' \in C : \text{Label}(x_i) = \text{Label}(x_i')$$

Where C is the contrast set, and N is the number of the statements in the contrast set. x_i' is the perturbed statement for x_i and $f(\cdot)$ computes the final prediction from the model. For the semantic-altering interventions, we evaluated the model using faithfulness, i.e.

$$Faithfulness = \frac{1}{N}\sum_{1}^{N} \left|f(x_i') - f(x_i)\right|$$
$$x_i' \in C : \text{Label}(x_i) \neq \text{Label}(x_i'), \text{ and } f(x_i) = \text{Label}(x_i)$$

4.3 Implementation details

We downloaded DeBERTa models from the Huggingface repository[3] and implemented our proposed method based on Python 3.10 and Pytorch 2.1.1. During the model training, we used the Adam optimizer and set the learning rate to $5e-6$ with a batch size of 4, following the original work (He et al., 2021). The maximum sequence length the model can take was set to 512. The epoch number was set to 20, and the early stopping based on the validation set was applied to avoid overfitting. The input format for the NLI task in this work is structured as follows: [CLS] + CTR + [SEP] + claim + [SEP]. In this structure, [CLS] serves as the initial token for classification in DeBERTa, and [SEP] acts as a separator token. For the vocabulary replacement, we used the bio-medical domain embedding from the work by (Zhang et al., 2019), which has been pre-trained over the MeSH knowledge graph[4]. For preprocessing, such as stop word filtering and part-of-speech tagging, we used the NLTK library[5] in Python. We include prompts for numerical question-answering data generation and semantic perturbation in Table 2.

[5]https://www.nltk.org/

5 Results

We conducted experiments with different-sized DeBERTa models, iteratively adding augmented data from three different interventions to the training set. As shown in Table 3, incorporating all three types of augmented data greatly improved the average faithfulness and consistency scores. Specifically, we witnessed gains of 8.17% on DeBERTa-l and 2.37% on DeBERTa-b. This result also suggests that the augmented training data provided more benefit to the larger-sized DeBERTa model in terms of robustness. The additional augmented examples may have provided useful regularization, helping it generalize better on both the unaltered control and contrast datasets. Our best-performing model ranked 12th in terms of faithfulness and 8th in terms of consistency, respectively, out of the 32 participants.

From this iterative process, we can see that semantic perturbation with generative AI contributes mainly to the performance gain for both NLI models. Compared with this, vocabulary replacement in the biomedical domain has only a minor effect. This may suggest that vocabulary replacement in our work may be relatively less effective in this case because it only swaps out individual words, while semantic perturbation modifies the whole statement. Hence, semantic perturbation provides more meaningful variations to augment the training data.

While the augmented data improved the robustness to interventions, we noticed a slight performance drop in the control set. For example, the F1 score on the control set decreased by 3.16% for DeBERTa-l and 0.48% for DeBERTa-b after adding all the augmented data. This performance decline indicates there may have been a small trade-off between improving robustness to interventions and maintaining strong performance on the original data. One of the reasons accounting for this could be that the generative AI may generate noisy or irrelevant data. For example, in numerical question answering data generation, if the original entailed statement discusses an assumption about a 50-year-old patient not mentioned in the CTR, the generative model may create an unrelated question about the patient's age that cannot be inferred from the given information. Another example involves vocabulary replacement: we observed that there exist some cases where even two words having very similar embeddings in the biomedical domain

	Prompt
NQA	*Please convert the statement to a multiple choice question that requires the numerical or quantitative reasoning, and each question has 3 choices, using the given template: \n Question: [Question] \n Choices: 1. [Choice 1]\n 2. [Choice 2]\n 3. [Choice 3]\n Correct Answer: [Correct Answer].*

Table 3: Results on the development set and testing set for NLI4CT 2024 dataset. DeBERTa-l and DeBERTa-b are the large version and base version of the DeBERTa model, respectively. SP and VR stand for semantic perturbation and vocabulary replacement. The best results for F1 score on the control set, faithfulness, and consistency are highlighted.

knowledge graph embedding space may not be very closely related in the context of the current statement. Including these illogical examples in the augmented training data could mislead the original DeBERTa model, resulting in worse performance on the unaltered control set.

6 Conclusion

In this work, we proposed a data augmentation approach to enhance the robustness of natural language inference models for clinical trial report analysis. Our method leverages generative AI and biomedical knowledge graphs to augment training data along three dimensions: numerical reasoning, semantic perturbations, and domain-tailored lexical substitutions. Experiments on the NLI4CT 2024 dataset demonstrate that our approach effectively improves model faithfulness and consistency against controlled interventions, with significant gains against the DeBERTa baselines.

However, we observed a slight performance drop on the unaltered test set, indicating a trade-off between robustness to perturbations and maintaining strong performance on original data. Future work will focus on: 1) generating higher-quality augmented examples using numerical question-answering data generation to minimize or avoid performance drop; 2) validating the perturbed samples to help remove noisy or irrelevant examples (Wang et al., 2023c); 3) incorporating external structured knowledge via pre-training on knowledge graphs and not just lexical substitution, which can provide more contextual domain information.

SATLab at SemEval-2024 Task 1: A Fully Instance-Specific Approach for Semantic Textual Relatedness Prediction

Yves Bestgen
Statistical Analysis of Text Laboratory (SATLab)
Université catholique de Louvain
Place Cardinal Mercier, 10 1348 Louvain-la-Neuve, Belgium
yves.bestgen@uclouvain.be

Abstract

This paper presents the SATLab participation in SemEval 2024 Task 1 on Semantic Textual Relatedness. The proposed system predicts semantic relatedness by means of the Euclidean distance between the character ngram frequencies in the two sentences to evaluate. It employs no external resources, nor information from other instances present in the material. The system performs well, coming first in five of the twelve languages. However, there is little difference between the best systems.

1 Introduction

Semantic similarity between words, phrases and texts has long attracted the attention of NLP researchers. It is obviously a useful source of information in tasks such as information retrieval, text summarization, question answering or machine translation (Agirre et al., 2012). It has been the subject of several shared tasks within SemEval since 2012 (Agirre et al., 2012; Marelli et al., 2014; Cer et al., 2017). More recently, interest has also focused on Semantic Textual Relatedness (STR), which is supposed to be a more general concept. As Abdalla et al. (2023) point out, two sentences must be paraphrases or present an entailment relation to be semantically similar, whereas to be related, it is sufficient that they deal with similar themes or express similar points of view on a given issue. Work on STR is less advanced due to the lack of annotated datasets on this dimension (Abdalla et al., 2023). It should be noted, however, that the human annotators who evaluated semantic textual similarity for the SILK dataset (Marelli et al., 2014) clearly evaluated relatedness, since they considered pairs of sentences that contradict each other as semantically very similar (96% similarity), such as in SILK Instance 466:

- *A man is performing a trick on a green bicycle.*
- *There is no man performing a trick on a green bicycle.*

The SILK dataset contains many other examples of this kind of judgement. This observation suggests that the term "relatedness" is more appropriate to describe this field of research, at least when dealing with the intuition of native speakers. It also suggests that techniques that are effective in automatically estimating semantic similarity should also be effective in estimating relatedness. These are mainly state-of-the-art deep learning algorithms (Cer et al., 2017).

In this context, Ousidhoum et al. (2024b) have proposed the SemEval 2024 Task 1, which has a number of specific features compared with previous work. Firstly, the task focuses on relatedness, and is based on material consisting of sentence pairs that have been annotated on this dimension by native speakers. Secondly, the task is highly multilingual, covering more than ten languages, some of which are very poorly resourced. Finally, it includes three subtasks: supervised, unsupervised and crosslingual. In the supervised subtask, the systems were to be trained using training datasets provided by the task organizers. In the unsupervised subtask, no datasets labeled according to semantic relatedness or semantic similarity could be used. In the crosslingual subtask, the system had to be trained on a language other than the target language.

2 The Proposed Approach

Due to its highly multilingual nature (twelve languages), the unsupervised subtask seemed a priori to be particularly interesting for the development of a generic approach, as language-independent as possible. This would be the case of a system that estimates the semantic relatedness of a pair of sentences without recourse to any resources external to the material and even without taking into account the other instances present in the material. A system takes other instances into account when, for example, it weights an instance features according

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 95–100

to their frequency in the complete material, using the classic TF-IDF. A system is completely independent of other instances when the processing of one instance is not affected in any way by the other instances it has to predict. The system proposed by the SATLab fulfills this requirement by using the Euclidean distance between the two sentences, calculated on the basis of the frequency of the ngrams of characters that make them up. If such a system proves successful to predict semantic relatedness, it could become a potential candidate for the analysis of any language.

Admittedly, such a system is more akin to a baseline than a state-of-the-art system. However, it should also be noted that systems based on character ngrams have for many years been considered particularly effective for NLP tasks such as language identification, error correction, information retrieval and even for hate speech and offensive content identification (Damashek, 1995; Bestgen, 2021b). Character ngrams have the advantage of not requiring material to be tokenized, which can be problematic in some Asian languages, and of being able to extract morphological information at very low cost (Peng et al., 2003).

This paper presents SATLab's participation in SemEval 2024 Task 1 with this fully instance-specific system. The following section introduces the task and describes the proposed system. The results obtained are then reported.

3 The Unsupervised Task

Subtask 1B of SemEval 2023 (Ousidhoum et al., 2024b) asked participating teams to estimate the semantic relatedness between pairs of sentences in twelve languages: five Afro-Asiatic (Algerian Arabic [arq], Amharic [amh], Hausa [hau], Modern Standard Arabic [arb], Moroccan Arabic [ary]), five Indo-European (Afrikaans [afr], English [eng], Hindi [hin], Punjabi [pan] and Spanish [spa]), one Austronesian (Indonesian [ind]) and one from the Niger-Congo family (Kinyarwanda [kin]). The material, collected by Ousidhoum et al. (2024a), was selected from various resources such as semantic similarity datasets, news articles and Wikipedia texts. After this material had been carefully checked, it was submitted to native speakers whose task was to assess the semantic relatedness between pairs of sentences using the Best-Worst Scaling procedure. Ousidhoum et al. (2024a) reported high to near-perfect inter-rater reliabilities (split-half correlations: Min = 0.64, Max = 0.96).

In this Task 1B, the systems had to be unsupervised, since no dataset including evaluations of semantic relatedness between sentence pairs or texts could be employed. It should be noted, however, that the organizers provided participants with development data similar to that provided later for the testing phase, and that a team's predictions for these data could be evaluated by submitting them to CodaLab. The few tests I carried out showed that performance varied greatly depending on the language. It therefore didn't seem advisable to rely on this development material to make general decisions about the system to be developed. In the testing phase, only one prediction for each language could be submitted, and the performance measure was Spearman's rank correlation coefficient.

4 The SATLab System

A single system was used for all twelve languages. It is adapted from the one developed for the authorship identification of source code (Bestgen, 2020). This system takes as input each pair of utterances and outputs a distance between them without any other information, either from the rest of the material or external to it. Each pair of utterances is therefore processed in a way that is completely independent of the other pairs present in the material.

The only pre-processing is the lower-casing of all texts as included in SAS. I have to admit that it's not obvious to me what impact this has on languages as unknown to me as Kinyarwanda or Amharic. No tokenization or lemmatization has been applied. The system uses character ngrams made up of 1 to 5 characters. All characters are taken into account, including spaces, punctuation marks, symbols, characters from other writing systems, etc. The ngrams at the beginning and end of each statement are distinguished from the others. All ngrams in a statement are retained, so there is no frequency threshold. The frequency of each feature is weighted by a logarithmic function using the formula: $1 + \log(Freq)$. Finally, the features of each statement are weighted by the L2 norm (thus instance-wise). Most of these system components have be taken from the one developed for a difficult language identification problem (Bestgen, 2021a).

The Euclidean distance between the sets of ngrams of each utterance in a pair is used to estimate the semantic dissimilarity between these utterances. Before submission, these distances are

transformed into similarity by ranking them from largest to smallest. No information is lost through such ranking, since the organizers have chosen a rank correlation as the efficiency criterion.

5 Analysis and Results

5.1 Official Results

Twelve teams took part in the test phase of Task 1B, but only five proposed solutions for all twelve languages. One team proposed a solution for all languages except Spanish. The organizers provided a baseline based on the number of shared words between the two sentences of a pair (SemRel Lexical Overlap Baseline, see Ousidhoum et al. (2024b) for details).

Figure 1 shows the performance of all the systems for the twelve languages, highlighting the baseline and the system proposed by the SATLab. Marks not connected by a line are from systems that did not submit a solution for all languages. I don't know whether the systems proposed by the other teams are identical for all twelve languages, as is the case for the baseline and the SATLab.

This figure merits several comments. Firstly, when we analyze the overall results, we observe that the profiles of the teams[1] who submitted for all languages are similar. This observation is confirmed by an analysis of the Pearson correlations between these profiles. The lowest correlation is 0.54, only two are below 0.63 and half of them are above 0.73. These profiles highlight strong variations in performance according to language. While almost all the teams performed well to very well for Afrikaans (afr), Amharic (amh), English (eng) and Spanish (spa), they performed poorly for Punjabi (pan), with the SATLab system even achieving a negative correlation. It therefore appears that the material for some languages is considerably more complicated than for others. A detailed analysis of the differences between these materials would therefore be very useful.

Figure 1 also shows that the SATLab's performance is as good as or better than that of other teams in the vast majority of languages, but there is little difference between the best teams. This second observation would certainly be confirmed if confidence intervals, obtained by bootstrapping (Bestgen, 2022), were presented, but their calculation requires access to the predictions of all systems. In any case, when performances are so close, it is essential to take into account other factors such as computational complexity, which will be possible when reading the system descriptions of the other teams.

Finally, Figure 1 also shows that the organizers' baseline is superior to all other systems for two languages: Hindi (hin) and Moroccan Arabic [ary]. Clearly, this is an underperformance by all participants.

5.2 System Component Analysis

To assess the contribution of each component to the system overall performance, all of them were modified, one at a time, and the system was re-evaluated using the gold standard provided by the task organizers for eleven languages. The results are shown in Table 1 using the difference between each modified system and the official SATLab system, whose performance is shown in the first row.

The only pre-processing of the material carried out, the lower casing, brings benefits in only two languages. Presumably, it doesn't affect the many languages that don't use Latin characters. Using ngrams whose maximum length is one character shorter or one character longer has very little impact. On the other hand, feature weighting by TF-IDF is beneficial in ten out of eleven languages. Not using L2 normalization profoundly alters performance. While it brings significant benefit in one language, the impact is negative in nine languages, and can reach -0.574. As far as distance is concerned, Dice is more efficient than the Euclidean distance, but the gain is significantly lower than that obtained by applying the Euclidean distance to the weights transformed by TF-IDF.

The last line gives the correlations obtained by the system when TF-IDF is used instead of the logarithmic weighting. The gains over the official SATLab submission are sufficiently large to conclude that a fully instance-specific approach is significantly less effective at predicting STR than an approach that takes into account the other instances of the test material (which TF-IDF does, as explained in the introduction). There is no point in comparing these correlations with those of the other participants, since they would certainly have submitted a different system if they had been able to optimize it as just done.

[1] In this discussion of results, the baseline is considered a "team".

6 Conclusion

This paper presents the SATLab participation in SemEval 2024 Task 1: Semantic Textual Relatedness (STR). The proposed system predicts semantic relatedness by means of the Euclidean distance between two sentences, calculated on the basis of the frequency of the ngrams of characters that make them up. It employs no resources external to the material and extracts no information from other instances present in the material. The system performs well, coming first in five of the twelve languages. However, there is little difference between the best systems. What's more, the baseline proposed by the organizers was better than all the systems proposed by the participants in two languages.

Analysis of the system's components shows that the decision to develop a fully instance-specific approach was clearly the wrong one. Simply taking into account the frequencies of features in the material as a whole, as the TF-IDF weighting system does, provides a significant benefit, as Damashek (1995) has already pointed out when character ngrams are used in other NLP tasks.

The performance of all teams varies considerably according to language. It would be very interesting to carry out further research to try and understand the origin of these fluctuations. Otherwise, this type of unsupervised approach cannot be recommended, since negative correlations are observed for one of the languages. It is possible that this is linked to the way in which the material has been designed, which varies greatly depending on the language for obvious reasons of unavailability of certain resources (Ousidhoum et al., 2024a).

7 Ethical Considerations

The ethical issues raised by this research are identical to those described by the researchers who collected the data (Ousidhoum et al., 2024a) and by the researchers who organized this task (Ousidhoum et al., 2024b).

Genaios at SemEval-2024 Task 8: Detecting Machine-Generated Text by Mixing Language Model Probabilistic Features

Areg Mikael Sarvazyan and **José Ángel González** and **Marc Franco-Salvador**
Genaios, Valencia, Spain
{areg.sarvazyan, jose.gonzalez, marc.franco}@genaios.ai

Abstract

This paper describes the participation of the Genaios team in the monolingual track of Subtask A at SemEval-2024 Task 8. Our best system, LLMIXTIC, is a Transformer Encoder that mixes token-level probabilistic features extracted from four `LLaMA-2` models. We obtained the best results in the official ranking (96.88% accuracy), showing a false positive ratio of 4.38% and a false negative ratio of 1.97% on the test set. We further study LLMIXTIC through ablation, probabilistic, and attention analyses, finding that (i) performance improves as more LLMs and probabilistic features are included, (ii) LLMIXTIC puts most attention on the features of the last tokens, (iii) it fails on samples where human text probabilities become consistently higher than for generated text, and (iv) LLMIXTIC's false negatives exhibit a bias towards text with newlines.

1 Introduction

The analysis of Machine-Generated Text (MGT) has gained popularity in recent times. This is important for detecting and attributing text to Large Language Models (LLMs) such as LLaMA (Touvron et al., 2023) and GPT (Ouyang et al., 2022), and combating fake-news, intellectual property violations (Henderson et al., 2023), data leakages (Nasr et al., 2023), among other malicious usages (Kasneci et al., 2023). Recent efforts include zero-shot (Bao et al., 2024) and supervised systems (Wang et al., 2023). However, large-scale scenarios that combine domains, data sources, or models are still challenging (Sarvazyan et al., 2023b; Eloundou et al., 2023). As a result, different frameworks to generate high-quality MGT datasets[1] (Sarvazyan et al., 2024) and evaluation campaigns have been released (Shamardina et al., 2022; Sarvazyan et al., 2023a). In this paper, we describe our solution as the Genaios team at SemEval-2024 Task 8: *Multigenerator, Multidomain, and Multilingual Black-Box Machine-Generated Text Detection* (Wang et al., 2024a).

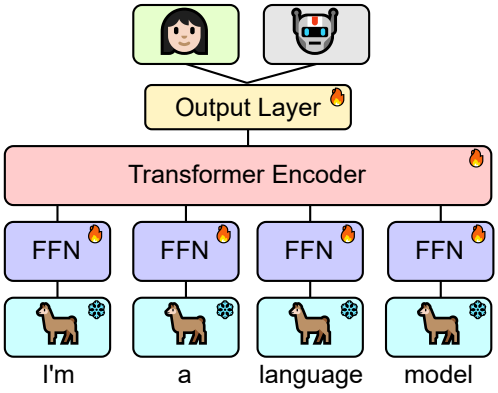

Figure 1: Overview of the proposed system. Modules marked with ❄ are frozen. Those with 🔥 are trainable.

Our starting point is the observation that LLMs assign higher probabilities to MGT than to human text. We propose LLMIXTIC, illustrated in Figure 1, which leverages this via a Transformer encoder (Vaswani et al., 2017) that mixes token-level probabilistic features extracted from four `LLaMA-2` models, both instructed and base flavors: `LLaMA-2-7b`, `LLaMA-2-7b-chat`, `LLaMA-2-13b`, and `LLaMA-2-13b-chat`. For each token, our features are (i) the log probability of the observed token, (ii) the log probability of the predicted token, and (iii) the entropy of the distribution.

These probabilistic features capture MGT style in a precise manner, favouring detection. As a result, we obtained the best results in the official ranking (96.88% accuracy) for the monolingual track of Subtask A: *Binary Human-Written vs. Machine-Generated Text Classification*. Our analysis shows that performance improves as more LLMs and probabilistic features are used. In addition, LLMIXTIC pays more attention to the last tokens of the sequence, where higher probabilities for human texts lead to misclassifications. Finally,

texts with newlines are predominant among false negatives.

2 Background

The monolingual track of Subtask A: *Binary Human-Written vs. Machine-Generated Text Classification* focuses on detecting whether an English text is entirely written by a 👩 **human** or generated by an 🤖 **LLM**. The data is an extension of the M4 dataset (Wang et al., 2024b) and combines texts from different domains and LLMs. We show the statistics of the dataset in Table 1. The official evaluation metric of the Subtask A is accuracy, which we also employ in our experiments.

3 System Overview

It is known that high-quality human text does not follow high-probability distributions over the next tokens (Holtzman et al., 2020). In contrast, LLMs are decoded to sample from regions of high probability, thus assigning higher probability to low-diversity constructions and lower to human texts. In practice, this causes MGT to be measurably different from human texts, e.g., showing less idiomatic expressions, scarce and repetitive discourse markers, or strictly complying with canonical orderings of constituents (Simón et al., 2023).

We developed our system by following these previous findings, and considering that most of the current LLMs share two key components which condition the probability distributions they learn: (i) the underlying backbone, namely Transformer decoder, with few architectural changes and (ii) large portions of their training data both for pre-training and instruction tuning. Our system relies on the hypothesis that token-level probabilistic features extracted from an specific set of LLMs can be used to differentiate human texts and MGT from a potentially different set of LLMs, which has been shown to be very effective in existing MGT detectors (Przybyła et al., 2023; Wang et al., 2023).

As depicted in Figure 1, our final system is a Transformer Encoder that mixes token-level probabilistic features extracted from four `LLaMA-2` models (Touvron et al., 2023), including base and instructed versions: `Llama-2-7b`, `Llama-2-7b-chat`, `Llama-2-13b`, and `Llama-2-13b-chat`. Following (Przybyła et al., 2023), we build feature sequences where each token is represented as the concatenation of three probabilistic features extracted from each LLM. Specifically, we employ the following features.

Log probability of the predicted token. Measures the highest probability assigned by θ to the next token as:

$$\alpha_i = \max_{y \in \mathcal{V}} \log p_\theta(y|x_{<i}) \quad (1)$$

Entropy of the distribution. Measures the uncertainty of θ for choosing the next token:

$$\beta_i = -\sum_{y \in \mathcal{V}} p_\theta(y|x_{<i}) \log p_\theta(y|x_{<i}) \quad (2)$$

Log probability of the observed token. Measures how likely is the observed token x_i according to the model θ and the prefix $x_{<i}$ as:

$$\gamma_i = \log p_\theta(x_i|x_{<i}) \quad (3)$$

Given a text $x = [x_1, ..., x_n]$ and a set of LLMs $\mathcal{L} = \{\theta_1, ..., \theta_m\}$, we represent x as a feature sequence $h = [h_1, \ldots, h_n]$ with each h_i denoting the probabilistic features from all the LLMs for the i-th token, $h_i = [\alpha_i^1; \beta_i^1; \gamma_i^1, \ldots, \alpha_i^m; \beta_i^m; \gamma_i^m]$. For instance, our final system uses four LLMs and three features from each one, $h \in \mathbb{R}^{n \times 12}$. Note that the features are extracted per-token, which constrains us to use LLMs with a shared tokenizer.

The feature vectors in h are projected to 128 dimensions through a feed-forward layer, and then mixed with a Transformer encoder of 1 layer and 4 attention heads. The output of the Transformer layer is averaged and a softmax layer is used to compute a probability distribution over the human and generated classes. This classifier on top of the probabilistic features, LLMIXTIC's only trainable component, is comprised of solely 85k parameters, being 0.0002% of the total.

4 Experimentation

We focus on the monolingual track of Subtask A, carrying out comparisons among models and ablations of the best system. For these we employ the original training and validation splits provided by the organizers. In the post-evaluation stage, we analyze the errors of LLMIXTIC in the test set by inspecting the probabilistic features extracted from `LLaMa-2`, the learned attention heads, and text patterns in the misclassified samples.

4.1 Model Comparison

We compare LLMIXTIC with classical and neural models, while also evaluating different LLMs to extract the probabilistic features. All the models in these comparisons are trained and evaluated on the original training and validation splits provided by the shared task organizers.

Classical baselines. We consider a Logistic Regression classifier, using either TF-IDF features with word n-grams ranging from 1 to 3-grams (`LR+TFIDF`), or readability features (`LR+READ`). For these, we employ `scikit-learn` (Pedregosa et al., 2011) and `readability`,[2] training the model with balanced class weights and default parameters.

Neural baselines. We also compare LLMIXTIC with two fully fine-tuned Transformer encoders, `roberta-base` (Liu et al., 2019) and `e5-base` (Wang et al., 2022). These models are trained for four epochs, using the cross-entropy loss, a batch size of 32 samples, and a learning rate of 5e-6.

LLMIXTIC's LLMs. We evaluate LLMIXTIC with probabilistic features from two LLM families, namely `GPT-2` (Radford et al., 2019; Sanh et al., 2019) and `LLaMA-2` (Touvron et al., 2023). For the `GPT-2` family,[3] we include `gpt2`, `gpt2-medium`, and `distillgpt2`. The `LLaMA-2` family is comprised of `LLaMA-2-7b`, `LLaMA-2-7b-chat`, `LLaMA-2-13b`, and `LLaMA-2-13b-chat`. These are trained for ten epochs, with a maximum text length of 512 tokens, a batch size of 32 samples, a learning rate of 1e-3, and the cross-entropy loss.

All neural models are trained with HuggingFace's Trainer (Wolf et al., 2020) in FP16 mode, employing early stopping, with a patience of 3 evaluation steps, on the validation set. The LLMs used for feature extraction are always frozen, with `LLaMA-2` models also being quantized to 8 bits. We implement LLMIXTIC in PyTorch (Paszke et al., 2019), and run all the experiments using a single NVIDIA RTX A6000.

Model	Accuracy (%)
`LR+READ`	42.32
`LR+TFIDF`	61.26
`roberta-base`	80.58
`e5-base`	74.48
LLMIXTIC (w/ `GPT-2`)	67.42
LLMIXTIC (w/ `LLaMA-2`)	**85.98**

Table 2: Model comparison results on the dev set.

Results are presented in Table 2. Here we observe how LLMIXTIC using `LLaMA-2` features outperforms every baseline by large margins, improving upon the best baseline's score by 5 points in accuracy, while having only 0.07% relative training parameters. Notably, all the neural models outperform classical baselines, which suggests that grammatical features, especially those based on readability measures, are not enough to properly discriminate between human-written and generated text. Also, the usage of probabilistic features from `GPT-2` models does not yield good results in comparison to neural baselines and LLMIXTIC with `LLaMA-2` LLMs. This suggests that the scale of the LLM used to extract features could have a large impact on the results. Considering that the `LLaMA-2` family is more similar than `GPT-2` models to the LLMs that generated the text of the dataset, we also hypothesize that using feature extraction LLMs that more closely resemble the LLMs in the dataset can yield better results.

4.2 LLM and Feature Ablations

We study the impact the number of LLMs and probabilistic features have on LLMIXTIC's performance by means of two ablation studies: at LLM and at feature level. These experiments are performed with the same experimental setup: first training with a single LLM or feature, and continually adding the other LLMs or features.

Ablation results are presented in table 3. In LLM ablation we observe improvements as more LLMs are included. Notably, the inclusion of `chat` models provides the largest improvements of up to ten points. Building upon our hypothesis about similarities in architecture, training strategies, and datasets

[2] https://github.com/andreasvc/readability/

[3] Chosen for its success in previous shared tasks (Przybyła et al., 2023) and to test for more efficient feature extractors.

Ablation	Configuration	Accuracy (%)
LLMs	LLaMA-v2-7b	74.90
	+ LLaMA-v2-13b	75.86
	+ LLaMA-v2-7b-chat	78.48
	+ LLaMA-v2-13b-chat	**85.98**
Features	Predicted	79.40
	+ Entropy	83.26
	+ Observed	**85.98**

Table 3: Ablation study over LLMs and features.

of instruction-tuned LLMs, it is expected that most of them, especially the chat models we used, have learned close distributions. Therefore, we consider that this improvement can be explained by the nature of the dataset, where all the generators were instruction tuned. We also note that LLMIXTIC with only non-instructed LLMs achieves similar results to one of the neural baselines, outperforming LLMIXTIC with GPT-2 by a large margin.

Similar to the LLM ablation, feature ablation results improve as more features are included, achieving an increment of more than six points when all the features are used. We observe that LLMIXTIC obtains similar performance to the best neural baseline just using the log probability of the predicted token and outperforms it after adding the entropy of the distribution. Besides, only with one feature, the performance is ten points higher than LLMIXTIC with GPT-2 using all the features.

5 Results

Our official submission is LLMIXTIC with LLaMA-2, trained on the training and validation sets, using the previously described experimental setting. Table 4 presents the results obtained by our system, where it reaches an accuracy of 96.88%, surpassing the other participants' approaches and ranking first. Due to time constraints, we focused our participation on the monolingual track. However, having seen the performance of LLMIXTIC on the test set of the monolingual track, we trained LLMIXTIC under the same setting for the multilingual track in a post-deadline stage (denoted in tables with *). Here, we obtained an accuracy of 89.97%, which would have placed us at 14th position.

6 Analysis

We further analyze the behavior of LLMIXTIC in the test set by examining the probabilistic features extracted from LLaMa-2, the learned attention heads, and patterns in misclassified samples.

Track	Rank	Name	Accuracy (%)
Monolingual	**1**	**Genaios**	**96.88**
	2	USTC-BUPT	96.09
	20	*baseline*	88.46
		(119 more)	
Multilingual	1	USTC-BUPT	95.98
	14*	**Genaios**	**89.97**
	25	*baseline*	80.88
		(44 more)	

Table 4: Final results on the official ranking. Bold denotes our team's placement.

LLMIXTIC fails when human text probabilities become larger than for generated texts. In contrast, LLMIXTIC works better when the generated text probabilities are consistently larger than those from human texts. To illustrate this behavior, Figure 2 shows each LLM's feature averaged both for correct and erroneous predicted samples. Errors occur with unusually high values of α and γ features in the human class, and unusually low values for the generated class. The effect of feature β is also notable, with the margin between human and generated curves being smaller in misclassifications. Additionally, for each class, chat and base models reveal different curves for all three features.

LLMIXTIC pays more attention to the last positions. Figure 3 shows the average of the attention heads across all the samples to illustrate it. This behavior could be the main cause of errors when human text probabilities become consistently larger than those for generated texts in the last positions, as shown in Figure 2. A diagonal pattern with high probability is also noticeable until approximately position 150, after which it disappears.

Human text is more often confused with generated text than vice versa. There are twice as many false positives as there are false negatives (714 vs. 355). This translates into a false positive rate of 4.38% and a false negative rate of 1.97%.

Newlines are predominant in false negatives. We manually analyze the errors with higher confidence, finding that most of LLMIXTIC's false negatives include \n to separate sentences or paragraphs, while false positives do not, to the same extent. Specifically, \n is present in 75.49% of false negatives, whereas it is only present in 34.59% of false positives. This difference could suggest (i) a potential bias in the training data, with human texts containing more \n than the generated texts,

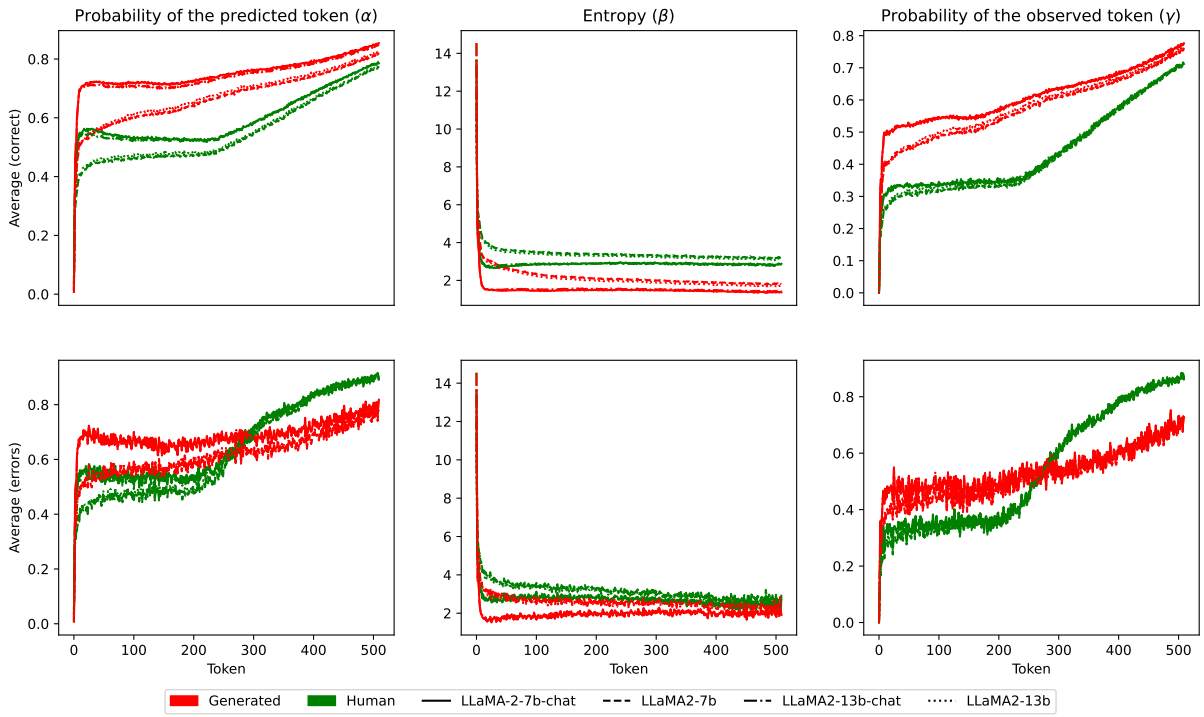

Figure 2: Sample-averaged probabilistic features of the four `LLaMa-2` models, for the two classes (generated and human). Both for correct predictions (top row) and errors (bottom row). The y axis denotes the average of the probabilistic feature (α, β, or γ) across all samples of a label in the test set, at a given position marked on the x axis. Throughout all positions, the probabilities of generated text for correct predictions consistently exceed those of humans. However, for errors, human probabilities surpass those of generated text from the middle of the sequences.

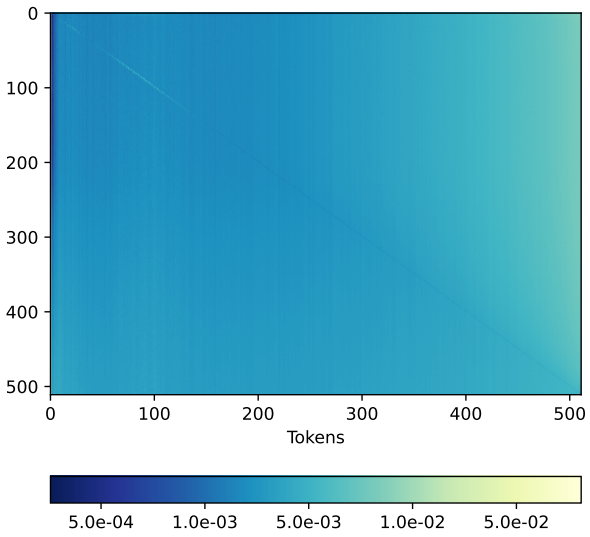

Figure 3: Sample-averaged and head-averaged attention scores from LLMIXTIC's Transformer encoder. LLMIXTIC pays more attention to the last positions.

or (ii) our system is learning a spurious correlation between `\n` and the human class.

7 Conclusion

We described the participation of the Genaios team in the monolingual track of Subtask A at SemEval-2024 Task 8. We proposed LLMIXTIC, a Transformer Encoder that mixes token-level probabilistic features extracted from four base and instructed `LLaMA-2` models, namely `LLaMA-2-7b`, `LLaMA-2-7b-chat`, `LLaMA-2-13b`, and `LLaMA-2-13b-chat`. Our system obtained the best results in the official ranking, with small false positive and false negative ratios.

Our ablation analyses showed that LLMIXTIC's performance improves as more LLMs and probabilistic features are used. We compared these features across correctly predicted and misclassified samples, finding that LLMIXTIC works better when MGT probabilities are consistently higher than for human text. In addition, attentions are mostly focused on the last tokens, which could be one of the causes of the errors made by LLMIXTIC. Finally, the newline character seems predominant in false negatives but not in false positives, which suggests biases either in the data or in our model.

Aiming to foster R&D in this area, future works will focus on TextMachina,[1] a framework to generate MGT datasets for tasks such the ones addressed in this SemEval shared task: detection, attribution, boundary, and mixcase detection.

Self-StrAE at SemEval-2024 Task 1: Making Self-Structuring AutoEncoders Learn More With Less

Mattia Opper [a] and **N. Siddharth** [a,b]
[a] University of Edinburgh; [b] The Alan Turing Institute
{m.opper,n.siddharth}@ed.ac.uk

Abstract

This paper presents two simple improvements to the Self-Structuring AutoEncoder (Self-StrAE). Firstly, we show that including reconstruction to the vocabulary as an auxiliary objective improves representation quality. Secondly, we demonstrate that increasing the number of independent channels leads to significant improvements in embedding quality, while simultaneously reducing the number of parameters. Surprisingly, we demonstrate that this trend can be followed to the extreme, even to point of reducing the total number of non-embedding parameters to seven. Our system can be pre-trained from scratch with as little as 10M tokens of input data, and proves effective across English, Spanish and Afrikaans.

1 Introduction

Natural language is generally understood to be compositional. To understand a sentence, all you need to know are the meanings of the words and how they fit together. The mode of combination is generally conceived as an explicitly structured hierarchical process which can be described through, for example, a parse tree. Recent work by Opper et al. (2023) presents the Self-StrAE (Self-Structuring AutoEncoder), a model which learns embeddings such that they define their own hierarchical structure and extend to multiple levels (i.e. from the subword to the sentence level and beyond). The strengths of this model lie in its parameter and data efficiency achieved through the inductive bias towards hierarchy.

Learning embeddings such that they meaningfully represent semantics is crucial for many modern NLP applications. For example, retrieval augmented generation (Lewis et al., 2020) is predicated on the fact that the correct contexts for a given query can be determined. The semantic relation between a query and a context is encompassed by the notion of semantic relatedness. They are not equivalent to one another (i.e. paraphrases), but are close in meaning in a broader, more contextual sense. The focus of task one of this year's SemEval (Ousidhoum et al., 2024a,b) is capturing this notion of semantic relatedness, with a particular focus on African and Asian languages generally characterised by a lack of NLP resources.

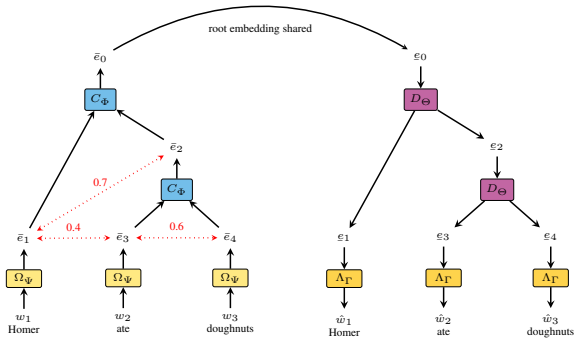

Figure 1: Self-StrAE forward pass. Red lines indicate cosine similarity between adjacent nodes. Shared colours indicate shared parameters.

In this work, we investigate whether Self-StrAE can learn embeddings which capture semantic relatedness, when trained from scratch on moderately sized pre-training corpora. We turn to the competition in order to examine whether the model can even compare with dedicated STR systems. In order to determine whether Self-StrAE can provide an alternative approach in low resource settings where systems that rely on large pre-trained transformers (Vaswani et al., 2017) may not have sufficient scale to prove effective. We show that with two simple changes, Self-StrAE's performance can be substantially improved. Moreover, we demonstrate that the the resulting system is not limited to English, but can work equally well (if not better) for both Spanish and Afrikaans [1].

2 Model and Objectives

2.1 Model

The core architecture at the heart of this paper is the Self-StrAE. A model that processes a given sentence to generate both multi-level embeddings and a structure over the input. The forward pass begins by first *embedding* tokens to form an initial frontier, using the embedding matrix Ω_Ψ. This is followed by iterative application of the following update rule:

1. Take the cosine similarity between adjacent embeddings in the frontier.
2. Pop the most similar pair.
3. Merge the pair into a single parent representation, and insert into the frontier.
4. If len(frontier) = 1, stop

Merge is handled by the recursively applied *composition function* C_Φ, which takes the embeddings of two children and produces that of the parent. The process is illustrated in 1. In the figure, the highest cosine similarity is between the embeddings of 'ate' and 'doughnuts', so these two embeddings are merged first. At the next step, 'Homer' and 'ate doughnuts' are merged as they have the highest similarity of the remaining embeddings. At this point the frontier has shrunk to a single embedding and the root has been reached.

If we consider the merge history at the root, we can see that it has come to define a tree structure over the input. This structure is passed to the decoder, which then generates a second set of embeddings, starting from the root and proceeding to the leaves. The decoder achieves this through recursive application of the *decomposition function* D_Θ, which takes the embedding of a parent and produces the embeddings of the two children. Once the decoder reaches the leaves, it can optionally output discrete tokens through use of a *dembedding function* Λ_Γ.

We denote embeddings produced during composition as $\bar{e}$ and produced during decomposition as $\underline{e}$. For a vocabulary of size *V*, each embedding $e \in \mathbb{R}^E$ consists of *k* independent channels of size *u*. With this notation established, we can now define the four core components of a Self-StrAE.

Embedding:
$\Omega_\Psi(w_i) = w_i\Psi$, where $\Psi \in \mathbb{R}^{V\times E}$

Composition:
$C_\Phi(\bar{e}_{c1}, \bar{e}_{c2}) = hcat(\bar{e}_{c1}, \bar{e}_{c2})\Phi + \phi$
where $\Phi \in \mathbb{R}^{2u\times u}$ and $\phi \in \mathbb{R}^u$

Decomposition:
$D_\Theta(\underline{e}_p) = hsplit(\underline{e}_p\Theta + \theta)$
where $\Theta \in \mathbb{R}^{u\times 2u}$ and $\theta \in \mathbb{R}^{2u}$

Dembedding:
$\Lambda_\Gamma(\underline{e}_i) = \underline{e}_i\Gamma$ where $\Gamma \in \mathbb{R}^{E\times V}$

Note that in the above the dembedding layer is treated as a separate parameter matrix to the embedding layer, however, it can just as easily be weight tied to increase efficiency.

2.2 Objectives

There are a few options for pre-training Self-StrAE. The simplest solution is to have the model reconstruct the leaf tokens, which can be achieved by simply employing cross entropy over the output of the dembedding layer. For a given sentence $s_j = \langle w_i \rangle_{i=1}^{T_j}$, this objective is formulated as:

$$\mathcal{L}_{\text{CE}} = -\frac{1}{T_j}\sum_{i=1}^{T_j} w_i \cdot \log \hat{w}_i. \tag{1}$$

An alternative approach adopted by Opper et al. (2023) is to use contrastive loss as the reconstruction objective. For a given batch of sentences s_j, the total number of nodes (internal + leaves) in the associated structure is denoted as M. This allows for the construction of a pairwise similarity matrix $A \in \mathbb{R}^{M\times M}$ between normalised upward embeddings $\langle \bar{e}_i \rangle_{i=1}^M$ and normalised downward embeddings $\langle \underline{e}_i \rangle_{i=1}^M$, using the cosine similarity metric (where embeddings are flattened to be of shape *E*). Denoting $A_{i\bullet}, A_{\bullet j}, A_{ij}$ the i^{th} row, j^{th} column, and $(i,j)^{\text{th}}$ entry of a matrix respectively, the objective is defined as:

$$\mathcal{L}_{\text{cont}} = \frac{-1}{2M}\left[\sum_{i=1}^{M}\log \sigma_\tau(A_{i\bullet}) + \sum_{j=1}^{M}\log \sigma_\tau(A_{\bullet j})\right] \tag{2}$$

where $\sigma_\tau(\cdot)$ is the tempered `softmax` (temperature τ), normalising over the unspecified ($\bullet$) dimension.

A final option is to combine these two objectives, applying the cross entropy reconstruction over leaves and the contrastive objective over all other nodes, where constructing a vocabulary is intractable due to the number of possible combinations. The contrastive objective remains identical except that A is now defined as pairwise similarity matrix $A \in \mathbb{R}^{I \times I}$, where I is the number of internal nodes of the structure. In its simplest form, this objective, which we will henceforth refer to as CECO, can then be defined as:

$$\mathcal{L}_{\text{CECO}} = \frac{1}{2}(\mathcal{L}_{CE} + \mathcal{L}_{cont}) \quad (3)$$

3 Experiments

3.1 Setup

For all experiments, we utilise a pre-training set of ≈10 million tokens. We make this choice because Self-StrAE is intended to be data efficient, especially if it is to be useful for low resource languages where scale may not be available. For English the data was sourced from a subset of Wikipedia, while for Afrikaans and Spanish we obtained corpora from Leipzig Corpora Collection[2]. We utilise a pre-trained BPE tokenizer for each language from the BPEMB Python package (Heinzerling and Strube, 2018). Though the package also provides pre-trained embeddings, we solely use the tokenizer and learn embeddings from scratch.

During the course of model development, we utilised additional evaluation sets as a further guide. For English, we used Simlex (Hill et al., 2015) and Wordsim353 (Agirre et al., 2009) as measures of how well the model captures lexical semantics, and STS-12 (Agirre et al., 2012), STS-16 (Agirre et al., 2016) and STS-B (Cer et al., 2017). For Afrikaans, due to lack of resources, we utilised a Dutch translation of STS-B (Huertas-García et al., 2021) as the two languages are closely related. For Spanish, we utilised a Spanish translation of STS-B from the same source, as well as the labelled train and dev sets from SemRel 2024 (Ousidhoum et al., 2024a). While these sets contain labels, we apply the model fully unsupervised and solely use them for zeroshot evaluation.

We train Self-StrAE for 15 epochs using the Adam optimizer at a learning rate of 1e-3 (Kingma and Ba, 2015). We set the embedding dimension to 256, with a batch size of 512 and τ of 1.2. We conducted our primary experiments on English and then applied the same system design to Spanish and Afrikaans.

[2]For both Spanish and Afrikaans we selected the mixed corpus and took a uniform subsample to reduce size to the requisite scale.

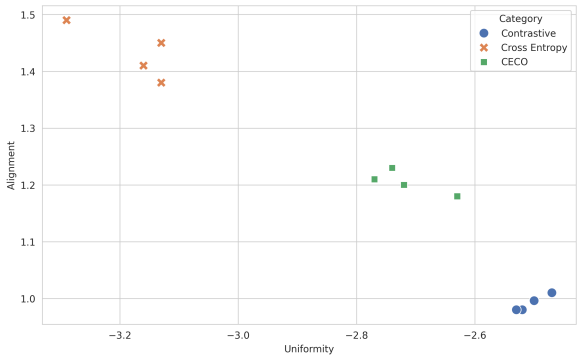

Figure 2: Uniformity and Alignment plot for contrastive, cross entropy and CECO pre-training objectives. Results taken across four random seeds. Lower is better for both measures.

3.2 Which Objective is Best?

The first thing we want to establish is which objective is most suitable for training Self-StrAE, as the original version only utilises contrastive loss. For parity with the original implementation, we treat the embeddings as square matrices (i.e. $k = u$) in this experiment.

Figure 2 show the uniformity and alignment analysis (Wang and Isola, 2020) of the representations learned by the different objectives. Uniformity describes the extent to which embeddings are spread around the space, while alignment characterises how similar positive target pairs are to each other. To be successful, representations should optimise both properties. We can observe that while the cross entropy objective leads to uniformity, it is comparatively poor at optimising alignment. This essentially implies that the decoder embeddings deviate from those of the encoder. Alignment is clearly a desireable property, as the results in table 1 show. The contrastive loss leads to both better sentence level representations and to more stable performance.

However, the best setting of all is CECO (the combination of cross entropy and contrastive). There are two factors worth considering that may explain this finding. Firstly, including reconstruction of discrete labels inherently provides additional meaningful information compared to just organising the representations alone. Secondly, at the token level the contrastive loss is most sus-

Objective	Simlex	Wordsim S	Wordsim R	STS-12	STS-16	STS-B	SemRel (Dev)

Table 2: Impact of number of independent channels on performance. Results are taken across four random initialisations. Models are trained on English. Top half of the table represents average performance, the bottom half contains the best performing initialisation. # Params is the number of non-embedding parameters.

ceptible to noise (e.g. the word 'the' may occur frequently in the batch, but each repeated instance will be treated as a false negative), and under such conditions the objective has been shown to lead to feature suppression (Robinson et al., 2021).

Summary: We find that combining cross entropy and contrastive loss leads to better representations than applying each objective individually, and consequently use this approach going forward.

3.3 How many channels?

Each embedding in Self-StrAE is treated as consisting of k independent channels of size u. This is intended to allow the representations to capture different senses of meaning. However, in the original paper the number of channels is set to be the square root of u, and not explored further. Consequently, we wanted to see what the optimal balance between the number of channels and their size was. Results are shown in 2. Surprisingly, we found that as the number of channels increased (and consequently u decreased) performance improves quite dramatically, even to the limit of treating each value in the embedding as independent. Furthermore, because the number of non-embedding parameters (i.e. the composition and decomposition functions) is directly tied to the channel size u, *decreasing model complexity improves embedding quality*.

However, it should be noted that this decrease in complexity comes with a tradeoff in terms of reliability. The smaller the size of the channel, the more variance we observed between random initialisations, with some initialisations failing to learn any meaningful representations whatsoever. We have found a solution that is able to maintain performance and ensure stability between seeds, but we leave discussion of this to the appendix, as we do not yet have a clear picture of what exactly is causing instability and wish to avoid speculation. We do however wish to emphasise that the problem is tractable and there is ample scope for further development, and direct the interested reader to A for more information.

Summary: Increasing the number of channels while decreasing their size leads to significant improvements in performance, though at the cost of some instability between seeds. For our submisson to SemRel we used the setting $k = 128$, $u = 2$ as this allowed for an acceptable failure rate while not compromising performance (roughly 1 in 4 seeds fail). Consequently, our system utilises only 22 non-embedding parameters.

3.4 Performance Across Languages

So far our experiments have only considered English. We now examine whether the framework is language agonistic, and pre-train Self-StrAE on both Spanish and Afrikaans. As before we pretrain on a small scale data (described in 3.1).

Results are in 3. We can see that the improvements to Self-StrAE hold across different languages and are not the result of some quirk in our English pre-training set. In fact performance is either comparable or better than on English. The

Language	NL STS-B (Dev)	NL STS-B (Test)	Afr SemRel (Dev)	Afr SemRel (Test)	Competition Rank
Afrikaans	52.8	64.5	23.4	76.5	2
Language	ESP STS-B (Test)	ESP SemRel (Train)	ESP SemRel (Dev)	ESP SemRel (Test)	Competition Rank
Spanish	61.5	58.5	68.7	63.5	6

Table 3: Self-StrAE Performance on Spanish and Afrikaans. Results correspond to those of the submitted systems, which we selected using the best run from four random initialisations.

results on Afrikaans are particularly interesting as the model performs significantly better on this language. Whether this is due to how the test set was created or to underlying features of the language provides an interesting question for future work. Moreover, the Afrikaans model, despite never having been trained on Dutch, is able to generalise fairly well to it, shown by the results on the translated STS-B sets.

4 Related Work

Recursive Neural Networks: Self-StrAE belongs to the class of recursive neural networks first popularised by (Socher et al., 2011, 2013). Recursive neural networks are extremely similar to recurrent neural networks, they differ because they process inputs hierarchically rather than sequentially (e.g. going up a parse tree).

Learning Structure and Representations: Recursive neural networks require structure as input. An alternative approach is to train a model that learns structure and the network at the same time. Recent unsupervised examples include Drozdov et al. (2019, 2020); Hu et al. (2021). However, these mechanisms generally use search to determine structure making them highly memory intensive. Self-StrAE differs from these as it asks the representations to define their own structure, making it much more resource efficient, though less flexible in certain aspects.

Contrastive Loss: Contrastive loss is an objective which optimises the representation space directly. In broad terms this objective requires the representations of a positive pair to be as similar to each other as possible, while minimising similarity to a set of negative examples. The closest examples of this objective, for the approach employed in this paper, are Chen et al. (2020); Shi et al. (2020); Radford et al. (2021).

5 Conclusion

We show that two simple changes can make Self-StrAE significantly more performant: adding a discrete reconstruction objective and increasing the number of independent channels. The latter also has the added benefit of reducing the number of parameters in the model, and surprisingly means that simpler is better. More broadly, we believe these findings demonstrate the potential of an inductive biases towards explicit structure. Self-StrAE, at present, is a very simple model. The only thing it really has going for it is the inductive bias which tasks embeddings with organising themselves hierarchically. While the gap between Self-StrAE and SoTA systems still remains, the fact that it is able to perform at all demonstrates the promise. Moreover, the fact that the two simple changes demonstrated in this paper can lead to such improvements indicates that the full potential of the inductive bias has yet to be reached, and it is likely that further refinements can lead to even more substantial benefits. Finally, because this model does not require significant scale to optimise pursuing further improvements may provide substantial benefits for low resource languages where pre-training data is scarce.

6 Limitations

The results in this paper represent steps towards an improved model rather than a complete picture. We still do not fully understand what causes the instability in training when the number of channels increased, and though we can provide a solution (see A), further analysis is needed. The performance of contrastive loss can depend quite heavily on how positive and negative examples are defined and it is likely that the explanation rests there. Secondly, while we have shown that Self-StrAE can be applied to languages other than English the results are limited to Indo-European languages. An interesting avenue for future work would be investigating a broader spectrum of languages, and whether specific characteristics can be identified which influence how well the model performs.

A Stabilising High Channel Self-StrAE

One solution we have found to the instability issue is modifying the objective. This formulation, loosely inspired by SimCSE (Gao et al., 2021), runs the same input through the model twice, with different dropout masks applied each time. The objective is cross entropy reconstruction for the leaves, and contrastive loss between the two different sets of decoder embeddings for the non-terminals. Currently we have two theories as to why this might work:

- Better negatives: because the decoder embeddings represent the contextualised meaning of node rather than it's local one, the issue of false negatives is somewhat mitigated.
- Encoder consistency: because we ask the two sets of decoder embeddings to be similar to each other the encoder is encouraged to produce the same structure regardless of dropout mask. It may be that this pressure towards regularity leads to the improved consistency.

Results are shown in 4. For lack of a better term we refer to this alternative objective as StrCSE. In its current form we do not consider this objective to be well formed, and solely provide it here as a possible starting point for further research.

RGAT at SemEval-2024 Task 2: Biomedical Natural Language Inference using Graph Attention Network

Abir Chakraborty
Microsoft
Abir.Chakraborty@microsoft.com

Abstract

In this work, we (team RGAT) describe our approaches for the SemEval 2024 Task 2: Safe Biomedical Natural Language Inference for Clinical Trials (NLI4CT). The objective of this task is multi-evidence natural language inference based on different sections of clinical trial reports. We have explored various approaches, (a) dependency tree of the input query as additional features in a Graph Attention Network (GAT) along with the token and parts-of-speech features, (b) sequence-to-sequence approach using various models and synthetic data and finally, (c) in-context learning using large language models (LLMs) like GPT-4. Amongst these three approaches the best result is obtained from the LLM with 0.76 F1-score (the highest being 0.78), 0.86 in faithfulness and 0.74 in consistence.

1 Introduction

Clinical trials are advanced treatments and tests to evaluate new ways of treating life-threatening diseases where interventions include new drugs, cells and other biological products, advanced surgical or radiological procedures and devices. As the trial progresses the observations are documented systematically in a Clinical Trial report that includes the subject selection criteria ('Eligibility'), treatments ('Interventions') and results at group level including adverse effects. These reports constitute a rich source of past endeavours to learn from and help in formulating new treatment plans. However, the sheer volume of CT reports[1] makes it impossible to conduct extensive manual evaluation. Thus, it is necessary to have an automated pipeline that can enquire a CT report for specific hypothesis and provides high accuracy and reliability at the same time.

[1]As of Jan 17, 2024, ClinicalTrials.gov lists 480,795 CT studies

Natural language inference or NLI (Devlin et al., 2019) is one of the standard NLP tasks where a hypothesis is qualified as true (entailment) or false (contradiction) or even undetermined (neutral) given a premise. This task is adopted for reasoning over CT reports by Jullien et al. (2023) where two new tasks are created based on NLI4CT dataset, (1) NLI over CT reports and (2) extracting the evidence/mention from CT reports to support the inference label. The Semeval 2024 Task 2 NLI4CT is also based on the same NLI4CT dataset (identical for training) with modifications in the test split (more details in the Data section). The inferencing is challenging as it requires multi-hop reasoning, i.e., dependency and aggregation are required over different pieces of the document.

Other than the complexity associated with multi-hop reasoning, the domain and the associated word-distribution also creates significant challenge due to the presence of aliases, acronyms and biomedical terminologies (Lee et al., 2019a; Shickel et al., 2018; Jin et al., 2019). This results in significant drop in model performance as is evident in the NLI results last year (Jullien et al., 2023) where it was found that majority of the submitted solutions failed to outperform the baseline solution with a significant margin. The challenge is also evident in the overall performance of models on general NLI datasets (e.g., Stanford NLI or SNLI) where the best model results in 93.1% F1-score (Wang et al., 2021).

When it comes to different modeling approaches, many of the top-performing models for the SNLI dataset are ensemble in nature. While initial individual models are based on RNN, most of the latest ones are based on the Transformer architecture and pretrained language models like RoBERTa or T5. Similar trend can also be seen in Jullien et al. (2023) where the best model is an ensemble and both DeBERTa and Flan-T5 made their way to the top. Interestingly, LLMs like GPT3.5 could not

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 116–122

make a significant boost in the performance.

In our approach, we explored three different modeling paradigms, namely, (1) custom Graph Attention Network (GAT) based discriminative model with novel features based on the dependency tree of the input query, (2) generative models based on T5 and Flan-T5 but enriched with synthetic data used for both pre-training and fine-tuning, and (3) LLM like GPT-4 applied with and without few-shot examples. It is not surprising that the best performance was obtained by GPT-4 stressing on the importance of generic knowledge (that is embedded in these LLMs) rather than fine-tuning, especially when the dataset is not large enough.

The organization of the paper is as follows. In the next section we provide a detailed literature survey on the techniques employed for NLI. Next, we present the details of the proposed approaches. Subsequently, the model predictions and comparisons with other baseline methods are discussed. Finally, conclusions are drawn and scope for future works is outlined.

2 Related Work

The existing body of work for the general NLI is quite rich where they are based on the Stanford NLI (SNLI) dataset (550k examples but restricted to a single text genre) (Bowman et al., 2015) and three other NLI datasets present in GLUE (Wang et al., 2018), namely, MNLI, QNLI and WNLI. The MNLI (Multi-Genre Natural Language Inference Corpus) dataset (Williams et al., 2018) is a crowd-sourced NLI dataset gathered from different sources, e.g., government reports (and covers different genres, e.g., fiction, travel). Given a premise-hypothesis pair of sentences, the task is to predict one of the three classes, namely, whether the premise sentence entails the hypothesis (entailment), contradicts the hypothesis (contradiction), or neither (neutral). The QNLI is modified from Stanford Question Answer Dataset (Rajpurkar et al., 2016) where the task is to determine whether the context sentence contains the answer to the question. Similarly, the WNLI dataset is created from the Winograd Schema Challenge (Levesque et al., 2012) where a coreference resolution problem is converted into an entailment problem involving a pronoun and its referent. Another large NLI dataset is multi-genre NLI (MNLI) that has 433k examples covering multiple genres and supporting cross-genre evaluation. Some of the best performances are obtained by RoBERTa (Liu et al., 2019b), XLNet (Yang et al., 2020), Multi-Task Deep Neural Network (MT-DNN) (Liu et al., 2019a) and generative pre-training (GPT) approach (Radford et al., 2018).

There are few NLI datasets in the biomedical domain, namely, MedNLI (Romanov and Shivade, 2018) and BioNLI (Bastan et al., 2022). MedNLI has 14k example pairs created by clinicians on 4,683 premises with three categories, entailment, contradiction and neutral. BioNLI, on the other hand, goes beyond sentence-level inference and includes large context as premises that requires handling complex texts as well as domain knowledge. Bastan et al. also includes negative examples as adversarial hypothesis using nine strategies which is a speciality of this dataset.

There are three biomedical domain specific models that are typically used on these datasets. Starting with the available weights of BERT (pretrained on general domain corpora), BioBERT (Lee et al., 2019b) is trained on PubMed abstracts and PMC full-text articles and shown to outperform BERT on NER, relation extraction and Q&A, all in the biomedical domain. PubMedBERT (Gu et al., 2021) is a BERT model created from scratch (rather than starting with general domain corpora) on large biomedical domain dataset like PubMed and achieved impressive performance for tasks like NER and Q&A. BioLinkBERT (Yasunaga et al., 2022) further exploited links between PubMed documents to create a richer context that is used to build a language model (LM). This model has obtained SOTA performance on biomedical datasets such as BLURB (Gu et al., 2021) and BioASQ (Nentidis et al., 2020). Another model that achieved SOTA performance on MedNLI is SciFive (Phan et al., 2021) which is based on T5 paradigm.

There are not many studies on the application of Graph Neural Network for NLI. Inspired by KIM (Chen et al., 2018) where external knowledge is infused for NLI task, Song et al. (2020) developed a joint training model where Graph Attention Network (GAT) is used to represent the sub-graph associated with entities that are involved in the hypothesis. Another closely related GAT application is from Chen et al. (2021) applied for fact verification on Wikipedia articles. Typical applications of GAT in the NLP domain are for question answering, semantic parsing, information extraction and Named Entity Recognition (Wu et al., 2022;

Chakraborty, 2023).

3 Task Description & Data

The dataset for Multi-evidence NLI for Clinical Trial (NLI4CT) is based on a collection of breast-cancer CT reports[2] containing statements, explanations and labels annotated by domain expert annotators (Jullien et al., 2024). Each CT report has four sections: (a) Eligibility criteria (a set of conditions for patients to be included in the trial cohort), (b) Intervention (information regarding the details of treatments administered), (c) Results (what is the outcome of these treatments) and (d) Adverse events (if anything was observed during the period of the trial). The annotated statements (hypothesis) are claims extracted from one of the four sections (with an average length of 19.5 tokens) and may even compare more than one report. Each statement is qualified as either 'Contradiction' or 'Entailment'.

There are 1700 examples in the training set and 200 in the development/validation set with exactly 50:50 split of the two classes. The test set has 5500 examples with unknown label distribution. A typical example looks like the following:

1. **Hypothesis**: 'All the primary trial participants do not receive any oral capecitabine, oral lapatinib ditosylate or cixutumumab IV, in contrast all the secondary trial subjects receive these.'
2. **Primary context**: 'Patients with early stage, ER positive primary breast cancer undergo FLT PET scan at baseline and 1-6 weeks after the start of standard endocrine treatment. The surgery follows 1-7 days after the second FLT PET scan.'
3. **Secondary context**: 'Patients receive oral capecitabine twice daily on days 1-14 and oral lapatinib ditosylate once daily on days 1-21. Courses repeat every 21 days in the absence of disease progression or unacceptable toxicity'
4. **Label**: 'Contradiction'

where the secondary context provides the justification of the label.

4 Methodology

We have explored three different modeling strategies for the prediction of the inference label. They are (1) custom discriminative model with GAT applied to create features from the dependency tree of the hypothesis statement, (2) sequence-to-sequence generative models based on T5 and Flan-T5 but enriched with synthetic data used in both pre-training and fine-tuning and (3) LLM based solution with and without Few-shot examples.

[2]extracted from https://clinicaltrials.gov/ct2/home

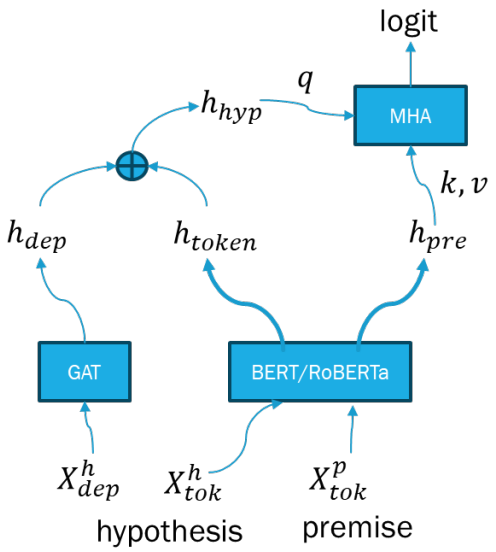

Figure 1: The architecture of the custom model using GAT and Multi-head attention (MHA).

4.1 Discriminative Model

The architecture of our custom discriminative model is shown in Fig 1. We use the tokens of both the hypothesis and the premises to generate a representation using either a standard BERT or RoBERTa model (referred as h_{tokens} for the hypothesis and h_{pre} for the premise. Following the RGAT approach of Wang et al. (2020) (originally meant for aspect polarity detection) we utilize the dependency structure of the input hypothesis (X^h_{dep}) that captures the grammatical relations by connecting the words with the corresponding dependency type. However, we do not reorient the dependency tree since there is no aspect word in our application. Using GAT based processing of the hypothesis dependency tree we generate additional features h_{dep}. Details of the GAT based processing are provided in Appendix A. We concatenate both the features of the hypothesis (h_{dep} and h_{tokens}) and pass through a linear layer to create the final hypothesis feature, h_{hyp}. For the premise, there is only the token based feature, h_{pre}, which is used as a key and value in a standard multi-head attention (MHA) with h_{hyp} as the query vector. This process

is repeated multiple times (maximum 3) with the output of the previous MHA layer. Finally, we take the first vector of the MHA output (corresponding to [CLS]) and pass it through a linear layer to generate the logits. The model is trained for binary cross-entropy loss.

4.2 Generative Model

In the 2023 SemEval challenge (Jullien et al., 2023), it was found that generative models outperformed discriminative models on the entailment task. We also explore different T5 models (small and base T5 and base SciFive) for the current entailment task with the exception that we have also generated synthetic data for pre-training as well as fine-tuning.

4.2.1 Generation of Synthetic Data

For generating synthetic data for T5 pre-training we follow (1) the standard T5 random span masking[3] for both the hypothesis and premise sentences and (2) ask GPT-4 to identify spans and mask them subsequently. The first approach works better for the quality of the data and we use this approach for generating the final pre-training data. We have used noise density = 0.4 and average noise span length of 2 and generate 73,457 pre-training examples.

For generating additional fine-tuning data, we use GPT-4 (with temperature = 0.7) with three additional tasks, namely, (a) Question answering on the premise text, and (b) additional inference data from the same set of premises and (c) create a contradictory hypothesis from the original hypothesis. For the first task, examples look like

1. Question: 'How many weeks after the start of standard endocrine treatment is the second FLT PET scan conducted?', Answer: '1-6 weeks'

2. Question: 'On which days is oral capecitabine given in Arm A?', Answer: 'days 1-14'

Additional NLI examples are

1. Hypothesis:No adverse events were reported in the clinical trial., Label: Entailment

2. Hypothesis: The clinical trial report had 765 adverse events in one section and 88 in another section., Label: Contradiction

In this process we generate 11k Q&A pairs and 45k NLI pairs and 1700 contradictory NLI examples from the original 1700 training examples.

4.3 Large Language Model

It was also observed in 2023 SemEval challenge (Jullien et al., 2023) that increase in model size also improves the performance. We further validate this hypothesis by applying GPT-4 to the NLI task with and without few-shot examples.

4.4 Implementation Details

For the discriminative model we use the bi-affine parser (Dozat and Manning, 2016) from AllenNLP for dependency parsing. For all experiments, the embedding dimension for the dependency relation is same as the hidden dimension of the BERT/RoBERTa model. We use 3 MHA layers with 8 heads and 2 GAT layers with 6 heads and all the dropouts are fixed at 0.3. The model has a total of 110 million parameters for BERT-base and 351 million parameters for BERT-large. The last hidden state of the pre-trained BERT[4] is used for the initial token representations which is subsequently fine-tuned. All models are trained for 50 epochs using Adam optimizer (Kingma and Ba, 2014) (with the default parameters), a learning rate of 5×10^{-5} and a batch size of 8.

We have pretrained both small and base T5 models for subsequent NLI task. Pretraining is done for 20 epochs with a batch size of 16 and learning rate of 5×10^{-5} with Adam optimizer. From the 73,457 span masked examples, we use 66111 for training and 7346 for validation that is used to keep track of the validation loss and saving the model.

5 Results

In this section, first we describe the performance of the custom discriminative model followed by the performance of the fine-tuned T5 model and finally the results from GPT-4. Although we compute precision, recall and F1-score for all our experiments we report only F1-score here. It is to be noted that we did not evaluate our model on the test dataset for all our experiments and submitted test results only for the best validation performance. Thus, for most of our experiments we report only the validation F1-score and also mention the test F1-score wherever available. Table 1 summarizes the results from the custom discriminative model. There are

Table 2: Performance of different generative models including GPT-4.

four flavors of this model, one with BERT-large and three with BERT-base. Within BERT-base, we have one with cross-attention, one without ('combined-pooler' that only concatenates the two BERT outputs) and the third one with cross-attention and GAT. It can be seen that the presence of GAT improves the validation F1 score over the other variants. However, the performance does not improve with the larger BERT model. Surprisingly, the corresponding test F1-score shows significant degradation implying substantial difference in the test data distribution (tokens, nature of problem or label) from that of the validation dataset. The small number of validation dataset also contributes to this mismatch.

Table 2 captures the details of different experiments with generative models like, T5, Flan-T5 and GPT-4. The size of the generative model (small vs. base) has strong contribution to the performance as confirmed earlier (Jullien et al., 2023). However, the addition of synthetic data does not improve (rather degrade) the F1-score which is evident for both the small and base version of T5. This challenges the traditional belief of improvement due to multi-task learning and indicates potential conflicts in the synthetic data due to either a mismatch in the nature of the problem (e.g., Q&A) or accuracy of the synthetic data (since they are not manually verified). The best result is obtained by a base Flan-T5 model trained without any synthetic dataset that results in a test F1-score of 0.61. Finally, using GPT-4 (version `0613`, maximum context length of 8192) without any Few-shot examples results in the best test F1-score of 0.76.

6 Conclusion

In this work we have explored both discriminative and generative models for NLI applied to CT reports. While our custom discriminative model outperforms generative models like T5-base and Flan-T5-base the same is not true when evaluated on the test dataset indicating the limitation of the small validation dataset and significant change in data distribution. Since the training dataset is small (1700) we also explore enriching the same with synthetic data created by LLMs like GPT-4 for additional task (e.g., Q&A) and the same NLI task. However, the addition of these synthetic data substantially degrades the performance rather than improving pointing to a deeper analysis of the role of synthetic data for NLI task. The only exception is in the pretraining synthetic data created for small Flan-T5 model that boosted the final performance. The best result is obtained by GPT-4 without using Few-shot examples and we suspect both the addition of examples and modification of the prompt can further improve the performance.

A Graph Attention Network

The dependency tree can be represented by a graph structure where each node is a word and the edges between them are represented by the dependency relation, e.g., nominal subject, adverbial modifier, etc. Following Wang et al. (2020), given a neighborhood of a node $\mathcal{N}_i$, the node embeddings can be iteratively updated using multi-head attention (with K attentional heads) as

$$h_{att_i}^{l+1} = concat_{k=1}^{K} \sum_{j \in \mathcal{N}_i} \alpha_{ij}^{lk} W_k^l h_j^l, \quad (1)$$

$$\alpha_{ij}^{lk} = attention(i, j), \quad (2)$$

where $h_{att_i}^{l+1}$ is the attention head of node-i at layer $l+1$ and α_{ij}^{lk} is the normalized attention coefficient computed by the k-th attention at layer l and W_k^l is an input transformation matrix.

In addition to the attention head of word-i a relational head is also computed for this node as

$$h_{rel_i}^{l+1} = concat_{m=1}^{M} \sum_{j \in \mathcal{N}_i} \beta_{ij}^{lm} W_m^l h_j^l, \quad (3)$$

$$g_{ij}^{lm} = \sigma(relu\left(r_{ij} W_{m1} + b_{m1}\right) W_{m2} + b_{m2}) \quad (4)$$

$$\beta_{ij}^{lm} = exp(g_{ij}^{lm}) / \sum_{j \in \mathcal{N}_i} exp(g_{ij}^{lm}) \quad (5)$$

where r_{ij} denotes the relation embedding between node-i and j and M is the number of relational heads. The final representation of each word (node) is a concatenation of the attention and relational embeddings:

$$x_i^{l+1} = concat(h_{att_i}^{l+1}, h_{rel_i}^{l+1}) \quad (6)$$

$$h_i^{l+1} = relu\left(W_{l+1} x_i^{l+1} + b_{l+1}\right) \quad (7)$$

BDA at SemEval-2024 Task 4: Detection of Persuasion in Memes Across Languages with Ensemble Learning and External Knowledge

Abstract

This paper outlines our multimodal ensemble learning system for identifying persuasion techniques in memes. We contribute an approach which utilises the novel inclusion of consistent named visual entities extracted using Google Vision's API as an external knowledge source, joined to our multimodal ensemble via late fusion. As well as detailing our experiments in ensemble combinations, fusion methods and data augmentation, we explore the impact of including external data and summarise post-evaluation improvements to our architecture based on analysis of the task results.

1 Introduction

In this paper, we describe our approach to identifying persuasion techniques for SemEval 2024 Task 4. The task involves the identification of up to 22 persuasion techniques in memes, which are inherently multimodal. We participated in Subtask2a and Subtask2b.

Subtask2a is a multilabel classification task, requiring the identification of 22 persuasion techniques using both textual and visual content. The subtask is evaluated by a hierarchical F1, as each label is part of a subset of techniques and contains a parent node. Subtask2b is a binary classification task, determining the presence or absence of any persuasion technique within a meme (propagandistic or non-propagandistic). For both subtasks, training data is provided in the English language and a development set also in English. As well as English, 3 surprise languages in Arabic, North Macedonian and Bulgarian were provided to officially evaluate our approach (Dimitrov et al., 2024).

Our system architecture is an amalgamation of traditional NLP and vision models, exploring late and early fusion techniques as well as carefully crafted confidence thresholds. We extend beyond the training data by incorporating resources such as Google Vision[1], which provides consistent named visual entities extracted from the image regardless of language; in a multilingual context this reduces reliance on sentence spans or tokens, which can be problematic due to linguistic variations in unseen language data. We also make our code publicly available.[2]

2 Background

Identifying persuasion techniques in memes is necessary endeavour for combating misinformation and fostering critical media consumption among the public, and the focus of a number of ongoing research areas for the prevention of harmful content, propaganda or disinformation spread through memes (Dimitrov et al., 2021a; Dupuis and Williams, 2019; Sharma et al., 2022).

Propaganda is generally referred to as information which is purposefully shaped or presented to support a particular agenda, often utilising the persuasion techniques in this shared task. Previous shared tasks have also considered the identification of persuasion techniques in text only (Da San Martino et al., 2020), multimodal contexts using memes (Dimitrov et al., 2021b), and persuasion techniques in multilingual text (Piskorski et al., 2023b). SemEval 2024 Task 4 is a shared task of a similar nature, however the task considers both image and text as well as multilingual test data.

As meaning is often generating through the interaction of both modalities in memes, meme related tasks are typically approached using pretrained convolutional neural networks (Beskow et al., 2020; Hossain et al., 2022; Sherratt et al., 2023; Suryawanshi et al., 2020) or vision transformers (Afridi et al., 2021; Cao et al., 2023) in combination with language models. Our ensemble approach therefore explores CNNs for the binary classifica-

[2] https://github.com/vemchance/BDA-SemEval4

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 123–132

tion task; for the more complex multilabel classification, we explore CLIP (Radford et al., 2021) to leverage its significant pretraining on large-scale natural language descriptions and images, as well as its notable performance in zero-shot classification and related downstream multimodal tasks such as social media sentiment analysis (Bryan-Smith et al., 2023).

Our motivation for including external knowledge sources is inspired by previous successful applications of external information (Zhu, 2020) and ongoing research to improve meme-related tasks with the addition of structured knowledge to provide context to memes (Sherratt, 2022; Tommasini et al., 2023).

3 Exploratory Analysis

We briefly explore the task data and use this analysis to inform our approach, particularly for the more challenging Subtask2a. Exploring Subtask2a, we calculated TF-IDF vectors for texts within each label and calculated the cosine similarity between these vectors. We noted that, for the majority of labels, there is significant crossover in textual content. We also examine the number of labels in a single meme, as Subtask2a was a multilabel classification problem where each meme could have more than one persuasion technique, in Figure 1.

Given this crossover, we initially explored leveraging the annotation guidelines for the task, which provides concrete examples of how to label each persuasion technique. We noted the annotation guidelines primarily provided examples annotation based on the location of nouns or adjectives per technique, but provided few examples of non-European languages aside from Russian. However, the guidelines did note the presence of 'personal characteristics, organisations, political orientation or opinions' in some techniques (Piskorski et al., 2023a).

We therefore explore a more concise representation of these attributes using the Google Vision API to extract 'web entities' and visual concepts from an image. For multilingual data, this allows us to rely less on sentence spans or tokens - elements that vary across language - and instead leverage visual entities that could consistently represent information for each label regardless of textual content. In Table 1, we outline a sample of extracted entities from Google Vision's web entities search.

Technique	Entity	Occurrence Count
Appeal to (Strong) Emotions	Russia	48
Appeal to (Strong) Emotions	United States	35
Appeal to (Strong) Emotions	Amnesty International	34
Doubt	Brand	52
Doubt	Politics	48
Doubt	Public Relations	40
Doubt	Speech	39
Red Herring	Entrepreneur	8
Red Herring	Business	7
Red Herring	Ukraine	7
Red Herring	Russia	7

Table 1: Example Entities Extracted via Google Vision

4 System Overview

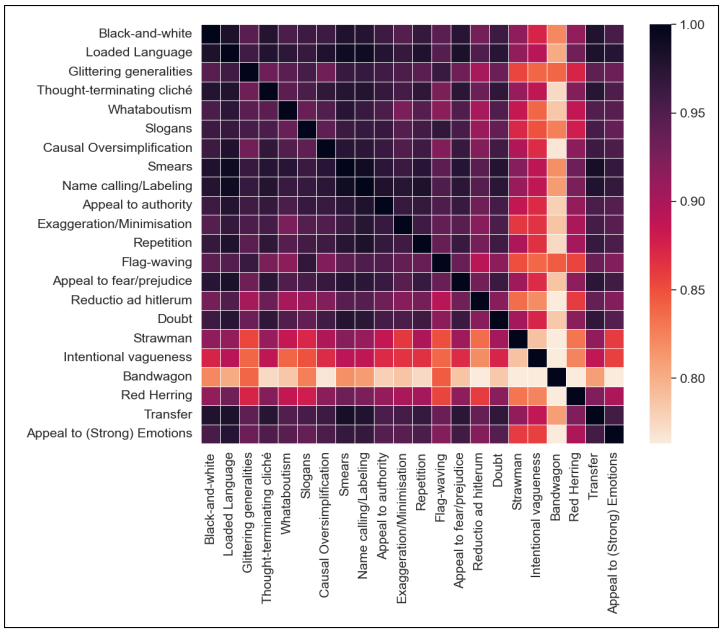
Our main system approach includes ensembling NLP models with vision models for both subtasks. We experimented with BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) family models as well as VGG19 (Simonyan and Zisserman, 2014), ResNet50 (He et al., 2015) and CLIP (Radford et al., 2021).

For Subtask2a, we initially design an architecture that combines multilingual text processing with visual analysis. Our vision stream also includes web entities from Google Vision, processed by a single BERT model. Our Subtask2b system similarly integrates visual and textual modalities with experiments in late and early fusion. We also include additional novel implementations beyond an ensemble of pretrained models:

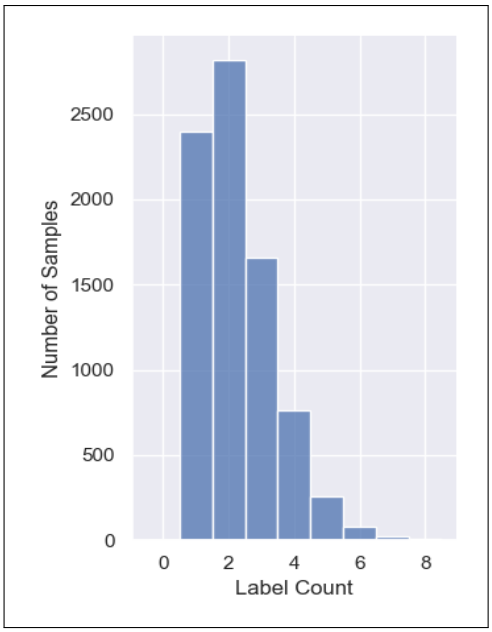
External Knowledge: We use Google Vision to extract information from meme images. The Google Vision API annotates an image using web detection, returning a list of predicted labels for objects, people or concepts in an image, as well as matching URLs and the Google Knowledge Graph ID (Singhal, 2012). We utilise only the named visual entities, with an example in Table 1.

Data Augmentation: We experiment with augmenting the task data. English training data is direct translated using GPT-3.5 (Brown et al., 2020) into a number of other languages, and then again translated when the test datasets are released.

F1 Confidence Threshold: For Subtask2a, we leverage the provided hierarchy of techniques (Dimitrov et al., 2024) to change the confidence threshold for predicted labels. The F1 Confidence Threshold reduces both the threshold required to classify a label from 0.50 to 0.40 (a full reward when scored) and a confidence between 0.35 and 0.40 will return the parent node of the label (partial reward when scored). We detail the impact of the F1 Confidence Threshold in Section 5.2.



(a) TF-IDF Cosine Similarity in Label Groups



(b) Count of Labels Per Meme in Subtask2a

Figure 1: Subtask2a Multilabel Classification Label Exploration

Late Fusion Engine: We implement a late fusion system to combine our separate NLP and vision streams together into a single predictive value. We calculate the per-label accuracy for each model, and use this to weight the contribution of each. In other words:

$$predict_{label} = \frac{(A_{label} \times accA_{label}) + (B_{label} \times accB_{label})}{accA_{label} + accB_{label}}$$

where $accA_{label} \in \{0..1\}$ and $accB_{label} \in \{0..1\}$ refers to the accuracy for the respective models for a given label.

5 Experimental Setup

We combine the training and validation sets for Subtask2a and Subtask2b to train each architecture, a total of 7,500 for Subtask2a and 1,350 for Subtask2b originally in English. We test our approach on the Development Set in English (1,000 samples for Subtask2a and 300 for Subtask2b). Detailed in Section 5.1, the total samples are increased by direct translating data for both subtasks. For all experiments, we set the validation split in the model to 30% of the total training data. When multiple languages are included in the data, we stratify the training and test splits based on language.

The number of epochs is determined by no improvement to validation loss after 5 epochs. We find that the majority of the language models in combination complete around 8 - 10 epochs, whereas CLIP often stops improving around 6 epochs. Table 2 details the specific parameters of our main models. We use pretrained models for both image and text modalities, and therefore the drop-out rate is applied before the respective classification layer detailed in Figure 2.

	mBERT	XLM-RBase	BERT	CLIP
Optimizer	AdamW	AdamW	AdamW	Adam
Dropout	0.4	0.4	0.3	0.5
Weight Decay	1e-5	1e-5	-	-
Learning Rate	1e-5	1e-5	1e-5	5e-5
Batch Size	8	8	8	16

Table 2: Model Parameters

5.1 Additional Data

We explore the use of the Persuasion Techniques Corpus (PTC) (Da San Martino et al., 2020) as additional training data. We use the Google Vision API to extract descriptive entities for all task data images, which is returned in English from the API under the 'web entities' search response. We also augment our dataset using GPT-3.5 (Brown et al., 2020) to direct translate a sample of 500 texts from Subtask2a for each unseen language in the task (1,500 additional samples, or 20% of the available training data). We perform the same process for Subtask2b. Notably we do not augment or change the image for this additional data.

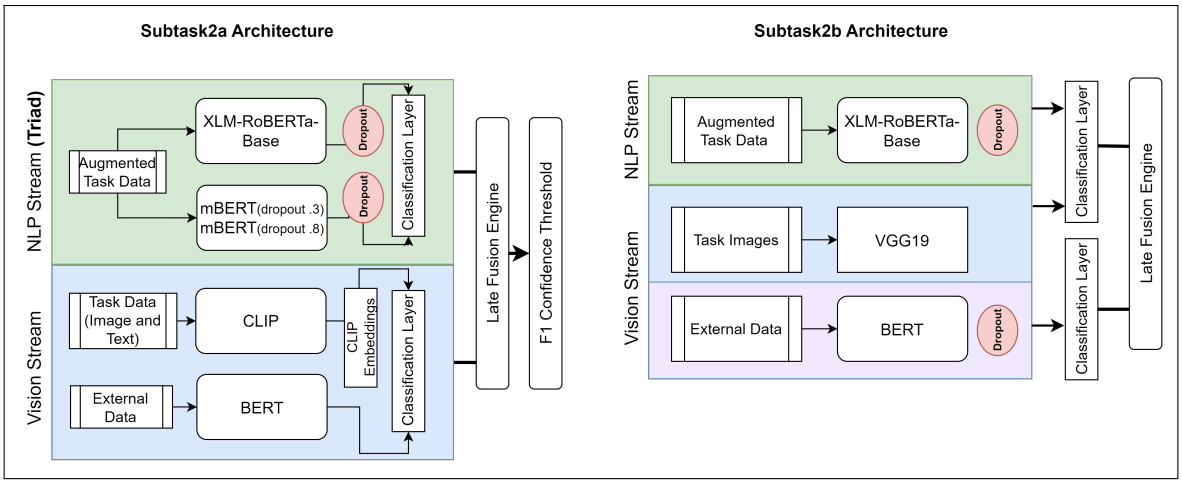


Figure 2: Subtask2a and Subtask2b Architecture

In our results detailed in Section 6, we refer to the Persuasion Techniques Corpus as *PTC*, the original task data as *TD*, the task data with added samples as *ATD* (augmented task data) and data extracted via Google Vision as *ED* (External Data). When external data is used as input, this is followed by (ex) (e.g., BERT(ex)) in Section 6.

5.2 Subtask2a Details

For Subtask2a, we experiment with a number of individual and ensemble models as detailed in Section 6, as well as different fusion strategies and the inclusion of the F1 Confidence Threshold. In early fusion, models are jointly trained and their learned feature vectors concatenated before passed through final classification layer. In late fusion, we use the late fusion engine detailed in Section 4 on the predicted probabilities of each model.

The original architecture is detailed in Figure 2. The three-model NLP stream is referred to the 'Triad' model in experiments, which includes an additional mBERT model with high drop-out to combat over-fitting. However, as we experimented with a number of model combinations, input data and fusion techniques, we opted to choose the model which performed the best on the English development data for the official submission.

As detailed in Table 3 in Section 6, our original architecture was less effective than other experiments. In our final submitted architecture we remove CLIP, so only the BERT model with external data as input remains in the vision stream, and use late fusion to merge this with the Triad NLP architecture. This model is referred to as Traid + BERT(ex) in Table 3.

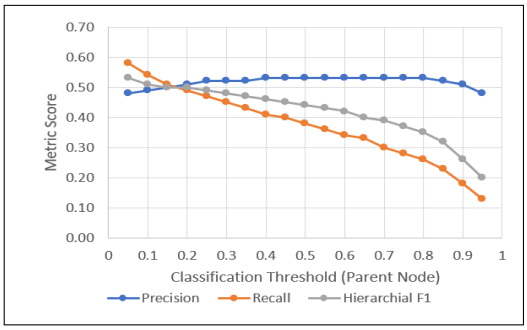

Figure 3: F1 Score Against Parent Node Threshold

We also examine the impact of changing the required confidence threshold for a label, testing a single mBERT model from our ensemble. Figure 3 provides an example each metric score mapped against the threshold to return a parent node label. The F1 Confidence Threshold reduces the threshold required predict a technique, and then introduces another lower threshold to predict the technique label's parent node from the task hierarchy (Dimitrov et al., 2024). We opted to use a configuration which balances the Hierarchical F1, Precision and Recall. In the F1 Hierarchy Threshold, the parent node prediction is always 0.05 less than the label confidence threshold. The configuration used is 0.40 for the label threshold, and 0.35 to return the parent node of the label.

5.3 Subtask2b Details

For Subtask2b, if a model is reused from Subtask2a (e.g., BERT(ex) models to process external data) we reuse the parameters described above. For the vision models, we use a different learning rate for ResNet50 and VGG19 with the AdamW optimizer

Model	Fusion	Finetune Data	H. F1	Precision	Recall

Table 3: Subtask2a Experiment Results on Development Set (English)

of 1e-8, a batch size of 8 and the same early stopping parameters as Subtask2a.

Both image models utilise ImageNet weights (Deng et al., 2009). We apply the same dropout rate specified in Table 2 to the text model before this is passed through a classification layer in the case of early fusion. As Subtask2b is a binary classification task, we do not require the F1 Confidence Threshold for this architecture. In our final architecture, VGG19 and XLM-RoBERTa-Base are trained jointly on the augmented task data, and the late fusion engine combines predictions from from the Google Vision web entities.

6 Development Set Results

We detail the results of our experiments for Subtask2a in Table 3 and Subtask2b in Table 4. In the Table 3, the F1 Confidence Threshold modification is indicated by [Model] *F1*.

For Subtask2a, we found the Triad combination performed best with BERT (trained on the extracted Google Vision entities, model BERT(ex) in Table 3) predictions combined with late fusion. The F1 Hierarchy threshold increased the score of the same model in the majority of cases.

Whilst we explored the use of PTC to finetune our models, we found that, due to the different naming conventions of some techniques, performance did not improve with incorporation of the PTC data. We also noted the PTC data was drawn from a different domain (e.g., news articles) were the context of techniques would be longer than short sentences in memes, and potentially this corpus was less effective as a finetuning dataset for the task.

We originally aimed to leverage CLIP's text and image embeddings to inform a novel early fusion neural network model for multilabel multiclass persuasion techniques classification. However, this architecture including CLIP was slightly less effective than others. The reasons behind this suboptimal performance could be multifaceted, including the complexity and subtlety of propagandistic content within memes, the inherent challenges of cross-modal understanding in this particular domain. One reason is suggested that, whilst the visual modality is important for identifying whether

Model	Fusion	Data	F1 Macro	F1 Micro
BERT(ex)	-	ED	0.577	0.580

Table 4: Subtask2b Experiment Results on Development Set (English)

a technique is present, *distinguishing* between the specific types of techniques may primarily be a linguistic task.

For Subtask2b, our architecture achieved overall better scores than Subtask2a. We tested architectures retrained for a binary classification task from Subtask2a on Subtask2b as a comparison, noting these models did not perform as well. In Subtask2b, therefore, the vision modality was significant in the binary classification task. We note from the results monolingual language models outperform multilingual models, and suggest this may be due to the limited sample size for the augmented data in Subtask2b. In line with our system strategy, we include BERT(ex) only in conjunction with multilingual models, as the aim of this additional data is to improve zero-shot classification irrespective of language. We observed significant performance increase using the BERT(ex) model in late fusion for Subtask2b.

7 Test Set Performance and Analysis

For the test set, we submitted the best performing model from each subtask experiment. For Subtask2a, this was the Triad + BERT(ex) with late fusion. For Subtask2b, we submitted the VGG19 + BERT model for English test sets and the VGG19 + XLM-RoBERTa-Base + BERT(ex) for all other languages.

Evaluating our results on the test set in Table 5, we found that our model for Subtask2a generalised better on different languages, outperforming the results on the English Development dataset in some cases. Our system performed the best on North Macedonian and the worst in Arabic for this task. The original and augmented task data for Subtask2a was larger than Subtask2b, and we effectively traded English language performance for better generalisability on other languages.

	Rank	F1	Baseline (*Diff.*)
Subtask2a			
English	12	0.504	0.447 (+*0.057*)
Bulgarian	6	0.483	0.500 (-*0.017*)
North Macedonian	**5**	**0.514**	0.555 (-*0.041*)
Arabic	7	0.416	0.486 (-*0.070*)
Subtask2b			
English	**6**	**0.793**	0.250 (+*0.543*)
Bulgarian	9	0.506	0.167 (+*0.339*)
North Macedonian	11	0.435	0.091 (+*0.344*)
Arabic	9	0.510	0.227 (+*0.283*)

Table 5: Results on Official Test Set Leaderboard

For Subtask2b, our architecture under-performed from tests on the English Development dataset aside from the VGG19+BERT model used in the English test set. This approach was less able to generalise on non-English data than our approach from Subtask2a, with a significant score reduction in North Macedonian, our highest scoring language for Subtask2a.

7.1 Subtask2a Test Set Results Analysis

We examine the importance of each modality using the English Development set using the late fusion engine, which calculates the per accuracy label from each model. Table 6 shows the weights of our original architecture (Triad plus CLIP) alongside visual entities extracted from Google, including only the top entity categories with the highest occurrence count.

Technique	NLP Weight	Vision Weight	Top Entities (English)
Appeal to (Strong) Emotions	0.793	0.949	Amnesty International; United States; Product; Russia
Appeal to authority	0.831	0.932	Quotation; US President; United States; Public Relations
Appeal to fear/prejudice	0.916	0.920	Russia; US President; United States; Product
Bandwagon	0.902	0.982	US Vice President; Product; United States; US President
Black-and-white Fallacy/Dictatorship	0.881	0.896	Russia; US President; United States; Product
Causal Oversimplification	0.921	0.943	Public; United States; Public Relations; Product
Doubt	0.912	0.944	Public speaking; Speech; Public Relations; Product
Exaggeration/Minimisation	0.868	0.927	Product; United States; US President
Flag-waving	0.847	0.897	Flag; Product; US President; United States; Speech
Glittering generalities (Virtue)	0.690	0.907	Product; Public Relations; United States; US President
Loaded Language	0.694	0.747	US President; Public Relations; United States; Product
Misrepresentation of Someone's Position (Straw Man)	0.817	0.989	Humor; Russia; US President; United States
Name calling/Labeling	0.648	0.743	Public Relations; US President; United States; Product
Obfuscation, Intentional vagueness, Confusion	0.988	0.988	2023; Album cover; Getty Images; Product
Presenting Irrelevant Data (Red Herring)	0.990	0.990	Business; Ukraine; Russia; Entrepreneur
Reductio ad hitlerum	0.984	0.984	Al-Qaeda; Russia; Product; United States
Repetition	0.961	0.951	Public Relations; Politics; US President; Product; United States
Slogans	0.905	0.883	Public Relations; US President; United States; Product
Smears	0.645	0.468	United States; US President; Product; Public Relations
Thought-terminating cliché	0.906	0.486	Russia; Politics; United States; Product
Transfer	0.733	0.718	Ukraine; United States; Russia; Product
Whataboutism	0.942	0.818	Public Relations; US President; Presentation; Product

Table 6: NLP and vision stream weighting with corresponding visual entities (Subtask2a English Development set)

In Table 6 both streams have a high and sometimes equal weight. Examining the entities, we see that higher weights in the vision stream sometimes corresponds to an identifiable and obvious visual entity - for example, 'Straw Man' or 'Name Calling' techniques with a slightly higher weight for the visual stream are labels which are likely to require a target that may not be present in the text; the top entities for these types of meme usually include a US President or Russia in the English Development set.

Techniques where the weighting leans towards the NLP stream include abstract entities; public relations is often the most common entity before a named entity such as a 'US President' or 'Product'. Additionally, techniques that use linguistic techniques (such as 'Repetition' or 'Slogans', 'Whataboutism', 'Thought-terminating cliché) had a higher contribution from the NLP stream.

7.2 Subtask2b Test Set Results Analysis

For Subtask2b, we noted that the visual modality performed better than models re-trained from Subtask2a. We also noted that, whilst CLIP performed well, as with Subtask2a this was not the best performing visual model. We suggest that VGG19's ability to capture complex visual features were more relevant to the dataset in comparison to CLIP's generalised image-text representations.

Our approach for Subtask2b did not generalise well in comparison to Subtask2a. Whilst the performance drop could equally be attributed to a smaller augmented data sample in Subtask2b, we also examine North Macedonian memes to understand the reduction of performance on this set.

Language	Entity	Occurrence Count
English	Politics	68
English	United States	62
English	US President	38
Bulgarian	Product	24
Bulgarian	Bulgaria	17
Bulgarian	Public Relations	14
North Macedonian	Cartoon	78
North Macedonian	Public Relations	38
North Macedonian	Poster	28
Arabic	Product	29
Arabic	Humor	12
Arabic	Laughter	11

Table 7: Sample Web Entities for Test Dataset in Subtask2b

Visually, North Macedonian memes were different from memes in other languages, particularly in English; they included a significant number of 'cartoon' type memes and comic strips compared to others, which is also reflected in a sample of visual entities outlined in Table 7. As our Subtask2b architecture relied more on the visual modality than Subtask2a, the reduction of performance is therefore expected given this analysis.

7.3 Post-Evaluation Analysis

Post official evaluation, we used our analysis of the competition results to explore an improved architecture for each task. Whilst these are *not* part of the official SemEval Task 4 leaderboard, we include these as additional experiments.

For Subtask2a, we incorporated the VGG19

model instead of CLIP and removed the second mBERT model with the 80% drop-out rate with the aim to provide more information from the visual modality. For Subtask2b, we attempted to improve the linguistic part of the model by incorporating XLM-Roberta-Large.

Additionally, for Subtask2b, we direct translated 200 memes per test language from the Memotion (Sharma et al., 2020) dataset which were considered 'not offensive' and labelled these non-propagandistic, to significantly increase and re-balance the data provided for Subtask2b. In this new augmented data, each test language comprised 10% of the non-propagandistic label whereas English comprised 70%, also drawing memes from Memotion in English to balance the label sample size.

Despite incorporating the visual modality and additional data, our second attempt at Subtask2a under-performed. Considering the drop, we did not feel the inclusion of external knowledge via an additional BERT model as in prior experiments would improve performance. Since our augmentation technique cannot replicate the visual modality, the visual information contains cultural entities and concepts from English-memes which likely impacts performance, particularly for techniques that require more contribution from the visual modality.

In Subtask2b, all languages improved without BERT(ex). Performance on Arabic decreased slightly with the inclusion of external knowledge, with no change in Bulgarian and an increase in North Macedonian. The inclusion of external knowledge via late fusion, comparative to the results in Table 4, provided marginal improvement; likely the dataset re-balance and inclusion of a larger language model were also significant. The augmented data for this experiment were also more diverse in this case as they were drawn from a different dataset, whereas augmenting the multilabel classes in Subtask2a from another dataset was not possible without native language speakers trained in the specific annotation task.

Subtask2a	Test Language	F1	F1 Change
mBERT+XLM-RBase + VGG19	Bulgarian	0.424	-0.059
mBERT+XLM-RBase + VGG19	North Macedonian	0.358	-0.156
mBERT+XLM-RBase + VGG19	Arabic	0.376	-0.040
Subtask2b			
XLM-RL + VGG19	Bulgarian	0.571	0.065
XLM-RL + VGG19	North Macedonian	0.570	0.135
XLM-RL + VGG19	Arabic	**0.621**	0.111
XLM-RL + VGG19 + BERT(ex)	Bulgarian	0.571	0.065
XLM-RL + VGG19 + BERT(ex)	North Macedonian	0.578	**0.143**
XLM-RL + VGG19 + BERT(ex)	Arabic	0.603	0.093

Table 8: Post-Evaluation Model Results

8 Conclusion and Future Work

We presented our ensemble learning approach to SemEval-2024 Task 4, including a number of experiments with early and late fusion, the inclusion of external knowledge and modifying the label threshold. We found that the inclusion of external sources of knowledge, even basic descriptive entities as in our experiments, improved performance on both subtasks especially using late fusion.

By their nature, memes are multimodal; our approach to Subtask2a still utilised visual elements via entities extracted from the image, and thus provided essential context to interpret ambiguous textual content, however we found the balance between visual and textual importance varied across meme types and tasks. Whilst Subtask2a benefited from the integration of visual entities as a more concise representation of the visual modality, we found that much of the context required for identifying specific techniques required either better cross-modal understanding or finer text analysis. In contrast, Subtask2b benefited from a strong visual model.

The identification of named entities in visual modality of memes is a potential future area of research, as this would enable drawing on complex stores of knowledge (e.g., knowledge graphs) for deeper cross-modal understanding when disentangling persuasion techniques. We further suggest that there is promise in generating more high quality, multilingual data for persuasion techniques across languages based on our experiments with augmented data, particularly for low-resource languages. Although we augmented the task data to cover more languages using direct translation, a limitation in this method is the inability to change the visual modality.

We also note there is a cultural element to memes not considered in current research. We identified that North Macedonian memes were visually different from other memes; the different cultural perspectives and practices in developing memes is under-researched, with only limited studies investigating global meme practices (Nissenbaum and Shifman, 2018). As well varied training data, a better understanding of cultural meme production could contribute to defining the most appropriate approach for zero-shot multilingual meme tasks.

Abstract

Nowadays, memes are considered one of the most prominent forms of medium to disseminate information on social media. Memes are typically constructed in multilingual settings using visuals with texts. Sometimes people use memes to influence mass audiences through rhetorical and psychological techniques, such as causal oversimplification, name-calling, and smear. It is a challenging task to identify those techniques considering memes' multimodal characteristics. To address these challenges, SemEval-2024 Task 4 introduced a shared task focusing on detecting persuasion techniques in multilingual memes. This paper presents our participation in subtasks 1 and 2(b). We use a finetuned language-agnostic BERT sentence embedding (LaBSE) model to extract effective contextual features from meme text to address the challenge of identifying persuasion techniques in subtask 1. For subtask 2(b), We finetune the vision transformer and XLM-RoBERTa to extract effective contextual information from meme image and text data. Finally, we unify those features and employ a single feed-forward linear layer on top to obtain the prediction label. Experimental results on the SemEval 2024 Task 4 benchmark dataset manifested the potency of our proposed methods for subtasks 1 and 2(b).

1 Introduction

Modern social media represents a prominent environment to disseminate information to a vast community in real time. Hence, persuasion techniques are often embedded in social media content to subliminally influence people and their unconscious opinions. Such techniques are now incorporated in memes due to the increasing popularity among social media users. The visual aspect of memes adds to the effectiveness of grabbing people's attention than purely word-based messages. Manipulators and propagandists now treat it as an effective tool to promote and achieve their nefarious agendas. Sometimes different organizations use it to spread fake news or propaganda which causes social chaos and incitement of hate, which could result in harm or even human casualties. Hence, the detection of persuasion techniques embedded in memes appears as a formidable task to shield individuals from deceit. Moreover, detecting these techniques from memes is a challenging task since it requires a nuanced understanding of images, and texts, and a proper appreciation of the satirical characteristics of memes. To address these challenges, SemEval-2024 introduced a shared task focusing on detecting persuasion techniques from multilingual memes (Dimitrov et al., 2024). This task comprises three subtasks. Whereas the first task is based on identifying 20 persuasion techniques from meme texts. This is a hierarchical multilabel text classification task. Tasks 2(a) and 2(b) are based on multi-modal contents. Task 2(a) is a hierarchical multimodal multilabel classification task where the proposed system needs to identify 22 persuasion techniques from multimodal memes. Task 2(b) is a multimodal binary classification task where the participants need to apply the multimodal information expressed by memes to classify them into whether they contain a persuasion technique or not. A data sample of each task along with corresponding labels was articulated in Table 1.

However, some prior works have been done on identifying persuasion techniques from texts and visuals. SemEval 2023 shared task 3 introduced a subtask based on identifying persuasion techniques used in news articles (Piskorski et al., 2023). Most of the participants used different multilingual transformer models to tackle the challenge of this task. APatt (Purificato and Navigli, 2023) utilized an ensemble of different pre-trained transformer models e.g., XLNet, RoBERTa, BERT, ALBERT, and De-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 133–138

Table 1: Sample Data of subtask 1, 2(a), and 2(b) of SemEval 2024 Task 4

Task No.	Sample Data	Label
Subtask 1	WHEN THE POWER OF LOVE IS GREATER THAN THE LOVE OF POWER, THE WORLD WILL KNOW PEACE	Loaded Language, Black-and-white Fallacy/Dictatorship, Slogans
Subtask 2(a)	Time To Straighten Out What Is Happening In Our Country! `prop_meme_4398.png`	Flag-waving,Glittering generalities (Virtue),Black-and-white Fallacy/Dictatorship
Subtask 2(b)	I MISSED THE SUPERBOWL-WHO WON?\\nEVERYONE WHO DIDN'T WATCH IT `prop_meme_4388.png`	non_propagandistic

BERTa incorporated by weighted average. Another team, KInITVeraAI (Hromadka et al., 2023) used fine-tuned XLM-RoBERTa-large model to address the multilingual characteristics of this task. They experimented with different prediction threshold values to find the optimal one.

To detect persuasion techniques in texts and images, SemEval 2021 Task 6 introduced three subtasks including multilabel text classification, span identification, and multi-modal multilabel classification task (Dimitrov et al., 2021). The top-performing team on the multilabel text classification task (Tian et al., 2021) leveraged five fine-tuned transformer models: BERT, RoBERTa, XLNet, DeBERTa, and ALBERT. They made use of external PTC corpus (Da San Martino et al., 2020) along with given training data to train these transformer models. Team NLPIITR (Gupta and Sharma, 2021) made use of a fine-tuned RoBERTa model to address the challenge of this task. Team Volta (Gupta et al., 2021) explored the potency of fine-tuned BERT and RoBERTa models for both multi-label text classification and span identification tasks and used RoBERTa Large for the final model. Their proposed architecture ranked top on span identification tasks. For the multi-label multimodal classification task, they tested the performance of the ensemble of multimodal transformers e.g., UNITER, VisualBERT, and LXMERT alongside unimodal transformers e.g., BERT, and RoBERTa. The winning team on subtask 3 (Feng et al., 2021) experimented with the ensemble of fine-tuned DeBERTa and ResNET, DeBERTa and BUTD, and ERNIE-ViL models to address the challenge of leveraging features from different data modalities.

In this paper, we demonstrate our proposed architecture to address the challenges of Subtask 1 (multi-label hierarchical text classification) and Subtask 2(b) (multi-modal binary classification) of SemEval 2024 Task 4. For subtask 1, we utilize a fine-tuned Language-agnostic BERT Sentence Embedding (LaBSE) model to extract effective contextual features of meme texts. Next, we utilize an ensemble of Vision Transformer and XLM-RoBERTa models to address the challenge of multilingual and multi-modal characteristics of subtask 2(b).

The remaining part of the manuscript is outlined as follows: The pictorial description of our proposed methods for both tasks is articulated in Section 2. Section 3 presents the experimental setup, result, and evaluation. We conclude this manuscript with some future research directions in Section 4.

2 Proposed Architecture

2.1 Subtask 1: Hierarchical Multi-label Persuasion Techniques Classification from Meme Text

The main objective of our system is to detect available persuasion techniques in meme text from 20 pre-defined persuasion technique categories. An overview of our proposed persuasion technique detection framework is shown in Figure 1.

Upon obtaining the meme texts, we employed Language-agnostic BERT sentence embedding (LaBSE) on top of Flair's Transformer Document Embeddings to generate effective document embedding vectors. Further, those document vectors are then fed to a single-layer feed-forward linear classifier to obtain the prediction label.

2.1.1 Language-agnostic BERT Sentence Embedding (LaBSE)

LaBSE is a multilingual transformer-based Language-agnostic BERT Sentence Embedding model developed by (Feng et al., 2020). It was trained on 6 Billion translation pairs and can generate sentence-level shared embedding features for 109 languages. To obtain optimal representations of multilingual sentences, LaBSE integrates

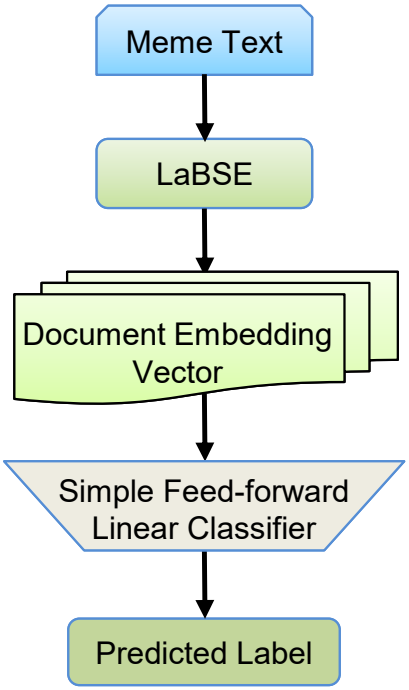

Figure 1: Proposed Framework of Subtask 1.

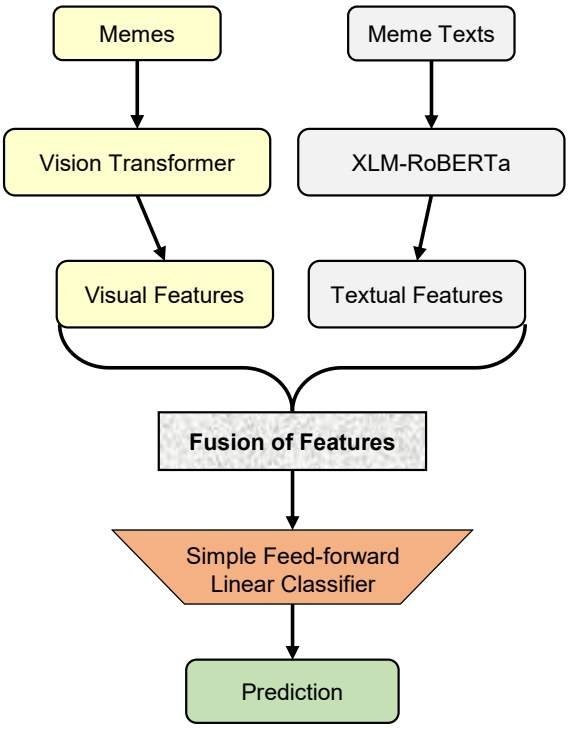

Figure 2: Proposed Framework of Subtask 2(b).

both monolingual and cross-lingual representations. It incorporates Multilingual BERT utilizing the masked language model and transformer language model with a translation ranking task alongside bidirectional dual encoders. We finetuned the LaBSE model on the benchmark dataset to capture the task-specific context effectively.

2.1.2 Transformer Document Embeddings

Document embedding represents embedding features of a full sentence rather than individual tokenized features. Flair's transformer document embeddings (Akbik et al., 2019) furnish an embedding for the entire text. We can extract embeddings directly from a pre-trained transformer model for a full sentence which enables us to capture the context of a sentence effectively. In our proposed architecture, we leverage the LaBSE model with transformer document embedding to obtain sentence-level embedding for a particular meme text.

2.2 Subtask 2: Multimodal Binary Classification Task

Figure 2 illustrates our proposed framework for subtask 2(b) where we tackled the challenges of multimodal meme classification.

Upon obtaining meme images and meme texts, we utilize a vision transformer and XLM-RoBERTa model to extract embedding features for both the meme images and meme texts. To tackle the multimodal characteristics of this task, we then integrated both visual and textual embedding features together and fed the integrated features to a single-layer feed-forward linear classifier to obtain the final prediction label.

2.2.1 Vision Transformer

The vision transformer (ViT) is a self-supervised transformer encoder model pre-trained on a large image corpus (Dosovitskiy et al., 2020). ViT generates lower dimensional linear embedding by splitting the input image into fixed-size patches and flattening the patches. After adding positional embeddings, the flattened patches are fed into a standard transformer encoder as a sequence of tokens. The ViT encoder's internal architecture is similar to that of the original transformer. We utilize the finetuned ViT model facebook/dino-vitb16 checkpoint[1] (Caron et al., 2021) to extract effective visual information from memes.

2.2.2 XLM-RoBERTa

XLM-RoBERTa is a cross-lingual sentence encoder introduced by the Facebook AI group (Conneau et al., 2019). It was trained on a large 2.5 TB Common Crawl(CC) corpus containing over 100

[1]https://huggingface.co/facebook/dino-vitb16

languages. XLM-RoBERTa showed SOTA performance in various cross-lingual tasks (Eronen et al., 2022, 2023b,a). Both the base and large variants of XLM-RoBERTa contain 250M and 560M parameters, respectively with 250K vocabulary. In our proposed multimodal architecture, we utilized the finetuned XLM-RoBERTa large version to extract an effective representation of meme texts.

2.2.3 Fusion of Features

The fusion of high-level features from different data modalities in a neural architecture is conventional to tackle the challenge of representing multimodal features (Kumar and Nandakumar, 2022), (Pramanick et al., 2021), (Velioglu and Rose, 2020). In our proposed multimodal framework, we concatenate visual and textual features extracted from the finetuned ViT and the finetuned XLM-RoBERTa model for the effective representation of multimodal features.

2.3 Prediction Module

For both subtasks 1 and 2(b), We employed a single-layer feed-forward linear layer with SoftMax activation function to obtain the prediction, like in the equation 1 below.

$$q = Wp + b \tag{1}$$

Here, the input and output feature vectors are represented by p and q respectively. W is the weight matrix and b indicates the bias.

3 Experiments

3.1 Dataset Description

For subtasks 1 and 2(b), we utilized the dataset provided by the SemEval 2024 Task 4 organizers (Dimitrov et al., 2024) to train and finetune our proposed frameworks. Table 2 shows the detailed statistics of the dataset.

To evaluate the performance of our proposed frameworks, we utilized the hierarchical F1 score for subtask 1 and macro F1 score for subtask 2(b) as per the benchmark of SemEval 2024 Task 4 (Dimitrov et al., 2024).

3.2 Experimental Setup

We utilized the Google Colaboratory platform for system implementation, training, parameter tuning, and performance analysis. For subtask 1, we utilized the LaBSE model on Flair's NLP framework. The parameters used to train and finetune our model are illustrated in Table 3.

We made use of the vision transformer and XLM-RoBERTa model to tackle the challenge of subtask 2(b). The parameters used to train the vision transformer and XLM-RoBERTa are shown in Table 4 and Table 5, respectively.

Table 2: The statistics of the dataset.

Language	#Train	#Val	#Dev	#Test
Subtask 1:

3.3 Results and Analysis

In this section, we assess the performance of our submitted systems in SemEval 2024 Task 4 subtasks 1 and 2(b). The test dataset comprises four languages including English, Bulgarian, North Macedonian, and Arabic. Table 6 and Table 7 illustrate the performance of our model for subtasks 1 and 2(b), respectively.

For subtask 1, the experimental result shows that our proposed method achieved a good Hierarchical F1 score across the English, Bulgarian, North Macedonian, and Arabic datasets. We also report the hierarchical recall and hierarchical precision scores. This signifies the versatility of our approach across multiple languages. In subtask 2(b), there is still a significant performance gap between the top-performing systems and our system. One plausible reason might be the imbalanced fusion of visual and textual features.

4 Conclusion and Future Works

In this manuscript, we presented our proposed frameworks to address the challenge of SemEval 2024 Task 4 subtasks 1 and 2(b). We employed the LaBSE model to address the multilingual characteristics of subtask 1 whereas Vision Transformer and XLM-RoBERTa models were employed to address the multi-modal and multilingual characteristics of subtask 2(b). Both of our methods showed competitive performance over other participant's systems.

In the future, we aspire to explore the effectiveness of different multimodal transformer models' performance on this task. We also have a plan to exploit the external knowledge for a better understanding of memes for this task.

Abstract

The advancement of large language models (LLMs), their ability to produce eloquent and fluent content, and their vast knowledge have resulted in their usage in various tasks and applications. Despite generating fluent content, this content can contain fabricated or false information. This problem is known as hallucination and has reduced the confidence in the output of LLMs. In this work, we have used Natural Language Inference to train classifiers for hallucination detection to tackle SemEval-2024 Task 6-SHROOM (Mickus et al., 2024) which is defined in three sub-tasks: Paraphrase Generation, Machine Translation, and Definition Modeling. We have also conducted experiments on LLMs to evaluate their ability to detect hallucinated outputs. We have achieved 75.93% and 78.33% accuracy for the model-aware and model-agnostic tracks, respectively. The shared links of our models and the codes are available on GitHub[1].

1 Introduction

Large language models are compelling in content generation. The ability of these models has led to their widespread use in various applications. Some of the use cases of these models are in sensitive fields, such as consulting in medicine and law. The eloquence of LLMs makes their content appear very acceptable, and these models respond with high confidence. An important shortcoming of these models is hallucination. Hallucination is the production of fabricated or false content (Gehman et al., 2020; Weidinger et al., 2021). Hallucination detection and mitigation are necessary to avoid the dangers of spreading false and harmful information. According to Zhang et al. (2023), hallucinations can be divided into input hallucinations, context hallucinations, and factual hallucinations. In input hallucination, the output content of the model has data that contradicts the input content. In context hallucination, the model's output content contradicts the content the model itself produced earlier. In the last case, factual hallucination, the output content of the model has information that contradicts the existing world knowledge. In the dataset provided for the Shroom task, each data sample has a reference to be checked with. Given that reference-based hallucination detection entails identifying contradictions between model output and the reference (either input or target), a natural language inference (NLI) approach presents an intuitive solution to detect such contradictions and consequently identify instances of hallucination, therefore we adopt an NLI approach as the foundation of our methodology.

Through this task, we have gained knowledge about hallucinations, their causes, and the various approaches to deal with them. Language model responses can be so fluent that it becomes difficult even for a human agent to detect hallucinations. Therefore, it is essential to train these models to recognize the limits of their knowledge. If they lack sufficient understanding of a subject, they should search for reliable sources and inform the human user if they are unsure of their answer. Our team ranked 19th and 30th in the model-aware and model-agnostic tracks, respectively, with a difference of 2.93% and 8.4% compared to the top-ranked team. We found that the decision boundary for detecting hallucinations can be very narrow in some cases. While our system has shown relatively good performance, there is still room for improvement.

2 Background

As mentioned earlier, there are three types of hallucinations. The types of hallucinations considered in this task are "factual" and "input". The "factual"

[1] https://github.com/z-rahimi-r/HalluSafe-at-SemEval-Task-6-SHROOM

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 139–147

type occurs in the definition modeling task, where the definition of a word or phrase must be provided, and the "input" type appears in the paraphrase generation and machine translation tasks. The hallucination detection track has two sub-tracks: model-aware and model-agnostic. In the model-aware subtrack, the model that generated the data is specified, and participants can use model parameters for diagnosis or analysis. However, our approach assumes the models are black-box and can be used for situations where we do not have access to the internal states and parameters of the model. It is important to note that overgeneration is another issue in LLM outputs. Samples with this issue should also be labeled as One, indicating the presence of hallucinations. Hallucination is not specific to LLMs, and before the emergence of these models, it has been investigated in NLP tasks such as summarization and machine translation (Azaria and Mitchell, 2023).

To deal with the hallucination problem in LLMs, it is essential to find the causes of the problem first. Two probable causes of hallucination, stated in Azaria and Mitchell (2023), are the model focusing on producing one token each time and random sampling to increase diversity in text production. Some believe overfitting to training data may lead to hallucination (McKenna et al., 2023). In contrast to this point of view, in Yao et al. (2023), they have shown that prompts consisting of only random meaningless tokens can also elicit hallucinations in LLMs. They believe that hallucinations are beyond training data and consider them as adversarial features. They have observed in their experiments that a slight change in the original prompt can produce a completely different claim by the LLM, which indicates that LLMs are very non-robust. In Rawte et al. (2023), they measure the relationship between linguistic factors such as readability, formality, and concreteness of prompts and hallucinations. Their results show that more concrete and formal prompts lead to fewer hallucinations, but no definite conclusion can be drawn regarding the effect of readability on hallucinations. According to this article, prompt engineering can be effective in reducing the problem of hallucinations. Lengthy prompts can hurt the understanding of the LLM. In some experiments, it has been observed that the LLM performs better when the critical information is placed at the beginning or end of the prompt. The performance quality decreases when the model needs to access the middle parts of the prompt for information.

Hallucination can be mitigated in different stages of an LLM's life cycle. As we know, the life cycle of an LLM consists of Pre-training, SFT (Supervised Fine-Tuning), RLHF (Reinforcement Learning with Human Feedback), and Inference (Zhang et al., 2023). The datasets with which LLMs are pre-trained are collected without human supervision. These data can include false or outdated information, which may cause hallucinations. The training in the SFT phase should also consider the knowledge of the model, and the model should not be fine-tuned for an application that has not acquired sufficient knowledge during the pre-training. One way to reduce hallucinations in both the SFT and RLHF phases is to teach the model to be honest. The language model should be trained to avoid commenting on a subject if it does not have enough information (Zhang et al., 2023). The methods investigated in this work are related to detecting and mitigating hallucination in the inference phase. The related previous works can be categorized as white box, gray box, and black box depending on the level of access to internal parameters of the LLM. The methods that use the internal state of the language model for diagnosis are white-box approaches. Gray box approaches are methods that access the output distribution of the model, such as detecting hallucinations at the token level. Finally, Blackbox approaches only have access to the textual output of the model.

2.1 White-Box Approaches

In Azaria and Mitchell (2023), the SAPLMA approach (Statement Accuracy Prediction, based on Language Model Activations) has been introduced. Their approach uses the internal state of the LLM to measure the truthfulness of the statements. This applies to both the statements provided to the model and the statements produced by the model itself. They use a relatively shallow feedforward network as a classifier, which measures the truthfulness probability of a statement based on the values of the hidden layer activators.

2.2 Gray-Box Approaches

These approaches use the uncertainty of models to detect hallucinations. The idea of these approaches is that when the model is sure of the correctness of a sentence, the distribution probability of tokens of the sequence is sharp. Still, in uncertain conditions, this distribution will probably be flat. Kadavath et al. (2022) suggests that a model's confidence in

answering a specific question correlates with the certainty of its response. They propose repeatedly sampling the answer at T = 1, yielding an answer distribution characterized by low entropy when the model is confident. Conversely, when the model is uncertain, it tends to produce "hallucinated" responses, resulting in an answer distribution with high entropy. Nevertheless, experimental results indicate that utilizing entropy as a metric for determining whether a model knows the answer to a question is not consistently reliable, particularly as models scale in size. Another work in this group of methods is Yuan et al. (2021), in which a score named BART-Score evaluates the text's quality generated by the model from different aspects such as informativeness, fluency, and factuality. Using token-level probabilities, BART-Score calculates the probability of an output sequence given a specific input sequence.

2.3 Black-Box Approaches

The methods presented in Martino et al. (2023) and Manakul et al. (2023) are black box methods. In Martino et al. (2023), where a large language model is used for the" Review Response" task, the knowledge injection method adds related information to the prompt. The relevant knowledge is extracted from a knowledge graph specific to that particular business. It includes information such as addresses, phone numbers, etc., which are naturally not available in the training data of an LLM. The target hallucination in this task is factual. Fact-based verification methods require an external database, and their inference is computationally expensive. The introduced method in Manakul et al. (2023) uses no external knowledge source. Their approach, self-checkGPT, is based on the idea that if an LLM knows a subject, sampled responses do not contradict each other. The proposed approach has five variants: BERTScore, question-answering, n-gram, NLI, and LLM prompting. The best-performing variant is LLM prompting, in which they ask an LLM if a sentence is supported by a context or not. This variant has a high computational cost. The second best is the NLI variant, which uses natural language inference to detect inconsistency between sampled responses.

In Mündler et al. (2023), a prompting-based framework is introduced to efficiently identify and address instances of self-contradiction, meaning context hallucinations. Their investigation delved into open-domain text generation utilizing a dual-LM setup: one LM for text generation and another as an analyzer. For each sentence generated by the initial LM, a corresponding sentence is produced based on the associated context, and both are subsequently subjected to analysis by the second LM. In cases where the analyzer LM identifies a contradiction between the two sentences, it is prompted to revise the given sentences and remove the contradiction so that the output is informative and coherent with the corresponding context. ChainPoll (Friel and Sanyal, 2023) represents another recent advancement in addressing hallucinatory phenomena within LLMs. The approach adopted for hallucination detection is straightforward: employing a carefully crafted prompt, the authors prompt the GPT-3.5-turbo model to assess whether the completion contains hallucinations driven by a chain of thought (CoT) explanation. Iterating this process several times and aggregating the "yes" responses yields a probability score ranging from Zero to One, indicating the likelihood of hallucination.

In Guerreiro et al. (2023), hallucinations in translation models are studied concerning two different sources: perturbations and natural hallucinations. Hallucinations induced by perturbations occur when the model memorizes the training data and outputs a faulty translation triggered by a slight change in the input sequence. In contrast, natural hallucinations occur due to poor quality of training data. Natural hallucinations are divided into two categories (Raunak et al., 2021): detached and oscillatory. In the detached type, the output is fluent but inadequate. In the oscillatory type, the output has repeated n-grams. In this article, a black box method (Top N-Gram (Raunak et al., 2021)) and a white box method (ALTI+ (Ferrando et al., 2022)) have been used to detect natural hallucinations. It has been observed that hallucinations in translations occur more often for low-resource languages. Another work concerning detecting machine translation hallucinations is COMET (Rei et al., 2020), a reference-based neural framework with superior performance compared to conventional approaches (Guerreiro et al., 2022). It has two architectures, one of which is an estimator model, which tries to directly regress on human judgment scores for quality assessment. In contrast, the other one, a ranking model, minimizes the distance between a "better" hypothesis and its corresponding reference and original source translations.

Trial	36	9	35	80
Test	1125	750	1125	3000

Table 1: Dataset Statistics

3 System Overview

In this section, we introduce our proposed system. The general system sketch is presented in Figure 1. Additionally, detailed statistics regarding the dataset are outlined in Table 1. Since the training data provided for this task was unlabeled, we labeled 3000 samples of the training data. Since LLMs have hallucination problems themselves, the labeling was done by a human agent. We have trained separate models for each task (MT, PG, and DM) to detect hallucinations. The model is DeBERTa-v3 large (He et al., 2023) and was first trained on the NLI task and then fine-tuned on the labeled data of each task. Finally, the model with the highest accuracy on validation data was saved. For training a binary classification model on the NLI task, only the data samples with labels of contradiction and entailment of the NLI dataset of Stanford University (Bowman et al., 2015) were used.

Examples of data samples for PG, MT, and DM tasks are presented in Table 2. Each sample has a source, target, and hypothesis in the MT task. The source sentence may be in languages other than English, but the target sentence is always in English. In the PG task, each sample has a source and hypothesis. We can detect hallucinations in these two tasks using the target sentence as the reference for the MT task and the source sentence as the reference for the PG task. Since the nature of hallucination in the PG and MT tasks is almost the same, the training data of both tasks were used to train the model for these two tasks. For Each task, the model with the highest accuracy on validation data was saved. The sequence classification method is utilized to detect hallucinations. The reference sentence is placed at the beginning, followed by the hypothesis sentence, separated with a "[SEP]" token. The hypothesis is the output of the LLM that may contain hallucinations. Finally, the entire sequence is fed into the NLI model, which outputs probabilities for each class, contradiction, and entailment. If the hypothesis contains information that contradicts the reference, the output label of our NLI model should be equal to 1, indicating contradiction. The probability of contradiction is considered equivalent to the probability of hallucination.

In addition to training classifier models, we have conducted tests to evaluate the performance of

PG	**src**	The budget cannot be adopted against the will of the European Parliament.
	hyp	The European Parliament does not approve the budget.
	label	Not Hallucination
MT	**src**	Doonii fayyadamuun meeshaa geejibuun namootabaay'ee fi meeshaalee galaanarra cesisuuf karaa baayee si'aataa dha.
	tgt	Using ships to transport goods is by far the most efficient way to move large amounts of people and goods across oceans.
	hyp	Using a gas-fired device is a way to stop people from using natural gas and other equipment.
	label	Hallucination
DM	**src**	Communistic birds. What is the meaning of communistic?
	tgt	Living or having their nests in common.
	hyp	Of or pertaining to communism.
	label	Hallucination

Table 2: Data samples of PG, MT, and DM tasks

two large language models, Falcon-7B and chat-GPT3.5, on the hallucination detection task. For this purpose, we have instruction-fine-tuned the falcon-7B model on the labeled training and validation data. For chat-GPT3.5, the accuracy was calculated on the trial set using zero and two-shot inference. For these two models, only the results on the trial set were presented.

We also thought we might find a meaningful connection between token probabilities in the output sequence and hallucination. For this, we took the top token probabilities of the output sequence of the LLM (PG, MT, and DM LLMs) with their labels. We fed them as input to an RNN model, such as LSTM, to predict hallucination based on model uncertainty of token probabilities. Unfortunately, we found out that when outputting hallucinated output, the model is as confident as non-hallucinated ones, and the classifier model could learn absolutely nothing from the token probabilities, no matter how we change the model complexity or hyperparameters.

4 Experimental Setup

To provide enough labeled data to train our models, a total of 3000 of the model-aware and model-agnostic training samples were labeled. Different data splits were tested to get the best accuracy on each task. The details of the split used to train the model with the best accuracy for each task are specified in colab notebooks on GitHub[1]. The results

Table 3: Results on Trial set

of the trial set are presented in Table 3.

All three models are trained for ten epochs with a learning rate equal to 2e-5 and batch size equal to eight samples. The base model for all three tasks is DeBERTa-v3-large (He et al., 2023), trained on the NLI task with two classes of contradiction and entailment. We have used the Hugging-Face transformers library (Wolf et al., 2020) to train DeBERTa models implemented with PyTorch. For instruction fine-tuning the Falcon-7B model, we also used the Hugging-Face library and LoRA method (Hu et al., 2022). The prompt used for fine-tuning Falcon and inference from chatGPT is similar to that used in the selfCheckGPT (Manakul et al.,

PG	**src**	A five, six, seven, eight.
	tgt	And 5, 6, 7, 8.
	hyp	A number between five and eight.
	gold label	Hallucination
MT	**src**	Est-ce que tu l'aimes?
	tgt	Do you love him?
	hyp	Do you love her?
	gold label	Not Hallucination
DM	**src**	Haul away, keeping strain on both parts of the halyard so that the <define> pigstick </define> remains vertical as it goes up and doesn't foul the spreaders.
	tgt	(nautical) A staff that carries a flag or pennant above the mast of a sailboat.
	hyp	(nautical) A halyard.
	gold label	Not Hallucination

Table 4: Examples of wrongly classified samples

2023). The examples can be found in the Appendix. All notebooks, labeled data, and links to saved models are present on our GitHub.

5 Results

We have achieved 75.93% and 78.33% accuracy for the model-aware and model-agnostic tracks of hallucination detection on final test data. We have ranked 19th and 30th in model-aware and model-agnostic tracks with a 2.93% and 8.4% difference with respect to the first-ranked team in the competition. The accuracies of the best model for each task, along with the accuracy of the base NLI model, are provided in Table 5. Also, examples of wrongly classified samples are provided in Table 4. As you can see the wrongly classified samples are challenging. The problem that exists with some samples of the MT task is that in some cases, relying only on the tgt field may result in a wrong label, and it is necessary also to consider the content of the src field as well. This is true about the MT example presented in the table. In this example, hyp and tgt are both correct translations of the source sentence, but when the content of hyp is evaluated against the tgt, it is wrongly labeled as hallucination.

6 Conclusion

In this work, we have trained classifiers based on Natural Language Inference to detect hallucinated outputs for the two model-aware and model-agnostic subtasks of the SemEval-2024 Task-6-SHROOM (Mickus et al., 2024). We have also conducted experiments to evaluate LLMs' ability to perform this task. The fluency of the output of LLMs makes it difficult even for a human evaluator to recognize the hallucinated output. To train the classifiers, we labeled 3000 training data. Labels may be a little affected by the subjectivity of the annotator, and for future work, it is better to have more than one person label each data sample. Our HalluSafe classifiers have achieved 75.93% and 78.33% accuracy for the model-aware and model-agnostic tracks of hallucination detection on final test data and have outperformed official baselines. Regarding future work, enhancing the quality of training data in the pre-training and fine-tuning stages can effectively reduce hallucinations. Given the potential limitations of storing all necessary information within the memory of models, coupled with the need for regular updates to certain information, it may be beneficial to equip models with

search tools rather than relying solely on memory. It is important to train LLMs during the fine-tuning and instruction-tuning stages to refrain from answering questions if they lack sufficient knowledge on a particular subject, which needs a mechanism to be incorporated into these models to enable them to identify the boundaries of their knowledge.

Abstract

The goal and dream of the artificial intelligence field have long been the development of intelligent systems or agents that mimic human behavior and thinking. Creativity is an essential trait in humans that is closely related to lateral thinking. The remarkable advancements in Language Models have led to extensive research on question-answering and explicit and implicit reasoning involving vertical thinking. However, there is an increasing need to shift focus towards research and development of models that can think laterally. One must step outside the traditional frame of commonsense concepts in lateral thinking to conclude. Task 9 of SemEval-2024 is Brainteaser (Jiang et al., 2024), which requires lateral thinking to answer riddle-like multiple-choice questions. In our study, we assessed the performance of various models for the Brainteaser task. We achieved an overall accuracy of 75% for the Sentence Puzzle subtask and 66.7% for the Word Puzzle subtask. All the codes, along with the links to our saved models, are available on our GitHub[1].

1 Introduction

With recent advancements in deep learning and especially language models, extensive research has been conducted about reasoning in various natural language processing tasks, including question answering. These reasoning methods adopt vertical thinking. However, lateral thinking is another type often associated with creativity. In the 9th task of SemEval, Brainteaser (Jiang et al., 2024), a task of answering multiple-choice riddle-like questions is defined. To answer these questions, the model needs to employ lateral thinking. This method of thinking differs from vertical thinking in that the reasoning process is not linear. To arrive at a conclusion, one must examine the subject from a perspective beyond the usual conventional thinking paradigms (Waks, 1997). An example of a comparison between the two types of thinking is provided in Figure 2 in the Appendix. Lateral thinking demands a mind that is open, flexible, and creative. Equipping AI models with cognitive abilities such as lateral thinking can enhance problem-solving, adaptability, and coping with new situations and challenges.

In this work, we have evaluated the performance of three categories of models on answering brainteaser questions. We trained and evaluated two language models, BERT (Devlin et al., 2019), and RoBERTa (Liu et al., 2019), the model presented in Yasunaga et al. (2021) (QA-GNN), and a T5 (Raffel et al., 2019) model for sentence puzzle and word puzzle subtasks. In the QA-GNN method, the ConceptNet knowledge graph (Speer et al., 2017) is used as the source of commonsense knowledge. Through the brainteaser task, we gained insights into two types of thinking - vertical and lateral. We also learned the significance of implementing lateral thinking in AI systems to bridge the gap between human and AI performance. Furthermore, this task piqued our interest in the captivating subject of creativity in artificial intelligence models. We achieved an overall accuracy of 75% and ranked 20th for the Sentence Puzzle subtask. For the Word Puzzle subtask, we ranked 19th and achieved an overall accuracy of 66.7%. All the codes, along with the links to our saved models, are available on our GitHub.

2 Background

The goal and dream of the artificial intelligence field has long been the development of intelligent systems or entities with human-like behavior and thinking. According to existing research, there are two types of thinking in humans: vertical and lateral. Most of the existing research focuses on vertical thinking. Vertical thinking involves a logi-

[1] https://github.com/z-rahimi-r/NIMZ-at-SemEval-Task-9-BRAINTEASER

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 148–154

cal and sequential approach, while lateral thinking requires creativity and flexibility to explore problems from unique and unconventional perspectives (Waks, 1997). The Brainteaser dataset (Jiang et al., 2023) contains 1100 riddle-like English questions requiring lateral thinking. The nature of questions often defies commonsense when approached with vertical thinking. The Brainteaser task includes two subtasks: sentence puzzle and word puzzle. The details of the dataset are presented in the Table 1.

Most research focuses on vertical thinking, using commonsense for implicit and explicit reasoning tasks such as commonsense question answering. Commonsense intelligence is intuitively reasoning about everyday situations and events, which requires knowledge of how the world works (Choi, 2022). In the task of commonsense question answering, two popular methods are fine-tuning language models and using graph neural network (GNN) models. In recent years, the use of knowledge graphs, the primary sources of commonsense knowledge, has increased. Commonsense knowledge stored in language model parameters is mainly descriptive and taxonomic knowledge, often explicitly stated in the language content that these models have been trained on (Hwang et al., 2021). The method presented in COMET (Bosselut et al., 2019) can be a means to teach language models other types of knowledge. The success of COMET can be attributed to the combination of neural and symbolic representations of knowledge, as well as the use of language to represent symbolic knowledge (Choi, 2022). The COMET model is fine-tuned on the ATOMIC knowledge graph (Hwang et al., 2021). This knowledge graph serves as a customized textbook for language models to learn commonsense knowledge and how the world works (Choi, 2022).

In the second popular category of methods, a knowledge graph is used as the complementary source of knowledge with the help of graph neural networks as the medium to harvest this knowledge (Feng et al., 2020; Wang et al., 2022; Zhang et al., 2022). One advantage of using graph neural networks is their interpretability. In QA-GNN (Yasunaga et al., 2021), the RoBERTa LM is used with graph neural networks. Each answer option is checked independently in their method to determine if it is the answer. For each answer option, a subgraph is extracted from the ConceptNet. This subgraph consists of the entities in question and the answer option, all the entities within two hops

	Sentence Puzzle	Word Puzzle
Train	507	395
Test	120	96

Table 1: Dataset Statistics

from question and answer entities on the ConceptNet graph, and the relations between them. In the presented method, the question and the answer option are concatenated and encoded using RoBERTa LM (Liu et al., 2019), then placed as a context node in the subgraph. Since some nodes in the subgraph are more related to the question and its answer, the RoBERTa LM is used to calculate a score for each node in the subgraph. This score is used as an additional feature to the node embeddings to increase the influence of more related entities. Training is done through the message-passing method. Finally, the score of each option being the answer is calculated and the answer option with the highest score will be the final answer to the question. The approach described in Zhang et al. (2023) is similar to QA-GNN but with one key difference. While QA-GNN evaluates each answer option independently using a local graph, this method also includes a global graph that allows for simultaneous evaluation and comparison of all answer options, leading to refined probabilities. Refining the probabilities of each answer option in this way can produce a more accurate result. They consider this method similar to how humans eliminate less likely options. The most similar available study to the Brainteaser task is Riddlesense (Lin et al., 2021), where a riddle dataset is presented. To solve the riddles, one needs advanced natural language understanding, commonsense, and counterfactual reasoning skills, which are complex cognitive processes. They have trained and evaluated several language models, GNN-based models, and text-to-text models on the Riddlesense dataset.

2.1 MCQA in LLMs

Inference from LLMs for multiple choice question answering is done using two methods: Multiple Choice Prompting (MCP) and Cloze Promting (CP) (Robinson et al., 2022). MCP involves presenting a question with several answer options to an LLM and asking it to select the most appropriate answer from the given choices. The other method, CP, involves creating a sentence or passage with a blank that the model needs to fill in with an appropriate

word or phrase. Robinson et al. (2022) criticizes using cloze-style prompts for evaluating LLMs, suggesting that this approach may not fully leverage these models' capabilities for MCQA tasks. However, the evaluation of LLMs with the MCP method has the problem that the order of presenting the options can change the final answer of the LLM. They have evaluated different LLMs, and based on the results, the model's size and providing examples (few-shot inference) to the language model can improve its performance and reduce the dependence of the final answer on the order of options.

2.2 How creative are LLMs?

Margaret Boden's criteria for creativity _novelty, value, and surprise_ are utilized to evaluate the creative capabilities of LLMs. Franceschelli and Musolesi (2023) discusses how much SOTA LLMs satisfy these criteria. LLMs can indeed produce valuable content, as evidenced by their impact and the quality of their outputs. The novelty of an idea or product is being dissimilar to existing examples, the reference of which can either be the person who comes up with it (psychological creativity) or the entire human history (historical creativity). Novelty in LLMs can occur accidentally or as a result of out-of-distribution production or careful prompts, and the degree of novelty is inherently limited by the models' design, focusing on probabilistic outputs based on historical data. The definition of surprise is how unexpected an idea is. Three types of surprise are defined: Combinatorial creativity, which is producing an unfamiliar combination of familiar ideas; Exploratory creativity, which is finding new and undiscovered solutions within the current style of thinking; and Transformational creativity, which is related to changing the current style of thinking. The autoregressive nature of LLMs makes the production of surprising content by them unlikely and only limited to combinatorial creativity, making truly surprising or transformational creativity challenging to achieve. True creativity requires self-awareness and self-evaluation capabilities, which current LLMs lack (Franceschelli and Musolesi, 2023).

3 System Overview

In this section, we will present the systems used to tackle the brainteaser task. The three main approaches in question-answering tasks are fine-tuning language models, graph neural networks, and text-to-text transformers. So, we decided to evaluate the performance of these models on the brainteaser task. Although the role of commonsense in this task is as a distractor (Jiang et al., 2023), we decided to evaluate the impact of using commonsense knowledge through ConceptNet knowledge graph and graph neural networks. While the answer may challenge commonsense in the Brainteaser questions, it does not violate it. All the models are trained for sentence puzzles and word puzzles separately. The general sketch for each type of system is presented in Figure 1.

3.1 Language models: BERT and RoBERTa

We trained and evaluated two language models, BERT-Base (Devlin et al., 2019) and RoBERTa-Large (Liu et al., 2019) on the Brainteaser dataset. The training was done on two different in-house splits of the training data, and the model with the best performance on the validation data was saved for final evaluation on the test set. During the training and inference phase for the two language models of BERT and RoBERTa, the probability of each option being the answer is checked separately. To do that, the question and the answer option are concatenated with the token [SEP] placed between them and given to the language model as input. The score of that option being the answer, is calculated using the output representation of the [CLS] token through a linear layer. Finally, the option that has the highest probability will be the answer to the question.

3.2 LM + GNN: QA-GNN

The QA-GNN model (Yasunaga et al., 2021) uses RoBERTa LM and graph neural networks for reasoning. The knowledge source used in this method is the ConceptNet knowledge graph (Speer et al., 2017). In this method, a separate subgraph is extracted for each answer option. The question and answer option are concatenated, and the resulting embedding from RoBERTa is used as a context node in the graph. This node is only connected to the entities belonging to the answer option and the question (it is not connected to other entities extracted from the knowledge graph). To train the QA-GNN model, pre-processing must be done on the dataset first. For each question and answer option pair, their entities and all of their neighbor entities up to two hops in the ConceptNet knowledge graph are extracted, along with the relations between them. Training is done through the message-

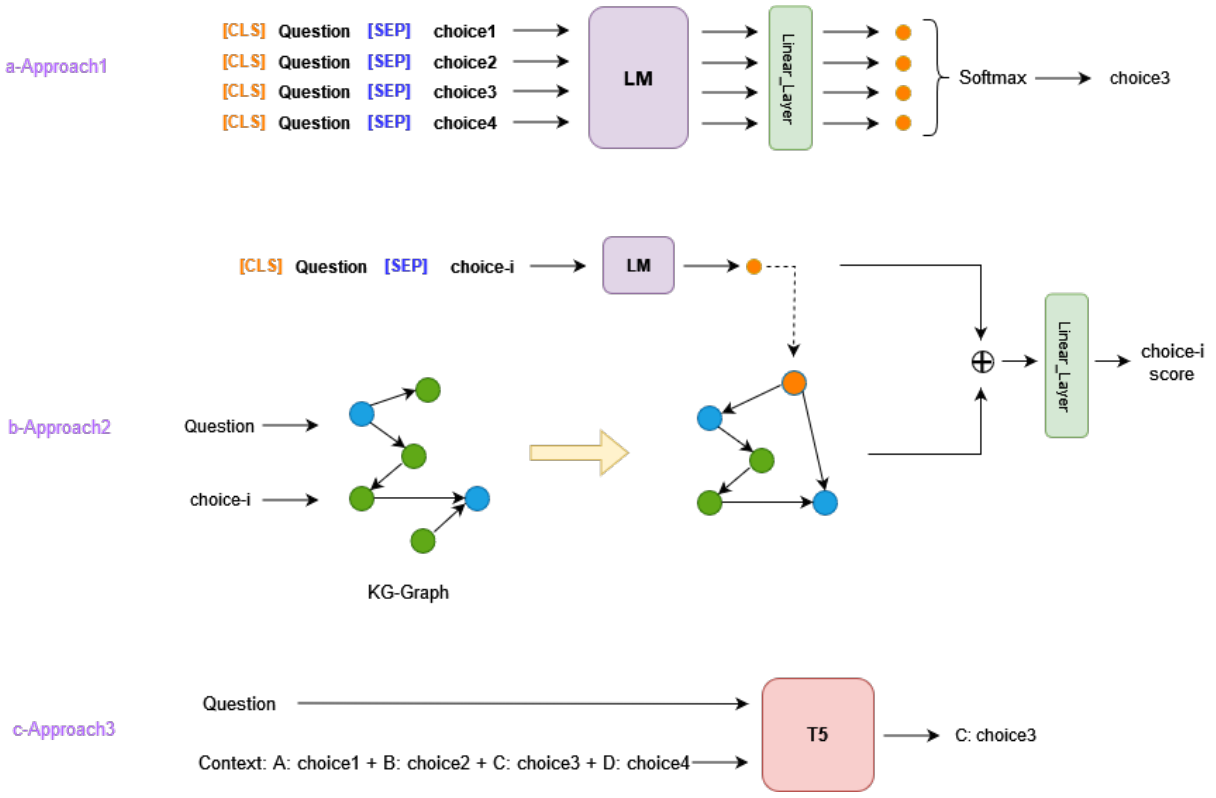

Figure 1: The three categories of methods evaluated for brainteaser task. **a-Approach1:** Fine-tuning LMs like BERT and RoBERTa; **b-Approach:** LM+GNN method, the blue circles are question and choice entities, and the green circles are extracted knowledge-graph entities; **c-Approach:** Fine-tuning a T5 model.

passing method. The score of each answer option, being the final answer, is calculated using the concatenation of the RoBERTa LM representation, context node representation learned through message-passing, and the pooled graph representation, through a linear layer. Finally, the option that has the highest score will be the answer to the question. The interested reader can refer to the original paper for more in-depth details.

3.3 Text-to-Text model

The third method we evaluated was the T5 text-to-text model (Raffel et al., 2019). In this method, the input question and the context, which includes all the options concatenated together, are passed to the T5 model as input. The answer will be in the form of a span extracted from the context, meaning the options. This model considers all options and makes a final decision, setting it apart from previous models.

4 Experimental Setup

We have trained and evaluated base and large sizes of BERT, RoBERTa, and T5 models using the Hugging-Face transformers library, with different hyperparameters to find the best setting. To train the QA-GNN model, we followed the procedure provided by the code available on the GitHub of Yasunaga et al. (2021). After preprocessing the Brainteaser dataset, the QA-GNN models were trained for 100 epochs with early-stopping. In the inference phase of the T5 model, in some cases, the extracted span was incomplete and did not include the letter of the answer option, in these cases the "none of above" option was selected. The code for the in-house train-dev split and the hyperparameters used for training the best-performing models are available in the notebooks on our GitHub[1].

4.1 Evaluation metrics

For each original question in the dataset, two additional adversarial variants are created: semantic reconstruction and contextual reconstruction. Semantic reconstruction rephrases the original question and does not change anything else. In contextual reconstruction, the context of the question does not change, but the surface form of the question and its answer options are changed. An example from

Table 2: Results on Test set. The baselines are zero-shot results

the dataset is available in Table 3 in the Appendix. The purpose of designing these two variants is to test the robustness of the model. If the model has not memorized the content and is capable of lateral thinking, it will correctly answer these two adversarial variants of each question (Jiang et al., 2023). Models are evaluated using two accuracy metrics: instance-based accuracy metric and group-based accuracy metric. In instance-based accuracy, each question is evaluated separately. In group-based accuracy, a question is evaluated with its adversarial variants, and only if all three are answered correctly, it is scored One. Otherwise, it is scored Zero.

5 Results

We evaluated models from different categories on this task. Due to the riddle-like and unique nature of the questions, it was difficult for the models to generalize to new questions of the test set. We achieved an overall accuracy of 75% and ranked 20th for the Sentence Puzzle subtask. For the Word Puzzle subtask, we ranked 19th and achieved an overall accuracy of 66.7%. The QA-GNN model performed best for the sentence puzzle in the evaluation phase. Still, for the word puzzle, the BERT-base model had the best performance, and QA-GNN performed poorly, which could be due to the absence of reasoning paths on the knowledge graph between the concepts of the answer option and the question. The results of the two phases, evaluation and post-evaluation, are presented in the Table 2. Some wrongly predicted examples for the Word Puzzle subtask are presented in Table 4 in the Appendix.

6 Conclusion

In this study, we evaluated the performance of three main categories of popular methods in the question-answering task on the two subtasks of Sentence Puzzle and Word Puzzle of the SemEval- task 9 Brainteaser. We have achieved an overall accuracy of 75% for the Sentence Puzzle subtask and 66.7% for the Word Puzzle subtask. The nature of the Brainteaser questions is such that they challenge commonsense and require lateral thinking and intellectual creativity to be solved. Models other than LLMs tend to perform poorly in generalizing to new and different examples, especially when it comes to tasks that require creativity, such as puzzles and brainteasers. While LLMs tend to perform better, they still have limited capability when it comes to being creative. Regarding the suggestions for future work, we believe utilizing the chain-of-thought (Wu et al., 2023) method and teaching LLMs to reason step by step with the in-context-learning method can be effective. Another idea is to develop two modules for LLMs or AI agents. The first module will aid in the creative production of knowledge, while the second module will check the rationality of the produced knowledge and its consistency concerning the context of the desired problem. As mentioned earlier, the autoregressive nature of current LLMs and reliance on probabilistic solutions have limited their ability to produce creative content. So, there is a need to design new architectures and different training methods to overcome this limitation. This can be a helpful step towards enhancing creativity and lateral thinking in AI systems.

Mistral at SemEval-2024 Task 5: Mistral 7B for Argument Reasoning in Civil Procedure

Marco Siino
Department of Electrical, Electronic
and Computer Engineering
University of Catania
Italy
marco.siino@unipa.it

Abstract

At the SemEval-2024 Task 5, the organizers introduce a novel natural language processing challenge and corpus within the realm of the United States civil procedure. Every datum within the corpus comprises a comprehensive overview of a legal case, a specific inquiry associated with it, and a potential argument in support of a solution, supplemented with an in-depth rationale elucidating the applicability of the argument within the given context. Derived from a text designed for legal education purposes, this dataset presents a multifaceted benchmarking task for contemporary legal language models. Our manuscript delineates the approach we adopted for participation in this competition. Specifically, we detail the use of a Mistral 7B model to answer the questions provided. Our only and best submission reaches an F1-score equal to 0.5597 and an Accuracy of 0.5714, outperforming the task's baseline.

1 Introduction

The content of the Task 5 hosted at SemEval-2024 (Held and Habernal, 2024), was originally introduced in (Bongard et al., 2022).

Asserting a legal argument represents a fundamental proficiency necessary for aspiring legal professionals to acquire. This proficiency demands not only a comprehension of pertinent legal domains but also advanced reasoning skills, including the utilization of analogy-based arguments and the identification of implicit contradictions. Despite recent strides in establishing objective metrics for contemporary natural language processing (NLP) models across diverse facets of legal language comprehension, the absence of a sophisticated task addressing argumentative reasoning within legal contexts persists.

In this article, is discussed a novel task alongside a corresponding benchmark dataset. The introduction of a genuinely challenging task, sourced from legal educational resources, will serve to elucidate strengths and weaknesses inherent in contemporary legal transformer models, including but not limited to Legal-BERT (Chalkidis et al., 2020). Specifically, at the SemEval-2024 Task 5 is unveiled a novel, openly accessible legal dataset tailored for the binary text classification of issues within U.S. civil procedure. The primary objective is to ascertain whether a proposed solution to a given inquiry is deemed accurate or erroneous. The corpus draws inspiration from "The Glannon Guide To Civil Procedure" authored by Joseph Glannon (Glannon, 2023), which caters to law students by offering a comprehensive examination of fundamental U.S. civil procedure topics, inclusive of multiple-choice queries designed to assess reader comprehension.

Through the inception of this freshly minted corpus, the intent extends to scrutinizing the efficacy of various methodological approaches while establishing performance benchmarks.

To address these objectives, there is an ongoing demand for automated tools capable of extracting and categorizing data, facilitating the classification with recent NLP models. Recent advancements in the area of the machine and deep learning architectures have spurred heightened interest in Natural Language Processing (NLP). Substantial endeavours have been directed towards devising techniques for the automated identification and categorization of textual content accessible on the internet today. In the literature, to perform text classification tasks, several strategies have already been proposed. In the last fifteen years, some of the most successful strategies have been based on SVM (Colas and Brazdil, 2006; Croce et al., 2022), on Convolutional Neural Network (CNN) (Kim, 2014; Siino et al., 2021), on Graph Neural Network (GNN) (Lomonaco et al., 2022), on ensemble models (Miri et al., 2022; Siino et al., 2022) and, recently, on Transformers (Vaswani et al., 2017; Siino et al., 2022b).

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 155–162

Participants in SemEval-2024 Task 5 were tasked as follows. The task at hand involves evaluating the accuracy of an answer candidate provided in response to a question, accompanied by a brief introductory passage pertaining to the subject of the question. The objective is to ascertain whether the candidate answer is indeed incorrect or correct. To face with the task, we propose a Transformer-based approach which made use of Mistral 7B (Jiang et al., 2023). We used the model in a zero-shot setup described in the rest of this paper. Specifically, we prompted the latest pretrained version of Mistral with each sample in the dataset. Specifically, we provided a *candidate answer* to a *question*, asking the model if the answer to the legal question was correct or not. The model replied with a yes or no, eventually providing some further explanation.

The subsequent sections of this work are structured as follows: Section 2 offers background information on Task 5, held at SemEval-2024. In Section 3, we outline the approach introduced in this study. Section 4 delves into the specifics of the experimental setup employed to reproduce our findings. The outcomes of the official task and relevant discussions are presented in Section 5. Finally, Section 6 concludes our study and suggests avenues for future research.

We make all the code publicly available and reusable on GitHub[1].

2 Background

For the Task 5 at SemEval-2024 is proposed a legal corpus, publicly accessible for binary text classification tasks focusing on issues within U.S. civil procedure. The primary objective is to determine the correctness of solutions provided in response to specific questions. This corpus draws its content from "The Glannon Guide To Civil Procedure" authored by Joseph Glannon (Glannon, 2023), tailored for law students. The book encompasses fundamental U.S. civil procedure topics and includes multiple-choice questions aimed at evaluating reader comprehension.

Through collaboration with the author and publisher, task organizers secured permission to utilize the content of "The Glannon Guide To Civil Procedure" for constructing this dataset, which is freely available to the research community. The book comprises 25 chapters, each containing multiple-choice questions pertaining to a particular topic, prefaced by an introduction. Every question is followed by 3 to 5 answer candidates, among which one is deemed correct. These answer candidates serve as hypotheses, necessitating an examination of their respective prerequisites for accuracy. The correctness or incorrectness of an answer is subsequently expounded upon in the accompanying analysis.

The dataset construction process involved automated parsing of the book's content, leveraging its structured format to extract individual components of each instance (i.e., introduction, question, answers, and analysis). Additional parsing rules were employed to detect anomalies in the structure, such as instances where the same introduction was shared across multiple questions. However, certain sections of the book required manual extraction, particularly regarding the correctness of answer candidates, as this information was typically embedded within the free-text analysis section. The analysis segments were organized to address each answer candidate separately, classifying them as true or false. To achieve this, the organizers adopted a strategy of isolating the relevant aspects for each answer, despite the absence of explicit keywords or structural indicators guiding the segmentation process. Despite efforts to maintain consistency, some structural inconsistencies were noted throughout the dataset.

Two samples from provided datasets are available online[2] and reported in the Table 3 in the Appendix sectionA. In this case, the two samples contain the same introduction and the same question while providing different answers. Given the Introduction and the Question, the first answer (first row) is wrong, while the second one (second row) is correct.

The organizers adhere to the schedule for SemEval24, which means the following dates:

- Tasks announced (with sample data available): 17 July 2023
- Training data ready 4 September 2023
- Evaluation start 10 January 2024
- Evaluation end by by 31 January 2024
- Paper submission due 19 February 2024
- Notification to authors 18 March 2024

[1] https://github.com/marco-siino/SemEval2024/

[2] https://github.com/trusthlt/semeval24

- Camera ready due 01 April 2024
- SemEval workshop: June 16–21, 2024 (co-located with NAACL 2024 in Mexico City, Mexico)

3 System Overview

Even if it has already been proved that the Transformers are not necessarily the best option for any text classification task (Siino et al., 2022a), depending on the goal, some strategies like domain-specific fine-tuning (Sun et al., 2019; Van Thin et al., 2023), or data augmentation (Lomonaco et al., 2023; Mangione et al., 2022; Siino et al., 2024a) can be beneficial for the considered task.

So far, several Large Language Models (LLMs) have proved to be able to address a plethora of different NLP tasks. For example, in the recent literature, there has been mention of LLaMA, as presented by (Touvron et al., 2023). LLaMA stands out as a collection of publicly available Large Language Models (LLMs) that rival the capabilities of closed-source counterparts like GPT-3.

However, to address the Task 5 hosted at SemEval-2024 we made use of a zero-shot learning approach (Chen et al., 2023; Wahidur et al., 2024), making use of Mistral 7B (Jiang et al., 2023). Mistral 7B, a language model boasting 7 billion parameters, is engineered to excel in both performance and efficiency. In comparison to the leading open 13B model (Llama 2), Mistral 7B demonstrates superior performance across all assessed benchmarks. Moreover, it outperforms the leading publicly available 34B model (LLaMA 1) across various tasks involving code generation, mathematical operations, and reasoning. The model capitalizes on grouped-query attention (GQA) to expedite inference, complemented by sliding window attention (SWA) to effectively process sequences of varying lengths while minimizing inference costs. Additionally, a fine-tuned variant, Mistral 7B – Instruct, is tailored for adhering to instructions. This version, outperforms Llama 2 13B – chat model across both automated and human benchmarks.

The introduction of Mistral 7B Instruct underscores the ease with which the base model can be fine-tuned to achieve notable performance enhancements. Notably, this variant lacks any moderation mechanisms.

Our approach is few-shot (Littenberg-Tobias et al., 2022) and make use of the above-mentioned Mistral 7B. More specifically, given the task hosted at SemEval-2024, we asked the model: *"Is the Answer to the Question above True or False? Answer using ONLY True or False:"*. To this request, the model replied with one or more words - usually starting with a *true* or *false* - that we parsed to extract one of the two labels (i.e., 0 for false and 1 for true). For example, given the introduction:

> *"Defendant in denial. Cardozo is in an accident on Main Street with two other cars, driven by Hooper and Lopes. Cardozo brings a suit in federal court against Hooper and Lopes for his damages. Paragraph 21 of Cardozo's complaint alleges that Hooper had signaled before he turned onto Main Street. The police report on the accident states that, according to a bystander, Hooper had signaled before turning onto Main Street. Lopes, who was coming from Hooper's left, had no view of the right side of Hooper's car, and did not see whether he signaled or not. At the time an answer is due, Lopes's counsel has seen the police report, but has not yet been able to locate other witnesses to obtain their testimony. The most appropriate response for Lopes to Paragraph 21 of Cardozo's complaint would be to."*

The answer:

> *"state that he is without sufficient information to form a belief about the truth of the allegation."*

And our question:

> *Is the Answer to the Question above True or False? Answer using ONLY True or False:*

The model replied with:

> *true. lopes' answer could state that he lacks sufficient information to admit*

that we mapped into the binary label *1* corresponding to *true*.

We did not find any inconsistency in the outputs generated by Mistral along all the provided prompts. Specifically, we did not notice any variation in the behaviours of the model at different times of prompting. This leads us to the conclusion that given always the same input context (i.e.,

few-shot samples) during the prompt, the output provided is always consistent disregarding the time and the previous prompts provided. Finally, we collected all the predictions provided on the test set to into a JSON file with the required format to submit our predictions.

As noted in the recent study by (Siino et al., 2024b), the contribution of preprocessing for text classification tasks is generally not impactful when using Transformers. More specifically, the best combination of preprocessing strategies is not very different from doing no preprocessing at all in the case of Transformers. For these reasons, and to keep our system highly fast and computationally light, we have not performed any preprocessing on the text.

4 Experimental Setup

We implemented our model on Google Colab. The library we used come from HuggingFace and as already mentioned is Mistral 7B[3]. We employed the v0.2 iteration of Mistral 7B, which represents an enhanced version of the Mistral-7B-Instruct-v0.1 model. To harness the capabilities of instruction fine-tuning, prompts must be enclosed within [INST] and [/INST] tokens. Additionally, the initial instruction should commence with a sentence identifier. The next instructions should not. The assistant generation will be ended by the end-of-sentence token ID. We also imported the Llama library (Touvron et al., 2023) from *llama_cpp*. The library is fully described on GitHub[4]. The dataset provided for all the phases are available on the official competition page. We did not perform any additional fine-tuning on the model. To run the experiment, a T4 GPU from Google has been used. After the generation of predictions, we exported the results on the format required by the organizers. As already mentioned, all of our code is available on GitHub.

5 Results

Given the binary nature of the classification task, the organizers proposed F1 score and Accuracy as the two evaluation metrics to be considered for the final ranking. The F1 score is defined in the Equation 1. Where TP stands for the number of correctly predicted right answers, FP stands for the number of wrongly predicted right answers, and FN stands for the right answers wrongly predicted as wrong answers.

	F1	Accuracy
Mistral 7B	0.5597	0.5714

Table 1: The method's performance on the test set. In the table, the results obtained and shown on the official GitHub page are reported.

$$F1 = \frac{2 * Precision * Recall}{Precision + Recall} \quad (1)$$

Given the previous definitions, the accuracy is defined as stated in the Equation 2.

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \quad (2)$$

In Table 1, we present the outcomes derived from our methodology. They are the same results publicly availble on the official final ranking shown on the official task page[5] and on CodaLab[6].

In the Table 2, the results obtained by the first three teams and by the last one, as showed on the official task page, are reported. Compared to the best performing models, our simple approach exhibits some room for improvements. However, it is worth notice that required no further pre-training and the computational cost to address the task is manageable with the free online resources offered by Google Colab. Finally, the proposed approach is able to outperform the baseline provided.

6 Conclusion

This paper presents the application of a Mistral 7B-model for addressing the Task 5 at SemEval-2024. For our submission, we decided to follow a zero-shot learning approach, employing as-is, an in-domain pre-trained Transformer. After several experiments, we found beneficial to build a prompt containing the question for the model. Then we provide as a prompt: the introduction, the question and an answer candidate. The model is asked to decide whether the candidate answer is correct or not. The task is challenging, and there is still opportunity for improvement, as can be noted looking at the final ranking. Possible alternative approaches include

Table 2: Comparing performance on the test set. In the table are shown the results obtained by the first three teams and by the last one. In parentheses is reported the position in the official final ranking.

utilizing the few-shot capabilities or also the use of other models like GPT and T5, eventually using further data, or directly integrating other samples from the training and from the development sets. Further improvements could be obtained with a fine-tuning and modelling the problem as a text classification task. Furthermore, given the interesting results recently provided on a plethora of tasks, also other few-shot learning (Wang et al., 2023; Maia et al., 2024; Siino et al., 2023; Meng et al., 2024) or data augmentation strategies (Muftie and Haris, 2023; Tapia-Téllez and Escalante, 2020; Siino and Tinnirello, 2023) could be employed to improve the results. Looking at the final ranking, our simple approach exhibits some room for improvements. However, it is worth notice that required no further pre-training and the computational cost to address the task is manageable with the free online resources offered by Google Colab.

Acknowledgments

We extend our gratitude to the anonymous reviewers for their insightful comments and valuable suggestions, which have significantly enhanced the clarity and presentation of this paper.

Abstract

SemEval-2024 Task 8 introduces the challenge of identifying machine-generated texts from diverse Large Language Models (LLMs) in various languages and domains. The task comprises three subtasks: binary classification in monolingual and multilingual (Subtask A), multi-class classification (Subtask B), and mixed text detection (Subtask C). This paper focuses on Subtask A & B. To tackle this task, this paper proposes two methods: 1) using traditional machine learning (ML) with natural language preprocessing (NLP) for feature extraction, and 2) fine-tuning LLMs for text classification. For fine-tuning, we use the train datasets provided by the task organizers. The results show that transformer models like LoRA-RoBERTa and XLM-RoBERTa outperform traditional ML models, particularly in multilingual subtasks. However, traditional ML models performed better than transformer models for the monolingual task, demonstrating the importance of considering the specific characteristics of each subtask when selecting an appropriate approach.

1 Introduction

Large Language Models (LLMs) are sophisticated natural language processing (NLP) models extensively trained on vast textual datasets (Wang et al., 2023). These models demonstrate an impressive proficiency in generating human-like text based on the input they receive. However, using LLMs for generating texts has raised concerns about potential misuse, such as disseminating misinformation and disruptions in the education system (Wang et al., 2023). Thus, urgent development of automated systems to detect machine-generated texts is essential (Mitchell et al., 2023; Wang et al., 2023).

Recently, several LLMs have been developed such as ChatGPT[1] Brown et al. (2020), Cohere[2], Davinci[3], BLOOMZ[4] (Muennighoff et al., 2022), and Dolly[5] (Conover et al., 2023). The versatility of these models extends across various domains, such as news, social media, educational platforms, and academic contexts, in multiple languages not only English (Wang et al., 2023). This wide application poses a challenge in developing an automated system capable of detecting machine-generated texts from various generators, across multiple domains and languages.

To tackle this challenge, SemEval-2024 Task 8: Multigenerator, Multidomain, and Multilingual Black-Box Machine-Generated Text Detection (Wang et al., 2024) introduces the task of detecting machine-generated texts obtained from different LLMs, in various domains and languages. This task consists of three subtasks: Subtasks A, B, and C. Subtask A involves binary classification of text as either human-written or machine-generated, with two tracks: monolingual (English only) and multilingual. Subtask B focuses on multi-class classification of machine-generated text, aiming to identify the source of generation, whether human or a specific language model. Subtask C addresses the detection of human-machine mixed text, requiring the determination of the boundary where the transition from human-written to machine-generated occurs in a mixed text. This paper focuses on Subtasks A and B. To tackle these tasks, we propose two approaches: (1) classical machine learning, leveraging NLP techniques for feature extraction, and (2) fine-tuning LLMs for the classification of human-written and machine-generated texts.

2 Related Work

Researchers have employed a variety of methods and tools to detect AI-generated texts. Broadly,

[5]https://huggingface.co/databricks/dolly-v2-12b

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 163–169

these approaches can be categorized into two main types: black-box and white-box detection methods (Tang et al., 2023). Black-box detection relies on API-level access to LLMs, utilizing textual samples from both human and machine sources to train classification models (Dugan et al., 2020). The study by Guo et al. (2023) integrated existing question-and-answer datasets and leveraged fine-tuning of pre-trained models to investigate the characteristics and similarities between human-generated and AI-generated texts.

As for white-box detection, Kirchenbauer et al. (2023) introduced a novel approach involving the embedding of watermarks in the outputs of LLMs to facilitate the detection of AI-generated text. Additionally, a variety of tools and methodologies, including XGBoost, decision trees, and transformer-based models, have been evaluated for their efficacy in detecting texts produced by AI (Zaitsu and Jin, 2023). These techniques incorporate multiple stylistic measurement features to differentiate between AI-generated and human-generated texts (Shijaku and Canhasi, 2023).

Specific tools and techniques in this domain include the GLTR tool developed by Gehrmann et al. (2019), which analyzes the usage of rare words in texts to distinguish between those generated by the GPT-2 model and human writers. The DetectGPT method posits that minor rewrites of LLM-generated texts tend to reduce the log probability under the model, a hypothesis that has been explored in depth (Mitchell et al., 2023). Furthermore, intrinsic dimension analysis, including methods like the Persistent Homology Dimension estimator (PHD), has been applied to distinguish between authentic texts and those generated artificially (Tulchinskii et al., 2023). Detectors specifically designed for certain LLMs, such as the GROVER detector for the GROVER model (Zellers et al., 2019) and the RoBERTa detector using the RoBERTa model (Liu et al., 2019), also play a significant role in this field.

In summary, the combination of statistical analysis with advanced language models is being employed by researchers to more effectively differentiate between content generated by humans and machines. The continuous evolution and refinement of these techniques reflect the dynamic nature of the field and the complexities involved in distinguishing between the increasingly nuanced outputs of LLMs and human-authored texts.

3 Methods

To tackle these tasks, we employ two distinct strategies. The first is classical machine learning, tailored for natural language preprocessing (NLP). The second approach involves transformer-based LLMs, with an emphasis on LoRA (Low-Rank Adaptation of Large Language Models) fine-tuning (Hu et al., 2021). We then enhance our results by integrating these methods through ensemble techniques.

3.1 Machine Learning Models

Our approach for textual data analysis in machine learning involves a concise yet comprehensive preprocessing pipeline. Initially, URLs and excess whitespace are removed from the text. Next, all punctuation is eliminated, focusing solely on alphanumeric characters. The text is further refined by excluding common stopwords and numeric characters. Emojis are decoded into text, providing additional context. Lemmatization standardizes words to their base forms, ensuring consistent analysis. Texts are then converted to lowercase for uniformity.

The final step involves using a *Term Frequency-Inverse Document Frequency* (TF-IDF), configured to handle a maximum of 8000 features and considering unigrams to trigrams. This vectorizer excludes terms appearing in less than 10 documents, balancing feature representation with computational efficiency. Furthermore, we enhance the feature set for machine learning by incorporating esteemed readability metrics such as the *Gunning fog index* (Scott, 2023) and *Flesch reading ease score* (Kincaid et al., 1975) into our text analysis, which assess the complexity and readability of the text respectively. This preprocessing strategy transforms raw text into a structured numerical format, ready for machine learning model analysis.

Expanding our feature extraction capabilities, we introduce additional dimensions of analysis including perplexity measures, sentiment analysis, document and error analysis, text vector features, the AI Feedback Query feature, and list lookup features. Perplexity measures assess text complexity through language models, offering insights into predictability. Sentiment analysis is deepened to reveal emotional tones and subjective nuances, providing a fuller understanding of the text's emotional landscape and authorial intent. Document and error analysis afford a detailed look at structure

and linguistic accuracy, enhancing content quality assessment. Text vector features, leveraging Sentence-BERT embeddings, enable sophisticated semantic content capture, facilitating nuanced thematic analysis. The AI Feedback Query feature is a binary response achieved through a structured inquiry where the AI model is presented with the text and asked to determine its generative source. List lookup features, examining elements like stop word frequency and special character use, offer stylistic and structural insights. Collectively, these advancements enable a comprehensive and detailed interpretation of textual data, significantly broadening our analytical capabilities by combining them.

In our study, we employed four distinct machine learning algorithms for both binary and multiclass classification tasks: Logistic Regression (LR), Multinomial Naive Bayes Classifier (MultinomialNB), eXtreme Gradient Boosting (XGBoost) (Chen and Guestrin, 2016) and Random Forest (RM).

- LR: A linear model used for classification tasks. It models the probability that a given input belongs to a certain class. Logistic Regression is particularly effective for binary classification due to its simplicity and efficiency in estimating probabilities.
- MultinomialNB: This algorithm is based on the Bayes theorem and is particularly suited for classification with discrete features (like word counts for text classification). It assumes independence between predictors and is highly scalable to large datasets.
- XGBoost: This is an efficient and scalable implementation of gradient-boosted decision trees. It is known for its performance and speed, especially in structured or tabular data, and can handle both binary and multi-class classification problems effectively.
- RF: A versatile ensemble learning method that builds multiple decision trees for classification or regression tasks. It improves accuracy by averaging or taking the mode of predictions from all trees, effectively reducing overfitting. Suitable for both binary and multiclass problems, it excels in handling large, high-dimensional datasets.

By integrating these algorithms, our approach leverages the strengths of linear modeling, probabilistic classification, and ensemble learning, aiming to enhance predictive accuracy and robustness across diverse classification scenarios.

3.2 XLM-RoBERTa

In our approach, we established XLM-RoBERTa[6] (Conneau et al., 2019) as the baseline model among transformer-based architectures. XLM-RoBERTa represents a multilingual adaptation of the original RoBERTa (Liu et al., 2019) model, specifically designed to understand and process a diverse range of languages. XLM-RoBERTa is pre-trained on a substantial dataset: 2.5TB of filtered CommonCrawl data (Zhang et al., 2020), encompassing text in 100 different languages. This extensive pre-training enables the model to capture nuanced language features and patterns across a broad linguistic spectrum, making it highly effective for tasks involving multiple languages. The use of such a diverse training dataset aids in achieving a robust understanding of various linguistic structures and vocabularies, which is crucial for accurate language processing and analysis in a multilingual context.

3.3 LoRA-RoBERTa

To improve the predictive performance of LLMs, we use LoRA for fine-tuning RoBERTa[7] model. LoRA is a technique enhancing the efficiency of fine-tuning large models with reduced memory consumption. It modifies the weight updates in neural networks using two smaller matrices derived through low-rank decomposition. These matrices adapt to new data while the original weights remain unchanged. The final output combines the original and adapted weights. In transformer models, LoRA is often applied to attention blocks for efficiency. The number of trainable parameters depends on the low-rank matrices' size, influenced by the rank and the original weight matrix's shape (Hu et al., 2021), as shown in Figure 1.

3.4 Majority Voting

The Majority Voting ensemble in this study combines the predictions of two transformer-based models: XLM-RoBERTa and LoRA-RoBERTa. The final prediction is determined by the majority vote of these two models, offers several advantages over a single-model approach. This technique, applicable in scenarios with N classifiers $(C_1, C_2, \ldots, C_N)$, determines the final out-

[6]https://huggingface.co/xlm-roberta-base
[7]https://huggingface.co/roberta-base

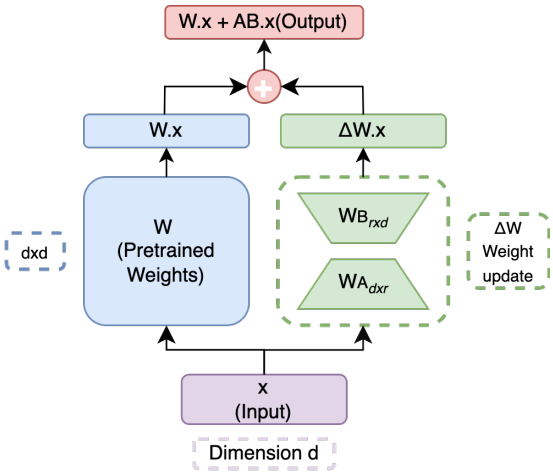

Figure 1: LoRA-based fine-tuning streamlines the process by freezing the original weights of LLMs and training a minimal number of parameters.

put $V(x)$ as the class receiving the most votes: $V(x) = \text{mode}\{C_1(x), C_2(x), \ldots, C_N(x)\}$. This method effectively reduces variance by balancing out individual model errors, leading to more stable predictions. Furthermore, it generally achieves higher accuracy due to the diverse perspectives of different models. Its robustness against overfitting is enhanced, as it combines various models' strengths, making it suitable for a wider range of data scenarios. The flexibility in model selection allows for a blend of different algorithms, each capturing unique data patterns, which contributes to better generalization on unseen data. Thus, majority voting stands out as a robust, accurate, and flexible approach in machine learning.

3.5 DistilmBERT

RoBERTa and XLM-RoBERTa are both powerful but computationally expensive. Therefore, we investigate an alternative model that is more computationally efficient, aiming to compare its performance against these models. We adopted *DistilBERT base multilingual cased*[8] (DistilmBERT) (Sanh et al., 2019), a distilled version of the BERT base multilingual model. It was pretrained on the concatenation of Wikipedia in 104 different languages. DistilmBERT consists of 6 layers, each with 768 dimensions and 12 attention heads, totaling 134 million parameters. This configuration balances model efficiency while retaining significant representational power Sanh et al. (2019).

[8]https://huggingface.co/distilbert-base-multilingual-cased

4 Experiments

In our study, subtask A focuses on distinguishing between human-written (label 0) and machine-generated text (label 1), offered in both monolingual (119,757 train, 5,000 dev, 34,272 test) and multilingual versions (172,417 train, 4,000 dev, 42,378 test), across various sources and languages are given in Table 1. Subtask B, with 71,027 train, 3,000 dev, and 18,000 test, goes further by identifying the specific model (including ChatGPT, Cohere, DaVinci, BloomZ, and Dolly) that generated the text, or if it's human-generated. Both tasks utilize datasets with an identifier, label, text content, model name, and source, focusing on the nuanced classification of texts.

Subtask	#Train	#Dev	#Test
A - Monolingual	119,757	5,000	34,272
A - Multilingual	172,417	4,000	42,378
B	71,027	3,000	18,000

Table 1: Dataset for text classification subtasks

4.1 Parameter Settings

In our experimentation, hyperparameter settings varied between classical machine learning models and LLMs. For the classical machine learning models, we adhered to default parameter settings during training. This approach simplifies the process and relies on the general applicability of these preset parameters.

In contrast, for LLMs, specific hyperparameters were carefully chosen. When training the XLM-RoBERTa baseline model, we set the batch size to 16 and the learning rate to $2.0e-5$ with the model being trained for 3 epochs. This configuration ensures efficient handling of data and optimal learning speed. For fine-tuning the LoRA-RoBERTa base model, the learning rate was adjusted to $1.0e-3$ over 5 epochs, a setting conducive to the specific demands of fine-tuning.

Furthermore, we employed configuration for the LoRA fine-tuning, defined with the following parameters: *task_type* set to *SEQ_CLS* indicating a sequence classification task, *r* (rank of the low-rank matrices) set to 4, *lora_alpha* (scaling factor for learning rate) at 32, *lora_dropout* to manage overfitting set at 0.01, and *target_modules* focused on the *query* module. These configurations are critical in guiding the fine-tuning process, ensuring that the

Method	Subtask A - Monolingual		Subtask A - Multilingual		Subtask B	
	Dev	Test	Dev	Test	Dev	Test
LR	0.673	0.764	0.473	0.721	0.251	0.393
MultinomialNB	0.555	**0.832**	0.483	0.717	0.435	0.511
XGBoost	0.692	0.800	0.515	0.738	0.540	0.545
RF	0.650	0.825	-	-	0.471	0.524
XLM-RoBERTa	**0.783**	0.717	0.679	**0.875**	**0.735**	0.600
LoRA-RoBERTa	**0.783**	0.811	0.726	0.672	**0.735**	**0.699**
Majority voting	0.735	0.828	**0.728**	0.862	0.717	0.602
DistilmBERT	0.702	0.730	0.670	0.810	0.629	0.619

Table 2: Performance comparison of ML and transformer models on text classification subtasks

adjustments to the model are precisely tailored to enhance performance on the specified task.

As for DistilmBERT, the maximum length of input sequences was set to 512. The AdamW optimizer was employed for training with a learning rate set to $1.0e-4$ and a batch size of 20. This model was trained for 5 epochs.

4.2 Results and Discussions

In our experiments, we evaluated various models on three distinct subtasks: Subtask A - Monolingual, Subtask A - Multilingual, and Subtask B. Each subtask involved both development (Dev) and test phases. The models tested included traditional machine learning algorithms - LR, MultinomialNB, XGBoost and RF - as well as advanced transformer-based models like XLM-RoBERTa, LoRA-RoBERTa, and DistilmBERT. However, due to the complexity of RF and time constraints, experiments on this approach for Subtask A - Multilingual are still ongoing, we plan to report the results in future work. Additionally, we employed a majority voting ensemble method combining XLM-RoBERTa and LoRA-RoBERTa.

The results, detailed in Table 2, reveal significant variations in model performance across the subtasks, highlighting the strengths and weaknesses of each model. One notable observation is the large performance gap between the dev and test sets for some ML approaches. This discrepancy could be attributed to several factors, such as overfitting, differences in data distribution between the dev and test sets, or the limited complexity of some ML models in capturing the intricacies of the task. Further investigation and error analysis are necessary to fully understand and address these issues.

Subtask A - Monolingual In the monolingual Subtask A, MultinomialNB emerged as a strong performer with the highest test score of 0.832. RF and XGBoost also showed robust performance with test scores of 0.825 and 0.800, respectively. The success of these ML models in the monolingual setting suggests that they can effectively capture relevant features and patterns when dealing with a single language. However, their performance on the dev set was notably lower, indicating potential overfitting or limitations in generalizing to unseen data. Among the transformers, LoRA-RoBERTa was notable with a test score of 0.811, outperforming XLM-RoBERTa, which scored 0.717. DistilmBERT, while not leading, still demonstrated a commendable test score of 0.730, indicating its effectiveness in monolingual contexts. The performance of transformer models in this subtask highlights their ability to capture complex language representations and generalize well to new data.

Subtask A - Multilingual In the challenging multilingual Subtask A, XLM-RoBERTa excelled with the highest test score of 0.875. The Majority Voting ensemble was also highly effective, achieving a test score of 0.862. These results demonstrate the strength of transformer models in handling diverse language inputs and their ability to learn language-agnostic representations. DistilmBERT, with a test score of 0.810, also showed notable effectiveness in multilingual text classification, outperforming traditional models and reflecting its potential in handling complex, diverse language data.

Subtask B In Subtask B, LoRA-RoBERTa led with a Test score of 0.699, follwed by DistilmBERT, achieving a test score of 0.619 and XLM-RoBERTa with 0.600. The strong performance

of transformer models in this subtask underscores their versatility and adaptability across different text classification scenarios. Among the traditional models, XGBoost was the most effective, with a test score of 0.545. However, the performance gap between ML models and transformers in Subtask B suggests that the latter are better equipped to handle the specific challenges and complexities of this task.

At the model level, we observed that ML models often struggled with handling rare or out-of-vocabulary words, leading to misclassifications. Transformer models, on the other hand, showed better resilience to such challenges, likely due to their subword tokenization and ability to capture broader context. However, transformers sometimes struggled with very short or noisy inputs, indicating room for improvement in their robustness.

5 Conclusions

The results showed that transformer models, particularly LoRA-RoBERTa and XLM-RoBERTa, performed exceptionally well in most text classification tasks. DistilmBERT represented a more streamlined transformer approach and was also proven to be efficient, especially in multilingual task. Contrary to popular belief, traditional ML models such as MultinomialNB and XGBoost can outperform transformers in monolingual tasks. These findings highlight the importance of carefully considering the characteristics of the task and the trade-offs between model complexity and performance when selecting an appropriate approach.

Our results contribute to the understanding of model selection strategies for text classification and emphasize the need for a nuanced approach that takes into account the specific demands of each subtask. Future research could explore the development of hybrid models that combine the strengths of traditional ML techniques and transformer architectures, as well as the design of more efficient and lightweight transformer models for resource-constrained environments. These findings reflected the dynamic nature of NLP tools and the importance of selecting models based on the specific requirements of the task.

Abstract

The task of textual entailment holds significant importance when dealing with clinical data, as it serves as a foundational component for extracting and synthesizing medical information from vast amounts of unstructured text.

To investigate the consistency with which Natural Language Inference (NLI) models capture semantic phenomena critical for intricate inference within clinical NLI contexts, SemEval−2024 has organized a shared task focused on NLI for Clinical Trials (NLI4CT). This task provides participants with a dataset annotated by humans for the purpose of model training and requires the submission of the results on test data for evaluation. We engaged in this shared task2 at SemEval−2024, employing a diverse set of solutions, with a particular emphasis on leveraging a Large Language Model (LLM) based zero-shot inference approach to address the challenge.

1 Introduction

Clinical NLI is a specialized application of Natural Language Processing (NLP) that focuses on understanding and inferring information from text within the healthcare domain. It involves analyzing and drawing conclusions from clinical narratives, such as electronic health records (EHRs), doctor's notes, medical transcripts, clinical trials and other forms of medical documentation (Percha et al., 2022). The goal of clinical NLI is to determine the logical relationship between premises and hypotheses (conclusions) in clinical text. By inferring information from clinical text, NLI can assist healthcare providers in making informed decisions by providing evidence-based recommendations and alerts. In addition, clinical NLI can be used to identify patient cohorts for clinical trials or research studies by inferring patient eligibility based on inclusion and exclusion criteria mentioned in clinical records. Applications of clinical NLI are not limited to the ones mentioned and there are lots of other usages in which clinical NLI can be useful (Percha et al., 2021). NLI for clinical trials faces unique challenges due to the complexity of medical language, the need for domain-specific knowledge, and the sensitivity and privacy concerns associated with health data. However, advancements in NLP and specifically Large Language Models (LLMs) are continuously improving the accuracy and applicability of clinical NLI, making it an increasingly valuable tool in the healthcare industry.

To foster collaboration and dissemination of novel insights within this field, SemEval 2024 (Jullien et al., 2024) has established a shared task exclusively devoted to clinical NLI. A publicly accessible dataset, annotated by humans, has been made available to facilitate the comparison of solutions proposed by different researchers.

To address the challenge, we developed an ensemble-oriented solution that combines various Large Language Models (LLMs) based models within the framework of prompting and fine-tuned classification. Our primary goals were to first understand the comparative performance of generative models versus classification models. Subsequently, we explored whether the use of automatic summarization models to condense the premises would influence the efficacy of both classifiers and generative models. Ultimately, our approach sought to facilitate synergistic interactions among the different models, leveraging their respective strengths to mitigate individual inference limitations.

Nevertheless, despite conducting a variety of experiments that involved combining summarization, fine-tuning classifiers, prompting, and more, the results demonstrated a clear superiority of generative models in comparison to the others, even when used independently.

The remainder of this paper is organized as follows: Section 2 provides a brief review of related

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 170–174

work. The proposed model and its constituent modules are detailed in Section 3. Sections 4 and 5 discuss the experiments conducted and the corresponding results. Finally, we conclude the paper in Section 6.

2 Past Work

Recent literature underscores the need for sophisticated models that can accurately capture the semantics of clinical narratives and support reasoning in line with medical knowledge. Jullien et al. (2023), introduced a shared task on NLI for clinical trials (NLI4CT), providing a dataset of annotated clinical trials and inviting researchers to develop models to tackle the associated challenges. The shared task comprises two sub-tasks: Textual Entailment and Evidence Retrieval, each designed to advance the state of NLI systems within the clinical domain.

Zhou et al. (2023), took part in the NLI4CT-2023 challenge, proposing a model that utilizes both sentence-level and token-level encoding to address the task at hand. Furthermore, they enhanced the model's overall performance by employing general (T5-based model) and domain-specific (SciFive) pre-trained LLMs.

Kanakarajan and Sankarasubbu (2023), conducted an evaluation of several instruction-tuned Large Language Models (LLMs) in a zero-shot setting and fine-tuned the best-performing instruction-tuned model (T5 family models). Their findings suggest that instruction-tuned models yield better results for datasets with limited training samples. Additionally, they explored the impact of various prompts on the overall performance of the model. (Vladika and Matthes, 2023) and (Chen et al., 2023), both created a model based on an ensemble approach that combines various fine-tuned iterations of biomedical LLMs. These models are designed to extract evidence from clinical trial report premises to support textual entailment in specific statements. Wang et al. (2023), developed a system that utilizes prompts created by humans to gather information from statements, section titles, and clinical trials. They then fine-tune pre-trained language models on these prompted sentences, training the models to identify the inferential connections between the statements and the clinical trials. Pahwa and Pahwa (2023), characterized the NLI task as a form of text pair classification and utilized the GPT-3 model to classify samples within the framework of few-shot prompting. This approach takes advantage of the semantic similarity between text samples and the examples provided for in-context learning.

Dias et al. (2023), employed supervised contrastive learning to enhance the sentence pair representations in the Biomed RoBERTa model. They then fine-tuned a linear classifier built upon these improved representations to identify evidence and execute textual entailment classification for sentence pairs.

Vassileva et al. (2023), introduced a two-tiered system to address the sub-tasks of NLI4CT-2023. Initially, the system employs a BERT-based classifier, supplemented by contextual data augmentation, to categorize evidence-statement pairs as relevant or irrelevant. Subsequently, leveraging the relevant segments of the clinical trial identified in the first stage, the system applies another BERT-based classifier to ascertain whether the relationship between the elements is one of entailment or contradiction.

Volosincu et al. (2023), illustrated that a transformer model pre-trained on biomedical data for the task of entailment relation in NLI4CT-2023 does not automatically outperform traditional approaches like CNNs. Nonetheless, their model exceeded the baseline system's performance and provided meaningful directions for future research on how the model's architecture can be developed further.

3 Proposed Model

In tackling the NLI4CT task, our approach involved the construction of an ensemble model that integrates the judgments of multiple distinct decision-makers. These decision-makers differ concerning the nature of input data they process, the foundational models they employ, and the methodologies they adopt for label determination. Figure 1 provides a comprehensive illustration of the proposed solution. Components of the ensemble pool were developed within the frameworks of classification or prompting, utilizing LLMs. For classification tasks, SciFive (Zhou et al., 2023) was selected as the base model due to its exemplary performance in the NLI4CT-2023 task. To enhance the models' ability to assimilate information from the input data, we employed both extractive and abstractive summarization techniques. The abstractive summarization was conducted using the T5-large model (Raffel et al., 2020) to condense the premises. For

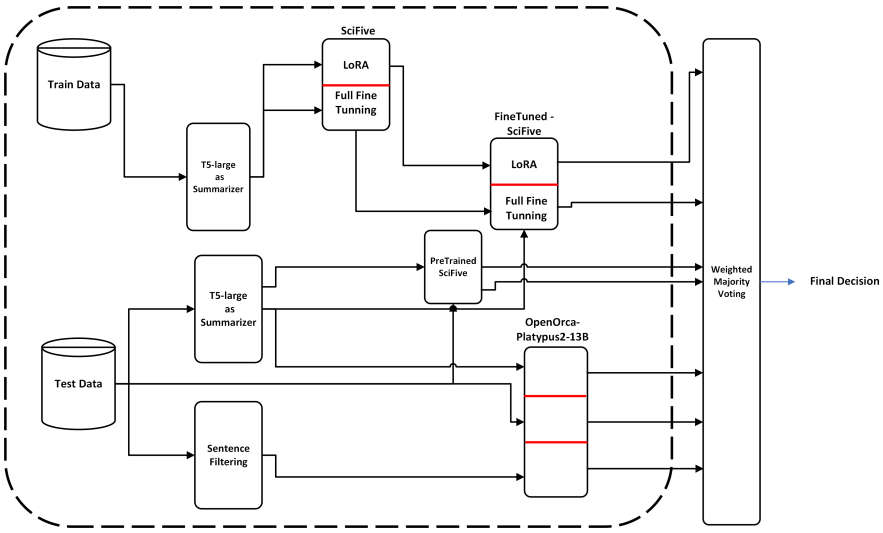

Figure 1: Ensemble Model Proposed

extractive summarization, the premises were initially segmented into individual sentences, after which those exhibiting lower semantic similarity to the hypothesis were excluded.

The pre-trained SciFive model ingests the text summarized by T5 to generate the initial component of the ensemble pool. Subsequently, this model undergoes fine-tuning through two distinct methodologies utilizing the summarized data: comprehensive fine-tuning and parameter-efficient fine-tuning, the latter of which is facilitated by employing LoRA (Hu et al., 2021) to produce subsequent members of the ensemble pool.

The remaining decision-makers within the ensemble are derived by prompting generative LLM[1] in a zero-shot inference context, utilizing both the original input data and variously summarized inputs. The specific prompt employed for the model is delineated in Listing 1.

```

Ultimately, the final decision for the test samples were made using a weighted majority voting approach. The performance of models on *practice_test* set were used for the combination process.

4 Experiments

We have conducted our experiments utilizing the dataset provided by the task's organizers that is explained in Section 4.1. For the models based on prompting, we utilized only the test and practice_test datasets, whereas the training data was employed exclusively for fine-tuning the classification-based models. Beyond experimenting with models within our ensemble framework, we also explored the integration of results from fine-tuned classification models as a form of external knowledge within the context of prompting. The efficacy of all models is evaluated using three metrics: Macro

[1]OpenOrca-Platypus2-13B, which is an autoregressive language model that utilizes the Lllama 2 transformer architecture. It is tailored for a variety of general-use applications, including chat, text generation, and code generation. This model has undergone training with a diverse mix of datasets, focusing on STEM and logic-based content, and it incorporates a carefully selected portion of data from the GPT-4 dataset within the OpenOrca collection.

F1 Score, Faithfulness, and Consistency, each of which is briefly described in Section 4.2.

4.1 Dataset

The corpus presented for analysis encompasses training, development, practice_test, and test datasets, each containing a distinct number of samples. Table 1 displays the quantity of samples for each dataset. The content of each sample, including statements and evidence, has been reconstructed by a collaborative effort of clinical domain experts, clinical trial organizers, and research oncologists associated with the Cancer Research UK Manchester Institute and the Digital Experimental Cancer Medicine Team.

Split	#Samples	#Entailment	#Contradiction
Train	1700	850	850
Practice_test	2142	730	1412
Development	200	100	100
Test	5500	1841	3659

Table 1: Overview of Dataset Splits: Distribution of Samples, Entailment, and Contradiction Labels

4.2 Evaluation

In assessing system performance, the organizers, in conjunction with the macro F1 score, opted to examine model efficacy on a contrast dataset comprising statements with interventions. The comprehensive ranking of the systems is determined by the mean of two novel metrics: Faithfulness (as defined in Equation. 1) and Consistency (as defined in Equation. 2), across all types of interventions.

$$FaithFulness = \frac{1}{N}\sum_{1}^{N} |f(y_i) - f(x_i)| \quad (1)$$

where $x_i \in C : Label(x_i) \neq Label(y_i), f(y_i) = Label(y_i)$.

$$Consistency = \frac{1}{N}\sum_{1}^{N} 1 - |f(y_i) - f(x_i)| \quad (2)$$

where $x_i \in C : Label(x_i) = Label(y_i)$. Faithfulness quantifies the degree to which a system reaches an accurate prediction based on the correct rationale. While, Consistency measures the degree to which a system yields identical outputs for semantically equivalent queries. The results obtained during the experimental trials are presented in the subsequent section.

5 Results

The performance result of individual models within the ensemble, as applied on both practice_test and test datasets, are illustrated in Table 2.

The proposed model exhibits faithfulness and consistency scores of 28% and 52%, respectively, suggesting a necessity for more robust models to effectively manage clinical trials involving diverse data types. The findings reveal that the proposed overall model performs similarly to the generative model in the prompting context. This similarity underscores the considerable potential of generative LLMs. These models can achieve better performance when instruction tuning is applied with domain-specific data. Additionally, using classification results as external knowledge for the prompting model showed minimal impact. Moreover, the use of extractive summarization yielded the lowest results, aligning with our expectations. This approach, which focuses on the similarity between individual sentences and the statement, can lead to a loss of comprehension of the entirety of the premises.

6 Conclusion

In conclusion, our participation in NLI4CT-2024 involved proposing an ensemble approach that incorporated multiple decision-makers, with two Large Language Models (LLMs) serving as foundational models. We explored various data preparation techniques, including abstractive summarization and similarity-based sentence filtering, for use in both prompting and classification contexts. The comparable performance of the prompt-based model to the overall ensemble model, coupled with its significant outperformance of the classification models, underscores the substantial potential of pretrained generative foundation models in solving similar problems. We posit that the application of instruction tuning and the incorporation of domain-specific data could markedly enhance the results.

CLaC at SemEval-2024 Task 4: Decoding Persuasion in Memes – An Ensemble of Language Models with Paraphrase Augmentation

Kota Shamanth Ramanath Nayak and **Leila Kosseim**
Computational Linguistics at Concordia (CLaC) Laboratory
Department of Computer Science and Software Engineering
Concordia University, Montréal, Québec, Canada
kotashamanthramanath.nayak@mail.concordia.ca,
leila.kosseim@concordia.ca

Abstract

This paper describes our approach to SemEval-2024 Task 4 subtask 1, focusing on hierarchical multi-label detection of persuasion techniques in meme texts. Our approach was based on fine-tuning individual language models (BERT, XLM-RoBERTa, and mBERT) and leveraging a mean-based ensemble model. Additional strategies included dataset augmentation through the TC dataset and paraphrase generation as well as the fine-tuning of individual classification thresholds for each class. During testing, our system outperformed the baseline in all languages except for Arabic, where no significant improvement was reached. Analysis of the results seem to indicate that our dataset augmentation strategy and per-class threshold fine-tuning may have introduced noise and exacerbated the dataset imbalance.

1 Introduction

The SemEval-2024 shared Task 4 (Dimitrov et al., 2024) proposed three distinct subtasks dedicated to identifying persuasion techniques conveyed by memes. The primary aim was to unravel how memes, integral to disinformation campaigns, employ various techniques to shape user perspectives. Subtask 1 focused on the analysis of textual content alone; while subtasks 2 and 3 involved the analysis of multimodal context that considers both textual and visual elements. Subtasks 1 and 2 used hierarchical multi-label classification metrics, while subtask 3 involves a binary classification task. The training dataset provided was in English but all subtasks mandated the evaluation of our model's zero-shot performance in three surprise languages: Bulgarian, North Macedonian, and Arabic and another fourth dataset in English. The goal during the testing phase was to explore our model's ability to generalize to these languages without explicit training.

This paper describes our participation to subtask 1, focusing on the detection of 20 persuasion techniques structured hierarchically within the textual content of memes. Inspired by successful approaches in multilabel text classification (Jurkiewicz et al., 2020; Tian et al., 2021), our strategy involved fine-tuning three language models i.e, BERT [`bert-base-uncased`], XLM-RoBERTa [`xlm-roberta-base`], and mBERT [`bert-base-multilingual-uncased`], followed by ensemble modeling using the mean aggregation technique using the English training set. To enhance performance, we used data augmentation through paraphrasing and adjusted the classification thresholds for each persuasion technique based on class-wise metrics optimised using the validation set using grid search. During testing, a zero-shot approach was implemented by translating the surprise language data into English.

At the shared task, our system demonstrated significant performance advantages over the baseline in all languages except Arabic, where the performance difference was not statistically significant. Our system's effectiveness, particularly in non-Arabic languages, underscores its potential for analyzing memes within disinformation campaigns, emphasizing the need for language-specific considerations in model development.

Section 2 provides an overview of the data utilized and offers insights into relevant prior research. Section 3 presents an overview of our classification pipeline, while Section 4 describes the experiments and data augmentation techniques that guided our final model decisions. Finally, Section 5 analyses the results of our model. All of the code used in the implementation of the models described in this paper is made available on GitHub.[1]

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 175–180

2 Background

SemEval 2024 Task 4 (Multilingual Detection Of Persuasion Techniques In Memes) proposed 3 subtasks, out of which we participated in the first one. The goal of subtask 1 was to categorize the textual content of memes into one or several persuasion techniques. An inventory of 20 techniques was provided (eg: *Smears*, *Loaded Language*, *Slogans*) and were structured hierarchically, rendering the task a hierarchical multi-label classification problem.

2.1 Datasets

The SemEval organizers collected memes in English, Bulgarian, North Macedonian, and Arabic from their personal Facebook accounts, scraping public groups discussing politics, vaccines, COVID-19, gender equality, and the Russo-Ukrainian War. For subtask 1, the input data comprised the text extracted from these memes. The training (7k samples), validation (500 samples) and development (1k samples) sets included only English texts; whereas the test set was multilingual with 1500 samples for English, 426 samples for Bulgarian, 259 samples for North Macedonian and 100 samples for Arabic. All datasets were the provided in the form of JSON files. The orange bars in Figure 1 shows the distribution of the data for each persuasion technique in the training set. As Figure 1 shows some techniques, such as *Loaded Language* and *Smears*, had a substantial number of samples, while others like *Straw Man* and *Red Herring* were severely underrepresented.

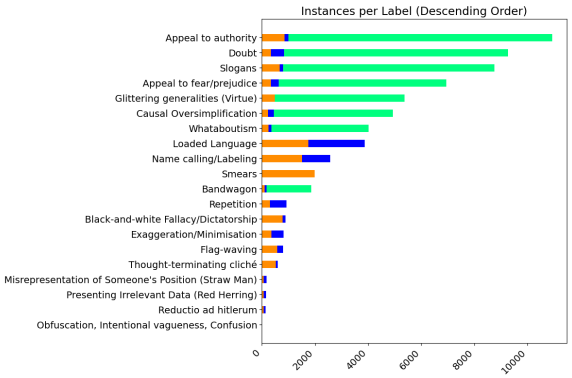

Figure 1: Distribution of the data for each persuasion technique in the SemEval 2024 (in orange), the `Comb-14k` (in orange + blue) and the `Para-54k` (in orange + blue + green) training datasets.

2.2 Previous Work

In the context of the SemEval 2020 Task 11 (Da San Martino et al., 2020), two subtasks were introduced addressing span identification of propagandistic textual fragments and a multi-label technique classification (TC) of propagandistic fragments using a corpus of ≈7k instances from the news domain. The subsequent SemEval 2021 Task 6 (Dimitrov et al., 2021) focused on the identification of propagandistic techniques from multimodal data including text and images from memes. This year's shared task build upon the 2021 task but included hierarchical metrics as well as a multilingual setting. The top-performing teams in 2020 and 2021, AppliCaAI (Jurkiewicz et al., 2020) and MinD (Tian et al., 2021) respectively, leveraged pre-trained language models and ensemble techniques to achieve top scores at the shared tasks. Inspired by these works, our methodology is also based on an ensemble of pre-trained language models.

3 System Overview

The aim of subtask 1 is to identify 0 or n persuasion techniques for each textual instance. Despite the hierarchical organization of the persuasion techniques, we opted to predicting solely the technique names (leaf nodes) and not their ancestor nodes. Figure 2 shows an overview of the classification pipeline we employed for this subtask. As shown in Figure 2, our methodology is based on fine-tuning three distinct pre-trained language models: BERT (Devlin et al., 2019), XLM-RoBERTa (Conneau et al., 2020), and mBERT (Devlin et al., 2019). This fine-tuning process is conducted on augmented datasets.

3.1 Data Augmentation

As Figure 1 shows, some persuasion techniques have very few samples (eg: *Red Herring*, *Straw Man* only have 59 and 62 instances respectively) in the SemEval 2024 dataset (in orange). To mitigate the lack of data we took advantage of data augmentation strategies: The Technique Classification subtask from SemEval 2020 task 11 (Da San Martino et al., 2020) (See Section 3.1.1) and automatically generated paraphrases (See Section 3.1.2).

3.1.1 SemEval 2020 Data (`Comb-14k` dataset)

The Technique Classification (TC) subtask from the SemEval 2020 Task 11 (Da San Martino et al.,

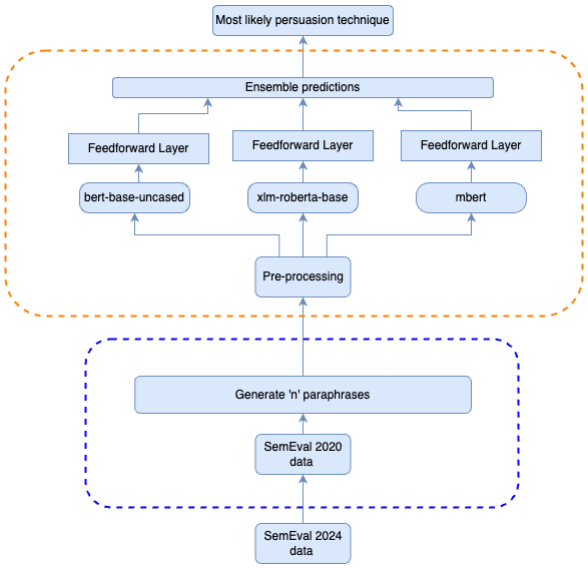

Figure 2: Schematic overview of our classification pipeline for the detection of persuasion techniques in memes.

2020) provided a dataset with ≈7k instances annotated with the same guidelines as this year's. In contrast to the 2020 task, this year's challenge featured a revised set of techniques compared to the 2020 inventory. In the 2020 TC dataset, a few techniques were merged into a single category due to lack of data, resulting in a list of 14 techniques. In the current year, an expanded inventory of 20 techniques was employed. To ensure consistency between the two sets, we preprocessed the 2020 TC dataset by splitting techniques that had previously been merged. For example, we singled out *Bandwagon* and *Reductio ad Hitlerum*, which had been merged into a single technique in the SemEval 2020 TC dataset.

We combined both datasets and fine-tuned models on this combined dataset. For easy reference in the rest of the paper, we call the combined dataset `Comb-14k`. Figure 1 (orange + blue) shows the resulting distribution of the persuasion techniques in this dataset.

3.1.2 Paraphrasing (`Para-28k`, `Para-52k` and `Para-54k` datasets)

Despite having almost doubled each class with the use of the 2020 TC dataset, some classes were still severely underrepresented; see Figure 1 (orange + blue). To address this, we augmented the dataset further by generating paraphrases for each instance. To generate paraphrases, we leveraged ChatGPT-3.5 turbo, setting the temperature to 0.7. This value aimed to introduce diversity in the paraphrases while maintaining relevance to the original instances.

For each instance in `Comb-14k`, we generated n paraphrases, then labeled these paraphrases with the same set of labels as the original instance. We experimented with n=1 and n=3. We call the resulting datasets `Para-28k` and `Para-52k`. The overall hierarchical F-score with the validation set given showed an increase when training with these datasets and $n = 3$ seemed to perform better than $n = 1$. A per-class analysis showed that not all classes benefited from the increase in support. For example, the persuasion technique *Bandwagon* increased its F1 from 0.17 to 0.29; whereas *Repetition* decreased its F1 from 0.56 to 0.31. We therefore identified the classes with improvement in F-score greater than 0.03 when using the `Para-52k` dataset compared to the `Comb-14k` dataset. These 8 techniques along with their increase in F-scores are shown in Table 1. This set of 8 techniques, referred to as benefited classes $\mathbf{B}$, formed the basis for our subsequent strategy. Since only these techniques seemed to benefit from the use of paraphrases, we only increased the number of paraphrases for these. Specifically, for all data instances d_i in `Comb-14k` labeled with techniques $\mathbf{T} = \{T_1, T_2, \ldots T_n\}$, for each $T_i \in \mathbf{B}$, we generate 10 paraphrases of d_i and label them with all techniques from $\mathbf{T} \cap \mathbf{B}$. This newly created dataset contained ≈54k instances, hence we call it `Para-54k`.

Figure 1 shows the distribution of instances for each technique in the `Para-54k` dataset (orange + blue + green), in comparison with the SemEval 2024 dataset and the `Comb-14k` dataset. As the figure shows, all datasets are severely imbalanced; something that we tried to address with the use of per-class custom thresholds (see Section 3.2).

3.2 Multi-label Classification

After creating the datasets, we preprocessed them using standard tokenization, then proceeded to fine-tune three distinct models: `bert-base-uncased`, `xlm-roberta-base`, and `bert-base-multilingual-uncased` in addition to an ensemble model, generated by averaging the predictions from all three models.

Additionally, we implemented thresholding in order to determine which techniques have a high enough score to be part of the output label set. We experimented with custom values for each of the techniques in order to address the data imbalance

Technique	Comb-14k		Para-52k		
	Support	F1	Support	F1	Δ F1
Bandwagon	169	0.17	676	0.29	0.12
Causal Oversimplification	449	0.00	1796	0.09	0.09
Appeal to fear/prejudice	631	0.26	2524	0.34	0.08
Doubt	843	0.08	3372	0.15	0.07
Appeal to authority	994	0.69	3976	0.74	0.05
Glittering generalities (Virtue)	488	0.38	1952	0.43	0.05
Slogans	796	0.42	3184	0.46	0.04
Whataboutism	366	0.32	1464	0.36	0.04

Table 1: Techniques that showed an improvement in F1 score when using n=3 paraphrases (i.e. Para-52k).

issue. We experimented with values ranging from 0.01 to 0.7 and picked the optimal values for each class based on the validation set (500 samples). These thresholds were applied to the scores obtained after passing the logits of each class through a sigmoid function. Table 2 shows the results of the validation with the optimal threshold for each class using the official scorer, which uses hierarchical metrics. As Table 2 shows, the best model with the validation set was the ensemble trained on the Para-52k dataset which reached an hierarchical F1 of 0.56. However, the ensemble model when trained on the Para-54k dataset, performed worse (hierarchical F1 of 0.54 with the validation set) than the ones that used lesser number of paraphrases (Para-28k and Para-52k). The ensemble, leveraging the collective insights of the three models, trained on the Para-52k emerged as the most effective in enhancing the overall system performance. Based on our results in the official leaderboard with the development set and validation results shown in Table 2, we chose to submit the ensemble model trained on the Para-52k dataset as it gave the best results with both the validation and the development set.

During the testing phase, the datasets in Bulgarian, North Macedonian, and Arabic were automatically translated to English for our model's zero-shot predictions. This was inspired by the approach of (Costa et al., 2023). The English test data was used as given.

4 Experimental Setup

4.1 Data Split and Augmentation

The training data provided in English initially comprised 7k samples. After combining it with 2020 TC dataset, the total increased to approximately 14k samples (Comb-14k). Subsequently, through paraphrase generation, the training dataset expanded to around 28k (Para-28k) when only 1 paraphrase per instance was used (n=1) and 52k (Para-52k), when n=3. Finally, the dataset with ten paraphrases for the benefited classes *B* reached approximately 54k samples (Para-54k). The original 500-sample validation set was used consistently for all our experiments. For the final submission, the ensemble model was trained on the union of (Para-52k) and the development set (1k samples), for a total of 53k samples.

4.2 System Pipeline and Training Details

The system pipeline code was implemented in PyTorch. The pre-trained models BERT [bert-base-uncased][2], XLM-RoBERTa [xlm-roberta-base][3], and mBERT [bert-base-multilingual-uncased][4] and their tokenizers were sourced from Hugging Face. Standard preprocessing, involving tokenization based on each model's tokenizer, was applied. Across all phases, models were trained for 10 epochs using the Adam optimizer with a learning rate of 2e-5. Batch sizes varied with BERT utilizing 128, and XLM-RoBERTa and mBERT using 64. A final feedforward layer with 20 logits (equal to the number of considered techniques) was added to each model. The Binary Cross Entropy with logits served as the loss function, with one-hot encoding applied to the true labels. For prediction, a sigmoid activation function was used on the logits, followed by thresholding. The ensemble model used an unweighted average of all predictions from the three individual models.

	Ensemble Model	0.54	0.55

Table 2: Hierarchical F1 scores of our models, when trained on different English-language datasets for both the validation and development sets.

Language	Baseline	Our Score	Best Score
English	0.36865	0.57827	0.75427
Bulgarian	0.28377	0.44917	0.56833
North Macedonian	0.30692	0.39471	0.51244
Arabic	0.35897	0.38070	0.47593

Table 3: Comparison of the final hierarchical F1 scores obtained by our classification system, the best corresponding classification system in the shared task and the baseline in each given language.

ChatGPT-3.5 turbo[5] API with a temperature set to 0.7 was used for paraphrase generation. During testing, external languages were translated into English using the deep-translator API[6].
Throughout all phases hierarchical metrics were employed for task evaluation using the official scorer. On the other hand, standard precision, recall, and F-score metrics were used to assess the per class performance.

5 Results

The official performance results of our system are shown in Table 3, along with the baseline score and the score obtained by the best performing system on each language. As Table 3 shows, although our ensemble model was not among the top models, it reached significantly better performance than the baseline in all languages except Arabic, where the improvement was not significant. Overall, we stood at 22nd out of 33 participants for English, 12th out of 20 for Bulgarian, 11th out of 20 for North Macedonian and 11th out of 17 for Arabic.

6 Conclusion

This paper described the methodology used in our participation to the Semeval 2024 Task 4 subtask 1, focusing on hierarchical multi-label detection of persuasion techniques in meme texts. We used an ensemble model with three fine-tuned language models and incorporated additional strategies such as data augmentation through paraphrasing and classification thresholds fine-tuning based on class-wise metrics. During testing, our system significantly outperformed the baseline in all languages except Arabic, where the increase in performance was not significant. Analysis shows that the data augmentation and threshold fine-tuning may have introduced noise and exacerbating dataset imbalance.

RDproj at SemEval-2024 Task 4: An Ensemble Learning Approach for Multilingual Detection of Persuasion Techniques in Memes

Yuhang Zhu
Uppsala University / Uppsala, Sweden
yuhang.zhu.2485@student.uu.se

Abstract

This paper introduces our bagging-based ensemble learning approach for the SemEval-2024 Task 4 Subtask 1, focusing on multilingual persuasion detection within meme texts. This task aims to identify persuasion techniques employed within meme texts, which is a hierarchical multilabel classification task. The given text may apply multiple techniques, and persuasion techniques have a hierarchical structure. However, only a few prior persuasion detection systems have utilized the hierarchical structure of persuasion techniques. In that case, we designed a multilingual bagging-based ensemble approach, incorporating a soft voting ensemble strategy to effectively exploit persuasion techniques' hierarchical structure. Our methodology achieved the second position in Bulgarian and North Macedonian, fifth in Arabic, and eleventh in English.

1 Introduction

Memes have gained immense popularity among the younger generation due to their entertaining nature. However, some memes can lead teenagers towards extreme ideas by employing persuasion techniques. Even well-educated people often need help to identify misleading memes. Thus, the development of a persuasion detection system holds significant value. This study aims to create a system to identify persuasion techniques within meme texts. This task is a multilabel and hierarchical classification task since memes may contain multiple persuasion techniques, and techniques have hierarchical structure (Dimitrov et al., 2024).

A description of the corpus provided by SemEval-2024 Task 4 (Dimitrov et al., 2024) reveals significant imbalances in the training data for the techniques. For instance, while there are 1990 instances for the "Smears" technique, only 258 instances pertain to "Whataboutism." Moreover, the training data for each technique is smaller compared with the entire corpus, leading to the imbalance between positive and negative instances for each technique. These observations lead us to formulate the following research questions: 1) How can we mitigate the data imbalance between techniques? 2) How can we ease the imbalance between positive and negative instances for each technique? 3) How can we effectively leverage the hierarchical structure of techniques? We devise a bagging-based ensemble learning system employing a soft voting strategy to solve these questions. We group techniques into ten subsets based on the amount of their training data and the hierarchical structure (Dimitrov et al., 2024), and construct a training set for each subset. Subsequently, we train classifiers (base learners), XLM-RoBerta$_{large}$[1] models with a classifier head, on these training sets. Finally, we compute the final distribution through a weighted average of the probability generated by classifiers, with a model of identical structure generating the weights in this step.

While our approach attained the second position in Bulgarian and North Macedonian, fifth in Arabic, and eleventh in English, the performance of our weight model did not exhibit significant improvement compared to our baseline. Moreover, the lower-resource techniques continue to suffer from imbalances between positive and negative instances. Our code is publicly available at https://github.com/Yuhang-Zhu-nlp/semeval2024_RDproj.

2 Background

2.1 Persuasion Detection

Previous research on persuasion detection has explored traditional classification techniques across a range of domains. Regarding data augmentation, Modzelewski et al. (2023) experimented with

[1] https://huggingface.co/FacebookAI/xlm-roberta-large

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 181–187

enhancing performance by expanding the training set using the DeepL API to translate data from source languages to target languages. Similarly, Falk et al. (2023) introduced a data augmentation method based on back-translation in the same year. Regarding text representation, Qachfar and Verma (2023) proposed a technique to generate language-agnostic features specific to this task, which were then concatenated with the CLS representation provided by XLM-RoBERTa to generate the final representation. Ensemble learning has also been explored in this domain. Purificato and Navigli (2023) developed a multilingual bagging-based ensemble learning system, combining five different BERT models using a soft voting strategy. Because of BERT's exceptional performance in sentence classification tasks, it has become a cornerstone in recent research, with almost all contemporary studies incorporating BERT into their methodologies (Costa et al., 2023; Ojo et al., 2023).

2.2 Ensemble Learning

The term ensemble learning is basically to improve the model's performance by combining different models (base learners) (Dong et al., 2020). Presently, ensemble learning strategies primarily include bagging, boosting, and stacking. Among these, bagging is training models on distinct datasets and combining them. One of the most renowned bagging-based ensemble learning algorithms is random forest (Cutler et al., 2012), which trains numerous decision trees on different data subsets and then combines these trees using a voting strategy. Regarding voting strategies, there are two main approaches: hard voting (Mohamed Kamr and Mohamed, 2022) and soft voting (Purificato and Navigli, 2023). Soft voting generates the final distribution by computing the weighted average of distributions from base learners, and has become a prevalent strategy in classification tasks (Xu et al., 2016; Kumari et al., 2021). Purificato and Navigli (2023) devised a bagging-based multilingual ensemble learning approach, employing five different BERT models with a soft voting strategy in this task. Their approach secured the first position in English during SemEval 2023, underscoring the effectiveness of bagging-based ensemble learning in this context. However, their approach determined model weights based on the normalized F1-micro score of diverse BERT models, ignoring the potential variability in model performance across different techniques.

2.3 Data

We use both the corpus offered by SemEval-2024 Task 4 Subtask 1 (Dimitrov et al., 2024) which contains English text of memes with 20 persuasion techniques and the corpus provided by SemEval-2023 Task 3 Subtask 3 (Piskorski et al., 2023) which includes news articles in six languages, English, German, French, Russian, Polish, and Italian, with 23 techniques.

3 System Overview

3.1 Data Preprocessing

In this task, we only focus on 20 techniques, but the corpus provided by SemEval-2023 Task 3 Subtask 3 contains 23 techniques. In that case, We have simply removed the three extra techniques from the label set of each data. The corpus provided by SemEval-2024 Task 4 Subtask 1 includes lots of meaningless symbols like "\n", we just simply remove them from the text. Moreover, we lowercase all data of both corpora.

3.2 Technique Grouping

To utilize the hierarchical structure of techniques, we categorize them into seven subsets based on their hierarchical structure (Dimitrov et al., 2024). For each subset, we assess whether data imbalance exists among the techniques. If imbalances exist, we create new subsets and copy the affected techniques or divide the subset into smaller subsets. For example, in the initial grouping, "Loaded Language", "Exaggeration/Minimisation", "Flag-waving", and "Appeal to fear/prejudice" are grouped in a subset. However, the training data for "Loaded Language" significantly outnumbers those for the other three techniques, so we separate "Loaded Language" into a new subset while removing it from the original subset. Additionally, if some techniques unavoidably suffer from data imbalances, we copy them to a new subset (supporting subset). Through this process, we ultimately establish ten distinct subsets, and the results of grouping are shown in Appendix.

3.3 Corpus Creating

For each technique subset, we first sample all data in the corpus provided by Semeval-2023 Task 3 Subtask 3 (Piskorski et al., 2023) (in the following section, we call it positive data). Then, we sample the data without techniques in the subset (in the following section, we call it negative data). Next,

we create the second corpus by doing the above step in the corpus offered by Semeval-2024 Task 4 Subtask 1 (Dimitrov et al., 2024).

3.4 Model Structure

We have 11 models in our approach, including 10 base learners and a weight model. All models have the same structure which is shown in Figure 1.

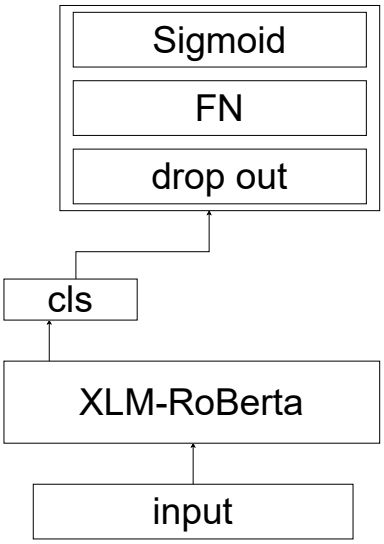

Figure 1: The structure of the base learners, and the weight model.

3.5 Training Strategy

Firstly, for each corpus sampled in the corpus provided by Semeval-2023 Task 3 Subtask 3 (Piskorski et al., 2023), we train a base learner on it (we call it pretrain in the following text). Then we fine-tune a base learner on each corpus sampled in the corpus offered by Semeval-2024 Task 4 Subtask 1 (Dimitrov et al., 2024). The task for base learners is to predict which persuasion techniques are applied in the given text. As for the weight model, we pretrain it on the original corpus provided by Semeval-2023 Task 3 Subtask 3 (Piskorski et al., 2023), and then fine-tune it on the corpus offered by Semeval-2024 Task 4 Subtask 1 (Dimitrov et al., 2024). The task of the weight model is to predict which technique subsets the persuasion techniques used in the given text belong to.

3.6 Prediction Pipeline

The prediction pipeline begins with preprocessing the text, which involves lowercasing and removing meaningless symbols. Subsequently, the text is sent to each base learner to obtain the technique distributions from each base learner. Similarly, the text is also sent to the weight model, and the output of the weight model is activated using softmax to generate the weight for soft voting. Finally, the final distribution is calculated using Equation (1).

$$D_{final} = \sum_{i=0}^{10} w_i D_i \tag{1}$$

where D_{final} is the final distribution, D_i is the distribution generated by the i^{th} base learner, and w_i is the weight generated by weight model for the i^{th} base learner.

4 Experimental Setup

We use binary cross-entropy (BCE) with weight as our loss function for each base learner. The equation is below:

$$\mathcal{L}(x_j, y_j) = \sum_{j=0}^{20} w_j (y_j log x_j - (1-y_j) log(1-x_j)) \tag{2}$$

where w_j is the weight for the j^{th} technique, y_j is the boolean value for the j^{th} technique, and x_j is the probability generated by the model for the j^{th} technique. We use BCE without weight for the weight model.

4.1 Training Setup

Each base learner has three hyperparameters: weights in the loss function, learning rate, and dropout rate. We set the learning rate to 2e-6 and the dropout rate to 0.2 for all base learners. The weights assigned to techniques belonging to the subset used to create the corpus on which the base learner is trained are set to 2, while all other techniques are assigned a weight of 1. Similarly, we use the same learning and dropout rates for the weight model as the base learner. During pretraining, we train each base learner for 60 epochs and the weight model for 50 epochs. During fine-tuning, we train each base learner for 20 epochs and the weight model for 10 epochs. The batch size is set to 16 for base learners and 8 for the weight model. we select 0.22 as our classification threshold.

4.2 Evaluation Metrics

Hierarchical-F1 (Kiritchenko et al., 2006) is used in this research. The benefit of the hierarchical-F1 is that it takes the hierarchical structure of techniques into account.

5 Results

5.1 Official Ranking

Table 1 shows our results in SemEval-2024 Task 4 Subtask 1. Although we get only the eleventh position in English, our results in three languages that are used to test zero-shot are competitive. We achieve the second position in both Bulgarian and North Macedonian, and the fifth position in Arabic.

5.2 Weight Model

We design a baseline model by removing the weight model, and set the weights for soft voting as $\frac{1}{10}$. In Table 2, we can find that our baseline and approach get almost the same score in English, Bulgarian, and North Macedonian. However, our baseline gets a relatively higher score in Arabic, which means that our weight model does not work well.

5.3 Error Analysis

In this section, we are aiming to find out the behaviour of our model facing different inputs by analyzing the samples which make our model give a wrong prediction in the dev set provided by SemEval-2024 Task 4 Subtask 1.

> **Text**: IF YOU SAY WE'RE IN THE MIDDLE OF A DEADLY PANDEMIC BUT YOU STILL SUPPORT OPEN BORDERS\\n\\nYOU'RE EITHER A LIAR OR A COMPLETE MORON
>
> ---
>
> **Gold labels**: Loaded Language, Name calling/Labeling, Black-and-white Fallacy/Dictatorship, Smears
>
> ---
>
> **Our prediction**: Appeal to fear/prejudice, Black-and-white Fallacy/Dictatorship, Loaded Language, Name calling/Labeling, Smears
>
> ---
>
> **Weight vector**: 0.0748, 0.0748, 0.0748, 0.1978, 0.2029, 0.0749, 0.0752, 0.0748, 0.0750, 0.0748

In this sample, we correctly identify all gold labels but detect "Appeal to fear/prejudice" by mistake. Analysis of the weight vector reveals that our weight model assigns a relatively higher weight of 0.2029 to the base learner trained on the corpora sampled for the subset (we call the base learner trained on the subset in the following text) containing "Appeal to fear/prejudice". However, it does not assign higher weights to subsets containing other techniques in the gold labels, except for "Loaded Language". To comprehend why our model can still make correct predictions despite the weight model's failure, we examine the output of several base learners. We observe that almost all base learners assign high probabilities to "Loaded Language", "Name calling/Labeling", and "Smears", indicating that each base learner can support techniques not included in the subsets on which they are trained. This suggests that each base learner can support the target techniques that are not included in the subsets they trained on.

> **Text**: Name: Ted Bundy\\nVictims: 30\\n\\nName: Al Gore\\nVictims: ???
>

>
> **Weight vector**: 0.1000, 0.1000, 0.1000, 0.1000, 0.1000, 0.1000, 0.1000, 0.1000, 0.1000, 0.1000

In this sample, we can find that our weight model does not work and give every subset a same weight. "Reductio ad hitlerum" is included in three technique subsets, and only the base learner trained on the supporting subset gives a high probability for this technique. However, other base learners give a very low probability, which shows our idea to create more subsets to support techniques suffering from data imbalance is working. The reasons for why we cannot distinguish "Reductio ad hitlerum" are 1) weight model cannot find which subsets the final prediction should be in, 2) positive and negative instances for "Reductio ad hitlerum" are too imbalanced, and our model tends to give a low probability.

language	rank/nt	F1	T1F1
English	11/34	0.64288	0.75247
Bulgarian*	2/20	0.54089	0.56833
North Macedonian*	2/20	0.49869	0.51244
Arabic*	5/17	0.41129	0.47593

Table 1: The ranking of our approach in the official ranking of SemEval-2024 Task 4 Subtask 1. Languages with star are to test zero-shot. nt is the number of teams. F1 is the hierarchical-F1 score. T1F1 is the hierarchical-F1 score of the top-1 approach.

language	Our Model	Baseline
English	0.64288	0.64194
Bulgarian*	0.54089	0.54133
North Macedonian*	0.49869	0.49894
Arabic*	0.41129	0.41454

Table 2: The hierarchical-F1 score of our approach and the baseline on the test set.

0.0922, 0.0923, 0.0922, 0.0922, 0.0922, 0.0922, 0.0922

The weight model gives a higher weight for the first two subsets, which is correct because both subsets contain "Doubt". Almost all base learners give a high probability for "Doubt", which provide another evidence that base learners trained on other subsets can support gold labels. However, some base learners also give high probabilities for other two techniques in our prediction, resulting in wrong prediction. We should find a way to expand the gap between the weight of base learners trained on the subsets that include gold labels and on other subsets.

We can find some common elements in all samples. For example, "Loaded Language" and "Name calling/Labeling" are always predicted by mistake. A possible reason for this is that 0.22 is a reasonable threshold for some techniques but too small for some techniques which have rich training instances. Moreover, the accuracy of the weight model is not high enough.

6 Conclusion

In this study we build a persuasion detection system to distinguish which techniques are used in the given text of memes. Our system consists of ten base learners trained on different technique subsets and a weight model to generate the weight for soft voting. In the official ranking of SemEval-2024 Task 4 Subtask 1, we get competitive results in the zero-shot setting. However, our weight model does not work very well, and does not show a significant improvement compared with our baseline. The problems may be 1) the accuracy of the weight model is not high enough, 2) the gap between the weight of base learners trained on target subsets and other base learners is not big enough. Our idea to create a new technique subset to support techniques suffering from data imbalance seems feasible but the data imbalance between positive and negative instances of a technique is still a problem. The above discussion suggests the ideas to improve our approach. Firstly, we can improve the accuracy of the weight model by applying some new training techniques because our training method is very simple. Secondly, we need a more sophisticated technique grouping strategy which considers imbalance of positive and negative instances of a technique better.

Acknowledgements

Abstract

Semantic Text Relatedness (STR), a measure of meaning similarity between text elements, has become a key focus in the field of Natural Language Processing (NLP). We describe SemEval-2024 task 1 on Semantic Textual Relatedness featuring three tracks: supervised learning, unsupervised learning and cross-lingual learning across African and Asian languages including Afrikaans, Algerian Arabic, Amharic, Hausa, Hindi, Indonesian, Kinyarwanda, Marathi, Moroccan Arabic, Modern Standard Arabic, Punjabi, Spanish, and Telugu. Our goal is to analyse the semantic representation of sentences textual relatedness trained on mBert, all-MiniLM-L6-v2 and Bert-Based-uncased. The effectiveness of these models is evaluated using the Spearman Correlation metric, which assesses the strength of the relationship between paired data. The finding reveals the viability of transformer models in multilingual STR tasks.

1 Introduction

The rapid increase in digital information has presented a critical challenge for researchers. The web hosts around 50 million pages of text, which is beyond the capacity of human interpretation alone. To interpret this extensive text data effectively, it is essential to comprehend the meanings of various words (Jain et al., 2020). Semantic Text Relatedness (STR) is a semantic analysis of the relationship between two pieces of text based on their meanings. STR of two language units has long been considered fundamental to understanding meaning (Miller and Charles, 1991; Lastra-Díaz and García-Serrano, 2015), It's a metric used to measure the similarity in meaning between two terms or documents. It is a subset of computational linguistics and one of the fundamental concepts of Natural Language Processing (NLP). STR can be measured using datasets designed by experts, which are made up of word pairs that are known to be related. It can be used in identifying a paraphrase or duplicate, as well as search engines to give users relevant and personalized results.

When two sentences have a paraphrase or entailment relation, they are considered to be semantically similar and When evaluating the semantic relatedness between them, humans typically focus on identifying shared meanings. In the case of the sentence pairs below, most English speakers would agree that the sentences in the first pair are more closely related in meaning than those in the second pair, whether they are from the same topic, express the same view or originate from the same time period etc.(Abdalla et al., 2023).

Pair 1: **a.** *There was a lemon tree next to the house.*
b. *The boy enjoyed reading under the lemon tree.*

Pair 2: **a.** *There was a lemon tree next to the house.*
b. *The boy was an excellent football player.*

Previous NLP research has mainly dealt with semantic relatedness primarily in English language. However, in this task, we address a variety of languages, including Afrikaans, Algerian Arabic, Amharic, Hausa, Hindi, Indonesian, Kinyarwanda, Marathi, Moroccan Arabic, Modern Standard Arabic, Punjabi, Spanish, and Telugu. The task featured the following tracks: Track A which is a supervised learning, track B is an unsupervised learning and Track C is a cross-lingual learning.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 188–192

2 Related Works

Sentences are considered semantically related when they share commonalities in meaning, such as paraphrasal or entailment relations. A study by (Abdalla et al., 2023) developed a Semantic Textual Relatedness dataset (STR-2022) to manually annotate English sentence pairs and explore the factors that contribute to the semantic relatedness of sentences. The dataset has been used to study the degree of semantic relatedness and the reliability of human intuition in determining the relatedness of sentence pairs while (Hasan et al., 2020) assessed the methods for semantic relatedness between words based on knowledge sources. These methods exploit features from both structural and statistical approaches, emphasizing on semantic representation, measures of semantic similarity, and knowledge-based text mining.
(Lastra-Díaz and García-Serrano, 2015) proposed Explicit Semantic Analysis (ESA), a recently introduced approach that signifies the meaning of texts by computing the semantic relevance of natural language texts. This approach assumes the need for substantial amounts of common sense and domain-specific knowledge, utilizing machine learning techniques to explicitly depict the meaning of any text. This is achieved by creating a weighted vector based on concepts from Wikipedia. ESA undergoes continuous development, ensuring a consistent expansion of its breadth and depth over time.

3 Task Description

STR Shared Task 1 (Ousidhoum et al., 2024b) consists of predicting the semantic relatedness of sentence pairs. Sentence pairs will be rank based on their closeness in meaning in 14 different languages. All sentence pairs will have manually determined relatedness scores between 0 (completely unrelated) and 1 (maximally related). Participants are provided with a gold label scores with a comparative annotation approach that led to a high reliability of the final relatedness rankings. The shared task consists of three tracks: supervised learning, unsupervised learning and cross-lingual learning. In this paper, we concentrate on all the three tracks.

3.1 Track A: Supervised

This track relies on labelled input and output training data. We used the labeled training datasets for 9 languages provided for the shared task which include: Algerian Arabic, Amharic, English, Hausa, Kinyarwanda, Marathi,Moroccan Arabic, Spanish and Telgu.

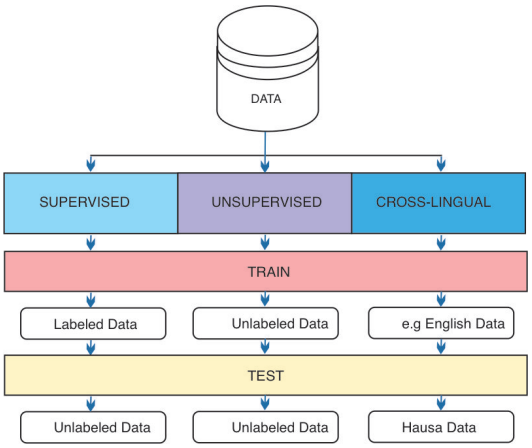

Figure 1: **Task Overview**

3.2 Track B: Unsupervised

Unsupervised learning analyzes and cluster unlabeled datasets, it is typically used when the goal is to identify patterns and relationships in data. We make this analysis using 12 languages: Afrikaans, Algerian Arabic, Amharic, English, Hausa, Hindi,Indonesian, Kinyarwanda, Modern Standard Arabic, Moroccan Arabic, Punjabi and Spanish.

3.3 Track C: Cross-lingual

Cross-lingual learning involves transferring models from one language to another, typically to improve performance. For this track we make use of 12 languages: Afrikaans, Algerian Arabic, Amharic, English, Hausa, Hindi,Indonesian, Kinyarwanda, Modern Standard Arabic, Moroccan Arabic, Punjabi and Spanish.

4 Experiment and Evaluation

This section describes the system overview which comprises the dataset description, model description and evaluation metric.

4.1 Dataset Description

The dataset consists of an instance of a sentence pair of both the training, development and test sets. Each instance is annotated with a gold label score that represents the degree of semantic text relatedness between two sentences (Ousidhoum et al., 2024a). The gold label scores are determine by manual annotation and range from 0 (not related

at all) to 1 (very related at all). A comparative annotation approach is used to avoid biases of the traditional rating scales and can result to a high reliability of final relatedness rankings. The dataset used in this shared task are from the following languages: Afrikaans, Algerian Arabic, Amharic, English, Hausa, Hindi, Indonesian, Kinyarwanda, Marathi, Morrocan Arabic, Modern Standard Arabic, Punjabi, Spanish, and Telugu.

4.2 Models Description

We experiment with multiple pre-trained models before deciding to go with the selected models based on the tracks. However, due to time constraint and resources, we reported for the competitive models across various languages based on the task specification.

4.2.1 mBERT

We used mBERT in a supervised aapproach, mBert is a multilingual derivative of BERT and trained on a diverse set of 104 languages. The pre-training process for mBERT involves masked language modeling (MLM) and the next-sentence prediction task (Libovickỳ et al., 2019). To tailor the model for our specific task, we fine-tune the mBERT-base-cased model, which boasts 172 million parameters. A 70-30 train-test split is executed with a learning rate of 1e-5 on Adam optimizer.

4.2.2 all-MiniLM-L6-v2

The all-MiniLM-L6-v2 model was used in an unsupervised approach in this task, it is a lightweight transformer-based model for semantic similarity comparison with optimized model size and faster inference (Wang et al., 2020). It has 66 Million Parameters compressed in a Student-Mimicking-Teacher network relationship. Using self attention distribution, we utilized the Teacher's last layer to guide the training of the student distillation in an unsupervised manner and generated effective and flexible results for the 12 languages used.

4.2.3 BERT-BASED-UNCASED

The Bert-Based-Uncased model was used in a cross-lingual approach in this task. It is a pre-trained autoencoding language model trained on vast English Wikipedia and BookCorpus with a sequence length of 512. The model is based on the architecture presented in (Devlin et al., 2018). As the track description, some of the languages were initially trained on different language before applying task on new language. Bert-Based-Uncased use WordPiece tokenizer, it has 110 parameters 12-layer, 768-hidden, 12- attention heads.

Task	Model	Language	Sp. Corr.
Track A: Supervised	mBERT	Algerian Arabic	0.388
		Amharic	0.269
		English	0.762
		Hausa	0.580
		Kinyarwanda	0.527
		Marathi	0.811
		Moroccan Arabic	0.696
		Spanish	0.696
		Telugu	0.791
Track B: Unsupervised	all-MiniLM-L6-v2	Afrikaans	0.468
		Algerian Arabic	0.398
		Amharic	0.098
		English	0.825
		Hausa	0.273
		Hindi	0.465
		Indonesian	0.384
		Kinyarwanda	0.131
		Modern Standard Arabic	0.200
		Moroccan Arabic	0.496
		Punjabi	0.011
		Spanish	0.603
Track C: Cross-Lingual	BERT-BASED-UNCASED	Afrikaans	0.710
		Algerian Arabic	0.780
		Amharic	0.660
		English	0.780
		Hausa	0.630
		Hindi	0.740
		Indonesian	0.790
		Kinyarwanda	0.750
		Modern Standard Arabic	0.660
		Moroccan Arabic	0.670
		Punjabi	0.730
		Spanish	0.810

Table 1: Results of various tasks.

4.3 Spearman Correlation

The Spearman Correlation is a non parametric and normality for monotonic relationship between variables (Ali Abd Al-Hameed, 2022). It measures the strength of relationship between paired data. It is similar to Pearson's Product Moment Correlation Coefficient (De Winter et al., 2016), or Pearson's r. It indicates magnitude and direction of the association between two variables that are on interval

or ratio scale. For this task, we used Spearman Correlation to measure the similarity between two sentences.

5 Results and Discussion

This section presents the results of the Shared task Tracks. Table 1 displays the Spearman correlation scores for the evaluation of 14 low-resource languages for semantic relatedness. The SemEval-2024 task on STR provided an opportunity to explore the effectiveness of transformer models. The models capture semantic relatedness across multiple languages. In This section, the analyses and interpretations of the results obtained from the given tasks are Task A (supervised learning), Task B (unsupervised learning) and Task C (cross-lingual).

In supervised learning track A, the multilingual BERT (mBERT) model was used. The model demonstrated different levels of performance across the languages. Notably, mBERT exhibited strong correlation scores in languages such as English with 0.76, Marathi with 0.81, and Telugu with 0.79 correlation. This indicates the model's ability to generalize well across linguistic contexts in semantic relatedness tasks. These findings suggest that mBERT can effectively capture semantic relatedness, even in low-resource languages, highlighting its robustness and cross-lingual generalization capabilities. However, challenges were observed in languages with complex morphological structures, underscoring the need for further research to address such linguistic nuances.

Conversely, the unsupervised learning track B featured the All-MiniLM-L6-v2 model, which achieved promising results in certain languages, particularly English with 0.82, Spanish with 0.60, and Moroccan Arabic with 0.5 Spearman correlation value. Despite its effectiveness, the model faced difficulties in languages such as Punjabi and Amharic, where semantic relatedness was harder to capture without labelled data. These challenges emphasize the importance of developing techniques to improve unsupervised learning models' performance, especially in low-resource language settings.

Similarly, track C (cross-lingual) which were entirely trained with BERT-BASED-UNCASED performed promisingly despite training and predicting on different language pairs. The Spearman correlation for Spanish achieved 0.81 and was trained on English, while Hausa achieved the lowest with 0.63 despite being trained on Kinyarwanda training dataset. This performance especially in Semantic Textual Relationship shows that cross-lingual hold a prospective future for generalization of NLP tasks.

However, the findings highlight the effectiveness of transformer models, in capturing semantic relatedness across diverse languages. The choice of evaluation metrics, such as Spearman correlation, proved instrumental in assessing the models' performance and understanding their ability to capture the ordinal relationship between predicted and true semantic relatedness scores. Furthermore, the results contribute valuable insights into advancing the understanding and application of semantic textual relatedness in multilingual NLP tasks, paving the way for future research in this domain.

6 Conclusion and Future Works

The study on Semantic Text Relatedness (STR) across multiple languages has demonstrated the effectiveness of transformer models in capturing semantic relatedness. The multilingual BERT (mBERT) model showed strong correlation scores in languages such as English, Marathi, and Telugu, indicating its ability to generalize well across linguistic contexts. The All-MiniLM-L6-v2 model achieved promising results in English, Spanish, and Moroccan Arabic, while facing challenges in languages like Punjabi and Amharic. The cross-lingual track, using BERT-BASED-UNCASED, also performed well, especially in Spanish, trained on English data. These findings underscore the potential of transformer models in NLP tasks and the importance of appropriate evaluation metrics like Spearman Correlation. The study contributes valuable insights into advancing semantic textual relatedness in multilingual NLP, highlighting areas for future research and development.

Future work should focus on exploring advanced transformer Large Language Models (LLMs) like GPT-3 and T5 to improve performance across diverse languages, including low-resource ones. Expanding language coverage, incorporating contextual and cultural information, and fine-tuning with language-specific data will enhance model accuracy. Cross-lingual transfer learning techniques can be investigated to adapt high-resource language models to low-resource settings. Hybrid approaches combining different learning methods may offer improved results, while new evaluation

metrics could better capture semantic nuances. Additionally, exploring multimodal STR and applying research findings to real-world applications will increase the practical impact of STR systems.

Abstract

This paper summarizes Team SCaLAR's work on SemEval-2024 Task 5: Legal Argument Reasoning in Civil Procedure. To address this Binary Classification task, which was daunting due to the complexity of the Legal Texts involved, we propose a simple yet novel similarity and distance-based unsupervised approach to generate labels. Further, we explore the Multi-level fusion of Legal-Bert embeddings using ensemble features, including CNN, GRU and LSTM. To address the lengthy nature of Legal explanation in the dataset, we introduce T5-based segment-wise summarization, which successfully retained crucial information, enhancing the model's performance. Our unsupervised system witnessed a 20-point increase in macro F1-score on the development set and a 10-point increase on the test set, which is promising given its uncomplicated architecture.

1 Introduction

The Domain of Law demands sheer expertise and experience for a human to master, but it takes much more to teach a machine the same. Legal NLP (Zhong et al., 2020) is advancing at a rapid pace, and the advent of Transformers (Vaswani et al., 2017) has widened the prospects of research in this area. However, the intricate nature of Legal Texts and the underlying complex relationships between entities make it difficult even for state-of-the-art Language models like BERT (Devlin et al., 2019) to capture the details effectively. To advance our understanding of the reasoning ability of LLMs in the legal domain (Bongard et al., 2022), task 5 of SemEval-2024 was proposed (Held and Habernal, 2024). The objective of this task is to discern the accurate responses to legal inquiries in U.S. Civil Procedure, as posited by the organizers. The questions and answers adhere to a Multiple-choice question-answering model, with accompanying explanations provided to facilitate comprehension of the legal concepts associated with each question. We have also released the code on GitHub [1]

We delve into the foundational paradigms of machine learning, specifically focusing on Supervised and Unsupervised Learning, to introduce innovative approaches and present a comprehensive comparative analysis. The explanation part of our dataset undergoes a two-level segment-wise summarization generated by T5 (Roberts et al., 2019), which is consistently utilized throughout our investigation. Within the framework of the supervised setup, we leverage a multi-level CNN fusion approach (Usama et al., 2019), integrating LSTM and GRU architectures. This amalgamation facilitates the extraction of ensemble feature representations from questions, answers, and summaries. Additionally, a one-dimensional CNN model (Jacovi et al., 2018), is trained. We employ a manual grid search technique to determine the optimal threshold that maximizes the macro F1 score, contributing to the refinement of our model.

In the unsupervised setup, we delve into the acquisition of diverse word representations such as word2vec and Glove. The assessment involves computing the similarity between question-answer pairs and answer-summary pairs, employing combinations like Glove-cosine, transformer embedding-cosine, transformer embedding-euclidean and word2vec-cosine. Notably, the best-performing supervised model achieved a macro F1 score of 66 % on the development set and 49.6 % on the test set. In contrast, the unsupervised approach yielded scores of 62 % (development) and 52.3 % (test). This outcome highlights a nuanced challenge related to generalization on the test set, prompting further exploration into the intricacies of model adaptability and robustness.

2 Background

The dataset provided by the organizers comprises three sets: Train Set, Dev Set, and Test Set, containing 666, 84, and 98 data points, respectively. Within the training and dev sets, each entry includes fields such as Question, Answer, Explanation, Label (with values of 0 or 1), Analysis, and Complete-Analysis providing a detailed examination. The test set, on the other hand, only consists of Question, Answer, and Explanation. The Label, when equal to 1, signifies a correct answer, while 0 denotes an incorrect one. The Explanation field provides context and background details for each question.

Field	Text
Explanation	The most basic point to understand about supplemental jurisdiction ..... on this basic purpose of Âr-ticle 1367(a).
Question	This and that. Garabedian, ... are treated fairly.
Answer	has constitutional authority ..... under Ârticle 1367(a).
Label	0
Analysis	Here, the Ârticle 1983 claim ..... Amend-ment claim.
Complete analysis	This is pretty straightfor-ward ..... D is the best choice here.

Table 1: Sample data-point from Train Set.

3 Related Works

Legal texts pose a unique challenge for pre-trained transformers (Vaswani et al., 2017) due to the inclusion of specialized terminology not commonly used in everyday language . As a result, leveraging pre-trained models like BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), and others becomes essential by training them on legal corpora to enhance their understanding of legal terminologies. Notable examples of transformers tailored for legal contexts include InLegalBERT (Paul et al., 2023), Legal-RoBERTa (Geng et al., 2021), and similar models.

Fine-tuning transformers, such as Legal-BERT (Chalkidis et al., 2020), on available legal data has been proposed as an effective strategy to improve performance on test sets, as suggested by Bongard et al. (2022) (Bongard et al., 2022). This approach capitalizes on domain-specific knowledge encoded during pre-training, enhancing the model's proficiency in handling legal language nuances.

In the domain of Legal Question Answering (LQA), recent works have extensively discussed significant advancements and challenges. The comprehensive review by Martinez-Gil provides insights into the key works in LQA, outlining challenges and proposing future research directions. Louis et al. (2023) (Louis et al., 2023) shed light on the limitations of existing Large Language Models (LLMs) in Legal Question Answering, emphasizing the need for interpretability.

4 System Overview

Transformers like T5, as demonstrated in the work of (Roberts et al., 2019), exhibit high efficiency in producing summaries for lengthy paragraphs. In this study, T5 was employed to generate segment-level summaries on explanation column using a two-step approach. The initial summary was created from the original text, with a segment length of 1000 tokens. These segment-wise summaries were then concatenated with spaces in between to form the first summary. Subsequently, the second summary was generated from the first summary, employing a segment length of 300 tokens, and similarly concatenated to provide a comprehensive summary of the input text. These summaries were used for further applications in place of explanation. Segment wise summary approach can be visualized as follows:

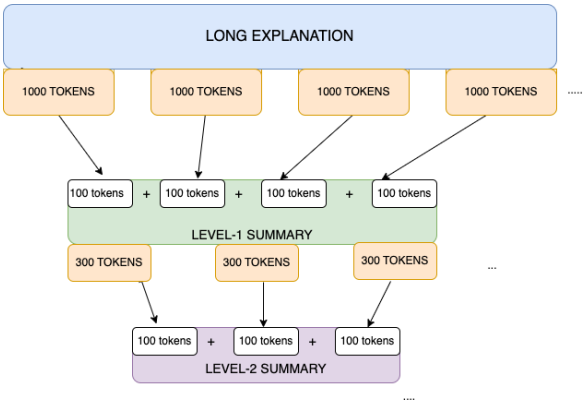

Figure 1: Segment wise summary

4.1 Supervised Models

4.1.1 Multi-Level Approach

Following the generation of summaries, we employed the Legal-Bert transformer to extract embeddings from the question, answer, and summary columns. Each Legal-Bert output consists of a 768-dimensional vector, resulting in tensors of shape (number of data points, 768) for each dataset. Subsequently, we executed the following steps:

1.The tensor underwent a series of transformations through three consecutive 1-dimensional CNN layers, with ReLU activation functions (Nair and Hinton, 2010), and Adaptive max-pooling applied at each step. At each pooling layer, the output was reduced to 100 dimensions. The kernel size and padding were linearly increased, as depicted in the Figure 2.

2.The outputs from the first and second pooling layers were concatenated, yielding a first-level concatenated feature embedding of 200 dimensions.

3.This first-level output was then merged with the output from the third pooling layer to obtain a second-level concatenated embedding with 300 features.

4. Concurrently, the Legal-Bert embeddings were fed into Bi-GRU (Chung et al., 2014) and Bi-LSTM (Hochreiter and Schmidhuber, 1997) models, resulting in 100 features from each. These features were concatenated.

5. The final multi-level feature representation was achieved by concatenating the second-level features with those from the GRU-LSTM models, resulting in a 500-dimensional vector. This process was applied to the question, answer, and summary, culminating in an exhaustive 1500-dimensional representation of the training data.

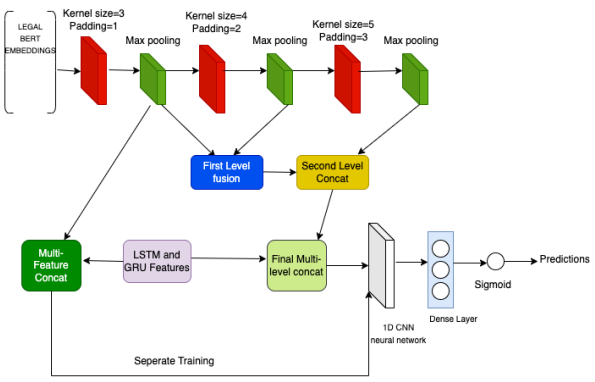

Figure 2: Multi Level fusion

4.1.2 Multi-Feature Approach

In this approach, the output of the first pooling layer was directly concatenated with the GRU-LSTM features, resulting in 300 features per entity, and hence, a 900-dimensional representation of the training data.

Training and custom sigmoid layer: To conduct a comparative analysis, we trained separate models using both multi-level and multi-feature representations. In each case, we employed a 1-dimensional CNN architecture implemented in TensorFlow, featuring a kernel size of 3 and 32 filters. Following max pooling, the resulting output was flattened and fed into a dense layer comprising 128 neurons. Finally, to enhance the variability of the probability distribution in the predictions, we introduced a custom Lambda layer. This layer subtracts the mean of the input tensor from each element and subsequently applies the sigmoid activation function.

$$\mathrm{f}(x) = y = \mathrm{sigmoid}(x - \mu) \qquad (1)$$

where μ is the mean of x

Grid search and predictions: Following the generation of probability vectors for the development set, we utilized manual grid search to determine the optimal threshold for classifying correct answers, aiming to maximize the macro-F1 score. Subsequently, the threshold associated with the highest F1 score on the development set was applied to make predictions on the test set

4.2 Unsupervised Models

4.2.1 Word2Vec-Cosine system

Word2Vec embeddings, as described in (Mikolov et al., 2013), were extracted for the question, answer, and summary columns. A window size of 7 and a vector size of 5 were utilized for each word. Cosine similarities were computed between question-answer pairs and answer-summary pairs. The prediction was based on the mean of these similarities.

During evaluation, it was observed that in cases where the difference between the highest and second-highest similarity scores for a question was minimal, the answer with the second-highest similarity often turned out to be the correct answer. Consequently, a refinement was implemented: if the disparity between the highest and second-highest similarity scores was small, the answer with the second-highest similarity was labeled as

1, while the remaining answers were labeled as 0. This adjustment yielded improved results in such scenarios. A threshold of 0.0005 was used in this case after optimization on train and dev set.

Algorithm 1: Word2Vec Similarity-based Labeling

```
Data: Word2Vec embeddings for question,
      answer, and summary columns
Result: Labels for answers based on
        similarity scores
for each question do
    max_id= highest similarity score;
    second_max_id = second-highest
     similarity score;
    if |similarity[max_id] −
     similarity[second_max_id]| ≤
     0.0005 then
        Label[second_max_id] = 1;
        Label the remaining answers as 0;
    end
    else
        Label[max_id] = 1;
        Label the remaining answers as 0;
    end
end
```

4.2.2 GloVE-Cosine system

In contrast to the Word2Vec-Cosine approach, the methodology now incorporates GloVE embeddings as opposed to Word2Vec embeddings, leveraging the GloVE model proposed by Pennington et al. in 2014 (Pennington et al., 2014). Despite this shift, the overarching algorithm for label assignment remains unaltered, ensuring continuity and comparability with the Word2Vec-Cosine approach discussed in the preceding section.

4.2.3 Transformer embeddings-Cosine system and Transformer embeddings-Euclidean system

We utilized the Deberta model (He et al., 2021) trained on legal texts, specifically "LambdaX-AI/legal-deberta-v1," accessible on Hugging Face (Wolf et al., 2020). This model provided embeddings of questions, answers, and summaries, each represented by vectors of size 1536. We employed both cosine similarity and Euclidean distance metrics for label assignment.

For cosine similarity, the algorithm remained straightforward: answers with higher cosine similarity scores were assigned labels accordingly.

However, in the case of Euclidean distance, a slightly different approach was employed. The answer with the minimum distance was initially assigned a label of 1. Subsequently, if the difference between the minimum distance and the second minimum distance was less than a predefined threshold which is 0.8 in this case, the answer associated with the second minimum distance was labeled 1 instead, replacing the initial assignment.

5 Experimental Setup

We utilized Google Colab for training and testing our models, taking advantage of the T4 GPU provided by the platform.

5.1 Supervised Models

The Multi-feature concatenation method involved the integration of 900 features, while the Multi-level approach incorporated 1500 features. Both methodologies underwent training for 15 epochs with a batch size of 32. The optimization algorithm chosen was "Adam" (Kingma and Ba, 2017), employing a learning rate set to 0.001.

5.2 Unsupervised Models

Word2Vec and GloVe embeddings were both generated with an embedding size of 5. However, there were differences in the window length used during training: for Word2Vec embeddings, a window length of 7 was utilized, while GloVe embeddings were trained with a window length of 10. In the case of GloVe, the training process spanned 30 epochs, employing a learning rate of 0.05 to optimize the model parameters. These values of hyperparameters were arrived after experimentation with several other values.

6 Results

The performance metrics of our models on the test set and development set are presented in Table 2, where "Acc" represents accuracy and "F1" denotes the macro F1 score. Notably, our model demonstrated strong performance on the development set. However, it is worth mentioning that the performance on the test set was comparatively lower. It is important to highlight that our top-performing model utilizes an unsupervised approach leveraging Word2Vec embeddings and cosine similarity.

Despite the varying performance, most of our models consistently outperformed the baseline.

Model Performance on Dev and Test set				
Model	Dev Set		Test set	
	Acc	F1	Acc	F1
Baseline	0.798	0.444	**0.7449**	0.4269
Multi-level approach	0.74	0.65	0.4898	0.4102
Multi-Feature approach	**0.81**	**0.66**	0.6224	0.4966
Word2vec-cosine	0.71	0.62	0.6429	**0.5238**
Word2vec-cosine without replacement	0.62	0.56	0.6020	0.5072
GloVE-cosine	0.64	0.56	0.6020	0.4694
Transformer-cosine	0.60	0.46	0.5612	0.4150
Transformer-euclidean	0.60	0.46	0.5816	0.4421
Transformer-manhattan	0.62	0.49	0.5612	0.4149

Table 2: Performance comparison of all our models

Analysis from Table 2 reveals a notable enhancement in model performance with the replacement of the second-best answer. The subsequent comparison, illustrated in Tables 3 and 4, highlights the impact of this replacement on the Wav2Vec-cosine model's results on both the training and development sets, considering the influence of two distinct similarity scores. Specifically, 'Q' signifies instances where the Question-Answer similarity surpasses the Summary-Answer similarity, while 'S' denotes the reverse scenario. The predictions of models in italics were submitted in Post-evaluation period.

Observing Tables 3 and 4, it becomes evident that the number of accurate predictions substantially increases in the development set, relative to its total size. In the Codalab leader-board we ranked 16 out of 21 teams, and in the overall laeder-board we ranked 15 out 21 teams.

7 Conclusion and Future scope

The dataset presents challenges for models to grasp the intricate legal context, resulting in subpar performance of regular supervised models. Unsupervised models heavily rely on embeddings, but available transformers inadequately capture the dataset's nuances. These models operate under the assumption of at least one correct answer per question; however, instances where all answers were labeled as incorrect hindered unsupervised model performance.

Q	W	11
S	R	46
S	W	13

Table 4: Distribution of right (R) and wrong (W) predictions after replacement

Future endeavors entail amalgamating these models into a unified super model. This super model would aggregate predictions from various models to yield a singular final prediction, enhancing overall performance and addressing the limitations of individual approaches. An alternative strategy involves leveraging Siamese networks to learn similarity, addressing challenges encountered by unsupervised models when all answers for a particular question are labeled as incorrect (0). By employing Siamese networks, we believe that the model can effectively capture nuanced similarities

between question-answer pairs, and provide better predictions. Exploring other kind of summarizers and using other transformers for summarization such BART (Lewis et al., 2020) may also increase the overall performance of all the systems used in this paper. Data augmentation (Feng et al., 2021) can also be implemented to get better Word2Vec and GloVE embeddings.

Abstract

This study introduces a dedicated model aimed at solving the BRAINTEASER task 9 (Jiang et al., 2024), (Jiang et al., 2023), a novel challenge designed to assess models' lateral thinking capabilities through sentence and word puzzles. Our model demonstrates remarkable efficacy, securing Rank 1 in sentence puzzle solving during the test phase with an overall score of 0.98. Additionally, we explore the comparative performance of ChatGPT, specifically analyzing how variations in temperature settings affect its ability to engage in lateral thinking and problem-solving. Our findings indicate a notable performance disparity between the dedicated model and ChatGPT, underscoring the potential of specialized approaches in enhancing creative reasoning in AI.

1 Introduction

The BRAINTEASER task (Jiang et al., 2023) aims to challenge the lateral thinking abilities of models, setting it apart from traditional tasks focused on vertical logical reasoning. It introduces lateral thinking puzzles in the form of multiple-choice questions to test the models' ability to think creatively and challenge common sense associations. The goal is to identify the gap between human and model performances in creative thinking, highlighting the need for progress in AI's creative reasoning abilities. NLP (Natural Language Processing) transformer models have revolutionized text understanding and generation with their architecture capable of processing word sequences more efficiently. For multiple-choice questions, these models utilize their ability to understand context and language nuances to select the most appropriate answer from several options. Thanks to deep learning and attention mechanisms, they excel in various NLP tasks, significantly improving the accuracy and relevance of responses generated in complex contexts. The integration of NLP transformer models into the BRAINTEASER task aims to explore their ability to solve lateral thinking puzzles in the form of multiple-choice questions. This approach highlights the challenges posed by deep language understanding and the creativity required to surpass traditional logical reasoning. It emphasizes the importance of advancing in the development of models capable of navigating beyond common sense associations, encouraging innovation in the interpretation and generation of complex and nuanced responses. In our study, we will explore the ability of language models to handle this task, with the following main contributions of this paper :

- Development of a dedicated model for this task with a good result for the sentence puzzle task (Rank 1 in the test phase).
- A comparative analysis with ChatGPT: Specifically, the relationship of temperature with lateral thinking and performance.

2 Shared Task Description

The BRAINTEASER Shared Task 9 is a Question Answering (QA) task based on evaluating the capacity of language models to engage in lateral thinking and to solve puzzles that require unconventional thinking. BRAINTEASER comprises two distinct subtasks: Sentence Puzzle and Word Puzzle, both of which involve defying commonsense "defaults" but through different methodologies.

- Sentence Puzzle: Create sentence-based brain teasers where the challenge lies in interpreting sentence snippets in a way that goes against commonsense expectations.
- Word Puzzle: Design word-based brain teasers that require rethinking the default meanings of words, with a focus on the composition of letters in the target question.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 200–205

Both tasks include an adversarial subset, created by manually modifying the original brain teasers without changing their latent reasoning path. They construct adversarial versions of the original data in two ways:

- (SR) Semantic Reconstruction rephrases the original question without changing the correct answer and the distractors.
- (CR) Context Reconstruction keeps the original reasoning path but changes both the question and the answer to describe a new situational context

Distractors are generated by identifying the implicit and explicit premises of a puzzle and then manually overwriting these premises, ensuring they remain incorrect but challenging.

The BRAINTEASER paper reveals a significant gap between human performances and AI models, and underscores the need to enhance lateral reasoning in language models.

3 Related Work

The task of commonsense reasoning has long been a challenge for deep learning and has been the subject of research for several years, accompanied by various benchmarks such as (Nie et al., 2020), which introduces a new large-scale NLI benchmark dataset created through an adversarial process involving humans and models. This improves NLI models' performance on popular benchmarks and reveals their weaknesses, offering a dynamic framework for continuous improvement in natural language understanding. A study demonstrated a simple and unsupervised method for commonsense reasoning using language models trained on vast text corpora, significantly outperforming state-of-the-art methods on Pronoun Disambiguation Problems and the Winograd Schema Challenge without the need for annotated knowledge bases or manually engineered features (Trinh and Le, 2019).

Transformer models like BERT (Devlin et al., 2019), GPT (Brown et al., 2020), and their variants have revolutionized natural language understanding, including question answering (Qu et al., 2019). Their architecture captures semantic and contextual nuances (Ethayarajh, 2019) (Zhang et al., 2020), proving exceptionally effective in comprehending and responding to complex inquiries. By training on extensive text corpora, they develop a deep understanding, enabling them to identify the most plausible answers among multiple choices (Roy et al., 2023) (Ravi et al., 2023).

Large pretrained language models (PLMs) can achieve near-human performance on commonsense reasoning tasks by generating contrastive explanations that highlight the key attributes needed to justify correct answers. This approach not only improves performance on commonsense reasoning benchmarks but also produces explanations judged by humans as more relevant and understandable (Paranjape et al., 2021)

Recent studies reveal that ChatGPT has notable capabilities to effectively solve a variety of problems in several languages, including the task of answering questions. Moreover, its performance improves with each new version. ChatGPT excels in certain areas but also has its limitations in terms of consistency and complex reasoning tasks.(Tan et al., 2023).

4 Proposed Approach

4.1 Methodology

In our study, we have developed a model based on transformers for multiple-choice questions, where each option is combined with the question to form separate pairs. These pairs are then pre-processed as distinct inputs for the already pre-trained model. The preprocessing includes adding special tokens like [CLS] at the beginning and [SEP] to separate the question from the choice. Each pre-processed question-choice pair is passed through the transformer model, which encodes each pair using its bidirectional attention mechanism, allowing every word in the pair to capture the context of the entire sentence and the related choice. For each question-choice pair, the model generates a feature vector from the output associated with the [CLS] token, which serves as a summary of the information contained in the pair. This means that for a question with four answer choices, the model would be run four times (once for each question-choice pair). This process allows for the consideration of the full context of the question as well as that of each individual answer choice, which is crucial for understanding which choice best answers the question.

The feature vector for each question-choice pair is then passed through a dense (or fully connected) layer, which reduces the vector's dimensionality to a number corresponding to the number of classes or answer categories. After the dense layer, a softmax activation function is applied to convert the scores

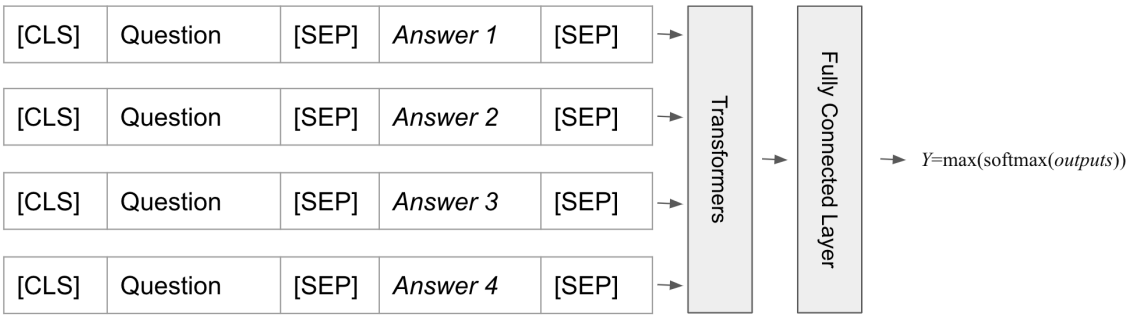

Figure 1: The overall architecture for predicting BRAINTEASER

Figure 2: The Ranking Leaderboard Displaying Our Position

into probabilities.

The softmax function is ideal for classification tasks because it transforms the scores into a set of probabilities that sum up to 1, making the scores directly interpretable as the probabilities that each choice is the correct answer. Figure 1 illustrates the prediction process described above.

The prediction formula can be expressed as follows in our model:

Each question-choice pair (Q, C_i) is preprocessed to form an input sequence X_i by concatenating the question Q with each choice C_i and adding special tokens:

$$X_i = [CLS] + Q + [SEP] + C_i + [SEP]$$

The transformer model processes each X_i separately to encode the pair, utilizing its bidirectional attention mechanism. The output for each token in X_i is obtained, but we are specifically interested in the output associated with the [CLS] token, $T_{[CLS],i}$, which captures the contextualized representation of the pair:

$$T_{[CLS],i} = TransformerModel(X_i)$$

The feature vector F_i is extracted from the transformer output associated with the [CLS] token for each question-choice pair:

$$F_i = ExtractFeatureVector(T_{[CLS],i})$$

Each feature vector F_i is passed through a dense layer to reduce its dimensionality to the number of classes N, resulting in a reduced feature vector R_i:

$$R_i = DenseLayer(F_i)$$

The softmax activation function is applied to R_i to convert the scores into probabilities P_i, indicating the likelihood that each choice is the correct answer:

$$P_i = Softmax(R_i) = \frac{e^{R_i}}{\sum_{j=1}^{N} e^{R_j}}$$

Where:

- Q represents the question.
- C_i represents the ith answer choice.
- X_i is the input sequence formed by concatenating Q and C_i with special tokens.
- $T_{[CLS],i}$ is the transformer output for the [CLS] token for the ith question-choice pair.
- F_i is the feature vector extracted from $T_{[CLS],i}$.
- R_i is the reduced feature vector after passing F_i through a dense layer.
- P_i represents the probabilities that each choice C_i is the correct answer, obtained after applying the softmax function to R_i.

4.2 Evaluation Method

The BRAINTEASER task proposes the following evaluation system, each system is evaluated based on the following two accuracy metrics:

Instance-based Accuracy: They consider each question (original/adversarial) as a separate instance. They report accuracy for the original and its adversaries.

Group-based Accuracy: Each question and its associated adversarial instances form a group, and a system will only receive a score of 1 when it correctly solves all questions in the group.

The final score corresponds to the average of all the scores.

4.3 Results

We trained our model using the pre-trained language model DeBERTa-v3-base (He et al., 2023) over 5 learning epochs, with a learning rate of 5e-5 and a batch size of 16. The results obtained are presented in official Leaderboard of the task in the evaluation phase 2.

Our model stands out for its good performance in sentence-type puzzles, ranking first with with an average accuracy score of **0.98** (leaderboard 2) . This means it excels particularly in thinking challenges where the puzzle, often contrary to common sense, is based on sentence excerpts. On the other hand, for word-based puzzles, which require finding a solution that goes against the usual meaning of words by focusing on the letter composition of the posed question, our model shows lower performance. It ranks 16th with a total score of **0.61** . This performance difference suggests that, although our model is very skilled at solving puzzles involving the understanding and manipulation of sentences, it could benefit from improvement in the area of word-based puzzles. This indicates an opportunity to deepen our research and development efforts on word-type puzzles to enhance the versatility and overall effectiveness of our model.

5 ChatGPT Analysis

5.1 Zero-shot Predictions

Given that we are currently in the era of ChatGPT, it's challenging to approach our study without including a comparison to evaluate the role of this task in relation to ChatGPT. We crafted a simple and explicit prompt with ChatGPT turbo 3.5 on February 5, 2024, assessing ChatGPT's logical reasoning ability using various prompts in a qualitative manner. However, we faced challenges in determining the optimal prompt, as the same input does not always lead to the desired output. Hallucinations related to conversation history were resolved by initiating a new session for each iteration. In the end, we settled on the following prompt:

> “””
> Question ?
> list of choices :
> 1- Answer 1.
> 2- Answer 2.
> 3- Answer 3.
> 4- Answer 4.
> Response should be in json format :
> { “answer”: Number of the choice }
> “””

We achieved a total score of **0.59** for the sentence-puzzle task and **0.27** for the word-puzzle task, scores that do not necessarily match the expected performance for a model like ChatGPT. This suggests that, although ChatGPT was not specifically trained for this task, it might not be able to compete with models that were specially designed for it. ChatGPT was trained on a vast dataset, but it is assumed that most of this data is well-structured and more aligned with linear thinking rather than lateral thinking, which explains its moderate performance in this area.

5.2 The Effect of Temperature

The temperature parameter in language models for natural language processing is a hyperparameter used to control the diversity of predictions made by the model during text generation. Temperature adjusts the likelihood of predictions based on their calculated probability, thereby influencing the level of risk or surprise in the choice of generated words. Adjusting the temperature allows for control over the trade-off between creativity and safety in text generation. Finding the right temperature depends on the specific application, the domain of use, and preferences for the balance between innovation and reliability in the generated responses. A low temperature close to 0 produces more conservative and repetitive responses, while a high temperature close to 1 yields more varied and creative responses.

Is there a relationship between temperature and lateral thinking ? Although the temperature

setting in language models and lateral thinking operate in different domains, they share a common goal of fostering creativity and innovation by breaking conventions and exploring possibilities beyond those that are immediately obvious. Lateral thinking encourages questioning assumptions and considering a variety of different perspectives. Similarly, by adjusting the temperature to favor less likely word selections, a language model can "think" more laterally, exploring linguistic options that would not be considered at a lower temperature. Therefore, we will measure the performance of ChatGPT based on temperature, relationship between temperature and lateral thinking.We will launch several runs by increasing the temperature from 0 to 1.2

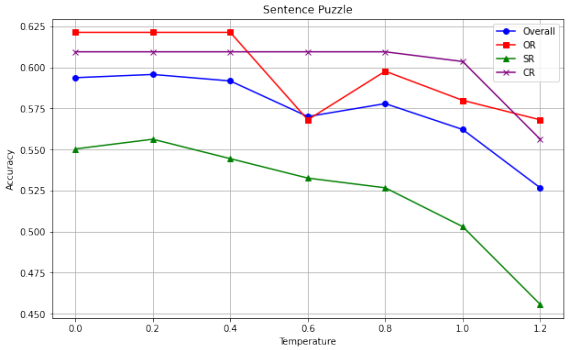

Figure 3: ChatGPT Performance Across Different Temperatures (Sentence puzzle)

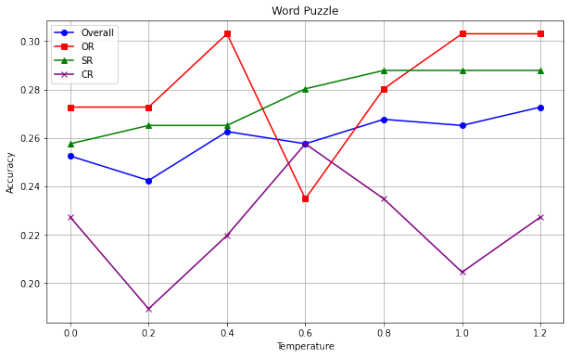

Figure 4: ChatGPT Performance Across Different Temperatures (Word puzzle)

Sentence Puzzle : The graphic 3 represents four data series corresponding to different test scenarios for the sentence puzzle task: Overall, OR (Original), SR (Semantic Reconstruction), and CR (Context Reconstruction). "Overall" indicates a benchmark or an overall average of performance, while OR shows stable results, suggesting a consistent baseline. CR follows a trend similar to OR, indicating that contextual reconstruction performs comparably to the original. In contrast, SR shows a notable degradation in performance towards the end, which could suggest that the semantic reconstruction method is less stable or effective under certain conditions. The data set suggests that while OR and CR methods maintain a degree of consistency, SR might involve a riskier or more innovative approach, which could be likened to a "higher temperature" in the context of lateral thinking, leading to more varied and potentially less predictable outcomes. However, increasing the temperature does not allow the model to perform better on a task, on the contrary, performance decreases.

Word puzzle : In the case of word puzzles 4, it is difficult to conclude as there are no clear trends observed. However, for the overall general case, it is noted that performance increases very slightly with temperature, which stands out in comparison to the sentence puzzle task, potentially because word puzzles better illustrate lateral thinking. In this case, the focus is not on the sentence, which contains more semantic aspects. The answer in this task violates the default meaning of the word and focuses on the letter composition of the target question.

6 Conclusion

Our research underscores the significance of dedicated models in advancing AI's capability to solve complex lateral thinking tasks, as exemplified by our model's top-ranking performance in the BRAINTEASER sentence puzzles. The comparative analysis with ChatGPT highlights the limitations of general-purpose models in specific creative reasoning challenges, despite their overall versatility. The study also reveals the nuanced role of temperature settings in modulating ChatGPT's performance, offering insights into optimizing AI models for enhanced creativity and lateral thinking. Future work should focus on bridging the gap in word puzzle performance and further refining the balance between creativity and logical reasoning in AI systems.

Abstract

The advancement of natural language processing has given rise to a variety of large language models (LLMs) with capabilities extending into the realm of complex problem-solving, including brainteasers that challenge not only linguistic fluency but also logical reasoning. This paper documents our submission to the SemEval 2024 Brainteaser task, in which we investigate the performance of state-of-the-art LLMs, such as GPT-3.5, GPT-4, and the Gemini model, on a diverse set of brainteasers using prompt engineering as a tool to enhance the models' problem-solving abilities. We experimented with a series of structured prompts ranging from basic to those integrating task descriptions and explanations. Through a comparative analysis, we sought to determine which combinations of model and prompt yielded the highest accuracy in solving these puzzles. Our findings provide a snapshot of the current landscape of AI problem-solving and highlight the nuanced nature of LLM performance, influenced by both the complexity of the tasks and the sophistication of the prompts employed. All the code, along with the data used, is available on our GitHub[1]

1 Introduction

The pursuit of creating artificial intelligence models with advanced reasoning and problem-solving capabilities has led researchers down the path of deploying brainteasers as a benchmark for AI systems' linguistic and reasoning prowess. These brainteasers are more than trivial or recreational challenges; they are testaments to the complexity of human cognition, embedding layers of semantics, pragmatics, and world knowledge that remain elusive to AI systems. The gulf between the operational logic of current AI models and the intricate understanding displayed by the human mind is significant, particularly in domains necessitating advanced reasoning and a robust common sense foundation. This disparity is not only observed but keenly felt in the context of AI systems' interaction with human language and thought (Mahowald et al., 2023).

The limitations of pattern recognition as the mainstay of AI systems' learning mechanisms have been critically examined, sparking a discourse that emphasizes the imperative for AI systems to transcend these confines. Rigorous benchmarks that challenge AI systems to demonstrate inferential reasoning are essential to catalyze this evolution (Sawada et al., 2023). Brainteasers emerge as one medium through which AI systems' competencies can be evaluated. They are not simply puzzles to be solved but are reflective of the complex, often ambiguous nature of human communication and problem-solving.

The BRAINTEASER task introduced at SemEval 2024 (Jiang et al., 2024) is part of this evolution of AI system assessment, standing at the center of linguistic analysis and computational intelligence. It is designed to evaluate what machines can understand and how they can apply this understanding in a manner similar to human thought processes. Language models, such as GPT-3.5[2] and GPT-4 (OpenAI, 2023), are increasingly being subjected to these tests to gauge their mastery over language and logic, as demonstrated in recent comparative analyses (Espejel et al., 2023). The BRAINTEASER task's format, which intertwines linguistic cues with logical conundrums, requires systems to not only comprehend the text at a superficial level but to delve into the implied, the inferred, and the intuitive aspects that are second nature to human beings.

By benchmarking language models against brainteasers within the framework of the BRAIN-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 206–212

TEASER task, we are able to learn more about the current capabilities of popular LLMs. This work can help to provide a direction for future research by pinpointing where current models fall short and where the next wave of innovation is urgently needed.

Our approach involved testing different LLM models. We web-scraped example riddles and used them as an example for the model. Additionally, we tested with the closest riddle and the most different riddle and found that GPT-4.0 oneshot with a similar riddle worked best for the Sentence Puzzle and GPT-4.0 oneshot with a different riddle worked best for the Word Puzzle. The Word Puzzle turned out to be a significantly harder task than the Sentence Puzzle.

2 Related Work

The exploration of reasoning abilities in large language models (LLMs) has been the focus of several studies in recent years. Notably, work by OpenAI provides foundational insights into the capabilities of GPT-3, especially highlighting its potential in solving reasoning tasks through few-shot learning (Brown et al., 2020). This work is particularly relevant as it demonstrates how providing a few examples can significantly improve an LLM's ability to solve reasoning problems, akin to the one-shot and few-shot techniques examined in our study.

Furthering the discussion on reasoning, work has been done that discusses the 'chain-of-thought' (CoT) prompting method, where models are guided to articulate intermediate steps when solving complex tasks (Wei et al., 2022). This process is similar to the explanation method in solving the brainteasers, which encourages models to elaborate on their reasoning, leading to improved performance.

The brainteasers in the training data provided often require making analogies and similarities in reasoning. Work has been done that offers an analysis of how word embeddings capture semantic relationships, which can be fundamental in retrieving similar examples to aid reasoning (Allen and Hospedales, 2019). This is directly linked to our one-shot similar and few-shot in-context learning approaches, where the ability of an LLM to use analogous examples influences its problem-solving effectiveness.

Moreover, the strategies for solving brainteasers with AI systems have been enriched by incorporating external knowledge bases. An investigation has been conducted into the inherent knowledge within language models and their ability to function as knowledge bases (Petroni et al., 2019). The integration of external knowledge is particularly pertinent to tasks requiring common sense and real-world information, underscoring the importance of knowledge retrieval in the context of a brainteaser. Lastly, a pivotal study has been done that introduces a dataset designed to probe AI systems' common sense reasoning capabilities (Talmor et al., 2018). This study aligns with our aim in solving brainteasers to evaluate the capacity of LLMs to handle questions that necessitate an understanding of the world as humans perceive it.

3 Methodology

Our experimental design relies on prompt engineering to explore the effectiveness of language models in solving brainteasers. In this study, we experimented with different prompt structures to determine their impact on the model's performance. The primary prompt format tested was structured as follows: "Please pick the best choice for the brain teaser. Each brain teaser has only one possible solution, including the choice 'none of the above.' The answer should only provide the choice text." This directive was chosen to explicitly instruct the model to select a single, most appropriate answer from a set of given options. To ensure a controlled variable, we explicitly presented the model with the choices, observing how it navigates the selection process when options are directly provided.

An interesting observation was made regarding the specification of the type of brainteaser. Initially, it was hypothesized that indicating whether the puzzle was a 'word puzzle' or a 'sentence puzzle' would aid the models in narrowing down their reasoning scope, thereby improving accuracy. However, the results indicated that such specifications did not significantly affect the models' performance. This finding suggests that the models possess a level of task generalization, wherein they apply similar reasoning processes to both types of puzzles without the need for explicit differentiation.

Furthermore, we explored the effect of including choices within the prompt. By contrasting scenarios with and without provided options, we aimed to assess whether the presence of choices would guide the model to a correct answer more efficiently. Prompts structured to request the model

to pick from provided choices explicitly did not significantly alter the success rate compared to when no choices were given. This aspect of the study aimed to discern the degree to which the models rely on contextual clues versus intrinsic problem-solving capabilities. For example, in a test with a bad prompt on GPT-3.5 without choice, a 27.60% accuracy was achieved, while with the same prompt with choices, a 28.80% accuracy was achieved. Due to the slight increase in accuracy, we decided to include choices for the rest of the prompts used.

We also implemented explanation and chain of thought (CoT) reasoning to guide the language model toward a more structured and reasoned approach when tackling brain teasers. Explanation prompts encouraged the model to articulate the rationale behind its chosen answers. Similarly, CoT prompts aimed to simulate a step-by-step reasoning process, mirroring how humans might approach problem-solving.

To further enhance the accuracy of our language model in solving brain teasers, we adopted a one-shot in-context learning approach, leveraging a large dataset of riddles as context for the model. We extracted a comprehensive collection of 3,899 riddles by downloading texts from the `riddles.com` website, including both the questions and their corresponding answers. This dataset was a reference for the model to draw upon when presented with new puzzles.

We employed two distinct strategies for selecting a relevant riddle from this dataset to use as an example in our one-shot method. The first strategy aimed to identify the riddle most *similar* to the brain teaser in question, believing that a similar context might prime the model more effectively for the task at hand. Conversely, the second strategy sought out the riddle most *dissimilar* to the brain teaser, hypothesizing that a contrasting example could stimulate a broader range of the model's reasoning capabilities.

To facilitate the rapid identification of the most similar or dissimilar riddle, we encoded each riddle question into a vector representation using the `all-MiniLM-L6-v2 model` (Reimers and Gurevych, 2019) in the `SentenceTransformers`[3] Python package. This allowed us to compute the cosine similarity between the vector representation of the new brain teaser and those of the riddles in our dataset. Using this similarity score, we could efficiently identify the riddle that was either closest or farthest in semantic space from the brain teaser presented to the model. The highest cosine similarity is used as the similar riddle, while the lowest cosine similarity is used as the dissimilar riddle.

This approach significantly improved the efficiency of selecting an appropriate example riddle, enabling a more streamlined integration of the one-shot learning method into our experimental setup. The rationale behind using cosine similarity was to leverage the high-dimensional space in which language representations reside, making it possible to quantify the semantic proximity between different textual inputs effectively. A depiction of the different elements of different prompts is depicted in Figure 1.

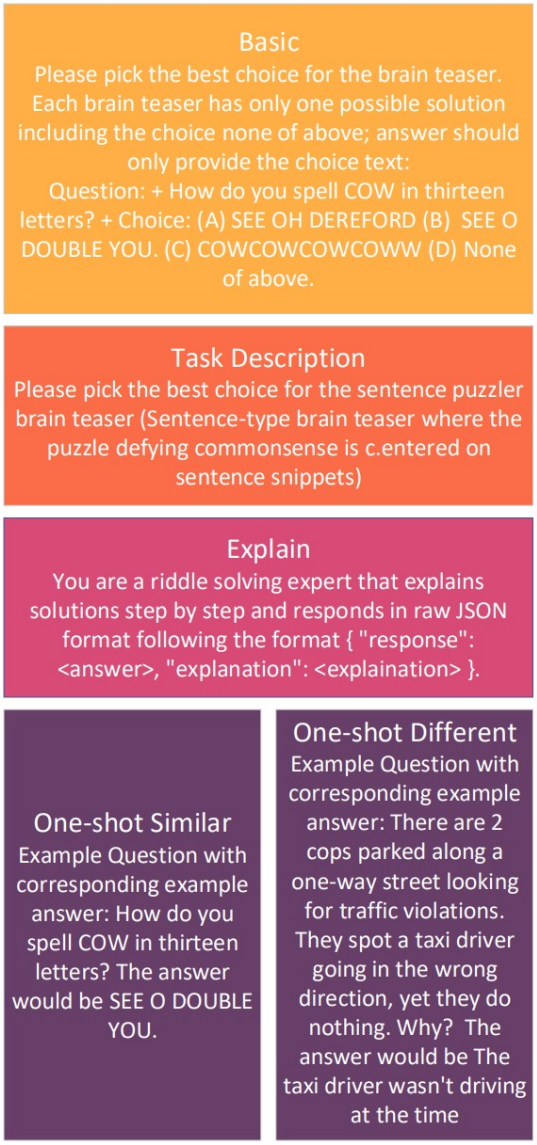

Figure 1: Example prompts tested

[3] https://sbert.net

In an effort to enhance the accuracy of solutions provided by the language model for word puzzles, we also experimented with an innovative approach modeled after collective human problem-solving dynamics. This method involved simulating a "council" of three hypothetical individuals engaged in a discussion about a puzzle, with the aim of reaching a consensus on the answer.[4] The intent was to emulate the collaborative approach often used in human group problem-solving, where different perspectives and thought processes can lead to more accurate solutions. The implementation of this method required the model to generate three distinct responses, each purportedly from a different "council member," who would then "discuss" their reasoning and perspectives on the puzzle. Following this simulated deliberation, the model was prompted to synthesize the viewpoints into a single, collective answer (see example in Appendix A). Despite the creative nature of this technique, the results were not as promising as anticipated. The accuracy of the word puzzles did not show significant improvement using the council-based discussion method. This outcome suggests that while the approach mirrors human group interactions, it may not translate effectively within the constraints of a single AI model's processing capabilities.

4 Results

We ran and tested the LLMs on the training set (Jiang et al., 2023) with each combination of model and prompt. This allows us to get a comprehensive view of the performance of the LLMs across different prompts. It is important to increase the general accuracy across all LLMs by adding more information about the question to the prompt, along with examples. The models we evaluated included GPT-3.5, GPT-4, Gemini Pro (Team et al., 2023), and a suite of memory-efficient language models from the `languagemodels` repository.[5] The models used from this package included neural-chat-7b-v3-1, flan-alpaca-xl, flan-alpaca-gpt4-xl, flan-t5-xl, fastchat-t5-3b-v1.0, LaMini-Flan-T5-783M, flan-t5-large, LaMini-Flan-T5-248M, flan-alpaca-base, flan-t5-base, dialogstudio-t5-base-v1.0, LaMini-Flan-T5-77M, flan-t5-small, phi-1_5, LaMini-GPT-774M, and LaMini-GPT-124M. This set explores sixteen models, yet they never outperformed the other LLMs (GPT and Gemini series). Therefore, we only report the results from the best of these models for each prompt and task in the final result tables, Table 1 and Table 2.

Prompt	GPT-3.5	GPT-4.0	Gemini	`languagemodels`
basic	0.288	0.649	**0.803**	0.359
task desc.	0.477	0.645	**0.753**	0.383
+ CoT	**0.722**	0.692	0.671	0.314
+one-shot sim.	0.650	**0.809**	0.753	0.633
+one-shot diff.	0.680	**0.825**	0.759	0.345
+one-shot sim. + CoT	**0.710**	0.686	0.637	0.686
+one-shot diff. + CoT	0.670	**0.704**	0.655	0.347

Table 1: Accuracy of LMs using different prompts on the **Sentence Puzzle** task. **Bold** indicates the best model for a given prompting strategy, and **underlined** indicates the best overall approach for the task. The `languagemodels` column shows the best score achieved by any model from the `languagemodels` library.

Prompt	GPT-3.5	GPT-4.0	Gemini	`languagemodels`
basic	0.346	0.508	**0.531**	0.341
task desc.	0.341	0.487	**0.494**	0.354
+ CoT	0.520	**0.641**	0.351	0.323
+one-shot sim.	0.485	**0.649**	0.530	0.553
+one-shot diff.	0.470	**0.621**	0.505	0.356
+one-shot sim. + CoT	**0.553**	0.540	0.384	0.242
+one-shot diff. + CoT	0.513	**0.586**	0.354	0.333

Table 2: Accuracy of LMs using different prompts on the **Word Puzzle** task. **Bold** indicates the best model for a given prompting strategy, and **underlined** indicates the best overall approach for the task. The `languagemodels` column shows the best score achieved by any model from the `languagemodels` library.

It was found that the one-shot method consistently had the top 2 accuracy in the prompts studied, proving the efficiency of one-shot methods for LLMs in general. Gemini's accuracy when only using the basic prompt was very high for the Sentence Puzzle task, which shows Gemini's versatility and adaptability to different questions with high accuracy without needing examples to perform well. The GPT-4 system with the basic prompt with a chain-of-thought method also proved to be highly accurate.

The Chain of Thought approach has been shown

[4] https://github.com/dave1010/tree-of-thought-prompting

[5] https://github.com/jncraton/languagemodels

to improve accuracies for LLMs. Despite these efforts, we observed that this strategy did not lead to a measurable increase in accuracy. This outcome suggests that while such prompts can often lead to more interpretable answers, they do not necessarily enhance the model's ability to deduce the correct solution in the context of brain teasers. Further research may explore whether the complexity of the puzzles or the inherent limitations of the models' understanding contributed to this result.

Despite the overall increase in accuracy observed with more informative prompts, GPT-4 did not always outperform GPT-3.5 with prompts like the task description + explain. This highlights that while advancements in model architecture contribute to enhanced performance, they do not guarantee superior outcomes in every scenario, particularly in specialized tasks like puzzle-solving. Since GPT-4 is trained on a larger range of data sources to improve general performance across a broad range of tasks, the generalized training approach may lead GPT-4 not performing as well in this specific task.

Furthermore, we found that employing chain-of-thought and explanation methodologies did not significantly improve performance in this context. This deviation from expected outcomes may indicate that for certain types of puzzles, these approaches do not align with the models' strengths or the nature of the problem-solving process required.

The performance of open-source packages like `languagemodels` was notably lower compared to their commercial counterparts. This gap underscores the developmental distance that open-source models need to traverse to reach the sophistication level of models like GPT-4 or Gemini, suggesting that access to extensive datasets, computing resources, and proprietary algorithms plays a significant role in model performance. Typically the models from this set that worked best were the LaMini-Flan-T5 class, which was always the case for the one-shot setting. The main exceptions to this were in the zero-shot scenario, specifically with the basic prompt (neuralchat worked best for Sentence Puzzle and dialogstudio worked best for Word Puzzle) and the task description prompt (phi-1.5 for SP and neuralchat for WP). These cases provide positive examples of situations in which lightweight, open models are more competitive with proprietary, closed models.

Additionally, the increased difficulty of word puzzles presents a notable challenge, potentially due to their reliance on nuanced understanding, cultural context, and semantic associations that can be challenging even for human solvers. This complexity is reflected in the lower accuracy rates across all models for word puzzles when compared to sentence puzzles, implying that word puzzles may represent a closer analog to human-level problem-solving and, as such, provide a more stringent test of AI reasoning and language capabilities.

The three submission prompts submitted are GPT-4 one-shot different for Sentence Puzzle and GPT-4 one-shot similar for word puzzles, GPT-4 one-shot similar for Sentence Puzzle and GPT-4 one-shot different for word puzzles, and Gemini basic for Sentence Puzzle and GPT-4 basic + CoT for word puzzle. The first submission received an accuracy score of 0.925 for the sentence puzzle and 0.9375 for the word puzzle, the second a score of 0.95 for the sentence puzzle and 0.78125 for the word puzzle, and the third a score of 0.625 for the sentence puzzle and 0.46875 for the word puzzle. Not that these accuracies are from the "Original" riddles. The second submission was the highest and ranked us 14th in terms of average score, 11th on the Word Puzzle task, and 10th on the Sentence Puzzle task under the name `vspuzzler`. Our submitted system performed exceptionally well on the "Original" version of the brainteasers (ranking 3rd overall for Sentence Puzzle and 7th for Word Puzzle within this subcategory) but underperformed on the "Context Reconstruction" variations of the brainteasers in which the original reasoning path was used within a new situational context.

5 Conclusion

This study's evaluation of LLMs across a range of prompt types provides insights into the strengths and limitations of current AI systems in solving brain teasers. Our findings revealed that in-context learning methods are highly effective, particularly for the Gemini model and GPT-4, when solving sentence puzzles. However, GPT-4 did not consistently outperform GPT-3.5 across all prompt types, which suggests that the latest models do not always guarantee an improvement in task-specific performance. The chain-of-thought and explanation strategies, while enhancing interpretability, did not necessarily translate into higher accuracy, indicating the need for further research into how these models process complex language tasks. The performance gap between proprietary and open-source

models highlights the significant role of resources and proprietary technology in developing LLMs. The increased difficulty of word puzzles suggests that tasks requiring a nuanced understanding and cultural context remain challenging for AI systems, closely mirroring the complexity of human cognition. This study underscores the importance of tailored prompting strategies to leverage the capabilities of LLMs and the potential for future advancements in AI-based problem-solving.

A Appendix

Chain of thought was used as one of the prompts. Below is an example of it in use:

> **Prompt:**
>
> Please pick the best choice for the sentence puzzle brain teaser (Sentence-type brain teaser where the puzzle defying commonsense is centered on sentence snippets). Each brain teaser has only one possible solution including the choice none of above, answer should only provide the choice:
>
> Question: Mr. and Mrs. Mustard have six daughters and each daughter has one brother. But there are only 9 people in the family, how is that possible? Choice:
>
> (A) Some daughters get married and have their own family.
>
> (B) Each daughter shares the same brother.
>
> (C) Some brothers were not loved by family and moved away.
>
> (D) None of above.
>
> **Answer:**

{"response": "B",

"explanation": "Each daughter has one brother, which means there is only one brother shared among all six daughters. If Mr. and Mrs. Mustard have six daughters and one son, together with the two of them, that makes a total of nine family members. Therefore, the correct answer is choice B." }

A council method was also used as one of the prompts. Below is an example of it in use:

Prompt:

Please pick the best choice for the sentence puzzle brain teaser (Sentence-type brain teaser where the puzzle-defying commonsense is centered on sentence snippets). Each brain teaser has only one possible solution including the choice none of above, answer should only provide the choice. Imagine three different experts are answering this question. All experts will write down 1 step of their thinking, then share it with the group. Then all experts will go on to the next step, etc. If any expert realises they're wrong at any point then they leave.

Question:Mr. and Mrs. Mustard have six daughters and each daughter has one brother. But there are only 9 people in the family, how is that possible? Choice:

(A) Some daughters get married and have their own family.

(B) Each daughter shares the same brother.

(C) Some brothers were not loved by family and moved away.

(D) None of above.

Answer:

{"response": "B",

"Expert1Thinking": "If there are six daughters and each has one brother, it would initially seem like there should be six brothers. However, the question is phrased in a way that suggests that each daughter has the same single brother.",

"Expert2Thinking": "Taking into account that there are Mr. and Mrs. Mustard, the six daughters can collectively have only one brother to make the total count nine. This brother would be shared among all sisters.",

"Expert3Thinking": "It's a puzzle meant to trick the reader into thinking there are more people than there actually are. The family must consist of Mr. and Mrs. Mustard, their six daughters, and one son who is the brother of all daughters. So, there's only one brother, not six." }

NLP-LISAC at SemEval-2024 Task 1: Transformer-based approaches for Determining Semantic Textual Relatedness

Abstract

This paper presents our system and findings for SemEval 2024 Task 1 Track A Supervised Semantic Textual Relatedness. The main objective of this task was to detect the degree of semantic relatedness between pairs of sentences. Our submitted models (ranked 6/24 in Algerian Arabic, 7/25 in Spanish, 12/23 in Moroccan Arabic, and 13/36 in English) consist of various transformer-based models including MARBERT-V2, mDeBERTa-V3-Base, DarijaBERT, and DeBERTa-V3-Large, fine-tuned using different loss functions including Huber Loss, Mean Absolute Error, and Mean Squared Error.

1 Introduction

Semantic Textual Relatedness (STR) is a natural language processing (NLP) task that focuses on measuring the degree of semantic relatedness between two pieces of text. Unlike tasks such as Semantic Textual Similarity (STS), which specifically assess the degree of similarity between texts, STR considers a broader notion of relatedness, encompassing various types of semantic relationships between words, phrases, or sentences.

The goal of STR is to quantify how closely related two pieces of text are in terms of their underlying meaning or semantic content. This relatedness can encompass a wide range of semantic relationships, including:

- **Synonymy**: Words or phrases that have similar meanings.
- **Hyponymy/Hypernymy**: Hierarchical relationships where one word is a more specific instance (hyponym) or a more general category (hypernym) of another word.
- **Meronymy/Holonymy**: Meronymy is a semantic relation between a meronym denoting a part and a holonym denoting a whole.
- **Antonymy**: Words with opposite meanings.
- **Entailment**: One statement logically implies another statement.
- **Association**: Words or concepts that are commonly associated with each other.

In the context of STR, annotators or models are typically presented with pairs of text and asked to judge the degree of relatedness based on the presence of shared concepts or semantic associations. Annotators might provide relatedness scores or labels indicating the strength of the relationship between text pairs.

In this paper, we present our findings on SemEval 2024 Task 1 Track A: Supervised Semantic Textual Relatedness (Ousidhoum et al., 2024b). Our method consists of various transformer-based approaches (Vaswani et al., 2017) fine-tuned using different loss functions including Huber Loss, Mean Absolute Error, and Mean Squared Error.

The rest of the paper is structured in the following manner: Section 2 provides the main objective of the Task. Section 3 describes our system. Section 4 details the experiments. And finally, Section 5 concludes this paper.

2 Task Description

This task aims to predict the semantic textual relatedness (STR) of pairs of sentences across 14 different languages. Participants will rank sentence pairs based on their semantic closeness, ranging from 0 (completely unrelated) to 1 (maximally related), as determined manually. Teams can submit entries for one, two, or all of the following tracks:

- **Track A: Supervised**: Participants are required to submit systems trained using provided labeled training datasets. They may utilize publicly available datasets, but must disclose additional data used and assess its impact on results.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 213–217

- **Track B: Unsupervised**: Participants must submit systems developed without using labeled datasets on semantic relatedness or similarity between text units longer than two words in any language. However, the use of unigram or bigram relatedness datasets from any language is allowed.
- **Track C: Cross-lingual**: Participants must submit systems developed without labeled semantic similarity or relatedness datasets in the target language, but may use labeled dataset(s) from at least one other language. Note: Utilizing labeled data from another track is mandatory for submissions to this track.

3 System Description

To tackle the SemEval 2024 Task 1 Track A: Supervised Semantic Textual Relatedness, we fine-tuned several transformer-based models on an augmented training dataset and with different loss functions including Huber Loss, Mean Absolute Error, and Mean Squared Error. The different steps of our system are described as follows:

- We combined the training and development sets separately for each language in which we participated in. Besides, we duplicated the obtained datasets input, but we shifted the pairs order and we kept the same semantic relatedness score. Table 1 and 2 depict an example of augmenting the English training set.
- We replaced the newline character **\n** with **[SEP]** token in order to separate the input pairs. For example, this input: "Then, in twenty minutes, gather at the runway. \n gathering on the runway, in 20 minutes." will be converted to "Then, in twenty minutes, gather at the runway. [SEP] gathering on the runway, in 20 minutes."
- We tokenized the data using tokenizers associated with the fine-tuned transformer based models.
- We fine-tuned MARBERTv2 (Abdul-Mageed et al., 2021) on the Algerian Arabic data, DarijaBERT (Gaanoun et al., 2024) on the Moroccan Arabic data, DeBERTa-V3-Large (He et al., 2021a,b) on the English data, and mDeBERTa-V3-Base (He et al., 2021a) on the Spanish data.

In the context of semantic textual relatedness tasks, the choice of loss function plays a critical role in guiding the training process and optimizing model performance. Given the diverse nature of textual data and the wide range of semantic relationships to be captured, employing a variety of loss functions can offer several advantages.

Firstly, the Huber Loss function provides robustness to outliers by combining the advantages of Mean Absolute Error (MAE) and Mean Squared Error (MSE). MAE, which calculates the average absolute difference between predicted and target values, is less sensitive to outliers compared to MSE, which squares the differences. By behaving like MSE for large errors and like MAE for small errors, Huber Loss ensures that the training process is less influenced by outliers, thereby enhancing the model's ability to generalize to unseen data.

Secondly, Mean Absolute Error (MAE) serves as a straightforward and intuitive loss function that penalizes deviations from the target scores equally, irrespective of their direction. In tasks such as semantic textual relatedness, where the goal is to predict similarity scores between sentence pairs, MAE provides a direct measure of the magnitude of errors, facilitating easy interpretation and evaluation of model performance.

Lastly, Mean Squared Error (MSE) emphasizes the importance of accurately predicting similarity scores by penalizing larger errors more severely than smaller errors. In scenarios where precise estimation of the degree of relatedness between sentence pairs is crucial, MSE can effectively guide the training process towards minimizing the squared differences between predicted and target values, thereby optimizing model performance.

By leveraging a combination of these loss functions during the fine-tuning process, we aim to capitalize on their respective strengths and enhance the robustness and effectiveness of our models in capturing semantic relationships within textual data. This approach enables us to optimize model performance across various linguistic contexts and achieve competitive results in tasks requiring accurate assessment of semantic textual relatedness.

The decision to augment the data was validated through fine-tuning the models on concatenated train and dev sets, as well as on concatenated train and dev sets with pair shifting. Interestingly, our analysis revealed that pair shifting significantly enhanced the results on the development sets.

PairID	Text	Score
ENG-train-0047	Then, in twenty minutes, gather at the runway. \n gathering on the runway, in 20 minutes.	0.97
ENG-dev-0010	Meat is dropped into a pan. \n A woman is putting meat in a pan.	0.73

Table 1: Sample of the English training set after combining both training and development sets

PairID	Text	Score
ENG-train-0047	Then, in twenty minutes, gather at the runway. \n gathering on the runway, in 20 minutes.	0.97
ENG-dev-0010	Meat is dropped into a pan. \n A woman is putting meat in a pan.	0.73
ENG-train-0047-shifted	gathering on the runway, in 20 minutes. \n Then, in twenty minutes, gather at the runway.	0.97
ENG-dev-0010-shifted	A woman is putting meat in a pan. \n Meat is dropped into a pan.	0.73

Table 2: Sample of the English training set after combining both training and development sets and after shifting the pairs

4 Experimental Results

We experimented our model on the SemEval 2024 Task 1: Semantic Textual Relatedness (STR) test set (Ousidhoum et al., 2024a). The experiment has been conducted in Kaggle environment[1], The following libraries: Transformers - Hugging Face[2] (Wolf et al., 2020), and Keras[3] were used to train and to assess the performance of our models.

4.1 Datasets

Each instance in the training, development, and test sets (Ousidhoum et al., 2024a) is a sentence pair. The instance is labeled with a score representing the degree of semantic textual relatedness between the two sentences. The scores can range from 0 (maximally unrelated) to 1 (maximally related). Figure 1 depicts the training, dev and test sets distributions for Algerian Arabic, Moroccan Arabic, English and Spanish.

The datasets are available via GitHub[4]

4.2 Experimental Settings

We conducted numerous experiments on the development set to obtain the ideal number of epochs and identify the most effective loss function for fine-tuning each model. This paper presents the hyperparameters that yielded the best results on the development set across the target languages:

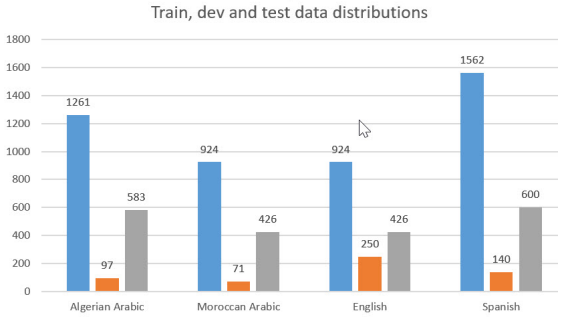

Figure 1: Train, development and test sets distributions for Algerian Arabic, Moroccan Arabic, English and Spanish

- **Algerian Arabic**: We fine-tuned MARBERTv2 using 12 epochs, a maximum sequence length of 200, and Mean Absolute Error as the loss function.

- **Moroccan Arabic**: We fine-tuned DarijaBERT using 5 epochs, a maximum sequence length of 200, and Huber loss as the loss function.

- **English**: We fine-tuned DeBERTa-V3-Large using 5 epochs, a maximum sequence length of 150, and Huber loss as the loss function.

[1] https://www.kaggle.com/
[2] https://huggingface.co/docs/transformers/index
[3] https://keras.io/
[4] https://github.com/semantic-textual-relatedness/Semantic_Relatedness_SemEval2024

- **Spanish**: We fine-tuned mDeBERTa-V3-Base using 12 epochs, a maximum sequence length of 200, and Mean Squared Error as the loss function.

The same parameters were utilized during the final submission phase. Additionally, Table 3 displays the additional hyperparameter settings employed during the fine-tuning process for all models.

Hyperparameters	Settings
Learning rate	10^{-5}
Batch size	4
Optimizer	Adam (Kingma and Ba, 2015)

Table 3: Hyperparameters settings for the model in the experiments

4.3 System Performance

Table 4 depicts the results of our proposed approaches on SemEval 2024 Task 1 Track A Supervised Semantic Textual Relatedness. The official evaluation metric for this task is the Spearman's rank correlation coefficient, which captures how well the system-predicted rankings of test instances align with human judgments.

Language	Score (Spearman)	Ranking
Algerian Arabic	0.6035781253	6
Spanish	0.7171198162	7
Moroccan Arabic	0.7893667707	12
English	0.8345843316	13

Table 4: Results of our proposed models on SemEval 2024 Task 1 Track A : Supervised Semantic Textual Relatedness test set

Based on the experimental results, our approaches for SemEval 2024 Task 1 Track A: Supervised Semantic Textual Relatedness demonstrated competitive performance across multiple languages. Here's a summary of our findings:

- **Algerian Arabic** : Our model achieved a score of 0.6035781253, ranking 6th out of 24 submissions. This indicates that our approach effectively captured the semantic relatedness between sentence pairs in Algerian Arabic, outperforming a significant portion of the participating systems.

- **Spanish** : In Spanish, our model achieved a score of 0.7171198162, securing the 7th position out of 25 submissions. This suggests that our approach successfully captured semantic relationships in Spanish text, performing competitively compared to other systems.

- **Moroccan Arabic** : Our model attained a score of 0.7893667707, ranking 12th out of 23 submissions in Moroccan Arabic. While our performance in this language was slightly lower compared to others, our approach still demonstrated notable effectiveness in capturing semantic relatedness in Moroccan Arabic text.

- **English** : For English, our model achieved a score of 0.8345843316, placing 13th out of 36 submissions. Despite the larger number of submissions in English, our approach still showcased strong performance, indicating its capability to accurately assess semantic relatedness in English sentence pairs.

Overall, our experimental results highlight the robustness and effectiveness of our proposed approaches across different languages in capturing semantic textual relatedness. These findings underscore the potential of transformer-based models fine-tuned with appropriate hyperparameters and loss functions to excel in tasks requiring semantic understanding of textual data. Additionally, the competitive rankings across multiple languages signify the versatility and generalizability of our approach, further validating its suitability for real-world applications requiring accurate assessment of semantic relatedness in diverse linguistic contexts.

5 Conclusion

In conclusion, this paper has presented our system and findings for SemEval 2024 Task 1 Track A: Supervised Semantic Textual Relatedness. The primary objective of this task was to detect the degree of semantic relatedness between pairs of sentences across multiple languages. Our submitted models, leveraging various transformer-based architectures including MARBERT-V2, mDeBERTa-V3-Base, DarijaBERT, and DeBERTa-V3-Large, fine-tuned with different loss functions such as Huber Loss, Mean Absolute Error, and Mean Squared Error, achieved competitive rankings across different language tracks.

Our approach highlights the effectiveness of leveraging advanced transformer-based models and fine-tuning techniques to capture intricate semantic relationships within textual data. By incorporating diverse loss functions during the training process, we aimed to optimize the models' performance and enhance their robustness across various linguistic contexts.

Moving forward, further research in semantic textual relatedness should focus on refining existing methodologies, exploring novel architectures, and addressing cross-lingual challenges. Additionally, efforts to incorporate additional linguistic features and develop more comprehensive evaluation metrics can contribute to advancing the state-of-the-art in this field.

Overall, our contributions underscore the significance of semantic textual relatedness in natural language processing tasks and pave the way for the development of more sophisticated and context-aware systems capable of understanding and interpreting textual data with greater precision and accuracy.

ZXQ at SemEval-2024 Task 7: Fine-tuning GPT-3.5-Turbo for Numerical Reasoning

Zhen Qian, Xiaofei Xu, Xiuzhen Zhang
School of Computing Technologies, RMIT University, Australia
S3888611@student.rmit.edu.au
S3833028@student.rmit.edu.au
xiuzhen.zhang@rmit.edu.au

Abstract

In this paper, we present our system for the SemEval-2024 Task 7, i.e., NumEval subtask 3: Numerical Reasoning. Given a news article and its headline, the numerical reasoning task involves creating a system to compute the intentionally excluded number within the news headline. We propose a fine-tuned GPT-3.5-turbo model, specifically engineered to deduce missing numerals directly from the content of news articles. The model is trained with a human-engineered prompt that integrates the news content and the masked headline, tailoring its accuracy for the designated task. It achieves an accuracy of 0.94 on the test data and secures the second position in the official leaderboard. An examination on the system's inference results reveals its commendable accuracy in identifying correct numerals when they can be directly "copied" from the articles. However, the error rates increase when it comes to some ambiguous operations such as rounding.

1 Introduction

Huang et al. (2023) noted a deficiency in contemporary encoder-decoder models when applied to headline generation, specifically addressing imprecisions in the numerals within the generated headlines. To facilitate a thorough investigation of this issue, the authors introduced a novel dataset (i.e., NumHG dataset[1]), consisting of over 21,000 news articles rich in numerals and accompanied by detailed annotations. The dataset is linked to two sub-tasks. The first sub-task centres on numerical reasoning, requiring models to calculate the missing numerals within the headline based on the news articles. The second sub-task focuses on headline generation, requiring models to generate a headline grounded in the provided news content.

This paper focuses on the first subtask of numeral reasoning, aiming to assess the fine-tuned GPT 3.5 turbo's performance in handling numerical reasoning tasks within the context of the newly introduced dataset. Inspired by the idea of instruction tuning (Wei et al., 2022a), we carefully design the textual prompts for training GPT 3.5 turbo to calculate the missing number in the masked headline. Additionally, drawing from the concept of mapping reasoning problems to annotations alongside final answers (Amini et al., 2019; Chiang and Chen, 2019), we carry out experiments to utilize the annotations given in the NumHG dataset. The best fine-tuned model from our experiments achieves an accuracy of 0.94, securing the second position on the official leaderboard. However, we acknowledge that our best model does not rely on the annotations provided in the dataset to generate numerals. Instead, the best model calculates numerals based solely on the news content.

2 Related Work

This work draws inspiration from two key research areas: instruction tuning and leveraging intermediate reasoning steps for solving math word problems. Instruction tuning shows that incorporating prompts or instructions into training datasets, as proposed by Wei et al. (2022a), can improve the language models' performance on unseen data. Sanh et al. (2022) also suggest that using diverse prompts to augment training datasets can help language models to achieve better generalization. Regarding the use of intermediate reasoning steps, some researchers express these steps in symbolic format, such as Chiang and Chen (2019) who train language models to generate equations leading to final answers, and Amini et al. (2019) who map math word problems to predefined operations. Others opt for natural language descriptions, like Cobbe et al. (2021), who propose a system utilizing a language model to generate reasoning steps and final answers in natural language, along with a verifier

model to assess the generated answers.

3 Problem Definition

The NumHG dataset comprises 21,157 pieces of news articles, each ranging between 200 to 300 words in the content. The headlines of these news articles include one or more numerals, with one numeral intentionally omitted from each headline. The novelty of the NumHG dataset lies in its provision of meticulous annotations detailing the computational processes used to arrive at the missing numerals in the headlines. This dataset articulates 12 fundamental operations for numeral computation, encompassing actions such as copying, addition, and multiplication. The pre-defined operations are listed in Table 1 (Huang et al., 2023). While in certain cases, computing the correct numerals may require a single operation, such as straightforwardly copying the numerals from the news content as the correct answers, in other instances, it may involve a sequential combination of multiple operations. For example, this could involve rounding the result after adding two numerals found in the news content. The sub-task of numerical reasoning requires us to develop a system capable of accurately calculating the omitted numerals based on the news contents and potentially utilizing the provided annotations.

4 System Overview

In this section, we provide a detailed introduction to our system. Figure 1 illustrates a general outline of our system.

4.1 Model Description

This paper aims to assess the performance of a fine-tuned GPT-3.5-turbo-0613 model in numerical reasoning, specifically its accuracy in computing the desired numerals within news headlines based on content of the news articles. Through the process of fine-tuning, we aim to harness the capability of the GPT-3.5-turbo model by training it with the NumHG dataset, tailoring its performance to our designated task. As of the period during which our experiments were conducted, GPT-3.5-turbo-0613, unveiled in June 2023, stands as the most recent iteration released by OpenAI. This version offers enhanced steerability and reduced costs associated with input tokens. The experiments conducted centre around the refinement of the base model through the fine-tuning process.

The fine-tuned model is then employed for making inferences on the test data. We also imple-

role	content
system	“you will be given a piece of news with prefix ’news:’. you will also be given an incomplete headline with the prefix ’masked headline:’. based on the news content, please output the missing number in the masked headline. please ensure the output is the number only rather than the whole sentence.”
user	“news: news content for each instance in the dataset. masked headline: masked headline for each news article in the dataset”
assistant	“the omitted number from the headline”

Table 2: prompts employed in experiment 1 – training the model to calculate the numerals directly from the news content

role	content
system	“you will be given a piece of news with prefix ’news:’. you will also be given an incomplete headline with the prefix ’masked headline:’. based on the news content, please output how the missing number in the masked headline is calculated together with the final answer. please ensure the operations follow the format below: Copy(v), Trans(e), Paraphrase(v, n), Round(v, c), Subtract(v0, v1), Add(v0, v1), Span(s), Divide(v0,v1), Multiply(v0,v1).”
user	“news: news content for each instance in the dataset. masked headline: masked headline for each news article in the dataset”

ment a program for verifying the data types of the model’s outputs. For the sub-task of numerical reasoning, the expected outputs should be numerical values. Our program systematically converts any non-numerical outputs to the value of 0.

4.2 Prompt Design

To fine-tune a GPT-3.5-turbo using the OpenAI API, it is necessary to convert each instance in the dataset into a format compatible with the model[2]. This involves defining the content for three distinct roles for each instance. The roles include system, user, and assistant. The content assigned to the system role consists of instructions and prompts directed towards the model. For the user role, the corresponding content involves inputs provided to the model, including questions. The content allocated to the assistant role consists of the expected outputs or answers. We mainly carried out two experiments. For the first experiment, we train the model to calculate the numerals directly from the news content. For the second, in addition to the numerals, we also instruct the model to generate the operations required to reach the numerals. The specific prompts employed in this process are presented in Table 2 and Table 3. More detailed examples are shown in Figure 2 and Figure 3.

[2] https://platform.openai.com/docs/guides/fine-tuning

5 Experiment setup

The dataset allocated for the sub-task of numerical reasoning comprises 21,157 instances, which is further split into 80% for training data and 20% for test data. Fine-tuning of the GPT-3.5-turbo-0613 model is performed via the OpenAI API, adhering to the guidelines outlined in the OpenAI API documentation. The hyper-parameters for model training, including learning rate, batch size, and epochs, are configured to auto. Throughout the training phase, evaluation metrics such as training loss, training token accuracy, validation loss, and validation token accuracy are provided by OpenAI. Following the completion of the training process, the fine-tuned model is employed to generate inferences on the test data with temperature set to default.

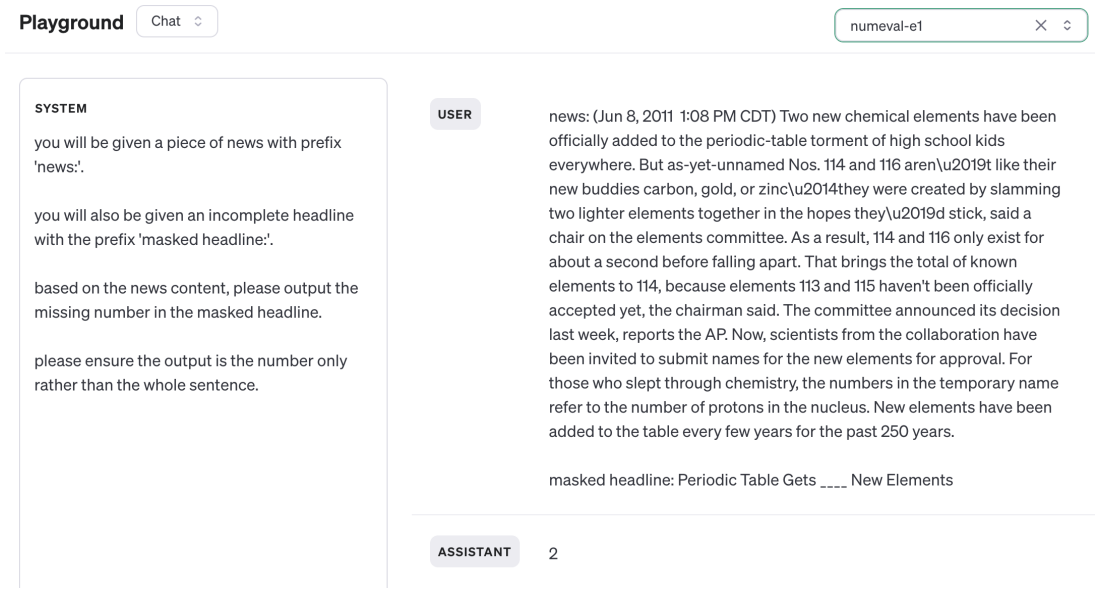

Figure 2: one example for the prompts used for instructing the model to calculate the numerals directly

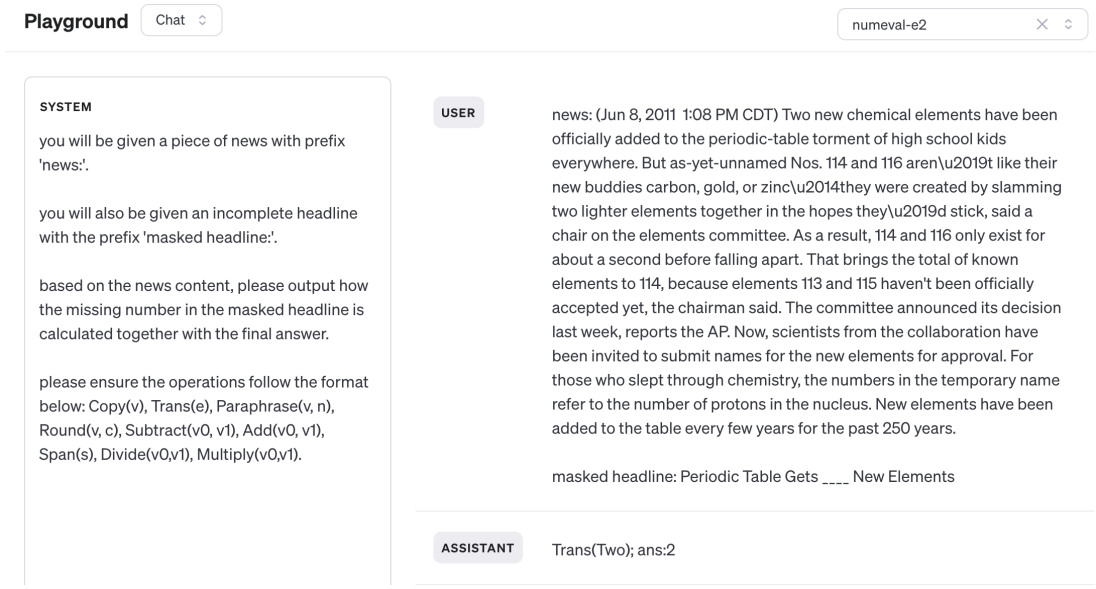

Figure 3: one example for the prompts used for instructing the model to also generate the operations

6 Results

The fine-tuned GPT-3.5-turbo-0613 model from the experiment 1, which calculates the numerals directly from news content, demonstrates a commendable accuracy of 0.94, securing the second position on the leaderboard. The model from the experiment 2, which also output the intermediate operations required to arrive at the numerals, only achieves an accuracy of 0.90. An analysis of model errors has been conducted, with detailed statistics presented in Table 4.

The test data comprises 4,921 instances, featuring a total of 5,237 operators in the annotations. Table 4 reveals that error rates, for both models, are notably low for operations such as Copy, Trans, and Paraphrase, while they are comparatively high for Round, Multiply, Add, and Divide. Given that 88.5% of the operations in the test data pertain to Copy, Trans, and Paraphrase, the model's commendable performance in these three operations significantly contributes to its overall accuracy.

It is important to note that our models cannot detect unanswerable questions in the test data. This anomaly arises from the fact that there are no unanswerable questions in the training data. The models do not learn to predict unanswerable questions in

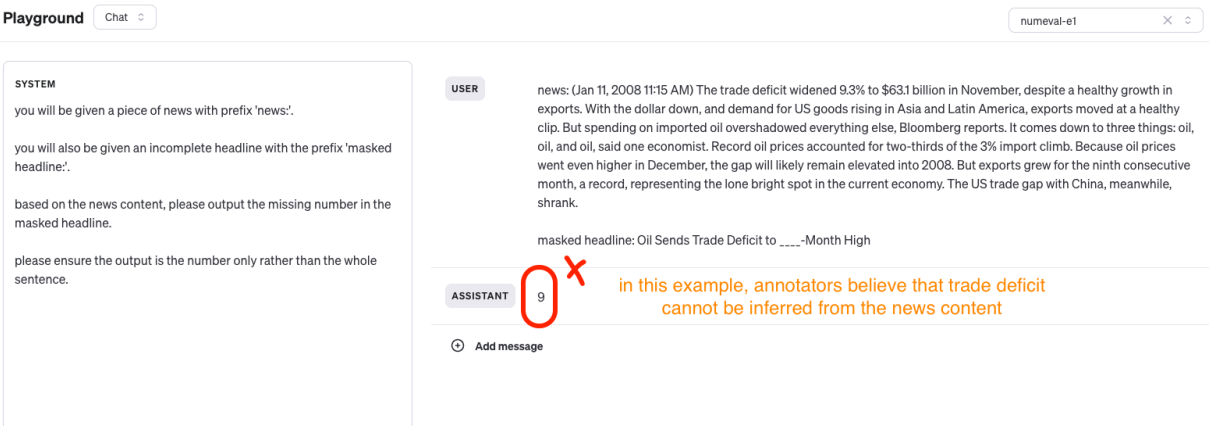

Figure 4: one example for unanswerable questions

Operator	Model 1 Error Rate	Model 2 Error Rate
Copy	4.32%	6.79%
Trans	3.13%	11.37%
Paraphrase	7.39%	15.43%
Round	41.08%	62.70%
Subtract	18.69%	43.93%
Add	24.00%	49.00%
Span	10.34%	30.17%
Divide	23.68%	55.26%
Multiply	35.71%	52.38%

Table 4: error analysis on the test data

the training phase. The unanswerable questions refer to instances identified by annotators when the numerals cannot be inferred from the news content. Figure 4 shows one example of the unanswerable questions in the test data. Another anomaly arises as the model trained for generating intermediate operations shows lower accuracy, contradicting prior works' conclusion that incorporating intermediate reasoning steps in symbolic formats should enhance language model performance by Chiang and Chen (2019) and Amini et al. (2019). To improve the model's ability to utilize annotations and boost overall accuracy, future research should explore alternative methods such as experimenting with different language models, adjusting model architecture, and employing Chain-of-Thought prompting (Wei et al., 2023; Ling et al., 2023).

7 Conclusion

In this paper, we propose to finetune the GPT-3.5-turbo specifically tailored for handling numerical reasoning in the headline generation context. Through the carefully engineered prompt that aggregates the content of news articles and the masked headlines during the fine-tuning process, we achieved an accuracy of 0.94 and ranked second in the official leaderboard. However, our model exhibits relatively high error rates particularly in operations such as rounding numbers. Additionally, further development is needed to better utilize the annotations to improve the model's accuracy.

BAMO at SemEval-2024 Task 9: BRAINTEASER: A Novel Task Defying Common Sense

Baktash Ansari, Mohammadmostafa Rostamkhani, Sauleh Eetemadi
Iran University of Science and Technology
{baktash_ansari, mo_rostamkhani97}@comp.iust.ac.ir, sauleh@iust.ac.ir

Abstract

This paper outlines our approach to SemEval 2024 Task 9, BRAINTEASER: A Novel Task Defying Common Sense. The task aims to evaluate the ability of language models to think creatively. The dataset comprises multi-choice questions that challenge models to think 'outside of the box'. We fine-tune 2 models, BERT and RoBERTa Large. Next, we employ a Chain of Thought (CoT) zero-shot prompting approach with 6 large language models, such as GPT-3.5, Mixtral, and Llama2. Finally, we utilize ReConcile, a technique that employs a 'round table conference' approach with multiple agents for zero-shot learning, to generate consensus answers among 3 selected language models. Our best method achieves an overall accuracy of 85 percent on the sentence puzzles subtask.

1 Introduction

Evaluation methods in the NLP community predominantly emphasize Vertical thinking, characterized by sequential, analytical processes based on rationality, logic, and rules. However, SemEval-2024 Task 9, BRAINTEASER (Jiang et al., 2024b), which is based on the original BRAINTEASER dataset (Jiang et al., 2023), aims to introduce a task that promotes lateral thinking (or "thinking outside the box"), a divergent and creative process involving the exploration of new perspectives when addressing problems. The BRAINTEASER QA task consists of two subtasks for the English language: Sentence Puzzles and Word Puzzles. This task is designed to challenge the common sense reasoning capabilities of NLP models and stimulate the development of models that can think laterally.

- **Sentence Puzzles**: Sentence-type brain teaser where the puzzle-defying commonsense is centered on sentence snippets.
- **Word Puzzles**: Word-type brain teaser where the answer violates the default meaning of the word and focuses on the letter composition of the target question.

We generate baselines for two attention-based models, BERT (Devlin et al., 2019) and RoBERTa-Large (Liu et al., 2019), as selected in the task paper, to solve these types of multiple-choice problems. Then we fine-tune them with the same configs. After achieving some accuracy through fine-tuning, we explore zero-shot prompting with various large language models (LLMs). To further improve results, zero-shot prompting is conducted using a Chain of Thought technique (Wei et al., 2023). As illustrated in Figure 1, we compel the model to analyze and provide step-by-step reasoning for its answer instead of simply providing a correct option alone. This approach helps the model focus more on details and answer questions with fewer errors.

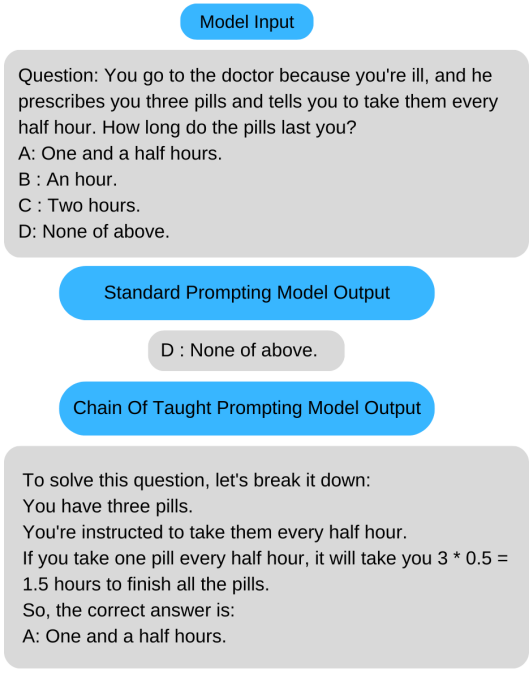

Figure 1: Chain Of Thought Prompting (GPT3.5)

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 224–232

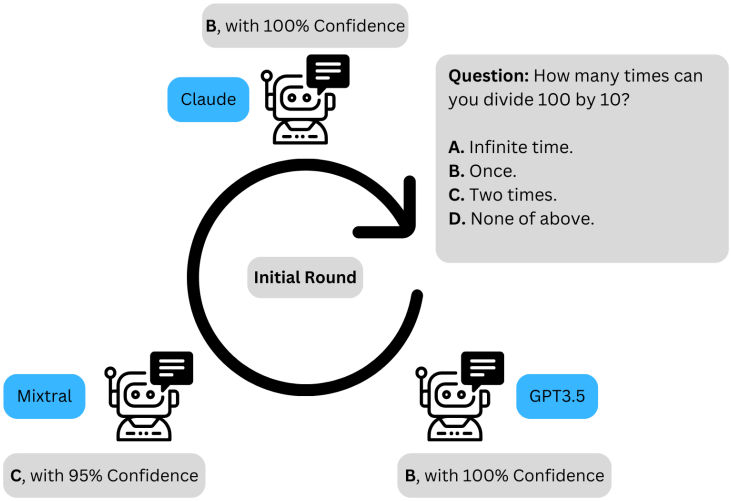

Figure 2: An Illustration of RECONCILE for Initial Round

Communication among multiple agents is fundamentally important in complex decision-making processes. Therefore, as our main strategy, we use the ReConcile technique (Chen et al., 2023), which generates answers by gathering the consensus of multiple models based on their confidence levels, to address these problems. To make this technique compatible with this type of dataset, we extend the application of ReConcile from yes/no questions to the BRAINTEASER questions. In this system, we apply the concept of a society of minds to multiple agents. For round table decision-making, we execute three phases: Initial Response Generation, Multi-Round Discussion, and Final Answer Generation on three language learning models: Mixtral8x7b (Jiang et al., 2024a), Claude [1], and GPT3.5 [2]. As illustrated in Figure 2, in each phase, we generate specific prompts (see Appendix B) for models to answer the question, along with their confidence level between 0 and 1. We then use their answers for the next round and derive an overall consensus answer for each round. The method that gave us our best result achieved a rank of 11 out of 33 for the sentence puzzles in the task leaderboard. Further details of our implementations are available through our GitHub repository. [3].

2 Background

2.1 Related Works

The exploration of reasoning abilities in large language models, lateral thinking, and common sense reasoning has been the focus of several studies in recent years. The BRAINTEASER is a novel task in this context, requiring a unique blend of these capabilities. In the paper (Zhang et al., 2022), foundational insights into the use of knowledge graphs for self-supervision in common sense reasoning tasks are provided. This work is particularly relevant as it demonstrates how external knowledge can significantly improve an LLM's ability to solve reasoning problems. Furthering the discussion on reasoning, LatEval (Huang et al., 2024) introduces an evaluation benchmark for LLMs based on lateral thinking puzzles. This process is similar to the method in solving the BRAINTEASER, which encourages models to elaborate on their reasoning, leading to improved performance. The paper RiddleSense (Lin et al., 2021) offers an analysis of how LLMs handle riddle questions that require linguistic creativity and common sense knowledge. This is directly linked to our approaches, where the ability of an LLM to use analogous examples influences its problem-solving effectiveness. Also, (Dou and Peng, 2022) investigates the inherent knowledge within language models and their ability to function in zero-shot common sense question answering tasks. The integration of external knowledge is particularly relevant to tasks requiring common sense and real-world information, underscoring the importance of knowledge retrieval in the context of the BRAINTEASER. MVP-Tuning (Huang et al., 2023) introduces a novel approach to knowledge retrieval using prompt tuning. This aligns with our aim in solving BRAINTEASER to evaluate the capacity of LLMs to handle questions that necessitate an understanding of the world as humans

[1] Available at https://claude.ai/ .
[2] Available at https://openai.com/ .
[3] Github Repository

perceive it. Lastly, ReConcile (Chen et al., 2023) and (Liang et al., 2023) both discuss the use of multiple LLMs to improve reasoning capabilities. These works highlight the potential of using a diverse set of models to solve complex tasks like the BRAINTEASER, further enriching the strategies for solving such tasks with AI systems.

2.2 Datasets

The organizers provide datasets for one language: English. As mentioned previously, the dataset consists of two categories: Sentence Puzzles and Word Puzzles. The task providers construct reconstruction versions of the original data in two parallel ways: Semantic Reconstruction and Context Reconstruction. This is done to ensure that the task evaluates lateral thinking ability rather than mere memorization. The Semantic variant reformulates the initial question while preserving its answer, whereas the Context variant retains the misleading commonsense assumption as is and modifies the question and its answer to fit a different situational context.

The dataset is split into two parts for the evaluation phase: train and test sets for each category. In the sentence puzzles category, the train set comprises 507-row samples, while the test set consists of 120-row samples. Similarly, in the word puzzles category, the train set contains 396-row samples, and the test set has 96-row samples. Each sample includes a question with its corresponding answer and three distractors. We utilize both word and sentence puzzle datasets during the training phase, but only the sentence puzzles dataset is used for zero-shot phases.

2.3 Evaluation Metrics

The accuracy metric is employed for evaluation as described in the task paper. Performance evaluation is conducted using two accuracy metrics: Instance-based Accuracy and Group-based Accuracy for Original, Semantic, and Context questions.

3 System overview

3.1 Preprocessing

In the fine-tuning phase, we employ two transformer-based models, BERT and RoBERTa, for multiple choice tasks. Both models are pre-trained on large text corpora. The input to these models is a sequence constructed by concatenating the question with each choice, separated by special tokens. This process is facilitated by the models' tokenizers, which convert the text into a format that the models can understand. For a given question "Q", and choices, the input to the models would be:

$$\text{Input}_i = \text{[CLS] Q [SEP]Choice}_i\text{[SEP]} \quad (1)$$

where "i" represents the index of the choice. Each sequence represents a different choice, and the models' understanding of the context and the choices allows them to predict the correct answer. The fine-tuning process adapts the models to this specific task, optimizing their parameters to minimize the difference between the predicted and actual answers.

3.2 Model Training

We utilize BERT-Base and RoBERTa-Large models, along with their respective tokenizers, for word embeddings in the multiple choice task, sourced from the Hugging Face library. These models are finetuned using the Hugging Face trainer. Initially, we load the models and establish a baseline on the test set for both sentence and word puzzles. Subsequently, each model undergoes finetuning with the default Hugging Face Cross-Entropy loss function for classification, and overall accuracy is computed as the metric using the same hyper-parameter configurations as detailed in Table 1.

Hyperparameter	Value
Learning Rate	1×10^{-5}
Optimizer	Adam
β_1, β_2	$0.9, 0.999$
Weight Decay	0.01
Batch Size	1
Loss Function	Cross-Entropy
Logging Steps	100
Evaluation Metric	Accuracy
Global Seed	255

Table 1: Hyperparameters Configuration

3.3 Chain of Thought Prompting

We use 6 LLMs for CoT zero-shot: Mixtral(8x7b), Claude, GPT3.5, Llama-2-70b (Touvron et al., 2023), OpenChat (Wang et al., 2023), and Microsoft Copilot [4]. We use graphical web page interfaces for Claude, GPT3.5(chatGPT), and Microsoft

[4]Available at https://copilot.microsoft.com/

Copilot (precise mode). We use the same prompt as the ReConcile initial round. Microsoft Copilot gives the best performance of this section.

3.4 ReConcile Round Table

Models make mistakes in one or more types of questions and cannot provide the correct answer on the first attempt. We need to ask them to pay attention to certain parts of the question or give hints to the model so it can provide the correct answer. To ensure human involvement is minimized and models can help each other, we have employed the ReConcile method. Using this approach, each model complements the other. The process of this system is as follows:

- **Initial Response Generation**: First, using an initial prompt, we ask each model to provide the answer to the question, provide a reason for the answer, and declare a confidence level between 0 and 1.
- **Multi-Round Discussion**: We give the responses, reasoning, and confidence levels of the three models, along with the initial prompt, as input to the models once again. This enables them to consider both the context of the question and the responses of the three models when making a selection.
- **Final Answer Generation.** In this stage, we initialize a weight for each of the 4 options of the question, and these weights are summed up with the confidence level of each model. Finally, the option with the highest weight is chosen as the correct option.

Let's denote the confidence of the model m_i for its selected choice c_j as $conf(m_i, c_j)$. Then, the total confidence of each choice can be calculated as:

$$\text{TC}(c_j) = \sum_{i=1}^{3} \text{conf}(m_i, c_j) \tag{2}$$

Where the sum is over all models that selected choice c_j. Finally, the choice with the highest total confidence is selected as the correct choice:

$$\text{c}_{\text{correct}} = \arg\max_{c_j \in C} TC(c_j) \tag{3}$$

This means that the correct choice is the one that maximizes the total confidence over all choices.

The notable point is that this method should be implemented by models that roughly have equal performance to grow together after several rounds. If a model has much lower performance compared to other models, its reasoning and confidence level may negatively affect others. For this reason, we performed this task on three models: Mixtral8x7b, GPT3.5, and Claude, which have almost similar accuracy in the initial round. This iterative process can be continued until all models reach a consensus and all agree on a specific option for the questions. We repeated this process for two discussion rounds.

4 Experiments and Results

4.1 Experimental Setup

The training and test sets of the sentence and word puzzle datasets are used with a split of 0.8 and 0.2, respectively for fine-tuning. Additionally, we utilize Google Colab's T4 GPU with the hyperparameters as shown in Table 1. For zero-shot prompting, we use the 120-row test set from the sentence puzzles.

We leverage HuggingChat [5] for Mixtral8x7b, OpenChat, and Llama2-70b. Furthermore, we utilize the official web interface of Claude, Microsoft Copilot, and GPT3.5. Results for each model and their corresponding training codes are available in the GitHub repository.

4.2 Results

As illustrated in Table 2 for the sentence puzzles and Table 3 for the word puzzles, we present the performance of BERT and RoBERTa Large in both their base and fine-tuned versions.[6] We load the best model based on Overall Accuracy at the end of each training. The best performance is achieved by RoBERTa for both sentence and word puzzles. As illustrated in Appendix A For every 100 training steps, we log the overall accuracy for two models.

The submission scores computed by the task organizer for CoT zero-shot are available in Table 4. Among these LLMs, Microsoft Copilot achieves the best performance. The success of LLMs in responding to these questions depends on the model's ability to recognize that these questions are tricky and that it doesn't need to provide logical reasoning in many cases; the question merely plays with words. Microsoft Copilot understood this phenomenon in many questions. However, it

Table 3: Models' Performance on Word Puzzles

also made mistakes in several questions. For example, consider Appendix C for an illustration.

For Reconcile, the results of each model in every round, as well as the consensus reached in each round, are presented in Table 5. In the table, we observe that Claude achieves the highest overall accuracy among the models in each round. Nearly every model in the Reconcile system either improves or maintains its best performance in overall accuracy with each round. This suggests that they are all capable of making informed decisions based on the reasoning provided by all agents during the discussion rounds. At the conclusion of round 2, the consensus overall accuracy stands at 0.758, which is 0.3 to 0.5 points higher than the initial round results of all three models. Furthermore, we note that the consensus result improves by approximately 1 percent from the initial round to round 1, and by approximately 0.8 percent from round 1 to round 2. This indicates that after several rounds, the models converge and reach a consensus on the questions. See Appendix D. Also for an example, see Appendix E

5 Conclusion

In this paper, we present our approach to SemEval 2024 Task 9, BRAINTEASER: A Novel Task Defying Common Sense, which challenges models to think creatively beyond conventional reasoning. Through fine-tuning BERT and RoBERTa models, as well as employing zero-shot prompting techniques using various large language models, we achieved notable performance improvements. Particularly, Microsoft Copilot performs the best without being taught beforehand, showing it understands the tricky task really well. Furthermore, our ReConcile Round Table method demonstrates the efficacy of collaborative decision-making among models, leading to a progressive improvement in overall accuracy across multiple rounds of discussion.

C Copilot Examples

As illustrated in Table 6, the model correctly answers the first three samples but provides an incorrect response for the fourth. This model lacks accuracy in calculation questions, often correctly presenting the equation but solving it inaccurately. Additionally, in some cases, the model accurately formulates the equation and even solves it correctly. However, when the desired option is not among the choices, instead of choosing the 'None of the above' option, it attempts to reinterpret the question in a way that one of the numerical options becomes correct.

D Reconcile Convergence

Table 7 indicates the number of questions to which all three models provide the same answer choice in each round. This suggests that after each round, the models achieve a relative convergence.

Question	Answer
How can you toss a fragile glass ball against a sturdy brick wall from a distance without shattering it? A. No problem, because sturdy bricks are very hard to crack B. You need to throw the glass ball hard. C. You need to throw the glass ball gently. D. None of above.	Solution: A: No problem, because sturdy bricks are very hard to crack Reasoning: The question is a play on words. It's not the glass ball that we're worried about cracking, it's the brick wall. And brick walls are indeed very hard to crack.
Ana's school has 4 students in Alaska: Maria, James, Jonghyun. What is the name of other student? A. Mark. B. Ana C. Michael D. None of above.	Solution: B: Ana. Reasoning: The question states "Ana's school has 4 students in Alaska: Maria, James, Jonghyun." So, Ana is the fourth student.
In a house, there are three major rooms. The first is stuffed with cash. The second is stuffed with crucial documents. The third is stuffed with jewels. One day, all of these rooms caught fire. Which room did the cops initially put out the fire? A. The one with jewelry. B. The one with important papers. C. The one filled with money. D. None of above.	Solution: D: None of above. Reasoning: The question is a play on words. It's not the cops' job to put out fires, it's the firefighters' job.
During a 5-day competition, a professional fisherman caught 30 fish. He caught three more fish each day than the day before. On the first day, how many fish did the fisherman catch? A. Two B. One C. Three D. None of above	Solution: A: Two. Reasoning: If the fisherman caught 30 fish in 5 days, and each day he caught three more fish than the day before, we can set up the equation: x + (x+3) + (x+6) + (x+9) + (x+12) = 30. Solving for x gives us x = 2. So, the fisherman caught two fish on the first day.

Table 6: Microsoft Copilot Answers to Some Questions

Round	Question Count
Initial Round	74
Round 1	88
Round 2	104

Table 7: ReConcile Models Convergence

E Reconcile Example

The iterative process of answering the question below is illustrated in Table 8.

If a boat is parked in a marina and tied to a nearby station, how did its owner found the boat a couple of hours later in the middle of the ocean?

A. The station wasn't fixed in the marina

B. The dolphins untied the knots.

C. The waves were powerful, which pushed the boat and the marina together.

D. None of above.

Model	Solution	Reasoning	Confidence
Initial Round			
GPT3.5 Solution	A	If the station (presumably a mooring or dock) wasn't securely fixed in the marina, it could have drifted into the ocean, taking the boat with it.	1.0
Claude Solution	B	This explains how the boat ended up drifting into the ocean after being tied up.	0.7
Mixtral Solution	A	If the station wasn't fixed properly in the marina, it's possible that the boat became loose and drifted away into the ocean due to wind or tidal influences. Over time, the gap between the boat and the dock could increase, eventually pushing the boat further out into deeper waters.	0.85
Round 1			
GPT3.5 Solution	A	If the station to which the boat was tied was not properly fixed in the marina, it could have drifted away into the ocean, taking the boat with it.	0.9
Claude Solution	A	I agree with Agents two and three that an unsecured floating station drifting away best explains how the boat ended up adrift in the ocean.	1.0
Mixtral Solution	A	While all options are plausible scenarios for how the boat might have ended up in the ocean, option A provides the most likely explanation given our current understanding of physics and marine environments. Both agent two and agent three suggest that if the station was not fixed properly, it could have been moved by external forces such as wind or tide, thereby pulling the boat along with it. In contrast, option C assumes that the waves were strong enough to move both the marina and the boat simultaneously, an event that seems less probable than the movement of a single object like the station. Option B attributes the boat's displacement to intelligent behavior on part of dolphins, which lack the necessary appendages to manipulate rope knots underwater. Therefore, we can infer that the station must have been unsecured, allowing it to drift out into the ocean while carrying the boat with it.	0.95
Round 2			
GPT3.5 Solution	A	If the station to which the boat was tied was not properly fixed in the marina, it could have drifted away into the ocean, taking the boat with it.	0.95
Claude Solution	A	I agree with Agents two and three that an unsecured floating station drifting away provides the most logical explanation for how the boat ended up adrift.	1.0
Mixtral Solution	A	All three agents came to the conclusion that option A is the most likely scenario because it's more feasible that an unsecured floating station would be moved by external forces such as wind or tide, rather than assuming that powerful waves managed to push the marina and the boat together at once, or attributing the boat's displacement to intelligent behavior from dolphins who wouldn't possess the physical capability to manipulate rope knots underwater.	0.98

yangqi at SemEval-2024 Task 9: Simulate Human Thinking by Large Language Model for Lateral Thinking Challenges

Qi Yang, Jingjie Zeng, Liang Yang*, Hongfei Lin
School of Computer Science and Technology, Dalian University of Technology, China
{2665643739, jjtail}@mail.dlut.edu.cn, {liang, hflin}@dlut.edu.cn

Abstract

This paper describes our system used in the SemEval-2024 Task 9 on two sub-tasks, BRAINTEASER: A Novel Task Defying Common Sense. In this work, we developed a system SHTL, which means simulate human thinking capabilities by Large Language Model (LLM). Our approach bifurcates into two main components: Common Sense Reasoning and Rationalize Defying Common Sense. To mitigate the hallucinations of LLM, we implemented a strategy that combines Retrieval-augmented Generation (RAG) with the the Self-Adaptive In-Context Learning (SAICL), thereby sufficiently leveraging the powerful language ability of LLM. The effectiveness of our method has been validated by its performance on the test set, with an average performance on two subtasks that is 30.1 higher than ChatGPT setting zero-shot and only 0.8 lower than that of humans.

1 Introduction

Human reasoning processes comprise two types of thinking: vertical and lateral. Vertical thinking, also known as linear, convergent, or logical thinking, is a sequential analytical process that is based on rationality, logic, and rules. Meanwhile, lateral thinking is a divergent and creative process that involves looking at a problem from a new perspective and defying preconceptions.The success of language models has inspired the natural language processing community to attend to tasks that require implicit and complex reasoning, relying on human-like Common Sense mechanisms. While such vertical thinking tasks have been relatively popular, lateral thinking puzzles have received little attention. Recently, the team led by Yifan Jiang proposed Task 9 for SemEval-2024, named "BRAINTEASER: A Novel Task Defying Common Sense," (Jiang et al., 2023)(Jiang et al., 2024) aimed at addressing this gap, it was a task on a pure English dataset, testing models' ability to demonstrate lateral thinking and challenge default common sense associations. This shared task explores methods to improve models' lateral thinking capabilities.

In this paper, we introduce our entries into two BRAINTEASE subtasks. Inspired by recent research on using LLM to design Agents (Xi et al., 2023), our approach leverages an LLM to architect a system that adeptly simulates the intricacies of human divergent thinking processes. Specifically, our model capitalizes on the advanced linguistic capabilities inherent within the LLM, thereby obviating the need for supplementary training protocols. This strategy enables our system to demonstrate commendable performance across both targeted subtasks.

Furthermore, we also focus on the issue of hallucinations in LLM. LLM can sometimes generate erroneous or highly inaccurate responses. The tendency for LLM to produce these hallucinations becomes particularly noticeable when confronted with such phenomena in our investigations. To solve this problem, we draw inspiration from RAG (Lewis et al., 2020) strategies. We also discover that the performance of LLM can vary greatly depending on the specific prompt words used. As a result, we develop several sets of prompt words and ultimately select the set that achieved the highest performance on our validation tests.

Our method achieves competitive results on SemEval-2024 task 9, ranking well on all tasks, especially on more fine-grained classification tasks. Our method far exceeds the performance of ChatGPT, and on the officially provided test set, there is only a slight gap with the results of human evaluation.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 233–238

Question	Choice
A man shaves everyday, yet keeps his beard long.	He is a barber. He wants to maintain his appearance. He wants his girlfriend to buy him a razor. None of the above.
What part of London is in France?	The letter N. The letter O. The letter L. None of the above.

Table 1: Example of sentence puzzle and word puzzle.

Adversarial Strategy	Question	Choice
Orignal	A man shaves everyday, yet keeps his beard long.	He is a barber. He wants to maintain his appearance. He wants his girlfriend to buy him a razor. None of the above.
Semantic Reconstruction	A man preserves a lengthy beard despite shaving every day.	He is a barber. He wants to maintain his appearance. He wants his girlfriend to buy him a razor. None of the above.
Context Reconstruction	Tom attends class every day but doesn't do any homework.	He is a teacher. He is a lazy person. His teacher will not let him fail. None of the above.

Table 2: Example of semantic reconstruction and context reconstruction.

2 Task Description

The BRAINTEASER QA task consists of two subtasks, sentence puzzles and word puzzles, as shown in Table 1. It requires awareness of common sense "default values" and covering them with unconventional thinking that distinguishes these default values from hard constraints.

Sentence Puzzle: Sentence-type brain teaser where the puzzle defying common sense is centered on sentence snippets.

Word Puzzle: Word-type brain teaser where the answer violates the default meaning of the word and focuses on the letter composition of the target question

It is worth noting that both tasks include an adversarial subset, created by manually modifying the original brain teasers without changing their latent reasoning path. In order to accurately evaluate the reasoning ability of our proposed system and ensure that it truly possesses lateral thinking ability, this task constructs adversarial versions of the original data in two ways:

Semantic Reconstruction: Rephrasing the original question without changing the correct answer and the distractors, as showing in table 2.

Context Reconstruction: Keeping the original reasoning path but changing both the question and the answer to describe a new situational context.

Finally, the task also proposes two evaluation metrics to ensure the accuracy of the system in both the overall test set and each adversarial subset. These two evaluation indicators are described as follows:

Instance-based Accuracy: Consider each issue (original/adversarial) in the test set as a separate instance to test the overall accuracy of the system's output on the test set.

Group-based Accuracy: Each question and its associated adversarial instances form a group, and a system will only receive a score of 1 when it correctly solves all questions in the group.

3 Methodology

We propose a system that simulates human lateral thinking patterns, which consists of two stages. During the first stage, our system engages in a simulation of how humans typically read and interpret Brainteaser question stems. The aim here is to check the question stems meticulously, intending to pinpoint specific elements that appear to contravene established common sense norms. The second stage is to combine the parts that violate common sense with four options for thinking, find the option that can "resolve" the parts that defy common sense, and use it as the final answer. The overall architecture of the system is shown in Figure 1.

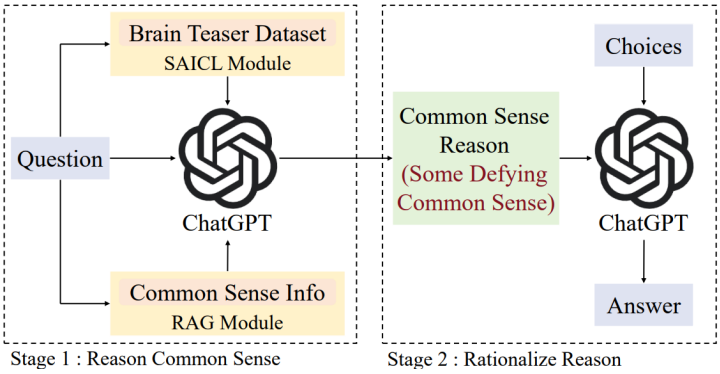

Figure 1: The overall architecture of our proposed system

3.1 Common Sense Reason

In this stage, we use a LLM as the core to conduct common sense reasoning. We input Brainteaser's problem directly into LLM and use LLM's powerful language ability to infer the unreasonable aspects of the problem. At the same time, in order to suppress the hallucination problem of LLM, we design two modules, namely the RAG module and the SAICL module.

3.1.1 Retrieval Augmented Generation

The RAG module integrates deep learning technologies such as Retrieval and Generation. This module is designed to enhance the LLM's understanding of input questions by retrieving relevant information from a vast array of unstructured documents as well as structured knowledge graphs, specifically for Brainteaser questions, in order to produce more accurate, richer, and more relevant Defying Common Sense Reasoning. The workflow of the RAG module includes the following two steps:

Retrieval Phase: Retrieve relevant information from a large number of unstructured documents and structured knowledge graphs according to the given Brainteaser problem.

Integration Phase: The retrieved information snippets are then integrated and merged to be effectively utilized by the generation model. This includes reordering, filtering, or encoding the retrieval results to better suit the subsequent generation tasks.

3.1.2 Self-Adaptive In-Context Learning

We are inspired by Wu et al. (Wu et al., 2023) and develop a SAICL module.The SAICL module adaptively selects better In Context example data from the training set for each Brainteaser problem to improve the effectiveness of In Context Learning. The workflow of the SAICL module also consists of two phases:

Selection Phase: Using the top-K method, search for the K question and its options and answers that are closest to the Brainteaser question in the semantic space.

Sorting Phase: Using the Minimum Description Length (MDL) principle to find an organization that minimizes the compressed encoding length of the output given the input and context. This can be represented by equation (1):

$$c^* = \arg\min_{c \in \mathbf{C}} L_\theta(y \mid c, \mathbf{x}) + L(\theta), \quad (1)$$

where each c represents one possible organization of examples. $L_\theta(y \mid c, \mathbf{x})$ is the code-length required to compress and transmit testing label y given the organization c and testing input $\mathbf{x}$. $L(\theta)$ is the code-length required to describe the model, and it can be calculated in the following equation (2):

$$L_\theta(y \mid c, \mathbf{x}) \approx -\mathbb{E}_{q(y_i|Y)} \log_2 p\left(y_i \mid c, \mathbf{x}\right), \quad (2)$$

where $q\left(y_i \mid Y\right)$ is the prior of y_i among all possible labels Y. Through the above calculation, further select a suitable subset from the K examples selected in the previous phase as the context examples for Brainteaser, combine them with the output of the RAG module, and input them into LLM.

By combining these two modules with the powerful language capabilities of LLM, we can derive reasonable yet contradictory common sense reasoning from the Brainteaser problem. For example, when our question is: "How could a cowboy ride into town on Friday, stay two days, and ride out on Wednesday?" We will gain some common sense reasoning as follows:

- Cowboy rides into town on Friday.
- Cowboy stays in town for two days.
- Cowboy rides out on Wednesday.
- Sunday is two days after Friday.

In this way, we can clearly see the defying common sense part in the Brainteaser question.

3.2 Rationalize Defying Common Sense

At this stage, we combine the conflicting reasoning obtained in the previous stage with the first three options of Brainteaser. This fusion is achieved through the careful design of specific prompt words, which are crafted with the express purpose of evaluating whether any of these three preliminary options possess the capability to logically reconcile the previously identified conflicting reasoning.

For example, in the example given in section 3.1, the option: "His horse is named Wednesday" can effectively solve the Defying Common Sense part inferred from the Common Sense Reason. So it is the correct answer.

But, it is crucial to highlight that in instances where none of the first three options succeeds in producing a satisfactory rationale that effectively addresses the contradictory reasoning, our model is programmed to adopt a fallback strategy. In such scenarios, the model is designed to automatically select the fourth option, aptly labeled "None of above". This decision-making protocol ensures that our model retains the flexibility to understand situations where the presented options fail to provide a coherent resolution to the discrepancies identified, thereby maintaining the integrity of our analytical process. This strategic approach underscores the meticulousness with which our system evaluates the available options, ensuring a comprehensive and reasoned determination of the most appropriate response.

4 Experimental Setup

In this section, we introduce our system settings, and baseline model.

4.1 System Settings

In the RAG module of our system SHTL, we initially remove the stop-words from the original Brainteaser question, then use ConceptNet to retrieve the meanings and relationships of the remaining parts, followed by deduplication and sorting based on relevance to the question. Subsequently, we design appropriate prompt words to concatenate them. In the SAICL module, during the search phase, we utilize the Bert model to obtain feature vectors for each question in the training set. In the vector space, we compare these vectors with the target question's feature vector using cosine similarity, selecting the ten most similar entries. During the ranking phase, we follow the method of the original paper (Wu et al., 2023),randomly select eight entries, extracting them sixteen times, and then calculate the score for each combination obtained from these extractions according to Section 3.1.2. We then select the best combination and use appropriate prompts to link them. At the end of the first stage, we use appropriate prompts to combine the results from both the RAG and SAICL modules with the original Brainteaser question and input them into ChatGPT, obtaining Defying Common Sense. This is then combined with the options of the Brainteaser question using appropriate prompts and input into ChatGPT to derive the best answer.

4.2 Baseline

Our baseline models are categorized into three types: one consists of Large Language Models with a minimal number of prompts, another incorporates models endowed with common sense knowledge, and finally, human evaluation.

Prompted Models:

We evaluate the instruction-finetuned LLMs in few-shot setting:

• **ChatGPT** It is one of the publicly available state-of-the-art Large Language Models in the GPT series (Brown et al., 2020).

• **T0** (Sanh et al., 2022) It is an LLM trained through multi-task instruction tuning, possessing strong zero-shot generalization capabilities.

• **FlanT5** (Chung et al., 2022) It is an enhanced version of T5 (Raffel et al., 2020).

To ensure a fair comparison with human performance, when prompting ChatGPT in a zero-shot setting, we add a description indicating that the question is a brain teaser requiring creative thinking for its resolution. For the other models, we employ the same instruction templates found in their training datasets.

Common Sense Models:

To understand the impact of common sense knowledge on our task, we evaluate the following models enhanced with common sense:

• **RoBERTa-L (CSKG)** (Ma et al., 2021) It is a model fine-tuned on synthetic QA pairs generated from various Common Sense Knowledge Graphs (CSKG) (Ilievski et al., 2021).

• **CAR**(Wang et al., 2023) It is a model finetuned in a similar pipeline as (Ma et al., 2021) but with enhanced negative sampling strategy and reportedly superior performance.

For reference, we also include the native RoBERTa model (Liu et al., 2019) to understand

Category	Model	Instance-based			Group-based		overall
		Original	Semantic	Context	Ori & Sem	Ori & Sem & Con

Table 3: Main zero-shot results over two BRAINTEASER subtasks across all models in all metrics, "Ori" is Original, "Sem" is Semantic and "Con" is Context. The best performance among all models is in bold.

the impact of common sense knowledge.

Human Evaluation:

We recruit four volunteers who are completely unfamiliar with our task to help us test the test set, and take the average of their results as the human test result.

5 Results and Analysis

The final results of our experiments are presented in Table 3. As can be seen from Table 3, the outcomes of the majority of Prompted Models as well as Common Sense Models are essentially random, and some are even below random performance. It is noteworthy to mention the ChatGPT model, which achieves a score of 62.7 in Sentence Puzzles and 53.5 in Word Puzzles, making it the best-performing model aside from Humans and our system, SHTL. From the evaluation results of Humans, it is evident that for both Sentence Puzzles and Word Puzzles, the Human Evaluation scores for Ori & Sem and Ori & Sem & Con were identical, indicating that human lateral thinking capabilities are remarkably stable and unaffected by the Adversarial Subset. Finally, our proposed system, SHTL, can surpass Human performance in most categories, with an average score in the two subtasks that is only 0.8 lower than that of Humans. This significantly exceeds the performance achieved using ChatGPT alone, suggesting that the latent linguistic capabilities of LLMs need to be further explorer appropriately.

6 Conclusion

In this paper, we introduce a lateral thinking system named SHTL, designed to simulate human lateral thinking capabilities for solving brain teaser questions. The system is divided into two stages. The first stage focuses on common sense reasoning, primarily comprised of the RAG module and the SAICL module, which are interconnected through appropriate prompt words to generate instances of defying common sense. The second stage involves identifying the correct options to rationalize the defying common sense generated in the previous stage. This system achieves competitive results, significantly outperforming the ChatGPT setting in a zero-shot scenario, and its performance on the test set is close to that of human evaluation.

BadRock at SemEval-2024 Task 8: DistilBERT to Detect Multigenerator, Multidomain and Multilingual Black-Box Machine-Generated Text

Marco Siino
Department of Electrical, Electronic
and Computer Engineering
University of Catania
Italy
marco.siino@unipa.it

Abstract

The rise of Large Language Models (LLMs) has brought about a notable shift, rendering them increasingly ubiquitous and readily accessible. Across diverse platforms such as social media platforms, news outlets, educational platforms, question-answering forums, and even academic domains, there has been a notable surge in machine-generated content. Recent iterations of LLMs, exemplified by models like ChatGPT and GPT-4, exhibit a remarkable ability to produce coherent and contextually relevant responses across a broad spectrum of user inquiries. The fluidity and sophistication of these generated texts position LLMs as compelling candidates for substituting human labour in numerous applications. Nevertheless, this proliferation of machine-generated content has raised apprehensions regarding potential misuse, including the dissemination of misinformation and disruption of educational ecosystems. Given that humans marginally outperform random chance in discerning between machine-generated and human-authored text, there arises a pressing imperative to develop automated systems capable of accurately distinguishing machine-generated text. This pursuit is driven by the overarching objective of curbing the potential misuse of machine-generated content. Our manuscript delineates the approach we adopted for participation in this competition. Specifically, we detail the fine-tuning and the use of a DistilBERT model for classifying each sample in the test set provided. Our submission is able to reach an accuracy equal to 0.754 in place of the worst result obtained at the competition that is equal to 0.231.

1 Introduction

Large language models (LLMs) are increasingly pervasive and readily accessible, leading to a surge in machine-generated content across a multitude of platforms (Fang et al., 2024). LLMs have demonstrated an impressive ability to generate highly fluent responses to diverse user queries. The eloquent nature of these generated texts renders LLMs appealing candidates for replacing human labour across various scenarios. However, this widespread adoption has sparked concerns regarding the potential misuse of such texts, including the dissemination of misinformation in journalistic contexts and disruptions within educational systems (Tang et al., 2023).

The increasing adoption of Transformer-based architectures in academic research has also been bolstered by various methodologies showcased at SemEval 2024. These methodologies tackle diverse tasks and yield noteworthy findings. For instance, at the Task 2 (Jullien et al., 2024), where to address the challenge of identifying the inference relation between a plain language statement and Clinical Trial Reports is used T5 (Siino, 2024b); Task 4 (Dimitrov et al., 2024) and Task 10 (Kumar et al., 2024) where is employed a Mistral 7B model to detect persuasion techniques in memes (Siino, 2024a) and to perform Emotion Recognition in Conversation (ERC) within Hindi-English code-mixed conversations respectively (Siino, 2024c).

Despite human evaluators marginally outperforming random chance in distinguishing between machine-generated and human-written text (Mitchell et al., 2023), the need for automatic methods to detect machine-generated content has become increasingly urgent. This necessity prompted the organizers of Task 8 at SemEval-2024 to focus on developing such methods with the aim of mitigating potential misuse.

Previous efforts in detecting machine-generated text have been made. For instance, (Guo et al., 2023) devised methods to discern whether a text was generated by ChatGPT or authored by a human across various domains. However, these endeavours primarily concentrated on the outputs of ChatGPT.

The RuATD Shared Task 2022 tackled artificial

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 239–245

text in Russian, spanning models for paraphrase generation, text simplification, text summarization, and machine translation (Shamardina et al., 2022). However, their emphasis was on models fine-tuned for specific tasks or domains, which differs from the focus of the Task 8. While (Mitchell et al., 2023) detected outputs of various LLMs such as GPT-2, OPT-2.7, Neo-2.7, GPT-J, and NeoX, it's pertinent to note that these models have become obsolete with the advent of GPT-3 and even GPT-4. The Task 8 hosted at SemEval 2024 was built upon the previous work discussed in (Wang et al., 2023b).

To address these objectives, there is an ongoing demand for automated tools capable of extracting and categorizing data, facilitating the classification with recent NLP models. Recent advancements in the machine and deep learning architectures have spurred heightened interest in Natural Language Processing (NLP). Substantial endeavours have been directed towards devising techniques for the automated identification and categorization of textual content accessible on the internet today. In the literature, to perform text classification tasks, several strategies have already been proposed. In the last fifteen years, some of the most successful strategies have been based on SVM (Colas and Brazdil, 2006; Croce et al., 2022), on Convolutional Neural Network (CNN) (Kim, 2014; Siino et al., 2021), on Graph Neural Network (GNN) (Lomonaco et al., 2022), on ensemble models (Miri et al., 2022; Siino et al., 2022) and, recently, on Transformers (Vaswani et al., 2017; Siino et al., 2022b).

Participants in SemEval-2024 Task 8 could compete for three Subtasks better described in the rest of this paper. However, our team participated in the first Subtask only. The first Subtask (i.e., Subtask A) is the Binary Human-Written vs. Machine-Generated Text Classification one: Participants are tasked with determining, based on a given full text, whether it is human-written or machine-generated. There are two tracks for Subtask A: monolingual (only English sources) and multilingual.

The subsequent sections of the paper are structured as follows: Section 2 offers background information on Task 6, held at SemEval-2024. In Section 3, we outline the approach introduced in this study. Section 4 delves into the specifics of the experimental setup employed to reproduce our findings. The outcomes of the official task and relevant discussions are presented in Section 5. Finally, Section 6 concludes our study and suggests avenues for future research.

We make all the code publicly available and reusable on GitHub[1].

2 Background

The task 8 hosted at SemEval-2024 (Wang et al., 2024) is made of three different Subtasks.

- Subtask A. Binary Human-Written vs. Machine-Generated Text Classification: Given a full text, determine whether it is human-written or machine-generated. There are two tracks for Subtask A: monolingual (only English sources) and multilingual.
- Subtask B. Multi-Way Machine-Generated Text Classification: Given a full text, determine who generated it. It can be human-written or generated by a specific language model.
- Subtask C. Human-Machine Mixed Text Detection: Given a mixed text, where the first part is human-written and the second part is machine-generated, determine the boundary, where the change occurs.

An example from the original dataset - better described in (Wang et al., 2023b) - is the one that follows.

Given the prompt:

> *"Write a Wikipedia article with the title Ẅilliam Whitehouse̵, the article should at least have 250 words."*

While the original human-written version is available online[2], the output produced by a ChatGPT 3.5 Turbo was:

> *"William Whitehouse was a 19th-century British engineer and inventor who made significant contributions to the field of hydraulics. He was born in 1825 in Birmingham, England, where he grew up and eventually became an apprentice at the Soho Foundry. This apprenticeship instilled in him a passion for steam engines and hydraulics that would shape his future career. After completing*

[1] https://github.com/marco-siino/SemEval2024/

[2] https://en.wikipedia.org/wiki/William_Whitehouse

his apprenticeship, Whitehouse worked for the Birmingham Water Works Company as an engineer. It was during this time that he began experimenting with hydraulic machinery and invented several innovative devices. In 1850, he developed the first hydraulic press, which was able to exert immense amounts of pressure and became widely used in industrial manufacturing processes. He also created hydraulic lifts for raising and lowering heavy loads and hydraulic cranes for lifting and moving heavy objects. Whitehouse's inventions revolutionized manufacturing and construction industries and helped to increase productivity and efficiency. In addition to hydraulic machinery, he also worked on steam engines and locomotives, improving their performance and reliability. He was regarded as an expert in his field and wrote several papers on hydraulic engineering that were widely read and respected. Whitehouse's achievements did not go unnoticed by the scientific community, and he was awarded the Royal Society's prestigious Telford Medal in 1875. He also became a fellow of the Royal Society and was elected to the Institution of Civil Engineers and the Institution of Mechanical Engineers. Despite his success, Whitehouse remained humble and dedicated to creating innovative and practical solutions to engineering problems. He passed away in 1905, leaving behind a legacy of groundbreaking hydraulic inventions that continue to play a vital role in modern manufacturing and construction industries."

3 System Overview

Even if it has already been proved that the Transformers are not necessarily the best option for any text classification task (Siino et al., 2022a), depending on the goal, some strategies like domain-specific fine-tuning (Sun et al., 2019; Van Thin et al., 2023), or data augmentation (Lomonaco et al., 2023; Mangione et al., 2022; Siino et al., 2024a) can be beneficial for the considered task.

However, to address the Task 8 hosted at SemEval-2024 we employed a zero-shot learning strategy (Chen et al., 2023; Wahidur et al., 2024), making use of DistilBERT (Sanh et al., 2020), fine-tuned on the SST-2 dataset (Socher et al., 2013).

DistilBERT, akin to its larger counterparts (i.e., BERT), exhibits commendable performance across a diverse array of tasks when fine-tuned. While prior research predominantly delved into distillation techniques for crafting task-specific models, the distillation approach in this case harnesses knowledge distillation during the pre-training phase. DistilBERT demonstrate the feasibility of reducing the size of a BERT model by 40%, while retaining 97% of its language understanding prowess and achieving 60% increase in speed. To harness the inductive biases inherent in larger models during pre-training, a triple loss mechanism is introduced with this model. This mechanism combines language modelling, distillation, and cosine-distance losses. The compact, expedited, and resource-efficient model not only streamlines the pre-training process but also showcases its potential for on-device computations through a proof-of-concept experiment and comparative on-device analysis.

The Stanford Sentiment Treebank stands as the inaugural corpus equipped with fully labeled parse trees, facilitating comprehensive exploration of the compositional effects of sentiment in language. It comprises 11,855 individual sentences culled from film reviews. Leveraging the Stanford parser, the corpus encompasses a total of 215,154 unique phrases, each annotated by three human evaluators. This novel dataset affords an opportunity to delve into the intricacies of sentiment analysis and capture nuanced linguistic phenomena. Numerous examples within the corpus exhibit distinct compositional structures. The granularity and breadth of this dataset are poised to empower the community in training compositional models grounded in supervised and structured machine learning methodologies. While extant datasets primarily focus on document and chunk labelling, there remains a pressing need to enhance sentiment capture from concise remarks, such as those found in Twitter data.

Utilizing DistilBERT trained on the SST Stanford dataset for detecting human or AI-generated text holds significant promise due to its nuanced understanding of sentiment and context. By leveraging DistilBERT's fine-grained sentiment analysis capabilities, coupled with its proficiency in discerning contextual nuances, the model we used is supposed to effectively distinguish between human-

generated and AI-generated text. The SST dataset, annotated for human sentiments classification task, enables DistilBERT to grasp the subtleties of human language, making it adept at identifying deviations indicative of AI-generated content. Moreover, fine-tuning DistilBERT on this dataset enhances its sensitivity to linguistic cues that differentiate human-authored texts from those generated by AI algorithms, thereby offering a robust solution for text authenticity verification in various applications, including misinformation detection, content moderation, and forensic linguistics.

In this study, we employed a fine-tuning approach to enhance the performance of DistilBERT, initially trained on the SST dataset, for the task of distinguishing between human and AI-generated text. The fine-tuning process involved training the model for three epochs on the provided training set, utilizing a portion of the data for validation. Specifically, we partitioned 20% of the training set samples to form a validation set, crucial for assessing the model's performance and preventing overfitting. After completing the fine-tuning process, we systematically evaluated the model's performance across the three epochs on the validation set. Subsequently, we selected the tuned version of the model that exhibited superior performance, as determined by its validation set accuracy. This validation methodology ensures the reliability and generalization capability of the fine-tuned DistilBERT model for the targeted task of differentiating between human and AI-generated text.

In a recent study (Siino et al., 2024b), has been shown that the contribution of preprocessing for text classification tasks is generally not impactful when using Transformers. More specifically, the best combination of preprocessing strategies is not very different from doing no preprocessing at all in the case of Transformers. For these reasons, and to keep our system highly fast and computationally light, we have not performed any preprocessing on the text.

4 Experimental Setup

We implemented our model on Google Colab. The library we used comes from HuggingFace[3] and is the uncased version of DistilBERT specifically trained on the above-mentioned SST2 dataset [4]. We did perform a three-epochs additional fine-tuning, before generating the prediction on the unlabelled test set. This model is versatile and can serve as a foundational tool for topic classification tasks. While it can function as a raw model for masked language modelling or next sentence prediction, its primary utility lies in its adaptability for fine-tuning on downstream tasks. Users can explore the model hub to discover fine-tuned versions tailored for specific tasks beyond its original scope. As already mentioned, all of our code is available on GitHub.

5 Results

Given the binary nature of the classification task, the organizers proposed *Accuracy* as the evaluation metric to be considered for the final ranking. The accuracy is defined in the Equation 1. Where TP stands for the number of correctly predicted right answers, FP stands for the number of wrongly predicted right answers, and FN stands for the right answers wrongly predicted as wrong answers.

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \quad (1)$$

In Table 1, we present the outcomes derived from our methodology. They are the same results publicly availble on the official final ranking shown on the official task page[5] and on CodaBench[6].

Compared to the best performing models, our simple approach exhibits some room for improvements. It is worth notice that required no further pre-training and the computational cost to address the fine-tuning stage is manageable with the free online resources offered by Google Colab. However, even with the low effort required, it is possible to achieve interesting results with our proposed approach. Out of the 137 participants, our approach, based on the use of a fine-tuned version of DistilBERT, is able to rank between the position 68 and 69 in the final ranking.

6 Conclusion

This paper presents the application of a DistilBERT-model for addressing the Task 8 at SemEval-2024.

TEAM NAME	Accuracy
safeai (1)	0.969
comp5 (2)	0.961
halwhat (3)	0.961
baseline (19-20)*	0.885
DistilBERT (68-69)*	0.754
saibewaraditya (137)	0.231

Table 1: Comparing performance on the test set. In the table are shown the results obtained by the first three teams, by the last one and by our approach. In parentheses is reported the position in the official final ranking. Our approach is not ranked in the official final ranking, but the score obtained ranks between the positions 68 and 69.

For our submission, we decided to fine-tune a pre-trained Transformer. The model was used to perform a sequence classification task to detect if a piece of text is written by a human or by a generative model. The task is challenging, and there is still opportunity for improvement, as can be noted looking at the final ranking. Possible alternative approaches to our can include utilizing the few-shot capabilities or also the use of other models like Llama and T5, eventually using further data, or directly integrating other samples from the training and from the development sets. Further improvements could be obtained with a fine-tuning and modelling the problem as a text classification task. Furthermore, given the interesting results recently provided on a plethora of tasks, also other few-shot learning (Wang et al., 2023a; Maia et al., 2024; Siino et al., 2023; Meng et al., 2024) or data augmentation strategies (Muftie and Haris, 2023; Tapia-Téllez and Escalante, 2020; Siino and Tinnirello, 2023) could be employed to improve the results. Looking at the final ranking, our simple approach exhibits some room for improvements. However, it is worth notice that it has required no further pre-training and the computational cost to address the task is manageable with the free online resources offered by Google Colab.

Acknowledgments

We extend our gratitude to the anonymous reviewers for their insightful comments and valuable suggestions, which have significantly enhanced the clarity and presentation of this paper.

Abstract

This work participates in SemEval 2024 Task 1 on Semantic Textural Relatedness (STR) in Track A (supervised regression) in two languages, English and Moroccan Arabic. The task consists of providing a score of how two sentences relate to each other. The system developed in this work leveraged a cross-encoder with a merged fine-tuned Low-Rank Adapter (LoRA). The system was ranked eighth in English with a Spearman coefficient of 0.842, while Moroccan Arabic was ranked seventh with a score of 0.816. Moreover, various experiments were conducted to see the impact of different models and adapters on the performance and accuracy of the system.

1 Introduction

Semantic Textual Relatedness (STR) is a measure of how closely related or connected two linguistic units are in terms of their meanings or concepts (Abdalla et al., 2023). STR is a valuable concept in Natural Language Processing (NLP), as it helps us to understand the connections and similarities between different pieces of text. By determining the degree of relatedness between sentences or phrases, we can improve various NLP tasks such as information retrieval, question answering, and text summarisation. This understanding of semantic relatedness enables us to create more accurate word embeddings and sentence representations, enhancing the performance of language processing models. One way to represent STR is a supervised regression task in which the output is a continuous score number between 0 and 1.

For the STR task in SemEval 2024 (Ousidhoum et al., 2024b), the organisers on Track A (supervised) provided datasets (Ousidhoum et al., 2024a) for nine languages or dialects. They provided pairs of sentences and annotated the degree of relatedness via a human score between 0 and 1. The languages considered in this work are English and Moroccan Arabic. These two were selected because they are comprehensive for the team.

There are various methods that can be used to estimate the relatedness of two sentences. One of the methods is to utilise the Pre-Trained Language Models (PLMs). PLMs are currently state-of-the-art in the field of NLP, and follow the transformer architecture introduced in (Vaswani et al., 2017) with the attention mechanism. Another variation that uses a mechanism of cross-attention is the cross encoder (Reimers and Gurevych, 2019), whichthat of takes two inputs and outputs a score between 0 and 1 on how related these two inputs are. They are efficient in determining the correlation between two inputs.

Parameter-efficient fine-tuning (PEFT) aims to tune the pre-trained model with high accuracy but with less cost and complexity. One of the PEFT methods is adapters (Poth et al., 2023), which tune extra parameters or layers instead of tuning the whole model while maintaining competitive accuracy. They can be considered as few-shot learners as per (Beck et al., 2022). One type of adapter is the low-rank adapter (LoRA). Instead of tuning the whole weight, LoRA adds small matrices in each layer, and these matrices would be fine-tuned.

Hence, this work applies a tuned LoRA adapter on a pre-trained cross-encoder to estimate the score of the relatedness of two sentences. The code is publicly available[1].

The paper is organised as follows: Section 2 presents the background, including related work and dataset overview; Section 3 covers the system overview; Section 4 presents the results; Section 4 discusses the error analysis and limitations; and the paper concludes.

2 Background

This section will cover the related work, dataset description and a brief introduction to PEFT.

2.1 Related Work

There have been previously related versions of the STR datasets, such as (Asaadi et al., 2019) and (Abdalla et al., 2023). Different versions use different languages, annotations or available datasets.

Another related dataset is Semantic Textual Similarity (STS) (Cer et al., 2017). There are differences between STS and STR. Specifically, STS tasks aim to assess how similar two text segments or sentences are, focussing on tasks such as identifying paraphrases or entailment relationships. On the other hand, STR looks at the overall closeness in meaning between linguistic units, considering various factors such as topic-relatedness and stylistic similarities. Thus, STR is more general, and STS can be treated as a subset of STR. Secondly, the outputs differ slightly, as the output of the previous STS tasks is between zero and five, while in STR, the output is between zero and 1. STS datasets were beneficial in this task, as can be seen later in the paper.

The task of STS is a common natural language understanding task. Several approaches have been used for STS. One of the popular approaches utilises the generation of robust contextual embeddings and then uses a similarity measurement like cosine similarity to get the required score. The embeddings can be extracted with a Universal Sentence Encoder (USE) (Cer et al., 2018), Language-agnostic BERT Sentence Embedding (LabSE) (Feng et al., 2022) or Sentence BERT (SBERT) (Reimers and Gurevych, 2019). These are different approaches to get meaningful embeddings that can capture the semantics of the input sentences.

2.2 Dataset

The datasets (Ousidhoum et al., 2024a) provided for training consist of two sentences and a score of how related they are between 0 and 1. Sample instances of the English training dataset can be seen in Table 1. The first example shows two sentences with the same meaning, and therefore the score is 1. The second example shows partially related sentences with a score of 0.5. The last example includes two unrelated sentences with a score of around 0.

Sentences	Score
Actor Gazzara dead at 81 Actor Ben Gazzara dies at 81	1.0
yeah and so is bubbles lol Bubbles used to reside next door	0.5
A child wielding a snow shovel. A cat bites a human's nose.	0.03

Table 1: Dataset training sample instances.

The datasets are split into 3 sets: training, development, and testing. The number of instances in each set in the English and Moroccan Arabic languages can be seen in Table 2. The main reason for injecting adapters directly is that there are few training samples in Moroccan Arabic. So, few-shot learning is a better approach for this language and, therefore, for the overall task.

Set/Language	English	Moroccan Arabic
Train	5500	925
Evaluation	250	70
Testing	2500	427

Table 2: STR Dataset split.

2.3 Parameter Efficient Fine-Tuning

PLMs follow the Encoder/Decoder architecture introduced by Transformer (Vaswani et al., 2017). Models such as BERT (Devlin et al., 2018), RoBERTa (Liu et al., 2019), ALBERT (Lan et al., 2019), T5 (Raffel et al., 2020), and DeBERTa (He et al., 2020) are other variations of the transformer architecture.

Another variation that uses cross-attention is the cross-encoder (Reimers and Gurevych, 2019), which takes two inputs and outputs a score between zero and one. A cross-encoder trained on the STS-B benchmark (Cer et al., 2017) would result in an output score between 0 and 1 instead of 0 to 5.

One of the PEFT techniques is the use of adapters, which are efficient few-shot learners as per (Poth et al., 2023). There are various adapter architectures. Instead of tuning the entire model weights, the adapters would tune additional parameters, layers or weight matrices. The three types of adapters investigated in this work are Houlsby (Houlsby et al., 2019), Pfeiffer (Pfeiffer et al., 2021), and LoRA (Hu et al., 2021). The Houlsby adapter adds two additional layers before and after the feed-forward (FF) layer in each encoder, while

Pfeiffer adds only a single layer after the FF layer. The LoRA adapter adds small weight matrices in each layer of the transformer layers.

This work tunes several adapters on different pre-trained models and checks which combination performs best. The best architecture will be explained in the next section.

3 System Development

This section covers the cross-encoder, LoRA adapter, the developed system architecture, and the evaluation metric.

3.1 Cross-Encoder

The cross-encoder takes two inputs simultaneously and uses the concept of cross-attention allowing the model to capture interactions between the two sentences. The cross-encoder would generate a score between 0 and 1 indicating how similar the two inputs are. The technical architecture of the cross-encoder can be seen in Figure 1. The cross-encoder adds two special tokens: SEP to separate the two sentences and CLS. The CLS token gets added at the beginning of the concatenated sentences along with the SEP token and represents a classification vector. The initial CLS token identifies the representation of two sentences. The final CLS token captures the cross-attention between all previous CLS tokens and produces one final semantic vector. A classification head maps the final CLS vector to a score between 0 and 1 based on the chosen model.

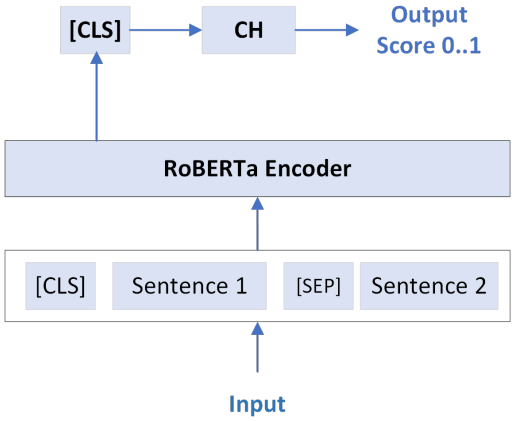

Figure 1: Cross-Encoder Architecture.

3.2 LoRA Adapter

The LoRA adapter (Hu et al., 2021) adds two additional low-rank matrices that are trainable instead of training the whole model. To explain LoRA mathematically, assume the input to a neural network to be X and the output to a single hidden layer is $h(x)$, then the output with full fine-tuning would equal the input multiplied by a weight matrix W_0 as per Equation 1. The weight matrix W_0 belongs to the dimension of $(d * k)$.

$$h(x) = W_0 X \qquad W_0 \in \mathbb{R}^{d \times k} \tag{1}$$

In LoRA, an additional weight matrix ΔW_0 is added into the input and initial weight matrices to get the hidden layer output as per equation 2. It belongs to the same dimension as the original matrix.

$$h(x) = W_0 X + \Delta W_0 X \qquad W_0, \Delta W_0 \in \mathbb{R}^{d \times k} \tag{2}$$

The new matrix is decomposed into two trainable matrices, B and A, with dimensions $(d * r)$ and $(r * k)$, respectively. The value of r (rank) is much smaller than d and k ($r \ll d, r \ll k$), so the new two matrices are smaller than the initial matrix. This reduces the model's trainable parameters while maintaining high accuracy. The value of r is a hyper-parameter and it is used as 8 in this work.

$$h(x) = W_0 X + (BA)X \qquad B \in \mathbb{R}^{d \times r}, A \in \mathbb{R}^{r \times k} \tag{3}$$

Applying LoRA can reduce the size of the model from hundreds of megabytes to just a few megabytes (Hu et al., 2021) while maintaining a high level of accuracy.

3.3 System Architecture

The architecture of the system developed for the STR task can be seen in Figure 2. The following are the simplified steps.

1. Initialise the adapter with random weights.
2. The LoRA adapter is trained given the training sets. During training, only the low-rank matrices are fine-tuned.
3. The adapter merges with the classification head of the cross-encoder.
4. The testing data are fed into the cross-encoder with the attached adapter to get the relatedness score.

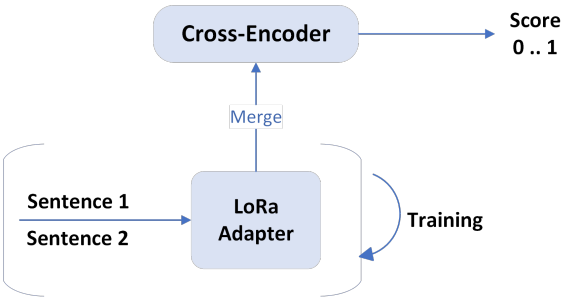

Figure 2: System Overview.

3.4 Evaluation

The evaluation is based on Pearson's correlation coefficient as in Equation 4. The values of X_i and Y_i represent individual instances while the values $\bar{X}$ and $\bar{Y}$ represent the mean of X and Y. The higher the coefficient, the better the model evaluation. The value of the coefficient ranges between -1 to 1 where 1 represents a higher correlation between the inputs. The metric value is generated with submissions being uploaded through CodaLab (Pavao et al., 2023). CodaLab is a platform for competitions and research purposes. The platform returns the scores for development and testing.

$$r = \frac{\sum_{i=1}^{n}(X_i - \bar{X})(Y_i - \bar{Y})}{\sqrt{\sum_{i=1}^{n}(X_i - \bar{X})^2 \sum_{i=1}^{n}(Y_i - \bar{Y})^2}} \quad (4)$$

In addition to the datasets, the organisers provided a baseline for all languages based on LabSE (Feng et al., 2022), which provides sentence embeddings. Scores were calculated based on cosine similarity between these embeddings.

4 Results

The system would initially be trained on the training set and evaluated with the development set, and the official results would be produced by applying the model to the testing sets. This work's approach is incremental and experimental. So, variations of models and adapters would be tested, and the models achieving better metrics would be selected.

4.1 Experimental Development Results

All the initial experiments were conducted in English. Then, the best approach was applied to Moroccan Arabic. The experiments carried out in the development phase were incremental in 10 epochs. Firstly, several models (BERT, ALBERT, RoBERTa, DeBERTa, and T5) were fine-tuned with the Pfeiffer adapter and the model with the best-yielding scores was selected. The models and their respectable Spearman scores can be seen in Table 3. The model with the highest score was RoBERTa, with a development score of 0.8155. The exact model names in Huggingface (Wolf et al., 2019) are available in Appendix A. Huggingface is a platform with a large number of pre-trained models. The initial selected models were general and not domain-specific. Therefore, a model trained for similarity could be investigated. The chosen model was a cross-encoder trained with the STS-B dataset. The results were better than the base RoBERTa model, reaching a development score of 0.8296. So, the system continued using this model.

Model	Score
BERT	0.8023
ALBERT	0.7755
DeBERTa small	0.8088
T5 small	0.8003
RoBERTa base	0.8155
RoBERTa STSB-CE	0.8296

Table 3: Selected models and their development scores.

Then, the impact of merging several single adapters (Houlsby, Pfeiffer and LoRA) on the cross-encoder was studied. Table 4 shows the scores with the attachment of the three adapters. The LoRA adapter scored the highest with a Spearman coefficient of 0.8343. To further improve the accuracy, the training epochs were increased to 30 to improve the generalisation of the model, and this was achieved by producing a final development score of 0.8417.

Adapter	Score
Pfeiffer	0.8296
Houlsby	0.8309
LoRA	0.8343

Table 4: Impact of different adapters on the RoBERTa STSB-CE in the development phase.

The same configuration was used for the Moroccan Arabic language, resulting in a development score of 0.8577.

To see whether an Arabic model would perform differently in an Arabic pre-trained model, another experiment in Moroccan Arabic was conducted in the development set using the CAMeLBERT model (Inoue et al., 2021). This model was trained

on a large corpus of Arabic for different tasks with several dialects (modern standard Arabic, dialectal Arabic, and classical Arabic). There is also a version of the CAMeLBERT model trained on the combination of the three dialects. This version produced a higher score of 0.871 on the Moroccan Arabic development set. However, this result was not submitted for the official competition.

4.2 Official Results

The same configuration used in the development phases was applied in the test set. The model used for both languages was the cross-encoder RoBERTa trained on STS-B. The adapter was LoRA and the training epochs were 30. The rest of the parameters can be seen in Appendix B. The official results reported can be seen in Table 5. The scores for English and Moroccan Arabic were 0.8425 and 0.8163 respectively. Both exceed the baseline scores of 0.83 and 0.77 respectively.

System	Baseline	Our System
English	0.83	0.8425
Morrocan Arabic	0.77	0.8163

Table 5: Official submitted scores of the competition in the English and Morrocan Arabic.

5 Discussion

5.1 Error Analysis

One interesting negative result was found during development. The developed system was applied to Algerian Arabic, which yielded a low evaluation metric of 0.54. This could be attributed to the fact that this dialect had majorly unseen data for the model. The STS-B dataset has some overlap with the two languages (English and Moroccan Arabic) worked on in this paper.

The development set with labels was not utilised in the testing phase. Moreover, the differences between applying the adapters on the cross-encoder are minor. So, applying these models to the testing set may yield different results.

The results on CAMelBERT on Moroccan Arabic were better than the cross-encoder in the development phase, but this was not considered in the system's official results to maintain the consistency of the used model (cross-encoder). The usage of CAMelBERT yielded a metric value of 0.8347, which is higher than the cross-encoder. This was noticed in the post-evaluation phase and, therefore, not reported in the official results. This indicates that using a pre-trained model on a large corpus of Arabic yields a better result than the cross-encoder trained on the STSB dataset.

5.2 Limitations

Due to time constraints, this work has several limitations. Firstly, the models were not fully fine-tuned with the training data. It would be comprehensive to compare the full fine-tuning to the adapter tuning and discuss the obtained results. Secondly, there was no hyper-parameter optimisation was done in this system except for the number of epochs. The effect of applying different parameters to different models would yield a better overview of the effect of these hyper-parameters on the training process. Thirdly, full training of the cross-encoder would be an interesting scope of future work. Lastly, there was no pre-processing, and the sentences were tokenised as they were. The impact of pre-processing could be studied.

5.3 Ethical Statement

This work used only the STS-B and STR datasets, which are both publicly available. Although the dataset has some overlap between the development and testing sets, this work maintains that the development set was not used for training. This is attributed to the ethical convention in machine learning of using the appropriate set for the suitable task.

Conclusion

This work involves participating in the SemEval 2024 STR task in two languages (English and Moroccan Arabic). The regression task is to predict a score relating to two sentences. The developed system consists of a LoRA adapter trained on the given training instances and then attached to a cross-encoder previously trained on the STS-B dataset. The system achieved excellent performance, exceeding the baseline and ranking seventh in Moroccan Arabic and eighth in English, with Pearson Coefficient scores of 0.8163 and 0.8425, respectively.

Acknowledgements

The authors thank the organisers for answering questions about the task and express their gratitude to the anonymous reviewers for their constructive feedback.

B Hyper-parameters Configuration

The hyper-parameters used to develop the system are available in Table 7. The number of epochs during the development phase was 10, while in testing, it was increased to 30.

Parameter	Value
Epoch	10 - 30
Learning rate	5×10^{-4}
Batch size	30
LoRA (r and alpha)	8
GPU	Tesla A100 (40GB)

Table 7: Parameter configuration.

C Used Libraries

This section includes the Python libraries used in the code and their versions according to Table 8.

Library	Version
adapters	0.1.1
transformers	4.35.2
datasets	2.17.0
sklearn	1.2.2
torch	2.1.0
accelerate	0.27.0
pandas	1.5.3
numpy	1.23.5

Table 8: Used Python libraries.

NU-RU at SemEval-2024 Task 6: Hallucination and Related Observable Overgeneration Mistake Detection Using Hypothesis-Target Similarity and SelfCheckGPT

Abstract

One of the key challenges in Natural Language Generation (NLG) is "hallucination", in which the generated output appears fluent and grammatically sound but may contain incorrect information. To address this challenge, "SemEval-2024 Task 6 - SHROOM, a Shared-task on Hallucinations and Related Observable Overgeneration Mistakes" is introduced. This task focuses on detecting overgeneration hallucinations in texts generated from Large Language Models for various NLG tasks. To tackle this task, this paper proposes two methods: (1) hypothesis-target similarity, which measures text similarity between a generated text (hypothesis) and an intended reference text (target), and (2) a SelfCheckGPT-based method to assess hallucinations via predefined prompts designed for different NLG tasks. Experiments were conducted on the dataset provided in this task. The results show that both proposed methods can effectively detect hallucinations in LLM-generated texts.

1 Introduction

Natural Language Generation (NLG) is a field within Natural Language Processing (NLP) that focuses on enabling machines to produce human-like texts. In NLG, one of the challenges is the phenomenon of "hallucination", where the generated output is fluent and grammatically sound but contains incorrect information or extends beyond the provided information. This issue is particularly significant in NLG applications where correctness is crucial, such as machine translation and paraphrasing. It can compromise the quality and reliability of the generated content, resulting in a loss of fidelity to the sources or models from which the content is generated. To address this challenge, "SemEval-2024 Task 6 - SHROOM, a Shared-task on Hallucinations and Related Observable Overgeneration Mistakes" (Mickus et al., 2024) is introduced. This task aims to identify grammatically correct outputs that contain incorrect semantic information or overgenerated content, with or without access to the model that produced the output. The outputs are obtained from various Large Language Models (LLMs) in three distinct NLG tasks: definition modeling (DM), machine translation (MT), and paraphrase generation (PG).

Recent efforts have been made to develop frameworks for detecting hallucinations in LLM-generated texts. One approach involves calculating information overlap and contradictions between generated and reference texts (Dhingra et al., 2019; Shuster et al., 2021). Higher mismatches suggest a greater likelihood of hallucination. Another popular approach is an LLM-based evaluation. This approach focuses on prompting LLMs to assess a machine-generated text and determine the probability of this text being a hallucination (Kadavath et al., 2022; Manakul et al., 2023).

Despite the success of these existing methods, they have mainly focused on detecting factual hallucinations. This paper further explores how information overlap calculation and LLM-based evaluation approaches can be applied to detect overgeneration hallucinations. Specifically, we propose two methods to detect overgeneration hallucinations in SemEval Task 6. The first method is hypothesis-target similarity, which measures text similarity between a generated text (hypothesis) and an intended reference text (target). The second method is an LLM-based evaluation approach that utilizes a state-of-the-art framework called SelfCheckGPT (Manakul et al., 2023). This method assesses hallucinations via distinct predefined prompts tailored for texts generated from different NLG tasks.

2 Related Work

Recently there have been some attempts to develop frameworks for evaluating hallucinations in LLM-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 253–260

generated texts. One approach is to consider lexical features of LLM-generated texts and reference texts and calculate the information overlap and contradictions between the generated and the reference texts. The higher the mismatch counts, the lower the faithfulness and thus the higher the hallucination score. For example, Dhingra et al. (2019) proposed PARENT (Precision And Recall of Entailed n-grams from the Table), which is capable of assessing hallucinations by referencing both the source and target texts. Shuster et al. (2021) introduced a metric for knowledge-grounded dialogue tasks aimed at measuring the alignment between LLM-generated texts and the relevant knowledge judged by humans. Martindale et al. (2019) proposed the Bag-Of-Vectors Sentence Similarity (BVSS) metric for assessing sentence adequacy in machine translation. This metric aids in identifying disparities in information between the output and the translation reference. Despite the simplicity and effectiveness of information overlapping, it has limitations in handling syntactic or semantic variations, which can impact its accuracy in evaluating faithfulness.

Another recent approach is an LLM-based evaluation where an LLM is prompted to evaluate generated texts, e.g., to predict the probability that a generated text is a hallucination. For instance, Kadavath et al. (2022) used LLMs to evaluate the validity of their own claims by asking models to first generate answers and then to evaluate the probability that their answers are correct. Manakul et al. (2023) proposed an approach called SelfCheckGPT with prompts. In their approach, each LLM-generated sentence was compared against multiple generated responses from an LLM. An LLM was asked to assess whether an LLM-generated sentence was supported by the generated responses. If it was consistently supported by multiple responses, then it was likely to not be a hallucination. Friel and Sanyal (2023) proposed the ChainPoll approach where an LLM was asked to decide whether an LLM-generated text contained hallucinations, using a detailed and carefully engineered prompt. However, the majority of existing approaches have primarily focused on detecting factual hallucinations related to incorrect information in texts, rather than overgeneration hallucinations. Thus, there remains a critical need to explore and adapt these approaches for the detection of overgeneration hallucinations.

3 Problem Formulation

The objective of this task is to predict whether the actual model production (generated text) is a hallucination, with or without having access to the model that generated the text. Specifically, each input in this task consists of the following information:

- Task (task): the task for which the model was optimized, which can be either Definition Modeling (DM), Paraphrase Generation (PG), or Machine Translation (MT).
- Source (src): the input provided to the model.
- Target (tgt): the intended reference 'gold' text that the model is expected to generate.
- Hypothesis (hyp): the actual model output.
- Reference (ref): specifies whether the target, source, or both fields contain the semantic information necessary to establish whether the hypothesis is a hallucination.
- Model Checkpoint (model): Identifies the model used to produce the hypothesis (only applicable for model-aware inputs).

For each input, the goal is to predict a label indicating whether the hypothesis is a hallucination, along with the probability of the hypothesis being a hallucination (p(Hallucination)).

In this task, two datasets were provided: **model-aware dataset** and **model-agnostic dataset**. In the model-aware dataset, model checkpoints (available on HuggingFace) were provided for every sample. Conversely, in the model-agnostic dataset, these checkpoints were not included. For each dataset, an unlabeled training set, a validation set (with true labels), and a test set were provided. Also, a trial set was given without categorizing the samples based on whether they were model-aware or model-agnostic. The validation, trial and test sets contain binary annotations provided by at least five different annotators, along with a majority vote gold label.

4 Methods

To achieve the task of detecting overgeneration hallucinations, we propose two methods: (1) hypothesis-target similarity and (2) SelfCheckGPT-based methods. The details of each approach are discussed in the following subsections.

4.1 Hypothesis-Target Similarity Method

The proposed hypothesis-target similarity approach is an intuitive method for evaluating whether a generated text (hypothesis) contains hallucinations by comparing it with an intended reference or gold text (target). Specifically, we compute the text similarity between a hypothesis and a target and use the resulting value to determine whether the hypothesis contains hallucinations. The lower the similarity, the more likely it is that the hypothesis may contain a certain degree of hallucination. To compute text similarity, a text embedding method is first applied to generate embeddings of the generated and intended reference texts. In this work, we adopt *SentenceTransformers*[1] (Reimers and Gurevych, 2019) (*paraphrase-MiniLM-L6-v2*) to generate such embeddings since it has demonstrated success across various applications (Reimers and Gurevych, 2020; Choi et al., 2021; Markchom et al., 2020). Then, a cosine similarity metric is applied to these embeddings to compute the similarity. It is worth noting that other metrics are also applicable. This work selects cosine similarity due to its widespread usage and simplicity (Lin et al., 2014; Zhang et al., 2023).

After obtaining the similarity between a hypothesis and a target, we set a threshold δ to determine whether a hypothesis is a hallucination or not. If the similarity is lower than δ, it means that the hypothesis is different from the target and may contain hallucinations. Mathematically, given a hypothesis h and a target t, let e_h and e_t denote embeddings of the hypothesis and target, respectively. We define a function $f(h, t)$ that outputs the labels "Hallucination" and "Not Hallucination" for a given hypothesis h and target t as follows:

$$f(h,t) = \begin{cases} \text{Hallucination}, & \text{if } s(e_h, e_t) < \delta \\ \text{Not Hallucination}, & \text{otherwise} \end{cases} \quad (1)$$

where $s(e_h, e_t)$ denotes the cosine similarity between the hypothesis h and the target t. Furthermore, we compute $p(\text{Hallucination})$ based on the computed cosine similarity by applying a sigmoid function to the similarity as follows:

$$p(\text{Hallucination}) = \sigma(s(e_h, e_t)) \quad (2)$$

where σ denotes a sigmoid function. This function scales the computed similarity to the $[0, 1]$ interval and treats the resulting value as the probability of the hypothesis being a hallucination. Note that, in the PG task, target texts are unavailable for certain samples. Consequently, we consider source texts as target texts in these instances. In other words, we assess the similarity between a generated (paraphrased) text and its corresponding source text instead.

4.2 SelfCheckGPT-Based Method

In the SelfCheckGPT-based method, we adopt the SelfCheckGPT with Prompt approach in (Manakul et al., 2023) and design prompts to validate hallucinations. Specifically, for each sample, a prompt is crafted to assess whether a hypothesis is supported by a context, which includes a provided source and target (if available). If a hypothesis is not supported by a context, it is considered a hallucination. The prompt formats vary slightly for each task. Table 1 shows the prompt formats for samples from each task, where {src} denotes a source, {tgt} denotes a target, {hypo} denotes a hypothesis, and {term} denotes the term to be defined in a source only for the DM task. As shown in this table, the prompt for the DM task is noticeably different from the others. This is because we would like to semantically use the term as additional information apart from the source and hypothesis.

Task	Prompt format
DM	Context: {src} The term "{term}" means {tgt} Sentence: The term {term} means {hypo} Is the sentence supported by the context above? Answer Yes or No:
PG	Context: {src} Sentence: {hypo} Is the sentence supported by the context above? Answer Yes or No:
MT	Context: {src} {tgt} Sentence: {hypo} Is the sentence supported by the context above? Answer Yes or No:

Table 1: Prompt formats for samples from each task where {src} represent a source, {tgt} represents a target, {hypo} represents a hypothesis, and {term} represents the term to be defined in a source of the DM task.

Each prompt is run through the GPT-3.5 model (*gpt-3.5-turbo-1106*)[2] (Brown et al., 2020; OpenAI, 2022) N times, and the final label is determined by the majority of these responses. The probability $p(\text{Hallucination})$ of each sample is computed based

Figure 1: The accuracy on (a) the model-aware validation set, (b) model-agnostic validation set, and (c) the trial set when different threshold values are applied in the hypothesis-target similarity method

on the corresponding N responses as follows:

$$p(\text{Hallucination}) = \frac{1}{N}\sum_{i=1}^{N} l_i \qquad (3)$$

where l_i denotes the ith predicted label (1 for "Hallucination" and 0 for "Not Hallucination") identified from the ith response.

5 Experiments

The experiments were conducted on both **model-aware** and **model-agnostic** datasets. For each of these datasets, we applied the proposed methods to both the validation and test sets to evaluate their performance. Two evaluation metrics were employed: the *accuracy* of binary classification and the *Spearman correlation* of the predicted probabilities (p(Hallucination)) with the proportion of the annotators marking the hypothesis as "Hallucination". We compared the proposed methods with the baseline provided by the task organizers on the test set. This baseline is based on the SelfCheckGPT with Prompt approach, employing an open-source Mistral model (Jiang et al., 2023). In this baseline, for samples from a PG task, only the source text is provided as context to the Mistral model, similar to our SelfCheckGPT-based method. For DM and MT tasks, the baseline utilizes only the target text as context. In contrast, our SelfCheckGPT method incorporates both source and target texts as context. Also, in this baseline, each prompt was run through the Mistral model only once.

5.1 Hyperparameter Settings

Hypothesis-Target Similarity Method To determine the threshold δ, we conducted an analysis on the validation set to identify the optimal value. We varied the threshold from 0.5 to 0.9, increasing it by 0.1 at each step, and evaluated the accuracy on the validation and trial sets. Figure 1 displays the accuracy on the model-aware validation set, model-agnostic validation set, and the trial set when different threshold values were applied. From this figure, a threshold of 0.6 achieved the highest accuracy on the validation sets and closely approached the highest accuracy on the trial set. Therefore, we selected $\delta = 0.6$ when applying this method to the test set. To further examine the performance of using $\delta = 0.6$, it was applied to determine hallucinations on both the model-aware and model-agnostic training sets. However, since the training set is unlabelled, it is not possible to examine the accuracy. Therefore, our focus shifted to examining the frequency of "Hallucination" and "Not Hallucination" predictions. This was to ensure that using $\delta = 0.6$ would not result in the tendency of exclusively predicting one or the other. As shown in Figure 2, with $\delta = 0.6$, 27.3% and 41.3% of the samples in the model-aware and model-agnostic sets, respectively, were predicted as hallucinations.

SelfCheckGPT-Based Method To select the number of generated responses (N), we varied N from 1 to 5. The accuracy and Spearman correlation results on both model-aware and model-agnostic validation sets, with different values of N, are presented in Figure 3. This figure indicates that as N increased, accuracy generally improved with fluctuations observed in both datasets. However, Spearman correlation consistently increased with no fluctuations as N increased. Therefore, we set N to 5 to obtain five responses for each sample in the test set. All hyperparameters of *gpt-3.5-turbo-1106* were configured with their default values. For any model response that indicated undetermined answers, the corresponding sample was considered

Dataset	Method	Validation set		Test set	
		Accuracy	Spearman correlation	Accuracy	Spearman correlation
Model-aware	Baseline	0.707	0.461	0.745	0.488
	Hypothesis-Target Similarity	0.699	**0.536**	0.734	0.518
	SelfCheckGPT-based	**0.722**	0.510	**0.768**	**0.582**
Model-agnostic	Baseline	0.649	0.380	0.697	0.403
	Hypothesis-Target Similarity	0.699	**0.574**	0.687	0.467
	SelfCheckGPT-based	**0.707**	0.567	**0.728**	**0.595**

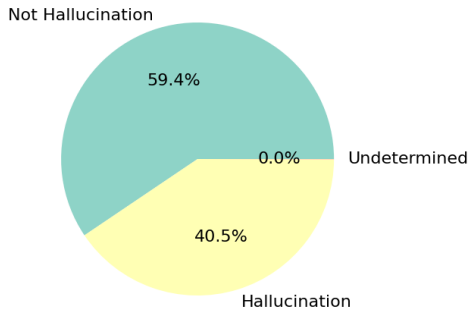
as "Hallucination".

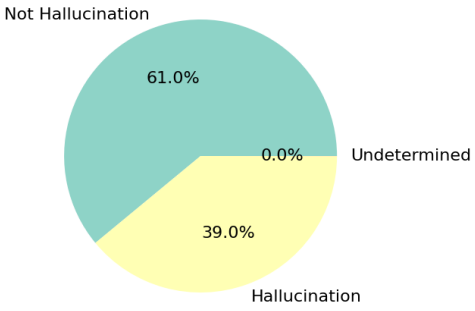
5.2 Results and Discussions

Table 2 shows the comparative performance of the proposed methods measured by accuracy and Spearman correlation on the validation and test sets. From this table, the proposed method based on SelfCheckGPT outperformed the baseline in terms of both accuracy and Spearman correlation on both model-aware and model-agnositc datasets. This indicates the effectiveness of using the GPT-3.5 model with prompts that include both source and target as context. Also, it suggests the benefit of running each prompt through an LLM multiple times to obtain a final prediction.

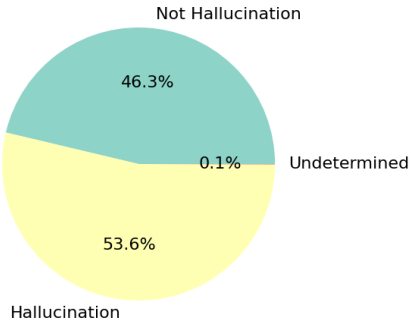
The proposed hypothesis-target similarity method closely approached the performance of the SelfCheckGPT-based approach on the validation sets, showing higher Spearman correlation values. However, on the test sets, the latter surpassed it. The reason could be that the selected threshold might not be precisely suitable for the test sets. Figure 4 shows the accuracy results on model-aware and model-agnostic test sets when different thresholds δ were used. From this figure,



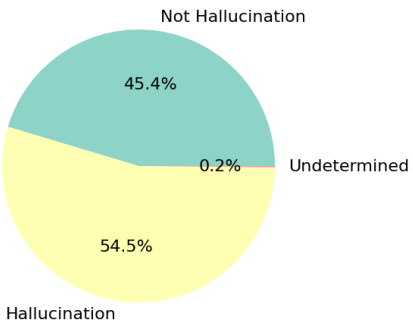
(a) Model-aware validation set



(b) Model-aware test set



(c) Model-agnostic validation set



(d) Model-agnostic test set

Figure 5: The percentages of response types, including "Not Hallucination", "Hallucination", and "Undetermined", obtained from the proposed SelfCheckGPT-based method on (a) model-aware validation set, (b) model-aware test set, (c) model-agnostic validation set, and (d) model-agnostic test set

using $\delta = 0.6$ resulted in the highest accuracy on the model-aware test set. However, on the model-agnostic test set, using $\delta = 0.5$ resulted in better accuracy. This indicates the challenge of selecting an optimal threshold based solely on observed data for generalizing to unseen data.

We investigated the number of undetermined responses in the SelfCheckGPT approach to validate whether this approach can effectively generate definitive answers for this task. Figure 5 shows the percentages of response types, including "Not Hallucination", "Hallucination", and "Undetermined", obtained from the proposed SelfCheckGPT-based method on the model-aware validation set, model-aware test set, model-agnostic validation set, and model-agnostic test set. According to this figure, the proposed SelfCheckGPT approach predicted less than 0.2% of undetermined answers across all datasets. This indicates that the SelfCheckGPT approach is effective in terms of producing definitive answers. Nonetheless, one limitation of this approach is its reliance on the availability of prior knowledge or expected outcomes (which, in this case, are the targets). In real-world situations, such information may not be available.

In the official competition rankings, the top-performing model achieved an accuracy of 0.813 and a Spearman correlation of 0.699 on the model-aware test set, and an accuracy of 0.847 and a Spearman correlation of 0.770 on the model-agnostic test set. Consequently, our SelfCheckGPT model secured the 26th position on the model-aware test set and the 35th position on the model-agnostic tes set.

6 Conclusions

This work proposes two methods for detecting hallucinations and observable overgeneration mistakes in texts generated by LLMs. The first method, the hypothesis-target similarity method, involves calculating the information overlap between a generated text and a reference text. This method utilizes a pre-trained SentenceTransformer model to calculate text embeddings for both the generated and reference texts, and cosine similarity to measure their similarity. The second method employs an LLM-based evaluation approach. It uses the SelfCheckGPT technique with prompts tailored to LLM-generated texts from various NLG tasks. The experimental results highlight the effectiveness of the proposed hypothesis-target similarity method in detecting hallucinations, particularly

when the similarity threshold is carefully chosen. Additionally, the findings reveal that the proposed SelfCheckGPT-based method outperformed the baseline, and effectively identified hallucinations in texts generated by LLMs. Moreover, these results underscore the significance of prompt design in evaluating hallucinations using LLMs. However, there is still room for improvement in the performance of our methods.

For future work, other SentenceTransformers models, such as Multi-QA or MSMARCO Passage models (SBERT.net, 2022) or alternative embedding models, such as InferSent (Conneau et al., 2018) or Universal Sentence Encoder (Cer et al., 2018) for the Hypothesis-Target Similarity approach will be considered. As for the SelfCheckGPT-based approach, other LLMs besides GPT-3.5 will also be investigated. Moreover, various prompt formats and the use of few-shot examples in the prompt will be explored.

Abstract

Headline Generation is an essential task in Natural Language Processing (NLP), where models often exhibit limited ability to accurately interpret numerals, leading to inaccuracies in generated headlines. This paper introduces CoT-NumHG, a training strategy leveraging the Chain of Thought (CoT) paradigm for Supervised Fine-Tuning (SFT) of large language models. This approach is aimed at enhancing numeral perception, interpretability, accuracy, and the generation of structured outputs. Presented in SemEval-2024 Task 7 (task 3): Numeral-Aware Headline Generation (English), this challenge is divided into two specific subtasks. The first subtask focuses on numerical reasoning, requiring models to precisely calculate and fill in the missing numbers in news headlines, while the second subtask targets the generation of complete headlines. Utilizing the same training strategy across both subtasks, this study primarily explores the first subtask as a demonstration of our training strategy. Through this competition, our CoT-NumHG-Mistral-7B model attained an accuracy rate of 94%, underscoring the effectiveness of our proposed strategy, detailed in our project repository[1].

1 Introduction

Headline Generation is a key task in the field of Natural Language Processing (NLP), aimed at condensing the content of a given article into a concise, accurate, and information-rich single-sentence headline. This process requires not only an understanding of the article's core content but also the ability to creatively express this content (Matsumaru et al., 2020). Recently, Huang et al. (2023) conducted an in-depth analysis of the application of models (Lewis et al., 2019; Liu et al., 2022; Raffel et al., 2020; Wang et al., 2022a; Zhang et al., 2020) in the task of headline generation, revealing limitations of these models in processing numerical information. They identified that inaccuracies in the use of numbers significantly contribute to errors in generated headlines, a particularly critical issue in news headline generation where numbers often carry key information. To further explore the issue of numerical accuracy in news headlines, Huang et al. (2023) introduced a new dataset, NumHG, focused on the accuracy of numerical usage within news headlines. Their analysis revealed that news headline generation typically involves nine distinct methods for handling numbers—Copy, Translate, Round, Paraphrase, Add, Subtract, Divide, Multiply, and Span—each varying in complexity. These techniques enhance the interpretability and clarity of the headline generation process, showcasing a sophisticated blend of precision and creativity in distilling numerical information. Based on these insights, Chen et al. (2024) designed two independent tasks: the first requires models to mask numbers in given news articles and their headlines, then to accurately predict the masked numbers; the second involves generating news headlines with accurate numerical information based on the provided news content.

In the domain of NLP, Large Language Models (LLMs) have gained recognition for their capability to execute a wide array of tasks, including text generation, summarization, and question answering, using straightforward instructions. This demonstrates their remarkable versatility (Guo et al., 2023; Sahoo et al., 2024). To further enhance the adaptability of LLMs, fine-tuning techniques (Zhang et al., 2023) have been extensively applied, improving model performance on specific tasks while preserving a wide scope of application. LLMs typically utilize a decoder-only architecture (Radford et al., 2018) and adopt primarily two strategies for task-specific challenges: prompt engineering and fine-tuning. Prompt engineering enables the direct execution of tasks

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 261–269

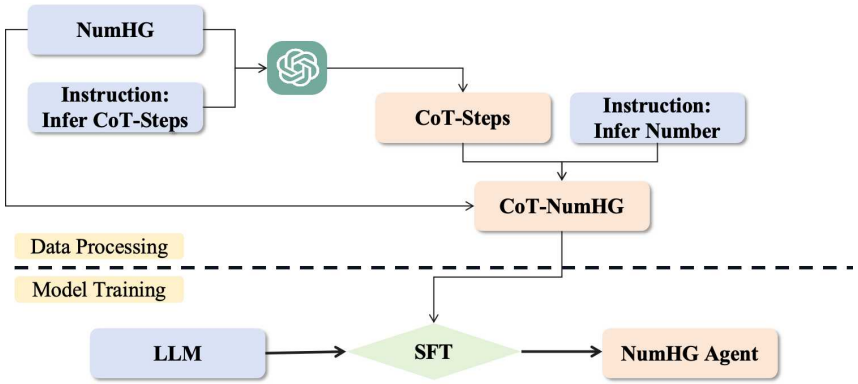

Figure 1: CoT-Based SFT Training Strategy Framework: The framework comprises two main parts: data processing and model training. In the first phase, data processing involves two steps. The first step combines specific instructions with the NumHG dataset, and through knowledge distillation using GPT-3.5-Turbo, new CoT-Steps are generated. These steps are then integrated with the corresponding instructions and the original dataset to produce the CoT-NumHG dataset. In the second phase, the CoT-NumHG dataset is utilized for the full-parameter SFT of the base model.

through various techniques, such as zero-shot (Radford et al., 2019), few-shot (Brown et al., 2020), chain of thought (CoT) (Wei et al., 2022), CoT with self-consistency (Wang et al., 2022b), and tree of thought (Yao et al., 2024), without requiring additional training. This underscores the models' ability to quickly adapt to new tasks by leveraging existing knowledge. Fine-tuning, via further training, refines the models' performance on specific tasks, particularly through Supervised Fine-Tuning (SFT) methods. To improve SFT efficiency, Parameter-Efficient Fine-Tuning (PEFT) techniques (Hu et al., 2023) including LoRA (Hu et al., 2021), prompt-tuning (Lester et al., 2021), and prefix-tuning (Li and Liang, 2021) have been introduced. These significantly enhance the models' adaptability and the quality of outputs for specific tasks without substantially increasing the model size or computational demands. This approach not only preserves the versatility of LLMs but also boosts their output quality and the ability to generate structured outputs in specific domains. Despite these approaches achieving certain levels of performance enhancement, there remains room for improvement in perceiving numerical information, reasoning ability, and generating structured outputs (Ouyang et al., 2023). Particularly in the task of news headline generation, reliance solely on prompt engineering may lead to uncontrollable outputs and insufficient structuring. Meanwhile, SFT, despite its ability to improve performance, shows limitations in the interpretability of the reasoning process and suffers from attention decay, potentially leading to the omission of important information.

To address these challenges, we propose a training strategy based on the CoT approach, designed to significantly enhance LLMs in the task of number-focused headline generation. Our method consists of two key components. First, drawing on the concept of knowledge distillation (Dasgupta et al., 2023), we utilize GPT-3.5-Turbo (Brown et al., 2020) and instructions to process the original NumHG dataset, generating a series of reasoning steps. Given the issue of attention decay when handling long-distance information (Xiao et al., 2023), we created a new CoT-NumHG dataset by combining the question statement with reasoning steps. This process aims to bolster the model's attention mechanism and improve the interpretability of the reasoning process (Wang et al., 2023). Secondly, we selected three LLMs as base models and performed full- parameters SFT using the constructed CoT-NumHG dataset on these base models. Through this approach, we not only significantly improved performance on the specific task, but also optimized structured outputs while maintaining the models' versatility. Our research contributions are threefold:

1. Based on the NumHG dataset, we developed the CoT-NumHG dataset, enhancing model interpretability and structured output capabilities. Importantly, we introduce a dataset construction technique specifically designed for the CoT-NumHG.

2. We demonstrate the enhancement of model performance through task-oriented SFT train-

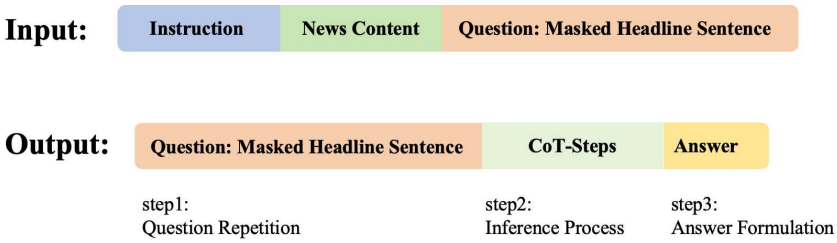

Figure 2: CoT-NumHG Dataset: The input of the dataset consists of three parts: Instruction, News Content, and Masked Headline Sentence (Question). The output is comprised of three components: Question Repetition, Inference Process, and Answer Formulation.

ing on the CoT-NumHG dataset across three base models, significantly improving news headline generation while maintaining general-purpose capabilities.

3. Through ablation studies, we demonstrated that the CoT-based training strategy effectively boosts the model's performance.

2 CoT-Based SFT Training Strategy Design

The training strategy of this study is divided into two main parts, as shown in Figure 1: the construction of the CoT-NumHG dataset and model training. Initially, through a knowledge distillation strategy, we enhanced the original dataset to improve the model's interpretability in handling the task of generating news headlines. Subsequently, the selected base LLMs were trained using full-parameter SFT techniques to achieve performance optimization and structured output for specific tasks.

2.1 CoT-Dataset Generation

To enhance the model's understanding of the relationships among news content, headline sentences, and answers, we employed a knowledge distillation approach during the data construction and optimization phases. Utilizing the original NumHG dataset and instructions, we generated inference processes through the GPT-3.5-Turbo model, termed CoT-Steps. CoT-Steps consist of three steps:

Step 1: **Identifying the Relevant Information**: This involves analyzing semantic relevance to pinpoint sentences in news articles that are closely related to the masked headline sentences and answers. This step ensures that the selected sentences are crucial for understanding the content of the news articles and for generating headlines.

Step 2: **Interpreting the Numerical Information**: For each identified key sentence, its direct numerical relevance to the generation task and the reasons for its selection are interpreted.

Step 3: **Choosing and Applying the Math Method**: For the numerical information in key sentences, appropriate methods are used for transformation and completion to accurately reflect in the generated headline sentences while maintaining logical consistency and accuracy.

This approach aims to bolster the model's data understanding and information processing capabilities by emulating the human problem-solving thought process, thereby enhancing attention scores and interpretability. Then, We integrated the reasoning process (CoT-Steps) into the training set to build a dataset specifically for SFT. Figure 2 shows that the input of this training set includes the instruction, news content, and the masked headline sentence; the output covers question restatement, CoT-Steps, conversion methods, and the final answer. This design aims to train the model to generate answers following given logical steps, thereby improving the accuracy and reliability of the generated results.

2.2 Model Training

For the model training part, we selected three large language models with a decoder-only architecture: ChatGLM3-6B (Du et al., 2022), Mistral-7B-Instruct-v0.2 (Jiang et al., 2023), and Zephyr-7B-Beta (Tunstall et al., 2023), for full-parameter fine-tuning. These models were chosen for their outstanding performance in text generation and comprehension, as illustrated in benchmarks comparing their capabilities to other LLMs of similar size (Zheng et al., 2023). During the fine-tuning

process, we focused on enhancing the models' comprehensive understanding and generation capabilities, especially in handling news headlines that contain numerical information. Through meticulous training methods, we ensured that the models could achieve higher performance on specific tasks.

3 Data Construction

3.1 CoT-Steps Generation

The primary source of the NumHG dataset is Newser[2], a news aggregation platform that provides headline news from both American and international media. News articles typically contain between 200 and 300 words. The entire NumHG dataset consists of news articles with titles that integrate numerical information, comprising 21,157 news articles for training and 2,572 for validation, totaling 23,729 articles. The data includes four keys: news, masked headline sentence, answer, and calculation. Initially, we employ a few-shot approach to distill the reasoning steps. The complete prompt given to the model comprises three parts: instruction, news, masked sentence (question), calculation, and answer. Figure 3 shows the instruction content used.

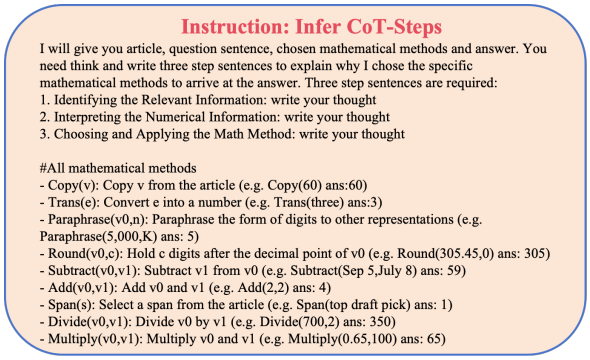

Figure 3: Instruction Prompt of Inferring CoT-Steps

Table 1 lists the detailed examples from the NumHG dataset, along with the inference steps obtained using knowledge distillation techniques. These steps not only reveal the key reasoning pathways in the news headline generation process but also provide clear guidance for models to more effectively handle numerical information and generate structured headlines.

3.2 CoT-NumHG Datasets Generation

In preparing the CoT-NumHG datasets for model training, we have adopted an approach inspired by the methodologies outlined in the "Never Lost in the Middle" study (Junqing et al., 2023). This strategy ensures that the model can efficiently identify and utilize key information within extended texts. Our dataset is specifically tailored to enhance the models' attention mechanisms, thereby improving their reasoning capabilities and their ability to produce structured outputs for complex tasks.

Table 1: Example of NumHG datasets and CoT-Steps

News: (Apr 18, 2016 1:02 PM CDT) Ingrid Lyne, the Seattle mom allegedly murdered while on a date, left behind three daughters—and a GoFundMe campaign set up to help the girls has raised more than $222,000 so far, Us reports. A friend of the family set up the campaign, and says that all the money raised will go into a trust for the girls, who are ages 12, 10, and 7. Lyne's date was charged with her murder last week.
Masked Headline (Question): $____K Raised for Kids of Mom Dismembered on Date
Calculation: Paraphrase(222,000,K)
Answer: 222
CoT Steps: 1. Identifying the Relevant Information: The relevant information in this question is the amount of money raised for the kids of the mom who was dismembered on a date. 2. Interpreting the Numerical Information: The numerical information given is $222,000. 3. Choosing and Applying the Math Method: I chose the Paraphrase method to convert the numerical information from the form of digits to other representations. By paraphrasing 222,000 as K, I am representing the amount as 222 thousand dollars.

The dataset (see the example in Table 4) is meticulously organized, comprising three elements in its input section: instruction (as referenced in Figure 4), news content, and masked headline sentences (posed as questions). This configuration is designed to keep the model focused during the processing of information and to encourage a logical and structured approach to output generation. In the output section, we employ a stepwise methodology to formulate answers. Initially, the model is instructed to repeat the question, a step that not only deepens its understanding of the query, but also counteracts attention drift by enhancing attention scores. Following this, the model boosts the interpretability of its reasoning process by executing CoT-Steps, which involve generating a sequence of intermediate reasoning steps. These steps are designed to mimic human problem-solving processes, thereby clarifying the model's reasoning pathway. Ultimately, the model presents the final answer, ensuring the creation of a structured and precise headline while preserving the integrity of the news content. Through this dataset design, our

[2] https://www.newser.com/

objective is for the model to demonstrate enhanced accuracy and interpretability in news headline generation tasks, in addition to maintaining consistent performance when managing information over long distances.

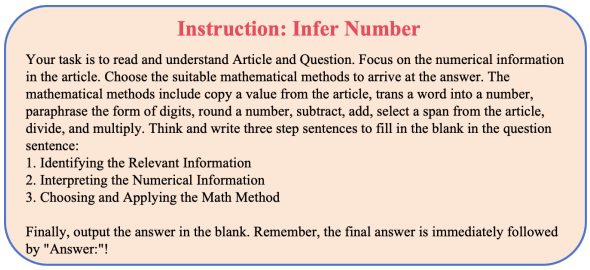

Figure 4: Instruction Prompt of Inferring Number

By incorporating these strategies into our dataset design, we aim to equip models with the ability to achieve superior accuracy and interpretability, particularly in tasks such as news headline generation, while also ensuring steady performance in the processing of long-range information. This methodology embodies the proverb "the pen is mightier than memory," emphasizing the importance of a structured and considered compilation of training data to bolster model capabilities in the NLP field.

4 Experiments and Results

4.1 Experiments Settings

Ultimately, we constructed the CoT-NumHG dataset, which comprises 23,729 samples. To ensure the randomness and fairness of the experiments, the dataset was randomly shuffled and 3,000 samples were selected as the validation set, leaving 20,729 samples for the training set. We chose three state-of-the-art LLMs as our base models: ChatGLM3-6B, Mistral-7B-Instruct-v0.2, and Zephyr-7B-Beta. SFT was performed on these base models.

For each base model, training was conducted over 2 epochs on 16 $\times$ A100 GPUs (80GB). During training, we set the batch size to 32, the learning rate to $1 \cdot 10^{-6}$, and the warmup ratio to 0.01. A cosine annealing schedule was used for learning rate adjustment, and training was accelerated using `bfloat16` precision. Cross-entropy loss was used to compute the loss. We monitored the evaluation loss (eval loss) of each model on the validation set during training. ChatGLM3-6B achieved the lowest eval loss (0.176) at epoch 1.95, with a corresponding training loss (train loss) of 0.121. Mistral-7B-Instruct-v0.2 reached its lowest eval loss (0.153) at epoch 1.81, with a training loss of 0.111. Zephyr-7B-Beta achieved the lowest eval loss (0.151) at epoch 1.96, with a training loss of 0.110.

Table 2: Example of CoT-NumHG-Mistral-7B's output

News: (Jul 20, 2009 3:41 PM CDT) The special inspector overseeing Treasury's TARP program says federal assistance to banks and other financial entities could end up costing taxpayers $23.7 trillion, Bloomberg reports. Aside from the $700 billion bailout, Neil Barofsky says in testimony prepared for told Congress tomorrow, other trillion-dollar federal programs could balloon...
Masked Headline (Question): TARP Watchdog: Bailouts May Cost US $____T
CoT-NumHG-Mistral-7B Output: To fill in the blank in the question sentence: TARP Watchdog: Bailouts May Cost US $____T. 1. Identifying the Relevant Information: The relevant information is the cost of the bailouts, which is given as $23.7 trillion. 2. Interpreting the Numerical Information: The numerical information is in the form of a decimal, with two digits after the decimal point. 3. Choosing and Applying the Math Method: I chose the math method Round(23.7,0) to round the number to the nearest whole number.This is because the question asks for the answer to be filled in the blank as a whole number, and rounding 23.7 to the nearest whole number gives us 24. Summary: math methods: Round(23.7,0) Answer: 24

To ensure the accuracy of the results, we performed ablation studies. Specifically, we used only the instruction prompt (also CoT) to generate outcomes with three base models, along with a benchmark model, GPT-3.5-Turbo. Additionally, we trained these three base models solely with the NumHG dataset, comparing the results against those trained using the CoT-NumHG dataset. The vLLM framework (Kwon et al., 2023) was consistently employed for inference.

4.2 Results

The competition provided a dataset containing 4,921 samples. The results showed that the first-place participant achieved an accuracy of 95%, while the participants in second to fourth places all reached an accuracy of 94%. Our team's submission, the CoT-NumHG-Mistral-7B model, also achieved an accuracy of 94% in this task, demonstrating the effectiveness of the CoT training strategy in enhancing model performance. Table 2 presents an example of the result.

To further analyze model performance, we conducted ablation studies across all models. We observed incremental improvements in accuracy, start-

ing from models prompted solely by CoT, progressing through those trained on the NumHG dataset, and culminating with those trained on the CoT-NumHG dataset. The accuracy of the CoT-NumHG-Mistral-7B model increased from 0.58 to 0.94, surpassing the untrained baseline, and improved from 0.73 to 0.94 compared to NumHG-Mistral-7B, showcasing significant improvements. This indicates that the CoT-Based SFT training strategy not only enhances model accuracy, but also improves the stability of generating structured outputs. Models without fine-tuning produce less stable outputs, sometimes requiring manual intervention to identify generated answers. Furthermore, their reasoning processes exhibit a higher degree of interpretability.

Table 3: Accuracy of Different LLMs; the result of the final submission is bolded

Model Name	Accuracy
ChatGLM3-6B	0.51
Mistral-7B-Instruct-v0.2	0.58
Zephyr-7B-Beta	0.56
GPT-3.5-Turbo	0.74
NumHG-ChatGLM3-6B	0.62
NumHG-zephyr-7b	0.71
NumHG-Mistral-7B	0.73
CoT-NumHG-ChatGLM3-6B	0.83
CoT-NumHG-Zephyr-7B	0.90
CoT-NumHG-Mistral-7B	**0.94**

5 Conclusion and Future Work

In this paper, we have introduced a CoT-based SFT training strategy aimed at enhancing the performance of LLMs in the task of news headline generation. Initially, we constructed the CoT-NumHG dataset, based on the existing NumHG dataset through knowledge distillation techniques. By simulating the human thought process, this dataset enhances the interpretability of the reasoning path from problem to answer. Subsequently, we utilized the CoT-NumHG dataset to perform SFT on a selected baseline model and verified significant improvements in model performance through ablation studies. The competition results further validated the efficacy of our approach, with the CoT-NumHG-Mistral-7B model achieving an accuracy rate of 94%. However, a manual review of the competition outcomes revealed some uncertainties in the model's handling of numerical information in titles, such as the need for approximations. This indicates that there is still room for improvement in understanding numerical information and generating structured outputs.

Future work will focus on the following directions: further optimization of the dataset by deduplicating and enhancing data diversity to improve the model's generalization capabilities. This includes identifying and removing duplicate or low-quality data samples, as the current proportion of copied methods is excessively high. We will adjust the proportions through sampling to address this issue. To align the generated headlines more closely with the standards of human editors, we will explore constructing a dataset in DPO (Rafailov et al., 2024) format from incorrect generation outcomes.

A Example of CoT-NumHG Datasets

Table 4: Example of CoT-NumHG Datasets

Input: Your task is to read and understand Article and Question. Focus on the numerical information in the article. Choose the suitable mathematical methods to arrive at the answer. The mathematical methods include copy a value from the article, trans a word into a number, paraphrase the form of digits, round a number, subtract, add, select a span from the article, divide, and multiply. Think and write three step sentences to fill in the blank in the question sentence: 1. Identifying the Relevant Information 2. Interpreting the Numerical Information 3. Choosing and Applying the Math Method Finally, output the answer in the blank. Remember, the final answer is immediately followed by Änswer:Ï #Article (Dec 25, 2020 2:25 PM) Around 1,000 British soldiers were spending Christmas Day trying to clear a huge backlog of truck drivers stuck in southeast England after France briefly closed its border to the UK, then demanded coronavirus tests from all amid fears of a new coronavirus variant. Even though an estimated 4,000 or so international truck drivers are spending yet another day cooped up in their cabs, some progress was evident Friday, with traffic around the English Channel port of Dover moving in an orderly fashion toward the extra ferries that were put on to make the short crossing across to Calais in northern France. Rail operator Eurotunnel was also back in action, the AP reports, offering a way back into France. The military personnel were directing traffic and helping a mass testing program for the drivers, who must test negative to enter France. French firefighters have been drafted to help the military test drivers for coronavirus. Poland's Territorial Defense Force also sent reinforcements to help with testing and food distribution. #Question Fill in the blank: British Troops Work to Clear ____K Trucks
Output: To fill in the blank in the question sentence: British Troops Work to Clear ____K Trucks. 1. Identifying the Relevant Information: The question asks for the number of trucks that the British troops are working to clear. 2. Interpreting the Numerical Information: The article mentions that there is an estimated 4,000 international truck drivers stuck in southeast England. 3. Choosing and Applying the Math Method: To arrive at the answer, I chose the Paraphrase method to convert the numerical information of 4,000 into a different representation. By paraphrasing 4,000 as K̈,Ï can represent the number of trucks as 4. Summary: math methods: Paraphrase(4,000,K) Answer: 4

Byun at SemEval-2024 Task 6: Text Classification on Hallucinating Text with Simple Data Augmentation

Cheolyeon Byun

byuncheolyeon@akane.waseda.jp

Abstract

This paper aims to classify sentences to see if it is hallucinating, meaning the generative language model has output text that has very little to do with the user's input, or not. This classification task is part of the Semeval 2024's task on Hallucinations and Related Observable Overgeneration Mistakes, AKA SHROOM, which aims to improve awkward-sounding texts generated by AI. This paper will first go over the first attempt at creating predictions, then show the actual scores achieved after submitting the first attempt results to Semeval, then finally go over potential improvements to be made.

1 Introduction

How AI and Large Language Models are able to understand and generate human language is elusive, to say the least. The underlying ingenuity behind the architecture of such models, involves technology and methods that are considered a black box like neural networks, named after the fact that the inner workings are impossible to grasp and properly digest for even experts (Castelvecchi, 2016). But language models are far from perfect, to the point where sometimes, text generated by complex natural language generation models are considered to be hallucinating. The term hallucination here refers to text that has been generated or processed to solve tasks like machine translation or Natural Language Generation, that are easily subject to the issue of being grammatically correct but being untethered from the user's input or the source material (Lee et al., 2019). This paper attempts to classify these hallucinating texts using different models and methods, in order to see which can get the best results in terms of accuracy.

2 Task Description

Semeval's task 6, hereinafter denoted as SHROOM, asks participants to successfully classify hallucination texts from non-hallucinating text, where each data has been annotated by 5 different annotators, where a majority vote is done to categorize each data point. Going over the JSON input data presented in Figure 1, The "hyp" row refers to the text that has been generated/processed by a model, so the output. The model here could refer to something like BERT, and can be seen as the "model" value. "src" refers to the user input or source material the model is working with in order to produce the output, and the "tgt" is the expected result that the model should be aiming for. In Figure 1, the model's "task" is "DM", or Definition Modeling. The model is expected to provide the definition for the word asked on the input. In this case input asks for the meaning of surmounting. The output of the model is "hyp", and the correct answer is "tgt". This output is put on a majority vote by 5 people, and finally the data in Figure 1 was labeled as hallucinating, where the probability of 0.6 because 3 out of 5 people voted in favor of hallucinating.

3 System Overview

3.1 Data Pipeline

The structure of the data pipeline is as follows. Language models such as BERT or RoBERTa were used to pre-process and tokenize text, which were then turned into high dimensional vectors by the word embedding layer that is able to capture rich contexts (Vaswani et al., 2017). Hyperparameters include, binary cross entropy as the loss function as it is a binary classification task, epochs were set as 20. The Adam optimizer was utilized for training the model, and learning rates were set as 0.0005. The Adam optimizer was used because it can lead to better results than stochastic gradient descent depending on the task thanks to its dynamic adjusting of learning rates,(Zhang, 2018) and tinkering around with SGD and Adam personally has led to the conclusion that Adam is slightly better in terms of accuracy.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 270–273

```
[

      "Hallucination"
    ],
    "label": "Hallucination",
    "p(Hallucination)": 0.6
  },
```

Figure 1: SHROOM Data

3.2 Input Data

The features that were used from the input data are "src", "data", and "tgt". The three columns were concatenated into one column, but with a prefix of the column name attached at the front of the text, which resulted in a sentence like the following.

Concatenated Columns

```
"src": "<define> Infradiaphragmatic
 </define> intra- and suprasellar
 craniopharyngioma",
"tgt": "(medicine) Below the diaphragm.",
"hyp": "(anatomy) Relating to the
diaphragm."
```

This simply made working with the text data easier and while working with the validation dataset, no significant difference in accuracy was exhibited in this approach compared to using all three different columns. The idea was to let the attention mechanism of the transformer model of BERT's do most of the heavy lifting of figuring out the the context and relationship between the words, in this case the column names and the texts that follow (Vaswani et al., 2017). The column "model" was not used as it also did not lead to any change in the accuracy of all models and methods whatsoever. The text were split into train and validation datasets. Then the BERT or RoBERTa models were fine tuned so that it is able to achieve better results specifically for the classification of texts. The softmax activation function on the output layer of the neural network was used to get the predicted probability between 0 and 1 (as per Devlin et al., 2019). Besides complex models like BERT, classification methods such as logistic regression, SVC, and Naive Bayes were also used with word vectors created from BERT.

3.3 Data Augmentation

Overall, the pipeline was relatively simple, but one strategy that was employed to achieve better accuracy was to increase the amount of data available. The trial and validation data provided by Semeval was on the smaller side, which contributed to overfitting. The data also had the issue of being somewhat imbalanced with the non-hallucinating data in the validation dataset amounted to 295, whereas the hallucinating data amounting to 206. Data Augmentation was utilized to combat these issues. Data Augmentation is the modification, and augmentation of the input data itself. The text inside the input data is sometimes dropped randomly, replaced by synonyms, or words can be randomly inserted, thus creating more sentences with labels to work with. As dropping or inserting random words seemed detrimental as described by previous studies (see e.g. Wei and Zou, 2019), for this task, the data augmentation was restricted to adding data where words had been replaced by synonyms for a subset consisting of 10% of the total data.

Before Data Augmentation

```
(idiomatic, intransitive) To begin a new
endeavor with vigor.
```

After Data Augmentation

```
idiomatic intransitive to start out a new
endeavor with vigor
```

4 Results

Refer to Table 1 for the results from the initial attempt. The accuracies there are what was achieved after using a simple 80-20 train and test split on the data. Models like BERT and RoBERTa were fine-tuned while regular classification methods such as logistic regression, SVC and Naive Bayes were used with the word embedding vectors retrieved from BERT. After reviewing the results, the predictions made with BERT were submitted to Semeval, as it had the highest accuracy. However the submitted results actually achieved an accuracy of only 60%.

Table 1: Accuracy of Models/Methods

Model	Accuracy (%)
BERT	80
RoBERTa	76
SVC	50
Naive Bayes	48
Logistic Regression	46

4.1 Probability of Hallucination

A Spear-man correlation score of the expected train and test data obtained from the soft-max layer of BERT resulted in a 0.64. But the actual submission spear-man correlation coefficient was a 0.23. Compared to the top ranked team whose numbers were above 0.7, a 0.23 is a bit underwhelming, and has lots of room for improvement.

5 Conclusion and Limitations

Some potential improvements that could be employed are the following.

5.1 Cross Validation

First, cross validation instead of a simple train and test split. Though data augmentation allowed for more data, which in turn made a simple train and test split theoretically suffice, since the more data one has the less likely it is that a train test split, by pure luck, can affect the accuracy significantly, simply trying out cross validation could have led to more insight on the actual accuracy on the validation data (Bates et al., 2022).

5.2 Reduce Over-Fitting

Second, methods of reducing over-fitting. It is highly likely that BERT was being over-fit with the input data, considering how the BERT model using only the validation dataset with a train and test split resulted in a 0.8 accuracy, but a 0.6 with the final test data. To counteract over-fitting, lasso regression could be incorporated to add a penalty term for high variance (Ranstam and Cook, 2018).

5.3 Ensemble Learning

Third, the "task" column was not utilized as it did not impact accuracy in, but perhaps a different approach could have been to separate data based on tasks and then to feed those data to the pipeline. Which means a holistic ensemble learning model, that uses multiple models, whether it be using the same model or different ones, in order to get a more generalized correlation score that leads to less over-fitting can be a great method. This holistic approach can lead to not just better accuracy, but also a better spear-man correlation score. The current data pipeline did not utilize the probability feature of the input dataset, and an ensemble learning pipeline that can utilize the probability feature properly, alongside the stacking of generalization could be a way of achieving better spear-man scores. (Su et al., 2013)

5.4 Better Utilization of Data Augmentation

Fourth, a more thorough utilization of data augmentation. In supervised machine learning, limited data often leads to over-fitting, which is precisely why data augmentation was the key strategy to counter the issue, but a more thorough and systematic approach to utilizing data augmentation seems to be the key. In the final attempt, the amount of data point was a 1000 each for hallucinating text and non-hallucinating text, for a total of 2000. Perhaps starting with 2000, then 10,000, then 20,000, while trying out different strategies of how the data is augmented like random deletions and addition of words, instead of just relying on replacement of words with synonyms, would have definitely benefited this research immensely.(Ying, 2019)

DeepPavlov at SemEval-2024 Task 6: Detection of Hallucinations and Overgeneration Mistakes with an Ensemble of Transformer-based Models

Ivan Maksimov and **Vasily Konovalov** and **Andrei Glinskii**
Moscow Institute of Physics and Technology
{maksimov.ivan.v, vasily.konovalov, glinsky}@phystech.edu

Abstract

The inclination of large language models (LLMs) to produce mistaken assertions, known as hallucinations, can be problematic. These hallucinations could potentially be harmful since sporadic factual inaccuracies within the generated text might be concealed by the overall coherence of the content, making it immensely challenging for users to identify them. The goal of the SHROOM shared-task is to detect grammatically sound outputs that contain incorrect or unsupported semantic information. Although there are a lot of existing hallucination detectors in generated AI content, we found out that pretrained Natural Language Inference (NLI) models yet exhibit success in detecting hallucinations. Moreover their ensemble outperforms more complicated models.

1 Introduction

Over the past few years, Natural Language Generation (NLG) models have experienced substantial advancements, particularly due to transformer-based architectures like a Generative Pretrained Transformer (GPT) (Radford et al., 2019). However, two interconnected issues challenge the field: firstly, the tendency of present neural systems to generate incorrect yet smooth outputs and, secondly, the inadequacy of existing metrics in evaluating accuracy over fluency. This causes NLG models to "hallucinate", i.e., produce fluent but incorrect outputs that we currently struggle to detect automatically (Ji et al., 2023).

The Shared-task on Hallucinations and Related Observable Overgeneration Mistakes (SHROOM) has been suggested to address this challenge. In particular, the SHROOM task aims at addressing the existing gap in assessing the semantic correctness and meaningfulness of NLG models.[1] Within the Shared task (Mickus et al., 2024), one needs to detect grammatically sound English output that contains incorrect semantic information (i.e.,unsupported or inconsistent with the source input) in case there is no labeled training data available.

We propose to address the SHROOM task by leveraging an ensemble of pretrained transformer-based Natural Language Inference (NLI) models. The NLI models are used to derive features of hallucination probabilities, and then a tree-based gradient boosting model (Prokhorenkova et al., 2019) provides a final decision. Our results indicate that NLI-based models can be effectively used to detect hallucinations. Moreover, the ensemble model highly outperforms the base estimators in correlation with annotators' decisions.

To summarize, this work includes the following contributions:

- We conducted a systematic study, re-evaluating existing NLI models for hallucination detection tasks.
- We trained an ensemble of NLI models to detect hallucination that correlates with human judgment.

Additionally, we made the code publicly available.[2]

2 Background

Nowadays, it is well known that NLG models often generate coherent outputs that are not faithful to the given input, commonly referred as hallucinations (Maynez et al., 2020). Hallucination has been studied in a wide range of tasks, including but not limited to summarization (Huang et al., 2021), dialogue generation (Shuster et al., 2021) and a variety of other NLG tasks.

[1] https://helsinki-nlp.github.io/shroom/

[2] https://github.com/ivan-kud/semeval-2024-shroom

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 274–278

There are several benchmarks for hallucination detection. HaluEval includes 5,000 general user queries with ChatGPT responses and 30,000 task-specific examples from three tasks, i.e., question answering, knowledge-grounded dialogue, and text summarization (Li et al., 2023). FaithDial is a benchmark for hallucination-free dialogues by modifying hallucinated responses in the Wizard of Wikipedia (WoW) benchmarks (Dziri et al., 2022).

The SHROOM shared task organizers went one step further. The shared task was conducted with a newly constructed dataset of 4,000 model outputs labeled by five annotators each, including three NLP tasks: machine translation (MT), paraphrase generation (PG), and definition modeling (DM). Participants were asked to detect hallucinations in two different settings: a model-aware track where the organizers also provided a checkpoint to a model that generated the output and a model-agnostic track where they did not. The checkpoints are publicly available on HuggingFace.

All three NLG tasks are in English, with the exception of the input for the MT task, which is in Russian for the model-agnostic task and in many other languages for the model-aware task (Mickus et al., 2024).

3 Dataset

The dataset for the SHROOM challenge comprises a compilation of model-generated text entries with the aim to classify each output as either a hallucination of the generative model or not.

Information for the data sample includes the following fields: (i) *src* – the input text given to the generative language model; (ii) *hyp* – the generated textual output of the model; and (iii) *tgt* – the intended reference or the ground truth text that the model is supposed to generate; (iv) *task* – the task being solved; (v) *labels* – five labels, either *"Hallucination"* or *"Not Hallucination"* labeled by five annotators, and finally, (vi) *p(Hallucination)* indicates the proportion of annotators that labeled the data sample as a hallucination.

The dataset was split in the following way: training data of 30,000 samples without annotations with 10,000 samples for each task; validation data of 499 labeled samples with 187, 187, and 125 samples for DM, MT, and PG tasks, respectively; and test data of 1,500 examples without annotations to evaluate and rank the results of the competitors with 563, 562, and 375 examples for DM, MT, and PG tasks, respectively. Validation data sample is presented in Table 1.

All participants' submissions were evaluated using two criteria:

- Accuracy that the system reached on the binary classification.
- Spearman correlation of the system's output probabilities with the proportion of the annotators labeling the item as a hallucination.

4 Methodology

NLI task determines whether a hypothesis follows a premise and classifies it as either entailment, contradiction, or neutral. Previous research showed that NLI can be successfully used for hallucination detection in summarization (Gekhman et al., 2023).

Our system is an ensemble of several NLI pre-trained transformer-based models. Each model defines a new feature set, then a tree-based gradient boosting final estimator is trained on top of these features.

It's well known that in-domain training data are crucial for classifier performance (Konovalov et al., 2016). However, organizers do not provide us with the labeled training set, so we train final estimator on the labeled validation set.

The following is a list of NLI transformer-based models used in our pipeline:

- RoBERTa by Liu et al. (2019) is a robustly optimized BERT that outperformed BERT on the MNLI task.
- Sentence-RoBERTa by Reimers and Gurevych (2019) that returns sentence embeddings. Thus, we calculate the probability of hallucination as $1 - S$, where S is cosine similarity between the premise and hypothesis embeddings.
- DeBERTa by Manakul et al. (2023) uses an disentangled attention mechanism and an enhanced mask decoder being pre-trained on MNLI-m/mm outperformed BERT and RoBERTa of comparable sizes.
- T5 by Honovich et al. (2022) was trained on a binary problem (entailment or contradiction) on the bunch of NLU datasets: SNLI (Bowman et al., 2015), MNLI (Williams et al., 2017), Fever (Thorne et al., 2018), Scitail (Khot et al., 2018), PAWS (Zhang et al., 2019), VitaminC (Schuster et al., 2021).

Task	Input	Output	Reference	p(Halluc.)
DM	Because redpillers are usually normies or <define> Chadlites </define> while incels are ugly low - value males that women feel innately repulsed by .	(slang) An incel.	(incel, _, slang) A man of a slightly lower ranking on a scale of physical attractiveness than Chad.	0.2
MT	Ядрён батон!	Nuclear Baton!	Blimey!	1.0
PG	Are we resolved?	So, what, we're in the clear now?	Do we have a deal?	0.4

Table 1: Data examples from the validation sample of the model-agnostic track. Hallucination probability of 0.2 means that one of the annotators classified the example as a hallucination and the remaining four annotators classified it as not a hallucination. The resulting class label is determined by majority voting. For the DM task, the model had to define a word between two special tokens: <define> and </define>.

In addition to the output of the before-mentioned models, we add as features the lengths of input, output and reference texts. Then we train CatBoost (Prokhorenkova et al., 2019) models as metamodels on top of these features. Besides CatBoost model, we also train Random Forest (Breiman, 2001) implemented in scikit-learn library (Pedregosa et al., 2011) and LightGBM (Ke et al., 2017). CatBoost yields the best results among them.

5 Experimental setup

We do not use any preprocessing of input texts (premises and hypotheses). Neither do we use an unlabeled training set. So, the transformer-based models serve to obtain features from the validation and test sets, then the CatBoost metamodel is trained on the validation set and predicts the test set.

As for the CatBoost metamodel, we performed the following steps:

- We found the hyperparameters on the validation set by using Optuna (Akiba et al., 2019). Stratified k-fold cross-validation [3] with 10 splits was used for the classification model and k-fold cross-validation with 10 splits – for the regression model. The best parameters for the classification model for the model-agnostic task: `iterations = 216`, `learning_rate = 0.010`, `depth = 12`, and for the model-aware task: `iterations = 129`, `learning_rate = 0.005`, `depth = 9`. The best parameters for the regression model for the model-agnostic task: `iterations = 356`, `learning_rate = 0.029`, `depth = 5`, and for the model-aware task: `iterations = 317`, `learning_rate = 0.012`, `depth = 9`.
- We evaluated the metrics on the validation sample using repeated stratified k-fold cross-validation with 10 splits and 5 repeats.
- We trained it on the whole labeled validation set.
- We predicted test set labels.

6 Results

The results on the test set for both model-agnostic and model-aware tracks are presented in Table 2. There are scores for the baseline provided by organizers, best scores from the leader-board, individual transformer-based models and our system as a whole.

Among NLI pre-trained models, T5 model significantly outperformed other NLI models. However, our ensemble approach using features from all NLI pre-trained models significantly outperformed T5 in terms of correlation with annotators' decisions.

Our approach for model-agnostic case provided us with an accuracy of 82.1% and Spearman correlation of 0.752. With this approach, our team achieved the 6th place out of 41 in the competition for model-agnostic track. Only two teams achieved a higher Spearman correlation.

The same approach was applied for the model-aware track and provided us with an accuracy of 79.9%, which is the 8th place out of 38 in the com-

petition. The value of Spearman correlation turned out to be 0.713.

More detailed results of the competition can be found in Mickus et al. (2024).

7 Conclusion

In this paper, we describe the ensemble system for hallucination detection by using transformer-based models. We present a simple, yet effective ensemble pipeline that provided us with results comparable with the best scores for the both tracks.

Future work might include thoughtful error analysis. Improved quality can be achieved by annotating unlabeled training set with LLMs (Ostyakova et al., 2023). In addition, a multilingual setup of NLI models can be used to develop multilingual hallucination detection system (Chizhikova et al., 2023; Konovalov et al., 2020). The proposed approach can be used standalone or can be integrated into the DeepPavlov framework (Burtsev et al., 2018).

Abstract

In data and numerical analysis, Quantitative Question Answering (QQA) becomes a crucial instrument that provides deep insights for analyzing large datasets and helps make well-informed decisions in industries such as finance, healthcare, and business. This paper explores the "HIJLI_JU" team's involvement in NumEval Task 1 within SemEval 2024, with a particular emphasis on quantitative comprehension. Specifically, our method addresses numerical complexities by fine-tuning a BERT model for sophisticated multiple-choice question answering, leveraging the Hugging Face ecosystem. The effectiveness of our QQA model is assessed using a variety of metrics, with an emphasis on the f1_score() of the scikit-learn library. Thorough analysis of the macro-F1, micro-F1, weighted-F1, average, and binary-F1 scores yields detailed insights into the model's performance in a range of question formats.

1 Introduction

Quantitative Question Answering (QQA) is a crucial tool in the large field of data and numerical analysis because it uses sophisticated computer methods to extract and interpret significant information from large datasets. Imagine it as a strong force that has particular sway over important industries like finance, healthcare, and business, where it plays a crucial role in forecasting trends and assisting in the making of well-informed decisions. QQA acts as a driving force behind wise decisions by skillfully converting apparently complicated data into useful knowledge and clearing a way through the complexities of numerical data.

Our team, "HIJLI_JU," participated in Task 1 (Quantitative Understanding) of NumEval within SemEval 2024[1], thereby actively engaging in the competitive landscape. An annual series of international natural language processing (NLP) competitions called SemEval (Semantic Evaluation) evaluates the state-of-the-art in a range of tasks pertaining to semantic analysis and understanding. These challenges serve as a forum for practitioners and scholars from both academia and industry to investigate and expand the field of computational linguistics. SemEval is well known for its broad range of tasks, which address a variety of difficulties in natural language processing.

The presented QQA task in the context of the SemEval 2024 NumEval competition provides a platform for researchers and developers to showcase advancements in quantitative understanding (num). SemEval, an annual challenge, encompasses diverse language tasks, including sentiment analysis and word meanings, contributing to the ongoing progress in systems designed for language understanding and processing. Table 1 shows the example of the SemEval-2024 Task dataset.

This paper is organized as follows: in Section 2, a survey of related literature is presented, and in Section 3, a detailed description of the dataset is provided. Section 4 explores the details of our suggested model while Section 5 explains the experimental setup. Experiments using our model are shown in Section 6, and observations are discussed in Section 7. Bringing everything together, we wrap up the paper in Section 8 and offer some suggestions for future directions for study.

2 Related Work

The HIJLI_JU team participated in the IJCNLP-2017 Task 5 on Multi-choice Question Answering, focusing on vector representations and machine learning for classification (Sarkar et al., 2017). Their model, designed exclusively for English language questions. The methodology involves representing questions and answers in vector space, computing cosine similarity, and employing a classification approach to identify the correct answer

option.

Sandip presented a novel approach to enhance science-based Multiple Choice Question Answering (MCQA) systems by leveraging distributed semantic similarity and a classification approach. Three models (Model 1, Model 2, and Model 3) were developed to address differences in dataset formats, specifically focusing on IJCNLP Task 5 and SciQ datasets (Sarkar et al., 2020).

Zuccon looks into using fancy word techniques from computer language models for finding information better. They use special methods to understand words and put them into a translation model. The results show that this approach improves how well information is found, and it's flexible – it works well even if the word understanding is done differently or comes from a different set of information (Zuccon et al., 2015).

Researchers in the field of Quantitative Question Answering (QQA) have been investigating ways to enhance computer systems' capacity to respond to numerical questions. They've tried a range of tactics, such as deep learning and sophisticated machine learning. To improve response accuracy, certain studies might incorporate external data.

For QQA, standardized tests (datasets) covering a range of numerical questions in disciplines like science and finance are being developed. They're also developing equitable methods to evaluate the efficacy of these Q&A platforms.

The brittleness of existing AI systems, including large-scale language models, in arithmetic reasoning within natural language understanding is addressed by the proposed multi-task benchmark NUMGLUE (Mishra et al., 2022a). In order to prepare AI systems for increasingly difficult mathematical tasks, the benchmark attempts to promote the development of systems that are able to reason robustly about arithmetic in language.

EQUATE is a framework assessing quantitative reasoning in textual entailment for natural language understanding systems (Ravichander et al., 2019). State-of-the-art models don't consistently outperform a basic baseline, highlighting a potential gap in implicit quantity reasoning. This framework aims to spur the development of models focusing on quantitative reasoning in language understanding.

Chen and his colleague investigates whether neural network models can acquire numeracy skills, focusing on predicting numeral magnitudes in text (Chen et al., 2019). Introducing the Numeracy-600K benchmark dataset, the study explores various models. Additionally, they highlights a practical application scenario by demonstrating the task's utility in detecting exaggerated information.

Chen also addresses innumeracy issues in pretrained language models, focusing on the fundamental task of teaching language models to understand numerals in text (Chen et al., 2023). It suggests a method that combines a comparing-number task with number notation exploration, modification, and pre-finetuning. Their research shows enhanced performance in three benchmark datasets for tasks related to quantitative analysis, especially for RoBERTa.

3 Dataset

Semeval-2024 Utilizing current benchmark datasets for three different task types—Quantitative Prediction (QP), Quantitative Natural Language Inference (QNLI), and Quantitative Question Answering (QQA)—is the one of the task of NumEval Task 1: Quantitative Understanding (Chen et al., 2023; Mishra et al., 2022b). Managing numbers, forecasting numerical values, deciphering logical connections in numerical sentences, and responding to inquiries requiring numerical data are all part of these tasks. The goal is to assess and improve the performance of models in handling these quantitative tasks.

The provided data format appears to represent a set of questions along with options, correct answers, and additional attributes [2], [3]. Table 2 shows the different fields of Task 1 of NumEval Dataset. On the other hand, Table 3 gives the description of the statics of the dataset. Here's a description of the key components in the data format:

- **"question":** The primary question text is contained in this field.
- **"Option1" and "Option2":** There are two options available to answer the question in these fields.
- **"answer":** Indicates which option is the correct answer.
- **"type":** Specifies the type of question.
- **"question_sci_10E":** Represents the same question as "question" but with numerical values expressed in scientific notation (e.g., 1.4000000000×10^1 inches).
- **"question_char":** Represents the same question with numerical values written as characters (e.g., "1 4 inches").
- **"question_sci_10E_char":** Combines scientific notation and characters for numerical values in the question.
- **"question_mask":** Presents the question with placeholders like "[Num]" indicating where numerical values are expected to be filled.

In summary, this data format is designed to offer various question formats, including options and the

right response, as well as various ways to represent numerical values (scientific notation, characters, masked placeholders, etc.). It appears to be intended as a test of numerical information interpretation and comprehension in various formats.

4 System Description

We explored the realms of natural language processing, immersing ourselves in Hugging Face's dynamic ecosystem known for its transformative libraries such as transformers and datasets. At the heart of our machine learning endeavor was the fine-tuning of a BERT model for nuanced multiple-choice question answering, including numerical complexities. Hugging Face's BertTokenizer and TFBertForMultipleChoice powered our training, and the fine-tuned model effortlessly transitioned into competent inference on the test dataset [4].

We started our data preparation process by adding "context" and "label" to JSON files. Next, we transformed the data into Dataset objects that were kept in a DatasetDict. We managed a preprocess_function, used BertTokenizer, and used the Datasets map method with 'batched=True' with caution to optimize our operations. Performance was improved by enabling dynamic sentence padding during collation using the Data Collator For Multiple Choice modification. Figure 1 shows the system description of HIJLI_JU for the participation in SemEval-2024 Task 7.

BERT, or Transformers' Bidirectional Encoder Representations, which had been pre-trained using masked language modeling and next sentence predictions on a substantial amount of unlabeled text data. Our approach was based on its bidirectional capabilities, which enabled it to simultaneously capture semantic subtleties from both sides.

5 Experimental Setup

We set up the parameters for training with a batch size of 16 over ten epochs, a starting learning rate of 0.00001, and no warm-up phases. Our datasets' dimensions, comprising 564 examples for training, 81 for development, and 162 for testing, demonstrated accuracy. The purpose of this rigorous training setup was to guarantee our QQA model's generalizability and robustness.

Using Jupyter Notebooks, Google Colab is a cloud-based platform that offers an interactive and collaborative environment for Python coding. Well-known for providing free access to GPU and TPU resources, Colab has grown to be a well-liked option in the data science and machine learning domains. Its smooth integration with Google Drive makes sharing and collaborative editing simple, which improves the effectiveness of team projects. Because of its intuitive interface and free availability of robust computational resources, Google Colab is an indispensable resource for individuals and groups working on a variety of computational tasks.

6 Results

In our quest to evaluate the efficacy of our Quantitative Question Answering (QQA) model, we employed a comprehensive set of metrics and examined its performance across various question formats. The `scikit-learn` library's `f1_score()` function served as our tool for this evaluation, offering insights into the model's proficiency in different contexts.

$$F1 = \frac{2 \times (Precision \times Recall)}{Precision + Recall} \quad (1)$$

$$Precision = \frac{TP}{TP + FP} \quad (2)$$

$$Recall = \frac{TP}{TP + FN} \quad (3)$$

Here, TP represents the number of true positives, FP represents the number of false positives, and FN represents the number of false negatives.

The F1 Score is a fundamental metric in machine learning, providing a balanced evaluation of classification models by combining precision and recall. This versatile metric has several variants, each suited to different scenarios. In this essay, we delve into macro-F1, micro-F1, weighted-F1, average, and binary-F1, exploring their applications and significance.

6.1 Macro-F1 Score

The macro-F1 Score calculates the F1 Score for each class independently and then computes the unweighted average. This approach treats all classes equally, making it valuable when assessing a model's performance across diverse classes without bias towards larger ones.

[4] https://huggingface.co/docs/transformers/en/tasks/multiple_choice

Files	Size
QQA_train.json	564
QQA_dev.json	81
QQA_test.json	162

Table 3: Statistics of SemEval-2024 Task 7 Dataset

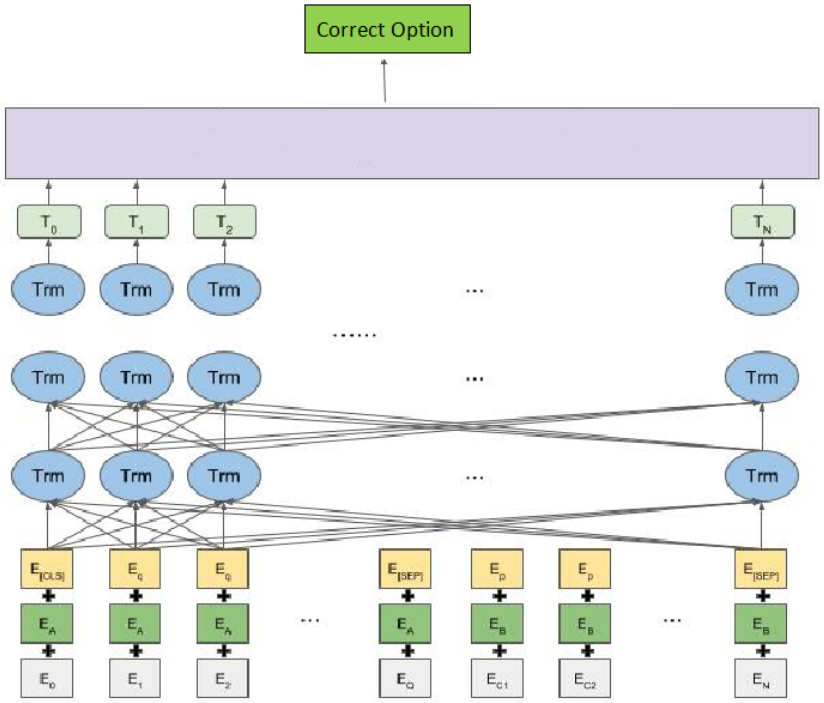

Figure 1: BERT Model

6.2 Micro-F1 Score

In contrast, the micro-F1 Score aggregates the contributions of all classes into a single F1 Score. Particularly useful for imbalanced datasets, it considers the varying sizes of different classes, providing an overall evaluation that accounts for class imbalances.

6.3 Weighted-F1 Score

The weighted-F1 Score extends the macro-F1 approach by considering class sizes. It calculates F1 Scores for each class and then computes a weighted average based on the number of instances in each class. This adjustment ensures that larger classes contribute proportionally more to the overall score.

6.4 Average F1 Score

The term "average F1 Score" is a general descriptor that encompasses various approaches to aggregating F1 Scores across multiple classes. It may refer to micro-F1, macro-F1, or other weighted or unweighted averages, depending on the context.

6.5 Binary F1 Score

The binary F1 Score is the traditional F1 Score applied to a binary classification problem with two classes – positive and negative.

7 Observations

The observed results highlight the nuanced performance of the Quantitative Question Answering (QQA) model across different question formats. Notably, questions presented in the character format consistently outperform other representations, demonstrating its robustness in handling diverse classes independently, particularly in imbalanced datasets. The Macro-F1, Micro-F1, and Weighted-F1 scores consistently identify the question_char format as the most effective in achieving a balanced evaluation. This format excels not only in independently handling varied classes but also in proportionally contributing to overall performance based on class instances. The Average F1 scores further affirm the versatility of the question_char format, emphasizing its capacity for a well-rounded

evaluation across multiple classes.

8 Conclusion and Future Work

In conclusion, we found that Quantitative Question Answering (QQA) is like a helpful tool for understanding numbers better. It's useful in important areas like business, healthcare, and finance, helping with predicting trends and making smart decisions. QQA is like a guide that empowers organizations and people to understand and use tricky data. The research we did shows how important QQA is for understanding numbers better.

Looking ahead, there are exciting possibilities for more research on QQA. We could explore new tasks and find ways to use QQA in specific areas like healthcare. Working with experts in different fields could help make QQA more useful in different situations. Also, we can improve how we measure the success of QQA and make it better by using the latest technology and techniques in language understanding. This ongoing exploration will keep pushing QQA to new places and make it even more important in understanding both language and numbers.

Abstract

In this study, we introduce an MLP approach for extracting multimodal cause utterances in conversations, utilizing the multimodal conversational emotion causes from the ECF dataset. Our research focuses on evaluating a bi-modal framework that integrates video and audio embeddings to analyze emotional expressions within dialogues. The core of our methodology involves the extraction of embeddings from pre-trained models for each modality, followed by their concatenation and subsequent classification via an MLP network. We compared the accuracy performances across different modality combinations including text-audio-video, video-audio, and audio only.

1 Introduction

In recent times, multimodal sentiment analysis has become a critical research frontier in the realm of natural language processing, moving beyond the confines of traditional text analysis to embrace a richer blend of audio, visual, and text data. This comprehensive approach aims to deepen our understanding of sentiments and emotions.

Previous research has highlighted the effectiveness of hierarchical fusion techniques and context modelling in improving the precision of multimodal sentiment analysis by adeptly merging features from varied modalities (Wang et al., 2023). Additionally, initiatives such as the Unified Multimodal Sentiment Analysis and Emotion Recognition UniMSE have proven the benefits of applying contrastive learning techniques to enhance performance in both sentiment analysis and emotion recognition, underscoring the significance of integrated frameworks within this field (Hu et al., 2022). CubeMLP delves into the realm of feature mixing for multimodal data processing (Sun et al., 2022). Meanwhile, the MMLatch model sheds light on the critical roles of bottom-up and top-down fusion mechanisms (Paraskevopoulos et al., 2022), offering insights into the impact of high-level representations on the synthesis of sensory information.

This study proposes the development of a Multilayer Perceptron network, specifically designed to extract causal utterances from the Multimodal Emotion-Cause Pair Extraction in Conversations (ECF) dataset (Wang et al., 2024).

2 Data Description

For this research, the ECF dataset has been selected as the primary source of data for training and testing our model. The ECF dataset contains several key elements that are integral to our study:

- Video Clips: Each sample in the dataset includes a video clip from the show Friends, capturing the visual expressions, body language, and interactions between characters.
- Audio Tracks: Audio tracks in the video clips, which include the spoken dialogues, tone of voice, laughter, and other paralinguistic features.
- Transcribed Text: For each clip, the spoken dialogues are transcribed to provide textual context to the interactions.
- Emotion and Sentiment Annotations: The dataset provides detailed annotations for each dialogue segment, including the emotion category, the emotion utterance, and the cause utterance.

Our research leverages the video and audio components of the ECF dataset. By analyzing the video and audio modalities, our goal is to uncover the underlying patterns and triggers of emotional expressions, without the direct influence of textual information.

To adapt the ECF dataset for our specific research objectives, a meticulous data preparation

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 285–290

process is undertaken. This involves: - Annotation Mapping: Aligning the cause utterance annotations with the corresponding audio and video segments for supervised learning. - Dataset Split: The dataset is divided into training validating subsets as 8:2, the testing subset is provided by the task provider.

Our research endeavours to architect a model that harnesses the strengths of each modality to provide a comprehensive understanding of sentiment. At the core of our methodology is a model architecture designed to seamlessly integrate these diverse data types, leveraging the power of pre-trained models to extract embeddings from text, video, and audio streams for sentiment extraction and classification.

The model lies in the process of concatenating the embeddings generated by these modularity extractors. This approach not only preserves the richness of each modality data but also facilitates the creation of a unified representation that embodies the composite sentiment conveyed across text, video, and audio. The concatenated embeddings serve as input to a Multilayer Perceptron (MLP) classifier, which is designed to discern the integrated sentiment.

3 Methodology

We propose an MLP network architecture designed to synergize the embeddings extracted from video and audio. This network aims to process and integrate these multimodal inputs, facilitating the classification of cause utterances within the framework of sentiment analysis without relying on textual information. The decision to exclude textual data from our analysis stems from a desire to investigate the intrinsic value of audio-visual cues in sentiment analysis.

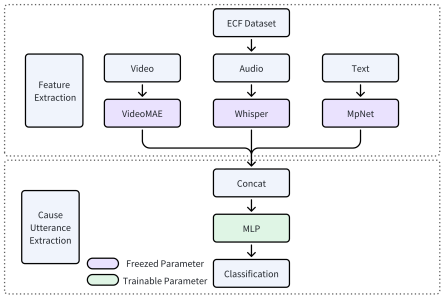

Figure 1: Overview of the cause utterance classification model.

As shown in Figure 1, this model contains two parts, feature extraction and classification. First, we extract audio, video, and text embedding from the pre-trained model. The text embedding extraction is for the comparison of experiments. Then the embeddings are concatenated and put into the MLP network which acts as the classifier for extracting cause utterances. To facilitate the extraction of emotion category and cause utterance, these tasks are regarded as classification tasks. The labels associated with the emotion category and cause utterance are regarded as the classes for these two tasks. This approach enables the MLP to execute the classification.

3.1 Embedding Extraction

VideoMAE is utilized for extracting video embeddings. This model, based on the Masked Autoencoder principle, selectively masks portions of the input video frames and reconstructs the missing parts, thereby learning robust video representations. (Tong et al., 2022) Given an input video V, the model produces an embedding E_V as follows:

$$E_V = \text{VideoMAE}(V) \tag{1}$$

To obtain the video embedding, frames are initially extracted from the video at their native resolution and compiled into a list. Temporal subsampling is applied to this collection of frames, a measure aimed at reducing computational time. Each subsampled set of frames applied normalization and resizing as data augmentation before being inputted into the pre-trained VideoMAE model to acquire the corresponding embeddings.

Whisper is used to extract audio embeddings from the corresponding audio tracks. Whisper processes the raw audio signals, focusing on capturing the nuances of speech, tone, and other auditory features relevant to sentiment analysis (Radford et al., 2022). For an audio input A, the Whisper model outputs an embedding E_A as:

$$E_A = \text{Whisper}(A) \tag{2}$$

Audio information was segregated from the video content and resampled to a 16000Hz sample rate to align with the Whisper model. In leveraging the pre-trained Whisper model for embedding extraction, the classification head was removed to get the pooler output.

MPNet is used to extract text embeddings. MPNet integrates the strengths of both masked language modelling (MLM) and permuted language modelling (PLM) to effectively capture the context

of words in a sentence, both from left-to-right and right-to-left, making it effective for understanding the full context of textual data.For an text input T, the Whisper model outputs an embedding E_T as:

$$E_T = \text{MPNet}(T) \tag{3}$$

3.2 Integration of Embeddings

The embeddings E_V and E_A are concatenated to form a unified representation E_{VA} of the video and audio modalities:

$$E_{VA} = \text{Concat}(E_V, E_A) \tag{4}$$

The embeddings E_V, E_A and E_T are concatenated for the ablation test:

$$E_{VAT} = \text{Concat}(E_V, E_A, E_T) \tag{5}$$

This concatenated embedding serves as the input to the MLP network. The decision to concatenate these embeddings is based on the hypothesis that doing so preserves the distinctiveness of each modality while allowing the network to learn from the intermodal dynamics, essential for identifying cause utterances.

3.3 Network Design

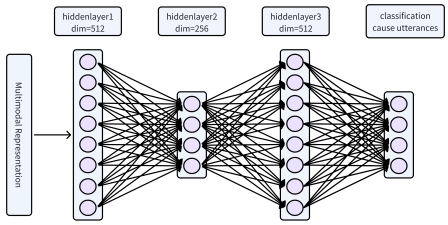

Figure 2: An MLP model aims to classify cause utterance from multimodal embeddings.

Our model employs a MLP architecture, crafted to process and classify concatenated video and audio embeddings. The simplicity and interpretability were significant considerations in choosing the MLP network as the classifier.

The MLP consists of four fully connected layers. The first layer expands the input to 512 hidden units, followed by a reduction to 256 units in the second layer, and an expansion back to 512 units in the third layer, before concluding with the output layer that matches the number of cause utterance classes.

Each hidden layer is equipped with a ReLU activation function to introduce non-linearity, allowing the model to learn complex patterns in the data. To combat overfitting, a dropout rate of 0.5 is applied after each ReLU activation, regularizing the network by randomly omitting a subset of features at each iteration of the training process.

The MLP network is designed with four fully connected layers, integrating nonlinear activation functions and dropout for regularization. Given the concatenated embedding E_{VA}, the forward pass through the MLP can be described by the following set of equations:

- **First Layer Transformation:** The input is passed through the first fully connected layer, transforming it to a higher-dimensional space.

  $$H_1 = \text{ReLU}(W_1 E_{VA} + b_1) \tag{6}$$

  where W_1 and b_1 are the weights and biases of the first linear layer, respectively, and E_{VA} represents the concatenated embeddings. ReLU activation follows to introduce non-linearity.

- **Applying Dropout:** To prevent overfitting, dropout is applied to the output of the ReLU activation,

  $$D_1 = \text{Dropout}(H_1) \tag{7}$$

- **Second and Third Layer Transformations:** The second and third layers further process the data through linear transformations and ReLU activations:

  $$H_2 = \text{ReLU}(W_2 D_1 + b_2) \tag{8}$$

  and

  $$H_3 = \text{ReLU}(W_3 D_2 + b_3) \tag{9}$$

  where W_2, W_3, b_2, and b_3 correspond to the weights and biases of these layers. Each transformation is followed by dropout to enhance model generalization.

- **Final Layer Transformation:** The last step in the network involves passing the output through a final fully connected layer without subsequent ReLU activation, resulting in the output logits,

  $$O = W_4 D_3 + b_4 \tag{10}$$

  This layer maps the processed features to the target output space.

Where W_i and b_i represent the weights and biases of the i^{th} layer, respectively, and ReLU is the Rectified Linear Unit activation function. The dropout is applied after each activation except the final layer to mitigate overfitting.

The output O represents the logits corresponding to each class, which in this case are the possible cause utterances. The model employs a cross-entropy loss function to compute the difference between the predicted probabilities and the actual class labels. This loss guides the training process through backpropagation, adjusting the weights W_i and biases b_i to minimize prediction errors. The network is optimized using the Adam optimizer, with a learning rate of 0.0002.

4 Experiments

In the subtask2 dataset, 1,374 conversations have been annotated by human evaluators. The dataset comprises 13,619 video clips, each tagged with a cause utterance label, delineating the specific cause associated with the clip. These cause utterances are distributed across 29 distinct categories. 66.49 percentage of the cause utterances can be attributed to the context provided by the current video clip itself.

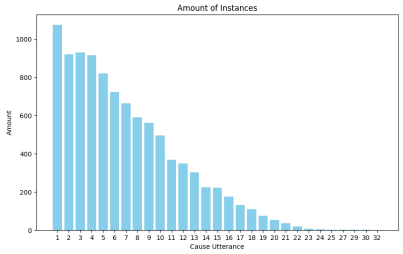

Figure 3: Overview of the cause utterance instances distribution. The cause utterance tends to be more related to earlier situations.

The histogram of Fig.3 illustrates the frequency of instances for each cause utterance category, with a descending order of occurrence. Categories are indexed from 1 to 32 on the x-axis, reflecting a diverse range of causes utterances. The y-axis quantifies the amount of instances, highlighting the prevalence of lower-indexed categories.

4.1 Training Process

The training of our MLP model follows a systematic approach. We utilize the cross-entropy loss, which combines a softmax activation and a log loss in one function. This choice is particularly suited for multi-class classification problems, as it measures the performance of a classification model whose output is a probability value between 0 and 1. The Adam optimizer is chosen for its effectiveness in handling sparse gradients and adapting the learning rate for each parameter, which is crucial given the complexity of our model and the diverse nature of our data. The learning rate is set to 0.0002, offering a balance between fast convergence and the risk of overshooting minimal loss. Our model undergoes training for 2000 epochs. This training period ensures that the model has the opportunity to learn from the entire dataset, optimizing its parameters to identify cause utterances. The alignment of these choices with our research objectives and dataset characteristics ensures a rigorous yet efficient training process, tailored to maximize performance while mitigating the risk of overfitting.

4.2 Metrics

To evaluate the model's performance, we employ the F1 score and weighted F1 score as our primary metrics. These metrics are particularly chosen for their relevance in classification tasks.

F1 Score is calculated as the harmonic mean of precision (P) and recall (R), providing a comprehensive measure of the model's accuracy across all classes. It is given by the equation:

$$F1 = 2 \times \frac{P \times R}{P + R} \tag{11}$$

This metric effectively balances the precision and recall, offering a singular view of model performance.

Weighted F1 Score extends the F1 score by weighting each class's score according to its presence in the dataset. This adjustment makes the metric more representative of the model's performance across classes of varying sizes. The weighted F1 score can be expressed as:

$$\text{Weighted F1} = \sum_{i=1}^{n} w_i \times F1_i \tag{12}$$

where w_i is the weight or relative frequency of class i in the dataset, and $F1_i$ is the F1 score for class i. This calculation ensures the final score reflects the proportional significance of each class, making it invaluable for datasets with class imbalances. These metrics provide an assessment of the model's performance, reflecting its effectiveness in classifying the embeddings in alignment with cause utterance extraction.

5 Ablation Studies

In the context of investigating the ECF dataset, our research undertook a series of ablation studies. These studies were aimed at elucidating the impact of various combinations of modalities on the efficacy of cause utterance classification. These studies are crucial for understanding how combining video, audio, and text data can enhance performance. These studies also help people assess the individual impact of each modality of data on the task cause utterance classification. Ablation Study Design The ablation studies were designed to compare the following configurations:
- Utilization of video, audio, and text embeddings. We utilized video, audio, and text embeddings to assess the maximum potential of multimodal data fusion. This configuration represents the most comprehensive approach.
- Utilization of video and audio embeddings without text. By employing video and audio embeddings while excluding text, our objective is to test whether the information conveyed by the audio modality is equivalent to that of the text modality. This comparison helps us understand the extent to which visual and auditory information alone can drive the classification process.
- Utilization of either video or audio embeddings exclusively. This test helps determine the standalone capabilities of visual and auditory data in identifying cause utterances.

5.1 Ablation Study Results

The network design does not incorporate any combination of modalities.

Configuration	F1	wF1
Video + Audio + Text	0.0253	0.0552
Video + Audio	0.0237	0.0694
Video Only	0.0144	0.0255

Table 1: Ablation Study Results on the ECF Dataset development set.

Configuration	F1	wF1
Video + Audio + Text	-	-
Video + Audio	0.0152	0.0146
Video Only	0.0222	0.0119

Table 2: Ablation Study Results on the ECF Dataset test set.

The combination of video and audio embeddings emerged as a configuration, showcasing its ineffectiveness in the absence of textual data.

6 Conclusion

We proposed a bimodal framework incorporating visual and acoustic modalities for emotion extraction from the "Friends" series, with the addition of a text modality to discern its performance enhancement. The results demonstrate that as the number of modalities increases, the accuracy of emotion extraction gradually improves. Particularly, the Visual-Acoustic model exhibits relatively good accuracy, with a significant improvement upon the addition of the textual modality. The experiment highlights:

- The crucial role of the text modality in sentiment analysis.
- In scenarios lacking textual data, the application of bi-modal models incorporating visual and acoustic modalities can effectively accomplish recognition tasks.

However, the experiment has several limitations concerning the target task. For instance, it did not utilize state-of-the-art pre-trained models, resulting in intra-modality comparisons without specifying the most suitable model for the task. To overcome this limitation, we will develop an evaluation system in our future work to further investigate the effects of embedding extraction using different modalities with pre-trained models. Due to time and resource constraints, the experiment did not extensively tune the models, thereby might not show their optimal performance. Future research could explore using Multi-modal LLMs and task-specific pre-trained models to predict emotion cause in conversations.

DeBERTa at SemEval-2024 Task 9: Using DeBERTa for Defying Common Sense

Marco Siino
Department of Electrical, Electronic
and Computer Engineering
University of Catania
Italy
marco.siino@unipa.it

Abstract

The significant achievements of language models have motivated researchers in the natural language processing (NLP) community to confront challenges requiring nuanced and implicit reasoning, inspired by human-like common-sense understanding. Although efforts focusing on vertical thinking tasks have received substantial recognition, there remains a notable lack of investigation into lateral thinking puzzles. To bridge this void, the authors at SemEval-2024 propose BRAINTEASER: a multiple-choice Question Answering task designed meticulously to assess the model's lateral thinking capabilities and its capacity to question default common-sense assumptions. Specifically, at the SemEval-2024 Task 9, for the first subtask (i.e., Sentence Puzzle) the organizers asked the participants to develop models able to reply to multi-answer brain-teasing questions. For this purpose, we propose the application of a DeBERTa model in a zero-shot configuration. The proposed approach achieves an aggregate score of 0.250. Suggesting a significant room for improvements in future works.

1 Introduction

Human reasoning encompasses two fundamental types of cognitive processing: vertical and lateral thinking. Vertical thinking is marked by its sequential and analytical approach, drawing upon principles of rationality, logic, and rule-following, often attributed to the left-brain hemisphere (Knauff, 2013; Huang et al., 2023). This mode of thinking is essential for creating logical pathways, such as understanding physical scenarios or solving riddles based on direct associations. In contrast, lateral thinking, often referred to as "thinking outside the box," is a creative cognitive process. It entails exploring problems from unconventional perspectives and challenging ingrained assumptions. Lateral thinking, associated with the right-brain hemisphere, is crucial for resolving unconventional puzzles by defying common-sense associations and considering alternative perspectives.

While natural language processing (NLP) models have made significant strides in vertical thinking tasks, particularly in the field of large language models (LLMs). Their performance in lateral thinking remains largely unexplored. LLMs have demonstrated remarkable performance across various reasoning tasks, even when provided with minimal or no training examples. These models excel in tasks requiring vertical thinking abilities, such as reasoning over physical interactions and social implications (Siino et al., 2022b), showcasing strong common-sense association and inference capabilities. However, prior research has largely overlooked the evaluation of LLMs' lateral thinking abilities, as creative thinking problems are often filtered out during data preprocessing, and only those aligned with common-sense associations are retained.

To address this gap, a novel benchmark called BRAINTEASER (Jiang et al., 2023) to evaluate the lateral thinking abilities of state-of-the-art LLMs is proposed at SemEval-2024 Task 9 (Jiang et al., 2024). The organizers frame lateral thinking puzzles as multiple-choice Question Answering (QA) tasks, a format that is intuitive for humans to engage with and straightforward to assess automatically. The BRAINTEASER benchmark comprises two tasks: Sentence Puzzles and Word Puzzles, designed to assess lateral thinking at different levels of granularity. To develop the dataset, organizers employ a data collection pipeline that retrieves relevant puzzles from publicly available websites, filters out irrelevant question categories, and ensures high data quality. Additionally, to mitigate concerns regarding LLM memorization and consistency, the organizers enhance BRAINTEASER with two reconstruction strategies: semantic reconstruction and context reconstruction. These strate-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 291–297

gies aim to promote deeper understanding and reasoning rather than mere memorization of patterns.

To meet these objectives, there is a growing demand for automated tools capable of understanding data using recent advancements in NLP models. The emergence of machine and deep learning architectures has sparked increased interest in NLP, prompting substantial efforts to develop techniques for automated identification and understanding of textual content available on the internet. In the literature, various strategies have been proposed so far. Over the past fifteen years, some of the most successful approaches have included Support Vector Machines (SVM) (Colas and Brazdil, 2006; Croce et al., 2022), Convolutional Neural Networks (CNN) (Kim, 2014; Siino et al., 2021), Graph Neural Networks (GNN) (Lomonaco et al., 2022), ensemble models (Miri et al., 2022; Siino et al., 2022), and Transformers (Vaswani et al., 2017).

The sections of this paper are structured as follows: Section 2 offers background information on Task 9, held at SemEval-2024. In Section 3, we outline the approach introduced in this study. Section 4 delves into the specifics of the experimental setup employed to reproduce our findings. The outcomes of the official task and relevant discussions are presented in Section 5. Finally, Section 6 concludes our study and suggests avenues for future research.

We make all the code publicly available and reusable on GitHub[1].

2 Background

The increasing adoption of Transformer-based architectures in academic research has also been bolstered by various methodologies showcased at SemEval 2024. These methodologies tackle diverse tasks and yield noteworthy findings. For instance, at the Task 2 (Jullien et al., 2024), where to address the challenge of identifying the inference relation between a plain language statement and Clinical Trial Reports is used T5 (Siino, 2024c); Task 4 (Dimitrov et al., 2024) where is employed a Mistral 7B model to detect persuasion techniques in memes (Siino, 2024b); and Task 8 (Wang et al., 2024), that utilizes a DistilBERT model to identify machine-generated text (Siino, 2024a).

The Task 9 hosted at SemEval-2024, is based on the human reasoning processes comprising the two already-mentioned types of thinking: vertical and lateral.

Specifically, the BRAINTEASER QA task consists of two subtasks: the Sentence and the Word Puzzle ones, that require awareness of commonsense "defaults" and overwriting them through unconventional thinking that distinguishes these defaults from hard constraints.

In detail, for the Sentence Puzzle one, the puzzle defying common-sense is centred on sentence snippets. On the other hand, for the Word Puzzle subtask, the response diverges from the conventional interpretation of the word and concentrates on the letter arrangement within the target question.

Both subtasks incorporate an adversarial subset, crafted by manually altering the original brainteasers while preserving their underlying reasoning paths.

An example from the official CodaLab page[2] takes as example the following original sentence:

> *"A man shaves everyday, yet keeps his beard long."*

The four possible explanations are:

1. **He is a barber.**
2. He wants to maintain his appearance.
3. He wants his girlfriend to buy him a razor.
4. None of the above.

However, the task organizers also included two other samples based on the previous one. In these two cases, a semantic and a contextual reconstruction have been made to challenge a classification model. The two reconstructions (with the same four possible explanations as in the original) are:

- SEMANTIC RECONSTRUCTION: *"A man preserves a lengthy beard despite shaving every day."*
- CONTEXT RECONSTRUCTION: *"Tom attends class every day but doesn't do any homework."*

3 System Overview

Despite evidence suggesting that Transformers may not always yield optimal results for every text classification task (Siino et al., 2022a), various strategies, such as domain-specific fine-tuning (Sun et al.,

[1] https://github.com/marco-siino/SemEval2024/

[2] https://codalab.lisn.upsaclay.fr/competitions/15566

2019; Van Thin et al., 2023) and data augmentation (Lomonaco et al., 2023; Mangione et al., 2022; Siino et al., 2024a), have proven to be advantageous depending on the task's objectives.

However, to address the task 9 hosted at SemEval-2024 we made use of a zero-shot learning approach (Chen et al., 2023; Wahidur et al., 2024), making use of the DeBERTa Transformer (He et al., 2020).

Our approach is zero-shot (Pourpanah et al., 2022) and make use of the above-mentioned DeBERTa model. Specifically, we employed the multilingual version 3 fine-tuned on the SQuAD2.0 dataset[3]. DeBERTa improves upon the BERT and RoBERTa models by introducing disentangled attention mechanisms and an enhanced mask decoder. Leveraging these enhancements, DeBERTa outperforms RoBERTa across most Natural Language Understanding (NLU) tasks when trained on a dataset of 80GB in size. In DeBERTa V3, efficiency is further enhanced by integrating ELECTRA-Style pre-training with Gradient Disentangled Embedding Sharing. Comparative analysis against DeBERTa reveals notable enhancements in model performance across downstream tasks in the V3 version. Further elaboration on the novel techniques employed in this new model can be found in the original paper. The version of DeBERTa utilized in our experiments is mDeBERTa, a multilingual variant of DeBERTa. It maintains an identical architecture while being trained on CC100 multilingual data. The mDeBERTa V3 base model comprises 12 layers with a hidden size of 768. It encompasses 86 million backbone parameters and a vocabulary of 250,000 tokens, resulting in 190 million parameters in the embedding layer. This model underwent training using 2.5 trillion tokens of CC100 data, akin to the XLM-R model.

For the experimental settings, we started evaluating several prompt engineering strategies (White et al., 2023; Liu et al., 2023) to optimize the model replies and to obtain satisfactory results guided by the labelled samples in the training set. For example, we included in the prompt/question to the model, the premise that the given question is a brain-teaser one. Furthermore, we also evaluated the performance of the model on the training set using a few-shot learning setup. In this case, we provided as input (included in the prompt) ten questions indicating the correct answer. Also in this case we did not obtain satisfactory results.

More specifically, given the task hosted at SemEval-2024, we asked the model: *"What is the correct answer to the brain teaser question from the following choices? (Pick only one Option (A)-(D)"*. To this request, the model replied with one or more words that we parsed to extract one of the choices. For example, given the context:

> *"Romeo and Juliet are discovered dead on the bedroom floor. Glass shards and some water were on the floor when they were found. A bookcase and a bed are the sole pieces of furniture in the space. Other than the neighboring railroad track, the house is located in a rural area. How is that even doable? "*

And our question:

> *"What is the correct answer to the brain teaser question from the following choices? (Pick only one Option (A)-(D)"*

And the answers/options:

> (A): They were sleeping and scared by the sound of track.
>
> (B): The rumble of the train moved the shelf which crushed them.
>
> (C): Romeo and Juliet are fish. The rumble of the train knocked the tank off the shelf, it broke and Romeo and Juliet did not survive.
>
> (D): None of above.

The model replied with:

> *"Romeo and Juliet are fish."*

that we mapped into the label *2* corresponding to the third answer. Finally, we collected all the predictions provided on the test set to into a JSON file with required format to submit our predictions.

During our experiments to build our prompt, we also evaluated other LLMs like GPT-Neo and GPT-NeoX (Gao et al., 2020). However, on the labelled training set, we found better performance of DeBERTa in the responses provided. It is also worth notice that we conducted several experiments to find an effective prompt strategy to address the task.

As indicated in a recent investigation by Siino et al. (Siino et al., 2024b), preprocessing does

[3] https://rajpurkar.github.io/SQuAD-explorer/

not significantly impact text classification tasks when employing Transformers. Specifically, the optimal combination of preprocessing strategies closely resembles the performance achieved without any preprocessing at all, particularly in the context of Transformer models. Therefore, to maintain a highly efficient and computationally lightweight system, we opted not to apply any preprocessing to the text.

4 Experimental Setup

We implemented our model on Google Colab. The library we used come from Hugging Face and as already mentioned is a multilingual version of DeBERTa[4]. The dataset provided for all the phases are available on the official competition page. We did not perform any additional fine-tuning on the model. To run the experiment, a T4 GPU from Google has been used. After the generation of the predictions, we exported the results on the format required by the organizers. As already mentioned, all of our code is available on GitHub.

5 Results

Participants in Brain Teaser may participate in any or all of the two subtasks. The organizers created two adversarial questions, semantic and context reconstruction, for each brain-teaser (examples can be found on the Task Home Page). The evaluation metrics applied are Instance-based Accuracy and Group-based Accuracy, defined as follows:

- Instance-based Accuracy: Each question, whether original or adversarial, is treated as an individual instance. Accuracy is reported for the original question, its semantic reconstruction, and context reconstruction.

- Group-based Accuracy: Questions and their corresponding adversarial instances are grouped together. A system earns a score of 1 only if it correctly answers all questions within the group. Accuracy is reported for original and semantic reconstruction and original and semantic and context reconstruction.

In Table 1, we present the outcomes derived from our methodology. They are the same results publicly available on the official final ranking shown on the official task page[5]. The results are about the sentence task, given the fact that we did not take part in the word-related task.

DeBERTa	
Original	0.225
Semantic	0.250
Context	0.275
Ori+Sem	0.200
Ori+Sem+Con	0.075
Overall	0.250

Table 1: The method's performance on the test set. In the table are reported the results obtained and shown on the official task page.

Table 2 presents the performance results of the top three teams alongside the results achieved by the final-ranking team, as displayed on the official task page. While our straightforward approach shows potential for enhancement compared to the top-performing models, it is noteworthy that our method required no additional pre-training. Moreover, the computational resources needed to address the task were manageable, utilizing the free online resources provided by Google Colab.

6 Conclusion

This paper introduces the utilization of a DeBERTa model for addressing Task 9 at SemEval-2024. In our submission, we opted for a zero-shot learning approach, leveraging a pre-trained and fine-tuned Transformer model without further adaptation. Through various experiments, we found it advantageous to construct a prompt containing the question for the model. Subsequently, we provided the context, question, and answer candidates as the prompt, prompting the model to discern the correct candidate answer. Despite the task's inherent complexity, as evidenced by the final ranking, there remains ample room for improvement.

Potential alternative methodologies include leveraging the few-shot learning capabilities of the model or exploring alternative models such as GPT and T5. Additionally, integrating additional data or incorporating samples from training and development sets could yield performance enhancements. Further refinements could be achieved through fine-tuning and framing the problem as a text classification task. Moreover, given the promising results

observed across various tasks, the adoption of few-shot learning or data augmentation strategies could also be explored for improved outcomes (Wang et al., 2023; Maia et al., 2024; Siino et al., 2023; Meng et al., 2024; Muftie and Haris, 2023; Tapia-Téllez and Escalante, 2020; Siino and Tinnirello, 2023).

While our straightforward approach demonstrates potential for refinement, it is noteworthy that it required no additional pre-training. Moreover, the computational resources needed to address the task were manageable, utilizing the free online resources provided by Google Colab.

Acknowledgments

We extend our gratitude to the anonymous reviewers for their insightful comments and valuable suggestions, which have significantly enhanced the clarity and presentation of this paper.

TransMistral at SemEval-2024 Task 10: Using Mistral 7B for Emotion Discovery and Reasoning its Flip in Conversation

Marco Siino
Department of Electrical, Electronic
and Computer Engineering
University of Catania
Italy
marco.siino@unipa.it

Abstract

The EDiReF shared task at SemEval 2024 comprises three subtasks: Emotion Recognition in Conversation (ERC) in Hindi-English code-mixed conversations, Emotion Flip Reasoning (EFR) in Hindi-English code-mixed conversations, and EFR in English conversations. The objectives for the ERC and EFR tasks are defined as follows: 1) Emotion Recognition in Conversation (ERC): In this task, participants are tasked with assigning an emotion to each utterance within a dialogue from a predefined set of possible emotions. The goal is to accurately recognize and label the emotions expressed in the conversation; 2) Emotion Flip Reasoning (EFR): This task involves identifying the trigger utterance(s) for an emotion-flip within a multi-party conversation dialogue. Participants are required to pinpoint the specific utterance(s) that serve as catalysts for a change in emotion during the conversation. In this paper we only address the first subtask (ERC) making use of an online translation strategy followed by the application of a Mistral 7B model together with a few-shot prompt strategy. Our approach obtains an F1 of 0.36, eventually exhibiting further room for improvements.

1 Introduction

Affective computing has experienced a resurgence, largely propelled by recent advancements in artificial intelligence. Emotion Recognition in Conversations (ERC) has emerged as a prominent task within affective computing, garnering increasing attention (Poria et al., 2019; Kumar et al., 2023). Its objective is to discern the emotion conveyed in each utterance during conversations, with implications for various applications including the development of effective dialogue systems, facilitating social viewpoint mining, and creating intelligent medical systems. Current research in ERC primarily focuses on capturing the emotional state of speakers through contextual analysis and establishing distinct contexts for different speakers, often leveraging multimodal data to support this endeavour. Despite recent strides, two major challenges persist: (1) Ensuring emotional consistency and (2) Generating contextual information. Current research efforts broadly fall into two categories: the first involves obtaining contextual representations of utterances using temporal neural networks, while the second entails capturing long-distance information through graph networks. However, these approaches overlook a crucial aspect: changes in utterance order can alter the meaning of utterances, potentially leading to varying emotional expressions. A shift in utterance order impacts the underlying meaning of the utterance, consequently influencing the speakers' emotions.

The increasing demand for automated tools capable of extracting and categorizing data from online sources underscores the need to address both established and emerging societal concerns efficiently. Recent strides in machine and deep learning architectures have sparked significant interest in Natural Language Processing (NLP). Efforts have been intensified towards developing techniques for automating the identification and categorization of textual content prevalent on the internet today. In the literature, various strategies have been proposed for performing text classification tasks. Over the past fifteen years, some of the most successful strategies have included Support Vector Machines (SVM) (Colas and Brazdil, 2006; Croce et al., 2022), Convolutional Neural Networks (CNN) (Kim, 2014; Siino et al., 2021), Graph Neural Networks (GNN) (Lomonaco et al., 2022), ensemble models (Miri et al., 2022; Siino et al., 2022), and more recently, Transformers (Vaswani et al., 2017; Siino et al., 2022b).

At SemEval-2024 Task 10 (Kumar et al., 2024a) – Emotion Discovery and Reasoning its Flip in Conversation (EDiReF) – three Subtasks were proposed. All the three subtasks are presented and

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 298–304

discussed in the Section 2.

To face with the first subtask (ERC), we proposed a Transformer-based approach which made use of Mistral 7B (Jiang et al., 2023). We used the model in a particular few-shot way described in the rest of this paper. Specifically, after translating all the code-mixed samples in English, we provided the samples from the labelled train and dev set to the model, asking while prompting to predict the emotion for the current utterance (i.e., the current sample from the test set).

The rest of the paper is made as follows. In Section 2 we provide some background on the Task 10 hosted at SemEval-2024. In Section 3 we provide a description of the approach presented. In Section 4 we provide details about the experimental setup to replicate our work. In Section 5, the results of the official task and some discussions are provided. In section 6 we present our conclusion and proposals for future works.

We make all the code publicly available and reusable on GitHub[1].

2 Background

This section furnishes background information regarding Task 10 (Subtask 1), held at SemEval-2024.

The EDiReF shared task at SemEval 2024 (Kumar et al., 2024a) encompasses three distinct subtasks, namely: Emotion Recognition in Conversation (ERC) within Hindi-English code-mixed conversations, Emotion Flip Reasoning (EFR) within Hindi-English code-mixed conversations, and EFR within English conversations (Kumar et al., 2022, 2024b). The ERC task involves the assignment of emotions to each utterance within a dialogue, drawn from a predefined set of potential emotions. Conversely, the EFR task focuses on identifying the trigger utterance(s) responsible for inducing an emotion-flip within a multi-party conversation dialogue.

In the Figure 1, is reported a sample from the official competition website[2] and specifically related to the Subtask 1 (i.e., ERC).

For Subtask 1, a submission entails a singular JSON file with each emotion in a new line. Every emotion correspond to each utterance in the official provided test set.

The second and the third subtasks differ on the language used. In one case, the language is code-mixed Hindi-English and in another case only in English. In both cases, the participants were asked to propose automatic detection systems able to detect a trigger utterance that determined a changed in the emotion. Also in this case, an example from the official task webpage is reported in the Figure 2. The EFR sample contains a trigger (i.e., 1) in proximity of the fourth sentence contained in the dialogue.

Speaker	Utterance
Sp_1	Aaj to bhot awful day tha! *(I had an awful day today!)*
Sp_2	Oh no! Kya hua? *(Oh no! What happened?)*
Sp_1	Kisi ne mera sandwich kha liya! *(Somebody ate my sandwich!)*
Sp_2	Me abhi tumhare liye new bana deti hun! *(I can make you a new one right now!)*
Sp_1	Wo great hoga! Thanks! *(That would be great! Thanks!)*

ERC aims to assign emotions to each utterance

Speaker	Utterance	Emotion
Sp_1	Aaj to bhot awful day tha! *(I had an awful day today!)*	Sad
Sp_2	Oh no! Kya hua? *(Oh no! What happened?)*	Sad
Sp_1	Kisi ne mera sandwich kha liya! *(Somebody ate my sandwich!)*	Sad
Sp_2	Me abhi tumhare liye new bana deti hun! *(I can make you a new one right now!)*	Joy
Sp_1	Wo great hoga! Thanks! *(That would be great! Thanks!)*	Joy

The example dialogue has two emotion flips. Sp_1's emotion changed from Sad to Joy while Sp_2's emotion also shifted from Sad to joy. EFR aims to justify such emotion flips using triggers.

Figure 1: Example of some samples from the dataset. In this case, we report samples related to the first ERC task in which we took part.

Speaker	Utterance	Emotion	Trigger
Sp_1	Aaj to bhot awful day tha! *(I had an awful day today!)*	Sad	0
Sp_2	Oh no! Kya hua? *(Oh no! What happened?)*	Sad	0
Sp_1	Kisi ne mera sandwich kha liya! *(Somebody ate my sandwich!)*	Sad	0
Sp_2	Me abhi tumhare liye new bana deti hun! *(I can make you a new one right now!)*	Joy	1
Sp_1	Wo great hoga! Thanks! *(That would be great! Thanks!)*	Joy	0

Figure 2: Example of some samples from the dataset. In this case, we report samples related to the EFR task.

3 System Overview

While it has been established that Transformers may not always be the optimal choice for text classification tasks (Siino et al., 2022a), the efficacy of various strategies, such as domain-specific fine-tuning (Sun et al., 2019; Van Thin et al., 2023) and data augmentation (Lomonaco et al., 2023; Mangione et al., 2022), depends on the specific objectives.

The increasing adoption of Transformer-based architectures in academic research has also been bolstered by various methodologies showcased at SemEval 2024. These methodologies tackle di-

[1] https://github.com/marco-siino/SemEval2024/
[2] https://lcs2.in/SemEval2024-EDiReF/

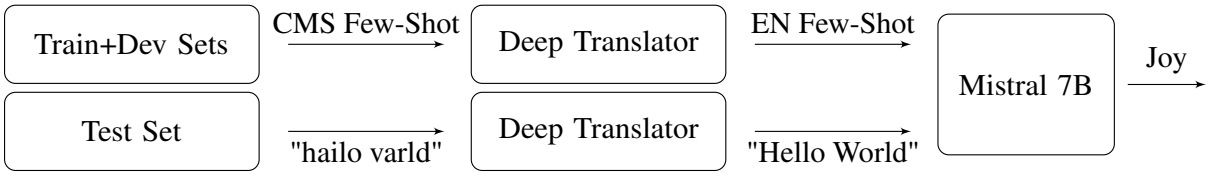

Figure 3: The system overview of our proposed approach. Given a set of Code Mixed Samples (i.e., CMS) from the train and dev sets, they are translated to English using Deep Translator (i.e., ENglish samples). Then they are all provided as input - a few-shot samples from the training set, together with the emotion definitions - to Mistral 7B. Following these few shot samples and the definitions as input, there is one utterance from the test set for which the emotion has to be predicted.

verse tasks and yield noteworthy findings. For instance, at the Task 2 (Jullien et al., 2024), where to address the challenge of identifying the inference relation between a plain language statement and Clinical Trial Reports is used T5 (Siino, 2024c); Task 4 (Dimitrov et al., 2024) where is employed a Mistral 7B model to detect persuasion techniques in memes (Siino, 2024b); and Task 8 (Wang et al., 2024), that utilizes a DistilBERT model to identify machine-generated text (Siino, 2024a).

Our approach is few-shot (Littenberg-Tobias et al., 2022) and make use of Mistral 7B. Mistral 7B, a language model boasting 7 billion parameters, is engineered to excel in both performance and efficiency. In comparison to the leading open 13B model (Llama 2), Mistral 7B demonstrates superior performance across all assessed benchmarks. Furthermore, it surpasses the top released 34B model (Llama 1) in tasks related to reasoning, mathematics, and code generation. The model capitalizes on grouped-query attention (GQA) to expedite inference, complemented by sliding window attention (SWA) to effectively process sequences of varying lengths while minimizing inference costs. Additionally, a fine-tuned variant, Mistral 7B – Instruct, is tailored for adhering to instructions, and it outperforms Llama 2 13B – chat model across both human and automated benchmarks. The introduction of Mistral 7B Instruct underscores the ease with which the base model can be fine-tuned to achieve notable performance enhancements.

For our task, before prompting the model with the current sample from the test set, we made an online and real-time use of *Google Translator* from the *deep_translator*[3] library. Then we randomly selected eighty samples from the provided labelled training set and other eighty from the provided labelled dev set. Then we formatted the samples in each set in the following way:

[3] https://pypi.org/project/deep-translator/

EMOTIONS
1. *disgust*
2. *joy*
3. *neutral*
4. *anger*
5. *sadness*
6. *contempt*
7. *surprise*
8. *fear*

Table 1: The list of all the motions available for the task.

speaker1 - utterance1 - emotion1
speaker2 - utterance2 - emotion2
...
speakerX - utterance80 - emotionY

After merging the formatted samples from both the training and the dev set, we fed the model, appending to the few-shot samples the current unlabelled sample from the official test set. At this point, the full text containing the few-shot samples plus the sample to be classified were provided as prompts to Mistral.

Then the question provided as prompt to the model was: *" Use the CONTEXT to complete the SENTENCE using ONLY one emotion among: disgust, joy, neutral, anger, sadness, contempt, surprise, fear. Do not explain!"*. Where the *CONTEXT* were the few-shot samples provided. For all the samples from the test set the model correctly predicted one of the available emotions from the list provided and shown in the Table 1.

As noted in the recent study by (Siino et al., 2024b), the contribution of preprocessing for text classification tasks is generally not impactful when using Transformers. More specifically, the best combination of preprocessing strategies is not very different from doing no preprocessing at all in the case of Transformers. For these reasons, and to keep our system fast and computationally light, we

have not performed any preprocessing on the text.

4 Experimental Setup

Our model implementation was executed on Google Colab, utilizing the Mistral 7B library from Hugging Face, specifically the Mistral-7B-Instruct-v0.2-GGUF [4] version. Additionally, we utilized the *deep_translator* package with Google Translator [5] for the translation task. The Mistral 7B version employed represents an enhanced iteration of the Mistral-7B-Instruct-v0.1 model, geared towards instruction fine-tuning. Instructions for instruction fine-tuning should be enclosed within [INST] and [/INST] tokens, with the initial instruction beginning with a sentence identifier, and subsequent instructions omitting this identifier. The generation process is terminated by the end-of-sentence token ID. Furthermore, we imported the Llama library (Touvron et al., 2023) from *llama_cpp*, with comprehensive details available on GitHub [6].

All datasets required for the various phases of the experiment are accessible on the Official Competition page. No additional fine-tuning was conducted on the model. The experiment was executed using a T4 GPU provided by Google. Upon generating the predictions, the results were exported in the format specified by the organizers. As previously mentioned, our complete codebase is accessible on GitHub.

5 Results

As described on the official task page[7], the evaluation criteria for the three tasks are delineated as follows:

- Task 1 (ERC for code-mixed): Weighted F1 score computed across all emotions.
- Task 2 (EFR for code-mixed): F1 score computed specifically for triggers (label '1.0').
- Task 3 (EFR for English): F1 score computed for triggers (label '1.0') in English.

To generate the prediction file:

1. For Task 1: Each line should depict an emotion associated with an utterance, with no additional lines separating dialogues. Each emotion should be in lowercase, devoid of extra spaces.
2. For Tasks 2 and 3: Each line should represent either 0.0 or 1.0, reflecting the label of triggers assigned to an utterance. The formatting should adhere to a string format with a floating precision of 1 (e.g., 0.0 or 1.0, rather than 0 or 1).

Then, it was asked to aggregate the outputs from all tasks into a single file named 'answer.txt', structured as follows:

- Lines 1–1580: Predictions for Task 1.
- Lines 1581–9270: Predictions for Task 2.
- Lines 9271–17912: Predictions for Task 3.

Upon compilation, the organizers asked to create a zip file encompassing *'answer.txt'* and proceed with submission as per guidelines.

	T1-F1	T2-F1	T3-F1
TransMistral 7B	0.36	0.10	0.22

Table 2: The method's performance on the test set. Even if we did not participate in the tasks 2 and 3, in the *answer* file we included a list of 0s to complete all the lines as suggested by the task organizers.

In the Table 2 we report the result obtained by the proposed approach on the official test set. Thanks to our application of an online translation followed by a Mistral 7B we have been able to reach the twenty-second position on the final ranking for the evaluation phase.

The Table 3 presents the performance outcomes achieved by the top three teams and the last-ranked team, as delineated on the official task page. While our simplistic approach showcases potential for enhancement in comparison to the leading models, it is noteworthy that our method necessitated no additional pre-training. Moreover, the computational resources utilized to tackle the task remained feasible, courtesy of the complimentary resources provided by Google Colab.

Table 3: Comparing performance on the test set. In the table are shown the results obtained by the first three users and by the last one ordered considering the first task. In parentheses is reported the position for each task in the official final ranking.

6 Conclusion

This paper presents the application of Mistral 7B-model for addressing the Task 10 at SemEval-2024. For our submission, we decided to follow few-shot learning approach, employing as-is, an in-domain pre-trained Transformer. After several experiments, we found it beneficial to build a prompt containing some samples from the training and from the dev set. Then we provide as a prompt the current translated sample together with the few-shot samples. The model was asked to select one of the emotion among the ones available. The task presents inherent challenges, with evident scope for refinement, as underscored by the final ranking. Potential alternative methodologies encompass leveraging the zero-shot capabilities inherent in other models such as GPT and T5, expanding the training set size through the incorporation of additional data, or adopting alternative strategies for integrating ontology-based domain knowledge beyond the approaches delineated in our study. Furthermore, refinement opportunities exist through fine-tuning and recontextualizing the problem as a text classification task.

Furthermore, given the interesting results recently provided on a plethora of tasks, also other few-shot learning (Wang et al., 2023; Maia et al., 2024; Siino et al., 2023; Meng et al., 2024) or data augmentation strategies (Muftie and Haris, 2023; Siino et al., 2024a; Tapia-Téllez and Escalante, 2020; Siino and Tinnirello, 2023) could be employed to improve the results. Looking at the final ranking, our simple approach exhibits some room for improvements. However, it is worth notice that it required no further pre-training and the computational cost to address the task is manageable with the free online resources offered by Google Colab. Also, thanks to the proposed approach, we have been able to outperform the baseline provided by the task organizers.

Acknowledgments

We express our sincere appreciation to the anonymous reviewers for their constructive feedback and invaluable suggestions. Their insightful comments have greatly contributed to the refinement and clarity of this paper.

Abstract

In this paper, we introduce a multi-agent debating framework, experimenting on SemEval 2024 Task 2. This innovative system employs a collaborative approach involving expert agents from various medical fields to analyze Clinical Trial Reports (CTRs). Our methodology emphasizes nuanced and comprehensive analysis by leveraging the diverse expertise of agents like Biostatisticians and Medical Linguists. Results indicate that our collaborative model surpasses the performance of individual agents in terms of Macro F1-score. Additionally, our analysis suggests that while initial debates often mirror majority decisions, the debating process refines these outcomes, demonstrating the system's capability for in-depth analysis beyond simple majority rule. This research highlights the potential of AI collaboration in specialized domains, particularly in medical text interpretation.

1 Introduction

Clinical Trial Reports (CTRs) are indispensable in clinical research, providing critical data that reveal the efficacy of new treatments on patients. However, the exponential growth in the volume of CTRs, due to the increase in clinical trials, challenges researchers in conducting individual report analyses. With the swift progress in Natural Language Processing (NLP) technologies, leveraging machine learning algorithms for automating the review of CTRs is increasingly recognized as a feasible and promising solution (Saban et al., 2024)(Amar et al., 2024).

For SemEval-2024 Task 2 (Jullien et al., 2024a), the organizers introduced an English dataset derived from CTRs (Jullien et al., 2023), aimed at evaluating the truthfulness of CTR-statement pairs by discerning their veracity. This dataset includes a series of CTRs alongside associated statements, each designed to represent a hypothesis that must be classified as either Entailment or Contradiction, based on its alignment with the CTR content.

In addressing this intricate challenge, our study introduces a novel multi-agent debating framework. Characterized by a diverse assemblage of expert agents – including but not limited to a Bio-Statistician, Medical Linguist, and Pharmacologist – this system facilitates structured debates to adjudicate on the classification of each statement as an entailment or contradiction. By harnessing the distinctive expertise and viewpoints of various agents, we significantly augment the precision and dependability of our assessments. Our observations indicate that consensus among agents typically emerges within the second or third round of discussion, with agents exhibiting varied opinions on the statements under review. This multi-agent debate approach has demonstrably surpassed the outcomes achievable through single-agent or direct Large Language Model (LLM) interventions. Despite not achieving top-tier placement on the leaderboard, largely due to our adoption of a zero-shot approach without model fine-tuning, our system's broad applicability across different domains remains a compelling advantage.

2 Background

2.1 Related Works

Large Language Models (LLMs) LLM represent a significant stride in machine learning, offering the capability to generate coherent natural language text based on given contexts (Shanahan, 2023). The advent of InstructGPT (Ouyang et al., 2022) epitomizes this progression, heralding a new era of LLMs with enhanced instruction-following and logical reasoning skills. Although proprietary models like OpenAI's GPT-3.5 and GPT-4 set performance benchmarks, the rise of open-source LLMs presents a compelling narrative of achieving comparable state-of-the-art (SOTA)

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 305–310

performance with cost-effective implementations (Li et al., 2023)(Jiang et al., 2024).

Multi-Agent Collaboration Drawing parallels to human teamwork, integrating LLMs as collaborative agents has shown improved efficacy across diverse tasks. Initiatives like BabyAGI (Nakajima, 2023) introduced frameworks for automatic task generation and execution, based on predefined objectives. AutoGPT (aut, 2023) extends LLMs' capabilities to interact with external tools for executing real-world tasks, such as web scraping and code execution. Furthermore, HuggingGPT (Shen et al., 2023) functions as a model selector within the Hugging Face ecosystem, optimizing task-specific model selection. MetaGPT (Hong et al., 2023) emulates a software development team, assigning distinct roles to LLMs to streamline the design and development process. This body of work underscores the significant enhancements and novel functionalities afforded by multi-agent collaboration.

LLM Debating System Debates, a cornerstone in assessing the viability of ideas within human discourse, have been adapted to the realm of LLMs. Initial investigations by (Liang et al., 2023) into multi-agent debating revealed that a structured, mildly antagonistic debate could refine LLM outputs. Subsequent research (Xiong et al., 2023) corroborated the potential of LLMs to achieve consensus through debate. However, studies by (Chen et al., 2023) and (Agashe et al., 2023) on the evaluation of multi-agent debating systems highlighted a critical issue: the risk of consensus being swayed by majority opinion rather than individual agent analysis. This introduces an element of uncertainty regarding whether the consensus reached is genuinely reflective of a reasoned agreement or merely a product of majority rule. This paper seeks to explore and address this ambiguity in the context of LLM debating systems.

2.2 Dataset Discription

The dataset for our study, meticulously curated by clinical domain experts, trial organizers, and research oncologists affiliated with the Cancer Research UK Manchester Institute and the Digital Experimental Cancer Medicine Team (Jullien et al., 2023), comprises the following elements:

- **1–2 CTRs**: Record some key information during clinical trial, constitute by these four parts:
  - **Eligibility Criteria:** Specifies the required conditions for patients to participate in the clinical trial.
  - **Intervention Details:** Outlines the type, dosage, frequency, and duration of the treatments under study.
  - **Trial Results:** Details the number of participants, outcome measures, measurement units, and the observed results.
  - **Adverse Events Reporting:** Records any symptoms or signs noted in patients during the course of the clinical trial.
- **Statement**: An assumption based on CTRs, which hasn't been verified to be correct or not
- **Section Marker**: Which section in the CTRs is the statement based on.
- **Entailment/Contradiction label**: The statement is Entailment/Contradiction to the CTRs.

Table 1 describe the constitute of the dataset, and Table 2 is a example of test data.

Dataset	Comparison	Single	Total
Train	665	1035	1700
Dev	60	140	200
Test	2947	2553	5500

Table 1: Constitute of the dataset.

Attribute	Value
Type	Single
Section_id	Results
Primary_id	NCT02640053
CTR_context	Outcome Measurement: Area Under the Curve (AUC) EORTC CIPN20 Sensory Neuropathy Subscale...(omitted)
Statement	Patients in the primary trial that didn't receive topical cryotherapy had worse symptoms than patients that did receive topical cryotherapy.
Label	Contradiction

Table 2: Test data example.

3 System Overview

3.1 Motivation

Existing multi-agent collaboration frameworks, while adept at executing tasks like coding, often fall short in fostering substantive dialogues among agents. This limitation hinders the development of critical thinking skills, as agents are not encouraged to engage in detailed discussions or critically evaluate one another's viewpoints. Recognizing this gap, we introduce a novel framework designed specifically to enable multi-agent debate. Our approach centers on facilitating a collaborative environment where agents are encouraged to thoroughly consider and reflect on the perspectives of their counterparts. By prioritizing in-depth discussions and critical analysis, we aim to advance the capabilities of multi-agent systems beyond mere task execution to include nuanced, critical deliberations.

3.2 Multi-Agent Debating Framework

The multi-agent debating framework constitute by several costume *agents*, a *issue* to determine and a *logical judgment unit*. Below Algorithm 1 are pseudocode that describe how the framework operates:

Algorithm 1: LLM Multi-Agent Debate Framework

Data: *Issue* to be debated, *Agents* involved in the debate
Result: Conclusive outcome(**Entailment** or **Contradiction**)

initialization: Set turn $t_i = 0$;
Agents generate initial responses r_i with ***Opinion*** and ***Decision***;
while *not reached maximum number of turns and no consensus* **do**
    Assess consensus among ***Opinions***;
    if *consensus* **then**
        Adopt ***Opinions*** as outcome and terminate;
    else
        Increment turn t_{i+1};
        Update agents with others' ***Decisions***;
        Agents revise responses r_{i+1};
    end
end
if *no consensus after maximum turns* **then**
    Take most ***Opinions*** as final result;
end

Upon presenting an issue, the framework, in its initial turn denoted as t_i, solicits from agents the generation of an initial response r_i. Each response is required to concurrently encompass ***Opinion*** and ***Decision***, wherein ***Opinion*** constitutes a paragraph articulating the agent's stance on the issue, and ***Decision*** represents one of two potential outcomes: Entailment or Contradiction. Subsequent to the formulation of responses by all agents, the logical judgment unit assesses the presence of consensus within their opinions. In the event of consensus, their ***Opinions*** are adopted as the conclusive outcome, thereby terminating the framework. Conversely, in the absence of consensus, the debate advances to the subsequent turn t_{i+1}. In this phase, each agent is apprised of the ***Decisions*** made previously by other agents and is prompted to generate a revised response r_i. This iterative process persists until a consensus is established among the agents, or upon reaching the predefined maximum number of turns, at which point the framework is concluded and the amalgamation of multiple ***Opinions*** is deemed the final result.

4 Experiments

Our experiments were conducted using the Mixtral-8x7B model (Jiang et al., 2024), selected for its exceptional performance and cost-efficiency.

4.1 Sections Select

The task of pinpointing the relevant sections within Clinical Trial Reports (CTRs) for statement verification was entrusted to a Large Language Model (LLM). This procedure entailed providing the LLM with a detailed prompt, encompassing explicit instructions, the statement under scrutiny, and the entirety of the CTR text. The LLM's assignment was to ascertain the sections of the CTR pertinent to the statement. An example of the LLM's output is delineated below, illustrating its capability to effectively identify and isolate relevant text segments.

Listing 1: LLM's output to select sections

```
{
  "Primary_CT": {
    "Adverse Events": true,
    "Results": false,
    "Eligibility": true,
    "Intervention": false
  }
}
```

4.2 Agents Design

We designed five agents, which are all experts in medical field:

- **Dr. Emily Nguyen**: Biostatistician focusing on data interpretation and analysis in clinical trials.
- **Dr. Alex Johnson**: Medical Linguist specializing in clinical text analysis and medical jargon clarification.
- **Dr. Aisha Patel**: Pharmacologist dedicated to drug action understanding and safety evaluation in trials.
- **Dr. Liang Wei**: Epidemiologist studying health and disease patterns in populations for disease control.
- **Dr. Maria Gomez**: Cardiologist treating cardiovascular diseases and managing heart-related conditions.

5 Results

5.1 Official Evaluation Metrics

SemEval-2024 Task 2 organizers had mentioned several evaluation metrics: Macro F1-score, Faithfulness and Consistency(Jullien et al., 2024a), we will use these metrics to evaluate the result.

- **Faithfulness**: Quantifies the precision with which a system arrives at the correct conclusion based on the right reasons. Assessed by examining the system's ability to adjust its predictions accurately in response to semantic alterations. Evaluated using N statements x_i from a contrast set (C), their related original statements y_i, and the model's predictions $f()$.
- **Consistency**: Measures a system's capacity to produce identical outputs for semantically equivalent scenarios. Determined by the system's capability to consistently predict the same label for both original and contrast statements, even in the case of semantically preserving interventions. This involves analyzing N statements x_i in a contrast set (C), their corresponding original statements y_i, and the model's predictions $f()$.

Agent	F1	Fth	Con
Debated	**0.69**	0.51	0.56
Dr. Emily Nguyen	0.65	**0.55**	**0.58**
Dr. Alex Johnson	0.67	0.52	0.56
Dr. Aisha Patel	0.67	**0.55**	0.57
Dr. Liang Wei	0.66	0.53	0.57
Dr. Maria Gomez	0.66	0.53	0.57

F1 = Macro-F1, Fth = Faithfulness, Con = Consistency

Table 3: Performance metrics of different agents.

5.2 Impact of Multi-Agent Debates on Performance

Table 3 delineates the comparative performance metrics on the test dataset for decisions made by individual agents versus the consolidated outcome of the multi-agent debating, as evaluated on the official Codalab platform (Jullien et al., 2024b). The data distinctly showcases that the integration of multi-agent debating significantly enhances the F1-score, surpassing the performance of any single agent's decision-making capabilities.

Regarding our standing in the competition, our team, identified as "Yuan_Lu," achieved the 22nd position out of 32 participating teams.

5.3 Demonstration of Debating Process

The excerpt below showcases the dynamic of our multi-agent debating process, wherein agents engage in a layered analysis of the problem from their unique vantage points. Notably, our methodology facilitates not just the articulation of each agent's perspective but also the receptiveness to alternate viewpoints. This iterative exchange allows agents to both influence and be influenced, showcasing the framework's capacity for fostering a comprehensive and nuanced understanding through collaborative debate.

5.3.1 Turn 1

DR. EMILY NGUYEN: Based on the data provided, I cannot confirm the statement about the occurrence of asthenia and pyrexia... **The data does not include any information on these adverse events** for either the primary or secondary clinical trials... So, my decision is: **Contradiction**

DR. ALEX JOHNSON: After carefully reviewing the data provided and considering the opinions expressed, I agree that **there is**

no evidence in the data to support the statement about the occurrence of asthenia and pyrexia... So, my decision is: **Contradiction**

5.3.2 Turn 2

DR. EMILY NGUYEN: After further discussion and considering the perspectives shared, **I now see the importance of rigorous data analysis and transparent reporting**. This ensures healthcare professionals and patients have a complete understanding... In summary, **the provided data does not support the statement**... So, my decision is: **Contradiction**

DR. ALEX JOHNSON: Reflecting on the discussions, I acknowledge my initial decision might have been premature. **Given the lack of evidence in the provided data**, I adjust my stance... Therefore, **I align with the consensus that the statement is a contradiction**... So, my decision is: **Contradiction**

5.4 Beyond Majority Rule: The Dynamics of Multi-Agent Debating

To examine the effectiveness of the multi-agent debating framework, we introduce two key metrics: the F1 score of the majority decision in the first round of debate, and the rate of alignment between the initial majority decision and the final decision.

- **F1 Score of Correct Majority Decision**: This metric measures the precision and recall of the majority decision in the first round of debate. The calculated F1 score of 0.567 suggests moderate accuracy of the initial majority opinion. This indicates that while the majority decision is somewhat aligned with the correct labels, there is still considerable room for improvement.

- **Rate of Alignment Between First Majority and Final Decision**: This metric reflects the consistency between the initial majority decision and the final decision after the debate. A high rate of 91.93% suggests that the final decisions of the multi-agent system are predominantly in line with the initial majority opinions. This high alignment rate might indicate a strong influence of the initial majority view on the final outcome of the debate.

Considering these results, the multi-agent debating framework demonstrates a significant tendency to converge towards the initial majority decision. However, the fact that the final decision's F1 score is 0.69, which is higher than the initial majority's F1 score, indicates that the debating process adds value beyond simply following the majority rule. This suggests that while the final decision often aligns with the initial majority opinion, the debate process itself contributes to refining the decision, potentially correcting or enhancing the initial judgment. Therefore, despite the high alignment rate, the multi-agent debating framework plays a critical role in facilitating a more comprehensive and informed decision-making process.

6 Conclusion

We have presented a novel multi-agent debating framework to participate SemEval-2024 Task 2. This approach, integrating the expertise of diverse agents like Biostatisticians, Medical Linguists, and Pharmacologists, significantly enhances the analysis of Clinical Trial Reports (CTRs). Our findings demonstrate improved performance in entailment or contradiction determination of CTR-statement pairs, as evidenced by enhanced Macro F1-scores compared to individual agent assessments. Despite a tendency to align with initial majority decisions, the debating process refines these initial judgments, indicating the framework's effectiveness beyond simple majority rule.

Abstract

In multidimensional dialogues, emotions serve not only as crucial mediators of emotional exchanges but also carry rich information. Therefore, accurately identifying the emotions of interlocutors and understanding the triggering factors of emotional changes are paramount. This study focuses on the tasks of multilingual dialogue emotion recognition and emotion reversal reasoning based on provocateurs, aiming to enhance the accuracy and depth of emotional understanding in dialogues. To achieve this goal, we propose a novel model, MBERT-TextRCNN-PL, designed to effectively capture emotional information of interlocutors. Additionally, we introduce XGBoost-EC (Emotion Capturer) to identify emotion provocateurs, thereby delving deeper into the causal relationships behind emotional changes. By comparing with state-of-the-art models, our approach demonstrates significant improvements in recognizing dialogue emotions and provocateurs, offering new insights and methodologies for multilingual dialogue emotion understanding and emotion reversal research.

1 Introduction

The EDiReF shared task at SemEval 2024 encompasses three subtasks(Kumar et al., 2024): Task 1 involves Emotion Recognition (ERC) in mixed Hindi-English dialogues, Task 2 focuses on Emotion Flipping Reasoning (EFR) in mixed Hindi-English dialogues, and Task 3 involves EFR in English dialogues. In Task 1 ERC, the goal is to assign emotions to each utterance in the dialogue, while in Task 2 and Task 3 EFR, the aim is to identify trigger utterances leading to emotion flipping in multi-party dialogues. The definitions of these tasks provide a crucial framework for understanding the dynamics of emotions in natural language conversations.

Firstly, we are committed to addressing two subtasks: Emotion Recognition in Conversations (ERC) in Task 1, and Emotion Flipping Reasoning (EFR) in Tasks 2 and 3. For Task 1, we constructed the MBERT-TextRCNN-PL model based on MBERT(Pires et al., 2019) and Prompt Learning to identify emotions in mixed-language dialogues. By leveraging the multilingual capability of the MBERT model and incorporating Prompt Learning, we successfully guided the model to focus on key aspects of emotion recognition. This approach can effectively handle mixed Hindi and English conversations while achieving the sharing of model parameters between different languages. Finally, to improve the robustness of the model, this paper integrates FGM to enhance the model's generalization ability.

Secondly, for Tasks 2 and 3, we proposed the XGBoost-EC (Emotion Capture) method aimed at identifying triggers of emotion flipping. We segmented dialogues into fixed-size windows and extracted emotion encodings from each window. To better encode the emotions of the final speaker, we used -1 to fill in blank emotion states within the window. Then, we employed the XGBoost algorithm(Chen and Guestrin, 2016) for classification to identify windows that could potentially be triggers of emotion flipping. By guiding the model to learn patterns and features of emotion flipping triggers through annotated data during training, we were able to effectively identify triggers of emotion flipping in dialogues.

In the EDiReF shared task at SemEval 2024, our[1] proposed MBERT-TextRCNN-PL model achieved 6th place in Task 1. Additionally, our XGBoost-EC model secured 1st place in Task 2 and 5th place in Task 3.

2 Background

2.1 Dataset Description

Task 1, the Emotion Recognition (ERC) task, corresponds to the MASAC-ERC dataset compiled by extracting dialogues from Indian television dramas. The dataset comprises 446 dialogues, with 8 emotion categories: disgust, contempt, anger, neutral, joy, sadness, fear, and surprise. The training set consists of 343 dialogues containing 8,506 sentences, the validation set consists of 45 dialogues containing 1,354 sentences, and the test set consists of 56 dialogues containing 1,580 sentences, The data analysis for Task1 is shown in Table 1.

Set	Dlgs	Utts
Train	343	8506
Val	45	1354
Test	56	1580

Table 1: Data statistics for Task1.

For Task 2, corresponding to MASAC-EFR, the dataset includes 5,667 dialogues. The training set comprises 4,893 dialogues containing 98,777 sentences, the validation set comprises 389 dialogues containing 7,462 sentences, and the test set comprises 385 dialogues containing 7,690 sentences, The data analysis for Task2 is shown in Table 2.

Set	Dlgs	Utts
Train	4893	98777
Val	389	7462
Test	385	7690

Table 2: Data statistics for Task2.

Regarding Task 3, corresponding to MELD-EFR, the dataset consists of 5,428 dialogues. The training set comprises 4,000 dialogues containing 35,000 sentences, the validation set comprises 426 dialogues containing 3,522 sentences, and the test set comprises 1,002 dialogues containing 8,642 sentences, The data analysis for Task3 is shown in Table 3.

Set	Dlgs	Utts
Train	4000	35000
Val	426	3522
Test	1002	8642

Table 3: Data statistics for Task3.

2.2 Related Work

Emotion Recognition in Conversation. Emotion recognition in dialogues is categorized into monolingual and multilingual dialogue emotion recognition. Under monolingual conditions, the DialogXL(Shen et al., 2021) model utilizes the XL-Net(Yang et al., 2019) architecture for Emotion Recognition in Conversation (ERC). They encode dialogue discourse and leverage dialogue-aware self-attention to incorporate dialogue semantics. Additionally, (Jiao et al., 2019) employs a hierarchical gated recursive unit framework involving two different levels of GRU. The lower-level GRU models word-level inputs, while the higher-level GRU captures contextual information at the discourse level. Furthermore, (Lian et al., 2021) proposes a correction model named "Dialogue Emotion Correction Network (DECN)." The aim of this work is to enhance emotion recognition performance by automatically identifying errors made by emotion recognition strategies. (Shou et al., 2022) employs graph-based approaches to tackle ERC. They introduce a session-level sentiment analysis model that combines dependency parsing and graph convolutional neural networks. Self-attention mechanisms capture the most effective words in the dialogue and then construct a graph. In multilingual settings, (Kumar et al., 2023a) proposes an advanced fusion technique that first translates into a uniform language, followed by the integration of commonsense knowledge with the dialogue comprehension module.

Emotion Flipping Reasoning. (Kumar et al., 2022)introduces a novel Emotional Flip Reasoning (EFR) aimed at identifying the utterance that triggered an emotional state flip in an individual at a certain point in the past. Additionally, a Transformer-based network is proposed to carry out the Emotional Flip Reasoning. To identify emotional instigators, (Kumar et al., 2023b) proposes the TGIF framework for multilingual dialogue data. It utilizes a combination of Transformer and GRU to identify emotional instigators.

3 System Overview

3.1 ERC

In Task 1's data format, we designed the MBERT-TextRCNN-PL model based on prompt learning, as illustrated in Figure 1, to contextualize the conversation. The input data for this model is organized according to the format in Table 4.

Speaker	Utterance	Emotion
Sp1	Aaj to bhot awful day tha!	Sad
Sp2	Oh no! Kya hua?	Sad
Sp1	Kisi ne mera sandwich kha liya!	Sad
Sp2	Me abhi tumhare liye new bana deti hun!	Joy

Table 4: Data instance for ERC task

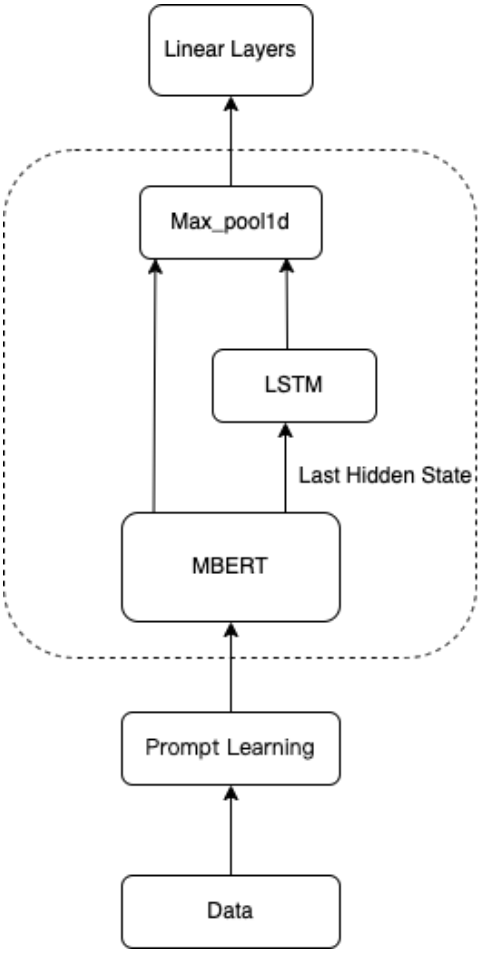

Figure 1: The architecture diagram of MBERT-TextRCNN-PL.

Specifically, we employ prompt learning to construct the model's input, where the inputs for Sp1 and Sp2 are formatted as follows: "The following is 's conversation history. Sp1: Aaj to bhot awful day tha!" and "The following is 's conversation history. Sp1: Aaj to bhot awful day tha!, Sp2: Oh no! Kya hua?". Through this formatted input, the model can better understand the conversation history and context, thereby comprehensively capturing semantic correlations in the text.

Building upon this, we propose a vector representation approach that combines the features of MBERT and TextRCNN. Firstly, we utilize the MBERT pre-trained model to encode the text sequences into semantic vectors, leveraging its multilingual semantic understanding capability. Subsequently, contextual information of the sequences is further enhanced by capturing it through a bidirectional LSTM layer, strengthening the model's comprehension of the dialogue history. Next, the last hidden state output of MBERT and the output of LSTM are concatenated in the feature dimension to fuse word-level and sequence-level semantic information. Finally, classification of the text data is achieved through a fully connected layer, enabling effective categorization of the text.

This architecture fully leverages the multilingual semantic understanding of MBERT and the sequence modeling capability of TextRCNN, enabling the model to better understand and classify text data. Such design not only enhances the performance and effectiveness of the model in text understanding tasks but also improves its understanding of context, allowing the model to more accurately capture semantic information in the text.

3.2 EFR

For EFR's Task 2 and Task 3, we propose the XGBoost-EC model, as illustrated in Figure 2. The XGBoost-EC model is an emotion recognition model based on XGBoost, designed to utilize emotion feature encoding for training and prediction.

In the XGBoost-EC model, we initially encode the emotion features, converting them into numerical forms for processing by the XGBoost algorithm. Specifically, we map emotion labels to integer values, such as encoding 'joy' as 1, 'sadness' as 2, and so forth. To better capture emotion information, we employ emotion windows for encoding and assign -1 for missing emotions.

By encoding emotions, the XGBoost-EC model can learn the associations between emotions and other features, thereby predicting the emotional states in text or dialogue more accurately. Leveraging the efficient performance of the XGBoost algorithm and its capability to handle large-scale

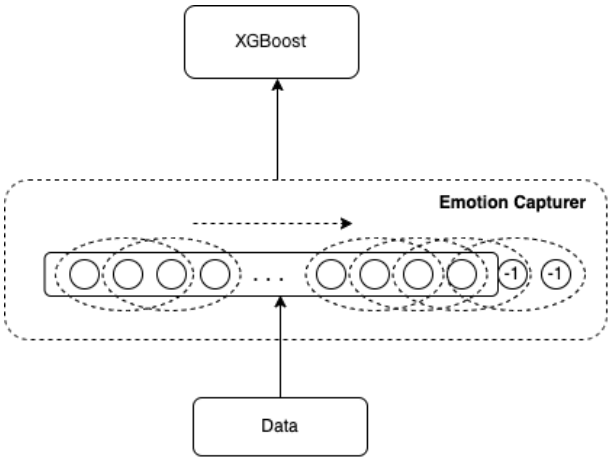

Figure 2: The architecture diagram of XGBoost-EC.

datasets, this model holds significant value for emotion recognition tasks.

4 Experimental Setup

Task 1. For the ERC Task 1, our model was built using the Hugging Face Transformers library, where we directly employed pre-trained tokenizer and language models for further fine-tuning. Specifically, we utilized the MBERT-TextRCNN-PL model with parameter configurations of a learning rate of 3e-6 and a batch size of 16 for training. We opted for the AdamW optimizer to update the model parameters. To ensure the model could handle longer text sequences, we set the maximum sequence length of the tokenizer to 512. During the model's validation evaluation process, we employed the F1 score as the performance metric. Hardware-wise, we utilized the NVIDIA RTX3090 (24G) graphics card to accelerate both model training and inference processes.

Task 2. For the EFR Task 2 and Task 3, we built the XGBoost-EC model based on the XGBoost library. In Task 2, after validation, we chose to set the scale-pos-weight parameter in the XGBClassifier to 1.08 to address the issue of imbalanced samples. Additionally, we fixed the random seed to 42 to ensure reproducibility of the results. To better capture changes in emotion, we set the emotion window size to 4.

Task 3. In Task 3, we adjusted the scale-pos-weight parameter in the XGBClassifier to 1.6 to accommodate different levels of sample imbalance. Similarly, we fixed the random seed to 42 and set the emotion window size to 3, enabling the model to capture trends in emotion changes more effectively.

5 Results

5.1 Task1

Based on Table 5, we observe that the performance of MBERT-TextRCNN-PL is more competitive compared to BERT, RoBERTa, MBert, MURIL, CoMPM, DialogXL, BERT+COFFEE and MBert+COFFEE as contrasted by Shivani Kumar et al(Kumar et al., 2023a). MBERT-TextRCNN-PL, based on prompt learning, provides a better summary of the former's remarks, which aligns more closely with conventional expression norms. Leveraging the multilingual MBERT-TextRCNN model enhances the representation of semantic information, rendering the model state-of-the-art. As a result, it achieved the 6th position on the official leaderboard.

Model	F1
BERT	0.40
RoBERTa	0.41
MBert	0.30
MURIL	0.35
CoMPM	0.35
DialogXL	0.41
BERT+COFFEE(Kumar et al., 2023a)	0.41
MBERT+COFFEE(Kumar et al., 2023a)	0.31
Ours(MBERT-TextRCNN-PL)	0.46

Table 5: The results of Task 1.

5.2 Task2

As shown in Table 6, the proposed XGB-EC achieved an F1 score of 0.79 in the evaluation of Task 2, securing the first position in this task.

Model	F1
TECHSSN Team	0.1
IASBS Team	0.12
IITK Team	0.56
Knowdee Team	0.66
FeedForward Team	0.77
Ours(XGB-EC)	0.79

Table 6: The results of Task 2.

5.3 Task3

As indicated in Table 7, the proposed XGB-EC outperformed AGHMN, TL-ERC, DGCN, DialogXL, and BERT by a significant margin, exhibiting a substantial improvement compared to the TGIF

framework with a 38-point increase in F1 score. In Task 3, it obtained the 5th position. The XGB-EC framework not only considers the current emotion but also captures emotion variations through emotion windows, enabling a better understanding of emotional provocations.

Model	P	R	F1
AGHMN	0.15	0.17	0.16
TL-ERC	0.07	0.33	0.13
DGCN	0.10	0.67	0.17
DialogXL	0.09	0.34	0.15
BERT	0.14	0.55	0.21
TGIF(Kumar et al., 2023b)	0.26	0.55	0.33
Ours(XGB-EC)	0.71	0.71	0.71

Table 7: The results of Task 3.

6 Conclusion

In this paper, we focus on addressing the challenges of multilingual conversation emotion recognition and emotion flipping reasoning tasks. To this end, we propose two models to tackle these tasks.

Firstly, for the multilingual conversation emotion recognition task, we introduce the MBERT-TextRCNN-PL model. This model combines prompt learning and the MBERT-TextRCNN approach to better recognize emotions from multiple speakers. Through prompt learning, we can provide richer contextual information, thereby accurately capturing the emotional content in the text. Leveraging the features of MBERT-TextRCNN, this model effectively utilizes the capabilities of multilingual semantic understanding and sequence modeling to enhance the accuracy and effectiveness of emotion recognition.

Secondly, for Task 2 and Task 3 of EFR, we propose the XGBoost-EC (emotion capturer) model, aimed at identifying emotion instigators. This model, employing emotion windows and XGBoost classifier, captures emotion instigators more effectively. The setting of emotion windows allows the model to consider the historical trend of emotion changes, leading to a more comprehensive analysis of emotional data. The application of the XGBoost classifier enables efficient classification and reasoning of emotional data, thereby enhancing the model's ability to identify instigators.

The introduction of these two models provides effective solutions for multilingual conversation emotion recognition and emotion flipping reasoning tasks, offering new insights and methods for research and applications in related fields.

Abstract

In this paper, we present an approach for solving SemEval-2024 Task 3: The Competition of Multimodal Emotion Cause Analysis in Conversations. The task includes two subtasks that focus on emotion-cause pair extraction using text, video, and audio modalities. Our approach is composed of encoding all modalities (MFCC and Wav2Vec for audio, 3D-CNN for video, and transformer-based models for text) and combining them in an utterance-level fusion module. The model is then optimized for link and emotion prediction simultaneously. Our approach achieved 6th place in both subtasks. The full leaderboard can be found at https://codalab.lisn.upsaclay.fr/competitions/16141#results.

1 Introduction

The *SemEval-2024 Task 3: The Competition of Multimodal Emotion Cause Analysis in Conversations* (Wang et al., 2024) is aimed at extracting emotion-cause pairs (ECPs) in conversations. The main data source to tackle this task is recordings from the sitcom *Friends* in the English language – Emotion-Cause-in-Friends dataset Wang et al. (2022).

The detection of emotions and a deeper analysis of what causes them is one of the interesting and important tasks that have recently been tackled within the NLP community. Previously, researchers focused their efforts on text-only emotion-cause extraction (Gui et al., 2018; Gao et al., 2017; Bostan et al., 2019). However, representing dialogues solely through the text (speech transcription) is not entirely adequate, as people use different intonations and other prosodic features. Moreover, the fact that something happens during the conversation (e.g. someone walks in or something breaks) affects the dialogue in terms of emotions and their causes. We can also mention different facial expressions for different emotions. So, the fact that a conversation in its natural form is multimodal (text, audio and video) opens a big space for research.

Our approach is targeted at both subtasks of the above-mentioned Semeval 2023 task. The main difference between them is the number of different modalities used for predicting ECPs. For Subtask 1, the prediction of ECPs is solely based on the text transcription without recordings. The goal is to provide text spans along with ECPs: i.e. the segment of an utterance primarily responsible for emotion-cause. Subtask 2, does not require extracted text spans (in some cases it is impossible because the emotion-cause is not expressed in the textual form), but it is required to use other modalities embedded in available `mp4` video files to extract emotion-cause pairs together with a target emotion.

Our approach uses all modalities and encodes them into a common utterance-level representation, which is then used for *link* and *emotion* prediction. The objective is to learn both prediction tasks with two loss functions that are combined. The main idea behind this is that emotions might positively influence the links (pairs) and vice versa.

Another point we would like to highlight is that the textual input is a whole dialogue, so the context is taken into consideration. This improves the link results significantly, as shown further. After validating our codes by the SemeEval task organizers, the final implementation will be released[1].

2 Task and Background

The goal of the emotion-cause pair extraction (ECPE) task (Xia and Ding, 2019) is to extract potential pairs of emotions and corresponding causes in a conversation/document and/or other source of dialogue. It is an extension of the emotion-cause extraction – ECE task (Lee et al., 2010), where the goal is to decide if a clause/utterance is the corresponding cause, given the annotation of emotions.

[1]https://github.com/martinekj/semeval_2024_Task3_ECPE

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 316–325

This SemEval task does not require only the extraction of corresponding pairs but also the prediction of emotions. In other words, extracted pairs must be complemented by the prediction of the target utterance emotion. So, for the evaluation, we have a triplet (a source utterance, a target utterance, an emotion of the target utterance). E.g., **3_joy, 2** which means that the emotion *joy* in *utterance 3* is caused by *utterance 2*.

Our team participated in both competition subtasks. We aimed to extract not only the pairs (as illustrated in the previous example) but also text spans – the exact parts of utterances/clauses primarily responsible for the emotion-cause (e.g. **3_joy, 2_You made up!** – meaning that the emotion *joy* in *utterance 3* is caused by the text span *You made up!* in *utterance 2*)

Hence, we work with all input data (i.e., multimodal – text, sound, image sequence/video) of the dataset **Emotion-Cause-in-Friends** that serves as the competition dataset.

2.1 Related Work

Lee et al. (2010) presented a text-based approach for the ECPE task. They created a rule-based system and tested it on a Chinese dataset created from the Sinica corpus.

Chen et al. (2020) proposed an approach that takes the ECPE task as a unified sequence labeling task. Their method combines a convolutional network with two bi-directional long short-term memory networks. They show that the approach outperforms several baselines. However, the score is slightly lower than baselines including BERT.

Poria et al. (2018) created the multimodal MELD dataset as an extension of the EmotionLines corpus and performed a baseline evaluation of the emotion recognition task on this data. Another multimodal dataset is presented in (Firdaus et al., 2020).

Wang et al. (2022) presented a multimodal approach for the emotion-cause pair extraction. The authors created a dataset including text, audio and video modalities. The baseline approach obtained F1 score of 0.51.

3 System Overview

We decomposed the main objective into emotion and link prediction (the estimation of pairs) tasks. The final result then consists of source and target utterances provided by the link and emotion of the target utterance.

The architecture is depicted in Figure 1. First, we encode the different modalities at the utterance or dialogue level to incorporate more context. Next, we fuse the representations at the utterance level. Once we have representations of all individual utterances in a dialogue, we predict links and emotions (Subtask 2). Based on this output, we employ our separate model for text span prediction, which is necessary for Subtask 1.

We have followed the competition rules and used pre-trained language models (PLMs), but no additional training data.

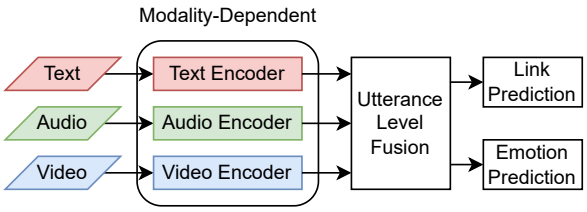

Figure 1: System architecture

3.1 Text Encoder

We employed a transformer-based encoder, such as BERT (Devlin et al., 2019), for text encoding. As depicted in Figure 2, the input consists of an entire dialogue. It commences with a CLS token and proceeds with tokens representing individual utterances. As usual, positional encoding corresponding to token position is applied. The utterances are separated by a SEP token, and the input is further extended by utterance embeddings. After encoding the tokens, we average the tokens of every single utterance to derive its representation. This way, the dialogue context is available in every single utterance.

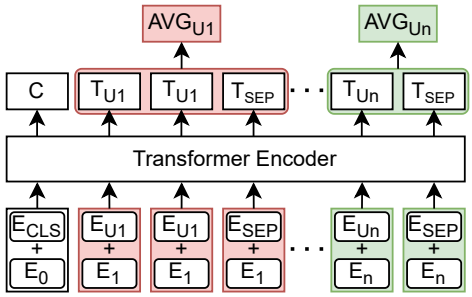

Figure 2: Text Encoder

3.2 Audio Encoder

For encoding the audio, we evaluated two methods. The first is referred to as *MFCC* feature extraction

and is based on Mel frequency cepstral coefficients (Tiwari, 2010). The second method is based on *Wav2Vec* model (Baevski et al., 2020).

3.2.1 MFCC Feature Extraction

We firstly denoise the audio files removing the background noise (background laughing track, people speaking in the café, etc.). We use the REPET-SIM (Rafii and Pardo, 2013) separation method to separate the main speaker voice line. The separated main speaker voice line audio is then used for computing the MFCC, and this audio representation is used in a long short-term memory (LSTM) model trained for the emotion recognition task. Audio feature vectors with a dimension of 2048 are acquired from the last hidden state of the model. The model comprises one bidirectional LSTM and two linear layers. The whole model is trained on the emotion recognition task.

The REPET-SIM method is a generalization of the REPET method (Rafii and Pardo, 2012). The basic idea behind the REPET method is to find repeating elements in audio, compare them with repeating models derived from them, and separate the repeating patterns through time-frequency masking. REPET-SIM specifically identifies these repeating elements by using a similarity matrix (Rafii and Pardo, 2013).

MFCC capture the shape of the power spectrum of a sound signal. They are computed by first transforming the audio into the frequency domain using the Discrete Fourier Transform and then applying the "mel" scale to approximate the human auditory perception of the sound frequency (Tiwari, 2010).

3.2.2 Wav2Vec

As an alternative, we used pre-trained version (Field, 2022) of Wav2Vec model as an audio encoder. It was fine-tuned for the emotion classification task, and subsequently, we conducted further fine-tuning on competition data. We averaged the audio sequence representations provided by the final layer resulting in a 1024-dimensional audio representation of the utterance. During the fine-tuning phase, the representation was utilized by a two-layer perceptron to predict emotion.

3.3 Video Encoder

We utilized the ResNext 3D-CNN (Hara et al., 2018) model with depth 101 pre-trained on the Kinetics (Carreira and Zisserman, 2017) dataset. For every 16 frames, this model provides an output vector with a dimension of 2048. In the case of longer videos, the final feature vector is computed with a global average pooling over the temporal dimension.

The input to the model are preprocessed image frames from the video file (using the *ffmpeg* python library). The preprocessing consists of scaling to 240x240 pixels (while preserving the aspect ratio with zero padding).

3.4 Fusion Module

The multimodal fusion relies on a transformer-based encoder. Since the dimensions of text, audio, and video representations may vary, they undergo linear projection using a linear layer with the fusion size (*fs*) as a parameter. Subsequently, they serve as tokens for the encoder input. The encoder consists of 6 layers with $fs/64$ heads and GELU activation function. The intermediate size is $4 \cdot fs$.

The fusion is done on the utterance level, so no explicit dialogue context is available, but it may be provided by encoded representations of individual modalities. For the fusion, we ignore the positional encoding.

We consider several fusion strategies. The first straightforward scenario is to use the aggregation function for each component of the encoded tokens: *AvgFusion* (averaging the representations); *MaxFusion*, *MinFusion* (taking the maximum/minimum activation across modalities).

Further, we incorporate an additional learnable fusion token (FT) that is added to the input. It is used to aggregate information for the utterance in a similar way as the CLS token is used in BERT, for example. They are labeled as: *SingleFT* (a single FT that is used as a result after encoding); *MainSpeakerFT* (a different FT for each main speaker and one FT for other speakers; *AllSpeakerFT* (incorporating FT for each speaker).

Other possible fusion strategies exist (e.g. Nagrani et al. (2021)), and incorporating some of them is our potential future work.

3.5 Emotion Prediction

Emotions are predicted directly from the fused utterance representations using a two-layer perceptron with LeakyReLU activation function. The hidden size matches the fusion size.

3.6 Link Prediction

The link prediction module is also inspired by the transformer-based encoder. The fused utterance

representations are used as the input tokens. However, our focus shifts from encoded tokens to attention matrices in this context. These matrices are processed and utilized as the adjacency matrix of the graph. Positional encoding is optional since it may be included in the utterance embedding provided by the text, audio, or video encoder.

We used six transformer-based encoder layers, followed by a specialized layer that computes the attention matrices for each head. Subsequently, these matrices are aggregated across all heads using *average*, *maximum*, or *minimum* activation. In contrast to the transformer-based encoder layer, the specialized layer also does not normalize the attention scores, as they are directly provided as logits for the links.

3.7 Text Span Analysis

This section covers the approach used for *Subtask 1*: the prediction of text spans responsible for the cause of emotion. A baseline approach with which we compare is using the entire utterance as a text span. As expected, this trivial approach results in quite a low *strict match F1* metric. The main evaluation metric for this subtask, though, is the *Proportional F1* (which considers the overlap proportion of the predicted span and the annotated one). If we uploaded the text-spans result based on this trivial approach, the resulting *Proportional F1* value is around 20% based on test data provided for the competition evaluation.

Based on this result, we can state that a significant part of training data has no specific text span that causes emotions. This might indicate that even for human annotators, it is not easy to determine a particular text span in a significant number of utterances, and he/she labeled the whole utterance.

According to the training data, we specified five text span categories and created a classifier for their prediction based solely on individual utterances with no context. Furthermore, we have defined a set of regular expressions whose goal is to automatically detect individual categories.

The most common label is `Whole Utterance`, as we declared above. Figure 3 shows all categories of text spans resulting from regular expressions. Regular expressions are used to split an utterance by the punctuation marks `(',', ';', '.', '!', '?')` and compare their results with annotated text spans.

The `First part` label corresponds to the beginning of an utterance until the first punctuation mark. In a similar way, the `Last part` category is taken, except that it is taken from the end. The `Middle part` label is the part in the middle (an utterance part without the beginning and end). It appears usually in cases where an utterance is long. For cases when all regular expressions fail (a text span is neither the whole utterance nor the first, last, or middle part), we created a category `Other`. As illustrated in Figure 3, this category is quite common in training data.

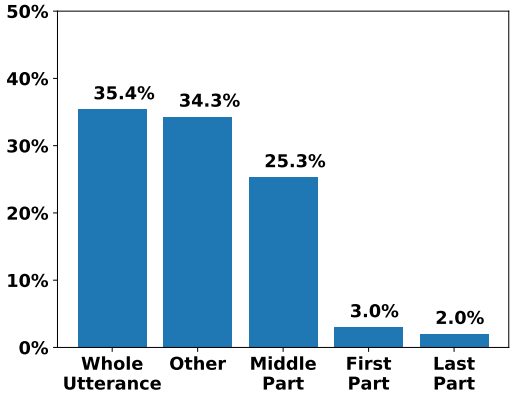

Figure 3: Distribution of the specified categories of text spans

3.7.1 Text Span Classifier

Our first intention was to use a transformer-based model and carry out the question-answering training scenario that aims at providing an "answer" (text span which causes an emotion) identified using the start span and end span generated by the model (similarly to the BERT SQuAD model Devlin et al. (2018)). All our efforts for training such a model, though, failed, due to the lack of training data. The competition rules forbid the usage of another annotated private/public data to fine-tune a model, so we decided to use another model with a much simpler learning objective.

The input text comprises tokens of the current utterance (no context is considered in this case, i.e. no information about previous/subsequent utterances in a dialogue) and is fed into a transformer model as usual with a prediction head with five output neurons.

Once the class (text span category) is predicted from the CLS token, we apply a regular expression (assigned to the predicted class) to extract a substring from the utterance and, in the sequel, the start and end index of this substring.

During the prediction phase, the class `Other` is

taken as `Whole Utterance` label since there is no regular expression associated with this class. We remind that the text span extraction task is solely text-based. The results are presented in Table 4.

4 Experimental Set-up

In the data provided, there is a mapping of video names on train/dev/test splits. According to this information, we dedicated 9,966 utterances (1,373 dialogues) for training, and the remaining dialogues/utterances have been used as development (validation) data. Our preliminary experiments, as well as the experiments resulting in the final system, have been evaluated on this development part of the dataset.

Due to the memory limitations, we fine-tuned audio and video encoders separately. After that, the whole pipeline is trained End-to-End with frozen audio/video encoders and, therefore, constant audio/video representations. We made this choice based on the preliminary experiments, where we obtained the best results with textual modality so we take audio/video features as an auxiliary input.

If not stated differently, we used the AdamW optimizer with a learning rate of 5e-5. Categorical and binary cross-entropy loss was used for emotion and link prediction, respectively. We started with 2 "warmup" epochs with frozen encoders to limit "forgetting" of the pre-trained knowledge. Further, we continued with 50+ epochs until convergence.

To increase the importance of positive links, the positive link weight is set to 5. The fusion size is set to 1024 or 1536. The batch size ranges from 2 to 24. Due to memory limitations, we adapted gradient accumulation technique. The number of samples used for weight update is 8, 12, or 24. These hyper-parameters are further studied in Appendix A. In Tables 1, 2, and 3, we report the combination of these hyper-parameters that obtained the best result among runs.

4.1 Text Encoder

We employed several Pre-trained Language Models (PLMs) and corresponding configurations (see e.g. Table 3). The learning rate for the text encoder was lowered to 1e-7 to further limit the "forgetting" of the PLM.

As described in Section 3, the input is the whole dialogue text to provide context. We set the maximum input length to 450 tokens and the maximum number of utterances to 26, according to the training part of the dataset. That condition is not met in one dialogue in the test part. In that case, the predictions are done in a sliding window manner, so it is impossible to predict the link between the first and last utterance, for example.

For the comparison, we encoded the utterances separately with no dialogue context. This scenario is depicted as ✂ in *Text* column of Tables 1, 2, and 3.

4.2 Text Spans Classifier

All our models have been trained for 30 epochs, with learning rate=1e-05, AdamW optimizer and cross-entropy loss. We picked the best model (the best epoch), based on the validation accuracy. Results for various models are presented in Table 4

4.3 Evaluation Metrics

As stated in the Semeval task information web page[2], the evaluation is based on F1 scores with the help of which we can evaluate the emotion-cause pairs of each emotion category separately and further calculate a weighted average of F1 scores (*wF1*) across the six emotion categories (*Anger*, *Disgust*, *Fear*, *Joy*, *Sadness* and *Surprise*). It is the main evaluation metric for Subtask 2.

Besides the official Semeval metrics provided by the organizers, we have also employed other metrics such as *accuracy* and *macro F1* score for emotion classification task. The *jaccard index* was used for link prediction, since the adjacency matrix is sparse and, therefore, we are not very interested in true negatives.

For Subtask 1 which involves the textual cause span, two strategies are adopted to determine whether the span is extracted correctly: *strict match* (the predicted span should be exactly the same as the annotated span) and *proportional match* (considering the overlap proportion between the predicted span and the annotated one). Although at the beginning of the competition, the main evaluation metric had been *strict match*, later *proportional match* was chosen instead due to the poor results of *strict match* based on trial data published by the organizers. The main reason behind this is that it is challenging to determine the precise boundaries of cause spans.

Table 2: Comparison of link prediction methods employing various modalities, fusion scenarios, and combined multi-task training. ✂ denotes separately encoded utterance text.

5 Results

In this section, we present and analyse the results from multiple perspectives.

5.1 Emotion Detection

According to the results presented in Table 1, text plays a crucial role in the emotion prediction task. The context (whole dialogue) is not essential for emotion predictions, as the results are not significantly influenced positively or negatively. We obtained very similar results regardless of whether we used utterances separately (denoted by the symbol ✂) or not.

The best model for the emotion prediction task does not include audio/video features, leading us to conclude that they are not essential for the emotion detection task. The multimodal results suggest that the most effective fusion strategy involves the utilization of the fusion token (*SingleFT* or *MainSpeakerFT*). Other fusion strategies generally yield inferior results.

To support our emotion detection results, we have created a confusion matrix for further error analysis (see Figure 4). The first column (predicted label: `neutral`) indicates that the model has tendencies to predict *neutral* label more often, probably due to the fact that this label is most common in training data. The most challenging emotions are *fear* and *disgust* (see the third and last rows).

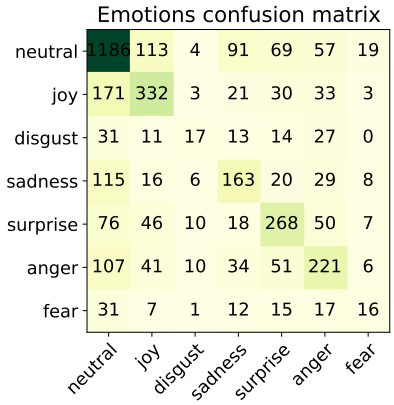

Figure 4: Confusion matrix for the emotion prediction using the submitted model – true labels are at y-axis, predicted labels are at x-axis

Since the overall score is calculated for the predicted triplet: a cause, a target utterance, and an emotion of the target utterance, we estimate the effect of emotion detection accuracy for the ECPE task by comparing the final results with the results of emotions loaded from ground truth (GT). The weighted F1 score on the dev dataset increases from

Text PLM	Text	Audio	Video	Fusion	wF1
bert-base-cased	✓	✗	✗	–	0.320
bert-base-cased	✓	MFCC	✓	MaxFusion	0.318
bert-base-cased	✓	Wav2Vec	✗	MinFusion	0.313
bert-base-cased	✓	MFCC	✓	MinFusion	0.311
bert-large-cased	✓	MFCC	✓	SingleFT	0.310
j-hartmann/emotion-english-roberta-large	✓	MFCC	✓	MinFusion	0.294
dbmdz/bert-large-cased-finetuned-conll03-english	✓	MFCC	✓	MainSpeakerFT	0.289
j-hartmann/emotion-english-distilroberta-base	✓	MFCC	✓	MainSpeakerFT	0.278
bert-base-cased	✂	MFCC	✓	SingleFT	0.262
–	✗	MFCC	✓	SingleFT	0.028

Table 3: Comparison of models trained in multi-task scenario for SemEval task. ✂ stands for separately encoded utterance text.

0.331 to 0.602 if the emotions are correct. Such results suggest that improving the emotion detection model (and increasing the precision and recall) will cause a significantly better overall ECPE score.

5.2 Link Prediction

Our findings demonstrate that injecting emotion information through multi-task training is advantageous for link prediction. The top-performing Jaccard index of 0.359 was attained with multi-task training, while without it, the highest results reached 0.336, marking an improvement of 2.3%.

Results from Table 2 clearly show that the text modality is crucial, as well as the context of the whole dialogue. Using other modalities is helpful in this case.

We have an interesting observation that is contrary to the emotion detection task. In the case of link prediction, it seems beneficial to use fusion strategies based on the aggregation function instead of the fusion token (FT).

5.3 Emotion2Emotion Link Analysis

Our next analysis should shed light on how the model behaves when linking source and target emotions regardless of the utterance texts. We created two matrices (see Figure 5) as follows. We gradually loop through all ground truth and predicted emotion-cause pairs and calculated emotion2emotion pair counts.

Both matrices are very similar (except for the first column, which is automatically zeroed as a part of postprocessing, because ECPE containing *neutral* emotion is irrelevant[3]). It shows that the information about emotions is important for the link prediction task. We supported this observation experimentally, incorporating emotion injection in multi-task training.

The high values in both matrices appear on the diagonal. These represent cases where the source emotion (cause) matches the emotion of the target utterance. The model has evidently learned this behavior, reflecting the human annotations.

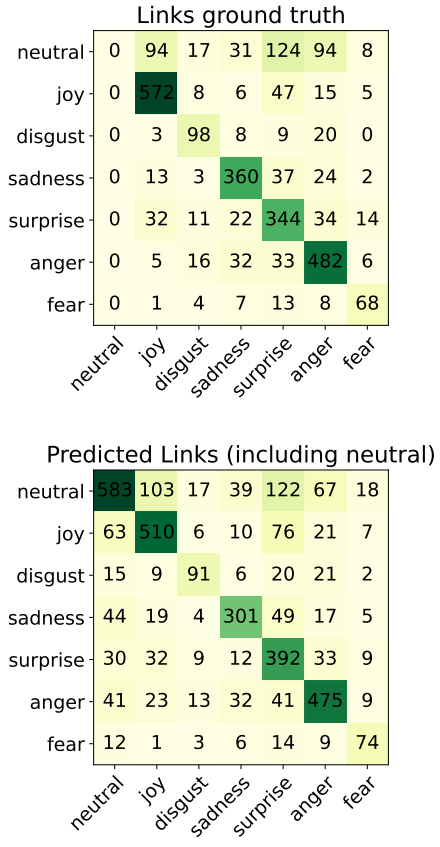

Figure 5: Links in ground truth (top) and predicted links (bottom), emotions loaded from the ground truth – dev dataset

[3]The model creates emotion-cause pairs in *neutral* emotions that should not be possible (no such pairs are present in the training dataset). We remove such pairs before we create the final prediction `json` file.

5.4 Text Span Classification

Table 4 shows the results of various models for the task of text span classification. All models have obtained *accuracy* around 74% – 77% and *Macro-averaged F1 score* above 60%.

Model	Acc.	Macro F1
bert-base-cased	74.1	62.3
bert-large-cased	76.0	60.8
conll03-bert-large-cased[4]	76.6	63.1
roberta-base	**76.8**	61.2
roberta-large	76.7	**67.6**
emotion-roberta-base[5]	76.5	62.4

Table 4: Text span classification results (in %)

For the final submission, we used the bert-large-cased model. However, after the end of the competition, we conducted further experiments with Roberta-like models (see the bottom part of Table 4), and we achieved significantly better scores, particularly in F1 macro.

5.5 Overall Results

For Subtask 2, the main evaluation metric is the weighted F1 score (wF1), as indicated in Table 3 for various models. However, our final submission for the competition is a combination of two models: the best one from emotion detection experiments (Table 1) and the best one for link prediction (Table 2). Such a combination resulted in 0.331 wF1 on dev dataset and 6th place overall in the competition[6]. This is significantly better than the best model from Table 3. All qualitative and error analyses presented above were made based on this setup since test labels are not available at the time being.

For subtask 1, our best model also achieved 6th place in the competition. Our *weighted-avg. proportional F1 score* on test data is 0.208.

Our key findings during the result analysis are as follows:

1. Basic processing of audio/video modalities has brought us only a small positive impact in the case of the link prediction task.

2. The context of the whole dialogue (processing multiple utterances) is crucial for link prediction.

3. We encountered conflicts in fusion strategies (whether to use the aggregation or the fusion token); our best model for emotion prediction is text-only with no fusion mechanism, while the best model for linking benefits from the aggregation fusion strategy.

4. We have obtained better overall results with two separate models.

5. The information about emotion is important for the link prediction task and significantly improves the results.

6 Conclusion

We have participated in two tasks in the *SemEval-2024 Task 3: The Competition of Multimodal Emotion Cause Analysis in Conversations* and obtained 6th place overall.

Our model incorporates all modalities (text, audio and video features). The main information lies within the text since the models based solely on textual modality are consistently among the best ones (see Tables 1 – 3). We proposed and implemented several strategies for the fusion of modalities at the utterance level.

To benefit more from video features, we mean that better preprocessing might be helpful (e.g., detecting a main speaker and focusing on her/his face). A possible bottleneck is in the fixed representation of the audio/video features. Optimizing them during the learning process might improve their positive impact and, subsequently, the overall task success rate. Moreover, we can benefit from the usage of a bigger model.

Our experiments have shown that the one multi-task model may not be ideal since optimal hyper-parameters differ for link prediction and emotion detection tasks. Therefore, our final submission is the composition of two models. We have provided a good starting point and a set of analyses for further research.

As a future work, one of our ideas is to use a single learning objective. In such a model, it would not be necessary to have an emotion module since everything would be managed by the link module with a multi-head self-attention matrix where each head would represent a link of one emotion. The training objective should be simpler since it uses single-label classification across components of attention matrices of individual heads. In this way, we can prevent the prediction of neutral links.

A Additional Results

Additional results to support the choice of hyper-parameters such as fusion size, positive link weight, and update size, are presented in Tables 5, 6, and 7, respectively.

Fusion size is the hyper-parameter of the Fusion Module (see Section 3). There is a possible pattern in Table 5, that a larger fusion size is beneficial for emotion classification in terms of macro F1 score models. On the other hand, it depends also on the model size. Larger models such as "bert-large-cased" may benefit from larger fusion size, but it seems the opposite for smaller ones such as "bert-base-cased".

Fusion Size	PLM	Jaccard	Acc.	Macro F1	wF1
768	all	0.339	0.845	0.467	–
1024	all	0.338	0.848	0.469	0.295
1536	all	0.336	0.843	0.482	0.293
768	bert-base-cased	0.340	0.847	0.464	–
1024	bert-base-cased	0.339	0.849	0.465	0.294
1536	bert-base-cased	0.325	0.838	0.472	0.277
768	bert-large-cased	0.335	0.844	0.469	–
1024	bert-large-cased	0.338	0.846	0.485	0.305
1536	bert-large-cased	0.342	0.844	0.494	0.302

Table 5: Average results for fusion size hyperparameter across PLMs: Jaccard index is used for link prediction, Accuracy and Macro F1 for emotion prediction, and wF1 for ECPE task

Positive link weight is used in the loss function to increase the importance of positive links in a sparse adjacency matrix. According to Table 6, the hyper-parameter importance is not so significant and the differences are more likely due to other settings such as fusion scenario or PLM. Generally, it worked well with a weight set to 5, which is also the best in terms of macro pair F1 score (*mpF1*).

Weight	Jaccard	Acc.	mpF1
1	0.311	0.836	0.331
5	0.325	0.833	0.345
10	0.319	0.829	0.336
20	0.329	0.834	0.339
50	0.319	0.838	0.335

Table 6: Average results for different weights of positive link: Jaccard index is used for link prediction, Accuracy for emotion prediction, and mpF1 for ECPE task

Update size represents the number of samples used for one weight update using gradient accumulation technique. There is a drop in performance with larger update size in Table 7.

Update Size	Jaccard	Acc.	Macro F1	wF1
8	0.338	0.846	0.484	0.310
12	0.336	0.845	0.480	0.297
24	0.345	0.849	0.469	0.301
60	0.340	0.852	0.462	0.302
120	0.290	0.841	0.414	0.207

Table 7: Average results for different update size (batch · gradient accumulation steps): Jaccard index is used for link prediction, Accuracy and Macro F1 for emotion prediction, and wF1 for ECPE task

GAVx at SemEval-2024 Task 10: Emotion Flip Reasoning via Stacked Instruction Finetuning of LLMs

Abstract

The Emotion Flip Reasoning task at SemEval 2024 aims at identifying the utterance(s) that trigger a speaker to shift from an emotion to another in a multi-party conversation. The spontaneous, informal, and occasionally multilingual dynamics of conversations make the task challenging. In this paper, we propose a supervised stacked instruction-based framework to finetune large language models to tackle this task. Utilising the annotated datasets provided, we curate multiple instruction sets involving chain-of-thoughts, feedback, and self-evaluation instructions, for a multi-step finetuning pipeline. We utilise the self-consistency inference strategy to enhance prediction consistency. Experimental results reveal commendable performance, achieving mean F1 scores of 0.77 and 0.76 for triggers in the Hindi-English and English-only tracks respectively. This led to us earning the second highest ranking[1] in both tracks.

1 Introduction

The EDiReF shared task at SemEval 2024 (Kumar et al., 2024) encompasses two challenges in natural language processing (NLP): *Emotion Recognition in Conversation* (ERC) and *Emotion Flip Reasoning* (EFR). Our work focuses on the latter challenge—EFR, which aims at identifying the utterances responsible for triggering a shift in a speaker's emotional state, hereafter referred to as an *emotion flip*, within a multi-party conversation. The task offers two tracks: one involving Hindi-English code-mixed conversations and the other focusing on English-only conversations. The first track particularly addresses the complexities inherent in multilingual contexts. Each track comes with its respective dataset annotated by the organisers, wherein each utterance is labelled to represent one of the six primary emotional states—*anger*, *disgust*, *fear*, *joy*, *sadness*, and *surprise* (Ekman, 1999). Additionally, the emotion *neutral* is assigned to utterances devoid of any expressed emotion (Kumar et al., 2024). Given these emotion labels, locating the emotion flip is straightforward. Our task is to identify the triggers behind it.

Figure 1 shows a Hindi-English code-mixed conversation conducted between two speakers, complemented by English translations. During the chat, Speaker A undergoes an emotion flip from *sadness* to *joy*, while Speaker B transitions from *surprise* to *joy*. Utterance *u4* is identified as the trigger causing both speakers' emotion flip. Particularly, when Speaker B delivers utterance *u4*, their emotional state also undergoes a change, rendering *u4* as a self-trigger for Speaker B's own emotion flip. It is worth noting that, for an emotion flip, there can be no trigger utterances at all, or there can be one or multiple trigger utterances originating from any involved speakers, including themselves (Kumar et al., 2024).

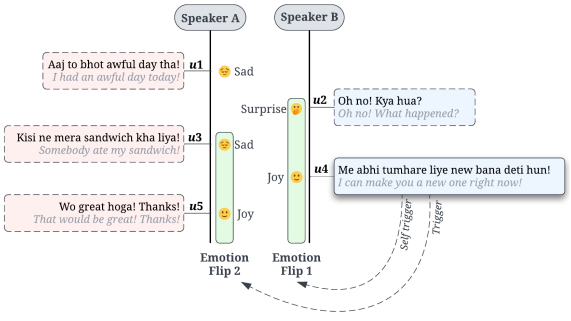

Figure 1: A conversation with five utterances between two speakers involving two emotion flips. Translations are not part of the conversation.

[1]https://codalab.lisn.upsaclay.fr/competitions/16769

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 326–336

The EFR task can be formulated as follows: Given a conversation between p speakers $s_i^{i=1..p}$ involving q utterances $u_j^{j=1..q}$, each assigned an emotion $e_j^{j=1..q}$, if speaker s_i changes their emotion at utterance u_k, there may exist a set of utterances u_l, wherein $1 \leq l \leq k$, that trigger the emotion flip. If we use 1 to denote a *trigger utterance* and 0 to denote a *non-trigger utterance*, then the array $[t_1, t_2, \ldots, t_k]$, in which t_m equals either 0 or 1 and its position in the array corresponds to the position of the utterance in the conversation, can conveniently represent the task's label for an emotion flip. For instance, considering the conversation in Figure 1, the array [0, 0, 0, 1, 0] indicates that the utterance at position 4 caused Speaker A to shift from *sadness* to *joy*.

In this paper, we introduce an instruction-based framework designed to finetune large language models (LLMs) for addressing the EFR task. Initially, leveraging the training data, we construct multiple distinct instruction sets to guide the model in identifying triggers for emotion flips. These instructs emulate human cognitive processes, incorporating both human feedback and self-evaluation procedures as integral components of the reasoning process. Subsequently, we execute a supervised stacked finetuning pipeline to refine the model using these instructions. Once the model is tuned, we employ an inference strategy called *self-consistency* (Wang et al., 2023) to generate predictions for the test data.

Besides the system description, we made the following observations in our experiments:

1. Our framework demonstrates competent performance for both English-only and Hindi-English code-mixed datasets, indicating its capacity to effectively handle both monolingual and multilingual contexts.
2. Providing high-quality instructions to LLMs is crucial for achieving the desired output. Our model's performance improves each time we provide more refined instructions.
3. The self-consistency inference strategy helps mitigate the randomness in the output generated by LLMs, allowing us to attain more uniform results across executions.

In the next section, we discuss various related works. Subsequently, we detail our proposed system in Section 3. Following this, we outline our experimental setup in Section 4, analyse its results in Section 5 before concluding in Section 6.

2 Related Work

The EFR task was first introduced by Kumar et al. (2022), who utilised a masked memory network and a transformer-based architecture to tackle it. In subsequent research in 2023, they delved deeper into the instigators behind emotion flips and introduced a neural architecture named TGIF. This architecture integrates transformer encoders and stacked gated recurrent units (GRUs) to comprehensively capture the conversation context, speaker dynamics, and emotional sequences.

While EFR remains a relatively recent task, it is closely related to the widely studied task of *Emotion-Cause Pair Extraction* (ECPE) (Kumar et al., 2022). The objective of ECPE is to identify a text span that elicit a specific emotion (Xia and Ding, 2019). Earlier endeavours to address ECPE using deep learning faced challenges associated with position bias (Ding and Kejriwal, 2020). Zheng et al. (2022) introduced UECA-Prompt, a BERT-based universal prompt tuning method. Subsequently, Wu et al. (2024) proposed the DECC framework, which incorporates inducing inference and logical pruning to guide LLMs to reason. Both prompt-based approaches outperformed previous works on this task. The promising results observed in ECPE using prompt-based methods motivates us to adapt them to the EFR task.

Prompt-based learning refers to prompting pre-trained language models to tackle downstream tasks (Liu et al., 2021). Recently, LLMs like GPT (OpenAI, 2023) and LLAMA (Touvron et al., 2023) demonstrate exceptional performance across various NLP tasks, even with zero-shot or few-shot prompts (Brown et al., 2020; Sun et al., 2023). Several prompting techniques have emerged recently. Chain-of-thoughts (CoT) prompting, one of the most popular techniques, replicates human cognitive process by integrating intermediate reasoning steps (Wei et al., 2023). Instead of attempting to reach the answer in a single leap, this approach encourages the model to divide complicated problems into smaller, more manageable components, imitating the way humans think. Tree-of-thoughts prompting extends CoT by constructing a tree of logical steps towards the solution (Yao et al., 2023). Multimodal CoT combines text and vision into a two-phase cognitive process (Zhang et al., 2023). On the other hand, instead of fixed prompts, LLMs themselves can be used to dynamically generate prompts for downstream tasks (Zhou et al., 2022) or to produce

and execute programming code as intermediate steps (Gao et al., 2022). Interestingly, LLMs are demonstrated to be capable of generating and analysing recursive reasoning, a unique cognitive ability akin to human thinking processes (Dąbkowski and Beguš, 2023).

Despite these emerging techniques, LLMs often generate outputs that deviate from the ground truth labels (Wadhwa et al., 2023). To address this challenge, instruction tuning emerges as a solution, employing supervised learning on a set of instructions to narrow the gap between the output generated by the base LLMs and the desired output (Zhang et al., 2023). Additionally, human and augmented feedback play a crucial role in mitigating this issue. Akyurek et al. (2023) introduced a reinforcement learning framework equipped with a critique generator to guide GPT-3 in improving its output. Diao et al. (2023) proposed the Active-Prompt method, which entails human manual annotation of uncertain rational chains. Furthermore, Paranjape et al. (2023) devised a novel framework that freezes LLMs and integrates reasoning steps from an external program.

These prior studies underscore the significance of furnishing high-calibre instructions and feedback, as well as employing suitable prompting techniques, to achieve the desired output with LLMs.

3 Our System

In this section, we describe the general approach and the implementation of our system.

3.1 General Approach

Our system must be built upon an *instruction tuneable LLM*. The approach involves two stages: instruction tuning and inference.

3.1.1 Instruction Tuning

Our approach is founded on the premise that problems necessitating reasoning often allows multiple reasoning paths to arrive at the same correct solution. To instil the desired reasoning capabilities in an LLM, we adopt a supervised tuning approach using instructions derived from the training data (Zhang et al., 2023) and implement a stacked framework employing diverse instruction sets to foster the model's ability in navigating varied reasoning paths. A summary of each step is provided below.

Step 1. We train the base model with *Chain-of-thoughts (CoT) instructions*. These instructions can be generated from the training data. This step trains the model on *what is right*.

Step 2. We further provide *feedback-based instructions* to tuned model, expecting it to *rectify the discrepancy* between its current reasoning manner and the desired reasoning manner.

Step 3. We further provide *self-evaluation instructions* to the tuned model, expecting it to enhance its ability to improve itself through *autonomous* evaluation.

Figure 2 summarises the main steps in this supervised finetuning pipeline. Section 3.3.1 describes how we construct these instruction sets.

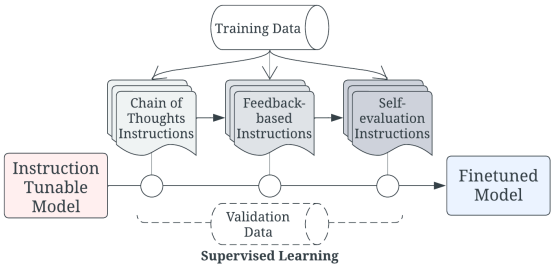

Figure 2: Supervised instruction tuning pipeline.

3.1.2 Inference Procedure

Language models are susceptible to random errors in reasoning, potentially resulting in incorrect conclusions (Wang et al., 2023). To mitigate this issue, these researchers introduced the *self-consistency* (SC) inference strategy. It operates on the principle of generating diverse reasoning paths and selecting the most consistent conclusion by marginalising any inconsistent ones. We adapt this inference strategy to align with the characteristics of our own model.

In our tailored version of SC, we iteratively prompt the model with a progressively increasing *temperature*, a parameter controlling the randomness of the output (Wang et al., 2020), until the answers converge. We introduce a threshold α to determine the convergence point. The convergence condition is if the average of the predicted labels for an utterance is not less than α or not greater than $1-\alpha$. Once the answers converge, the final label for each utterance is the average prediction rounded to the nearest integer, which is eventually either 0.0 or 1.0. Besides the α threshold, we also impose a minimum and maximum number of prompts so that sufficient runs are performed while ensuring the algorithm

still stops if it does not converge. Figure 3 presents a piece of pseudo-code for this inference strategy.

***Global variables*:** *min*, *max*, α

***Converged*(*prediction*):**
If each *item* in *prediction* array ≥ α or ≤ 1 − α:
Return True
Return False

***Infer*(*prediction, dialogue, temp, count*):**
Prompt for *dialogue,* with temperature as *temp*
Assign result array to *new_prediction*
Set *prediction* to mean of all predictions so far
Increase *count* by 1
Increase *temp* by a constant
If (*max* ≤ *count*) or
(*min* ≤ *count* and *Converged*(*prediction*)):
Return *round*(*prediction*)
Return *Infer*(*prediction, dialog, temp, count*)

Figure 3: Our tailored version of SC.

3.2 System Implementation

In this section, we describe how we implement the framework we conceptualise above.

3.2.1 Instruction Construction

We use the training data to construct the instruction sets. Each instruction comprises two components: a *prompt* and a *desired output*. Our finetuning pipeline requires three different instruction sets to be built as follows.

CoT instruction set—The *prompt* includes a labelled conversation sampled from the training data, a CoT that describes the progression of emotional states for the last speaker, and a query tasking the model with identifying the triggers. The *desired output* is a CoT that leads to the accurate identification. We programmatically generate these instructions using a dynamic text template that outlines the sequence of reasoning. The template contains placeholders that can be populated with matching information derived from the conversation. Figure 4 shows how a CoT instruction is crafted for a typical conversation, where each utterance originates from a single speaker, an emotion flip trigger is present, and it is not a self-trigger. Our implementation of the text template is versatile, capable of accommodating various scenarios, including those with no triggers, self-triggers, multiple triggers, and instances where an utterance is attributed to multiple or all speakers.

Feedback-based instruction set—The *prompt* is constructed by sampling a labelled conversation and asking the model to identify the emotion flip triggers directly. Subsequently, its output is then compared with the ground truth labels. If discrepancies arise, the *prompt* is extended with feedback regarding missed or misidentified triggers, and a request for the model to retry the task. We utilise the model tuned using CoT instructions for this step, which enables us to assess its current reasoning manner. Following this, the *desired output* is a CoT that leads to the correct answer. Figure 5 provides an overview of constructing a feedback-based instruction through the integration of a labelled conversation and a baseline model. In our implementation, we again employ dynamic text templates to generate the prompt and desired output for various scenarios, including instances where multiple triggers are missed or misidentified, all triggers are misidentified, and self-triggers are misidentified.

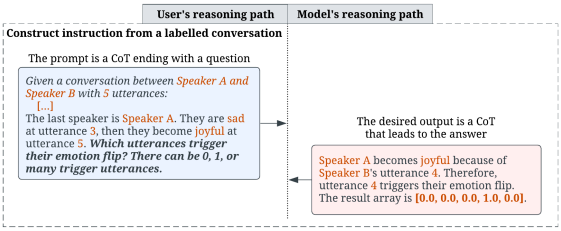

Figure 4: The construction of a CoT instruction for a conversation. Texts in colour indicate placeholders.

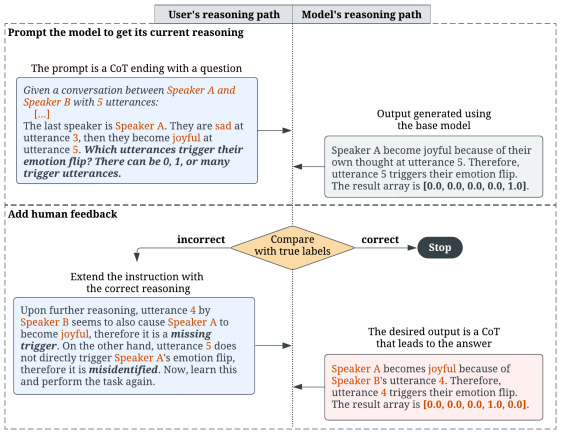

Figure 5: The construction of a feedback-based instruction for a conversation. Texts in colour indicate placeholders.

Self-evaluation instruction set—The *prompt* is structured similarly to a feedback-based instruction, involving the selection of a labelled conversation, and prompting the model finetuned in Step 2 to replicate its current reasoning approach. However, in cases where the output is inaccurate, the prompt extends to instruct the

model to evaluate its own output and iteratively retry the task until satisfaction is achieved. The *desired output* is an augmented CoT that emulates a recursive reasoning and evaluation process, culminating in the correct answer. Our approach to constructing self-evaluation instructions is inspired by research indicating that LLMs possess recursive reasoning abilities (Dąbkowski and Beguš, 2023). Leveraging this capability, we instruct LLMs to engage in autonomous evaluation. To implement this idea, we compile a dynamic text template to simulate a recursive thinking process with information extracted from the given conversation. This template enables the generation of a variable number of iterations, mirroring the iterative cognitive process observed in humans, which may not always yield perfect results in the initial iterations. Figure 6 illustrates the construction of the prompt and the simulation of an expected output using two reasoning iterations before reaching a correct answer.

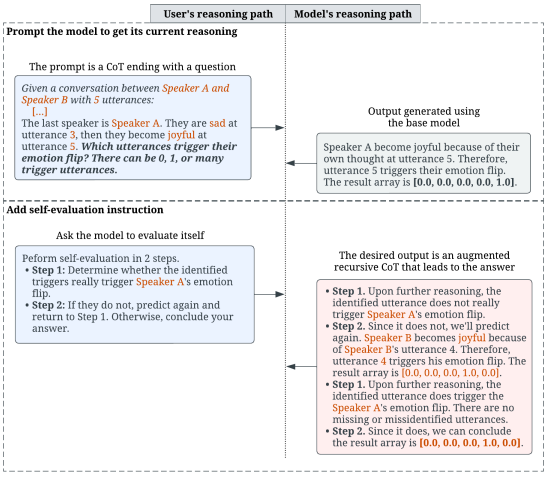

Figure 6: The construction of a self-evaluation instruction for a conversation. Texts in colour indicate placeholders.

As the building of the feedback-based and the self-evaluation instruction sets requires the model to undergo learning from the preceding step, our system must be finetuned in a sequential pipeline.

3.2.2 Prompting Finetuned Model

Following the finetuning of the base LLM with the three prepared instruction sets, we proceed with the SC inference procedure to make predictions for unlabelled data. A critical aspect of this process involves prompting the finetuned model in diverse manners to elicit varied reasoning paths. Given the utilisation of three instruction sets, we employ three distinct prompt variants to prompt the model in identifying emotion flip triggers. The prompt variants utilised are detailed in Figure 7.

Extracting the label from the output sequence generated by the model requires engineering effort due to the dynamics of LLMs. When multiple labels exist in the output, our implementation selects the last label. This aligns with our tuning technique, where intermediate predictions may undergo adjustments during subsequent re-evaluations.

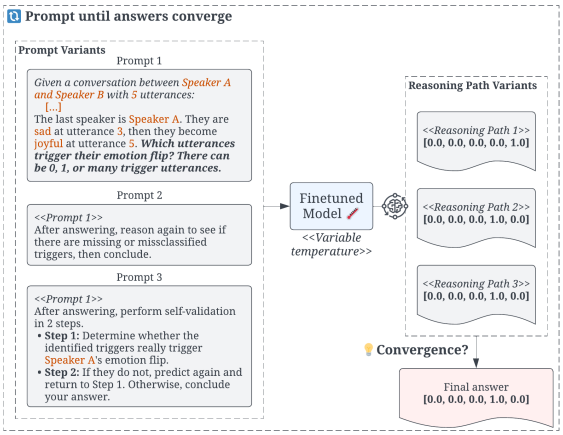

Figure 7: Multiple prompts variants are utilised to produce varied reasoning paths.

4 Experimental Setup

4.1 Datasets

In our experiments, we utilise the datasets provided by the organisers. The data for both tracks originate from previously published datasets. The Hindi-English dataset is sourced from MaSaC, a multimodal dataset compiled from the Hindi TV series *Sarabhai vs Sarabhai* (Bedi et al., 2023). The English monolingual dataset is sourced from MELD, a dataset containing dialogues from the American TV sitcom *Friends* (Poria et al., 2019). In the Hindi-English track, a new emotion, *contempt*, appears, which does not impact our approach since it solely focuses on the positions of the utterance before and after the emotion flip, not the emotions themselves. Table 1 summarises the shape of both datasets.

Upon closer examination of the training splits, it is evident that a significant portion of triggers lies within a proximity of either 1 or 2 utterances preceding the emotion flip. Furthermore, conversations in the Hindi-English dataset exhibit greater length and involve more speakers on average compared to the English-only dataset.

Statistics on the training splits for both tracks are shown in Table 2.

Split	Instances	Utterances	Triggers	% Triggers
Hindi-English dataset				
Train	4,894	98,777	6,542	6.62%
Val	3,89	7,462	434	5.82%

Max	24.00	12.00	8.00	17.00

Table 2: Statistics on the training splits.

4.2 Evaluation Method

We utilise the F1 score of the identified trigger utterances, labelled as 1, as the primary evaluation metric. The F1 score, which balances precision and recall, serves as a robust metric to evaluate the model's ability to accurately identify emotion flip triggers while considering both false positives and false negatives (Goutte and Gaussier, 2005).

To assess the efficacy of our system, we establish a baseline by referring to the results obtained using masked memory networks and transformers by the researchers who proposed the EFR task (Kumar et al. 2022). Subsequently, we conduct an ablation study, aiming to discern the impact of each component in the architecture on the overall performance of the model. Furthermore, we also perform cross-lingual inference to assess the cross-lingual capability of our approach.

4.3 Tuning and Inference Settings

We use the model GPT-3.5-Turbo-1106 by OpenAI[2] as the base model and Azure[3] as the infrastructure. For each track, we separately finetune the model in five epochs using a batch size of 8 and a learning rate multiplier of 1.0, while also incorporating a prompt loss weight. Due to the impromptu and informal nature of conversations, a low content filter setting is consistently used throughout all stages so that the model accepts more contents in their original form.

After finetuning, we generate predictions for the test data using the SC inference strategy. We incorporate a minimum of 3 prompts and a maximum of 10 prompts, alongside an α threshold set at 0.75. This stringent threshold dictates that a consensus of at least 3 out of 4 (75%) agreement amongst predicted labels for an utterance must be achieved before the final label is determined. Furthermore, the temperature parameter is initialised at 0.0 and progressively incremented by 0.1 in each iteration. This iterative adjustment facilitates the introduction of increasing randomness into the model's output, thereby mitigating the risk of overfitting.

5 Results and Analysis

5.1 Main results

In this section, we conduct five executions for each test and report the averages to obtain reliable results. Table 3 provides a summary of the models' performance across all tests conducted.

Initially, to evaluate the base LLMs, we conduct one-shot prompting using the GPT-3.5-Turbo-1106 and GPT-4-0613 models. This prompt construction mirrors that of the CoT instruction set. Our results reveal that GPT-4-0613 achieves an F1 score of 0.60 for the English-only track, surpassing the baseline by 0.061 points, without prior training. Similarly, it shows comparable performance in the Hindi-English track, achieving an F1 score of 0.57.

Subsequent tests demonstrate that finetuning the base GPT-3.5-Turbo-1106 model with additional instructions consistently enhances its performance. We utilise a distinct prompt variant at each tuning stage for zero-shot prediction to prompt the model to reason according to our desired approach, as described in Section 3.3.1. We then apply the SC procedure on the fully tuned model. Integrating all proposed techniques into the final model yields a plateau F1 score of 0.77 and 0.76 for the Hindi-English and English-only tracks respectively. Note

[2] https://platform.openai.com/docs/models

[3] https://azure.microsoft.com

that in the SemEval-2024 Task 10 leader board, we achieved 0.79 for the former track, which was our best run. The results reported in this paper are the mean F1 scores across five runs.

System	Prompt	Accuracy	F1 (0)	F1 (1)
Hindi-English track				
GPT-3.5-Turbo-1106	1-shot	0.95	0.97	0.53
GPT-4-0613	1-shot	0.95	0.97	0.57
GPT-3.5 tuned Step 1	0-shot	0.96	0.98	0.67
GPT-3.5 tuned Step 2	0-shot	0.97	0.98	0.71
GPT-3.5 fully tuned	0-shot	0.97	0.99	0.73
GPT-3.5 fully tuned	SC	0.98	0.99	**0.77**
English-only track				
GPT-3.5-Turbo-1106	1-shot	0.88	0.93	0.57
GPT-4-0613	1-shot	0.89	0.93	0.60
GPT-3.5 tuned Step 1	0-shot	0.91	0.95	0.69
GPT-3.5 tuned Step 2	0-shot	0.92	0.96	0.72
GPT-3.5 fully tuned	0-shot	0.93	0.96	0.74
GPT-3.5 fully tuned	SC	0.95	0.96	**0.76**

Table 3: Model performance in different settings.

5.2 Error Analysis

Our quantitative analysis indicates that the test data provided are representative of the training data. Table 4 shows the confusion matrices of the fully tuned models for both tracks. In the Hindi-English code-mixed track, the model exhibits a tendency to misclassify triggers as non-triggers. Conversely, in the English-only track, a notable balance exists between misidentified triggers and misidentified non-triggers, despite the class imbalance.

Upon closer examination, Table 5 displays the frequency of each type of emotional flip, along with the corresponding number of accurate predictions. In this table, a prediction for a conversation is considered accurate only when all triggers and non-triggers are correctly identified. The data shows that across both tracks, emotion flips from *neutral* to *joy* and from *joy* to *neutral* are the most prevalent. The model achieves accuracy rates of 67.27% and 70.16% in identifying the triggers for these flips in the Hindi-English and English-only tracks respectively.

5.3 Ablation Analysis

In our ablation analysis, we note a consistent improvement in model performance with the addition of each instruction set. Table 6 illustrates these findings, indicating that each successive step reduces the number of false positive and false negative errors from its previous step. Despite that, it also introduces new errors into the predictions; however, the number of new errors is consistently lower than the errors reduced. Notably, tuning the model with CoT instructions at Step 1 emerges as the most impactful, reducing error rates by 38% and 25%, thus increasing F1 scores by 0.15 and 0.12 points for the Hindi-English and English tracks respectively. This highlights the efficacy of instruction tuning. Even with only one instruction set, the disparity between the base model's reasoning manner and the desired reasoning manner is significantly diminished. Subsequent steps further diminish errors, ultimately resulting in the plateau performance observed when employing all techniques in conjunction.

5.4 Effectiveness of SC Inference Strategy

Previous sections show that SC improves the F1 score for both tracks. This section proceeds to deep dive into this strategy. Table 7 shows a conversation excerpted from the test data between Mark and Rachel, wherein there exists no triggers for Rachel's emotion flip from *anger* to *neutral*, hence the ground truth label is [0, 0, 0]. This instance is tricky, as Mark's question, Rachel's response, and her subsequent exclamation all appear relevant to the emotion flip. With α set at 0.75, after the first three prompt variants, the model's outputs do not align. However, as we prompt with a progressively higher temperature, convergence is achieved after 8 iterations, with at least 75% of the predictions for each utterance now in agreement. As a result, the predicted label matches the true label. This example aptly illustrates the efficacy of SC in resolving disagreements between different reasoning paths.

Mark: *Why do all your coffee mugs have numbers on the bottom?* [***Surprise***]
Rachel: *Oh. That's so Monica can keep track. That way if one on them is missing, she can be like, "Where's number 27?!"* [***Anger***]
Rachel: *Y'know what?* [***Neutral***]

Iter	Prompt	Temp	Prediction	Running Average
1	1	0.0	[0, 1, 0]	[0.00, 1.00, 0.00]
2	2	0.1	[0, 0, 0]	[0.00, 0.50, 0.00]
3	3	0.2	[0, 0, 1]	[0.00, 0.33, 0.33]

5	2	0.4	[0, 0, 0]	[0.00, 0.20, 0.40]
6	3	0.5	[1, 0, 0]	[0.17, 0.17, 0.33]
7	1	0.6	[0, 0, 0]	[0.14, 0.14, 0.28]
8	2	0.7	[0, 1, 0]	**[0.14, 0.25, 0.25]**

Table 7: Efficacy of SC in helping resolve disagreements between different reasoning paths for a sample conversation excerpted from test data.

5.5 Cross-lingual Inference

To assess the cross-lingual generalisability of our approach, we use the model trained on the Hindi-English dataset to predict outcomes for the English-only track, and reciprocally, the model trained on the English-only track for the Hindi-English dataset. The results presented in Table 8 demonstrate that our models achieve commendable performance, both surpassing GPT-4-0613, despite not being finetuned on data representative of the test data provided.

Model	Test Data	Accuracy	F1 (0)	F1 (1)
Hindi-English	English-only	0.92	0.95	**0.69**
English-only	Hindi-English	0.96	0.98	**0.64**

Table 8: Model performance using cross-lingual inference.

5.6 Model Hallucination

When fine-tuning GPT-3.5, we encountered a peculiar form of hallucination—an instance where the model generates outputs that largely deviate from the provided training data (Ji et al., 2023). Despite being explicitly instructed to classify *each utterance* as '0' or '1', the model predictions include '2' for some utterances in one execution and include more labels than the number of utterances in another execution. We eventually decided to omit these anomalous executions to maintain the integrity of our results. Currently, controlling this type of hallucination remains a challenge. Further research is necessary to mitigate this phenomenon and improve the model's adherence to its operational constraints.

5.7 Other Constraints

In our experiments, we leverage GPT models hosted on Azure cloud infrastructure. While this offers convenience and efficiency, they are not without their associated costs. Our finetuning process demands 3.5 hours of training time, encompassing approximately 2 million training tokens alongside nearly 200,000 prompting tokens. Additionally, the SC strategy necessitates multiple prompts to attain convergence, thereby extending the time required to derive final predictions. With our settings, the average model speed is 1.22 seconds per prompt for the Hindi-English track and 0.83 seconds per prompt for the English-only track. In light of these considerations, it is crucial to

diligently address cost and resource constraints when building the models.

6 Conclusion & Future Work

The paper presents an instruction based LLM finetuning framework to address the EFR task. Our strategy employs a multilayered finetuning pipeline, utilising three diverse instruction sets to steer the model towards recognising emotion flip triggers and, and finalised with the application of the SC inference strategy. The framework benefits significantly from the provision of high-quality instructions, as evidenced by the progressively improved performance of our model as better-quality feedback and instructions are incorporated into the finetuning pipeline. The robustness of our framework is demonstrated by its proficient handling of both English-only and Hindi-English code-mixed datasets, affirming its effectiveness in varied linguistic scenarios. Through these findings, we trust that our study makes a meaningful impact on the field of prompt-based learning techniques by harnessing the evolved capabilities of LLMs.

Moving forward, our focus will be on an in-depth exploration of various instruction types to devise the optimal way to amalgamate them for the most generalisability. Furthermore, we plan to develop a systematic method for constructing a processing pipeline tailored to this task and potentially applicable to related NLP tasks. This pipeline will be designed to encompass a CoT prompts, incorporate feedback mechanisms, and integrate self-evaluation instructions to ensure a robust, repeatable process for enhancing model performance.

Abstract

This paper describes our participation in the SemEval-2024 Task 1, "Semantic Textual Relatedness for African and Asian Languages ." This task detects the degree of semantic relatedness between pairs of sentences. Our approach is to take out the sentence pairs of each instance to construct a new sentence as the prompt template, use MASK to predict the correlation between the two sentences, use the BERT pretraining model to process and calculate the text sequence, and use the synonym replacement method in text data augmentation to expand the size of the data set. We participate in English in track A, which uses a supervised approach, and the Spearman Correlation on the test set is 0.809.

1 Introduction

We participated in the English language of track A in Task 1, "Semantic Textual Relatedness for African and Asian Languages." Track A uses a supervised approach where systems are trained on labeled training datasets. This task detects the degree of semantic relatedness between pairs of sentences for African and Asian Languages (Ousidhoum et al., 2024b).

Semantic Textual Relatedness (STR) is an important measure of the relationship between texts. It is considered to be the basis for understanding meaning(Miller and Charles, 1991) and is crucial for many natural language processing tasks. By computing semantic textual relatedness, we can perform applications such as text matching(Xu et al., 2013), information retrieval(Wagh and Kolhe, 2011), text categorization(Alsamurai, 2017), and question answering systems(Das and Saha, 2022).

However, previous NLP work has focused on semantic similarity (a small subset of semantic relatedness), in large part due to the lack of datasets on relatedness. For example, SemEval-2015 task1 is paraphrase and semantic similarity in twitter(Xu et al., 2015). And SemEval-2016 task1 is semantic textual similarity, monolingual and cross-lingual evaluation(Agirre et al., 2016).

Semantic relatedness and semantic similarity are two ways to explore the closeness of meaning. Two terms are considered semantically similar if there is a synonym, contextual, or modal relation relationship between them. Two terms are considered semantically related if there is any lexical semantic relation between them. Thus, all similar pairs are also related, but not all related pairs are similar(Abdalla et al., 2021). In semantic textual relatedness, we focus on the meaning and semantic information of the text, not just the surface word or sentence structure. Thus, the semantic relatedness between two texts can relate to their themes, intentions, emotions, etc.

The semantic relatedness of texts can be computed using the content and links of hypertext encyclopedias(Yazdani and Popescu-Belis, 2013). Semantic relatedness between texts can also be measured by calculating the similarity between text representations using a pre-trained language model.

In the following, we describe in detail the methods we used and give the evaluation results and conclusions.

2 Background

In this section, we present important details about the task setup. Each instance in the train set, dev set, and test set is a sentence pair, and these two sentences are separated by a newline character. The instance is labeled with a score representing the degree of semantic textual relatedness between the two sentences(Ousidhoum et al., 2024a). As shown in Table 1, there are two sentence pairs examples to present the semantic textual relatedness.

The scores can range from 0 (maximally unrelated) to 1 (maximally related), which are obtained using a comparative annotation framework. The

sentence1	sentence2	STR score
A girl is communicating with sign language.	A young girl is using sign language.	0.83
You should have respect for your mother.	Even if this is your own mother!	0.41

Table 1: Sentence pairs examples

	Train	Dev	Test
before text data augmentation	5500	250	2600
after text data augmentation	11000	250	2600

Table 2: Size of the data set

train and dev sets give sentence pairs and semantic textual relatedness scores, and the test set only gives sentence pairs. The train set was enlarged by using text data augmentation. The size of the dataset is shown in Table 2. The task we participated in was the English in track A. The task is a regression task whose input is a sentence pair and the output is the semantic textual relatedness score for that sentence pair.

3 System Overview

In this section, we present our approach applied to the task of predicting STR. We use the BERT pre-training model(Devlin et al., 2018) for text sequence processing and computation, and also employ text data augmentation to improve the training results. We adopted prompt tuning(Liu et al., 2023) to construct a new sentence, "The correlation of the next two sentences sent0 and sent1 is [MASK].", and used this constructed new sentence as a prompt template, where [MASK] is used to predict the correlation between the two sentences.

3.1 Model

We use the BERT pre-training model, designed to pre-train deep bidirectional representations from the unlabeled text by joint conditioning on both the left and right context in all layers. As a result, the pre-trained BERT model can be fine-tuned with just one additional output layer to create state-of-the-art models for a wide range of tasks. STR tasks are related to the semantics of the text, so using the case-insensitive English BERT pre-training model works better than the case-sensitive English BERT pre-training model.

We use the BERT model for encoding and feature extraction of text sequences. The structure of the system is shown in Figure 1(Mutinda et al., 2021). The two special tokens [CLS] and [SEP] are added to the model's input data to convert the text into the format expected by BERT. The forward function accepts a batch as input. It extracts $input\_ids$ and $attn\_mask$ from the batch, where $input\_ids$ is a sequence that converts the input text into a numeric representation acceptable to the model, $attn\_mask$ is a sequence of binary masks used to indicate which tokens are real input and which tokens are padded. Then it encodes the $input\_ids$ and $attn\_mask$ to obtain the $enc\_outputs$, which are hidden states of the model's output. Next, the corresponding embedding representation is extracted from the hidden state based on the mask position. These embedding representations are processed through a linear transformation to end up with a scalar value $logits$. Sigmoid activation is performed on $logits$ to get the output score.

3.2 MASK Prediction

Since the labels in the train set are continuous, we modeled this task as a regression problem. We adopted prompt tuning and used the Pattern-Exploiting Training (PET) method(Schick and Schütze, 2021) to construct a new sentence "The correlation of the next two sentences sent0 and sent1 is [MASK]." as a prompt template. In this prompt template, sent0 and sent1 are two sentences, and [MASK] is used to predict the correlation between the two sentences. Thus, it could convert the downstream task into a Complete Fill-in-the-Blank(cloze) task(Ding et al., 2021), and Masked Language Modeling(MLM)(Wettig et al., 2023) BERT can be used for prediction. Since the language of our participation is English, this prompt template is constructed in English. If we want to evaluate the semantic textual relatedness in other languages, we need to modify this template to the corresponding language. The constructed prompt template is fed into the model using the pre-training

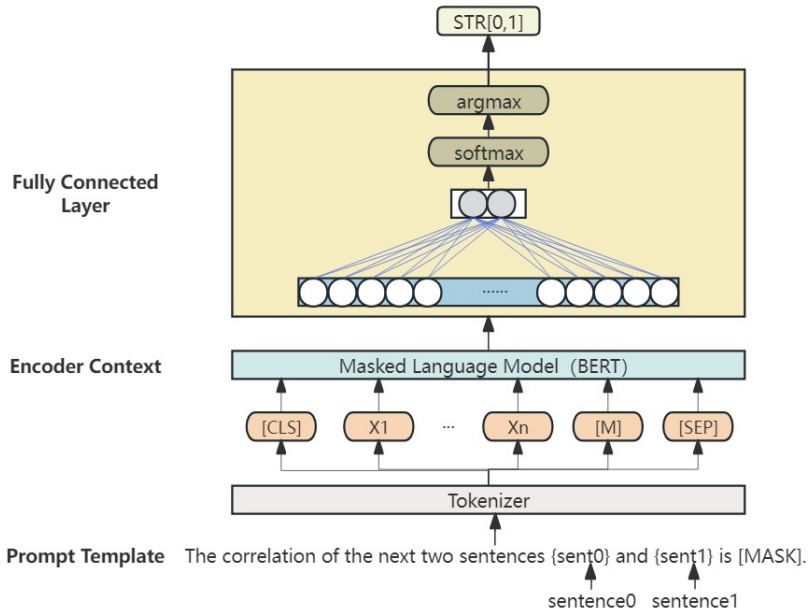

Figure 1: System model structure

model BERT, and the model predicts the representation of the correlation based on the context and the position of [MASK].

3.3 Text Data Augmentation

Through text data augmentation, more training samples can be generated to expand the size of the train set. Besides, text data augmentation can improve the generalization ability and robustness of the model. For example, Connor Shorten and others used a CNN model combined with text data augmentation EDA when the training set size was 5000, and the result improved from 87.7 to 88.3(Shorten et al., 2021). This task is to find out the degree of semantic correlation between two sentences, considering the task requirements and data characteristics, the data samples after performing text data augmentation can change the expression of the sentences, but the overall semantics of the sentences should remain unchanged.

Therefore, we used the synonym replacement method in the text data augmentation method in our experiments instead of random insertion, deletion, and other methods. After using this method changes the number of samples in the train set from 5500 to 11000.

4 Experimental Setup

The data set is given in CSV file format by the SemEval 2024 shared task organizer. It has three columns: PairID, Text, and Score, where Text is a sentence pair. We take out the two sentences in the sentence pair and use these two sentences to construct a new sentence: "The correlation of the next two sentences sent0 and sent1 is [MASK].". This new sentence is then fed into the model for processing and training. When performing text data augmentation, we replace the two sentences with synonyms and then insert the newline character in the middle of the replaced sentence pairs to ensure that the data format is consistent with the original data set.

We use the BERT pre-training model to process and calculate text sequences. The text data augmentation method is synonym replacement. Since this task is a regression task, we use the mean squared error(MSE) loss function:

$$L_{mse} = \frac{1}{n}\sum_{i=1}^{n}(y_i - y_i^{'})^2 \quad (1)$$

where y_i is the ground truth for sample i, $y_i^{'}$ is the prediction score for sample i, n is the number of samples.

The batch size is set to 64, the number of training iterations is 6, and the learning rate is 2e-2. At the same time, in order to help the model converge better and achieve better performance, we set up a learning rate scheduler.

	Dev Score	Test Score
before text data augmentation	0.819	0.820
after text data augmentation	0.832	0.809

Table 3: Score on the dev set and test set

5 Results and Analysis

5.1 Results

This section shows the results of our system on the English STR task in track A of SemEval-2024 task 1. We use the Spearman correlation between system output and human annotation as an evaluation metric. Under the premise that other conditions are the same, we use the data set after text data augmentation for training. As shown in Table 3, the Spearman Correlation obtained on the dev set increased from 0.819 to 0.832, but the Spearman Correlation obtained on the test set dropped from 0.820 to 0.809.

5.2 Analysis

As shown in the results, after text data augmentation, the Spearman Correlation obtained on the dev set has improved, but the Spearman Correlation obtained on the test set has declined. Because before text data augmentation, the dev set was around 4.5% size of the train set and the test set was around 47% size of the train set. The size gap between the data sets is large. In addition, relying solely on semantic synonym replacement in sentences for data augmentation will have certain inaccuracies which leading to biased estimates. At the same time, text data augmentation doubled the size of the train set, resulting in a larger difference in the size of the train set, dev set, and test set.

6 Conclusion

This paper describes our participation in the SemEval 2024 competition in the Semantic Textual Relatedness for African and Asian Languages task. We participated in the English task in track A. Our approach is to use the BERT pre-training model for text sequence processing and computation, employing text data augmentation to enlarge the size of the train set, and adopting prompt tuning to construct a prompt template "The correlation of the next two sentences sent0 and sent1 is [MASK].", where [MASK] is used to predict the correlation between two sentences. The final Spearman Correlation obtained on the test set was 0.809.

In the future, we will use methods such as context awareness and manual intervention to address errors caused by text data augmentation to ensure their accuracy and rationality. At the same time, we will expand the size of the dev set, reduce the size difference between data sets, and try to use other more powerful pre-trained models.

Abstract

Hallucinations in large language models (LLMs) have recently become a significant problem. A recent effort in this direction is a shared task at Semeval 2024 Task 6, **SHROOM**, a *Shared-task on Hallucinations and Related Observable Overgeneration Mistakes (Mickus et al., 2024)*. This paper describes our winning solution ranked *1st* and *2nd* in the 2 sub-tasks of model agnostic and model aware tracks respectively. We propose a meta-regressor framework of LLMs for model evaluation and integration that achieves the highest scores on the leader board. We also experiment with various transformer based models and black box methods like ChatGPT, Vectara, and others. In addition, we perform an error analysis comparing GPT4 against our best model which shows the limitations of the former.

1 Introduction

The recent rapid deployment of large language models (LLMs) has led to a hallucination proliferation which poses a barrier to the reliability and trustworthiness of LLMs (Lin et al., 2022). One of the widely agreed upon definition of hallucinations (Maynez et al., 2020; Xiao and Wang, 2021) is output text containing information not relevant to the input or a desired output. Hallucinations should not be thought of as an occasional nuisance, but rather as a systemic issue inherent to these models and their web-sourced training data which can be rife with bias and misinformation. This can directly cause user discontent when these systems are implemented in production or real-world scenarios.

These type of hallucinations have been widely studied in the context of text related tasks like machine translation (Dale et al., 2022; Guerreiro et al., 2023a,b), summarization (Huang et al., 2023; van der Poel et al., 2022) and dialogue generation (Shuster et al., 2021a). Gaps in hallucination detection methods in LLM outputs persist across many such tasks.

Despite some progress in hallucination detection, existing methods may rely upon comparisons to reference texts, overly simplified statistical measures, reliance upon individual models, or annotated datasets which can limit their extensibility. Our approach leverages the uncertainty signals present in a diverse basket of LLMs to detect hallucinations more robustly.

In this paper, we present a meta-regressor framework for LLM model selection, evaluation, and integration.[1] The overall approach is depicted in Figure 1. For the first step, each LLM-generated sentence is compared against stochastically generated responses with no external database as with SelfCheckGPT (Manakul et al., 2023). A meta-model that leverages input from a diverse panel of expert evaluators evaluates and integrates the output of multiple iterations of the process.

Our framework focuses on creating a meta-model for identifying hallucinations, with the idea that the meta-model's prediction power is linked to the performance of the underlying base models. This model achieves the highest scores in the SemEval-2024 Task 6 competition across three subtasks: Machine translation, Paraphrase generation, and Definition modeling.

2 Related Work

In this section, we describe prior work on hallucination detection methods. We will examine two potential streams for hallucination detection: model-aware detection and black-box detection. Model-aware techniques have access to the model's internals, such as weights and logits while black-box methods do not has access to such model internals.

*Equal contribution

[1]The code of MetaCheckGPT is available at https://github.com/rahcode7/semeval-shroom

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 342–348

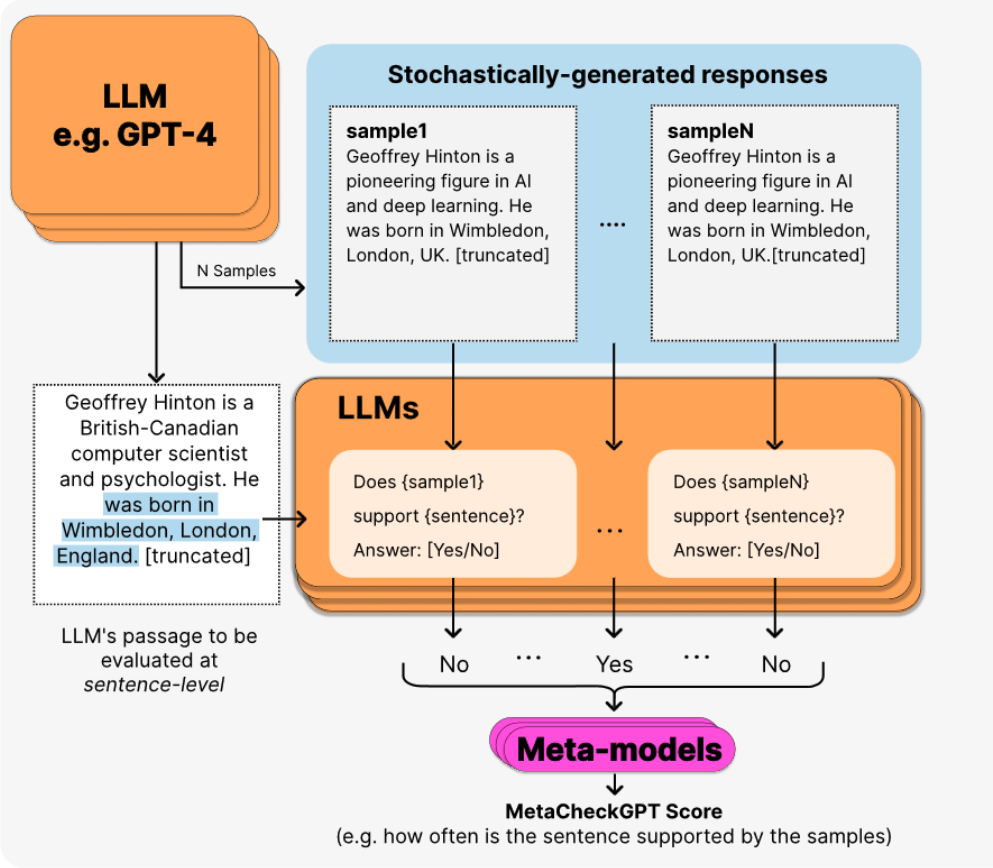

Figure 1: MetaCheckGPT: Generated sentences are compared against stochastically generated responses.

2.1 Model aware Detection

These methods require access to model weights and their logits (van der Poel et al., 2022). For machine translation task, Guerreiro et al. (2023b) showcased that sequence log-probability performs quite well compared to reference based methods. For article generation task, (Varshney et al., 2023) uncertainty estimation techniques(Azaria and Mitchell, 2023) (Tian et al., 2023) were used to detect hallucination in ChatGPT. Other methods to detect hallucinations include Retrieval Augmented Generation (Shuster et al., 2021b) and Chain of Verification based techniques (e.g., (Lei et al., 2023)).

2.2 Black box Detection

With the prevalence of closed source models, there has been recent work on black-box hallucination detection methods which doesn't require the model inputs, only the generated text. For example, a recently proposed system SelfCheckGPT (Manakul et al., 2023) utilizes a sampling-based technique based on the idea that sampled responses for hallucinated sentences will contradict each other.

This model achieves the highest scores across two sub-tasks: Machine translation, Paraphrase generation, and Definition modeling. We perform extensive studies of LLMs like ChatGPT, Mistral, and others to showcase their failure points.

3 Task Description and Datasets

In the SHROOM Task-6, the organizers propose a binary classification task to predict a machine generated sentence is a hallucination or not.

The organizers considered 3 types of text generation tasks - Definition Modelling, Machine Translation and Paraphrase Generation.

3.1 Task Tracks

The shared task was further divided into 2 tracks: **model agnostic** and **model aware**. Figure 2 describes sample examples of hallucinations containing source, reference and output text for each task type.

3.1.1 Model Agnostic Track

In this track, only the inputs, references and outputs were provided The details of the model that produced the text was masked from the participants.

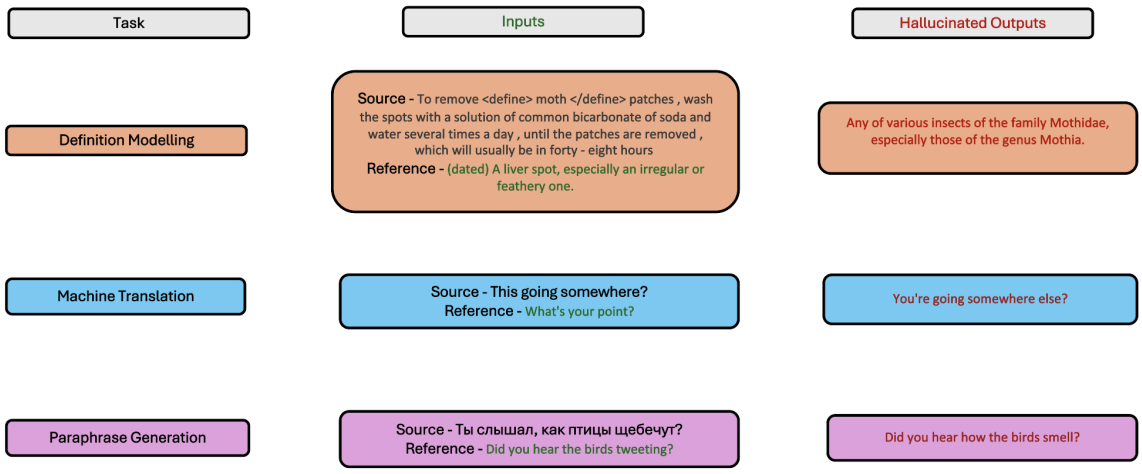

Figure 2: Hallucination examples for each task type

For data preparation, the SHROOM organizers followed the structure described in (Bevilacqua et al., 2020).

	Model Agnostic Track		
Task	Train	Dev	Test
Definition Modeling	10000	187	562
Machine Translation	10000	187	563
Paraphrase Generation	10000	125	375
Total	30000	499	1500

Table 1: Sample counts for the Model Agnostic Track

3.1.2 Model Aware Track

In this track, along with the inputs, references and outputs, the model name and its checkpoints were also provided from which the outputs were generated.

	Model Aware Track		
Task	Train	Dev	Test
Definition Modeling	10000	188	562
Machine Translation	10000	188	563
Paraphrase Generation	10000	125	375
Total	30000	501	1500

Table 2: Sample Statistics for the Model Aware Track

It is worthwhile to note that the organizers chose to share the training which was not labeled and only the development set was labeled.

4 Our Methodology

Algorithm 1 Meta-Model Training/Evaluation

Input: Base models M, Meta-models N, Threshold x
Output: Top performing meta-model
for each base model m in M **do**
    $score_m \leftarrow$ Evaluate m (MAE)
end for
$FilteredMs \leftarrow Models$.filter(MAE $< x$)
for each meta-model n in N **do**
    Train n with $FilteredMs$
    $metaScore_n \leftarrow$ Spearman MAE
end for
$TopMeta \leftarrow$ Meta-model in N with lowest Spearman MAE

Our approach is centered around building a meta-model for hallucination detection, with the hypothesis that the quality of prediction from underlying base models is highly correlated with the meta-model's predictive power. Given a set of base models $M = \{m_1, m_2, ..., m_n\}$ and actual labels $L = \{l_1, l_2, ..., l_n\}$ in the dataset, the Spearman correlation between predicted hallucination scores H and actual labels is given by:

$$\rho_s(H, L) = 1 - \frac{6 \sum d_i^2}{n(n^2 - 1)}$$

where d_i is the difference between the ranks of corresponding elements in H and L.

Our overall process was to identify the meta-model that minimized this mean absolute error

(MAE) function ϵ, where

$$\epsilon = \frac{1}{n}\sum_{i=1}^{n}(Y_i - \hat{Y}_i)$$

because Spearman correlation was one of the secondary metrics for Task 6 evaluation. Here, Y_i represents the actual Spearman correlation values for hallucination and $\hat{Y}_i$ represents the predicted values. Our overall process is captured in Algorithm 1.

Algorithms 2, 3, and 4 detail how some of our different meta-models were trained. These algorithms follow a unified framework, initiating with the setup of training data and labels, with the ultimate aim of fine-tuning a meta-regressor model. A meta-search cross-validation approach was used to conduct a hyperparameter space for each model's architecture. The process involves iterating over the defined hyperparameter space for each algorithm, fitting the meta-regressor with the training data, and concluding with the identification and preparation of the highest-performing model for deployment. The training process for selecting meta-models is included in the Appendix. RMSE, MAE, and R-squared were used as additional proxies in meta-model evaluation.

Because this problem was assessed with binary classification accuracy, data was classified based on the Spearman correlation coefficient according to:

$$\text{Class} = \begin{cases} \text{'Hallucination'}, & \rho_s > 0.5 \\ \text{'Not Hallucination'}, & \text{otherwise} \end{cases}$$

to convert our regression problem into a binary classification task, simplifying the analysis and interpretation of results. Once converted to a classification problem, the primary metric used for evaluation was accuracy. Precision, Recall, F1 Score, and a confusion matrix were used for secondary evaluation.

5 Experiments & Results

5.1 Experimental set-up

Training was conducted both on cloud using APIs as well as locally on V100/A100 GPUs for faster processing times.

We conducted our initial experiments with simpler base models including DeBERTa (He et al., 2021), DistilBERT (Sanh et al., 2020), RoBERTa (Liu et al., 2019), LLaMA 2 (Touvron et al., 2023), and Mixtral of Experts (Jiang et al., 2024) among others. Preliminary results indicated an accuracy of 0.5 to 0.6, prompting us to continue our search for more performant base models.

Additional analysis indicated our base models ChatGPT(Achiam et al., 2023), SelfCheckGPT(Manakul et al., 2023) and Vectara(Hughes, 2023) showed promising results in initial tests, with accuracy in the range of 0.6 to 0.7. Prompt engineering, self-consistency checks and uncertainty based modeling techniques were used to maximize performance in base models. The training process for more performant meta-models, including random forest and elementary neural ensemble models, can be found in the Appendix.

5.2 Results

Classification performance obtained on the training data, which includes an accuracy of 0.8317, precision of 0.7447, recall of 0.875, and an F1 score of 0.8046.

	Positive	Negative
Positive	TP: 49	FN: 5
Negative	FP: 12	TN: 35

Cross-validation and regularization techniques were applied to increase confidence that the performance observed on the training data would be maintained on test data.

Track	Accuracy	Rho	Rank
Aware	80.6	0.71	1/46
Agnostic	84.7	0.77	2/49

Table 3: Final Modeling results on the test set

5.3 Discussion

Our results, as summarized in Table 3, demonstrate the effectiveness of meta-regressor models in detecting hallucinations across various text generation tasks. One of the key strengths of the approach is that a diverse set of base models is able to better capture a wide range of features indicative of hallucinations than a single model or knowledge base alone may be able to. High performance metrics underline the promise of combining base models/knowledge bases through meta-learning.

Our approach is not without its limitations. The black-box nature of some base models (e.g. GPT4), limits understanding of the internal mechanisms

driving the generation and detection of hallucinations. More detailed limitations of the system and directions for future work are examined in the following section.

5.4 Limitations

There are several limitations to the current work. For example, all language models have inherent limitations such as bias and lack of world grounding. Unfortunately, more recent models such as GPT have also started to function as black box systems. The corpus for training data for base language models is predominantly English. The system also would not readily integrate into a production system without additional effort. The system could also benefit from the ability to learn from feedback. All of the base language models may also suffer from potential safety issues like false confidence and over-reliance, etc.

6 Conclusion

Our meta-model strategy represents a step forward in addressing the challenges of mitigating hallucinations and the importance of a nuanced approach to model selection, evaluation, and integration. The work also acknowledges the need for additional research into more transparent, interpretable, and multilingual models, as well as the integration of external knowledge sources and feedback mechanisms to refine and improve hallucination detection methods. In the future, some areas we would like to work on include utilizing additional multilingual datasets, expand the scope of our work to more set of text generation task, and focus more on white box hallucination detection systems.

While the current system was tested on some machine translation tasks, we believe it could benefit from more work on multilingual datasets. The current system could improve by integrating with external knowledge bases via retrieval augmented generation. The system could also be made more usable by distilling its knowledge into a portable fine-tuned model widely available to others. Another area for potential improvement includes integration of human or agent feedback through reinforcement learning.

QFNU_CS at SemEval-2024 Task 3: A Hybrid Pre-trained Model based Approach for Multimodal Emotion-Cause Pair Extraction Task

Zining Wang, Yanchao Zhao, Guanghui Han, Yang Song
School of Computer Science, Qufu Normal University, Ri Zhao, China

Abstract

This article presents the solution of Qufu Normal University for the Multimodal Sentiment Cause Analysis competition in SemEval2024 Task 3.The competition aims to extract emotion-cause pairs from dialogues containing text, audio, and video modalities. To cope with this task, we employ a hybrid pre-train model based approach. Specifically, we first extract and fusion features from dialogues based on BERT, BiLSTM, openSMILE and C3D. Then, we adopt BiLSTM and Transformer to extract the candidate emotion-cause pairs. Finally, we design a filter to identify the correct emotion-cause pairs. The evaluation results show that, we achieve a weighted average F1 score of 0.1786 and an F1 score of 0.1882 on CodaLab.

1 Introduction

The competition of multimodal emotion cause analysis(Gandhi et al., 2023) involves not only understanding linguistic content but also recognizing and comprehending various forms of information such as emotional expressions, sounds, and images. The significance of this competition lies in its ability to comprehensively understand and interpret emotions and motivations in human communication. By analyzing various forms of information in conversations, we can more accurately identify the sources and reasons for emotions, thereby enhancing our understanding of human behavior and communication methods. This holds importance across various fields including psychology, human-computer interaction, and affective computing, aiding in the development of more intelligent and human-centric technologies and systems, improving communication efficiency and quality, and promoting better understanding and communication among individuals.

This paper details our contribution to SemEval-2024 Task 3: Multimodal Emotion Cause Analysis in Conversations(Wang et al., 2024), encompassing two sub-tasks: extracting emotion-cause pairs(Xia and Ding, 2019) from text-only dialogues and from multimodal dialogues that include text, audio, and video modalities. In this task, we place a particular emphasis on implementing Sub-task 2.

For Sub-task 2: Multimodal Emotion-Cause Pair Extraction, we aim to extract emotion-cause pairs from dialogues that contain representations in text, audio, and video. Each pair includes an emotional utterance, its emotion category, and a cause utterance. The challenge lies in integrating information from multiple modalities to accurately identify emotional expressions and their related causes.

In our approach to task 2, we first preprocessed the dataset, mapping the text, audio, and video data of the Emotion Cause in Friends (ECF) dataset to a unified feature space. Then, we utilized a baseline model with a two-stage training scheme: emotion recognition and cause pair extraction. This approach focused on utilizing modalities, selecting models such as Bert(Devlin et al., 2018) and LSTM(Yu et al., 2019), and adjusting parameters for two phases of model training. After that, we predicted on test data in two stages using the trained models and evaluated the results through CodaLab to obtain corresponding F1 scores.

Our best-performing solution involved using Bert for emotion recognition followed by LSTM for cause pair extraction across all three modalities, achieving an F1 score of 0.1882. This methodological progression demonstrates our systematic approach to tackling the complexities of multimodal emotion cause analysis, highlighting our efforts in dataset preprocessing, model experimentation, and performance evaluation, while also proving the effectiveness of the baseline model(Wang et al.).

2 Methodology

In this section, we describe the E-MECPE method

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 349–353

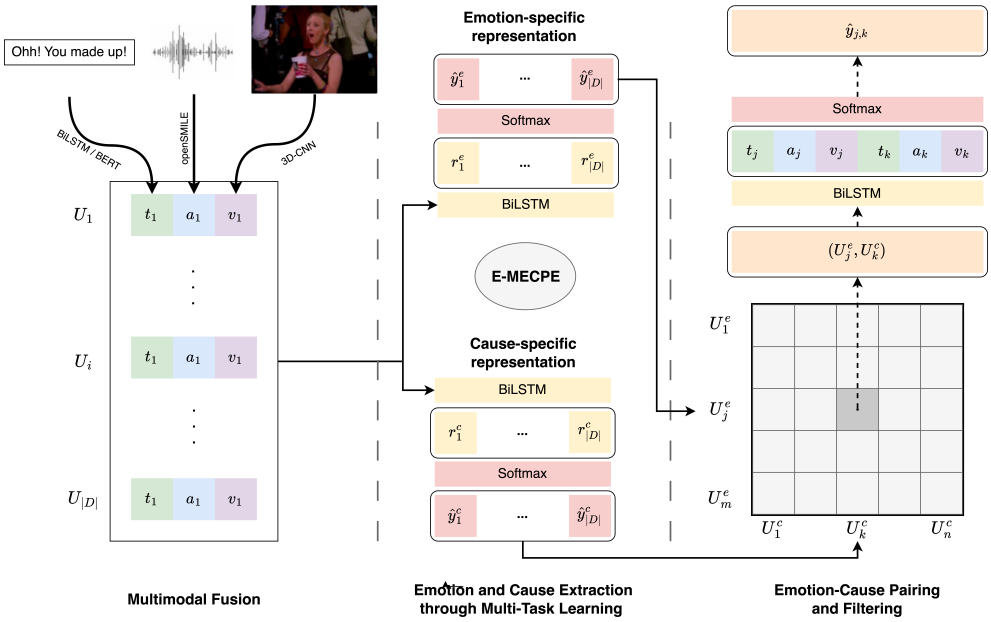

Figure 1: Framework diagram of the E-MECPE methodology

in depth. In general, this method is divided into three main parts: multimodal fusion, emotion and cause extraction through multi-task learning and emotion-cause pairing and filtering. The methodology of this paper is summarized in Fig. 1.

2.1 Multimodal Fusion

First, we obtain the representations of the three modalities from the text, audio and video modalities for their respective modalities. Then, the three modalities are stitched together in the order of text-audio-video to obtain the joint representation of the three modalities. The feature extraction method for each of these modalities is as follows:

For text, each token is initialized with pre-trained 300-dimensional GloVe vectors(Pennington et al., 2014). Subsequently, we used two different models to extract text features: the BiLSTM (Bidirectional Long Short-Term Memory Network) and the BERT (Bidirectional Encoder Representation Transformer).BiLSTM is a classical recurrent neural network that can effectively capture long-term dependencies in text sequences by a bidirectional structure that considers both forward and backward information. BERT, on the other hand, is a pre-trained language model based on the Transformer architecture, which is pre-trained on large-scale textual data and is able to capture rich semantic information. In this study, BiLSTM is used as a textual feature extractor to capitalize on its representational learning ability in sequential data; while BERT, as another textual feature extractor, acquires deeper semantic information by pre-training the model(Kim and Park, 2023). These two models are independently applied to discourse-level feature extraction tasks to evaluate their performance on sentiment and cause extraction tasks.

In the audio domain, we extract the 6373-dimensional acoustic features (a_i) using the openSMILE toolkit, leveraging the feature set designed for the INTERSPEECH 2013 Emotion Challenge. This comprehensive approach allows us to capture nuanced acoustic characteristics, providing a rich foundation for our subsequent analyses.

For video processing, we use a 3D-CNN network variant called C3D(Tran et al., 2015; Rao and Liu, 2020) to extract 16 frames from each video and process them through the C3D network to obtain 4096-dimensional video descriptors optimized for dimensionality reduction and to extract 128-dimensional visual features from each speech video.

2.2 Emotion Extraction

Our aim in sentiment extraction is to derive sentiment-related features from the discourse. We process each discourse to obtain sentiment-specific representations (re_i) by means of a specific bidirectional long short-term memory network (BiLSTM). The BiLSTM processes the forward and reverse sequences of the discourse separately by means of its two LSTM units, and ultimately combines the outputs of these two directions. This allows the network to take into account both the forward and backward information of the discourse, thus pro-

viding a more comprehensive understanding of the emotional content of the discourse.

Next, the sentiment-specific representation (re_i) is fed into a softmax layer, the output of which can be considered as the probability that the discourse belongs to each sentiment category. the formula for the softmax layer is as follows:

$$\hat{\mathbf{y}}_i^e = \text{softmax}\big(\mathbf{W}^e \mathbf{r}_i^e + \mathbf{b}^e\big) \tag{1}$$

where W_e and b_e are the weights and biases of the softmax layer, respectively, and $\hat{y}_i^e$ is the predicted sentiment distribution.

2.3 Cause Extraction

The purpose of the cause extraction part is to recognize causal relationships in discourse. We use another BiLSTM to extract cause-specific representations (rc_i). This BiLSTM works in a similar way to the BiLSTM used in sentiment extraction, but the parameters are not shared to ensure that the network learns the specific features for the cause extraction task.

The reason-specific representation (rc_i) is then fed into another softmax layer that focuses on determining the probability of different reason categories in the discourse. The formula for this softmax layer is as follows:

$$\hat{\mathbf{y}}_i^c = \text{softmax}\big(\mathbf{W}^c \mathbf{r}_i^c + \mathbf{b}^c\big) \tag{2}$$

Here, W_c and b_c are the weights and biases of this softmax layer, and $\hat{y}_i^c$ denotes the predicted cause distribution.

2.4 Loss calculation

Our goal is to minimize the cumulative loss of the model on the emotion extraction and cause extraction tasks. The total loss L_{total} is the sum of the losses of the two tasks and is calculated by the following formula:

$$\mathcal{L}_{\text{total}} = -\sum_{i=1}^{N} \left(\sum_{j=1}^{C} y_i^{e,j} \log(\hat{y}_i^{e,j}) + \sum_{k=1}^{K} y_i^{c,k} \log(\hat{y}_i^{c,k}) \right) \tag{3}$$

Where $y_{j,i}^e$ and $y_{k,i}^c$ denote the uniquely hot encoding of the true emotion and cause labels, respectively, N is the number of training samples, and C and K are the number of emotion and cause categories, respectively. This loss function ensures that the model learns to extract features related to emotions and reasons efficiently, thus improving the model's performance on both tasks.

2.5 Emotion-Cause Pairing and Filtering

Following the acquisition of Candidate Emotion Utterances and Candidate Cause Utterances, the pivotal task is to discern the existence of a causal relationship between sets E and C, ensuring the extraction of valid emotion-cause pairs. Initially, E and C are organized into a dot matrix, depicted in the third segment of Fig. 1, resulting in the generation of all conceivable candidate pairs denoted as $x(U_j^e; U_k^c)$. This vector amalgamates the self-contained multimodal representations of the emotion and cause expressions, along with a distance vector capturing the relational nuances between the two expressions.

The composite representation is then inputted into a softmax layer to determine the validity of the pairing x, filtering and extracting relevant emotion-cause pairs from numerous possibilities.

$$\hat{\mathbf{y}}_{j,k} = \text{softmax}\left(\mathsf{W}\mathbf{x}_{(\hat{U}_j^e, \hat{U}_k^e)} + \mathbf{b}\right) \tag{4}$$

3 Experiments

3.1 Data Resources

The official dataset consists of three modalities: text, audio, and video clips, and includes 1,374 conversations and 13,619 utterances annotated for 9,794 emotion-cause pairs across the three modalities. The relevant connections are stored in a JSON file and correspond to independent video segments through specified IDs. In order to fully utilize all the multimodal data, we first preprocess and reduce the dimensionality of the data according to the methods described in the paper.

Specifically, during the preprocessing stage, for the audio data in the video, we use the ffmpeg tool to extract the corresponding audio files for each video segment. We then utilize the open-source tool called openSMILE (Eyben et al., 2010) and apply The INTERSPEECH 2013 ComParE feature set (Schuller et al., 2013), which is the default feature set of openSMILE, to extract features from the audio data. As a result, we obtain a 6373-dimensional acoustic feature vector.For video data, we refer to the C3D model structure to extract video features and obtain a 4096-dimensional representation.As for text data, following the same approach as described in the paper, we utilize pre-trained Glove word vectors to obtain text embeddings.

3.2 Training

The training process is divided into two parts: the first part is emotion extraction and cause extraction,

and the second part is the extraction of emotion-cause pairs. We explored three different training conditions: utilizing only textual modalities, combining textual and audio modalities, combining textual and video modalities, and leveraging all data modalities and fine-tune the model parameters based on the baseline to select the appropriate parameters to obtain the best score.

Emotion extraction and cause extraction: The initial phase of our experiment compared emotion extraction using Bert and BiLSTM model architectures, conducted on an RTX 4070Ti Super GPU setup. Key training parameters were carefully selected to enhance model performance. The batch size for BiLSTM was fixed at 16, while for Bert, it was set to 4, with the training spanning 15 epochs. The loss weights for both emotion extraction and cause extraction tasks were set to 1.0, indicating their equal importance in our training objectives.

Emotion-cause pairs extraction: In the subsequent phase focusing on cause pair identification, the same model architecture was employed, trained under identical conditions to assess the effect of data modality on performance. The batch size was increased to 200 to potentially improve generalization, with a learning rate of 0.005 aimed at optimal convergence. A 0.5 dropout keep probability for word embeddings was introduced for added regularization, while maintaining a 1.0 keep probability for the softmax layer. The l2 regularization coefficient remained at 1e-5, consistent with our approach to model complexity control.

3.3 Evaluation

Similar to baseline, we utilize the macro-averaged F1 score (Gui et al., 2018) as the primary evaluation metric for our task. This metric accounts for both precision and recall, providing a balanced assessment of model performance. The F1 score is calculated using the following formula:

$$F_1 = \frac{2 \times P \times R}{P + R} \tag{5}$$

where:

- P denotes precision, calculated as the ratio of correctly predicted emotion-cause pairs to the total predicted pairs.
- R denotes recall, calculated as the ratio of correctly predicted emotion-cause pairs to the total annotated pairs.

In our evaluation, F_1 is the harmonic mean of precision and recall, indicating the model's balance in detecting emotion-cause pairs: a higher F_1 score signifies better performance.

Table 1: Experimental Results

Model	Modality	$F1_{emotion}$	$F1_{caution}$	$F1_{pair}$
BiLSTM	T	0.7441	0.7008	0.5041
	TA	0.7398	0.6986	0.5104
	TV	0.7431	0.7016	0.5162
	TAV	0.7422	0.6993	0.5226
Bert	T	0.7362	0.6687	0.5104
	TA	0.7356	0.6637	0.5160
	TV	0.7365	0.6700	0.5104
	TAV	0.7363	0.6648	0.5246

3.4 Results and analysis

We assessed Bert and BiLSTM models on various modalities: text (T), text-audio (TA), text-video (TV), and their combination (TAV), as shown in Table 1. Results underline the models' proficiency in extracting sentiment-cause pairs from multimodal dialogues, with distinct performance variations across modalities.

The BiLSTM model demonstrates incremental improvements in $F1_{pair}$ scores from T to TAV, indicating the advantage of utilizing multimodal data. The highest performance is observed in the TAV setup with a score of 0.5226, underscoring the benefits of combining text, audio, and video.

Conversely, the Bert model showcases superior performance in the TAV modality, achieving an $F1_{pair}$ score of 0.5246. This performance highlights Bert's ability to effectively leverage deep contextual embeddings across modalities for more accurate extraction of sentiment-cause pairs. The robustness of Bert, particularly in the multimodal TAV setup, confirms its efficacy in handling complex multimodal data.

Overall, Bert emerges as the preferred model for extracting sentiment-cause pairs across all modalities, with a peak performance in the TAV configuration, reflected by a weighted average F1 score of 0.1786 and an F1 score of 0.1882 on CodaLab. These findings advocate for the continued exploration of multimodal approaches, particularly leveraging models like Bert that excel in contextual understanding and integration of multimodal data.

4 Conclusion

In this paper, we present Effective Multimodal Emotion-Cause Pair Extraction (E-MECPE)

method. We used this method to perform emotional cause analysis on the Emotion-Cause-in-Friends (ECF) dataset. Ablation experiments were conducted for text unimodal and multimodal under different text encoders, respectively, and the relevant parameters associated with the experiments were tuned. The experimental results show that BERT encoding-based text representation and multimodal joint representation help in the extraction of emotional cause pairs, and that the parameter settings are crucial for the performance enhancement of this task. This finding not only validates the effectiveness of our method, but also points out an important direction for future research in the field of sentiment analysis kresearch by pointing out an important direction.

5 Prospects for Advancement

Due to the late entry time, limited hardware resources, and short submission period, we only had time to fine-tune and conduct ablation experiments based on the baseline. However, we believe that there is still a lot of room for improvement in adjusting this model. For example, further attempts can be made in aligning and filtering methods for multimodal data, selecting more encoders, and enhancing the model's understanding of causal relationships. We will also continue exploring on top of this model to continuously advance the development of this research direction.

Abstract

Large Language Models (LLMs) are becoming popular and easily accessible, leading to a large growth of machine-generated content over various channels. Along with this popularity, the potential misuse is also a challenge for us. In this paper, we use subtask A monolingual dataset with comparative study between some machine learning model with feature extraction and develop an ensemble method for our system. Our system achieved 84.31% accuracy score in the test set, ranked 36th of 137 participants. Our code is available at: https://github.com/baoivy/SemEval-Task8

1 Introduction

In our current time, large language models (LLMs), such as ChatGPT (Ouyang et al., 2022), GPT-4[1], LLaMA (Touvron et al., 2023) and BLOOMz (Muennighoff et al., 2023) can be easily observed to be becoming increasingly prevalent from diverse forms ranging of news, multimedia to education. How outstandingly LLMs answer to user's problems makes them appealing for automatic missions as well as diminishing human labor in many scenarios. Nevertheless, this also unexpectedly leads to problems with regard to human's misuses, spreading misinformation and causing disruptions in the education system in particular. Therefore, it is necessary to develop systems that can automatically distinguish AI contexts from human-written ones.

Recently, with the exponential growth of LLMs, many researchers have attempted to distinguish human-written texts from machine- generated ones. Uchendu et al., 2021, Wang et al., 2024b, He et al., 2024, Liu et al., 2023b have shown us about machine-generated and human writing data from various source. Mitchell et al., 2023, Bao et al., 2023, Deng et al., 2023 used zero-shot classification method to calculate probabilities from perturbated input text. Bhattacharjee and Liu, 2023 leveraged prompt-base method to utilize LLMs as detector. Gehrmann et al., 2019 used statistical method to detect machine-generated paragraph with language model to compute conditional probability. For fine-tuning language model method, Fagni et al., 2021 had a comparative study among pre-trained language model, feature-base and character level classification on DeepFake dataset and showed that pre-trained language model has a best result than others. Liu et al., 2023c used feature-base classification with RoBERTa as embedding and LSTM + Self-Attention in classification head. Bhattacharjee et al., 2023 used unsupervised and self-supervised learning by leveraging domain adaptation on unlabeled dataset and contrastive learning belonging with pre-trained language model to learn domain representations. Kirchenbauer et al., 2023, Liu et al., 2023a used a novel approach with watermark embedding to detect LLMs text that employed by LLMs or neural network.

Being inspired by feature-based classification technique, we propose to have a comparative study for simple and lightweight machine learning method beside the trend of LLM. Our system compares various machine learning models among with ensemble method for multiple machine learning method to find the best combination for our system.

The rest of the paper is as follows. The section 2 generalizes task description and dataset for our experiment. The section 3 shows the description of our system. The experimental setup and results are presented in section 4. Finally, section 5 is the conclusion and discussion about our work.

2 Task description & dataset

2.1 Task description

In SemEval 2024- Task 8 (Wang et al., 2024a), the topic for subtask A is ***Binary Human-Written vs.***

[1] https://openai.com/

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 354–360
June 20-21, 2024

Machine-Generated Text Classification. The full text is to determine whether an essay is human-written or machine-generated. There are two tracks for subtask A: monolingual (only English sources) and multilingual. On this subtask, we only focus on monolingual dataset.

2.2 Dataset overview

The SubTask-A monolingual dataset originated from various sources of content, including Wikipedia, WikiHow, Reddit, arVix, PeerRead, and OutFox (Koike et al., 2023). According to the author, this is an extended version of the M4 dataset (Wang et al., 2024b). All paragraphs in the dataset of subtask A monolingual are written in English. This dataset contains a total of 159,029 essays, which were split into a three-part train set, development set (dev set), and test set. The monolingual dataset contains two types of labels, 0 represented by human writing and 1 represented by machine-generated. In particular, the train set was constructed from 5 different generator (Human, ChatGPT, Dolly-v2, CoHere and Davinci003) and the development set was constructed only from Bloomz. For the test set, GPT-4 had been added along with the remaining generator to generate essays. The overview statistical and distribution of labels will be detailed in Table 1 and an example of the dataset is represented in Table 2. Additionally, the distribution between human labels and machine-generated labels on the train set is almost equal so the class imbalance technique is not used for this task.

Moreover, a pre-processing step was applied to the dataset by the following deletions and changes:

- Removing punctuation in sentence
- Lower casing text
- Removing any leading and trailing whitespace
- Remove URLs

Dataset	***#Number***	**Label Distribution (%)**	
		Human	Machine
Train set	119,757	52.9	47.1
Dev set	5,000	50.0	50.0
Test set	34,272	47.5	52.5

Table 1: Dataset statistical

3 System Description

We will describe our developed model in this section. On Section 3.1, we will discuss how we embedded sentences in essays using a pre-trained language model. Then, for the crucial section, we would like to present the detail of our model on 3.2. We perform our architecture based on Figure 1. First step, the essays need to be embedded through pre-trained language model. Next, we use ensemble method with base model and then give a final prediction by using meta-model.

3.1 Embedding

For the embedding stage, each token needs to be represented in a vector. Some essays have more than 512 tokens, which will lead to exceed at original BERT (Devlin et al., 2019), we determine to utilize Longformer (Beltagy et al., 2020) model to capture semantic embedding of each word within essays of dataset. Given the essay X, the vector embedding of each token will be calculated in the essay. The input will be formed as (w_i is a word in essay):

$$\texttt{<s>}\ w_1\ w_2\ \ldots\ w_i\ \texttt{</s>}$$

This produces an embedding matrix $\mathbf{E} \in \mathbb{R}^{N \times K}$ (K is a hidden size of word, N is a number of token) by taking the last hidden layer. After that, mean pooling is applied to each vector embedding of the matrix to flatten into a standard vector to aggregate feature of token. The dimension of the vector for each essay will be $\mathbf{X} \in \mathbb{R}^N$ where N is a number of tokens in essay and $\mathbf{X}$ is a feature vector of essay X.

3.2 Ensemble model

After text embedding, we develop our classification stage for the system. We will discuss each base model in section 3.2.1 and how we ensemble various base models in section 3.2.2

3.2.1 Base model

We utilized Support Vector Machine (SVM), XGBoost, Logistic Regression, and K-nearest neighbors (KNN) as the base model for our ensemble method.

Support Vector Machine (SVM) (Hearst et al., 1998) is a supervised learning model that is used for classification and regression tasks. SVM maximizes the hyperplane or set of hyperplanes to find the best boundary that separates different classes in a dataset.

ID	Essays	Label
1	...Step 10. Pause The Game. To pause the game, just press the "start" button...	Machine
56406	...If you haven't used it in the last six months there is little chance you'll use it in the next six months. Toss it.	Human

Table 2: Example dataset

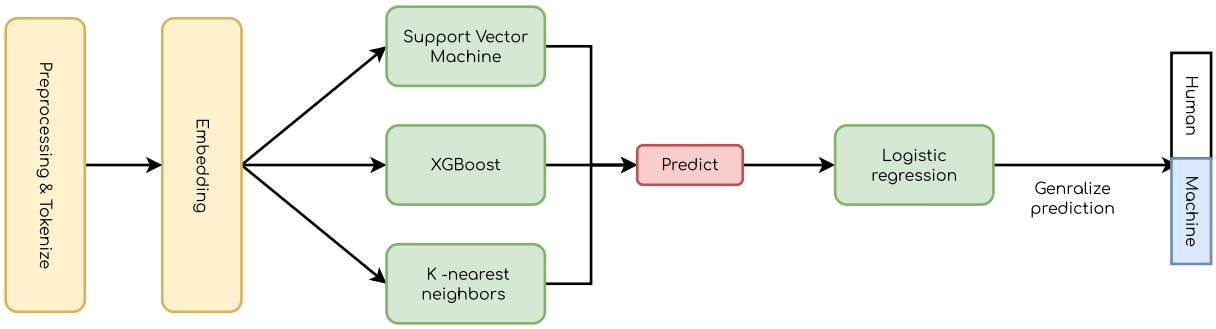

Figure 1: Overview of our system architecture. We demonstrate the best combination model from our experiment

Hyperparameter	Value
C	1.0, 10.0
λ	0.0001, 0.001, 0.1, 0.2, 0.5, 1, 10

Table 3: SVM configuration

Hyperparameter	Values
Learning rate	0.1, 0.2
Estimators	60, 80, 100
Max depth	2, 4, 6

Table 4: XGBoost configuration

Due to the non-linearity of the dataset, we decided to use the Radial basis function (rbf) kernel for SVM, which is defined as Formula 1. Moreover, to find the best parameter for the SVM model, we listed all the hyperparameter values of C and λ used in the grid search as Table 3.

$$K = Ce^{-\gamma||x-z||^2} \quad (1)$$

XGBoost (Chen and Guestrin, 2016) is a scalable end-to-end tree boosting technique which allows to correct the error of the previous tree by creating multiple trees sequentially. The classifier also assigned a weight value to each independent variable and used some techniques to prevent overfit like tree pruning, sparsity awareness, etc.

Same as SVM, we construct candidate hyperparameter values of max depth of the tree and λ used in the grid search as Table 4.

Logistic Regression (LR) is a simple technique for binary classification. Given feature variables, the output is a probability from $[0; 1]$. This can be achieved by applying of a sigmoid function to the linear combination of the independent variables. In our system, we only use the default configuration.

K-nearest neighbour (KNN) is a simple technique for classification which uses majority vote on k closest data point to target point. Grid search is also utilized to find the best value of k, where $k \in \{3, 5, 7, 9\}$.

3.2.2 Stack ensemble

Ensemble different machine learning models is the way to improve prediction accuracy to leverage the strengths and mitigate the weaknesses of the individual base models. In our system, we choose stack ensemble as an ensemble method for our system. For this technique, applicable in scenarios with N base model $(M_1, M_2, ..., M_n)$ and meta-model M, determine meta feature for meta model by predicting each base model $\hat{\mathbf{X}} = (M_1(X), ..., M_n(X))$. Then predict the final output by calculating meta model $y = M(\hat{\mathbf{X}})$. Many different base models and meta model have been evaluated and compared, including Naive Bayes, k-nearest neighbors, SVM, XGBoost, and Logistic Regression as section 3.2.1

3.3 Experiment setup

We describe our system setup procedure. As GPU, we use a single RTX 4090 24GB to train and infer our system for both stages. In the embedding stage, we use Hugging Face[2] library for the Longformer model. For maximum token length in the pre-trained language model, because some essays are longer than 512 tokens, we set it to a maximum of 1024 tokens with padding and truncating. We infer each essay without any training on it.

For the classification stage, with SVM, Logistic Regression, and KNN model, due to the large dimension of the dataset, we proposed to use cuML[3] library, which supports GPU-accelerated for machine learning algorithms. For XGBoost we use xgboost [4] library and sklearn[5] for stack ensemble. Hyperparameter tuning is used in each machine learning model to find the best parameter for each model (all candidate parameters are defined in section 3.2.1). A 5-fold cross-validation is used to find the optimal configuration for the ensemble.

4 Results & Discussion

4.1 Evaluation metric

For subtask A monolingual task, the metrics used to evaluate our result for the dataset are Marco-F1, Mirco-F1, and Accuracy. The main metric for ranking submission is Accuracy. In more detail, the accuracy metric is given by the ratio of the total number of correct predictions to the total predictions done by the model, regardless of true or false predictions. Micro F1-score is the harmonic mean of precision and recall and macro-F1 score is defined as the average of Mirco F1-score across different classes.

4.2 Results

In this section, we present the result of our model, focusing on its accuracy in the dev set and test set. Table 5 shows the performance of our models with some combination with the base model when using the ensemble method mentioned in section 3.2, compared to the dev set. All results were running on the best hyperparameter value of each base model. We first compare the efficiency of each individual model. SVM gives the best performance among all (0.6986). Surprisingly, LR have better performance than XGBoost in monolingual task.

From the result of each model, we also compare our main model with some combinations of the base model when using the stack ensemble method which is represented in Table 5. SVM is used as base models for all ensemble experiments since they give better performance than others. The results do not significantly differ from the three models in our experiment. For model 3, the result is slightly better than model 1 and model 2 which achieved 0.7101 accuracy score.

For the test set, we can notice that all results from 7 methods are not significant differences. The result of SVM (0.8399) still outperformed on individual tests. However, XGBoost has surpassed the performance of KNN and LR on the test set (0.8319 compared to 0.8244 and 0.8155). The LR has the worst performance among 4 models. Surprisingly, after evaluating the test set on the ensemble method, model 1 inferior when compared to the rest. In contrast, model 3 has the best result at the test set with an accuracy of 0.8458. We also visualize our performance of model by representing the confusion matrix in Figure 2

Table 6 shows the result at the stage. We evaluate our result on model 2. Our system achieves 0.8438 which is ranked 36th out of 137. Unfortunately, we can not surpass the result of baseline (achieves 0.8847), which is using RoBERTa model (Zhuang et al., 2021) for classification. Besides, this is a prospective result that can achieve to acceptable score when comparing the traditional machine learning method with the pre-train language model and LLMs. Moreover, we can have an insight into training on traditional machine learning methods and language models nowadays. We believe that if we have a better strategy on hyperparameter tuning, the result could be higher than our official submission.

5 Conclusion

In subtask A monolingual of SemEval task 8, we have represented our system for machine-generated detection. We proposed to develop our system based on ensemble of multiple traditional machine learning method with hyperparameter tuning. We found that XGBoost, SVM and KNN as base model and Logistic Regression in meta model would give the highest result. Our official system was ranked the 36th to 137 in test set of subtask A monolingual

Hidetsune at SemEval-2024 Task 3: A Simple Textual Approach to Emotion Classification and Emotion Cause Analysis in Conversations Using Machine Learning and Next Sentence Prediction

Hidetsune Takahashi
Waseda University
takahashi78h@toki.waseda.jp

Abstract

In this system paper for SemEval-2024 Task 3 subtask 2, I present my simple textual approach to emotion classification and emotion cause analysis in conversations using machine learning and next sentence prediction. I train a SpaCy model for emotion classification and use next sentence prediction with BERT for emotion cause analysis. While speaker names and audio-visual clips are given in addition to text of the conversations, my approach uses textual data only to test my methodology to combine machine learning with next sentence prediction. This paper reveals both strengths and weaknesses of my trial, suggesting a direction of future studies to improve my introductory solution.

1 Introduction

SemEval 2024 Task 3 (Wang et al., 2024) calls for assigning an emotion to each utterance and extracting its emotion cause in conversations. Subtask 2, which I participate in, requires emotion classification and identification of emotion cause utterances with audio-visual clips available whereas subtask 1 requires identification of specific textual span as well without audio-visual clips.

I participate in subtask 2, for which a speaker name, text and an audio-visual clip are given for each utterance. Instead of not identifying specific cause span in the emotion cause utterance in this subtask, I set a limitation to use textual data only while audio-visual data are also available. Therefore, my methodology uses textual data of utterances only as input to classify emotions and identify cause utterance numbers as output. For this reason, training data from subtask 1, for which video names are not given, are used instead of data from the subtask I participate in.

While the task (Wang et al., 2024) prohibits use of additional annotation data, I overlooked the sentence stating the rule and mistakenly used additional data for my solution. I would like to show my appreciation for the task organizers and readers acknowledging and understanding my mistake of using additional data.

For data preparation, official training data for subtask 1 (CSV converted version) (Wang et al., 2023), training data (translated and CSV converted version) from SemEval2024 Task10 subtask 1 (ERC) by Kumar et al. (2023) and data by Nikam (n.d.) are used. They all are concatenated in that order and adjusted so that the resulting dataset has first 7001 neutral utterances (including 7000th counting from 0) and first 5001 utterances at maximum for each emotion other than neutral.

Then, SpaCy-v3 model (Kömeçoğlu, 2023) is trained using the adjusted training data for emotion classification. In addition to that, next sentence prediction (Cathrine, 2023) is used for identification of emotion cause utterances. In that step, I decided to simplify the methodology by hypothesising that the emotion cause utterance is the utterance itself or its previous utterance. With this simple assumption, my algorithm checks the relatedness of each utterance and its previous utterance using next sentence prediction (Cathrine, 2023), which returns true or false. Previous utterance is chosen as cause utterance if the two utterances are deemed related, and the utterance itself if not.

The result shows a limited performance of my introductory solution, but it also clarifies a direction to its improvement. Although my combined methodology has a large room for improvement, it does have a potential in its simplicity and limitation to use textual data only. This paper aims to share an experimental trial to test my combined methodology, guiding a direction to its future application and improvement.

My code is available on GitHub [1].

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 361–364

2 Background

The subtask I participate in (subtask 2) focuses on emotion classification and emotion cause analysis with text data and audio-visual clips. Subtask 1, on the other hand, does not allow participants to use audio-visual clips and requires extracting specific textual cause spans as well. My participation in subtask 2 sets a limitation to use textual data only, which means that it is substantially the same as subtask 1 except that I do not extract specific textual cause spans. Training data from subtask 1 are used instead of that from subtask 2 because they seem to be identical to each other except that they have no video names in the dataset. Therefore, my methodology for subtask 2 uses data from subtask 1 and additional data from other sources for training. Given the evaluation dataset with audio-visual clips available, my methodology, which is trained by textual data only, assigns an emotion category and its cause utterance as output using textual data of the evaluation dataset.

This task is technically a mixture of two topics, which are emotion classification and emotion cause analysis. As for emotion classification, many previous studies have been conducted especially on social media including Twitter and Facebook. For instance, a work by Gaind et al. (2019) classifies text on social media into six emotion categories with high accuracy. Another study by Bryniels-son et al. (2014) investigates in people's emotions during crises using a support vector machine. In addition to its use for social media, its application to real conversations is also getting an attention. A study by Graterol et al. (2021), for example, applies emotion detection to social robotics, aiming to improve its ability to interpret feelings of humans from a viewpoint of NLP methods.

There are many previous studies for emotion cause analysis too. A study by Fan et al. (2019), for example, uses hierarchical neural network to get high accuracy. Another study by Ding et al. (2020) adopts a complicated approach, resulting in reliable accuracy.

On the other hand, this paper aims to test a simple approach to combine classical machine learning method with next sentence prediction with a certain assumption. My methodology has a strength in its simplicity, but the result shows a large room for improvement.

3 System overview

The main strategy of my system is a combination of classical machine learning method with next sentence prediction. Machine leaning is used for emotion classification and next sentence prediction is used for identification of emotion cause utterances. Audio-visual clips are available in this subtask, but only textual data of the utterances are used for my solution. A quick overview of my combined methodology is as follows.

1. **Training data preparation**: Official training data from subtask 1 (Wang et al., 2023) are converted from a json file into a pandas dataframe. Similarly, training data from SemEval2024 Task10 subtask 1 (ERC) (Kumar et al., 2023) are translated into English and converted into a pandas dataframe. The converted dataframes and data by Nikam (n.d.) are concatenated to compose an adjusted training data. The adjusted data have two columns, in which text and an emotion are stored respectively for each utterance.

2. **Emotion classification using machine learning**: Using the adjusted training data, SpaCy-v3 model (Kömeçoğlu, 2023) is trained and used for emotion classification. It assigns an emotion to each utterance from "neutral", "surprise", "anger", "sadness", "joy", "disgust" and "fear".

3. **Emotion cause utterance identification using next sentence prediction**: If an assigned emotion is not "neutral", next sentence prediction (Cathrine, 2023) identifies its emotion cause utterance. My methodology works under the simple assumption that emotion cause utterance is the utterance itself or its previous utterance.

In the first step, training data are prepared from multiple sources. The official training data from subtask 1 (Wang et al., 2023) are imported as a json file and converted into a pandas dataframe with text and an emotion for each utterance. Here, data from subtask 1 are used instead of that from subtask 2 because it is likely that the data are identical to each other except that video names are not given for data of subtask 1. Then, the resulting pandas dataframe, translated and converted version of training data from SemEval2024 Task10 (Kumar

et al., 2023) and data by Nikam (n.d.) are imported via CSV file format. As for the two additional datasets, irrelevant columns are dropped so that they are composed of two columns, in which text and emotions are stored respectively. They are concatenated into one dataframe and adjusted to have 7001 utterances (including 7000th counting from 0) for neutral and 5001 at maximum for each one of the other emotions related to this task (surprise, anger, sadness, joy, disgust and fear).

After this process of data preparation, SpaCy-v3 model (Kömeçoğlu, 2023) is trained using the prepared training data. An unlabeled evaluation dataset is imported as a json file, and the trained model assigns an emotion to each utterance.

At the same step, next sentence prediction with BERT (Cathrine, 2023) assigns an utterance number of emotion cause to each utterance if its assigned emotion is not "neutral". As stated before, it is hypothesised that the emotion cause utterance is either the utterance itself or its previous utterance. Under this assumption, next sentence prediction (Cathrine, 2023) checks whether or not an utterance that it is looking at is related to its previous utterance. The previous utterance is chosen as its emotion cause utterance if these are deemed related, and the utterance itself is chosen if not. After all these processes, lists that include emotions with the utterance numbers and emotion cause utterance numbers (['2_sadness', '1'] for example) are added to the original evaluation data for submission.

My participation in this task using the combined methodology reveals its limitations of the simple approach to emotion cause analysis. Since my methodology trains SpaCy-v3 model with over 33000 utterances, it is more natural to assume that the simplistic application of next sentence prediction is the main reason for the limited accuracy. My algorithm takes only the utterance itself and its previous utterance into account as possible emotion cause utterances. This premise does not allow my solution to cover cases where one utterance has an influence beyond multiple utterances, limiting the ability to deal with the entire conversation from a macroscopic point of view. On the other hand, there is no doubt that the accuracy of emotion classification is also a reason for the limited ability of my trial. Emotion cause utterances are assigned to non-neutral emotion utterances only, meaning that the algorithm loses its accuracy for both emotion classification and emotion cause analysis at a time if the trained model mistakenly assigns "neutral" to non-neutral emotion utterances.

4 Experimental setup

For the emotion classification part, multiple datasets needed to be processed to make an adjusted training dataset.

First of all, the official training data for subtask 1 (Wang et al., 2023) are imported as a json file. In the dataset, a conversation ID is assigned to each conversation, and one conversation has multiple utterances. For each utterance, an utterance ID, text, its speaker name and an emotion are assigned. The json file is converted into a pandas dataframe to make the data easier to deal with. Conversation IDs, utterance IDs and speaker names are dropped from the dataframe so that it has only "text" and "emotion" as columns. Data from SemEval2024 Task10 (Kumar et al., 2023), which have Hindi-English code-mixed utterances, are translated into English and converted into a pandas dataframe similarly. Data by Nikam (n.d.) are also imported as a pandas dataframe, and irrelevant columns of the two additional datasets are dropped so that they have text utterances and emotions as columns only. The number of utterances for each different emotion category is as shown on Table1. After these processes, the three dataframes (official training data for subtask 1, data from SemEval2024 Task10 (Kumar et al., 2023) and data by Nikam (n.d.)) are concatenated into one dataframe in that order. Only first 7001 (including 7000th counting from 0) neutral emotion utterances and first 5001 utterances for each one of the other emotions are extracted, dropping all the utterances that exceed the limitation from the concatenated dataset to compose an adjusted training data.

After this data preparation step, SpaCy-v3 model (Kömeçoğlu, 2023) is trained using the adjusted training data, and the trained model is used for emotion classification of the unlabeled evaluation dataset. Next sentence prediction (Cathrine, 2023) is also used for emotion cause analysis as stated in the previous section.

5 Results

In the evaluation phase, my solution was tested using the unlabeled test dataset. The result shows a limited ability of my approach, which combines classical machine learning with next sentence prediction under a simplistic assumption. The scores

Dataset	Anger	Disgust	Fear	Joy	Neutral	Sadness	Shame	Surprise	Contempt
Data from subtask1	1615	414	373	2301	5929	1147	0	1840	0
Data from Task10	819	127	514	1596	3909	558	0	441	542
Data by Nikam	4286	856	5409	11037	1811	6719	146	4062	0

Table 1: Datasets and emotion categories

w-avg. F1	F1	Ranking
0.1288	0.1389	12/16

Table 2: Task scores in evaluation phase

are displayed in Table 2.

6 Conclusions

To summarize, my methodology sets a limitation to use textual data only, testing a simple algorithm with a certain premise. I use classical machine learning for emotion classification, and next sentence prediction for identification of emotion cause utterances.

The next sentence prediction (Cathrine, 2023) in my simple approach takes only the utterance itself and its previous utterance into account, limiting its ability to cover the entire conversation from a macroscopic viewpoint. In addition to that, the accuracy of emotion classification between neutral and non-neutral turned out to be more important than previously thought since it has a significant effect on identification of emotion cause utterances as well.

Although the trial of my simple approach has a large room for improvement, it clearly guides a direction to its future studies. With improvements to enhance the ability to cover conversations from a macroscopic point of view, it might open the door for the potential of my combined methodology.

Abstract

This paper outlines our approach for the ERC subtask of the SemEval 2024 EdiREF Shared Task. In this sub-task, an emotion had to be assigned to an utterance which was a part of a code-mixed dialogue. The utterance had to be classified into one of the following classes - disgust, contempt, anger, neutral, joy, sadness, fear, surprise. Our proposed system makes use of an ensemble of language specific RoBERTA and BERT models to tackle the problem. A weighted F1-score of 44% was achieved by our system. We conducted comprehensive ablations and suggested directions of future work. Our codebase is available publicly[1].

1 Introduction

Language has been the primary mode of communication for humans since pre-historic times. In linguistics, code-mixing traditionally refers to the embedding of words or phrases into an utterance of another language (Myers-Scotton, 1993). In many multi-lingual societies we see the development of code-mixed languages. Hinglish is one such language which is a linguistic blend of Hindi and English which is spoken primarily in India. Hinglish generally refers to Hindi that is written in the roman script and is used in combination with some English phrases. The variance in spellings and the multiple interpretations of Hindi words, depending on specific contexts, pose challenges for the analysis of language.

The SemEval workshop (co-located with NAACL 2024) explores and advances the current state of semantic analysis to tackle increasingly complex problems in natural language semanitcs. This paper outlines our approach for the Emotion Recognition in Coversation (ERC) (Kumar et al., 2023) sub-task of the Emotion Discovery and Reasoning its Flip in Conversation (EdiREF) (Kumar et al., 2024) shared task. In this sub-task we had to assign a specific emotion to an utterance which the part of a dialogue. Each episode had multiple speakers speaking in Hinglish. We ranked 11^{th} in this subtask achieving a weighted F1-score of 44%. An end-to-end deep learning pipeline that uses an ensemble of transformer-based Hinglish models was used. We converged on the best models to use in the ensemble by rigorous experimentation using the available models. We also analyse the performance of the classification pipeline and present ablations. We also elaborate on the shortcomings of our systems and some future directions of work.

2 Related Work

Emotion Detection and Sentiment Analysis have been important topics that have been comprehensively studied since the inception of natural language processing. Supervised approaches for Emotion Detection require large datasets which may not be present for low-resource langauges like code-mixed languages.(Orsini, 2015) dates the origin of Hinglish as a language that is widely spoken in India in the post-colonial period. In several works like (Dwivedi and Sukhadeve, 2010), first translation from Hindi-English to English was attempted, however major challenges like non-uniform gram-

mar and randomised spellings exist could not be overcome.

(Murthy and Kumar, 2021) gives a comprehensive review of modern approaches to detect emotion from text. Extensive work has also been done in the field of Sentiment Analysis of Hinglish text. (Choudhary et al., 2018) made the use of Siamese Networks in order to map the sentences of the code-mixed language and a standard language to a common sentiment space in order to classify the sentences. (Mathur et al., 2018) introduced the Hindi English Offensive Tweets (HEOT) dataset and used a CNN on the embeddings of the data. (Singh and Lefever, 2020) made the use of cross-lingual embeddings obtained using FastText (Bojanowski et al., 2017) and used architectures like CNN, Bi-LSTM and RNN to classify the text. The use of BERT (Devlin et al., 2019) based models was inevitable in this area due to their success in other fields. (Liu et al., 2020) made the use of a pre-trained XLM-RoBERTa (Conneau et al., 2020) and used adversarial examples for the task of sentiment analysis of tweets. However, one thing to note is that most of the prior work has been done on large datasets containing tweets. Due to the large domain shift between analysing tweets and human conversations there was a lack of external training or pre-training data for our task.

For ensemble learning, (Siino et al., 2022) have proposed an ensemble model which generates predictions after the text passes through a vectorisation layer having 2 outputs, one of which is represented as a Bag-of-Words model and provided as input to 3 voters, namely Naive Bayes (NB), Support Vector Machine (SVM) and Decision Tree (DT); and another is a direct input to a CNN. (Kang et al., 2018) proposes a new sentiment analysis method, based on text-based hidden Markov models, that uses word orders without the need of sentiment lexicons. (Miri et al., 2022) proposed use of ensemble feature selection for multi-label text classification which has been used in our approach.

3 Data

The data is in the Hindi-English (Hinglish) code-mixed format which contains words spoken in Hindi but written in the Roman script and English words. The dataset consisted of 343 episodes or dialogues and contained a total of 8,506 utterances which had to classified into eight classes - disgust, contempt, anger, neutral, joy, sadness, fear, surprise. The validation dataset consisted of 46 episodes having 1,354 utterances. The system was then evaluated on a test dataset that contained 57 dialogues consisting of 1,580 utterances. We have illustrated the data distribution in the training dataset in Figure 1. There is acute class imbalance. The class "neutral" contains the most samples (3,123) while the class "disgust" contains the least samples (103). The imbalance ratio was almost 1:30. To mitigate this we tried oversampling to increase size of examples for classes having lower utterances, but they did not improve the performance of the system.

Model 1	Model 2	Model 3	Val F1	Test F1

HingMBERT	Hinglish-BERT	HingRoBERTa	46%	44%
HingBERT	MBERT	Hinglish-BERT	44%	44%

Table 2: Results of ensemble pipeline.

4 System Description

The chosen sub-task of emotion detection was a multi-class classification problem which required an utterance to be classified into one of 8 classes. We performed basic pre-processing on the text before passing it to the model. This includes removal of stopwords and punctuation marks from the text, as well as spelling normalisation from the dataset. Due to scarcity of domain specific data related to this task we decided to fine-tune existing transformer-based models to adapt them for our task. Models from (Nayak and Joshi, 2022) like HingBERT, HingRoBERTa, HingMBERT which are based on BERT and RoBERTa (Liu et al., 2019) that were pre-trained on Hinglish data scraped from Twitter were chosen for the task with multilingual models like M-BERT (Devlin et al., 2019). We also chose a variant of BERT (Hinglish-BERT) [2] and a HingBERT variant that was fine-tuned on on the L3Cube-HingLID (Nayak and Joshi, 2022) corpus to include in our system. A linear layer was connected to the pooler output of these models and they were fine-tuned on the dataset. We observed that the performance of the system was enhanced when an ensemble of models was used. We use the method of hard voting to obtain the results from the ensemble. If there was no consensus reached in the ensemble, then the label that the model with the highest F1-score predicted was used as the prediction of the system.

5 Experiments and Results

5.1 Experiments

All the models were used through the HuggingFace (Wolf et al., 2020) library. The data splits that were used during the training and evaluation phase are described in Section 3. The models were fine-tuned for 30 epochs with a learning rate of 1e-5, weight decay of 1e-6 and a batch-size of 32. CrossEntropy loss was used along with the Adam optimizer. We also fixed the seeds to 42. The scoring metric for the task was the weighted F1-score. The scores for the individual models are shown in Table 1. The best performing model checkpoint was chosen according to the epoch-wise validation weighted F1 score. As the individual models had comparable performance on the dataset we decided to create the ensemble by considering all possible combinations of the models. The best performing ensembles and their scores are shown in Table 2.

[2]This model is available here

5.2 Results

The performance of individual models is shown in Table 1 and the performance of the ensemble of models is show in Table 2. The highlighted portion shows our final submission that had a weighted F1-score of 44% consisted of the models MBERT, Hinglish-BERT and HingRoBERTa. We were ranked 11^{th} in the final leaderboard. The difference between our submission and the 5 teams above us was just 1%. We also observed that other combinations also yielded the same result on the dataset as all the models had comparable performance. We also experimented with an ensemble of 5 models (i.e. voting was carried out considering 5 models instead of 3) but the results were similar to our current system and hence, we decided to continue with our current implementation as it is more efficient. The confusion matrix for our submission is illustrated in Figure 3. Note that the confusion matrix has its rows (i.e. true labels axes) normalized according to the number of samples in the class. Here are some observations from our experiments:

1. **The label "anger" has the worst performance:** We observe from Figure 3 that the

label "anger" performs the worst by a significant margin as compared to the rest of the labels despite having relatively more samples compared to some classes. We believe it is due to the fact that the words which characterize anger have a significant overlap with the words that characterize other emotions like "fear" or "contempt".

2. **"joy" vs "surprise" :** We expected the models to confuse these emotions as they are very similar to each other. However, the models rarely confuse these emotions among each other despite the imbalance in the available samples belonging to these two classes. We believe this is due to the fact that these emotions have very distinct appearances in the corpus. We believe that the models captured the subtle difference in the tone that characterize these emotions and thus, could easily differentiate between them.

3. **Failure to capture nuance in negative emotions:** We observe that the overall confusion among negative emotions is higher than the positive emotions. We think that this is due to the fact that many of these emotions have very nuanced differences which the model could not capture due to the scarcity in examples belonging to some of these emotions.

4. **This is a scalable system:** Due to the robust pre-training of the models used, the system could be trained to classify new emotions as well. One could use this system in a continual learning setup in order to increase its capabilities.

6 Conclusion

This paper aims to describe our approach for the ERC sub-task of the 2024 EdiREF Shared Task. We conducted experiments with multiple transformer based models like HingBERT, HingBERT and MBERT. We also show that an ensemble of these models has the best performance on the evaluation dataset with a weighted F1-score of 44%. We foresee several future directions. One direction can be to develop and use more sophisticated methods for ensembling. Another direction is the generation or collection of such data which is more relevant in a real-world scenario in low-resource languages.

Hidetsune at SemEval-2024 Task 4: An Application of Machine Learning to Multilingual Propagandistic Memes Identification Using Machine Translation

Hidetsune Takahashi
Waseda University
takahashi78h@toki.waseda.jp

Abstract

In this system paper for SemEval-2024 Task 4 subtask 2b, I present my approach to identifying propagandistic memes in multiple languages. I firstly establish a baseline for English and then implement the model into other languages (Bulgarian, North Macedonian and Arabic) by using machine translation. Data from other subtasks (subtask 1, subtask 2a) are also used in addition to data for this subtask, and additional data from Kaggle are concatenated to these in order to enhance the model. The results show high reliability of my English baseline and a room for improvement of its implementation.

1 Introduction

SemEval 2024 Task 4 (Dimitrov et al., 2024) calls for classification of memes into different persuasion techniques in textual content only (subtask 1) or in textual and visual content (subtask 2a), and identifying whether or not memes are propagandistic (subtask 2b). I participate in subtask 2b, which is a binary classification problem between "propagandistic" and "non_propagandistic". Various memes are provided in English, Bulgarian, North Macedonian and Arabic to determine whether the memes are propagandistic or not.

My baseline is established so that it achieves fairly high accuracy in English. Although it adopts a classical machine learning method with training, the training data are adjusted by being concatenated with additional dataset. After setting up my baseline, the model is implemented into other languages using machine translation.

Participating in this task allows me to test the ability of my model, achieving a fairly high score for its simplicity. In future studies, the model can be strengthened well enough with appropriately adjusted training data. As for the other languages, on the other hand, the implementation of my English baseline does not necessarily show consistent reliability. Although my baseline works relatively well for Arabic to some extent, the scores go down drastically for Bulgarian and North Macedonian. One of the main reasons for this issue might be that accuracy of machine translation is not high enough, changing the original meanings of the memes and possibly making it more difficult for the English based model to identify propagandistic memes.

My code is available on GitHub [1].

2 Background

The subtask I participate in focuses on classification of memes. Given a json file that has an ID, an image name and text for each meme as input, the subtask requires assigning either "propagandistic" or "non_propagandistic" to the memes. In development phase, data in English were given and participants were allowed to test their solutions for the English data only. Participants were told that they would also have unlabeled test data in three non-English languages as the evaluation phase starts, meaning that no information was released about non-English languages in the development phase.

Propagandistic memes on social media have become a growing issue in the past few years. As more and more people use social media platforms, many types of information including propagandistic one is spread to a number of people (Bradshaw and Howard, 2019). These days, issues caused by propaganda on social media have become worse than most people might think, as a study by O'CONNOR and Weatherall (2019) gives a warning. In fact, these memes did change people's thoughts for elections influencing people's voting behaviors (Aral and Eckles, 2019). Therefore, it might become more and more important in the future for NLP to be able to recognize whether or not the information uses persuasion techniques with high accuracy.

[1] https://github.com/Hidetsune/SemEval2024_Task4.git

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 370–373

There are already many previous studies that adopt modern NLP techniques for propagandistic memes detection. A previous study by Abdullah et al. (2022) uses RoBERTa, which is the state-of-the-art pre-trained language model at the time, resulting in a F1 score of 60.2%. Another previous study by Sprenkamp et al. (2023) tries modern Large Language Models including GPT-3 and GPT-4, also resulting in reliable scores. Al-Omari et al. (2019) utilizes combinations of multiple deep learning models including BERT, BiLSTM and XGBoost with accuracy of around 0.67 in F1 score.

On the other hand of these previous studies, my methodology intends to test classical machine learning approach rather than state-of-the-art LLMs. During my methodology, SpaCy-v3 model (Kömeçoğlu, 2023) is trained with over 20000 memes in English, showing high reliability with accuracy of 0.71353 in F1 macro. Then, the trained model is implemented into non-English languages (Bulgarian, North Macedonian and Arabic) by using Google Translate (Nidhal, 2023).

My participation in this task reveals a high potential of applying classical NLP methods to detection of propagandistic memes with properly adjusted training data. The results reveal that a fairly high score can be achieved without state-of-the-art LLMs and complicated methods. Although the direct implementation of my English baseline into other languages has a room for improvement, the accuracy might go up easily with better machine translation models and careful consideration of differences in topics behind the memes. This paper introduces both strengths and weaknesses of my approach, guiding a direction to future application of classical machine learning to a modern issue of propagandistic memes that requires automatic binary classification.

3 System overview

The main strategy of my system is a classical machine learning method for English baseline and implementation of it into other languages using machine translation. A quick overview of my algorithm is as follows.

1. **Data preparation**: Using official datasets from all the subtasks and additional data on Kaggle[2], training data are prepared to have 11001 memes (including 11000th counting from 0) in English for both propagandistic and non-propagandistic at maximum, making up nearly 22000 memes in total.

2. **Training**: Train a SpaCy model (Kömeçoğlu, 2023) using the prepared training data. Both the training and test data are processed so that they do not have usernames that appear in the additional data and all the memes are lower cased for high efficiency to train the model.

3. **Implementation into non-English languages**: Translate non-English memes into English. This process enables my established baseline to perform in multiple languages, and machine translation is used in this step. After translation of the memes, the model is used in the same way as in English memes.

The system imports a prepared training CSV file as a pandas dataframe, where all the data from Task 4 (train and validation data of subtask 1, subtask 2a and subtask 2b) and additional data from Kaggle[2] are concatenated to compose a large training data with 20774 rows. Only first 20000 rows are used as for the additional data[2] due to its large data size, and all the rows that exceed the limitation of 11001 memes (for both "propagandistic" and "non_propagandistic") are eliminated from the concatenated dataset. Memes in the data are all in English for the purpose of establishing a baseline that guarantees fairly high accuracy in English. Then, SpaCy-v3 model (Kömeçoğlu, 2023) is trained using the resulting data, and test data with unlabeled memes in English is imported as a json file. After that, the trained model is used to assign either "propagandistic" or "non_propagandistic" to each unlabeled meme. As for other languages (Bulgarian, North Macedonian and Arabic), the memes are translated into English so that my English baseline can be implemented into them. Google Translate (Nidhal, 2023) is adopted in this part, and the same trained model is used similarly to the English baseline after translation.

My participation in this task allows for testing the classical NLP approach and simple implementation of it using machine translation. The English baseline, which uses classical machine learning methods, achieves its certain ability to identify propagandistic memes with a reliable score.

On the other hand, the scores go down as for non-English languages. This might be because of

[2] https://www.kaggle.com/datasets/thoughtvector/customer-support-on-twitter

slight changes in meanings in the translation process, which turns out to be the biggest weakness of my approach. Classification of English memes is fairly difficult even for humans given a single utterance. For instance, "VOTE REPUBLICAN. THEY MAY NOT BE PERFECT. BUT THE OTHER SIDE IS INSANE." can be easily classified as propagandistic, but sentences like "CRY ALL YOU WANT..... HE'S DOING EXACTLY WHAT I HIRED HIM FOR....." might not be that easy for the classification because their nuance might depend on situations (on SNS or at work etc.) to some extent. Since propagandistic memes classification is difficult in this way, possible changes of original meanings by machine translation might have resulted in a serious issue for classification of test data, lowering the scores of other languages dramatically.

Another possible reason for the lowered performance in non-English languages is that there are large differences in topics. Words like "Trump" and "Russia" frequently appear in English memes, but "Bulgarian" is one of the most frequently used words in North Macedonian memes. Since Bulgaria and North Macedonia have some diplomatic issues (KAMBERI, 2023), memes that have basis on them ("THE BULGARIANS ENTER THE CONSTITUTION" for example) tend to appear frequently. This kind of differences in topics probably caused the lowered accuracy in non-English languages, revealing a new challenging problem of the approach to implement my English baseline into other languages.

4 Experimental setup

Before moving on to the actual training of the model, data preparation was an essential part of my solution. First of all, all the data of this task (including other subtasks) are imported as json files and converted into pandas dataframes. The dataframes have "text" and "propagandistic/non_propagandistic" as columns. Training data and validation data from both subtask 1 and subtask 2 are composed of "propagandistic" only, so they are concatenated as "large_data1", which is a dataframe with 8307 rows and all "propagandistic" memes. Also, data from Kaggle[2] are imported as all "non_propagandistic" dataframe and processed so that it has no usernames in "text" column. Validation data of subtask 2b are previously imported, but I decided to increase weight of training data of task 2b by twice and not to use validation data after trial submissions in development phase. Therefore, the resulting training data are composed of training data from subtask 2b (weight increased by twice), "large_data1" and additional data from Kaggle[2]. The training dataframe is adjusted so that it has 11001 memes for both propagandistic and non-propagandistic at maximum, being shuffled to be ready for training.

The reason why the additional data from Kaggle[2] are chosen is that they are less likely to be propagandistic compared to many other existing datasets. The data are from customer support on Twitter including AppleSupport and AmazonHelp, so the topic there should be something related to their products or services. There are many other existing datasets extracted from social media platforms, but it takes too much time end effort to manually assign propagandistic and non-propagandistic to each utterances. For the purpose of getting non-propagandistic utterances only, it might be one of the easiest and most realistic approach to find an existing dataset whose topic is clearly unrelated to politics and diplomacy as included in my solution.

After these data preparation steps, the model (Kömeçoğlu, 2023) is trained with the training dataset, and test data with unlabeled memes are imported as a json file. The memes in non-English languages are translated into English as stated in the previous section. The trained model assigns either "propagandistic" or "non_propagandistic" to each meme. The training data and test data are cleaned with new line removal and lower casing prior to use of them.

LANGUAGE	F1 macro	F1 micro	Ranking
English	0.71353	0.79000	13/20
Bulgarian	0.32670	0.33000	14/14
North Macedonian	0.38942	0.46000	13/14
Arabic	0.52825	0.54375	9/14

Table 1: Task scores for multiple languages

5 Results

Table 1 shows official results of my solutions. They show fairly high accuracy of my English baseline with nearly 0.8 in F1 micro. It can be said that my methodology for English baseline using classical machine learning works fairly well with a thoughtful training data adjustment.

As for the non-English languages, the scores go

down due to the potential reasons as stated in prior sections. Even so, Arabic has relatively high accuracy, which is lower than English by around 0.18 in F1 macro but higher than Bulgarian by around 0.20. This difference might have been caused by accuracy of machine translation mainly. Arabic is a widely used language with a total of about 372.7 million native speakers in the world.[3] There is a possibility that Google Translate (Nidhal, 2023), which I use for machine translation, has higher accuracy for widely used languages including Arabic, maintaining the original meanings and nuances of the memes fairly correctly.

6 Conclusions

To summarise, my methodology firstly focuses on establishing a baseline that guarantee fairly high accuracy for English memes. After that, the baseline is implemented into non-English languages by translating the memes into English using machine translation.

The results show high reliability of my English baseline. The methodology for the baseline has its basis on classical machine learning, but my participation in this task reveals its fundamental abilities to deal with complicated classification task with properly adjusted training data.

On the other hand, the results also show that the simple application of my English baseline has a room for improvement. The scores of non-English languages dramatically dropped although Arabic has relatively reasonable accuracy compared to Bulgarian and North Macedonian. There can be many possible reasons for this including the accuracy of machine translation and changes in topics between memes in different languages.

In future studies, it might be worthwhile to enhance the model with many more memes for my English baseline. Collecting propagandistic memes might be a time consuming task, but non-propagandistic memes, on the other hand, can be easily found and used by utilizing existing datasets whose topics clearly have nothing to do with politics and diplomacy. As for non-English languages, higher accuracy might be achieved by using better machine translation models and enhancing the baseline model with specific political or diplomatic topics in the countries.

Hidetsune at SemEval-2024 Task 10: An English Based Approach to Emotion Recognition in Hindi-English code-mixed Conversations Using Machine Learning and Machine Translation

Hidetsune Takahashi
Waseda University
takahashi78h@toki.waseda.jp

Abstract

In this system paper for SemEval-2024 Task 10 subtask 1 (ERC), I present my approach to recognizing emotions in Hindi-English code-mixed conversations. I train a SpaCy model with English translated data and classify emotions behind Hindi-English code-mixed utterances by using the model and translating them into English. I use machine translation to translate all the data in Hindi-English mixed language into English due to an easy access to existing data for emotion recognition in English. Some additional data in English are used to enhance my model. This English based approach demonstrates a fundamental possibility and potential of simplifying code-mixed language into one major language for emotion recognition.

1 Introduction

SemEval 2024 Task 10 (Kumar et al., 2024) calls for assigning emotions to Hindi-English code-mixed conversations (ERC) and reasoning emotion flips (EFR) in Hindi-English code-mixed conversations and in English conversations. I participate in subtask 1 (ERC), for which Hindi-English code-mixed utterances are given in text for participants to recognize emotions behind them. An emotion from disgust, contempt, anger, neutral, joy, sadness, fear and surprise is assigned to each utterance as the correct emotion associated with it.

My methodology has its basis on emotion detection in English. I translate all the development data into English using machine translation (Adep, n.d.), and use the data to train a SpaCy model (Kömeçoğlu, 2023). I also use data by Nikam (Nikam, n.d.) to enhance my model, where utterances in English and their previously assigned emotions are given as a CSV file. He mainly introduces his own model, but I made use of the data only.

I leverage an easy access to emotion-assigned data in English and its linguistic simplicity. Therefore, the point of my approach is to test whether or not machine translation of Hindi-English code-mixed conversations into English can contribute to fundamental accuracy for emotion recognition with lower complexity and an easier access to additional data.

The result shows that combination of machine translation and machine learning works with reasonable accuracy for emotion detection considering its simplicity and numerous data in English that can be implemented in future studies.

My code is available on GitHub [1].

2 Background

The subtask I participate in focuses on emotion recognition in Hindi-English code-mixed conversations. Given Hindi-English code-mixed utterances ("kuchh karo sahil please kuchh karo. mera rosesh adopt ho karke chala gaya na to me, i know this sounds horribly melodramatic, monishaish, par me mar jaaungi. i swear mein mar jaaungi" for example) as input, the subtask requires assigning an emotion to each of them as output. Episode name and speakers' names are given as input as well, but they are not used for my solutions.

Before proceeding with this task, Hindi-English code-mixed language needs to be explained in detail. Hindi-English code-mixed language, which is often referred to as *Hinglish*, is a language in which speakers mix Hindi and English in conversations. According to a study by Chand (2016), there are some Hinglish speakers who cannot speak pure Hindi, and even those who speak both Hindi and Hinglish tend to speak Hinglish in conversations with monolingual speakers of Hinglish, causing the number of monolingual speakers of Hinglish to grow as a result. Therefore, the situation in this task is not a small topic but rather an essential one for the future Indian communities.

[1] https://github.com/Hidetsune/SemEval2024_Task10.git

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 374–378

Most previous studies aim to recognize emotions in Hinglish by collecting Hinglish sentences and using them directly for their approaches. A study by Vijay et al. (2018) uses n-grams for their solution with Hinglish on Twitter. The work detects emotions with high accuracy, but they state that the accuracy drops by nearly 16% without char n-grams. Another previous work by Sasidhar et al. (2020), which uses the solution by Vijay et al. (2018) as their baseline, collects more data with 12000 Hindi-English code-mixed sentences for training. In addition to these, a study by Wadhawan and Aggarwal (2021) achieves high accuracy with a transformer based BERT model, and another study by Kaur et al. (2019) deals with Hinglish on YouTube comment sections. In all of these works, they process Hindi-English code-mixed sentences without translating them into other languages.

On the other hand, one of the biggest issues with emotion recognition in Hinglish conversations might be shortage of datasets. Although there are many Hinglish sentences expressing emotions on social media platforms, the language they use on them might differ from in real conversations to some extent. Taking the availability of numerous existing datasets in English into account as well, I decided to explore a solution to use English translated data rather than the original Hinglish data. This trial requires machine translation, and this step is combined with classical machine learning method, achieving reasonable accuracy for its simplicity with an additional English dataset concatenated to the translated dataset.

Emotion recognition in Hinglish can be complicated because the language has technically two languages (Hindi+English). However, when simplified into all in English properly, there is much more potential to deal with Hinglish emotion recognition with an easy access to enormous English datasets and established NLP methods that have been mainly used for English. This paper aims to guide a direction to future application of this approach, establishing the basis with easily used datasets and model.

3 System overview

The main strategy of my system is a combination of classical machine learning method with simplification of Hindi-English code-mixed sentences into English sentences. Therefore, my methodology is composed of data preparation using machine translation and the classic machine learning process with training. A quick overview of my algorithm is as follows.

1. **Official training data and development data translation**: The official data in json file format are imported and converted into pandas dataframes. The dataframes have episode names, utterances, speaker names and emotions as columns. The utterances are translated into English and saved in a new column.

2. **Additional data concatenation**: Concatenate additional data, which have utterances in English and the emotions, with the translated official data.

3. **Addressing data imbalance**: Separate the concatenated data into each emotion and set a limitation of 3001 utterances (including 3000th counting from 0) per one emotion type.

4. **Model training and prediction**: Train a model with re-concatenated data to predict emotions for unlabeled evaluation data.

For data preparation, I use the official training and development dataset (Kumar et al., 2023), and additional data by Nikam (n.d.) to enhance my model and mitigate data imbalance. Firstly, I import the official datasets in json file format (Kumar et al., 2023), and convert them into pandas dataframes which have episode names, utterances in Hindi-English mixed language (pronunciation forms of Hindi + English), speaker names and emotions as columns. Then, I use Google Translate (Adep, n.d.) to translate all the utterances in Hindi-English mixed language into English, and I add the translated sentences to the dataframe as a new column named "utterances_English". Since episode name, utterances in mixed language and speaker names are of no use at this time, they are dropped from the dataframe to have only "emotion" and "utterances_English" as columns on the dataframes. After that, they are concatenated into one dataframe. There is a huge data imbalance and shortage of training data at this point, so I use additional data by Nikam (n.d.) to mitigate these problems.

In the next step, I train the SpaCy-v3 model (Kömeçoğlu, 2023) with the prepared data and use it to assign emotions to unlabeled evaluation data. The evaluation data are composed of episode

name, utterances in Hindi-English mixed language, speaker names as columns. "utterances_English" column, in which machine translated sentence is assigned to each given utterance, is added to have the model predict emotions behind the utterances.

Participating in this emotion recognition task using the combined strategy enables me to explore the potential of implementing machine translation into a specific situation as this task. The application of machine translation to machine learning makes it possible for a multi-label text classifier to predict emotions behind Hinglish sentences with reasonable accuracy for the entry of this trial. Considering the saved complicated steps needed to handle the data as text in two separate languages, you can see the potential of simplification that my methodology aims at by combing machine translation with machine learning. Future applications for higher accuracy might include more training data in Hindi-English mixed sentences and enhancement of the model with the implementation of machine translation into Hindi written sentences. Participating in this task reveals both strengths and weaknesses of my strategy, guiding directions of future studies to apply machine translation and classic NLP methods to emotion recognition in Hinglish conversations.

4 Experimental setup

Before moving on to the actual training of the model, some setups were required to prepare training data. As stated before, the utterances in the provided development data (Kumar et al., 2023) are all in Hindi-English mixed language. Since my participation in this task intends to combine machine translation with machine learning for emotion recognition, I decided to simplify the data by translating them into one language rather than taking the complexity of separating them into the two languages. This simplification by machine translation might have changed the original meanings of the utterances, but the difference might not be significant for recognizing the emotions only. Looking through the Hindi-English code-mixed sentences, I noticed that fairly large parts of the utterances are in pronunciation forms in Hindi and that English is used only partly. For instance, some short words or phrases like "goodbye!" are utterances where English appears only, but sentences like "lekin what about my ghadi? 17000 ki ghadi hai..." are mostly composed of pronunciation forms of Hindi (except "what about my" in this case). Pronunciation forms of Hindi are much more prevalent in many other utterances.

There could be two possible choices in my approach; translate all the mixed language sentences (Hindi+English) into Hindi or into English. It might be a good idea as well to choose the former considering the high prevalence of Hindi, but I chose the latter due to the higher availability of reliable additional data on emotion recognition in English.

As for machine translation, Google Translate (googletrans 3.1.0a-0) was used. The reference (Adep, n.d.) uses it to translate sentences in all actual Hindi characters (no English and in written form of Hindi; not in pronunciation form). On the other had, I undertook an experiment to try it for the official development dataset (Hindi-English code-mixed and pronunciation form for Hindi; not in written form) and founded that it works. Therefore, all the given utterances are translated into English and added to the dataset as a new column.

At the next step, additional data are collected and processed to be concatenated with the translated version of official data. Since there is a huge data imbalance and lack of training data as stated in the previous section, it is obvious that additional data is needed where most of the 8 emotions used in this task (disgust, contempt, anger, neutral, joy, sadness, fear and surprise) are labeled for utterances or sentences. For consistency of additional data, one source was used rather than concatenating multiple sources with different categories of emotions.

Data by Nikam (Nikam, n.d.) were chosen for additional data. The original concatenated data (the official training and validation data) are composed of text in English and 8 emotions (disgust, anger, neutral, joy, sadness, fear, contempt and surprise) for each utterance. The only two differences in categories of emotion are that the additional data does not have "contempt" while the official one have, and that the additional data have "shame" while the official one does not. Details are as shown on Table1. The concatenated version of official data and the additional data are concatenated separately for each emotion, and the number of utterances is adjusted after that. Conducting some experimental trial on development phase, I decided to limit the data so that it has 3001 utterances (3000th rows counting from 0) at maximum for each emotion type, and all the utterances that exceed the number (from 3002th rows) are dropped from the training

dataset.

5 Results

In the evaluation phase, my trained model worked with accuracy of 0.39 (weighted F1 score calculated by the organizers' system), and the ranking was 17th out of 39 participants. The result is not as good as to use for a practical use as of now, but it definitely shows a basic ability of my approach to apply machine translation to Hindi-English code-mixed language.

There are certain weaknesses in my algorithm as the result shows. One of the biggest weaknesses is the lack of dataset due to inevitable data imbalance. Concatenating the official data (Kumar et al., 2023) with additional data (Nikam, n.d.), there are only 1004 utterances associated with disgust for example while there are many more utterances than 3001 for anger. Limiting the number of utterances up to 1001 for each emotion yielded low accuracy of 0.27 in the development phase, so I chose to accept data imbalance to some extent with the limitation of 3001 utterances for each emotion so that the model is trained better. Larger data imbalance was inevitable to make use of more data, yielding lower scores in development phase, so I had no choice but to decide on around that limitation. However, it cannot be said that less than around 3000 training utterances per emotion are enough for accurate emotion recognition, which is one of the main weaknesses of my solution in this task.

In addition to that, the process of machine translation might have changed the original meaning of the utterances, which might have lowered the quality of training. I cannot look deeper into this possible issue because I am not a Hindi speaker, but the accuracy might go up with a better machine translator.

Another weakness of my solution is that the additional data I used (Nikam, n.d.) are provably not from actual conversations. There are many "@" followed by what I suppose are usernames, so the entire additional data (Nikam, n.d.) are probably from social media platforms. Since this task deals with text version of conversations, situations of the datasets are probably unmatched with each other.

On the other hand, the strength of my approach is the linguistic simplicity that enables the model to have its potential to utilize established NLP techniques and numerous data that have been developed for English. Since English is used widely around the world, there are tons of other data sources that can be implemented into my model. It goes without saying that there are already many existing data in which emotions are labeled with sentences, I can also write down daily conversations in English into text and label each utterance with an emotion for higher accuracy since this task deals with data from conversations.

6 Conclusions

To summarize, I firstly simplified utterances in Hindi-English code-mixed language by translating them into English. Machine translation (Adep, n.d.) is used in this step, and additional data (Nikam, n.d.) are concatenated to mitigate data imbalance and enhance the model. Utterances of evaluation data (Kumar et al., 2023) are also translated into English by machine translation in the same way, and the trained model predicted an emotion for each utterance.

Although my solution has a room for improvement, the result shows a basic ability of the simplification by machine translation to recognize emotions behind Hindi-English code-mixed utterances. Given the abundance of data and established NLP techniques in English, my approach, combining machine translation with classical NLP methods, might open the door for addressing the challenges in emotion recognition in Hinglish caused by its linguistic complexity.

All-MPNet at SemEval-2024 Task 1: Application of MPNet for Evaluating Semantic Textual Relatedness

Marco Siino
Department of Electrical, Electronic
and Computer Engineering
University of Catania
Italy
marco.siino@unipa.it

Abstract

In this study, we tackle the task of automatically discerning the level of semantic relatedness between pairs of sentences. Specifically, Task 1 at SemEval-2024 involves predicting the Semantic Textual Relatedness (STR) of sentence pairs. Participants are tasked with ranking sentence pairs based on their proximity in meaning, quantified by their degree of semantic relatedness, across 14 different languages. To each sentence pair is assigned a manually determined relatedness score ranging from 0 (indicating complete lack of relation) to 1 (denoting maximum relatedness). In our submitted approach on the official test set, focusing on Task 1 (a supervised task in English and Spanish), we achieve a Spearman rank correlation coefficient of 0.808 for the English language and of 0.611 for the Spanish language.

1 Introduction

The notion of semantic relatedness between language units has been foundational in understanding meaning. Automatic determination of relatedness has wide-ranging applications, including assessing sentence representation methods, question answering, and summarization (Guarino, 1997).

Two sentences are deemed semantically similar when they exhibit a relationship of entailment or paraphrases. In contrast, relatedness encompasses a broader concept, encompassing all commonalities between two sentences: whether they pertain to the same topic, convey the same viewpoint, stem from the same temporal context, one elaborates on the other, and so forth (Hadj Taieb et al., 2020).

Historically, much of NLP research has focused on semantic similarity, predominantly in English. However, in the shared Task 1 hosted at SemEval 2024 (Ousidhoum et al., 2024b,a), the organizers extend their coverage to include the following languages: Afrikaans, Algerian Arabic, Amharic, English, Hausa, Hindi, Indonesian, Kinyarwanda, Marathi, Moroccan Arabic, Modern Standard Arabic, Punjabi, Spanish, and Telugu.

With the advancement of machine and deep learning architectures in recent years, there has been a surge of interest in NLP. Numerous efforts have been dedicated to creating algorithms capable of automatically identifying and categorizing text information available on the internet. In the literature, several strategies have already been proposed. In the last fifteen years, some of the most successful strategies have been based on SVM (Colas and Brazdil, 2006; Croce et al., 2022), on Convolutional Neural Network (CNN) (Kim, 2014; Siino et al., 2021), on Graph Neural Network (GNN) (Lomonaco et al., 2022), on ensemble models (Miri et al., 2022; Siino et al., 2022) and, recently, on Transformers (Vaswani et al., 2017; Siino et al., 2022).

The increasing adoption of Transformer-based architectures in academic research has also been bolstered by various methodologies showcased at SemEval 2024. These methodologies tackle diverse tasks and yield noteworthy findings. For instance, at the Task 2 (Jullien et al., 2024), where to address the challenge of identifying the inference relation between a plain language statement and Clinical Trial Reports is used T5 (Siino, 2024c); Task 4 (Dimitrov et al., 2024) where is employed a Mistral 7B model to detect persuasion techniques in memes (Siino, 2024b); and Task 8 (Wang et al., 2024), that utilizes a DistilBERT model to identify machine-generated text (Siino, 2024a).

For our model development, we devised a two-stage architecture. In the first stage, we utilized a Sentence Transformer specifically trained in a multilingual domain. Subsequently, we computed the cosine similarity of the generated embeddings to predict the relatedness between the analyzed sentences.

The remainder of this paper is structured as follows: Section 2 provides background information

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 379–384

on Task 1 hosted at SemEval-2024. Section 3 presents an explanation of the submitted approach. We detail the experimental setup required to reproduce our work in Section 4. The results of the formal assignment and pertinent discussions are presented in Section 5. Finally, we conclude with our findings and suggestions for future research in Section 6.

We make all the code publicly available and reusable on GitHub[1].

2 Background

Data for Semantic Textual Relatedness (STR) Shared Task 1[2] includes sentence pairs labeled with scores representing the degree of semantic textual relatedness between them, ranging from 0 (completely unrelated) to 1 (maximally related). These scores have been determined through manual annotation using a comparative annotation approach to mitigate biases commonly associated with traditional rating scale methods. This annotation process ensures a high reliability of the relatedness rankings.

The task involves predicting the STR of sentence pairs in 14 different languages. Participating teams were asked to submit systems for one, two, or all of the following tracks:

- Track A: Supervised — Systems trained using labeled training datasets provided. Additional publicly available datasets can be used, but teams must report the additional data and its impact on results.

- Track B: Unsupervised — Systems developed without using labeled datasets related to semantic relatedness or similarity between text units longer than two words in any language. Use of unigram or bigram relatedness datasets is permitted.

- Track C: Cross-lingual — Systems developed without using labeled semantic similarity or relatedness datasets in the target language, but with the use of labeled dataset(s) from at least one other language. Using labeled data from another track is mandatory for submissions to this track.

[2] https://semantic-textual-relatedness.github.io/

3 System Overview

The illustration of the proposed approach is provided in the Figure 1. Upon selecting a sample (i.e., a pair of sentences) from the dataset, the initial step involves encoding the first sentence using the All-MPNet embedding, thereby generating an embedding vector. Subsequently, employing an identical procedure, the second sentence from the sample is also encoded. The resulting embedding vectors are then subjected to a cosine similarity computation, facilitating the derivation of the semantic similarity prediction between two sentences.

To develop our model, we thought of a two-stage architecture. In the first stage, we used a *Sentence Transformer*. This is a Python framework for cutting-edge sentence, text, and image embeddings. The initial work is described in (Reimers and Gurevych, 2019). More than 100 languages have sentences and text embeddings that can be computed using this method. Sentences with a similar meaning can subsequently be found by comparing these embeddings, for example, using cosine-similarity. Semantic search, paraphrase mining, and semantic textual similarity can all benefit from these embeddings. The framework offers a huge selection of pre-trained models suited for different tasks and is built on PyTorch and Transformers. Moreover, fine-tuning models is also feasible.

The model used as Sentence Transformer is *all-mpnet-base-v2*, and it is available on HuggingFace[3]. The model is based on MPNet (Song et al., 2020). MPNet introduces a novel pre-training approach that combines the strengths of BERT and XLNet while addressing their respective limitations. Unlike BERT's masked language modeling (MLM), MPNet utilizes permuted language modeling (PLM) to capture dependencies among predicted tokens more effectively. Additionally, MPNet incorporates auxiliary position information as input, allowing the model to process full sentences and mitigate position discrepancy issues present in XLNet. Pre-training of MPNet is conducted on a large-scale dataset exceeding 160 GB of text corpora, followed by fine-tuning on various downstream tasks such as GLUE (Wang et al., 2018) and SQuAD (Rajpurkar et al., 2016). Experimental findings demonstrate that MPNet significantly outperforms both MLM and PLM, achieving superior results across these tasks compared to previ-

[3] https://huggingface.co/sentence-transformers/all-mpnet-base-v2

Figure 1: Block diagram of our proposed approach. Given a sample from the dataset, the first sentence is encoded with an All-MPNet embedding for generating an embedding vector as output. Also, the second sentence in the sample is encoded in the same way. Then the two embedding vectors are compared using cosine similarity to produce the final prediction on the semantic similarity of the two sentences.

ous state-of-the-art pre-trained models like BERT, XLNet, and RoBERTa, all under the same model configuration.

The model was used to map all the words present in the text to a word embedding space. Following the embeddings, the cosine distance between two sentences was calculated. The cosine similarity between the two embedding vectors is calculated as shown in the Equation 1.

$$\cos(\theta) = \frac{A \cdot B}{\|A\|_2 \|B\|_2} \quad (1)$$

The value provided as cosine similarity was then provided as the requested prediction for the two sentences considered. Our code is available online together with the predictions generated and sent in relation to the test set.

The recent study by (Siino et al., 2024b) highlights that preprocessing for text classification tasks lacks significant impact when employing Transformers. Specifically, the study finds that the optimal preprocessing strategies do not substantially differ from performing no preprocessing at all, particularly in the case of Transformers. Consequently, in order to maintain our system's efficiency, speed, and computational lightness, we have opted to not conduct any preprocessing on the text. This decision aligns with the findings of the study and underscores the effectiveness of Transformers in handling raw text data without the need for extensive preprocessing steps.

4 Experimental Setup

We implemented our model on Google Colab[4]. The library we used was Sentence Transformer. The library requires Python[5] (>= 3.8) and PyTorch[6] (>=1.11.0). The dataset provided for all the phases are available on the official competition page. On the basis of our preliminary experiments, we found beneficial to set the threshold value upon the cosine similarity equal to 0.5. We did not perform any additional fine-tuning on the MPNet embeddings. To run the experiment, a T4 GPU from Google has been used. After the generation of the predictions, we exported the results on the JSON format required by the organizers. As already mentioned, all of our code is available on GitHub.

5 Results

The official evaluation metric for this task is the Spearman rank correlation coefficient, which evaluates how closely the rankings predicted by the system align with human judgments. The evaluation script for this shared task is available on the GitHub page, providing a standardized method for assessing the performance of participating systems. The formula to compute the Spearman correlation coefficient is provided in the Equation 2.

$$\rho = 1 - \frac{6 \sum d_i^2}{n(n^2 - 1)} \quad (2)$$

Where d represents the pairwise distances of the ranks of the variables x_i and y_i, while n is the number of samples.

In Table 1, are reported the results obtained on the two languages we considered for our participation at the task. Considered the very low effort required to run the proposed approach and to generate the predictions, the score of 0.611 and 0.808 appears to be an interesting baseline, while still exhibiting room for improvements. It is worth noticing that the approach is a Zero-Shot one with no prior knowledge on the specific task.

In the Table 2 and 3, the results obtained by the first three teams and by the last one, as showed on the official CodaLab page, are reported. Furthermore, we reported the baselines for the two languages. Compared to the best performing models, our simple approach exhibits some room for improvements. However, it is worth notice that it

required no further pre-training and the computational cost to address the task is manageable with the free online resources offered by Google Colab.

Even if our approach is simple and straightforward, here we want to qualitative analyze some results obtained with our approach to better motivate some classification mistakes. With regard to the English language, the first relevant misclassification sample is related to the sample pair: "This book is very compelling. – best book so far in the series!". Our system predicts a cosine similarity equal to 0.47 while the actual similarity is 0.73. In this case, in fact, it is very hard to assess if "being very compelling" is so semantically similar to the concept of "being the best so far in a series". Furthermore, looking at the sample: "A woman in a black coat eats dinner while her dog looks on. – A little boy is standing on the street while a man in overalls is working on a stone wall.", the prediction using our approach is equal to 0.0 (no semantic similarity) while the actual target for the provided test set is 0.29. Another interesting case — i.e., our approach predicts a high similarity of 0.92 while the actual target is 0.74 — is given by the sample: "My favorite by far is definitely Chris and I think he will win!! – My favorite and the selection for winner is Chris.". From a semantic perspective, however, both the sentences provide the same two concepts (i.e., Chris is my favorite, I think he will win). Given these and several others differences between our predictions and the actual target similarity in the provided test set, some concerns on the labelling process and on the correctness of the provided target similarity values can be raised.

6 Conclusion

This paper introduces the utilization of an All-MPNet model embedding to tackle Task 1 at SemEval-2024. In our submission, we opted for a straightforward Zero-Shot learning approach, leveraging pre-trained Transformers that are already tailored to a multilingual-domain. Following this approach, we utilized the contextual embeddings generated by the Sentence Transformer, and we employed cosine distance to measure the similarity between pairs of sentences, thus quantifying the STR between them. Despite the effectiveness of our method, there remains room for improvement, as indicated by the final ranking. Potential alternative approaches could involve leveraging the zero-shot capabilities of models such as GPT and T5, expanding the training data size by incorporating additional datasets, or exploring different methods of integrating ontology-based domain knowledge into our approach. Furthermore, given the interesting results recently provided on a plethora of tasks, also few-shot learning (Wang et al., 2023; Maia et al., 2024; Siino et al., 2023; Meng et al., 2024) or data augmentation strategies (Muftie and Haris, 2023; Siino et al., 2024a; Tapia-Téllez and Escalante, 2020; Siino and Tinnirello, 2023) could be employed to improve the performance. Compared to the best performing models, our simple approach exhibits some room for improvements. However, our qualitative analysis raised some concerns on the labels provided for the test set. Then, we are not able to correctly assess the actual performance of our proposed approach. Eventually, it

is worth notice that thanks to our approach no further pre-training is required and the computational cost to address the task is manageable with the free online resources offered by Google Colab.

hykao@mail.ncku.edu.tw

Abstract

The intersection of legal reasoning and Natural Language Processing (NLP) technologies, particularly Large Language Models (LLMs), offers groundbreaking potential for augmenting human capabilities in the legal domain. This paper presents our approach and findings from participating in SemEval-2024 Task 5, focusing on the effect of argument reasoning in civil procedures using legal reasoning prompts. We investigated the impact of structured legal reasoning methodologies, including TREACC, IRAC, IRAAC, and MIRAC, on guiding LLMs to analyze and evaluate legal arguments systematically. Our experimental setup involved crafting specific prompts based on these methodologies to instruct the LLM to dissect and scrutinize legal cases, aiming to discern the cogency of argumentative solutions within a zero-shot learning framework. The performance of our approach, as measured by F1 score and accuracy, demonstrated the efficacy of integrating structured legal reasoning into LLMs for legal analysis. The findings underscore the promise of LLMs, when equipped with legal reasoning prompts, in enhancing their ability to process and reason through complex legal texts, thus contributing to the broader application of AI in legal studies and practice.

1 Introduction

The process of reasoning in legal arguments is a crucial aspect of applying legal knowledge in real-world scenarios. Mastery of this skill enables individuals to effectively address legal issues and ascertain the legality of various cases. Recently, the field of Natural Language Processing (NLP) has seen significant advancements, leading to the growing trend of utilizing Large Language Models (LLMs) as tools to augment human capabilities. Given the extensive and often complex body of legal knowledge, which can be challenging and time-consuming for the average person to learn, LLMs present an opportunity to comprehend this information and offer valuable assistance.

In light of this, the organizers of SemEval-2024 Task 5 (Held and Habernal, 2024) have compiled a dataset from the domain of U.S. civil procedure. This dataset includes introductory materials on various cases, a set of questions, potential argumentative solutions, and labels indicating the accuracy of these solutions. This initiative provides a framework for evaluating the effectiveness of LLMs in the legal arena, thereby contributing to the development of more sophisticated and capable language processing tools for legal applications.

In this task, we explored legal reasoning prompts in Large Language Models (LLMs) (Burton, 2017). Our focus was on investigating their effectiveness in differentiating argumentative solutions in civil procedure cases. The results show that by guiding an LLM to think step-by-step like a lawyer, it significantly outperforms both Chain of Thought (CoT) (Wei et al., 2023) reasoning and direct output methods.

2 Background

2.1 Related Works

Large Language Model(LLM): LLM is a kind of machine learning model in Nature Language Processing(NLP), pre-trained on large scale of text and can generate text based on previous context (Naveed et al., 2023). Beside LLM's usage in general works such as ChatGPT, LLM had also show its impressive abilities several professional fields like finance, medical and legal(Kaddour et al., 2023), such as BloombergGPT (Wu et al., 2023), Med-PaLM (Singhal et al., 2023) and ChatLaw (Cui et al., 2023).

LLM in Legal Field: Legal defined rules of human community, helping to make order to our life. But legal field have lots of professional knowledge, making obstacles to common people. Lots of legal

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 385–390

LLM or related methods are developed to solve this problem, (Cui et al., 2023) and (Nguyen, 2023) had trained the LLM in the legal field in Chinese justice, (Savelka et al., 2023) found that GPT-4 performed great in explaining legal concepts, (Savelka, 2023) found that some LLM already has legal knowledge in itself. These findings demonstrate the ability and potential of LLM to address legal-related issues.

Legal Reasoning: Legal reasoning is a kind of reasoning approach which had been used in law school teaching (Bentley, 1994), this approach initially aims to help law school students thinking legal questions in professional structure. (Burton, 2017) had make a overview of several legal reasoning approaches, such as 'CLEO' (Claim, law, evaluation, outcome). These approaches originally only used in legal field, until (Savelka, 2023) used these approaches as prompt in LLM, and found that these approach can make LLM's perform well on legal reasoning task, inspired by their works, we will try to use these approach flexible in LLM to help check the truthiness of argument reasoning in civil procedure.

2.2 Dataset Description

The dataset, developed for SemEval-2024 Task 5, focuses on the domain of U.S. civil procedure, aiming to test legal language models on their argument reasoning capabilities. It is meticulously structured to include a variety of components such as a brief introduction to each case, specific legal inquiries, proposed arguments, and in-depth analyses, making it a comprehensive tool for evaluating the nuanced understanding of legal texts. Each record within the dataset is uniquely identified and contains fields that detail the legal question at hand, a potential answer, and an indicator of the answer's accuracy (limited to the training and development subsets). Additionally, the dataset offers rich analyses, including both a focused excerpt relevant to the given answer and a complete solution explanation, along with supplementary explanations to contextualize the question further. Below Tab1 is an example of the dataset:

Attribute	Value
id	0
question	1. Redistricting. Dziezek, who resides in the Southern District of Indiana, sues Torruella...
answer	Case Study: Dziezek vs. Torruella and Hopkins
label	0
analysis	So the remaining question is whether the Western District of Kentucky, where Torruella resides, is a proper venue...
complete analysis	DLet's see. Under §1391(b)(1), venue is proper in a district where all defendants reside. But here they don't all reside in the same district...
explanation	Venue in most federal actions is governed by 28 U.S.C. §1391(b), which provides: (b) Venue in...

Table 1: Dataset example

3 Methodology

3.1 Legal Reasoning Prompts

Upon examining the dataset, we found that a significant portion of the legal knowledge pertinent to the argumentation is encapsulated within the 'Introduction' segment of the dataset. This observation suggests that the primary function of Legal Language Models (LLMs) is to facilitate reasoning from the provided text, as opposed to generating novel legal insights. Consequently, we have curated a selection of legal reasoning methodologies that adhere to the principle of meticulous analysis of the given text, progressively leading to a well-founded conclusion. The methodologies selected for this purpose are as follows:

- **TREACC** (Topic, Rule, Explanation, Analysis, Counterarguments, Conclusion): Provides a comprehensive analytical framework that includes discussions on counterarguments, aiding in the consideration and evaluation of all relevant aspects of a case in Legal Language Models (LLM).

- **IRAC** (Issue, Rule, Application, Conclusion): The fundamental structure for legal issue analysis, involving the identification of the issue, the rule, application of the rule to the facts, and drawing a conclusion.

- **IRAAC** (Issue, Rule, Application, Alternative Analysis, Conclusion): In addition to the basic steps of IRAC, this method incorporates an alternative analysis of the case, showcasing different facets of the issue.

- **MIRAC** (Material facts, Issues, Rules, Arguments, Conclusion): Emphasizes the importance of material facts and arguments by discussing them in detail before proceeding with the analysis and conclusion.

3.2 Experiments

In the devised architecture, attributes such as "question," "answer," and "explanation" were judiciously chosen to elicit from the Language Model (LLM) analyses predicated on legal reasoning, utilizing a zero-shot approach. A prompt was meticulously crafted, articulating the elements of legal reasoning methodologies, thereby casting the LLM in the role of a domain specialist tasked with the meticulous evaluation of responses in accordance with legal statutes. Moreover, the LLM was directed to encapsulate facets of the legal reasoning process within designated tags, e.g., <Topic> and </Topic>, to forestall omissions and diminish the likelihood of inaccuracies. Detailed elaboration of these prompts can be found in the appendixA for consultation.

Subsequent to the generation of analysis, these analyses were employed to instruct the LLM to adjudicate the cogency of the answers provided. The Mixtral-8x7B (Jiang et al., 2024) model, noted for its cost-efficiency and superior performance, was selected for our experimental evaluations.

4 Results

4.1 Official Evaluation Metrics

Agent	F1	Acc
TREACC	0.59	0.62
IRAC	**0.60**	**0.63**
IRAAC	**0.60**	**0.63**
MIRAC	**0.60**	**0.63**
CoT	0.53	0.58
Directly	0.49	0.55

Table 2: Performance of different methods.

As demonstrated in Table 2, various methods exhibit distinct performances on the test dataset. In contrast, methodologies such as CoT and Direct Output solely leverage "question," "answer," and "explanation" to prompt the LLM to discern the veracity of the answers.

Our analysis revealed that strategies incorporating legal reasoning prompts uniformly outperformed the CoT and Direct Output approaches, underscoring the efficacy of our methodology. Intriguingly, the IRAC, IRAAC, and MIRAC methods manifested identical performance metrics on the test dataset. A deeper examination of the prediction outcomes suggested that this phenomenon could be attributed to the pronounced similarity in the analyses engendered by these methods.

The analyses generated predominantly adhered to the stipulated procedural steps, fostering a methodical and layered approach to thinking and reasoning. With the exception of approximately 1% of instances, the data conformed to our prompts, yielding comprehensive structural outputs. An illustrative excerpt from an analysis employing the IRAC method is presented below:

> <issue>...The pivotal legal question concerns the appropriate venue within the Southern District of New York for a negligence lawsuit...</issue> <rule>...Venue is determined by 28 U.S.C. §1391(b)(3), which stipulates its appropriateness in any jurisdiction where a defendant resides, provided all defendants are state residents...</rule> <application>...In initiating a negligence suit against Lenoir and Sorrel in Canada, with Sorrel being served in New York, the query arises regarding the venue's suitability for both defendants...</application> <conclusion>...Legal ambiguities surrounding the residency requirement for defendants complicate the determination of an eligible venue for proceeding with the case...</conclusion>

Our team, identified as "Yuan_Lu" on the leaderboard, achieved a commendable 10th place among 21 participating teams.

4.2 Case Discussion

Here's a comparison of a cases that classify by **IRAC**, **CoT** and **Directly** output methods.

- *Question*: Black White Taxicab, incorporated in Kentucky, seeks to do business at the Bowling Green railroad station but faces opposition from Brown Yellow Taxicab's exclusive contract with the railroad. Given Kentucky courts' stance against such contracts as against public policy, Black White sues Brown Yellow to prevent it from enforcing the contract. Assuming diversity jurisdiction and the amount-in-controversy requirement are met, should the

federal court apply Kentucky law under the Rules of Decision Act?

- *Answer*: Apply Kentucky law under the Rules of Decision Act.

- *Explanation*: This question references the historical case of Black White Taxicab Co. v. Brown Yellow Taxicab Co., highlighting the manipulation of corporate structure to create diversity jurisdiction and bring a case to federal court where federal common law, under Swift v. Tyson, would allow enforcement of a contract deemed invalid under state law. This scenario underscores the tension between federal and state law in diversity cases prior to the Erie decision.

- *Label*: **False**

4.2.1 Directly output's answer

> *The answer is TRUE. This interpretation relies on the Rules of Decision Act as understood before the Erie decision, suggesting that the federal court would apply state law unless a federal statute, constitutional provision, or treaty dictates otherwise.*

The direct output mistakenly considers the pre-Erie understanding applicable, ignoring the significant shift in legal practice introduced by Erie Railroad Co. v. Tompkins.

4.2.2 CoT's answer

> *Answer: TRUE, with a caveat. The response suggests a nuanced approach where federal courts, under the pre-Erie doctrine of Swift v. Tyson, might not strictly apply state law but would consider it alongside a broader interpretation of common law principles, particularly regarding public policy against exclusive contracts for taxi services at railroad stations.*

CoT's analysis presents a sophisticated understanding but incorrectly aligns with the pre-Erie legal framework, not recognizing Erie's directive for federal courts to adhere strictly to state law in diversity cases.

4.2.3 IRAC's answer

> *The analysis is NOT true. Erie Railroad Co. v. Tompkins overruled the Swift v. Tyson doctrine, mandating that federal courts apply state law in diversity cases. This correct interpretation implies that, in the scenario provided, the federal court would indeed apply Kentucky law, reflecting the post-Erie legal landscape accurately.*

The IRAC method accurately reflects the current legal standard, demonstrating a correct understanding of the Erie doctrine's requirement for federal courts to apply state law in diversity cases, thus providing the most legally sound interpretation.

4.2.4 Summary

Both Direct Output and CoT inaccurately conclude based on outdated pre-Erie interpretations, with Direct Output oversimplifying and CoT inadequately applying post-Erie legal standards. In contrast, the IRAC method accurately applies the Erie doctrine, demonstrating a nuanced understanding of current legal principles by methodically breaking down the issue and applying the correct rule. This approach not only ensures precision in legal analysis but also aligns conclusions with contemporary legal frameworks, showcasing its distinct contribution to legal reasoning and highlighting the importance of structured analysis in achieving accurate legal interpretations.

5 Conclusion

This study embarked on an exploration of the synergy between Large Language Models (LLMs) and legal reasoning methodologies to enhance the processing and understanding of legal texts. By integrating structured legal reasoning prompts derived from methodologies such as TREACC, IRAC, IRAAC, and MIRAC into the framework of LLMs, we demonstrated the potential of this approach to improve the models' capacity for legal argument evaluation.

Abstract

In this system description, we report our process and the systems that we created for the subtasks A monolingual, A multilingual, and B for the SemEval-2024 Task 8: Multigenerator, Multidomain, and Multilingual Black-Box Machine-Generated Text Detection. (Wang et al., 2024) This shared task aims at discriminating between machine-generated text and human-written text. Subtask A focuses on detecting if a text is machine-generated or human-written both in a monolingual and a multilingual setting. Subtask B also focuses on detecting if a text is human-written or machine-generated, though it takes it one step further by also requiring the detection of the correct language model used for generating the text. For the monolingual aspects of this task, our approach is centered around fine-tuning a deberta-v3-large LM. For the multilingual setting, we created a combined model utilizing different monolingual models and a language identification tool to classify each text. We also experiment with the generation of extra training data. Our results show that the generation of extra data aids our models and leads to an increase in accuracy.

1 Introduction

The SemEval-2024 shared task focuses on multigenerator, multidomain, and multilingual black-box machine-generated text detection. The shared task is split into three different subtasks. Each subtask is monolingual except for the first subtask, which has a monolingual (English) and a multilingual track. The languages covered in this shared task include English, Chinese, Russian, Urdu, Indonesian, Italian, German, and Arabic.

This paper presents our the systems that we created for the shared task. The paper provides an overview of our research strategies and results for subtasks A and B.

Subtask A focuses on the detection of machine- versus human-written text, we differentiate between mono- and multilingual data. Our approach involves fine-tuning LLMs, DeBERTa-v3 (large) in particular. We experimented with different parameters for the model, searching for the best performance possible.

Subtask B extends the challenge presented in subtask A, we now attempt to recognize the specific language model used for text generation. We do this in addition to distinguishing between human and machine-generated text. We again use DeBERTa-v3 (large) to classify the data. To optimize model accuracy, we fine-tune hyperparameters.

Additionally, we generate extra Wikipedia articles to further expand the training data. We hypothesize that extra data will lead to better model performance, and thus better applicability to real-world applications. Our research focuses on finding both the best possible language model settings to recognize machine- and human-written text and distinguish between different language generation models. Our code and the additionally generated data can be found on Github[1]

2 Related work

Previous research has been done on the topic of automatically discriminating between human-text and machine-generated text (Chichirau et al., 2023), where DeBERTa (v3) (He et al., 2021) is utilized as a target-only classifier. The model can distinguish machine translations well when tested on the test set after training on texts generated from different source languages and different ma-

chine translation systems. They found that both the monolingual and multilingual DeBERTa models outperformed other LLMs that they evaluated.

Langid.py (Lui and Baldwin, 2012) is a supervised language identification tool trained using a naive Bayes classifier. Langid.py has the following advantages: fast, usable off-the-shelf, unaffected by domain-specific features (e.g. HTML, XML, markdown), single file with minimal dependencies, and flexible interface. Langid.py was applied in our system to identify the multi-language training set of subtask A and we found that it can identify languages with very high accuracy.

3 Data

The dataset provided by the shared task creators originates from the benchmark M4 (Wang et al., 2023). M4 is a comprehensive dataset encompassing machine-generated text from diverse generators, domains, and languages. M4 focuses on the development of automated systems for detecting machine-generated text and identifying potential abuse.

The dataset comprises text samples sourced from various platforms, including Wikipedia, Reddit, WikiHow, PeerRead, Arxiv, Chinese QA, Urdu News, Russian RuATD, Indonesian News, and Arabic Wikipedia. It spans multiple languages and domains, presenting a rich and diverse collection of machine-generated text for analysis and classification.

Table 1 presents the statistics of the dataset, including the number of samples in the train, dev, and test sets for subtasks A and B. For subtask A, both monolingual (subtask A-Mono) and multilingual (subtask A-Multi) tracks are included, with train, dev, and test set sizes specified for each language. Subtask B involves multi-way classification of machine-generated text and includes corresponding train, dev, and test set sizes.

4 System overview

This section presents an overview of the methods we employed for subtask A, both the monolingual and multilingual data setting, as well as subtask B. We follow previous work on a similar topic (Chichirau et al., 2023), by fine-tuning LLMs, predominantly DeBERTa (He et al., 2021), on this task. We were further stimulated to explore this model specifically, as DeBERTa is developed as an improvement over the RoBERTa model (Liu et al., 2019), the latter being employed by the task organizers as a baseline. Specifically, we looked at using both the base and large variants of deberta-v3, as this improved version of DeBERTa is reported to significantly outperform previous iterations on numerous tasks.

As the goal of this task was to create systems that can discriminate between human-written and machine-generated text regardless of generator, textual domain, or language, we opted not to preprocess our data any further than what the task organizers already did. This will keep our data as close to instances that can be encountered in real-world scenarios as possible. We fine-tuned these pre-trained language models using the Transformers library from Huggingface (Wolf et al., 2020).

4.1 Subtask A: Monolingual

For the monolingual track of subtask A, we evaluated the performance of the base (86M parameters) and large (304M parameters) variants of DeBERTa. We tested out numerous combinations of hyperparameters such as learning rate, batch size, maximum input sequence length, and epochs to found out which model would perform best. The large DeBERTa model emerged superior over the base model, ostensibly due to its larger model size.

For this track of the task, we also experimented with generating additional training data. The goal for this subtask is for our model to differentiate between human-written and machine-generated text, regardless of what generative model was used to obtain data. We were inclined to experiment with

additional data generation by a model different from the ones already present in the provided base dataset, as this should allow our model to generalize better across generators and not learn only about those present in the base dataset. For potential real-world applications, this would be especially interesting to experiment with, as in such scenarios there would be no prior indication of what model could be used to generate such texts.

We employed Llama 2 (Touvron et al., 2023) to generate additional articles in the style of Wikipedia and manually skimmed through the generated texts to see if they were on a comparable level to the data provided by the task organizer. Subsequently, we took the hyperparameter configurations of our best-performing model trained on only base data and trained a new model using the same configurations on a combination of the base data and our additionally generated articles. The selection of Wikipedia as our domain of focus is based on its comprehensible documentation and the strong performance demonstrated by LLama 2 in generating texts within this specific domain.

4.2 Subtask A: Multilingual

Different from the monolingual strategy, we created a combined model for this subtrack. We explored a way to use separate monolingual models for different languages after determining the language of each text. After discovering that there was no data in the same language both in the original train and dev set (see Table 1, we decided to merge the two data sets and extract each language separately for analysis. We embarked on a language-specific modeling approach, recognizing the importance of selecting models optimized for each language's unique characteristics.

To determine the most suitable approach for each language, we compared the performance of multilingual DeBERTa with specific monolingual models. We employed a 10-fold cross-validation approach within each language, evaluating models based on accuracy and standard deviation. The best-performing model for each language was selected for further evaluation.

Upon completion of the cross-validation procedure, we selected the model that exhibited the highest performance on the development set for each language. The selected models were then applied to the test set for final evaluation, encompassing the full spectrum of languages represented in the dataset. To handle the multilingual nature of the test set effectively, we employed the language identification tool Langid, to discern the language of each text sample, which enabled us to tailor model predictions to the specific linguistic context of each sample.

Notably, we also employed Llama 2 to generate additional training data for each language. We utilized a 10-fold cross-validation process to assess the impact of additional training data on model performance across different languages and only kept those that improved the results.

4.2.1 LangID

In our multilingual subtask A experiment, we proposed the idea of using specific language models per language instead of a single model for each of the languages. Our motivation was that this approach could improve the accuracy of discriminating between machine-generated text and human-written texts better than a single multilingual model could. To achieve this goal, we employed LangID to enable language-specific modeling. After merging the train and dev sets and extracting samples for each language separately, we utilized LangID to determine the language of each text sample in the test set and employed MDeBERTa-v3-base for languages that were not in the train or dev sets and could not be recognized by LangID. Thus, we were able to effectively handle the multilingual nature of the task.

4.3 Subtask B

For this subtask, we, similarly to our approach for subtask A, compared the performance of the base and large variant of DeBERTa. By testing out different values for epochs, learning rate, maximum input sequence length, and batch size, we obtained the hyperparameter configurations of our best-performing model. The large variant of DeBERTa once again outperformed the base version.

We opted not to use additionally generated data for this subtask. The goal of subtask B is to determine not only if the text is human-written or machine-generated but also what generative model was used to do so. This would make generating data by models outside of the already provided list of models in the base dataset futile.

4.4 Generating data

While we realize that it is not allowed to add additional data for the shared task we see generating

it as a real-world contribution that can also easily be done by others. We generated our own extra training data with the use of Llama 2 (Touvron et al., 2023). Starting off, we wanted to exploit the largest model available, because this should offer the best performance in data generation. However, due to limited resources, we opted to utilize the 7 billion parameter version.

We focussed our generation endeavors on languages that were already in the dataset but were highly underrepresented. These included Russian, Arabic, German, and Indonesian. For each of these languages, we extended the dataset so that each of these languages had a total of 30,000 samples. Notably, for every sample generated by the model, we also included a human-written counterpart in the dataset. By doing this, we aimed to maintain a balance between computer- and human-written data in the training and development sets.

To match the already generated Wikipedia articles in the dataset, we adopted a similar method to the original M4 dataset, as outlined by (Wang et al., 2023). Using the Wikipedia dataset available on HuggingFace (Wikimedia-Foundation, 2023), we randomly selected articles with a minimum length of 1,000 characters. Subsequently, we prompted Llama 2 to generate Wikipedia articles based on provided titles. As an extra criterion, we told the model that the resulting articles should contain at least 250 words, as this was also the criteria used in the original paper (Wang et al., 2023). This approach enabled us to enrich our dataset across multiple languages, with the purpose of increasing the performance of our models.

5 Experimental setup

5.1 Datasets and Evaluation Metrics

For both subtask A's monolingual part and subtask B, we utilized standard data splits: train, dev, and test sets. The train set was employed for model training, the dev set for monitoring performance and hyperparameter tuning, and the test set for final evaluation. Accuracy is the main evaluation metric to assess model performance in each task.

For multilingual subtask A, we adopted a different strategy, as motivated in Section 4.2. We concatenated the train and dev sets, extracted samples for different languages, and employed separate models for each language. We utilized the 10-fold cross-validation approach within each language to select the most suitable model based on accuracy and standard deviation. The selected models from each language were then used to predict the test set.

5.2 Training Details

For monolingual subtask A, the final selected hyperparameters were as follows: batch size 2, gradient accumulation 64, learning rate 1e-5, three epochs, formatting style fp16, and an input length of 1024 tokens.

For multilingual subtask A, we employed uniform hyperparameters throughout the 10-fold cross-validation process within each language. These hyperparameters included a learning rate of 2e-5, three epochs, a formatting style of fp16, and an input length of 512 tokens.

For subtask B, the following hyperparameters were identified as optimal: batch size 4, gradient accumulation 32, learning rate 1e-5, three epochs, formatting style fp16, and an input length of 512 tokens.

All of our hyperparameter values were chosen after extensive experimentation on the dev set to optimize model performance. A full list of all the hyperparameter values that we experimented with regarding the monolingual subtasks can be found by referring to Appendix A. Regarding multilingual subtask A, specific model selection and results for each language can be seen in Table 6 of Appendix B.

Additionally, all training processes were conducted on several Nvidia A100 and V100 GPUs.

6 Results and Analysis

In this section, we show and analyze the results achieved for each of the subtasks. Table 2 shows the quantitative results we achieved when running our models on our dev set and the organizer's test set. Tables 4, 7 and 5 in the appendix show the accuracy across languages and the impact of the usage of extra data on each subtask. Besides that, we made a qualitative analysis to find out where we think our systems make the most mistakes.

6.1 Analysis

Our analysis showed us several noteworthy points. First, our monolingual models achieved significantly higher scores on the dev sets than on the test set, as can be seen in Table 2. A reason for this could be the introduction of texts created by LLMs

Subtask	Baseline	Dev	Test
A Monolingual	88.46%	87.80%	63.68%
A Multilingual	80.88%	65.90%	71.79%
B	74.60%	72.80%	61.50%

Table 2: Scores of each subtask in dev and test compared to the baseline.

that our system had not seen before. This shows us a risk our systems may lack robustness against different types of LLMs. Our multilingual system did perform better on test than on dev, however, which could be related to the different ratios of languages present in both datasets. e.g., more German texts were present in the test dataset than in the dev dataset, and our system is able to classify them effectively, which can be seen in Table 6.

Furthermore, our systems were unable to effectively detect human-written texts, in both the mono- and multilingual tasks, when classifying the test set. In subtask A monolingual, our system was able to get very impressive scores on all texts created by generative models, though it had a lackluster performance on human-written text. This might indicate our model's inclination to classify a text as machine-generated over human-written. Subtask B has a very similar distribution of predictions, the only notable exception being the obstacle of detecting texts written by Cohere.

Also noticeable was the performance of texts generated by the Llama 2 model. Both our models with- and without added data scored badly on these texts. What is interesting, is that the extra data added by us originates from Llama 2. A reason for this could be that we used the smaller, 7 billion parameter, version of Llama 2 due to performance and runtime issues.

We can see that both in the mono- and multilingual data setting of subtask A our model's performance had improved after training on our extra generated data. Although the increase in accuracy of the monolingual model was negligible, the multilingual model had a notable improvement in score. We propose that this stems from the absence of certain languages in the training set, which we were able to supplement with our extra data. Because of this, the monolingual models we employed in the multilingual setting were able to perform better.

7 Discussion/Conclusion

In conclusion, we think our participation in the shared task resulted in some valuable insights into the challenges of machine- versus human-written text. Despite our efforts, our systems unfortunately fell short of surpassing the baseline scores established by the task organizers.

Across the different subtasks, our models showed varying performance. For subtask A monolingual, our models achieved some promising results on the development set, with an accuracy of 87.80%. However, our model did not manage to generalize enough, leading to an accuracy of 63.68% on the test set.

For the multilingual part of subtask A, our model reached 65.90% on the development set. In this case, the model did manage to generalize the data, leading to an accuracy of 71.79% on the test set. However, this was still below our expectations, and the baseline accuracy of 80.88%.

In subtask B, our models struggled to identify the specific language model used for text generation accurately, with accuracies of 72.80% on the development, and 61.50% on the test set. Despite optimizing hyperparameters and training on both original and additional data, our models failed to outperform the baseline accuracy of 74.60%.

We think our analysis revealed several points for improvement. Our models tended to misclassify human-written text, indicating a potential bias towards machine-generated content. Furthermore, the models seemed unable to generalize, leading to worse performance on the test set for monolingual task A.

Moving forward, we think there are many improvements to be made. Future research could focus on using other model architectures or exploring other data augmentation techniques. Also, training the model in more languages could improve the performance of multilingual models. Of course, using larger pre-trained models could also lead to an easy increase in performance, although it does require significant resources. Lastly, our findings also show generating extra training data is essential for improving model performance. Therefore, a promising direction for future work is to explore new data sources and methods to create richer and higher-quality training data to further improve the performance and generalization ability of the model.

8 Acknowledgements

This submission has been carried out as part of the 2023-2024 edition of the master course Shared Task Information Science (LIX026M05) at the University of Groningen, taught by Lukas Edman and Antonio Toral. We want to express our gratitude to the university and to both of our lecturers for assisting us in this project.

Kathlalu at SemEval-2024 Task 8: A Comparative Analysis of Binary Classification Methods for Distinguishing Between Human and Machine-generated Text

Lujia Cao and **Ece Lara Kılıç** and **Katharina Will**
University of Tübingen
{lujia.cao, ece-lara.kilic, katharina.will}@student.uni-tuebingen.de

Abstract

This paper investigates two methods for constructing a binary classifier to distinguish between human-generated and machine-generated text. The main emphasis is on a straightforward approach based on Zipf's law, which, despite its simplicity, achieves a moderate level of performance. Additionally, the paper briefly discusses experimentation with the utilization of unigram word counts.

1 Introduction

This paper addresses the task of classifying textual data as human or machine-generated, focusing on Subtask A Wang et al. (2024) with monolingual English data. The rise of technologies like ChatGPT has led to a surge in the use of machine-generated content in academia and workplaces. The task is crucial for ensuring the authenticity of texts, especially as individuals may potentially claim authorship of machine-generated content as their own work, raising concerns about academic integrity. By focusing on Subtask A and utilizing English-language data, this research addresses the challenges associated with the increasing prevalence of machine-generated text in academic and professional contexts, offering effective classification methods. In this paper, we use simple methods based on linguistic intuition to distinguish between human and machine-generated text. Our primary approaches involve leveraging Zipf's Law as one method, and employing word unigram counts as another.

We explored multiple approaches, ultimately narrowing our focus to two strategies. Although we submitted only one approach for leaderboard consideration, we believe the other one offers valuable insights as well. Surprisingly, we found that our simple methods based on linguistic intuition can rival the performance of large language models in the same task. While this approach could have been applied to the multilingual track, regrettably, time constraints prevented us from pursuing this direction. We ranked in the middle compared to other teams participating in this task.

2 Background

In configuring our task, we utilized the subtask A monolingual training data to train all three approaches, encompassing texts from both humans and models such as ChatGPT OpenAI (2022), Cohere Cohere (n.d.), Davinci OpenAI (n.d.), and Dolly Hugging Face (n.d.). Each data entry included the text, its source, the model used, the assigned label (either 0 or 1), and a unique identifier. For development purposes, we employed the subtask A monolingual development data, which featured texts generated by humans and the Bloomz BigScience (n.d.) model, along with their corresponding source, model, label, and ID. The final test data exclusively included texts and their respective IDs, with all other information omitted. The output data comprised jsonl files containing only the text IDs and their predicted labels (either 0 or 1). These files were generated once using the development data to refine our approach and again for the final test data, aligning with the task objective of predicting the label for a given text using our approach.

Our research delved into the practical implementation of Zipf's Law for binary classification. While consulting Linders and Louwerse's paper Linders and Louwerse (2020), as well as Nguyen-Son et al. Nguyen-Son et al. (2017), we found theoretical mentions of its potential application. However, none of these sources provided an actual approach. In contrast, our approach involves the concrete implementation of Zipf's Law, resulting in a functioning system.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 399–402

3 System Overview

3.1 Zipf's Law

Following an extensive review of the literature concerning methodologies aimed at discriminating between human and machine-generated textual content, our inquiry identified Zipf's Law as a potentially promising avenue of investigation. Despite the limited prevalence of existing methodologies leveraging this distribution, we deemed it worthy of investigation. Our rationale for pursuing this direction stems from the observed advantages in terms of computational efficiency and simplicity compared to Large Language Model (LLM) based approaches, which typically incur higher computational demands.

Zipf's Law is characterized by the following equation.

$$f = \frac{C}{r^s}$$

- $f(r)$ represents the frequency of the rank rth term.
- C is a constant.
- s is the Zipf exponent, typically close to 1.

This formula illustrates the inverse relationship between the frequency of a term and its rank in a given dataset, with the Zipf exponent governing the rate of decline in frequency as rank increases.

Our code initiates by tokenizing the text into individual words, followed by the computation of each word's frequency within the text. This preliminary step is pivotal for acquiring the empirical frequency distribution of words. After computing word frequencies and their corresponding ranks, we fit a curve to the Zipfian distribution. This step takes into account the Zipfian distribution function, word ranks, and frequencies as input parameters. By optimizing the scaling parameter s of the Zipfian distribution, fitting the observed data to a curve reveals the text's adherence to Zipf's law. This process aims to determine the optimal parameters (such as the scaling parameter s and constant C) for the Zipfian distribution function.

Leveraging the parameter s, the Zipfian distribution, we computed mean values for texts of label 0 and label 1. Subsequently, we determined their midpoint (-0.125) to serve as the threshold for classifying a text as either label 0 (human-generated) or label 1 (machine-generated).

In the system overview, following label prediction for the development data in subtask A monolingual track, we conduct a thorough evaluation by manually computing a preliminary F1 score using the actual labels as references. Our prediction process involves assigning labels based on Zipfian values, where values below the predefined threshold receive label 0 and those exceeding it are labeled as 1. We systematically apply the Zipfian distribution method to the texts extracted from the development data, facilitating precise label determination during subsequent analysis.

Our system obtained an F1 score of 0.72 on the development set. We used the same threshold/model to predict the labels on the test set.

The F1 score obtained on the official leaderboard for this approach yielded a value of 0.729. This metric provides a robust assessment of our approach's performance in the context of the shared task.

	label 0	label 1
min	-0.539	-1.778
max	2.212e-09	-1.550e-10
mean	-0.111	-0.139

Table 1: Zipfian distribution of labels 0 and 1

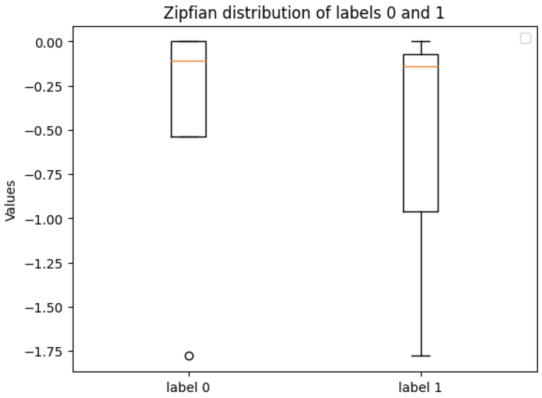

Figure 1: Zipfian distribution of labels 0 and 1

3.2 Unigram

Although we did not submit the predictions of the unigram approach, we will clarify its setup here. This method mirrors the structure of the Zipf's Law approach, yet diverges in its focus on calculating the number of words per text.

The mentioned values led us to establish a threshold of 450.303. With this threshold in place, the prediction process commenced: texts with word counts surpassing it were predicted as 0, indicating

	label 0	label 1
min	2	6
max	33220	2665
mean	583.755	316.850

Table 2: Word counts of labels 0 and 1

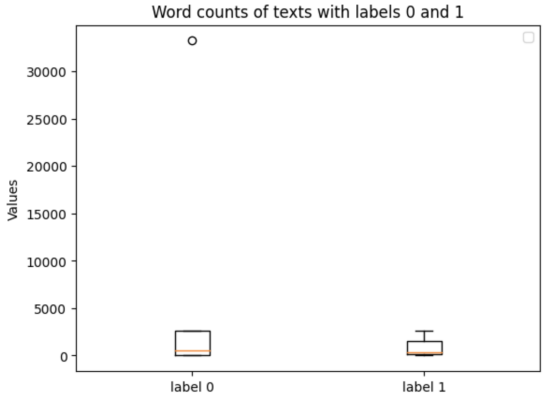

Figure 2: Word counts of labels 0 and 1

a human author, while those falling below were labeled as 1, indicating machine-generated text. Subsequently, we proceeded with text extraction for the test data, calculating the word counts for each text. We made predictions based on this.
Our preliminary F1 score for this approach stood at 0.59 on the development set, which, while respectable, fell short of the performance achieved by the Zipf's Law approach. This discrepancy led us to opt against pursuing further development of the unigram approach.

3.3 Comparing Zipf's Law and Unigram

The unigram method focuses on capturing information related to word frequencies, providing insights into the overall lexical diversity and richness of the text. In contrast, the Zipf method leverages the distributional characteristics of word frequencies, emphasizing patterns of occurrence and rank-order relationships. Together, these approaches offer complementary perspectives on textual content, enabling a more comprehensive analysis of linguistic features.
The unigram method may excel in scenarios where the distribution of word frequencies significantly impacts classification outcomes, such as detecting texts with distinct lexical signatures or vocabulary usage patterns. On the other hand, the Zipf method may prove more effective in identifying structural patterns and deviations from expected frequency distributions, particularly in texts generated by language models with predictable language patterns. While the unigram and Zipf methods differ in their primary focus and underlying principles, there is some overlap in the information they capture. The unigram method operates at the level of individual word occurrences, providing insights into the frequency and distribution of specific terms within the text, while the Zipf method considers the broader distributional patterns of word frequencies, focusing on rank-order relationships and overall distribution shapes.

4 Experimental Setup

For implementing the Zipf's Law and word unigram approach, we relied on Counter Python Software Foundation (2022), numpy NumPy (2022), and curve_fit from scipy.optimize SciPy (2022), without requiring any additional external tools or libraries. We utilized the provided data without creating additional splits. During testing on the development data, we employed the function f1_score from sklearn.metrics scikit-learn (2022).

5 Results

Our initial two approaches exhibit commendable performance in accurately predicting labels. The F1 score for the labels predicted by the Zipf's Law approach was 0.729 in the official ranking, with the task organizers' baseline set at 0.884. Our submission secured the 83rd position out of 137 in the official rankings. The preliminary F1 score for the unigram approach was 0.60, reflecting the test phase; however, this result was not included in the final submission.

6 Conclusion

In conclusion, we are satisfied with the performance of our Zipf's Law system in the shared task, particularly given its simplicity compared to other model-based approaches. The unigram system demonstrated commendable performance as well. We also explored training a linear Support Vector Classifier (SVC) scikit-learn (n.d.a) using character n-grams and employing a sublinear tf-idf scikit-learn (n.d.b) approach. We integrated several models, partitioning the training data into distinct files representing specific models used, such as ChatGPT, Cohere, Davinci, and Dolly, ensuring a balanced distribution of human-generated texts across all model categories. Despite our careful

preparations, all four models unexpectedly produced identical labels for all texts during prediction, rendering the system ineffective. This unexpected outcome highlights the necessity of rigorous testing and debugging to ensure the reliability of our methods. Identifying and resolving the underlying issues will be crucial for future improvements in model performance and credibility. Moving forward, we intend to enhance both the Zipf's Law and unigram systems through a comprehensive review of relevant literature. Additionally, we're dedicated to fixing the bug in our tf-idf vectorizer to maximize its potential in future iterations.

Abstract

This paper describes the approach of the UniBuc - NLP team in tackling the SemEval 2024 Task 8: Multigenerator, Multidomain, and Multilingual Black-Box Machine-Generated Text Detection. We explored transformer-based and hybrid deep learning architectures. For subtask B, our transformer-based model achieved a strong **second-place** out of 77 teams with an accuracy of **86.95%**, demonstrating the architecture's suitability for this task. However, our models showed overfitting in subtask A which could potentially be fixed with less fine-tunning and increasing maximum sequence length. For subtask C (token-level classification), our hybrid model overfit during training, hindering its ability to detect transitions between human and machine-generated text.

1 Introduction

Task 8 from SemEval 2024 competition (Wang et al., 2024a) aims to tackle the complex challenge of distinguishing between human and AI generated text. Doing so is crucial for maintaining the integrity and authenticity of information as it helps prevent the spread of misinformation and ensures that content sources are accountable. By developing tools for this task, which work in a multilingual setting, and releasing them open source we can combat non-ethical uses of AI such as propaganda, misinformation, deepfakes, social manipulation and others.

The systems developed for subtasks A and B are based on transformer models with different layers selection and merging strategies, followed by a set of fully connected layers. The training is split in two phases: a) freezing phase, where the transformer weights are not updated, only the fully connected layers are updated with a specific learning rate; b) fine-tuning phase, where the selected layers of the transformer and the fully connected layers are updated with a different (usually smaller) learning rate. For the subtask C, a different architecture was used, combining character level features, extracted with a CNN model, with word embeddings and fed into a Bidirectional LSTM followed by a set of fully connected layers. The same training strategy with different learning rates was used.

Our error analysis revealed that overfitting remains a primary challenge, despite our initial precautions. We learned that for future fine-tuning of transformer models, we should dedicate a lot more time to prevent overfitting. We made our models open source in a GitHub Repository.

2 Background

The competition had 3 tasks explained below (Figure 1). Subtask A had 2 sub-tracks: monolingual (English only) and multilingual.

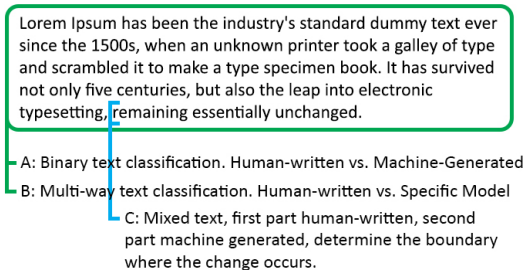

Figure 1: Three sub-tasks explained

We participated in all 3 tasks with the best result being second place on subtask B (Table 1).

2.1 Dataset

The data for this task is an extension of the M4 dataset (Wang et al., 2024b,c). Compared to subtask A and B, subtask C had much less data to work with. We found out that we could increase the size of our datasets for subtask A monolingual

by adding the dataset from subtask B and remove duplicated items (Table 2).

2.2 Previous Work

Since GPT-2, it has been particularly difficult to detect machine-generated text, such that classical machine learning methods can no longer help. Previously, when models used top-k sampling, this resulted in text filled with too many common words and models could detect this anomaly easily (Ippolito et al., 2020). But now with bigger and bigger models and other type of sampling (like nucleus sampling), fewer artifacts are left for a detector to spot. Solaiman et al. (2019) showed that by fine-tuning a RoBERTa model we can achieve state of the art results for GPT-2 generated text with a 95% accuracy.

If for GPT-2, expert human evaluators achieved an accuracy of 70% (Ippolito et al., 2020), for GPT-3 and later models their accuracy is on par with random chance (Clark et al., 2021). It is still an open question if we can improve automated detection. Many companies (like OpenAI and Turnitin) are releasing products and claim to do it, but suffer from low rates of accuracy. In July 2023, OpenAI removed its product for this reason.

3 System overview

In this paper, we focused our research on two different system architectures: **Transformer based models** (3.1) and **Hybrid deep learning models** (3.2).

Both architectures use a block of fully connected layers (Figure 2) with the base structure being initiated with a linear layer, succeeded by normalization, a tanh activation function, followed by a dropout layer (0.5). Finally, it concludes with a linear layer with an output size of 1 for subtask A and 6 for subtask B .

Figure 2: Fully connected layer base structure

3.1 Transformer based models

The core of this architecture is based on transformer models (Figure 3). The strategy is to use the transformer model as a feature extractor, pass the information through fully connected layers (Figure 2) and apply the activation function based on the predictions for each task.

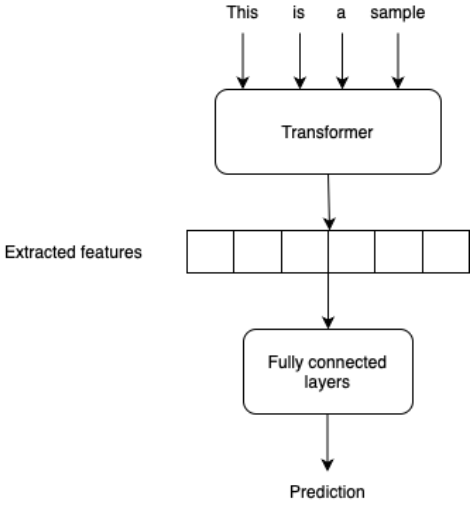

Figure 3: Transformer based models architecture

During the process of developing our system with this architecture, we encountered three difficulties that we had to address: 1) Long texts but limited number of tokens accepted by the transformer models (3.1.1); 2) Layer selection for feature extraction step (3.1.2); 3) Fine-tuning strategy to prevent overfitting (3.1.3).

3.1.1 Long text problem

Most of the transformer models accept a maximum of 512 tokens per sequence. We have also experimented the same strategies as described by Sun et al. (2020) in order to handle long texts.

I. **Truncation methods:**

- **Head only**: Keep only the first 510 tokens from the entire text. (extra 2 tokens for [CLS] and [SEP] tokens)

- **Tail only**: Keep only the last 510 tokens from the entire text. (extra 2 tokens for [CLS] and [SEP] tokens)
- **Head and Tail**: Combined the first 128 tokens with the last 384 tokens from the entire text.

II. **Hierarchical methods:** Each text is split into $k = L/512$ chunks. For each chunk we get the pooled representation of [CLS] token and merge all chunk representations using mean or max.

Our experiments proved that truncation method with **head only** works best for the given dataset as well.

3.1.2 Layer selection

Most transformer models have multiple layers and each layer is capturing different features from the input text (Sun et al., 2020). Intuitively, lower layers capture more general features at the token level and as we move up the layers, the captured features are more contextualized and more sensitive to the context of the tokens.

From our experiments, concatenating the last 4 layers and using only the last layer from the transformer proved to give the best results. Because of the limited resources, we chose to use only the last layer.

3.1.3 Fine-tuning strategy

Fine-tuning the transformer model for a downstream task is also challenging. Each layer of the transformer captures a different level of semantic and syntactic information from the input text (Yosinski et al., 2014; Howard and Ruder, 2018; Sun et al., 2020). We implemented a Head-First Fine-Tuning (HeFit) strategy (Michail et al., 2023) and used different learning rates for different layers (Sun et al., 2020):

1. For the first number of epochs $[1,\ k]$ we completely freeze the transformer layers without updating any of the weights.

2. For the rest of the epochs $[k+1,\ N]$ we fine-tune only the selected layers used for feature extraction.

Using this strategy, we are not only using less resources, but we can also preserve the more general information of the transformer (freezing lower layers) and updating information that is most relevant to the downstream task (fine-tuning selected upper layers).

3.2 Hybrid deep learning models

This model architecture (Figure 5) was inspired by the work of Chiu and Nichols (2016) which proved to be very efficient for named entity recognition task. The idea was to convert words and characters into vector representations using lookup tables and concatenate them in order to be fed into a neural network. For the character-level features we used a lookup table for the character embeddings and applied a 1D convolution followed by a 1D max pooling layer (Figure 4). For the word-level features we used a lookup table for the word embeddings. We concatenated the word and character features and fed them through a bidirectional LSTM and then a set of fully connected layers (Figure 5 - method 1).

This model was mainly used for the subtask C, which we treated as a token classification task. Therefore we have also made some experiments adding a conditional random field (Sutton and McCallum, 2010) on top of the fully connected layers (Figure 5 - method 2). This method was proved to be very efficient for sequence tagging by the work of Huang et al. (2015).

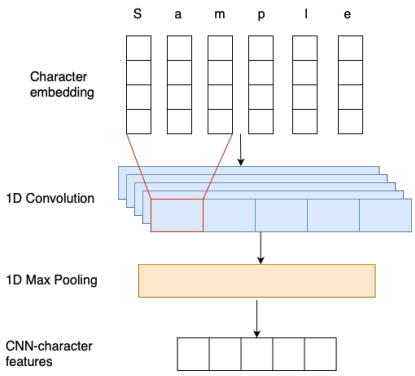

Figure 4: CNN-character level features

3.3 Experimental setup

During the training phase, we utilized the development (dev) dataset as our test set, while the training dataset was divided into a training subset and a validation subset, following an 80%-20% split. For the construction of the final model, the entire training dataset was used for training purposes, with the dev set serving as our validation set. In terms of text preprocessing, we experimented with

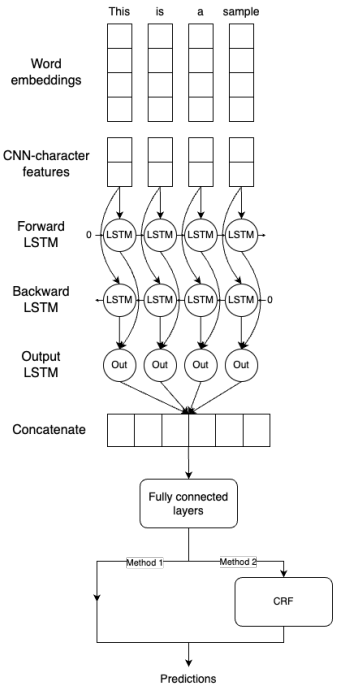

Figure 5: Hybrid deep learning model architectures. Method 1 to use the predictions directly from the fully connected block and method 2 using CRF before predictions.

three different approaches:

- **Heavy**: Involved removing pre-trained language model special tokens such as <pad>, <s>, <unk>, etc., converting numbers into words, and eliminating special characters or formats like emails and URLs.
- **Light**: Consisted of converting text to lowercase and removing special characters, including numbers.
- **None**: Text was used as is, without any preprocessing.

We observed that the model performed best with no preprocessing, a finding that aligns with the inherent flexibility of Masked Language Models to efficiently process raw text.

To determine the optimal number of training epochs, both when the pre-trained layers were kept frozen and during the fine-tuning phase, we monitored the validation set's loss and the test set's performance, opting for conservative epoch counts to prevent overfitting.

3.4 Subtask A

For this subtask, in order to be able to run the models based on the transformer architectures, we used the head only truncation strategy (3.1.2 - I.) with the first 512 tokens.

3.4.1 Monolingual

In the monolingual track, the final submission is a transformer-based model architecture (3.1) with RoBERTa-base pre-trained model. The extracted features from the transformer are only from the $[CLS]$ token of the last hidden layer with a 0.3 dropout applied. The fully connected block is built with 2 base structures (Figure 2) consisting of $[256, 64]$ neurons. A 0.5 dropout is applied and $sigmoid$ activation function is used in order to make the predictions. We trained this model in total for 5 epochs with the entire transformer architecture freezed and a batch size of 24 using the AdamW optimizer with a learning rate of $2e-4$ and the binary-cross entropy loss.

Regarding the layer selection, most of the experiments were done only using the last layer. We did some testing with last 4 layers (for some pre-trained transformers) but we could not batch size 24 anymore because of the limited resources if it were to also fine-tune the transformer's selected layers. We have also tested with multiple batch sizes and 24 seemed to work best in our case. Results in Table 4.

3.4.2 Multilingual

For the multilingual track we used models pre-trained in a multilingual context (Table 3) and for the final submission we chose mdeberta-v3-base which, even though it didn't support Indonesian, it gave the best results. The hyper-parameters that we chose were: batch size of 32, token max length of 512, a fully connecter layer (Figure 2) of 128, learning rate for the "frozen step" of 0.001 (where we train only the output layer) and smaller for fine-tuning: 0.0002.

3.5 Subtask B

In the subtask B, the final submission is a transformer-based model architecture (3.1) with RoBERTa-base pre-trained model. The extracted features from the transformer are only from the $[CLS]$ token of the last hidden layer with a 0.3 dropout applied. The fully connected block is built with 2 base structures (Figure 2) consisting of $[512, 128]$ neurons and the final output size of the model being 6. A 0.5 dropout is applied with no activation function for making the predictions. We trained this model in total for 8 epochs, first

6 epochs with the entire transformer architecture freezed, and the last 2 epochs also fine-tuning the last layer of the transformer (3.1.3). The batch size used was 32 and optimizer AdamW with a learning rate of $3e-4$ for the freeze part of the training (updating only the fully-connected block weights) and $2e-4$ for the fine-tuning part with a linear scheduler with 50 warmup steps and cross entropy loss.

Regarding the layer selection, most of the experiments were done only using the last layer. We did some testing with last 4 layers (for some pretrained transformers) but we could not batch size 32 anymore because of the limited resources if it were to also fine-tune the transformer's selected layers. We have also tested with multiple batch sizes and 32 seemed to work best in our case. Results in Table 5.

3.6 Subtask C

We treated this subtask as a token classification one and changed the labels from positions to list of 0 and 1, where 0 means that the token at that specific position is not machine generated and 1 otherwise.

The tokenization was done by splitting the text by space and kept only the first 1024 tokens from the entire text. As for the maximum character length of the tokens we went with 25.

The final submission is a hybrid deep learning model architecture (3.2). We used the method 2 variation of the architecture (Figure 5 with the CRF model right before making the predictions.

For the CNN-character features we set the character embeddings dimension to 10 and randomly initialized the lookup table using uniform distribution with range $[-0.5, 0.5]$. We used the convolution with kernel size 3 and 20 filters with a 0.5 dropout afterwards. The word embedding dimension used is 300 and the lookup table randomly initialized in the same manner. For the bidirectional LSTM we used 2 filters with 32 hidden dimension each. The fully connected block is build with a fully connected base structure (2) with 32 neurons and final output size of 2.

We trained this model in total for 3 epochs with a batch size of 12 and optimizer AdamW with a learning rate of $5e-3$ for the first 2 epochs of the training and $3e-3$ in the last epoch together with a linear scheduler with no warmup steps and cross entropy loss.

4 Results

4.1 Subtask A

For both monolingual and multilingual our model under-predicted the human-written class. In the case of the monolingual track our model performs equally well in detecting machine-generated text for each model, but under calls the negative class (Figure 6). It predicts 23043 items as machine generated and 11229 as human-written while the truth was more balanced (18000 vs. 16272). We obtain good accuracy for each machine generated model, but we under-call the human label (0.68 accuracy) so in the end the final score is 0.85.

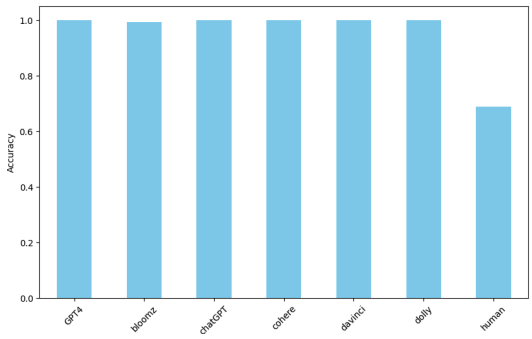

Figure 6: Subtask A: monolingual - accuracy by model for test set

In the case of multilingual, testing on dev data gave us an accuracy of 0.96 but the final test score was 0.79. Our model predicted 30764 samples as machine generated and only 11614 as human-written, while the true distribution was more balanced (22140 vs. 20238). This suggests that our model was overfit and had a bias for the positive class. If we look at the distribution per model we can see that we have a good accuracy on all models, except for human and a bit worse for chatGPT (Figure 7), ending up with a final score of 0.79.

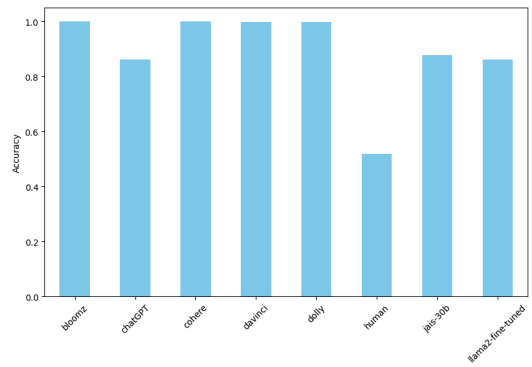

Figure 7: Subtask A: multilingual - accuracy by model for test set

If we look at sequence length we can see an U shaped graph at 500 - 1500 number of tokens, where the model performs worst (Figure 8) for both monolingual and multilingual tracks. We believe this is because our transformers had a limit of 512 for token length and we didn't have the resources to train on a bigger sequence length.

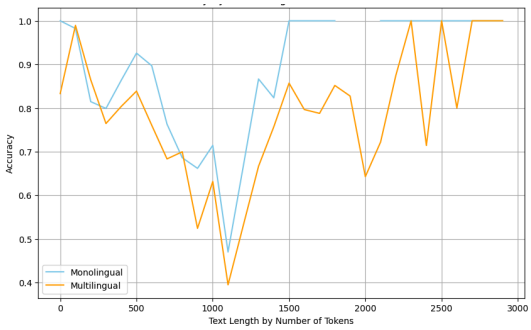

Figure 8: Subtask A: accuracy by sequence length in tokens, monolingual and multilingual

4.2 Subtask B

Our most notable performance was achieved in subtask B, where we secured the **second position** from a total of 77 participating teams, with an accuracy score of **86.95%**, very close to first position. Upon examining the accuracy breakdown by model, it becomes evident that our model exhibited strong performance, particularly with bloomz and chatGPT outputs, while facing more challenges with cohere (refer to Figure 9). The elevated score compared to Task A implies that our model's architecture and training methodology were well-suited for the demands of a multiclass classification task.

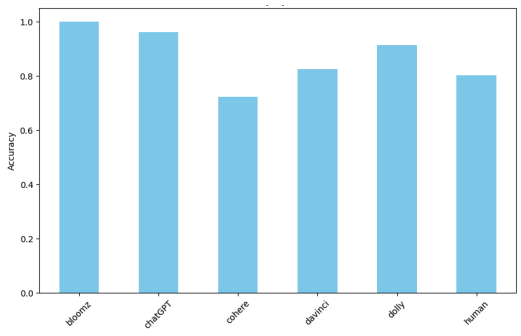

Figure 9: Subtask B: accuracy by model for test set.

4.3 Subtask C

Our results on the subtask C show that the model architecture we chose alongside the hyperparameters overfitted drastically on this dataset. The MAE on training data decreased from 18.8 to 4.39 and on validation data decreased from 18.04 to 8.34 during the training phase, while on the final test dataset the MAE increased to 74.28. This proves that the character and word embeddings could not generalize that good in order to be able to find that transition spot from human text to machine generated text.

5 Conclusions and Future Work

In conclusion, our architecture and training methods produced good results for subtask B (securing the second place). However, our models demonstrated signs of overfitting for subtask A. We could not find a proper explanation for why the model architecture work better on subtask B and is overfitting that much on the other task. Our future endeavors will explore several avenues:

- **Extended Sequence Lengths**: With more powerful machines we plan to increase the token length from 512 to 1024 in order to capture a wider context, which could improve their performance.
- **Ensemble Learning with Model Specialization**: Split the dataset by originating model (chatGPT, cohere etc.) and train specialized models on each subset. Each specialized model will become adept at discerning text generated by its corresponding model. By aggregating predictions from these specialized models, we aim to construct a meta-model capable of making better final predictions.
- **LLM**: We plan to investigate the efficacy of large language models (like Mistral/Mixtral or Solar) with either zero shot learning or few shot learning scenarios. For few-shot learning, we intend to exploit the in-context learning capabilities of LLMs by presenting them with pairs of examples (one human-written and one machine-generated) within the same context window. We will then ask the model to predict an unseen example.

A Further experiments - Subtask A

For most of the experiments in subtask A monolingual, we used two fully connected layers (2) with $[256, 64]$ neurons, batch size 24 and trained the model in total for 5 epochs. For all experiments we used AdamW optimizer with learning rate $2e{-}4$ and binary-cross entropy loss. For some of the experiments we have also tried fine-tuning the last n selected layers (in most cases just the last layer) for the last k epochs. In those cases, we have also used a linear scheduler with 50 warmup steps and changed the learning rate as well. The results can be seen in Table 4. Experiments for the multilingual track kept the same architecture as the monolingual one but used multilingual pre-trained models Table 3.

Model	Train	Validation	Test	Final
mdeberta-v3	0.96	0.95	0.94	**0.79**
xlm-roberta	0.97	0.95	0.92	0.78
bert-multi	0.95	0.92	0.91	0.75
distilbert-multi	0.93	0.90	0.89	0.73

Table 3: Experiment results by pre-trained model - multilingual. Validation was the dev set, test size was 0.2 and final score is the test score in competition.

B Further experiments - Subtask B

For most of the experiments in subtask B, we used two fully connected layers (2) with $[512, 128]$ neurons, batch size 32 and a trained the model in total 8 epochs. For all experiments we used AdamW optimizer with learning rate $3e - 4$ and cross entropy loss. For some of the experiments we have also tried fine-tuning the last n selected layers (in most cases just the last layer) for the last k epochs.

In those cases, we have also used a linear scheduler with 50 warmup steps and changed the learning rate as well. The results can be seen in Table 5.

Abstract

The "Emotion Discovery and Reasoning Its Flip in Conversation" task at the SemEval 2024 competition focuses on the automatic recognition of emotion flips, triggered within multi-party textual conversations. This paper proposes a novel approach that draws a parallel between a mixed strategy and a comparative strategy, contrasting a Rule-Based Function with Named Entity Recognition (NER)—an approach that shows promise in understanding speaker-specific emotional dynamics. Furthermore, this method surpasses the performance of both DistilBERT and RoBERTa models, demonstrating competitive effectiveness in detecting emotion flips triggered in multi-party textual conversations, achieving a 70% F1-score. This system was ranked 6th in the SemEval 2024 competition for Subtask 3.

1 Introduction

The field of emotion analysis continues to be rich with surprises (Kumar et al., 2022), especially within the context of conversations. For this competition, we have implemented a competitive method for Subtask 3 (Kumar et al., 2024). Uncovering the reasons (triggers) behind a speaker's emotional shift during a conversation—taking the example of "Friends," an American television sitcom—presents a unique challenge, especially in the realm of response generation (Gifu and Cioca, 2013). With the rising popularity of chatbots (Ouatu et al., 2020), it appears that emotions are the critical link missing between establishing trust and simulating genuine connections (Madasu et al., 2023). Furthermore, the detection of emotions and their triggers (Cristea et al., 2015) could play a significant role

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 412–419

in new digital marketing strategies, enhancing user feedback, and analyzing overall customer centricity.

This raises a pertinent question: *Is AI capable enough to identify emotions and their triggers with high accuracy within code-mixed dialogues?*

The remainder of this paper is organized as follows: Section 2 briefly reviews studies related to emotion recognition (Kumar et. al., 2023) and the concept of an emotion flip in conversations. Section 3 describes the system developed to detect the specific emotional dynamics that occur during a conversation. Section 4 outlines the experimental setups. Section 5 discusses the results of the experiments conducted, and Section 6 presents the conclusions.

2 Background

Recent research in dialogue emotion detection has witnessed significant advancements. The literature suggests that the challenge of recognizing emotions in conversations can be tackled from various perspectives. For instance, a notable approach involves the use of models based on transformers, as well as iterative emotion interaction networks.

The most prevalent method for emotional discovery and analysis in recent years involves employing various transformers. Variants of BERT have been frequently utilized, whether they are pre-trained or not. Some of the notable examples include mBERT (De Bruyne et al., 2022), LFTW-RoBERTa, YT-Bert, MNLI-BART-large, MNLI-RoBERTa (Bulla et al., 2023), and EmoRoBERTa (Bayram & Benhiba, 2022), among others. Additionally, a study by Li et al. (2020) introduced HiTrans, an innovative model specifically designed to discern emotions within multi-speaker conversations. A team of researchers (Kumar et al., 2023) has presented a pioneering approach that focuses on identifying the triggers behind emotion shifts in conversations. Using BERT as a foundation, their findings indicate that TGIF (a novel neural architecture) more effectively addresses the increase in instigator labels compared to existing baselines. Some studies concentrate on the application of zero-shot models to emotion classification and hate speech detection (Bulla et. al., 2023), while others adopt a modified approach, developing a semi-zero-shot model. This variation aims to investigate and determine whether significant challenges and differences exist in emotion detection across various language families (De Bruyne et al., 2022). Interestingly, the F1-scores for all transformer types employed in zero-shot scenarios are reported to be similar across both studies.

In the experiments dedicated to the KET model (Zhong et al., 2019), several key findings were highlighted: notably, the KET model demonstrated superior performance, surpassing existing state-of-the-art models in various datasets as measured by F1 score. This underscores its effectiveness in detecting emotions within textual conversations. Additionally, there is research (Lu et al., 2020) exploring non-transformer-based solutions, such as the innovative Iterative Emotion Interaction Network. This approach specifically addresses the challenge of the absence of gold-standard emotion labels during inference, offering a novel solution to a prevalent issue in emotion detection.

Additional research (Zhu et al., 2021) explores the use of baselines such as DialogueGCN and KET, but it is COSMIC that emerges as the superior model among these baselines. This advancement began with the development of a topic-augmented language model (LM), which includes a dedicated layer for detecting topics. These collective efforts significantly push the boundaries of dialogue emotion detection forward by incorporating a blend of knowledge, contextual insight, and cutting-edge neural architectures.

The third subtask of SemEval-2024 Task 10, titled 'Emotion Discovery and Reasoning its Flip in Conversation' (EDiReF), is dedicated to exploring the point in a dialogue at which the last emotion flip occurs For the Emotion Flip Reasoning subtask, Task 10 of SemEval-2024 provides three types of datasets: training, validation, and testing, detailed in the table below:

Training Dataset	Validation Dataset	Testing Dataset
400 entries	426 entries	1002 entries
13500 dialogue lines	3522 dialogue lines	8642 dialogue lines

Table 1: Task Dataset Statistics

The datasets contain dialogues extracted from different episodes of the 'Friends' series, stored in a JSON array. Each entry comprises the following fields:

- episode: the name of the episode (e.g. "episode": "utterance_0");
- speakers: a list of speakers in order of their participation in the conversation (e.g. "Chandler", "The Interviewer", "Chandler", "The Interviewer", "Chandler");
- emotions: a list of emotions in order (e.g. "neutral", "neutral", "neutral", "neutral", "surprise",);
- utterances: the list of utterances from the dialogue in sequential order (e.g. "also I was the point person on my company's transition from the KL-5 to GR-6 system.", "You must've had your hands full.", "That I did. That I did.", "So let's talk a little bit about your duties.", "My duties? All right.");
- triggers: a list of triggers in sequential order. This field is the output of our models and represents a list of '0.0s' and only one value of '1.0', indicating the trigger in that conversation.

Before proceeding further, we conducted a thorough examination of the training dataset for our subtask to gain insights into the appearance of triggers and the functioning of the Emotion Flip Reasoning (EFR) system. Our analysis revealed that all triggers are associated with the same (last) emotion flip in the dialogue. Additionally, we observed that triggers can manifest in any utterance within the same segment of the conversation where the emotion change occurs. To achieve this understanding, we initially examined the speakers, emotions, and triggers. Subsequently, we delved into the utterances, particularly focusing on cases where triggers were less clear. As observed in numerous papers, the implementation of models often revolves around transformers, with BERT being a prominent choice. This observation significantly influenced our approach, leading us to adopt a strategy centered on utilizing the DistilBERT transformer. DistilBERT, developed to reduce the size and enhance the computational efficiency of BERT while preserving a substantial portion of its functionality (Sanh et al., 2019), emerged as a key component of our investigation. Additionally, we incorporated the RoBERTa transformer into our architecture's model, reflecting our commitment to leveraging state-of-the-art techniques. This initiative can be seen in the baseline part of our architecture model.

3 System Overview

Our objective is to enhance emotion recognition technology by investigating the underlying reasons for sudden emotional changes. Specifically, our research concentrates on emotional flips, which denote abrupt shifts in emotions during conversation—an aspect often overlooked in existing studies. Despite the progress achieved by previous methods, recognizing emotions in conversation remains challenging due to the nuanced conveyance of emotions and the varying significance of utterances, influenced by the specific topics discussed and implicit understandings shared among participants.

Upon analyzing the dataset, we identified seven distinct emotion labels: neutral, joy, surprise, anger, sadness, fear, and disgust, with varying frequencies. Dialogues in the dataset involve a range of one to eight participants, with dialogues between two speakers being the most common.

The primary focus of this paper is to identify speaker-specific emotional dynamics occurring during conversation. Our approach utilizes two transformer-based baselines, RoBERTa and DistilBERT. Additionally, we compare their performance with a mixed and comparative method employing rule-based and Named Entity Recognition (NER) techniques.

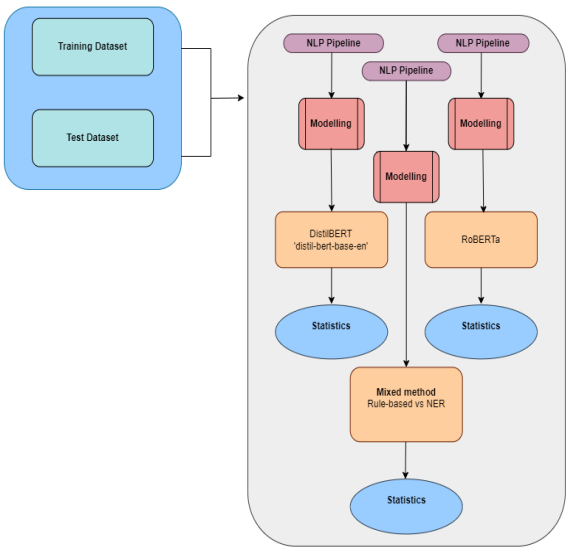

Figure 1: The LinguisTech system architecture

The first transformer baseline we utilized was a pre-trained RoBERTa model (TFRobertaModel) based on the BERT-base architecture. This model is described by: 2-layer, 768-hidden, 12-heads, 125M parameters. As for the parameters, we configured the model with the following settings:

- metrics=['acc', f1_m, precision_m, recall_m]
- loss='sparse_categorical_crossentropy'
- optimizer=tf.keras.optimizers.Adam(lr=1e-5)

In addition, we employed 'relu' and 'softmax' as activation functions. We segmented each conversation into utterances, and for each utterance, the training data is structured as a dictionary containing the following fields:

- utterance – the current utterance
- emotion - the current emotion
- context – containing arrays with: all emotions in that dialog, all speakers, all utterances

In the pre-processing phase for the RoBERTa baseline, we pursued several approaches and actions:

- Extracted all replicas from the context and applied tokenization, lemmatization, stopword removal, etc.
- Extracted emotions from contexts.
- Extracted emotions and utterances from context.
- Extracted emotions, utterances, and speakers from context.
- Retained the context along with the following: id, list of utterances, list of emotions, list of speakers.
- Retained the context along with individual replicas, list of utterances, list of emotions, list of speakers.
- Maintained the original context while eliminating the first half, followed by attempting to remove the first half of the context and combining speakers, emotions, speakers, and emotions.

As for the second baseline model, we chose the DistilBertClassifier from the keras_nlp framework. We utilized the 'distil_bert_base_en' preset, which is a 6-layer DistilBERT model maintaining case sensitivity. This model comprises 65.19 million parameters and was trained on English Wikipedia + BooksCorpus using BERT as the teacher model. For parameters, we configured the model with the following settings:

- loss=keras.losses.SparseCategoricalCrossentropy(from_logits=True)
- optimizer=keras.optimizers.Adam(5e-5)
- jit_compile=True
- metrics=['accuracy', f1_m, precision_m, recall_m], where f1, precision and recall are functions defined by us with the traditional method.

In the preprocessing phase for the DistilBERT baseline, we divided each conversation into utterances. For each utterance, the training data is structured as a dictionary containing the following fields:

- entry_index - the index of the utterance in conversation
- entry – a string representing the intervention of index entry_index, formed from entry_index - speaker - utterance - emotion
- context – a string formed by concatenating the entire conversation, every dialogue line being formed with this rule: speaker: utterance – emotion

After preprocessing, we applied a DictVectorizer from sklearn to convert the data into a numerical format. Additionally, we performed feature selection by selecting the 100 best features using SelectKBest (also from sklearn), with the chi-square test as the scoring function.

Examples of preprocessed data objects for RoBERTa and DistilBERT can be observed in the first and second annexes, respectively.

4 Experimental Setup

Based on the results obtained from implementing the two transformers, RoBERTa and DistilBERT, we observed outcomes that did not meet our expectations. Consequently, we initiated an experimental investigation aimed at combining and comparing two alternative methods to achievestyle

improved performance. These methods include a rule-based function constructed from observations on the dataset, as well as a Named-Entity Recognition (NER) Model.

Our initial observation revealed that triggers are generally present in the second part of the conversation. To validate our hypothesis, we calculated the instances where this statement holds true, as well as the percentage of cases where it does not. The results are as follows:

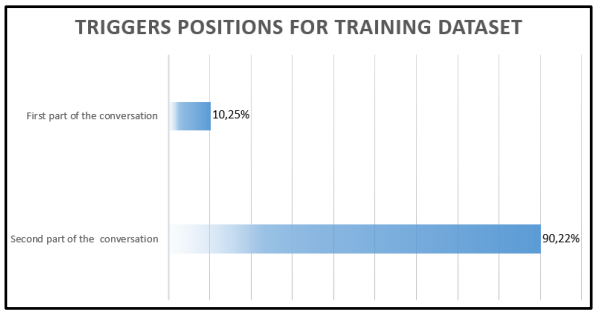

Figure 2: Trigger positions for training dataset in first/second part of conversation

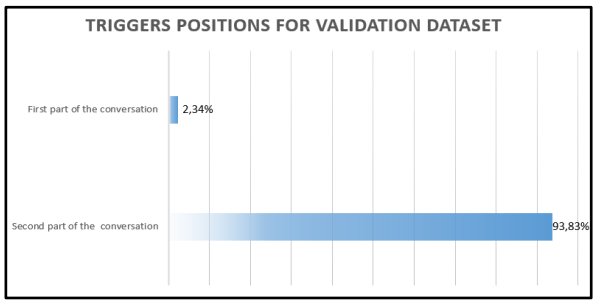

Figure 3: Trigger positions for validation dataset in first/second part of conversation

Having said that, the first rule we applied focused solely on the second part of each conversation.

The second rule is based on the emotion flips observed for each speaker. Whenever a change in emotion occurs between two consecutive interventions by a speaker, we designate the utterance preceding the second intervention as a trigger.

	Speaker	Utterance	Emotion	Trigger
1	Chandler	Hey, Mon.	Neutral	0
2	Monica	Hey-hey-hey. You wanna hear something that sucks.	Neutral	0
3	Chandler	Do I ever.	Joy	0
4	Monica	Chris says they're closing down the bar.	Sadness	0
5	Chandler	No way!	Surprise	1
6	Monica	Yeah, apparently, they're turning it into some kind of coffee place.	Neutral	0

Table 2: Dialogue example for the second rule detected

For the NER method, we utilized TFAutoModelForTokenClassification from python library transformers library with the 'bert-base-cased' preset.

As for the parameters, we configured the model with the following settings:

- optimizer=tensorflow.keras.optimizers.Adam(learning_rate=2e-5)
- epochs = 3 (the best score was obtained on running with 3 epochs)
- metrics: 'precision', 'recall', 'f1', 'accuracy'
- tensorflow.keras.callbacks.EarlyStoppig(monitor='val_loss', patience=3)

From the dataset, we only used emotions and triggers from every conversation. Because the model solves a tagging problem, we arranged the attributes in two separate lists, so that there is a 1-1 correspondence between their elements. We also renamed the triggers into labels: 0.0 = 'no' and 1.0 = 'yes'. An example of preprocessed data objects for NER can be observed in the third annexe.

{

"tokens": ["neutral", "neutral", "neutral", "neutral", "surprise"],

"labels": ["no", "no", "no", "yes", "no"]

}

After that, we applied tokenization with AutoTokenizer from transformers.

We also concatenate the train and validation dataset and applied a random split on the result, with the pivot value of 80% of the dataset length, so that we use 80% for training and 20% for validation.

5 Results

Upon comparing the Rule-Based Function and Named-Entity Recognition Methods, we obtained the results (F1 score of the triggers) displayed in the following table:

	Method	Score
1	Rule-based method	0.45
2	NER model with 3 epochs - cased	0.68
3	NER model with 3 epochs with rule-based method (XOR function applied on outputs) cased	0.47
4	NER model with 1 epoch cased	0.67
5	NER model with 5 epochs cased	0.66
6	NER model with 3 epochs uncased	0.70

Table 3: Comparing Scores (Rule-Based Function – NER) methods

From the results, it is evident that the highest F1 score is achieved by submission 2, which utilized the NER model trained over 3 epochs. Interestingly, as the number of epochs exceeded 5, we observed a consistent decrease in the F1 score.

	Method	F1 Score
1	RoBERTa Baseline	0.00
2	DistilBERT Baseline	0.00
3	NER model with 3 epochs - cased	0.68
4	NER model with 3 epochs - uncased	0.70

Table 4: Comparing Scores (Baselines vs NER)

The preceding table showcases the results achieved with the various methods we applied. Notably, the method using NER with 3 epochs outperformed the others, achieving F1 scores between 0.6 and 0.7 (Training/Validation). In comparison, our implementations using baseline methods yielded lower F1 scores: sthe DistilBERT Baseline method obtained a score of 0.1811%, and the RoBERTa Baseline method achieved 0.2452% (Training/Validation). It's crucial to note that these scores were calculated using our custom-defined F1 scoring function, tailored to the traditional method. Furthermore, a 0.00% score was observed when applying a different F1 scoring approach.

6 Conclusion

In this paper, we demonstrated that employing a Named-Entity Recognition (NER) model trained over 3 epochs for emotion flip detection yields superior results compared to classical approaches such as the RoBERTa and DistilBERT baselines, as well as a rule-based strategy. Our team's mixed and comparative solution outperformed the baseline models in terms of outcomes and provided valuable insights for future research on architecture and model enhancements. Notably, our method, utilizing the NER model trained over 3 epochs, achieved the highest F1 score. However, it is crucial to note that increasing the number of epochs beyond 5 led to a consistent decrease in the F1 score. Our evaluation indicates a significant performance improvement (~60% in F1-score) compared to previous studies.

In this way, we discovered that this is a complex problem, revealing numerous intriguing avenues for further exploration. Nevertheless, it is crucial to consider the potential benefits of incorporating audio and visual support, which could lead to enhanced performance. This insight prompts us to contemplate an exciting investigation for the future.

Text Mining at SemEval-2024 Task 1: Evaluating Semantic Textual Relatedness in Low-resource Languages using Various Embedding Methods and Machine Learning Regression Models

Ron Keinan
Department of Computer Science, Jerusalem College of Technology, Lev Academic Center
21 Havaad Haleumi St., P.O.B. 16031, 9116001 Jerusalem, Israel
ronke21@gmail.com

Abstract

In this paper, I describe my submission to the SemEval-2024 contest. I tackled subtask 1 - "Semantic Textual Relatedness for African and Asian Languages". To find the semantic relatedness of sentence pairs, I tackled this task by creating models for nine different languages. I then vectorized the text data using a variety of embedding techniques including doc2vec, tf-idf, Sentence-Transformers, Bert, Roberta, and more, and used 11 traditional machine learning techniques of the regression type for analysis and evaluation.

1 Introduction

Semantic Textual Relatedness (STR), which involves determining the degree of semantic similarity or relatedness between two pieces of text, has emerged as a significant task within Natural Language Processing (NLP). This task holds significant relevance and importance across various applications, including information retrieval, question answering, and summarization. By accurately measuring the semantic relatedness between sentences, we can enhance the performance of many NLP systems and improve their overall effectiveness.

In this paper, we describe our participation in subtask 1-A of SemEval 2024, for STR of texts written in 9 languages: Algerian Arabic, Amharic, Hausa, Kinyarwanda, Moroccan Arabic, Marathi, Telugu, Spanish, and English. Our approach to solving the task was based on a previous study that dealt with a similar sentiment classification task (Keinan & HaCohen-Kerner, 2023), and was based on a comparison of different embedding methods and then a comparison between different regression classifiers. We compared the results of each classifier with other vectors and chose the model that provided the best results on the training dataset, in favor of classifying the proximity between the sentences in the test dataset.

The full description of task 1 in general and the subtasks, in particular, is given in Ousidhoum et al. (2024B), and the dataset is described in Ousidhoum et al. (2024A).

2 Background

2.1 Semantic Textual Relatedness

Semantic Textual Relatedness (STR) is pivotal in automatically assessing the semantic similarity or relatedness between pieces of natural language text, thereby offering insights into the underlying relationships between subjects(Hadj et al., 2020). STR facilitates the exploration of individuals' opinions on specific topics and enables actionable insights for future planning(Abdalla et al., 2023).

In an era marked by the proliferation of textual data across various platforms, STR serves vital purposes such as information retrieval, question-answering, and summarization. Despite the inherent complexities in STR, including nuances in language and the varying degrees of relatedness between texts, researchers are actively engaged in refining and advancing STR systems to achieve greater precision in measuring semantic textual relatedness.

Challenges abound both for computational algorithms and human evaluators in STR. Achieving accurate results in STR demands not only an understanding of linguistic context but also cultural context and specific domain knowledge(Gabrilovich & Markovitch, 2007). Budanitsky and Hirst (2006) argued that relatedness is more general than similarity, as the former subsumes many different kinds of specific relations, including opposition, functional association, and others. They claimed that computational linguistics applications often

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 420–431

require measures of relatedness rather than the more narrowly defined measures of similarity.

2.2 Semantic Textual Relatedness in Low Resources African Languages

Detecting STR in low-resource African and Asian languages poses an even greater challenge for several factors. In the realm of STR, tackling the scarcity of annotated data emerges as a significant hurdle, particularly concerning low-resource languages. Annotated data, crucial for training ML algorithms in STR, denotes text labeled with sentiments, like positive, negative, or neutral. This dearth of annotated data hampers the development of high-quality STR systems. ML algorithms thrive on ample data to discern patterns and make precise predictions. Consequently, STR systems tailored for low-resource African/Asian languages, lacking sufficient annotated data, often exhibit diminished performance and accuracy.

Moreover, the variability of sentiment expressions in low-resource African/Asian languages poses another formidable challenge. Unlike English, many languages boast a diverse palette of emotional expressions, complicating sentiment determination. Cultural nuances further compound this complexity, influencing the sentiment encoded within the text.

Furthermore, the scarcity of NLP tools and resources makes the task even harder. Text preprocessing, a crucial step in preparing data for SA, becomes arduous due to the limited availability of essential tools like stemming and lemmatization tailored for low-resource languages. This scarcity impedes effective text processing and hinders progress in developing robust STR systems for these languages.

Muhammad et al. (2022) embarked on an extensive research endeavor aimed at constructing a comprehensive database encompassing four resource-poor African languages. Their work stands out for its innovative contributions, including the development of stopwords databases and sentiment dictionaries tailored specifically for Nigerian languages.

Kelechi et al. (2021) ventured into training a multilingual language model exclusively on low-resource African languages. Their creation, AfriBERTa, spans eleven African languages, pioneering language models for four of these languages.

Dossou et al. (2022) introduced AfroLM, a multilingual language model trained from scratch on a staggering twenty-three African languages, employing a self-active learning framework. Their research highlights AfroLM's remarkable performance surpassing several multilingual pre-trained language models, including AfriBERTa, XLM-Roberta-base, and mBERT, across various downstream natural language processing tasks such as Named Entity Recognition (NER), Text Classification (TC), and Sentiment Analysis.

2.3 Text Preprocessing

Text preprocessing is crucial in NLP fields such as STR. In both general and social text documents, noise such as typos, emojis, slang, HTML tags, spelling mistakes, and repetitive letters often appear. Improperly preprocessed text can result in incorrect analysis outcomes.

HaCohen-Kerner et al. (2019, 2020) investigated the impact of all possible combinations of six preprocessing methods on TC in three datasets. The main conclusion recommended is always to perform a systematic variety of preprocessing methods, combined with many ML methods to improve the accuracy of TC.

2.4 Text Embeddings

Text embeddings are representations of textual data in a continuous vector space, enabling algorithms to process and analyze text effectively. These embeddings capture semantic and syntactic similarities between words or documents, facilitating various NLP tasks such as sentiment analysis, document classification, and information retrieval. We used 5 basic embedding methods: TF-IDF, Doc2Vec, mUSE, LSA, LDA, and 2 improved embedding methods – BERT and Sentence Transformers with a variety of models.

TF-IDF (Term Frequency-Inverse Document Frequency) represents the importance of a word in a document relative to a collection of documents. It calculates a weight for each word based on its frequency in the document and inverse frequency across all documents. Words with high TF-IDF scores are considered more informative for distinguishing documents(Ramos, 2003).

Doc2Vec, an extension of Word2Vec, generates fixed-length vectors for entire documents. It captures semantic information by training a neural network to predict the context of words within a document. Doc2Vec assigns a unique vector to each document, enabling comparison and clustering of documents based on their content(Lau & Baldwin, 2016).

mUSE (Multilingual Universal Sentence Encoder) is a pre-trained sentence encoder

developed by Google Research. It maps variable-length text inputs into fixed-length vectors, capturing semantic similarity across multiple languages.

LSA (Latent Semantic Analysis) is a dimensionality reduction technique applied to large textual corpora. It analyzes the relationships between words and documents based on the co-occurrence of terms.

LDA (Latent Dirichlet Allocation) is a probabilistic generative model used for topic modeling. It assumes that documents are composed of multiple topics, each characterized by a distribution of words. LDA infers the underlying topic structure of a document collection and assigns a probability distribution over topics for each document.

BERT (Bidirectional Encoder Representations from Transformers), introduced by Google, employs a transformer architecture to capture bidirectional contextual information from text(Devlin et al., 2018). It consists of multiple layers of transformers, enabling it to understand the context of a word within a sentence based on both preceding and succeeding words(Chi et al., 2019).

Sentence-Transformers(ST), inspired by the success of BERT, extend its capabilities to encode entire sentences or paragraphs into fixed-length embeddings. Unlike BERT, which focuses on token-level representations, ST generates embeddings at the sentence level. These embeddings capture the contextual relationships between words within a sentence.

2.5 Task and Datasets Description

The SemRel Task 1-A is based on a collection of datasets in 9 different languages(Ousidhoum et al., 2024B). Each instance in the training, development, and test sets is a sentence pair. The instance is labeled with a score representing the degree of semantic textual relatedness between the two sentences. The scores can range from 0 (maximally unrelated) to 1 (maximally related. The size of the datasets is detailed in Appendix A. The official evaluation metric for this task is the Spearman rank correlation coefficient, which captures how well the system-predicted rankings of test instances align with human judgments.

3 System Overview

In our study, we implemented a systematic approach to enhance the learning process of our classifier. To augment the available training data, we merged the datasets of the training and development sets. This consolidation aimed to enrich the information on which our classifier is trained. Subsequently, we conducted experiments where each model was evaluated on both raw sentences and preprocessed sentences. The preprocessing steps included removing punctuation marks, numeric characters, and URL addresses, and converting text to lowercase.

At each stage of the learning process, we employed various text embedding methods to convert sentence pairs into vector pairs. These text embedding methods were pivotal in capturing the semantic relationships between sentences. Following the generation of vector pairs, we trained a regression model to learn the Semantic Textual Relatedness (STR) label between the vector pairs. The trained model was then tasked with predicting the STR level for unlabeled vector pairs present in the test set. Subsequently, we performed a comparative analysis of all results and selected the best-performing models for each language under investigation.

Furthermore, we evaluated the performance of eleven machine learning regressors to determine their efficacy in predicting the STR label. These regressors include:

Linear Regression: A basic regression model that models the relationship between independent and dependent variables linearly.

Ridge Regression: A regression model that uses L2 regularization to prevent overfitting.

Gradient Boosting Regressor: An ensemble learning technique that builds decision trees sequentially, each correcting the errors of the previous one.

AdaBoost Regressor: Another ensemble learning method that combines multiple weak learners to create a strong learner.

Support Vector Regressor (SVR): A regression algorithm that finds the hyperplane that best fits the data points while minimizing the error. SVM is a supervised learning algorithm that is used for classification and regression analysis(Cortes and Vapnik, 1995; Chang & Lin, 2011).

Stochastic Gradient Descent (SGD) Regressor: A linear model trained using stochastic gradient descent.

Bayesian Ridge Regression: A regression model that is based on the Bayes theorem (Kim et al., 2006), and assumes that features are conditionally independent given the target class, estimates the probabilities of each class and the probabilities of each feature given the class, and use it to make predictions.

Decision Tree Regressor: A regression model that partitions the data into subsets based on feature values.

Random Forest Regressor: An ensemble learning method that builds multiple decision trees and outputs the average prediction. (Breiman, 2001). It combines Breiman's "bagging" (Bootstrap aggregating) idea in Breiman (1996) and a random selection of features introduced by Ho (1995) to construct a forest of decision trees.

K Neighbors Regressor: A non-parametric regression model that predicts the output based on the average of the 'k' nearest neighbors.

MLP Regressor (Multi-layer Perceptron): A neural network model with multiple layers that learns complex data patterns. Inputs are received by the input layer, processed through the hidden layers, and produce the final output (Hassan et al., 2016).

Each regressor was evaluated based on its performance in predicting the STR label, providing insights into the effectiveness of different regression techniques in our task.

4 Experimental Setup

Our way of working was based on the train and dev datasets only. The goal was to train different models on the train dataset and select the best models according to the Spearman rank score (according to the competition requirement) on the dev dataset.

For all embedding methods(see Appendix B for details), we applied the following process. In the first step, for each language, converted the sentence pairs to vectors, using different embedding methods. Every method was checked twice – one with the original pair and one with a preprocessed pair. In total, for each language, we tested 5 classic embedding methods, 4 methods based on Sentence-Transformers, and 8 methods based on BERT.

That is, for each language different embedding methods were tested, once on raw text and once on pre-processed text, and for each of these methods we trained 11 regression models. We also trained additional BERT models for English, Spanish, Moroccan Arabic, and Algerian Arabic, so that in total we compared 3572 models (for all languages together), and at least 374 models for each language.

The following tools and information sources were utilized to apply these ML methods:

Python 3.8 programming language (Van Rossum & Drake, 2009),

Sklearn – a Python library for ML methods (Buitinck et al., 2013),

Numpy – a Python library for fast algebraic calculation (Harris et al., 2020),

Pandas – a Python library for efficient data analysis (McKinney, 2010),

TensorFlow – an open-source Python library for constructing ML-DL models (Abadi et al., 2015), and

Transformers – a Python library for natural language processing, offering pre-trained models based on transformer architecture (Wolf et al., 2020).

Hugging Face - provides a platform for data scientists to access and utilize cutting-edge models (Huggingface API, 2024).

5 Experimental Results

Table 1 presents the Spearman rank score of our models for task 1A. The table shows for each language the ideal model we received, its embedding method, whether it performed pre-processing, which regressor it used, what was the score we received in the training phase (distribution of train+dev in the ratio 20:80), what was the actual score we received after submission to the competition, and what was our position in the competition as well as what is the best result achieved. The full results can be seen in Appendix C.

It seems that vector assignment in BERT-based embedding methods was better than classical methods or Sentence Transformers library-based methods. This is probably due to the work that these models were massively trained on a lot of information, with the help of huge resources, and are therefore able to characterize vectors that optimally deliver the texts. Also, BERT models know how to characterize words with their context, and this may be a significant fact concerning the STR task.

In most languages, except Spanish and Kiryanwanda, a BERT model that is multilingual was better than a BERT model that was trained only on this or a similar language. This is a surprising figure as we were sure that a specific model would excel more reliably in this language. However, it seems that the models in low-resource languages are weaker and trained on less information compared to huge models from the multilingual genre.

Among the classical embedding methods, tf-idf seems to be the most successful method because it reaches reasonable achievements even for some of the BERT models, but is still far from the best of them.

The most prominent classifiers in the best models are the Random Forest Regressor, SVR regressor, and Bayesian regressor. They are based on classic machine learning algorithms - Random Forest, Support Vector Machine, and Naive Bayes which are recognized as classic classifiers but strong and good in many ML tasks.

Despite the well-known advantages of preprocessing methods in ML tasks, it seems that there is an overall balance between models that were quicker to preprocess their text and models that worked better on the raw text. It may be that more advanced preprocessing methods such as stemming or lemmatization will be more helpful for learning, but because In most languages it was difficult to find tools that would perform this processing of texts.

6 Conclusions and Future Research

In this paper, we describe our submissions to subtask 1-A and of SemEval-2024.

We applied 17 embedding methods to convert text into vectors, 11 supervised machine learning methods, to predict regression of STR, and did it to 9 different languages.

While our study demonstrates promising outcomes across multiple languages and embedding techniques, a comprehensive error analysis reveals nuanced challenges that warrant further investigation. We observed recurrent patterns of misclassifications, particularly in contexts characterized by linguistic ambiguities, and cultural nuances, and might be affected by the prevalence of sarcasm or irony. These findings highlight the need for robust feature representation and domain-specific adaptations to enhance the accuracy and reliability of sentiment analysis models.

Moreover, our error analysis sheds light on the impact of preprocessing strategies on model performance, revealing a delicate balance between text normalization and the preservation of linguistic subtleties. While preprocessing techniques such as stemming or lemmatization hold promise for improving model generalization, their efficacy varies across languages and datasets, necessitating careful consideration in model development pipelines. We assume that by focusing on one or two languages, we would be able to examine the specific effect of each pre-processing method, as well as focus on the unique characteristics of each language in terms of morphological structure or methods for simplifying and decomposing words, to enable better processing and better results.

There are various ideas for future research regarding the nature of Twitter messages:

(1) use mot preprocessing methods to bring the text to a more understandable shape.

(2) Trying to enrich our training dataset and tune more parameters and longer training because deep learning becomes better with more data to train and more time.

(3) Error analysis must be performed in-depth and repetitive patterns of errors, consistently incorrect classifications, etc. must be identified, to allow for the correction and improvement of the models.

The STR task is an important task that can contribute in many fields, and this study is a milestone in my acquaintance with this task and in developing the way to do it properly.

Language	Classifier	Embedding Type	Pre process	Train Score	Test Score	Rank	SemRel Best Score

Abstract

This paper presents the application of BERT in SemEval 2024 Task 2, Safe Biomedical Natural Language Inference for Clinical Trials. The main objectives of this task were: First, to investigate the consistency of BERT in its representation of semantic phenomena necessary for complex inference in clinical NLI settings. Second, to investigate the ability of BERT to perform faithful reasoning, i.e., make correct predictions for the correct reasons. The submitted model is fine-tuned on the NLI4CT dataset, which is enhanced with a novel contrast set, using binary cross entropy loss.

1 Introduction

NLI stands for Natural Language Inference. It is a task in natural language processing (NLP) where the goal is to determine the relationship between two text segments: a premise and a hypothesis. The task typically involves classifying whether the hypothesis is entailed, contradicted, or neutral with respect to the premise.

NLI has emerged as a beacon of hope for Clinical Trial Reports (CTRs). Its ability to handle vast amounts of medical evidence could revolutionize the interpretation and retrieval of CTRs. Clinical trials stand as pillars in experimental medicine, scrutinizing the efficacy and safety of novel treatments (Avis et al., 2006). CTRs meticulously outline trial methodologies and findings, guiding the development of targeted interventions for patients. Yet, the staggering quantity of published CTRs renders manual review impractical for devising new treatment protocols (DeYoung et al., 2020).

The proposed textual entailment task aims to advance the understanding of models' behavior and enhance existing evaluation methodologies for clinical NLI. By systematically applying controlled interventions, each engineered to probe a specific semantic phenomenon in natural language and numerical inference, the study seeks to assess the robustness, consistency, and faithfulness of models in clinical settings, thereby investigating their reasoning capabilities.

In this paper, we present our findings on SemEval 2024 Task 2, Safe Biomedical Natural Language Inference for Clinical Trials (Jullien et al., 2024). The aim of our method is to assess the robustness, consistency, and faithfulness of BERT (Devlin et al., 2019), Pre-training of Deep Bidirectional Transformers for Language Understanding, on the clinical NLI. Our method follows to steps: the first step is fine-tuning BERT on the Multi-evidence Natural Language Inference for Clinical Trial Data (NLI4CT) (Jullien et al., 2023) which is enhanced with a novel contrast set. Then, the prediction step, consists on the determining the inference relation (entailment vs contradiction) between CTR - statement pairs.

The rest of the paper is structured in the following manner: Section 2 provides the main objective of the Task. Section 3 describes our system. Section 4 details the experiments. And finally, Section 5 concludes this paper.

2 Task Description

This paper focuses on the task of textual entailment within the domain of clinical trial data analysis, specifically targeting Clinical Trial Reports (CTRs). CTRs serve as comprehensive documents containing essential information regarding various aspects of clinical trials, including eligibility criteria, interventions, results, and adverse events. Automating the analysis of CTRs through natural language processing techniques can significantly facilitate researchers' understanding and decision-making processes.

The task of NLI4CT involves analyzing annotated statements and determining their inference relation with the information contained in the CTR premises. These statements, characterized by an average length of 19.5 tokens, make claims about

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 432–436

various sections of the CTRs, including:

- **Eligibility criteria**: A set of conditions for patients to be allowed to take part in the clinical trial
- **Interventions**: Information concerning the type, dosage, frequency, and duration of treatments being studied.
- **Results**: Number of participants in the trial, outcome measures, units, and the results.
- **Adverse events**: These are signs and symptoms observed in patients during the clinical trial.

The NLI4CT task presents several challenges inherent to clinical trial data analysis, including numerical and quantitative reasoning, vocabulary and syntax variations, and comprehension of complex semantic structures. To address these challenges, interventions have been implemented targeting the following aspects:

- **Numerical Reasoning**: Models' abilities to apply numerical and quantitative reasoning are specifically targeted, given the importance of such inference in clinical trial analysis.
- **Vocabulary and Syntax**: Acronyms, aliases, and syntactic patterns common in clinical texts are addressed to improve model robustness and performance.
- **Semantics**: Complex reasoning tasks involving longer premise-hypothesis pairs are intervened upon to enhance model capabilities in handling intricate semantic structures.

3 System Description

To evaluate BERT on the SemEval 2024 Task 2: Safe Biomedical Natural Language Inference for Clinical Trials, we have fine-tuned BERT model on the NLI4CT dataset. we follow standard procedures for fine-tuning transformer-based models on natural language inference tasks. Here's a description of the process:

- **Data Preprocessing**: Tokenize the CTR premises and statements using the BERT tokenizer. Encode the tokenized sequences into input IDs, attention masks, and segment IDs as required by BERT.
- **Model Architecture**: Utilize the BERT architecture, which is a pre-trained transformer model. Add a classification layer on top of the BERT model to predict the entailment relation (entailment vs. contradiction) between the CTR premises and statements.
- **Fine-tuning Objective**: Fine-tune the pre-trained BERT model on the NLI4CT task using supervised learning. Minimize the binary cross-entropy loss between the predicted entailment labels and the ground truth labels.
- **Training Procedure**: Train the fine-tuned BERT model on the training data comprising CTR premises and statements along with their corresponding labels (entailment or contradiction).

4 Experimental Results

We experimented our model on on the SemEval 2024 Task 2: Safe Biomedical Natural Language Inference for Clinical Trials. The experiment has been conducted in Google Colab environment[1], The following libraries: Transformers - Hugging Face[2] (Wolf et al., 2020), and Tensorflow[3] were used to train and to assess the performance of the model.

4.1 Datasets

The premises within NLI4CT are sourced from 1000 publicly accessible Breast cancer Clinical Trial Reports (CTRs) in English[4]. These records are overseen by the U.S. National Library of Medicine and adhere to the HIPAA Privacy Rule. The CTRs are categorized into four sections: Eligibility criteria, Intervention, Results, Adverse Events (Jullien et al., 2023).

A team of domain experts, including organizers of clinical trials from a prominent cancer research institution, participated in annotating the data. Annotators were tasked with generating entailment statements based on two CTR premises. These entailment statements make objectively true claims about the content of the premises. Annotators could choose to create statements regarding one or both premises. Substantial statements typically involve

[1] https://colab.research.google.com/
[2] https://huggingface.co/docs/transformers/index
[3] https://tensorflow.org
[4] https://ClinicalTrials.gov

summarization, comparison, negation, relation, inclusion, superlatives, aggregation, or rephrasing, requiring an understanding of multiple aspects of the premise. Annotators then select a subset of facts from the premises to support the claims in the statement.

Subsequently, a negative rewriting technique (Chen et al., 2020) was employed, altering the previously generated entailment statements to include objectively false claims while maintaining the original sentence structure and length. This technique aims to mitigate the likelihood of stylistic or linguistic patterns favoring either entailment or contradictory statements. Annotators then extract a subset of facts from the premises that contradict the claims in the false statement.

The resulting dataset comprises 2400 annotated statements with labels, premises, and evidence. The dataset was divided into train/test/dev sets in a 70/20/10 ratio. The two classes and four sections are evenly distributed across the dataset and its partitions (Jullien et al., 2023).

4.2 Evaluation Metric

The assessment of task performance will entail multiple stages. Initially, the performance on the original NLI4CT statements without any alterations, employing the Macro F1-score for evaluation.

Subsequently, the performance will be assess on the contrast set, comprising all statements with interventions. In this evaluation, two novel metrics—faithfulness and consistency—will be utilized, with their definitions provided below.

- **Faithfulness**: quantifies how accurately a system predicts outcomes for the right reasons. Essentially, it assesses the model's capacity to adjust its predictions accurately when encountering semantic-altering interventions. To compute faithfulness for a set of N statements x_i in the contrast set C, alongside their original statements y_i and model predictions f(), Equation 1 is utilized.

$$Faithfulness = \frac{1}{N}\sum_{1}^{N} |f(y_i) - f(x_i)| \quad (1)$$

$$x_i \in C : Label(x_i) \neq Label(y_i), and f(y_i) = Label(y_i)$$

- **Consistency**: assesses how consistently a system generates identical outputs for problems that are semantically equivalent. Consequently, it gauges a system's capability to assign the same label to both original statements and contrast statements for interventions that preserve semantics. This means that even if the ultimate prediction is incorrect, the representation of the semantic phenomenon remains consistent across the statements. To calculate consistency for a set of N statements x_i in the contrast set C, along with their corresponding original statements y_i and model predictions f(), Equation 2 is employed.

$$Consistency = \frac{1}{N}\sum_{1}^{N} 1 - |f(y_i) - f(x_i)| \quad (2)$$

$$x_i \in C : Label(x_i) = Label(y_i)$$

4.3 Experimental Settings

During the fine-tuning of BERT model on the NLI4CT taining set, we set the hyper-parameters as follows: 10^{-5} as the learning rate, 30 epochs, 64 as the max sequence length, and 16 as batch size. Table 1 summarizes the hyperparameters settings of BERT base model.

Hyperparameters	Settings
Learning rate	10^{-5}
Batch size	16
Epochs	30
Max sequence length	64
Optimizer	Adam (Kingma and Ba, 2015)
Loss	Binary Cross Entropy

Table 1: Hyperparameters settings for the model in the experiments

4.4 System Performance

The reported results for the fine-tuned BERT model on the NLI4CT task are as follows:

- **Macro F1-score**: 0.62
- **Faithfulness**: 0.44
- **Consistency**: 0.54

The model achieved the 26th position in Macro F1-score, Faithfulness and Consistency among a total of 32 teams. The reported score of 0.62 in the Macro F1-score indicates that the model achieves moderate performance in accurately predicting the inference relation between CTR premises and statements. Moreover, the Faithfulness score, which is 0.44, suggests that the model struggles in making correct predictions for the right reasons. This indicates potential issues with reasoning or interpretation of the textual entailment task. On the other hand, the Consistency score, which is 0.54, indicates moderate consistency in the model's outputs for similar instances. However, there is room for improvement to achieve higher consistency.

The suboptimal performance of the fine-tuned BERT model on the NLI4CT task could be attributed to several factors: Firstly, clinical trial data, especially Clinical Trial Reports (CTRs), often contain domain-specific terminology, complex medical concepts, and nuanced language. BERT, being pre-trained on general-domain text, may struggle to comprehend and accurately reason over such specialized content. Secondly, The success of fine-tuning BERT depends on various hyperparameters, such as learning rate, batch size, and optimization algorithm. Suboptimal choices for these parameters can hinder convergence and degrade model performance. Thirdly, The interventions applied to the test set statements could introduce complexities or biases that the model is not equipped to handle, the model may struggle to generalize effectively. By addressing these factors the model performance can be improved in clinical trial data analysis tasks.

5 Conclusion

in this paper, an investigation is conducted into the utilization of BERT for NLI4CT, which underscores the complex nature of textual entailment tasks within the medical domain. The described approach tackles SemEval 2024 Task 2: Safe Biomedical Natural Language Inference for Clinical Trials. The model secured the 27th position among a total of 32 teams.

Despite challenges such as domain-specific terminology and nuanced semantics, our study reveals the potential for advancements in automated analysis of clinical trial reports. By recognizing the need for domain-specific approaches and leveraging the models, we pave the way for more accurate and reliable models tailored to the intricacies of medical data. Ultimately, our findings advocate for continued research and development efforts aimed at enhancing natural language processing techniques for clinical applications, thereby contributing to improved healthcare outcomes and medical decision-making processes.

Abstract

We present a baseline for the SemEval 2024 task 2 challenge, whose objective is to ascertain the inference relationship between pairs of clinical trial report sections and statements.

We apply prompt optimization techniques with LLM Instruct models provided as a Language Model-as-a-Service (LMaaS).

We observed, in line with recent findings, that synthetic CoT prompts significantly enhance manually crafted ones.

The source code is available at this GitHub repository github.com/ClementBM-CLB/semeval-2024.

1 Introduction

Since the introduction of large pre-trained transformer models such as GPT-3.5, released in early 2022, foundational models have begun to be utilized widely. While BERT-like models have proven to be effective in various NLP tasks such as Named Entity Recognition (Devlin et al., 2019), scaling up the number of parameters in transformer models not only enhances their capabilities but also endows them with new abilities not seen in smaller models (Zhao et al., 2023). These capabilities are particularly evident in natural language inference tasks, where the model must deduce the veracity of two given texts (Zhong et al., 2023).

LLMs, gaining popularity for their reasoning capabilities, still face trustworthiness concerns, crucial in the medical domain where decisions affect lives. Medical devices must exhibit reliability and undergo rigorous testing before they are brought to market. SemEval 2024 (Jullien et al., 2023b, 2024) focuses on assessing NLI system robustness, coherence, and accuracy, particularly LLMs prone to shortcut learning, factual discrepancies, and performance degradation from word distribution shifts (Liu et al., 2023).

Fine-tuning, while effective for task and domain adaptation, demands excessive resources in the case of large language models (LLMs). In the medical field, data is highly sensitive and protected by privacy regulations. Therefore, applying fine-tuning techniques to such sensitive data would imply that medical centers have readily available on-premise infrastructure (Sun et al., 2023). Considering these limitations, we investigate hard prompt optimization techniques such as Chain-of-Thought prompting (Wei et al., 2023). Acknowledging the in-context learning (ICL) as an indirect method of fine-tuning, we also explored in-context learning strategies (Dai et al., 2023). Among them, we were particularly inspired by MedPrompt, a promising composite prompting method applied to medical datasets, which achieved a 27% reduction in error rates on MedQA (Nori et al., 2023).

Following the SemEval 2024 task 7 (Jullien et al., 2023a), SemEval 2024 task 2 focuses on identifying the inference relationship (entailment vs. contradiction) between Clinical Trial Report (CTR) statement pairs. These statements and the supporting evidence are crafted by individuals with expertise in the clinical domain, including clinical trial organizers and research oncologists. The clinical trials information is sourced from the [1]clinicaltrials.gov website (maintained by the NIH). We have evaluated three LLM prompting methods to address this task.

2 Methods

2.1 Tasks

The challenge involves analyzing a statement alongside one or two clinical trial reports to ascertain if the statement logically follows from the information presented in the clinical trial. Typically, a statement is a concise text averaging 19.5 words and may contain one or several claims pertaining

[1]https://clinicaltrials.gov/

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 437–442

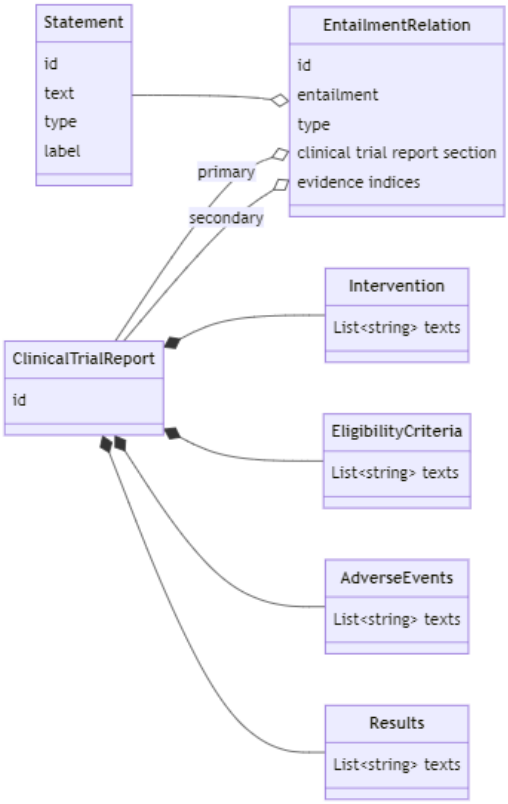

Figure 1: SemEval 2024 dataset data model

to the clinical trial. It refers to one of four sections of the clinical trial report: Adverse Events, Eligibility Criteria, Results, or Interventions. Each section represents a distinct part of the clinical trial documentation as recorded in the clinicaltrials.gov database. The text from these sections has an average length of 265 words.

For the purpose of evaluating this task, the evaluation dataset was generated to allow us to assess the reliability (faithfulness) and consistency of the inference predictions. This was achieved by paraphrasing the text to retain the same meaning, as well as by making minor alterations to the text that change the inference relationship.

2.2 Prompting

We explored three prompting optimization techniques: 1) OPRO approach, which iterates over labeled examples to determine the most effective instruction (Yang et al., 2023), 2) self-generated chain of thought (Kojima et al., 2023), 3) in-context learning (ICL) strategy by incorporating one example for one-shot prompting (Nori et al., 2023).

2.3 OPRO optimization

The OPRO technique exploits the model's capability to generate prompts based on a few exemplars and previous instructions.

In essence, the model is tasked with creating prompt instructions that are intended to solve the given problems. While this method enables the discovery of the most suitable instructions for each set, it still demands extensive resources due to its iterative optimization process. For this reason, we apply this technique to only a subset of representative examples from the development dataset.

Algorithm 1: OPRO prompt optimization

Data: N samples, M test samples and P instructions and their F1 scores
Result: P instructions
for *10 times* **do**
  Format the P instructions and N samples as a context C for the LLM
  Generate instruction with the LLM and context C
  for M *test samples* **do**
    Format the instruction and the test sample as a context
    Generate prediction with the LLM
  end
  Calculate the F1 score for the generated instruction
  Add the new instruction to the P list if its F1 score is greater than the lower instruction's score of the list
end

2.4 Zero-shot Chain-of-Thought prompt

Unlike the previous method, which constrained instructions based on the type and section of the sample, we allowed the model to generate a chain of thought reasoning using a task-agnostic meta-prompt.

The model first generate a CoT reasoning to answer the question. Then, given the previous, it is prompted to generate a conclusion and provide the final answer—whether it entails or contradicts—in a standardized json format (algorithm 2). See the figure 3 in appendix for a detailed example.

2.5 Dynamic one-shot Chain-of-Thought prompt

We hypothesized that selecting one meaningful example from a set (statement, clinical trial report)

Algorithm 2: Zero-shot Chain-of-Thought prompt

Data: N samples
Result: N predictions
for N *samples* **do**
  Format the N samples as a context $C_{reasoning}$
  Generate chain-of-thought with the LLM and the context $C_{reasoning}$
  Format the generated chain-of-thought with the sample and the formating instruction
  Generate the prediction with the LLM and the context $C_{formating}$
end

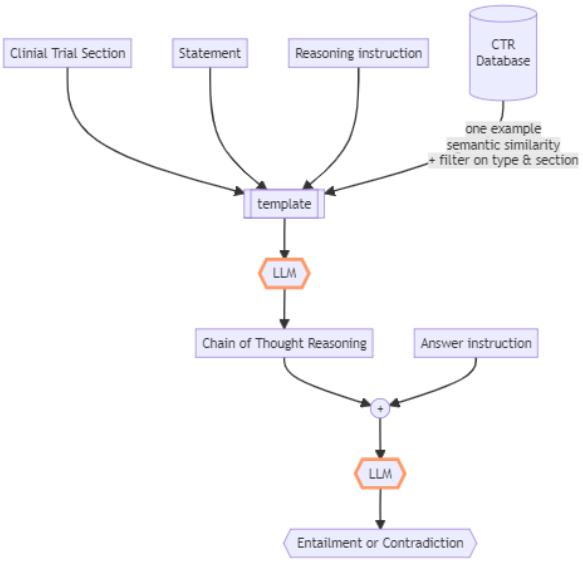

Figure 2: Dynamic one-shot prompting workflow

with a correct reasoning path could enhance the performance of the NLI system.

This experiment is divided into two tasks. First, we build a database of exemplars from the train dataset. Each sample corresponds to a statement and a clinical trial report section, along with its associated reasoning path (generated by the model) and predicted label. We filter the records where the model provides correct answers and index the embeddings of the statements into a vector database.

Next, for each test sample, we select a sample from the train dataset that is semantically close according to the squared L2 distance defined as $d = \sum \left(s_i - s_i^{train}\right)^2$. We choose the s^{train} sample with the lowest distance to the s sample that has either the same type, the same section, or both, preferably.

Algorithm 3: Vector database building

Data: N training samples
Result: Vector database of statement and reasoning paths
for N *samples* **do**
  Calculate the embeddings of the statement
  Generate prediction following the same procedure as in Algorithm 1
  If the prediction is accurate, add the embedding vector to the database
end

3 Language models

We evaluated Mixtral-8x7B-Instruct (Jiang et al., 2024), GPT3.5 (Ouyang et al., 2022), Qwen-72b-chat (Bai et al., 2023), and Mistral-7B-Instruct. For all inference tasks, except instruction generation, we did not use sampling techniques.

To calculate vector embeddings, we utilized the msmarco-bert-base-dot-v5 model, in conjunction with [2]chromadb to store the embeddings in a vector database, thereby facilitating similarity score calculations using L2 norm.

4 Evaluation metrics

Faithfulness measures the extent to which a given system arrives at the correct prediction for the correct reason. This is estimated by measuring the ability of a model to correctly change its predictions when exposed to a **semantic altering** intervention. Given N statements x_i in the contrast set (C), their respective original statements y_i, and model predictions $f()$ we compute faithfulness using Equation 1.

$$Faithfulness = \frac{1}{N}\sum_{1}^{N} |f(y_i) - f(x_i)|$$
$$x_i \in C : \text{Label}(x_i) \neq \text{Label}(y_i), \text{ and } f(y_i) = \text{Label}(y_i) \quad (1)$$

Consistency aims to measure the extent to which a given system produces the same outputs for semantically equivalent problems. Therefore, consistency is measured as the ability of a system to

[2]https://www.trychroma.com/

Model	Optimization	Base F1	Consistency	Faithfulness
Mixtral-8x7B	Zero-shot CoT	0.70	0.70	0.87
Mixtral-8x7B	Dynamic one-shot	0.60	0.71	0.89
Mixtral-8x7B	OPRO	0.59	0.65	0.81

Table 1: Prompt optimization strategies with Mixtral-8x7B-Instruct-v0.1 on the test dataset

predict the same label for original statements and contrast statements for **semantic preserving** interventions. Given N statements x_i in the contrast set (C), their respective original statements y_i, and model predictions $f()$ we compute faithfulness using Equation 2.

$$Consistency = \frac{1}{N}\sum_{1}^{N} 1 - |f(y_i) - f(x_i)| \quad (2)$$
$$x_i \in C : \text{Label}(x_i) = \text{Label}(y_i)$$

5 Results

5.1 Main results

Our team ranked sixth in faithfulness score, and we fell outside the top 10 for the baseline F1 score (0.70) and consistency (0.70). We observed that handcrafted prompts were generally less effective than optimized prompts or meta-prompts.

Prompting strategies were first tested on the dev dataset and then run on the test dataset. The results are shown in the table 1. Mixtral-8x7B-Instruct demonstrated the best quality-to-time ratio. The dynamic one-shot prompting achieved the highest Faithfulness score and Consistency score. While the best F1 score goes for the zero-shot CoT prompt approach. These results must be interpreted with caution because the model does not always return a well-formatted answer in JSON format. In cases where the answered entailment label is unknown, our approach was to prioritize the contradiction label.

Because of time limitations, we had to train and assess the prompt strategy using the development dataset, which consisted of 200 samples. We solely used the training dataset to gather examples for inputting into the vector database for the one-shot prompt strategy. The execution of the entailment task on the test dataset required 20 hours for each prompting strategy. The team's outcomes for the task are presented in table 2.

Ranking	Base F1	Base F1	Faithfulness	Consistency
1	dodoodo	0.78 (3)	0.92 (3)	0.81 (1)
2	aryopg	0.78 (5)	0.95 (2)	0.78 (2)
3	jvl	0.78 (4)	0.80 (13)	0.77 (3)
.	.	.	.	.
17	ClementBM	0.70 (18)	0.87 (6)	0.70 (17)
.	.	.	.	.

Table 2: Team ranking on the test dataset

5.2 Other evaluations

We also investigated reformulation methods, such as rephrasing negative statements, paraphrasing statements to maintain the original meaning, and rewording sections of the clinical trial report (Cheng et al., 2023), we did not observe an improvement in inference accuracy (data not shown).

We observed that applying dynamic one-shot technique (F1=0.60) obtained a 10-point drop compared to the Zero-Shot CoT (F1=0.70). We also observed that implementing preprocessing steps could improve the performance of the entailment task (such as enriching the clinical trial section with additional information, transforming negative statements into positive ones, etc.).

While experimenting with various prompt instructions to reformulate or paraphrase the statement before logical prediction on inference, we found that it didn't significantly improve performance. One detail worth mentioning is perhaps a processing step on the clinical trial report section. We observed that the model sometimes struggles to identify which paragraph of the report section matches which cohort. To address this, we explicitly added the cohort number to the subtitle of the section. All other lines of the section were concatenated without change, each separated by a newline.

6 Conclusion

By employing prompt optimization techniques with LLM Instruct models, we see the significant enhancement Zero-shot CoT prompts provide compared to manually crafted ones. This highlights the critical role of utilizing advanced techniques in LLM prompting to enhance inference tasks, particularly in domains like clinical trials.

SuteAlbastre at SemEval-2024 Task 4: Predicting Propaganda Techniques in Multilingual Memes using Joint Text and Vision Transformers

Ion-Marian Anghelina, Gabriel-Sebastian Buță and **Alexandru Enache**
University of Bucharest
Faculty of Mathematics and Computer Science
{ion.anghelina, gabriel.buta, alexandru.enache1}@s.unibuc.ro

Abstract

The main goal of this year's SemEval Task 4 is detecting the presence of persuasion techniques in various meme formats. While **Subtask 1** targets text-only posts, **Subtask 2**, subsections **a** and **b** tackle posts containing both images and captions. The first 2 subtasks consist of **multi-class** and **multi-label** classifications, in the context of a **hierarchical** taxonomy of 22 different persuasion techniques.

This paper proposes a solution for persuasion detection in both these scenarios and for various languages of the caption text. Our team's main approach consists of a Multimodal Learning Neural Network architecture, having Textual and Vision Transformers as its backbone. The models that we have experimented with include EfficientNet and ViT as visual encoders and BERT and GPT2 as textual encoders.

1 Introduction

In nowadays society, the role of social media in opinion formation is more important than ever. A fundamentally form of social media leisure, the meme has become a powerful resource which can easily be abused by various entities with political interests. The most well known platforms have a strict policy regarding misleading information, especially of political nature. However, posts containing such information are hard to automatically detect, and the administrators mostly rely on user reports.

This paper proposes an automatic detection solution for Arabic, Bulgarian, English and North Macedonian, suitable for both text-only and text-image memes. (Dimitrov et al., 2024)

Only English training data was provided for all the Subtasks, all the other languages' tasks requiring a One-Shot Learning approach.

The proposed model excels on **Subtask 2a**, scoring 2^{nd} place for all languages, besides English and also on **Subtask 2b** where it also ranked second, achieving an $F1$-score of over 0.8 in the binary setup. It struggled, however, on **Subtask 1**, especially in the case of the Subtask variants for languages without training samples, achieving an $F1$-score of about 0.2 on average.

The full results table can be found in the **Results** subsection in Table 6.

Python code for all the used models and algorithms is available in our GitHub Repository.

2 Background

2.1 Related Work

Dimitrov et al. in "Detecting propaganda techniques in memes" have also conducted their own approach of solving the **Subtask 1** and **Subtask 2b** on their own dataset in a Multimodal setup (Dimitrov et al., 2021).

Martino et al. in "A Survey on Computational Propaganda Detection" reviewed the state of the on computational propaganda detection from both the perspective of using Natural Language Processing in order to detect propaganda, as well as analysing users profiles in order to detect a propaganda networks on media platforms (Martino et al., 2020). They tackle **Subtask 1** and **Subtask 2b** as well, being, however, asked to also provide all the occurences' positions for each propaganda technique.

2.2 Input

The text information is given as a JSON which, for each meme, it has a unique **id** assigned, a **text** representing the text that is written on the meme. For the **Subtask 2a** and **Subtask 2b** we also have a **image** attribute representing the name of the image to which the previously mentioned information is corresponding.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 443–449

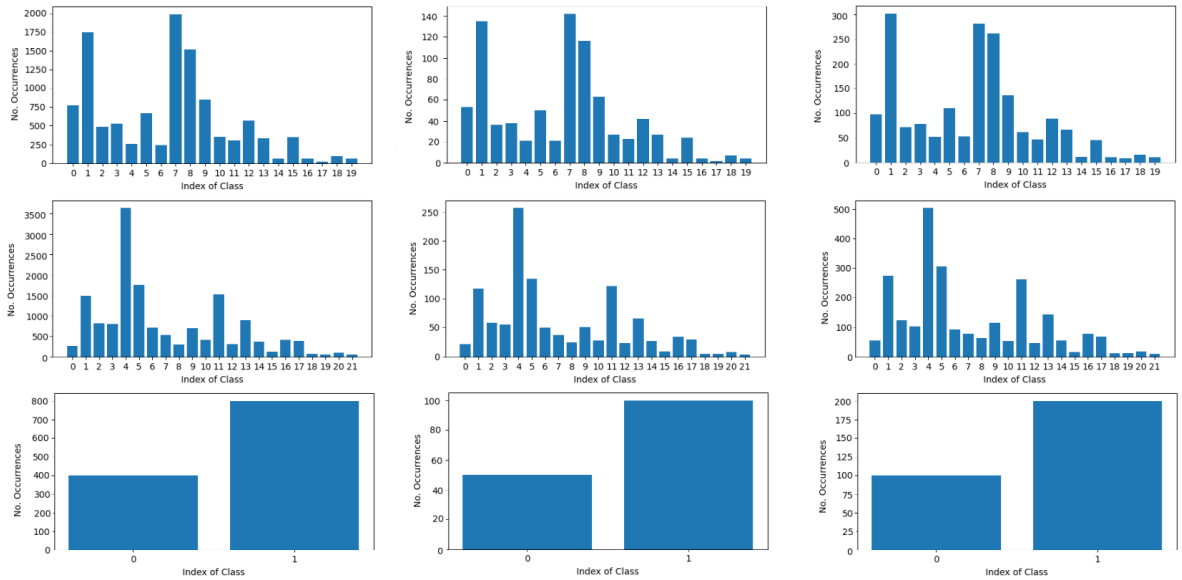

Figure 1: The class distribution for **Subtask 1**, **Subtask 2a** and respectively **Subtask 2b** (on rows) for the **train**, **validation** and respectively **dev** sets (on columns)

Below is an example extracted from the English test dataset for **Subtask 1**:

```
{
    "id": "64747",
    "text": "Just a few of the Rino's
        that need to go!!\\nRino season
        will be open soon!"
}
```

And another example from the English test dataset for **Subtask 2a**:

```
{
    "id": "79142",
    "text": "NOW ENTERING 2022",
    "image": "prop_meme_24023.png"
}
```

2.3 Output

For the **Subtask 1** and **Subtask 2a**, the output is returned in a JSON file which, for each meme, contains the unique **id** through which the photo was identified in the input, as well as a **labels** list containing the

labels corresponding to the meme. For **Subtask 2b**, instead of the labels list we will have only a **label** that is represented either by the string **propagandistic** or **non_propagandistic**. Below is an example extracted from a submission for the **Subtask 1** of the Arabic test dataset:

```
{
    "id": "00001",
    "labels": ["Black-and-white Fallacy/
        Dictatorship", "Presenting
        Irrelevant Data (Red Herring)"]
}
```

And another example from the Arabic test dataset for **Subtask 2b**:

```
{
    "id": "00007",
    "label": "non_propagandistic"
}
```

2.4 Dataset

The dataset is composed of memes with English captions present on them. For **Subtask 1** and **Subtask 2a**, we have **7000** train images, **500** validation images and **1000** dev images, while for **Subtask 2b**, we have **1200** train images, **150** validation images and **300** dev images.

From **Figure 1** we can observe that the class distribution is conserved throughout the train, validation and dev sets.

2.5 Datasets used

For the **English** task, for **Subtask 1**, **Subtask 2a** and **Subtask 2b**, we fine-tuned **limjiayi/bert-hateful-memes-expanded** (limjiayi, 2024) which is a model based on **bert-base-uncased** (Devlin et al., 2018a) which was previously fine-tuned on **HatefulMemes** (Kiela et al., 2020), **HarMemes** (Dimitrov, 2024) and **MultiOff**(Suryawanshi et al., 2020) datasets.

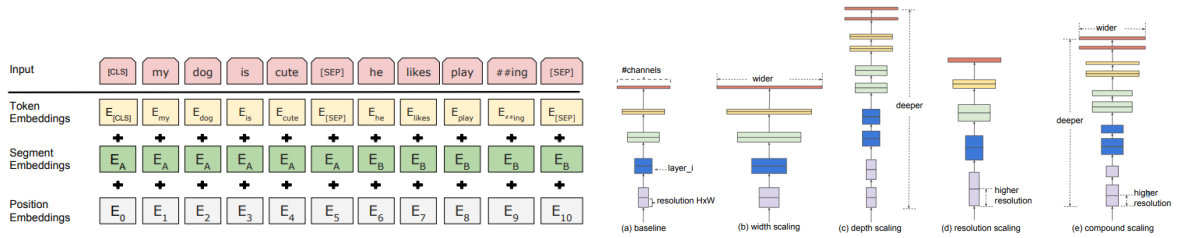

Figure 2: On the left side we have BERT Text Encoder Visual Representation (Devlin et al., 2018a) while on the right side we have the Model Scaling of an EfficientNet model (Tan and Le, 2019)

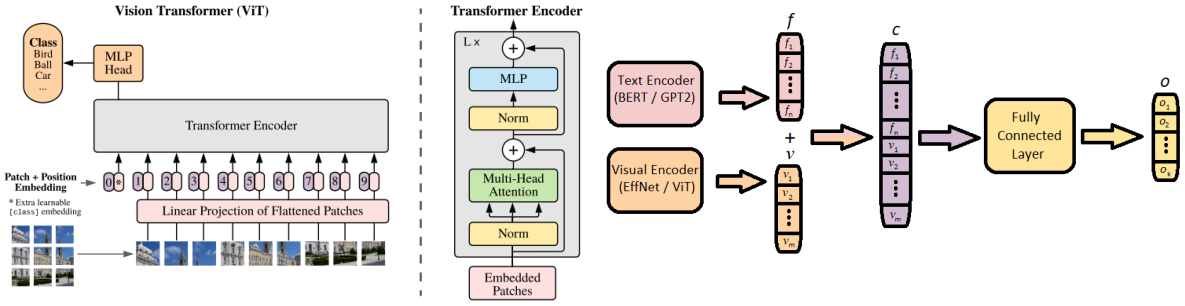

Figure 3: On the left side we have the model overview of a Vision Transformer (Radford et al., 2019) while on the right side we have our architecture of solving the proposed task

For the **Bulgarian** task, for **Subtask 1**, **Subtask 2a** and **Subtask 2b**, we used **usmiva/bert-web-bg** model (Marinova et al., 2023), an architecture pretrained from scratch BERT on Bulgarian dataset created at the Bulgarian Academy of Sciences.

For the **North Macedonian** task, for **Subtask 1**, **Subtask 2a** and **Subtask 2b**, we used **macedonizer/mk-gpt2** (Radford et al., 2019) model which is a model based on GPT2-large which was trained on English language using a causal language modeling.

For the **Arabic** task, for **Subtask 1** and **Subtask 2b**, we used **asafaya/bert-base-arabic** (Safaya et al., 2020) model which is a model based on BERT base fine-tuned on the arabic corpus. For **Subtask 2a** we used the **google-bert/bert-base-multilingual-uncased** model (Devlin et al., 2018b).

3 System Overview

3.1 Architecture Overview

For **Subtask 1**, our approach consists of using a text encoder which provides an accurate vectorial embedding of the memes captions. These representations are later used to train a **Fully Connected Neural Network**. The latter network's last layer consists of 20 **output neurons**, each representing the probability of existence of one of the 20 persuasion techniques.

For **Subtasks 2a and 2b**, the input format requires a special model branch for preprocessing the images. Similar to the **text encoder**, the **image encoder** outputs a dense feature vector representing a spacial embedding of the image. The results of the two encoders are used to train a similar Fully Connected Neural Network. In the case of **Subtask 2a**, the last layer of the neural network consist of 22 **output neurons**, each representing the probability of finding a certain persuasion technique. For subtask 2*b*, however, the last layer represents only 2 neurons, whose outputs are the probabilities of the text containing a persuasion technique or not.

While **Subtasks 1 and 2a** are treated as regression tasks with 20 and 22 output values, respectively, **Subtask 2b** is treated as a simple binary classification task.

3.2 Textual Encoders

For the text encoder branch of the model, pretrained variants of the following transformers were used:

- **BERT**(Devlin et al., 2018a) (Figure 2) is a very powerful text representation model, since it can capture large bidirectional links between words in order to build accurate word embeddings. It

relies on the self attention mechanism.

- **RoBERTa** (Liu et al., 2019) is an improved version of **BERT**, using a dynamic masking strategy during training, which is conducted over larger datasets and with a larger batch-size.

- **GPT-2** (Radford et al., 2019) is a transformer based model, pretrained on various dataset, which excels in the task of text generation based on a given prompt, but which can also be used as a backbone in any classification or regression task.

3.3 Visual Encoders

- **Vision Transformers** (Dosovitskiy et al., 2020) (Figure 3) are a class of Computer Vision models which, unlike their predecessors, do not rely on Convolutional Neural Networks as their backbone, but utilize the **Transformer** architecture, adapted from **NLP** tasks. It bears a resemblance to **BERT**, the main difference being that patches of the image are used instead of words. It was pretrained on the **ImageNet_21k** dataset. (Ridnik et al., 2021)

- **EfficientNet** (Tan and Le, 2019) (Figure 2) is a class of Convolutional Neural Network models which achieve high performance on image classification tasks. They mainly rely on automatically scaling the depth and width the network with respect to fixed parameters regarding the dataset to obtain the best possible results.

3.4 Predicting the answer

For **Subtask 1**, we denote $h_{i,j}$, the output of the **last hidden layer** of the textual encoder model the j^{th} token of the i^{th} sample.

Every sample in the training set has a fixed dimension of t tokens, and each token is embedded into a 768 dimensional vector. The fully connected neural network has a hidden layer of size d.

We first flatten $h_{i,j}$, obtaining f, a dense vector of embeddings for each word.

If we denote by (W, b) the tensor of weights between the transformer output layer and the output layer of the network, and the biases of the output layer respectively, the output of the output layer will be represented by:

$$W \cdot \tanh(f) + b$$

The output layer has 20 neurons. The result for each of them is computed by applying the $Sigmoid$ activation function, which outputs a probability.

Thus, the final output of the model is:

$$Sigmoid(W \cdot \tanh(f) + b)$$

For **Subtasks 2a and 2b**, the dense feature vector f is defined similarly, representing the textual extracted features.

We define similarly v, the vector of features extracted by the **Visual Encoder** and c, the vector obtained by concatenating f and v.

$$c = fv$$

For **Subtask 2a**, the output of the model is very similar to the one of **Subtask 1**, the main difference being that the output layer now has 22 neurons. (Figure 3)

The output of this model is:

$$Sigmoid(W \cdot tanh(c) + b)$$

For **Subtask 2b**, the output of the model is a probability distribution, the 2 classes of the binary classification being dependent of each other. We can obtain such an output using the $Softmax$ activation function.

The output is, thus:

$$Softmax(W \cdot tanh(c) + b)$$

Where W and b are defined similarly to **Subtask 1**.

The outputs of the model for **Subtasks 2a** and **2b** are, then, compared to a threshold, which represents the lower limit of the probability for a persuasion technique to be considered used.

3.5 Transfer Learning for the Visual Encoder

During the competition, the teams were not provided training datasets in **Bulgarian, North Macedonian or Arabic**. An interesting approach we tried was using the **English** labeled data for training our model and, after that, using the resulting **Vision Encoder** component of this model in conjunction with an adequate pretrained **Textual Encoder** for the desired language.

Using this approach, we made use of the image information in the dataset, which is agnostic to the language of the meme.

3.6 Adaptive Thresholding

Since we are treating **Subtask 1** and **Subtask 2a** as regression tasks (our models output a number between 0 and 1 for each persuasion technique), we needed to choose a threshold which determines the minimum value such that a persuasion technique should be included in the answer or not. In our final submissions, we have chosen **0.25** as the threshold for all the techniques. We have determined by experimenting on the dev dataset that this threshold maximizes the Hierarchical F1 score by creating a balance between the Hierarchical Precision and the Hierarchical Recall.

One idea which we tested only after the competition was to have a separate threshold for each persuasion technique. The method used to determine this was by using the validation dataset in order to find the threshold which maximizes the F1 score for that technique. An efficient way to find the best threshold is to sort the predictions and start with a threshold of 0. This would mean that all the samples are considered true, so $TP = sum(GT)$, $FP = N - sum(GT)$ and $FN = 0$, where N is the number of samples and GT is the array of ground truths. We can calculate the $F1$ score using the formula $2TP/(2TP+FP+FN)$. Now we go though all the prediction in order and assume that the current threshold is the value of the prediction. This means that the current sample i is now considered false, so if $GT_i = 1$, then $TP = TP - 1$ and $FN = FN + 1$, else $FP = FP - 1$. This allows to compute the current $F1$ score in $O(1)$.

Also, we have found that sometimes this algorithm would find very low values, so we have limited the thresholds to 0.2 as the minimum value.

Table 1: Results after the competition using adaptive thresholding on the test dataset

Subtask	F1-Score
1 English	0.647
2a **English**	**0.695**

This method performed worse for **Subtask 1** compared to our final submission (0.657), but performed better for **Subtask 2a**, where it improved our final result of 0.684 to 0.695. (Table 1)

We also tested a smaller threshold of 0.2 for the **Arabic Subtask 2a** which managed to get 1^{st} place on the final standings with a score of 0.585.

4 Experimental Setup

For the training of models we have used the data splits in the following manner. Before the dev gold labels were available, we have used the validation dataset in order to find the best hyperparameters and after that added the validation dataset to the training data. After the dev gold labels were published, in order to submit on the test dataset, we have also trained on the dev dataset. This maximized the number of training samples available.

The preprocessing techniques used for the images are:

- Resizing the image to 224×224 pixel size to match pretraining size for the Vision Transformer
- Scaling the values on all color chanels with a standard distribution $\mathcal{N}(0.5, 0.5^2)$ to increase numerical stability and facilitate learning

The preprocessing techniques used for the texts are:

- Lowercasing all characters, necessary especially in the context of memes which do not follow a casing norm
- Tokenizing the texts into representative tokens using the pretrained tokenizer associated with the used model
- Padding or truncating the texts to a standard dimension of 128 for the transformer model

All the external libraries (and their versions) used for the setup are listed in our GitHub Repository in the requirements.txt file.

The experiments conducted can be seen in tables 2, 3 and 4.

Epochs ALL	Epochs FC	Thresh	hP	hR	hF_1
5	5	0.25	0.62	0.60	0.612
3	3	0.25	0.63	0.66	**0.646**

Table 2: Experiments for **Subtask 1** on the dev dataset

Epochs ALL	Epochs FC	Thresh	hP	hR	hF_1
3	3	0.5	0.77	0.52	0.62
3	3	0.25	0.69	0.66	0.680
3	0	0.3	0.70	0.66	0.684
3	0	0.25	0.67	0.70	**0.687**

Table 3: Experiments for **Subtask 2a** on the dev dataset

Epochs ALL	Epochs FC	F_1 $macro$	F_1 $micro$
3	0	0.735	0.760
3	3	0.754	0.773
5	5	**0.819**	0.846

Table 4: Experiments for **Subtask 2b** on the dev dataset

Subtask	Visual Encoder	Text Encoder	Epochs ALL	Epochs FC
1 English	ViT	BERT	3	3
2a English	ViT	BERT	3	3
2b English	ViT	BERT	5	5
1 Bulgarian	ViT	BERT	3	3
2a Bulgarian	ViT	BERT	3	0
2b Bulgarian	ViT	BERT	0	5
1 N. Macedonian	ViT	GPT2	3	3
2a N. Macedonian	ViT	GPT2	3	0
2b N. Macedonian	ViT	GPT2	5	5
1 Arabic	ViT	BERT	3	3
2a Arabic	ViT	BERT	0	3
2b Arabic	ViT	BERT	0	5

Table 5: The configurations of our final submissions on the test dataset

In Table 5, by "Epochs ALL" and "Epochs FC" we refer to the epochs for which the whole model is trained, respectively to the epochs where only the last fully connected layers are trained and the encoders are frozen. In the case of the non-english subtasks, the text encoder was always frozen during the training. In the cases where "Epochs ALL" appears as 0, we have experimented with taking the trained encoder from the corresponding english subtask and freezing it in the training process.

The first task we approached was **Subtask 2b**. We first used varieties of the **EfficientNet** model for the Visual Encoder, later switching to **ViT** encoding thanks to its higher performance.

The metrics used for **Subtask 1** and **Subtask 2a** are Hierarchical Precission (hP), Hierarchical Recall (hR) and Hierarchical F1 score (hF_1). In the multi-label settings, we define $\hat{C}_i$ as the set of ground truth classes and all their ancestors and $\hat{C}'_i$ as the set of predicted classes and all their ancestors (Kiritchenko et al., 2006). Thus the metrics are represented by :

$$hP = \frac{\sum_i |\hat{C}_i \cap \hat{C}'_i|}{\sum_i |\hat{C}'_i|} \quad hR = \frac{\sum_i |\hat{C}_i \cap \hat{C}'_i|}{\sum_i |\hat{C}_i|}$$

$$hF_1 = \frac{2 \cdot hP \cdot hR}{hP + hR}$$

For **Subtask 2b**, the metrics used are the classic F_1 $macro$ and F_1 $micro$.

5 Results

Subtask	F1-Score	Place
1 English	0.657	9th
2a **English**	**0.684**	**5th**
2b **English**	**0.809**	**2nd**
1 Bulgarian	0.235	19th
2a **Bulgarian**	**0.610**	**2nd**
2b Bulgarian	0.594	7th
1 N. Macedonian	0.203	19th
2a **N. Macedonian**	**0.575**	**2nd**
2b N. Macedonian	0.177	14th
1 Arabic	0.234	16th
2a **Arabic**	**0.516**	**2nd**
2b Arabic	0.500	10th

Table 6: Results during the competition on the test dataset

As it can be seen from the results tables 5 and 6, the best approach, in terms of fully training our model, rather than only fine-tuning the final classification layer, was varied. The latter approach being more suitable, especially for **Subtasks 2a** and **2b** in the case of languages without additional training data.

Our model managed to outperform the Competition Baseline for **Subtasks 2a** and **2b** for all the provided languages.

In the case of **Subtask 1**, our model only outperformed the Competition Baseline for the English language dataset.

6 Conclusion

Our model accurately creates dense embeddings for both the memes and their captions, managing to make use of their most prominent features in computing the result. The performance peaks on **Subtask 2a**. The Transformer components used in the proposed architectures are capable of learning from vast datasets with low risk of overfitting. Thus, one way of improving the solution would be the use of additional datasets related to the subject, in various languages. Last but not least, our future work will revolve around decision making on the **Hierarchical DAG**, further making use of relationship between different labels.

7 Acknowledgments

We would like to especially thank our colleague and collaborator Adrian-Ștefan Miclăuș (University of Bucharest), for continuously reviewing our work and offering valuable advice.

Abstract

Nowadays, the usage of Large Language Models (LLMs) has increased, and LLMs have been used to generate texts in different languages and for different tasks. Additionally, due to the participation of remarkable companies such as Google and OpenAI, LLMs are now more accessible, and people can easily use them. However, an important issue is how we can detect AI-generated texts from human-written ones. In this article, we have investigated the problem of AI-generated text detection from two different aspects: semantics and syntax. Finally, we presented an AI model that can distinguish AI-generated texts from human-written ones with high accuracy on both multilingual and monolingual tasks using the M4 dataset. According to our results, using a semantic approach would be more helpful for detection. However, there is a lot of room for improvement in the syntactic approach, and it would be a good approach for future work.

1 Introduction

Large Language Models (LLMs) are widely used. They are easily accessible, and people can use them by passing their queries to chatbots to generate their desired texts for several purposes and, more importantly, in different languages. Although LLMs have their own advantages and simplify the text generation process for humans, they have increased concerns about the misuse of this technology for adversarial purposes such as generating hallucinations, misinformation, disinformation, and fake news. Furthermore, improper use of LLMs can cause disruption in students' learning process.

This issue has led to research on detecting AI-generated texts versus human-written ones, and a number of articles have investigated this classification task. However, the main focus of the presented works has mainly been on the semantic aspect of this text classification task. In this article, we have investigated this issue using two different approaches to consider both the semantic and syntactic aspects of texts. To achieve this aspiration, we have developed two different models for both syntactic and semantic-based analysis to apply them to both multilingual and monolingual datasets. In this way, we used the M4 article's dataset (Wang et al., 2023) for both multilingual and monolingual tasks.

For the syntax analysis of this task, we have developed an Attention-based Long Short-Term Memory(LSTM) model to cover the complexities related to long sentences and the relationship between different parts of a sentence, and regarding the semantic analysis of this task, we have developed a transformer-based model.

According to the results, our systems have performed better than M4's provided baseline in the multilingual task, and in the monolingual task, our results are really close to M4's provided baseline. In the end, we have provided our results and compared the results of both these models with each other and with previous works in this area.

2 Background

Today, due to the remarkable advancements in Natural Language Processing (NLP), models like ChatGPT, GPT-3 (Brown et al., 2020), Gemini (formerly known as Bard) (Team et al., 2023), and others have reached a point where they can generate texts that closely resemble human writing. Consequently, the task of identifying texts generated by AI has become increasingly important. This task holds significant value across various domains, including content moderation, plagiarism detection, and ensuring transparency in AI-generated content. The approaches for this task can be categorized into three categories: (1) Deep Learning-based Detection, (2) Statistical Discrepancy Detection, and (3) Watermark-based Detection. Deep learning-based models can be formulated as a classification task where the input is a text that can be generated by either a human or an AI. The model is trained with labeled data, where each text is assigned a label indicating whether it was generated by AI or by a human. This allows the model to learn patterns and features that can accurately classify texts based on their origin. These methods are susceptible to adversarial attacks, which can manipulate the input text to deceive the model's classification. However, deep learning-based models generally demonstrate good performance on the training data distribution (Guo et al., 2023). Statistical Discrepancy Detection methods first learn the patterns of AI-generated and human-written texts separately. Then, they iden-

[*]equal contribution

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 450–454

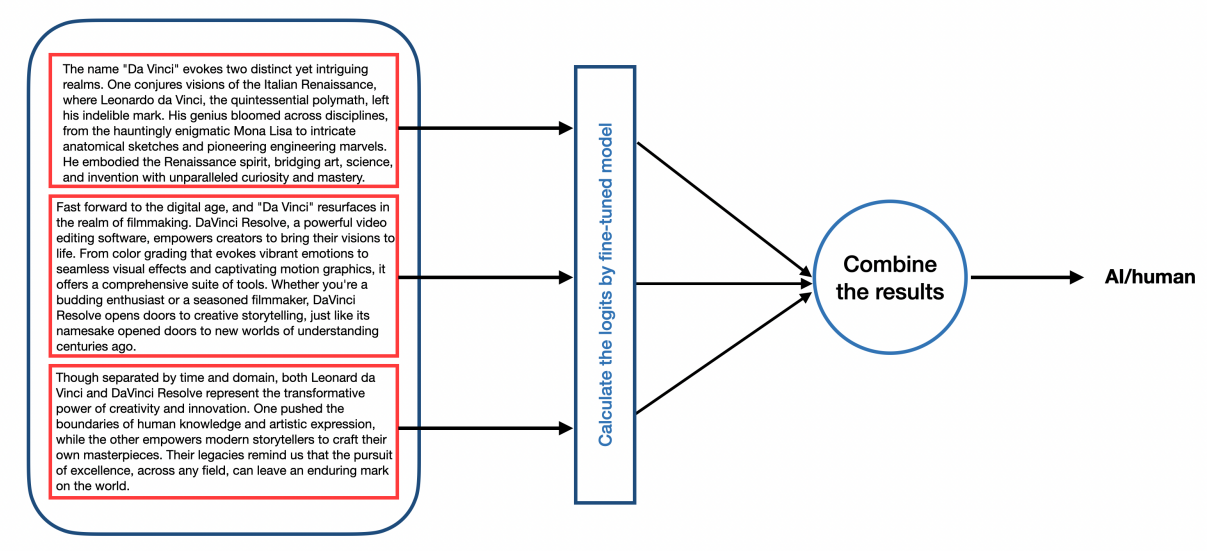

Figure 1: The input text is divided into meaningful units, and the probability of each segment based on their logits is assessed using a fine-tuned XLM-RoBERTa model; the combined evidence leads to a definitive classification.

tify statistical discrepancies between these patterns to distinguish between the two. By analyzing various linguistic features, such as word frequencies, sentence structures, or syntactic patterns, these methods can detect differences that arise from the distinct nature of AI-generated and human-written texts. Some tools like GPTZero (Mitchell et al., 2023) use perplexity (how well a language model predicts the next word based on the previous ones) and burstiness (variations in sentence length) to assess whether the text is AI-generated or human-written. The idea of watermarking initially emerged from the field of computer vision and has since been applied to NLP (Wu et al., 2023). This method involves embedding a hidden "watermark" during the text generation process with the objective of identifying text generated by a specific language model. In the context of black-box language models, (Yang et al., 2023) utilize this watermarking method to detect and identify text generated by such models.

In the SemEval2024 Task 8, (Wang et al., 2024), our attention was directed towards the multilingual and monolingual tracks of Subtask A. This subtask was designed for binary classification to distinguish between texts written by humans and those generated by machines. In terms of the dataset employed for this task, we utilized the multilingual dataset provided in the M4 article. The human-written texts in this dataset were collected from diverse sources spanning different domains. These sources include Wikipedia (March 2022 version), WikiHow, Reddit (ELI5), arXiv, and PeerRead for English. For Chinese, the texts were sourced from Baike and Web question answering (QA). Additionally, texts from news sources were included for Urdu and Indonesian, while for Russian, texts were obtained from RuATD. For Arabic, the texts were collected from Arabic Wikipedia. For the monolingual section, we have used the English corpora. In this dataset, AI-generated texts leverage multilingual LLMs such as ChatGPT, textdavinci-003, LLaMa, FlanT5, Cohere, Dolly-v2, and BLOOMz. These models undertake diverse tasks, including creating Wikipedia articles from titles and abstracts (from arXiv), generating peer reviews from titles and abstracts (PeerRead), answering questions from platforms like Reddit and Baike/Web QA, and composing news briefs based on the title. This dataset contains 122k human–machine parallel data in total, with 101k for English, 9k for Chinese, 9k for Russian, 9k for Urdu, 9k for Indonesian, and 9k for Arabic, respectively (Wang et al., 2023).

For our experiment, we used the English corpora of this dataset in the monolingual track. For the multilingual track, we utilized the whole dataset, which contains human-written and AI-generated texts from six different languages: English, Arabic, Chinese, Indonesian, Russian, and Urdu. As it is evident, our model's input is text documents, and its output is a single label that specifies whether the given text is human-written or AI-generated.

3 Method

To classify texts as either AI-generated or human-written, we have examined two crucial aspects: semantics and syntax. Our analysis of these aspects, which is detailed below, aims to identify distinctive features.

3.1 Semantic Approach

In our exploration of the semantic aspects of texts, we centered our analysis on two key elements: the vocabulary choices employed by the writer and the manner in which words are structured and combined. To achieve this, we leveraged transformers, which utilize word embeddings to capture meaning and positional encoding to account for word order and sentence structure. However,

a significant challenge lies in differentiating between AI-generated and human-written texts, especially in longer pieces, as AI models become increasingly adept at mimicking human writing styles. To address this challenge, particularly in longer texts, we proposed and adopted the strategy of splitting the text into smaller paragraphs. This allowed for a more focused and detailed analysis of each individual segment, potentially revealing subtle semantic nuances that might be overlooked in a holistic approach.

Our methodology is implemented in three distinct stages: (1) text segmentation, where the input text is divided into meaningful units; (2) probability calculation, where the likelihood of each segment being AI-generated or human-written is assessed; and (3) final prediction, where the combined evidence leads to a definitive classification. A visual representation of our approach is shown in Figure 1.

In the first stage, the input text was segmented into smaller units by splitting it at points where specific markers, such as exclamation marks, question marks, and periods, appeared within paragraphs. Additionally, during this stage, a dataset was generated to fine-tune our model.

For the second stage, we fine-tuned an XLM-RoBERTa model (Conneau et al., 2019) on the aforementioned dataset. Due to limited resources and constraints, the model was trained for only three epochs with a learning rate of `10^-8`. After the text was segmented and the model was fine-tuned, we proceeded to analyze the characteristics of each segment and calculate the probability of it being AI-generated or human-written according to their logits. To determine the final results, we employed several methods to combine the results, which are outlined below:

- **Soft voting prediction:** In this approach, we calculate the average probability of segments; if the calculated average is higher than the threshold (0.95), we conclude that the text is AI-generated.
- **Hard voting prediction:** In this approach, we calculate the probability of each segment; if it is higher than the threshold, we consider it to be AI-generated, and if more than half of the segments are considered AI-generated, then we conclude that the text is also AI-generated.
- **Weighted soft voting:** This approach is like soft voting, but we give weight to each segment; the weight of each segment is based on the number of words it contains.

We use this 0.95 threshold because of the small number of epochs the model has been trained on data.

3.2 Syntactic Approach

Another aspect that we examined was the syntactic properties of the texts. To analyze these properties, we utilized the Part-of-Speech (POS) labels associated with the words in the text. Our goal was to classify AI-generated and human-written texts based on their POS patterns.

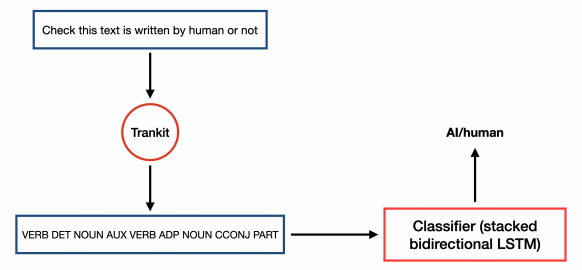

Figure 2: The bidirectional LSTM model predicts using part-of-speech labels associated with the words in the text assessed by Trankit.

To create a dataset for training a model on this aspect, we employed Trankit(Van Nguyen et al., 2021), which provided us with the Universal POS (UPOS) tokens. We integrated these UPOS tokens to form sequences of UPOS strings. In this approach, the focus is on identifying patterns within the sequences rather than the specific meaning of the tokens.

Given the challenge of working with long sequences, we opted to use an LSTM model. To handle the complexity of the task, we employed stacked LSTM layers. Additionally, to enhance the model's performance, we utilized bidirectional LSTMs, which consider the context from both directions of the sequence. In order to further improve the model's ability to capture important syntactic patterns and dependencies, we incorporated an attention layer into our LSTM model. The attention mechanism allows the model to focus on specific parts of the input sequence when making predictions, assigning different weights to different elements in the sequence. As illustrated in Figure 2, the UPOS strings produced by trankit are fed into our stacked bidirectional LSTM for classification.

By using LSTM models instead of transformer models, we aimed to prevent the potential effects of semantic meaning from overshadowing the syntactic patterns. This choice allowed us to place emphasis on the structural aspects of the texts and better isolate the syntactic features for classification purposes.

By combining the LSTM architecture with an attention layer, we aimed to enhance the model's ability to capture and utilize the important syntactic patterns in the text, ultimately improving the accuracy and effectiveness of the classification process. However, the results indicate that there is no specific difference between AI-generated and human-written texts in terms of their UPOS (Universal Part-of-Speech) patterns. We attained an accuracy of 49.75% and an F1 score of 33% for both the micro and macro averages. Therefore, we only considered the semantic aspects and overlooked the syntactic aspects.

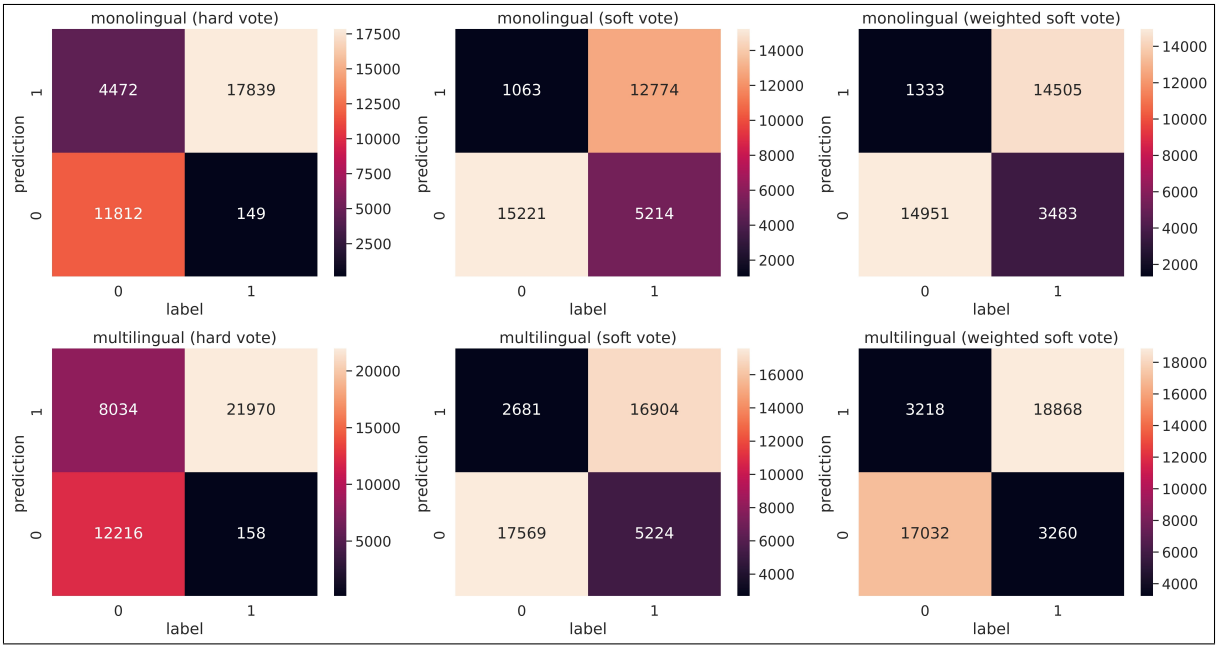

Figure 3: Confusion matrices of our model for test datasets on monolingual and multilingual tracks

4 Result

The results for our model are shown in Table 1. Our model achieved 0.847 and 0.859 accuracy for multilingual and monolingual test datasets, respectively, by training only on the multilingual training dataset.

As can be seen in the confusion matrix plots in Figure 3, the weighted soft vote approach performs better than the soft vote approach, which, in turn, outperforms the hard vote approach. Among these, the hard vote approach exhibits a higher false positive error rate compared to the other two. The soft vote approach, while having a slightly lower false positive error rate, incurs a significantly higher false negative error rate than the weighted soft vote approach.

By taking a look at mispredicted samples, we realized that the model is weak in predicting formal texts, like texts about history, law, or academic topics.

metric	multilingual	monolingual
accuracy	0.847	0.859
precision	0.854	0.916
recall	0.853	0.806
f1	0.853	0.858
false positive rate	0.159	0.082
false negative rate	0.147	0.194

Table 1: Performance of our classifier according to official metrics

5 Conclusion

In this study, we proposed a system to distinguish between human-generated and AI-generated texts. Our approach considered both semantic and syntactic aspects. For the semantic analysis, we focused on smaller text segments instead of the entire document, as we believed that AI models could produce similarly coherent long texts as humans. The results confirmed our assumption.

Our syntactic analysis, which employed a basic model to categorize texts based on their grammatical patterns using UPOS tags, revealed no significant differences in UPOS tag distribution between AI-generated and human-written texts. However, the analysis of word order identified distinct patterns in the semantic approach. This finding suggests that relying solely on UPOS tags for differentiation may be insufficient.

In conclusion, our proposed system demonstrated superior performance compared to the official baseline, achieving a 3.9% improvement in the multilingual subtask. These results emphasize the significance of considering texts in smaller segments rather than analyzing them as a whole. Moreover, our discoveries suggest that focusing solely on grammar, as indicated by their UPOS tags, may not sufficiently distinguish between AI-generated and human-written texts. Therefore, for future research efforts, it might be beneficial to utilize Graph Neural Networks (GNNs) to examine the grammatical connections among words. This involves representing word embeddings as nodes and their grammatical relationships as edges based on their constituency parsing or dependency parsing trees.

Abstract

This paper describes the BAMBAS team's participation in SemEval-2024 Task 4 Subtask 1, which focused on the multilabel classification of persuasion techniques in the textual content of Internet memes. We explored a lightweight approach that does not consider the hierarchy of labels. First, we get the text embeddings leveraging the multilingual tweets-based language model, Bernice. Next, we use those embeddings to train a separate binary classifier for each label, adopting independent oversampling strategies in each model in a binary-relevance style. We tested our approach over the English dataset, exceeding the baseline by 21 percentage points, while ranking in 23th in terms of hierarchical F1 and 11st in terms of hierarchical recall.

1 Introduction

In the multilabel classification problem (MLC), each instance may belong to zero, one, or multiple class labels. The goal is to learn a system to infer the correct labels of previously unseen instances (Gonçalves et al., 2018; Mylonas et al., 2023). MLC has several real-world applications, ranging from text categorization (Shimura et al., 2018) to protein and gene function prediction (Cerri et al., 2012). This work addresses a critical novel application of MLC: detecting persuasion techniques in memes, considering only their textual content, a subtask of SemEval-2024 task4[1].

The Merriam-Webster dictionary[2] defines *meme* as "an amusing or interesting item (such as a captioned picture or video) or genre of items that is spread widely online, especially through social media". Nonetheless, and unfortunately, in recent years, memes have been used not only to amuse people but also as a tool for disseminating disinformation in political campaigns (Renee, 2018; DeCook, 2018). Malicious actors embed sophisticated propaganda and persuasion techniques within these memes, employing psychological and rhetorical strategies. This manipulation extends to the memes' textual and visual components (Dimitrov et al., 2021).

Like other computational propaganda (Da San Martino et al., 2020), memes significantly influence public opinion. Their effectiveness stems from their widespread reach, potentially impacting millions of internet users globally. Additionally, memes are often not perceived as propaganda by these users, primarily because they do not mirror the appearance of conventional political advertisements (Nieubuurt, 2021).

As an effort to address this problem, SemEval-2024 Task 4 (Dimitrov et al., 2024) promoted a challenge in which competitors should develop algorithms to identify the use of persuasion techniques in memes, considering only their textual content (Subtask 1) or text and image together (Subtasks 2a and 2b). In this paper, we describe our approach to addressing Subtask 1. For this subtask, the shared-task organizers made available a collection of 8,500 texts in English extracted from real Internet memes (7,000 for training and the remaining divided into validation and dev sets). Each text may be assigned to a set of labels that indicate the persuasion techniques present in it[3]. There are a set of 20 possible labels organized in a hierarchy – thus, we have a hierarchical multilabel classification problem (Cerri et al., 2012). Some texts can have no label assigned, indicating they do not correspond to propaganda.

The shared task aimed to produce the best model according to the hierarchical-F1 metric. Test collec-

tions in four different languages were made available: English, Bulgarian, North Macedonian, and Arabic. Our team (BAMBAS) participated in the English challenge along with 31 other teams. We explored a lightweight approach based on three components. The first component is a language model from which we extract embedding features leveraging the [CLS] token. The second component is a binary relevance-based strategy to train 20 separate binary classifiers (one for each existing label) (Boutell et al., 2004). Our central inquiry focused on assessing the extent to which such a lightweight model that does not engage with the intricacies of hierarchical structures could be effective. The third core component handles the inherent imbalance of multilabel hierarchical problems by employing an independent oversampling strategy (Chawla et al., 2002; Menardi and Torelli, 2012) to reduce the imbalance between negative and positive examples present in each binary problem derived.

The hierarchical-F1 score of our submitted solution exceeded the baseline by 21 percentage points. In the hierarchical F1-based rank, we were the 23th out of 31 teams. However, when considering the hierarchical recall, we were ranked as 11st [4].

The rest of the paper is organized as follows. Section 2 briefly overviews MLC concepts relevant to this paper. Section 3 details our proposed system. In Sections 4 and 5, we present the experimental methodology and report the results, respectively. Finally, Section 6 brings the conclusion and future research directions.

2 Background

Over the last 20 years, MLC has been one of the most active research topics in machine learning (Mylonas et al., 2023). Among the several methods for multilabel learning in the literature (Bogatinovski et al., 2022; Prabhu et al., 2018), Binary Relevance (BR) (Boutell et al., 2004) stands out as one of the most prominent methods. This approach decomposes the multilabel problem into q binary problems, where q is the number of labels. Then, one binary classifier is independently trained for each label. The labels of new instances are predicted by combining the outputs of each classifier.

The BR method offers several key advantages. Firstly, its simplicity and intuitiveness make it highly accessible. Additionally, BR models can predict label sets not present in the training set, owing to their composition as a series of independent binary classifiers. Most crucially, BR has consistently exhibited high prediction accuracy values across various domains. In a recent extensive experimental comparison (Bogatinovski et al., 2022) involving 26 methods across 42 datasets, models utilizing BR outperformed all models trained with other different transformation strategies.

Nonetheless, the BR method suffers from three major drawbacks. First, it ignores the possible correlations among labels (Zhang et al., 2018). Second, BR has high training and prediction times for problems in which the number of labels is huge (tens of thousands to millions) (Prabhu et al., 2018). Third, its predictive performance is affected by class imbalance, which occurs when the number of examples relevant to each label is much inferior to the number of irrelevant ones (Mylonas et al., 2023; Zhang et al., 2018).

We consider that the first two drawbacks are not crucial for addressing SemEval-2024 Task 4 Subtask 1, as the number of labels in the problem is not large ($q = 20$) and there is no strong correlation between any pair of labels in the training set. More specifically, we found that the highest Pearson correlation value is 0.13 – between labels "Glittering generalities (Virtue)" and "Flag-waving". On the other hand, we consider that the issue of class imbalance needs to be taken into account as the imbalance ratio (ratio of negative to positive examples) is 47.38 on average in the training set, and the maximum value reaches 332.33 for the label "Obfuscation, Intentional vagueness, Confusion". Our approach is detailed in the next section.

3 System overview

The shared task proposed in SemEval-2024 Task 4 comprises an output of one or more labels – in case the meme is a propaganda – disposed in a hierarchical taxonomy of persuasion techniques. The root of such hierarchy is naturally labeled *persuasion*, while the second level has three possible branches: *ethos*, *pathos*, *logos*. While *ethos* and *logos* conduct to labels in a third level, *pathos* branch connects directly to the persuasion techniques – the leaves of the tree. This way, the final output can be one or more paths from the root to some leaf.

Handling such a hierarchical structure directly is quite challenging in machine learning. The algorithms should accurately predict multiple outputs

[4]Our code and experiments are available at https://github.com/MeLLL-UFF/bambas

while respecting the labels' hierarchical relationships. However, errors can propagate down the hierarchy. Moreover, some paths have very few instances, adding another layer of complexity to the problem: data sparsity and imbalance.

Therefore, our primary solution to the problem was to investigate how far an algorithm that disregards the hierarchy could go. Additionally, we also decided not to handle the multiple labels directly. However, employ the binary-relevance approach and consider a component to handle imbalance by adding synthetic instances with SMOTE (Chawla et al., 2002) and RandomOverSampler (Leevy et al., 2018), for each binary problem.

Algorithm 1 depicts the training procedure and Algorithm 2 the inference. Our method hinges on three core components. The first one creates the features from the meme textual content, leveraging a pre-trained language model (line 3 in Algorithm 1). The second component addresses class imbalance by creating synthetic instances (line 10 in Algorithm 1). The third component trains independent binary classifiers (line 12 in Algorithm 1), employing the binary-relevance strategy. During the inference phase, each label classifier undergoes evaluation, and the instance is assigned all the positive classifications predicted by each classifier.

3.1 Extracting embedding from a pre-trained language model

In line with our straightforward premise, we have implemented a feature-based strategy that utilizes embeddings from pre-trained language models (PTLMs). The textual content of each meme is processed through the PTLM, allowing our system to capture the numeric feature vector from the [CLS] token. This method effectively harnesses the power of PTLMs to distill complex language information into a manageable form for further training our classifiers.

Our selection choice for PTLMs includes a writing free-style multilingual model, namely, XLM-RoBERTa (Conneau et al., 2020) and two informal writing style models, one monolingual (BERTweet (Nguyen et al., 2020)) and one multilingual (Bernice (DeLucia et al., 2022)).

XLM-RoBERTa is a multilingual adaptation of the RoBERTa model, pre-trained on a 2.5TB of data across 100 languages. RoBERTa itself is a transformers model trained on large raw text corpora. The key training method used is Masked Language Modeling (MLM), where 15% of the words in a sentence are masked, and the model predicts these masked words, learning a bidirectional representation of the sentence. BERTweet is a monolingual model trained from 850M Tweets. It has the same architecture as BERT-base but was trained using the RoBERTa pre-training procedure. Bernice is a multilingual RoBERTa language model trained from 2.5 billion tweets.

3.2 Training classifiers for each class

In our approach, we implemented the binary relevance strategy to train a suite of independent classifiers, each tailored to manage a binary prediction, of whether a meme belongs to a specific label. Our model comprises independent binary classifiers, each aligned to a distinct persuasion technique. Un-

der this strategy, a classifier corresponding to a label k is trained using a targeted approach: instances labeled with k are treated as positive examples, while all other instances are considered negative. This selective process ensures that each classifier becomes specialized in precisely identifying its respective label.

For instance, consider a meme m_j tagged with three labels (k_1, k_2, k_3). This meme serves as a positive training example for the classifiers c_{k_1}, c_{k_2}, and c_{k_3}, contributing to their ability to recognize these specific labels. Conversely, another meme m_z tagged with label (k_1) not only acts as a positive example for training the classifier c_{k_1} but also serves as a negative instance for c_{k_2} and c_{k_3}. This dual role of memes in the training process, as both positive and negative examples depending on their label associations, underscores each classifier's nuanced and specialized training within our binary relevance framework.

During the inference phase, each meme is processed through all the classifiers in our system. If a particular classifier predicts the meme as a positive instance, the corresponding label is assigned to the meme. By the time this processing is finished, the input meme accumulates a set of labels, each representing a positive prediction from the respective binary classifiers. This method ensures that the meme is comprehensively evaluated for all potential labels.

3.3 Creating synthetic instances

Considering the inherently imbalanced nature typical of multilabel hierarchical tasks (Mylonas et al., 2023; Zhang et al., 2018), we address this challenge by oversampling the dataset with synthetic instances. This approach is designed to equalize the number of examples for each binary classifier, thereby mitigating the imbalance issue. Our system generates synthetic examples independently for each binary classifier.

We leveraged two strategies: a simple random oversampler and the widely-used SMOTE (Synthetic Minority Oversampling Technique) (Chawla et al., 2002). SMOTE operates by identifying examples that are closely situated in the feature space. It then generates a line connecting these examples and creates a new and synthetic sample at a point along this line.

More precisely, for each classifier c_{k_i}, the process starts by selecting a random example from the minority class. Next, it identifies n nearest neighbors for this example. From these neighbors, one is randomly chosen. Subsequently, a synthetic example is crafted at a randomly determined point between the chosen neighbor and the original example in the feature space.

4 Experimental setup

Our solution was implemented using HuggingFace (Wolf et al., 2020)[5] and scikit-learn (Pedregosa et al., 2011)[6] libraries. The experiments were conducted on an NVidia DGX-1, using a single Tesla P100 GPU with 16GB of VRAM. We conducted a step-by-step analysis to reach the final modeling decisions. The intermediate results, necessary to decide the components of our final solution, are reported with the validation set. The final solution was trained with the training set and we report the results of the English dev and test set. We proceed this way because the dev set could only be measured with the submission page before the release of its gold labels.

All results are reported with the competition's evaluation metric, a hierarchical variant of the F1-score (Kiritchenko et al., 2006). The metric considers the classification taxonomy, rewarding a full score for exact leaves prediction, and rewarding a partial score for ancestor predictions. The closer the predicted ancestor is to the correct labels, the higher the partial score. Additionally, we report the hierarchical variants of precision and recall.

The first analysis consists of defining the PTLM to extract the embeddings. We did not employ oversampling during this phase and applied a binary-relevance model using logistic regression. The PTLM and logistic regression hyperparameters were left as default. The meme textual content is presented to the PTLM without any pre-processing. Next, we explore 6 other classifiers besides logistic regression: decision tree, extra tree, extra trees, KNN, random forest, and ridge classifier. The last analysis focused on selecting the best oversampling strategy. We experimented with SMOTE and a random oversampling strategy, both implemented in the imbalanced-learn library[7]. All the results so far included 20 binary classifiers, each associated with a persuasion technique in the leaves of the tree. Then, we investigate a final possibility of including some internal nodes related to the classes that

[5] https://huggingface.co/
[6] https://scikit-learn.org/stable/
[7] https://imbalanced-learn.org/stable/

were worst classified. The best model from those analyses was submitted to the competition.

5 Results

Table 1 depicts the results achieved by each pre-trained language model mentioned in Section 3.1 considering logistic regression and no oversampling strategy. Bernice achieves the best overall hierarchical-F1 (H-F1) results. We hypothesize that it was trained with a large set of informal texts from tweets, presenting a writing style close to those found in memes. Then, we select Bernice for the next analyses and to submit our final solution.

PTLM	H-F1	H-Prec.	H-Rec.
Bernice	**0.4996**	0.6246	**0.4163**
BERTweet	0.4334	0.7202	0.3100
XLM-RoBERTa	0.2928	**0.7410**	0.1825

Table 1: Validation results for choosing the PTLM

The next analysis concerns the method used as the base classifier of the binary relevance strategy. Table 2 depicts the results of the binary relevance when executed with each classifier. Logistic regression conducted to the best H-F1 score. Because of that, we proceed to the final analysis with it.

Classifier	H-F1	H-Prec.	H-Rec.
Log. Regression	**0.4996**	0.6246	**0.4163**
Decision Tree	0.3993	0.3856	0.4141
Extra Tree	0.3885	0.3826	0.3946
Extra Trees	0.1024	0.6831	0.0554
KNN	0.4252	0.5824	0.3348
Random Forest	0.1561	**0.8091**	0.0864
Ridge	0.4027	0.7388	0.2768

Table 2: Validation results of distinct Classifiers

Next, we explore our third core component, the oversampling technique. Table 3 shows the results of running the random oversampler and SMOTE with 50/50 rate for oversampling, and also a hybrid version which combines the best oversampler for each binary classifier, using different oversampling rates: 0.1 to 1.0 with step of 0.1.

Finally, we included additional classifiers to some internal nodes of the hierarchy. Such an extension includes only the internal nodes corresponding to the least accurately classified leaf nodes. These nodes are "Ad Hominem", "Distraction" and "Logos". Table 4 shows the validation set results without and with the addition of those internal nodes. Recall improved with the combined strategy, while precision remained nearly identical.

Strategy	H-F1	H-Prec.	H-Rec.
No Oversampling	0.4996	**0.6246**	0.4163
50/50 SMOTE	0.5456	0.4510	0.6904
50/50 Random	0.5383	0.4395	**0.6944**
Combination	**0.5487**	0.4783	0.6435

Table 3: Validation Results of Oversampling Strategies

Classifier	H-F1	H-Prec.	H-Rec.
W/O int. nodes	0.5487	**0.4783**	0.6435
+ int. nodes	**0.5548**	0.4782	**0.6607**

Table 4: Validation results with some internal nodes

Given the preceding results, we selected that approach for the final submission. Table 5 shows the final results achieved by the solution we submitted to SemEval-2024 Task4 platform. In the first line, we highlight the results achieved on the dev set while the second line shows (in bold) the test set result.

Set	H-F1	H-Prec.	H-Rec.
dev	0.5759	0.5046	0.6707
test	**0.5767**	**0.5012**	**0.6788**

Table 5: Final results for the official submission on both dev and test sets

6 Conclusion

This paper addresses the SemEval-2024 competition with a lightweight solution to investigate how a model that neglects the hierarchy would behave in a hierarchical task. Our solution uses a tweets-based PTLM as a feature extractor, generates synthetic data to account for imbalance, and employs a binary relevance strategy to handle multiple labels. Our next step is to investigate training a structured output classifier that predicts the paths in the hierarchy. Moreover, given that oversampling strategies enhanced the performance of most of the classes, we plan to design other strategies explicitly tailored to the style of memes.

A Validation set classification results per-label

Due to the imbalanced nature of the explored problem, we further investigate the classification results on a per-label basis. Table 6 describes the results for each label in the validation set. We include the internal nodes in the hierarchy alongside all leaves. To calculate scores for the internal nodes, predictions of any of their children are considered as correct node predictions. The best-performing label was "Appeal to Authority", which achieved the highest F1 score. The internal nodes "Logos" and "Ad Hominem" follows in second and third place, respectively. Also, most of the worst performing labels have scarce examples on the datasets, like "Vagueness, Confusion" and "Straw Man".

B After competition deadline results: multilabel classifiers

The solution presented in the paper relaxes the multiple labels per example setting and trains independent binary classifiers for each class. We additionally explored an alternative setup that leverages a multi-layer perceptron (MLP) classifier with a multilabel classification layer. We trained two classifiers in this way: the first follows the previous feature-based approach to train a multilabel feedforward (FF) MLP; the second adds a multilabel classification layer on top of the PTLM and fine-tunes all its weights. As before, the PTLM is Bernice.

The feature-based approach classifier includes a single 768-dimension hidden layer with scikit-learn default parameters. The fine-tuning approach runs for five epochs, with a learning rate of $3.9e-5$ and weight decay of $1e-3$, all selected with the validation set. Both approaches did not involve oversampling, and the classifiers were trained with the union of the train and validation sets and evaluated on the dev set during training.

Tables 7 and 8 depict the results for the dev and test sets. The results show the superior performance of the fine-tuning approach, with test set H-F1 score higher than our official competition's submission. Also, the standalone FF classifier achieved F1 above average, indicating that a dedicated oversampling strategy for the multilabel approach is a promising research avenue to explore further in the future.

Label	F1	Prec.	Rec.

Team QUST at SemEval-2024 Task 8: A Comprehensive Study of Monolingual and Multilingual Approaches for Detecting AI-generated Text

Xiaoman Xu, Xiangrun Li, Taihang Wang, Jianxiang Tian, Ye Jiang
College of Information Science and Technology
Qingdao University of Science and Technology, China

Abstract

This paper presents the participation of team QUST in Task 8 SemEval 2024. We first performed data augmentation and cleaning on the dataset to enhance model training efficiency and accuracy. In the monolingual task, we evaluated traditional deep-learning methods, multiscale positive-unlabeled framework (MPU), fine-tuning, adapters and ensemble methods. Then, we selected the top-performing models based on their accuracy from the monolingual models and evaluated them in subtasks A and B. The final model construction employed a stacking ensemble that combined fine-tuning with MPU. Our system achieved 8th (scored 8th in terms of accuracy, officially ranked 13th) place in the official test set in multilingual settings of subtask A. We release our system code at:https://github.com/warmth27/SemEval2024_QUST

1 Introduction

Large language models (LLMs) enable quick, coherent responses and content creation but also raise ethical concerns about misinformation and academic integrity (Wang et al., 2023). To differentiate between machine-generated and human-created content, previous study (Guo and Yu, 2023) has been extensively discussed in industry and academic works.

Semeval 2024's Task 8 (Wang et al., 2024a) encourages the participants to develop an automatic system for detecting AI-generated text by leveraging an extended version of the M4 dataset (Wang et al., 2023, 2024b). We engaged in subtasks A and B, during which we encountered the challenges of overcoming linguistic differences, data scarcity, and inadequate cross-lingual generalization capabilities. Furthermore, existing multilingual models are less discussed in detecting AI-generated text, compared to monolingual ones, which further exacerbates the difficulty in model selection.

Meanwhile, we found that the multilingual dataset in subtask A contains data from both monolingual data and subtask B, as shown in Figure 1. To enhance the diversity and scale of the text dataset, we performed back-translation on the multilingual training set to increase the volume of monolingual data and conducted data cleaning to improve data quality.

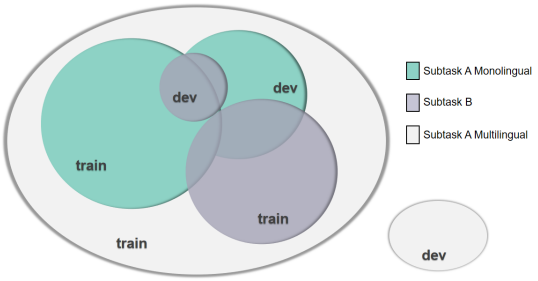

Figure 1: The data distribution in subtask A and B.

In our approach to subtasks A and B, we initially applied deep learning methods for a swift assessment in subtask A and proceeded to fine-tune multiple pre-trained language models (PLMs), inspired by recent studies highlighting the efficacy of fine-tuning methods in text classification. However, the training cost of the fine-tuning method is relatively high. We further utilize the Adapter (Hu et al., 2021) to parameter efficiency fine-tune (PEFT) (Hu et al., 2021) the model while preserving its performance. We also noted that despite the reduced training time, the performance of adapter models was not consistently stable, showing variability across experiments. Given the critical importance of model performance, decided not to utilize adapters in the testing phase.

To enhance model performance and generalizability, we adopted a stacking-based ensemble learning method, utilizing the logits from the top two performing models as inputs for a linear layer to generate final predictions. Finally, our experimental results on the test set show that integrating

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 463–470

data augmentation and ensemble learning significantly improves model efficacy in task-specific settings.

2 System description

2.1 MPU framework

Recent research on machine-generated text recognition has evolved into treating it as a binary classification problem, with the latest advancements including the Multiscale Positive-Unlabeled (MPU) (**?**) training framework. This approach introduces a length-sensitive MPU loss combined with abstract recurrent models and a text multi-scale module, significantly enhancing detection performance for short texts.

Upon analyzing the text lengths in official datasets, As shown in table 2, we observed a predominance of short texts, with those exceeding 512 characters making up a quarter of the total. This insight highlighted the MPU framework's suitability for subtask A. The MPU model, previously tested only on the HC3 (Guo et al., 2023) Chinese and English datasets, needed assessment for its effectiveness on multilingual datasets. To address this, we integrated the MPU framework with the XLM-Roberta (XLM-R) model to enhance its adaptability for multilingual tasks and employed stacking ensemble techniques, yielding significant improvements in our experimental outcomes.

2.2 Fine-tuning

Fine-tuning PLMs such as BERT or RoBERTa have been extensively discussed in text classification tasks (Jiang, 2023; Jiang et al., 2023, 2020). Recently, the DeBERTa model (He et al., 2020) is an enhancement built upon the foundations of BERT and RoBERTa through the incorporation of a disentangled attention mechanism and an enhanced masked decoder. We utilized the DeBERTa model and performed fine-tuning on it in our experiment. Although fine-tuning PLMs to specific domains or downstream tasks is a crucial and common practice, fully fine-tuning its large number of parameters becomes time-consuming and costly.

2.3 Adapter

In our experiments, due to the substantial size of the DeBERTa model and the size of the official datasets, each fine-tuning run required a significant amount of time. Adapter-based fine-tuning is an approach to fine-tuning a PLM that involves freezing the most of layers and inserting low-dimensional adapter modules into each layer to improve parameter efficiency. Research has shown that introducing adapters reduces the number of trainable parameters to 3.6%, with only a marginal performance drop of 0.4% (Houlsby et al., 2019). Furthermore, in some cases, models applying adapters perform even better (Bapna et al., 2019).

In our task, we employed the LoRA (Low-Rank Adapter) method (Hu et al., 2021), which injects trainable rank-decomposition matrices into each layer of the Transformer architecture, effectively freezing the PLM's weights. This significantly reduces the number of trainable parameters for downstream tasks. Therefore, we added a sequence classification head on top of the model to adapt the PLMs to the classification task. This has reduced the training costs and shortened the training time.

2.4 Stacking

Ensemble learning combines multiple base learners to form a predictive model with enhanced generalization capabilities (Sagi and Rokach, 2018). Initially, predictions are generated employing various machine learning algorithms. Then, these predictions serve as inputs for a subsequent classifier. Upon training the subsequent classifier, the integrated model is optimized to produce a new prediction set.

3 Methodology

Upon obtaining the dataset, we conducted a comprehensive statistical analysis of its scale and distribution. We observed that the multilingual training dataset contains both monolingual data and Subtask B-related data, along with an additional portion. To enhance the model's generalization capability, we opted to augment the training data through the following steps 2:

Firstly, we employed Google Translate to uniformly translate the multilingual training dataset into English. Subsequently, considering the presence of monolingual datasets within the multilingual training data and to prevent leakage of validation data, we excluded the validation dataset for monolingual tasks and Subtask B from the multilingual training dataset.

In accordance with the multi-class nature of Subtask B, we balanced the categories of the translated multilingual training dataset. We reorganized the dataset into multiple categories to better align with

the data distribution of Subtask B. To ensure data quality, we conducted thorough cleaning of the datasets.

Following data preprocessing, we separately fed the cleaned training datasets into the respective models for training. In order to leverage the strengths of different models and enhance classification accuracy, we contemplated performing stacking. We selected the top two models based on their performance on the validation dataset and saved their generated logits. Finally, we stacked these logits to obtain the ultimate results.

4 Experimental setup

4.1 Data preprocessing

The subtasks A and B involving diverse domains and sources with both human and machine-generated texts, we encountered chaotic symbols and extraneous content such as hyperlinks, numerals, and escape characters. To improve data quality, we undertook preprocessing steps including: removing special characters; eliminating excessive whitespace and line breaks; discarding Unicode escape characters and numerically formatted texts; removing hyperlinks; excluding irrelevant text lines like those for sharing, surveys, comments, ads, terms of use, and copyright notices; and deleting duplicate sentences. Notably, we avoided removing escape characters from multilingual training and validation sets to preserve original characters in non-English texts.

4.2 Data augmentation

We evaluated our models on the original dataset (**v1**) before the test set was released. We found that the multilingual set contained training and validation data for the monolingual and subtask B. To enlarge the monolingual dataset and improve model performance, we removed 5000 monolingual validation entries from the multilingual set, translated Chinese, Indonesian, Urdu, and Bulgarian data to English using Google API, and then cleaned the data to produce a refined dataset (**v2**).

we calculated the statistics of different versions of datasets, as shown in Table 1. For the multi-class subtask B, we re-labeled the dataset based on multilingual tags, addressing a severe imbalance by reducing instances in overrepresented categories for balance. After receiving the test set, we included the multilingual validation set into our training dataset and performed the same enhancement processes, creating a **v3** version for final model training and prediction.

We further analyzed the augmented version of the v2 dataset, as shown in Table 2. This analysis includes the average sentence length and average text length, as well as the proportion of texts exceeding 512 characters in length. The average sentence count was obtained through sentence tokenization using the sent-tokenize tool, while the average sentence length was calculated using the word-tokenize tool from the NLTK python library. Model performance for subtasks A and B was evaluated based on accuracy.

4.3 Monolingual models

In subtask A, submissions were made using two systems based on the different language tracks. For the monolingual English track, the system consisted of five approaches across ten models, as detailed in Table 3. The final submission system employed a stacking ensemble method, which was composed of the two best-performing models out of the ten.

In Table 3, these models had a learning rate of 1e-4, were trained for 3 epochs, and the best-performing models on the validation set were saved. For the fine-tuned models, we adhered to the inherent 512-token length limitation to ensure consistency in the input data and effective processing by the models.

The final monolingual model selected the top-performing two models, DeBERTa-v3-large and RoBERTa-base model based on MPU framework(RoBERTa-base-MPU), for stacking ensemble learning. The learning rate for the ensemble model remained set at 1e-4, trained for 1000 epochs. Only the best-performing stacking model was retained, and the final predictions were based on this optimal stacking model.

4.4 Multilingual models

In the multilingual track, we conducted experiments employing the top five models that exhibited promising performance in monolingual contexts. We opted to substitute the RoBERTa model with the XLM-R model, which is specifically designed for multilingual tasks.

Derived from the RoBERTa architecture, the XLM-R model has undergone training across 100 distinct languages, endowing it with multilingual capabilities. This versatility enables the model to process and comprehend various languages effec-

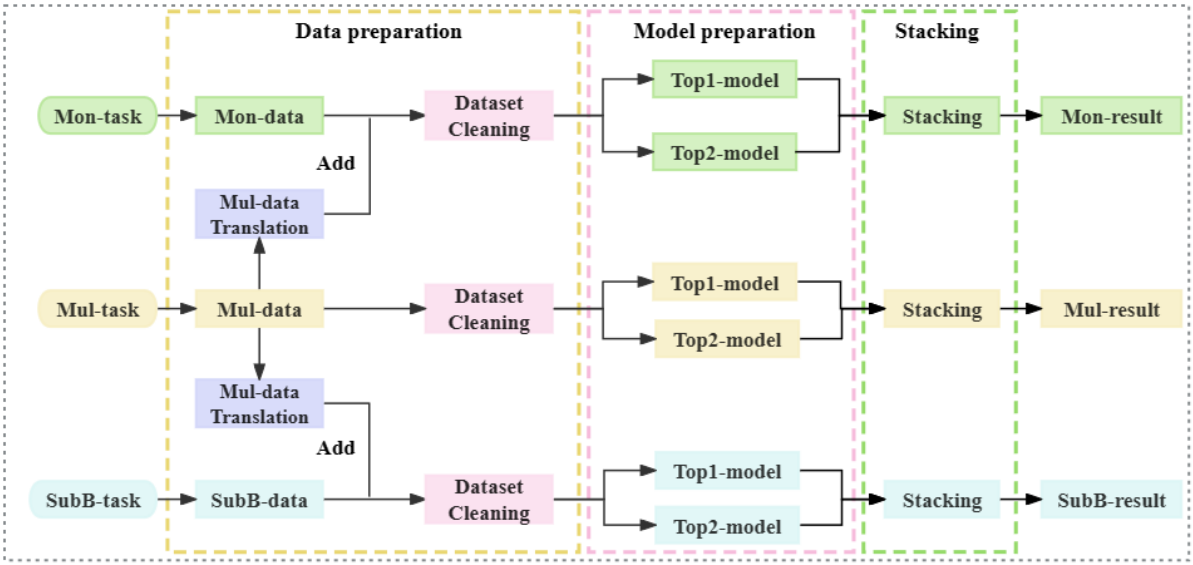

Figure 2: This is the workflow diagram for our paper."Mon-task" and "Mul-task" respectively refer to the monolingual and multilingual tasks for Subtask A, while "SubB-task" refers to Subtask B. "Mon-data", "Mul-data", and "SubB-data" respectively refer to the datasets for the corresponding tasks."Top1-model" and "Top2-model" respectively denote the models with the highest and second-highest performance among those utilized for the subtask.

Subtask	**v1**		**v2**		**v3**		
	train	dev	train	dev	train	dev	test
Monolingual	119,757	5,000	167,252	5,000	176,252	5,000	34,272
Multilingual	172,417	4,000	172,417	4,000	176,417	4,000	42,378
subtask B	71,027	3,000	105,908	3,000	176,252	3,000	18,000

tively, leading to notable enhancements in performance across diverse cross-lingual transfer tasks. Subsequently, we identified the top two models for integration through stacking ensemble. The integration of predictions from these two models yielded superior predictive performance.

Following this, we trained the multilingual models on the v2 version of the multilingual training dataset. We set the learning rate to 1e-4 and 3 epochs while retaining the models that performed best on the validation set.

During the experimentation, we observed that the addition of adapters to the DeBERTa-v3-large model resulted in unstable performance, while direct fine-tuning of the DeBERTa-v3-large model exhibited better results. Based on this observation, we ultimately chose to integrate the XLM-R-MPU model and the DeBERTa-v3-large model. To achieve this, we saved the best models from each training session and utilized these two optimal models to generate logits. Subsequently, we merged the logits from both sets of models as part of the training data for the stacking ensemble's input linear layer. We set the learning rate to 1e-4 and extended the training epochs to 1000 to ensure thorough model training. Throughout this process, we continuously monitored and retained the best-performing stacking model, which was ultimately applied to the test set for final predictions.

4.5 Subtask B models

We extended the binary classification capabilities of the RoBERTa-base model combined with the MPU method to address multi-class problems in subtask A, employing a one-vs-rest strategy for six categories including human, ChatGPT, etc. This resulted in six separate classifiers, with classification based on the highest confidence level among positive predictions from these classifiers for each category.

Statistic	SubA-mono			SubA-multi			SubB		
	Train	Dev	Test	Train	Dev	Test	Train	Dev	Test
avg-sent	16.5	13.0	18.4	15.7	8.9	17.1	15.3	10.2	17.5
avg-sent-len	24.7	26.8	23.7	25.5	22.9	23.1	23.5	24.1	23.6
sent-len>512	16.7%	13.1%	23.5%	17.3%	1.2%	14.6%	15.2%	6.6%	18.9%

Table 2: The statistics of the v2 dataset. "avg-sent" represents the average number of sentences per document, "avg-sent-len" represents the average number of words per document, "sent-len>512" represents the percentage of documents that their sent-len are greater than 512 words.

Following this, we opted for the consistently excellent performance of the LoRA adapter-based DeBERTa-v3-large (DeBERTa-v3-Large-LoRA) model and applied it to subtask B. Additionally, we introduced a new adapter-based RoBERTa-large model. The model configurations were consistent with the monolingual models. In the final ensemble model, we employed stacking with the DeBERTa-v3-Large-LoRA and RoBERTa-large models. The learning rate was set to 1e-4, with a training period of 3000 epochs, and only the model with the highest score was retained.

5 Results

5.1 Monolingual results

Our evaluation work is divided into two main stages: first, the evaluation based on the officially provided monolingual dataset (**Mon1**), and second, the evaluation based on our back-translated and processed monolingual dataset (**Mon2**).

In the **Mon1** evaluation stage, we aimed for a quick baseline model implementation, using traditional deep-learning methods. The results in Table 3 on the Mon1 dataset show that traditional models generally outperformed the fine-tuned deep learning models, likely due to the small size of the official monolingual dataset, which contains only about 110,000 entries. Consequently, large models like RoBERTa-base may not be adequately trained, while smaller models such as CNN or RNN could perform better by being less prone to overfitting.

By integrating the MPU framework with the RoBERTa-base model, performance improved by 20 percentage points over direct fine-tuning, highlighting MPU's benefits in boosting short-text performance and enhancing machine-generated long text detection. Despite being designed for long documents, Longformer-base-4096 underperformed compared to CNN and Self-Attention methods on the Mon1 dataset.

The DeBERTa model, an advancement over BERT and RoBERTa, excelled in our tests, especially after fine-tuning with adapters, which improved both efficiency and performance, slightly surpassing the fully fine-tuned DeBERTa. Stacking and re-predicting logits from the top two models led to a nearly 7% improvement over the best single model, underscoring the effectiveness of model fusion in increasing prediction accuracy and stability.

In the **Mon2** evaluation stage, we retrained them on the Mon2 dataset after selecting the top five best-performing models on the Mon1 dataset. After retraining, the performance of the models on the Mon2 dataset improved by approximately 20%. likely due to shorter texts enhancing feature detection, noise reduction from removing poor-quality data, and increased dataset diversity and size. These factors combined allowed the models to gain a deeper understanding of language characteristics.

5.2 Multilingual results

Experiments performed on a refined multilingual dataset employing the DeBERTa-v3-Large-LoRA model produced a performance score of merely 0.669, notably inferior to the baseline model's performance on the unprocessed dataset. This discrepancy may stem from improperly removing crucial features during the dataset cleaning process or introducing errors. Therefore, we opted to directly train the selected model on the raw official multilingual dataset, as detailed in Table 3 above. We found that the XLM-R model integrated with the MPU framework outperformed the baseline XLM-R model by 7% on the dataset, thus confirming the effectiveness of the MPU framework.

While the BERT model excels in monolingual tasks, its performance lags behind the baseline by approximately 7% in multilingual tasks, suggesting that BERT may be less suitable for multilingual classification tasks. The DeBERTa-v3-large model, which is an improvement based on BERT

	RoBERTa-large+DeBERTa-v3-large (Ours)	-	-	-	**0.94**

Table 3: The overall accuracy comparison in subtask A and B. "Mon1", "Mul", and "SubB" respectively represent the accuracy of monolingual models, multilingual models, and subtask B models trained on the v1 dev set. "Mon2" is the dev accuracy on the v2 dataset.

and RoBERTa, outperforms the baseline XLM-R by 3.55% on multilingual datasets. This improvement can be attributed to DeBERTa's optimizations to both architectures, which prove particularly effective in multilingual processing, enhancing the model's learning capabilities and generalization.

In our experimental results table, we observe that the performance of the DeBERTa-v3-Large-LoRA model is 5.1% lower than the baseline model, while also exhibiting a 9.4% decrease compared to directly fine-tuning the DeBERTa-v3-large model. This discrepancy in performance may stem from significant differences in data distribution between the pre-training task and incremental training.

Specifically, there exists a substantial difference in data distribution between the DeBERTa model and the model fine-tuned via LoRA adapters, resulting in insufficient parameter updates to effectively capture these differences. This phenomenon suggests that although LoRA adapters offer a parameter-efficient fine-tuning method, relying solely on limited parameter adjustments may not suffice to achieve optimal performance in situations with substantial disparities in data distribution.

The stacking results in the multilingual task failed to surpass the performance of the XLM-R-MPU model, which could be attributed to the already robust nature of XLM-R-MPU, potentially causing the ensemble model to overfit on the training data, thereby reducing performance on validation or test data. Another possibility is that the two top-performing models exhibit high correlation in predictions (i.e., commonly making the same type of errors), thus stacking them may not yield significant performance improvements.

5.3 Subtask B results

Table 3 indicates that the performance of the XLM-R-MPU model continues to deteriorate on the dataset for subtask B, indicating poor results. This could be attributed to the model originally being designed for binary classification tasks and not being well-suited for multi-class tasks.

We found that by directly freezing the model and fine-tuning the adapter-based DeBERTa-v3-Large (DeBERTa-v3-Large-LoRA) and RoBERTa-large (Roberta-large-LoRA) models, the classification effectiveness significantly improved, outperforming the official baseline by approximately 10 percentage points.The use of the LoRA adapter allows models to more effectively utilize pre-trained knowledge while avoiding over-fine-tuning and reducing the risk of overfitting on specific tasks. After data cleaning, the pre-trained data used by DeBERTa-v3-large and RoBERTa-large were closer to the target multi-class task, potentially further enhancing their performance.

6 Ablations

We conducted ablation experiments using the DeBERTa-v3-large and Roberta-base models on the Mon1 dataset. As shown in Table 4, the experimental results indicate that the introduction of the MPU framework and stacking ensemble method significantly improves the model's performance, resulting in a notable performance enhancement

However, despite the inclusion of the LoRA adapter, the performance improvement is not significant. This could be attributed to the insufficient number of parameters fine-tuned solely by the adapter when faced with complex tasks, which hinders the model from learning additional knowledge effectively.

Methods	Results
DeBERTa-v3-large	0.84
DeBERTa-v3-large w/ LoRA	0.843
Roberta-base	0.694
Roberta-base w/ MPU	0.894
Stacking	**0.96**

Table 4: Ablation experiments. "Stacking" refers to the aggregation of results from the "DeBERTa-v3-large with LoRA" model and the "Roberta-base with MPU" model.

7 Official test results

Our system ranks 8th on Semeval 2024 Task 8 official multilingual test set of subtask A. It is noteworthy that, employing the same method, Only the model trained on the multilingual dataset surpassed the baseline of 0.80 with a score of 0.90, while models on monolingual datasets and Task B exhibited comparatively inferior performance, with none of the submissions reaching the respective domain baselines.

This phenomenon could be attributed to several factors. Firstly, although monolingual validation sets were removed from the multilingual training set, the processed multilingual training data may still share similarities with monolingual validation sets. This could lead to superior model performance during evaluation; however, due to disparities between the final test set data and the processed multilingual data, models may fail to meet baseline performance on the test set. Secondly, model training based on fine-tuning may encounter instability and catastrophic forgetting issues, thus affecting the model's generalization ability. Therefore, even with the same model, discrepancies in performance on official test sets may arise due to differences between datasets, resulting in significant performance gaps.

8 Conclusion

In conclusion, our team developed three distinct systems for SemEval-2024 Task 8, targeting the monolingual and multilingual aspects of subtask A and addressing subtask B. We achieve 8th place in the multilingual setting of subtask A. We leveraged back-translation to expand the training datasets for both monolingual and subtask B. The RoBERTa-base and XLM-R models, enhanced by the MPU framework, showed improved detection of short texts in both monolingual and multilingual settings. Finally, the stacking method allowed us to combine the strengths of multiple models, improving our system's predictive accuracy. Future efforts will consider incorporating advancements in cross-lingual pre-trained models in our subsequent work to further enhance the model's understanding of texts across diverse languages and cultural backgrounds.

Abstract

This study describes the model built in Task 9: brainteaser in the SemEval-2024 competition, which is a multiple-choice task. As active participants in Task 9, our system strategically employs the decoding-enhanced BERT (DeBERTa) architecture enriched with disentangled attention mechanisms. Additionally, we fine-tuned our model using low-rank adaptation (LoRA) to optimize its performance further. Moreover, we integrate focal loss into our framework to address label imbalance issues. The systematic integration of these techniques has resulted in outstanding performance metrics. Upon evaluation using the provided test dataset, our system showcases commendable results, with a remarkable accuracy score of 0.9 for subtask 1, positioning us fifth among all participants. Similarly, for subtask 2, our system exhibits a substantial accuracy rate of 0.781, securing a commendable seventh-place ranking. The code for this paper is published at: https://github.com/123yunnandaxue/Semveal-2024_task9.

1 Introduction

The human reasoning process includes two types of thinking: vertical and horizontal. Vertical thinking is a sequential analysis process based on rationality, logic, and rules. Horizontal thinking is a divergent and creative process. The success of language models has inspired the natural language model (NLP) community to focus on tasks that require implicit and complex reasoning. Although this type of vertical thinking task is widespread, horizontal thinking puzzles have received little attention (Jiang et al., 2024). Task 9 in the SemEval-2024 competition: brainteaser is a multiple-choice task that tests the model's ability to demonstrate horizontal thinking and challenge default common sense associations. The task consists of two subtasks, sentence and word puzzles (Jiang et al., 2023).

- Subtask 1: Sentence-type brain teaser where the puzzle defying commonsense is centered on sentence snippets.
- Subtask 2: Word-type brain teaser where the answer violates the default meaning of the word and focuses on the letter composition of the target question.

In recent years, machine learning models have garnered significant attention. Traditionally, these models have employed a two-step process involving the extraction of hand-crafted features from documents followed by classification using algorithms like Naïve Bayes (Zhang, 2004), SVM (Cortes and Vapnik, 1995), HMM (Trabelsi et al., 2012), or random forests (Ren et al., 2015). However, this approach presents limitations, such as the need for meticulous feature engineering and reliance on domain knowledge for feature design. To address these shortcomings, neural approaches have emerged. Early attempts, such as latent semantic analysis (LSA) (Dumais et al., 1988) and neural language models, initially underperformed compared to classical models but paved the way for developing more powerful embedding models. Significant advancements were made with the introduction of word2vec (Mikolov et al., 2013), ELMo (Peters et al., 1802), RoBERTa (Liu et al., 2019), GPT (Radford et al., 2019), BERT (Devlin et al., 2018), and subsequent models like GPT-3 (Brown et al., 2020) and GShard (Lepikhin et al., 2020), which boast increasingly more significant parameters and training datasets (Minaee et al., 2021).

This paper proposes a deep learning system for Task 9 in SemEval-2024, titled brainteaser. We use the decoding-enhanced BERT (DeBERTa) (He et al., 2020) model with disentangled attention as the base model and use LoRA (Hu et al., 2021) to fine-tune the model. Focal loss was used to address the issue of label imbalance. The back-translation

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 471–476

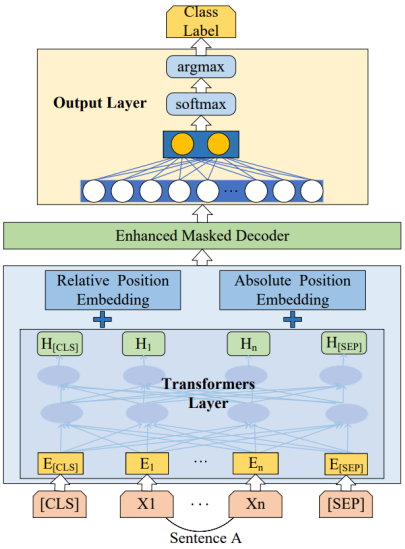

Figure 1: The overall architecture of the proposed method.

method is used to enhance the original dataset, and the processed dataset is used to train the model. The experimental results of this paper were ultimately presented in Task 9 of the SemEval-2024 competition. On the original dataset, the accuracy of Task 1 was 0.9, ranking fifth; The accuracy of Subtask 2 was 0.78, ranking seventh. The rest of this paper is organized as follows. In Section 2, we provided a detailed description of the proposed system and model. The experiment and results are discussed in Section 3. Finally, Section 4 presents the conclusion.

2 DeBERTa

Transformer (Vaswani et al., 2017) has become the most effective neural network architecture for neural language models. Unlike recurrent neural networks (RNNs) (Zaremba et al., 2014) that process text sequentially, transformers apply self-attention functionality to parallelly calculate the attention weight of each word in the input text. Therefore, compared to RNNs, they can perform large-scale model training in parallel. In this paper, the DeBERTa model we use is a new transformer neural language model that improves the Bert model using two novel techniques: a disentangled attention mechanism and an enhanced mask decoder. Figure 1 shows the structure of the system.

2.1 Tokenizer

Given a training data $\mathcal{D} = \{X^{(m)}, y^{(m)}\}_{m=1}^{M}$, $X^{(m)}$ is the input text, $y^{(m)}$ is the corresponding ground-true label, tokenizer is applied to transform $X^{(m)}$ as,

$$X = \{[\text{CLS}], x_1, x_2, ..., x_n, [\text{SEP}]\} \quad (1)$$

where x_i is the token in the text, [CLS] represents the classified characters, and [SEP] represents the terminating characters.

2.2 Encoder

DeBERTa's encoder is mainly composed of multilayer transformer encoders, and each transformer encoder is composed of multiple sub-layers. The following are the main components of the encoder of the DeBERTa model.

Token embeddings. Each token in the input text is first converted into the corresponding word embedding vector. First, we use an embedding layer to map each token x_i to its corresponding word embedding vector. The embedding matrix E is with dimension $V \times d$, where V is the size of the vocabulary and d is the dimension of the word embedding. Then, the embedding vector corresponding to the i-th token x_i can be expressed as $e_i = E[x_i]$.

Positional encoding. Positional encoding represents the absolute position of each word in the input sequence. Suppose we have a position encoding matrix P with dimensions $N \times d$, where d is the dimension of the word embedding. Then, the position encoding vector corresponding to the i-th position p_i can be expressed as $p_i = P[i]$. After adding positional encoding, the new word embedding sequence we get is $E(X) + [p_1, p_2, ..., p_N]$.

Relative positional encoding. The relative position encoding matrix is a learnable parameter matrix with dimensions$L \times 2D$, where L is the maximum sequence length and D is the word embedding dimension. In DeBERTa, the calculation process of relative position encoding is as follows:

For each pair of words (i, j), we calculate its relative position relationship vector r_{ij}.

$$r_{ij} = PE_{(i-j)} \quad (2)$$

where $PE_{(i-j)}$ represents the encoding vector at position $(i - j)$ in the relative position encoding matrix. Finally, the input text sequence X that needs to be sent to transformer encoder layers can be obtained by adding the word embedding vector, position encoding, and relative position encoding.

$$x_i = E[x_i] + p_i + r_{ij} \quad (3)$$

$$X = \{x_1, x_2, ..., x_n\} \tag{4}$$

Transformer encoder layers. Each transformer encoder layer contains the following sub-layers:

1. Multi-head self-attention. This sub-layer allows the model to focus on different parts of the input sequence simultaneously to capture global information.

2. Feed-forward neural network. This sub-layer contains a feed-forward neural network for non-linear transformation and feature extraction of the context vector at each position.

When the input text sequence passes through the encoder of the DeBERTa model, it can be expressed as:

$$H = \text{Encoder}(X) \tag{5}$$

where H is the encoded context representation, X is the input text sequence, and Encoder() is the Encoder part of the DeBERTa model.

2.3 Output Layer

In the DeBERTa model, the output layer is usually used to predict downstream tasks, such as text classification, named entity recognition, etc.

Linear transformation. First, map the output of the transformer encoder to the output space, usually through a linear transformation (fully connected layer). Assuming we have a weight matrix W and a bias vector b, the calculation of the linear transformation can be expressed as:

$$Z = H \cdot W + b \tag{6}$$

where Z is the output after linear transformation.

Activation function. The softmax function is a commonly used activation function in the output layer in multi-classification problems. The formulation of the softmax function is as follows:

$$softmax(x_i) = \frac{e^{x_i}}{\sum_{j=1}^{N} e^{x_j}} \tag{7}$$

where the x_i is the i-th element in the input vector Z, and N is the length of the input vector. Finally, the category label is obtained by the following formula.

$$\hat{y} = argmax(softmax(H \cdot W + b)) \tag{8}$$

Focal loss. Focal loss is a dynamically scaled cross-entropy loss. A dynamic scaling factor can dynamically reduce the weight of easily distinguishable samples during training, thereby quickly focusing the center of gravity on those difficult-to-distinguish samples. The formula for focal loss is as follows.

$$FL(p_t) = -\alpha_t(1 - p_t)^{\gamma} \log(p_t) \tag{9}$$

where the α_t is a trainable parameter, the γ is a hyperparameter, and the p_t represents the probability of the category of t obtained by softmax function.

2.4 LoRA

The low-rank adapter (LoRA) significantly reduces the number of trainable parameters for downstream tasks by freezing the weights of pre-trained models and injecting trainable rank decomposition matrices into each layer of the transformer architecture. Research has shown that the model quality and fine-tuning of LoRA on RoBERTa, DeBERTa, GPT-2 (Radford et al., 2019), and GPT-3 (Brown et al., 2020) are equivalent or better.

LoRA injects trainable low-rank matrices into transformer layers to approximate the parameter update. For a pre-trained weight matrix $W \in \mathcal{R}^{n \times d}$, LoRA decomposes the update with a low-rank factorization,

$$W + \Delta W = W + W^{down} W^{up} \tag{10}$$

where W^{down} and W^{up} are both trainable parameters. Specifically, LoRA applied such an update to the query and value projection matrix in the multi-head attention. For a specific input H_{l-1} to the linear projection in multi-head attention, LoRA can be defined as,

$$H_l = H_l + \gamma \cdot H_{l-1} W^{down} W^{up} \tag{11}$$

where γ was used to scale the contribution of LoRA.

3 Experimental Results

Datasets. The training set for subtask 1 (507 data) and subtask 2 (396 data) are processed using back-translation to enhance the model's efficiency. The dataset is translated into Chinese, Russian, Arabic, French, German, Spanish, Portuguese, Italian,

Method	Loss	Subtask 1	Subtask 2
LoRA	CE	0.93	0.51
	Focal	**0.83**	**0.67**
AdaLoRA	CE	0.37	0.37
	Focal	0.51	0.32
Prompt-Tuning	CE	0.17	0.22
	Focal	0.17	0.27
R-Drop	CE	**0.96**	**0.80**
	Focal	0.34	0.40

Table 1: Accuracy of each strategy in dev data. Results in bold are the best performance.

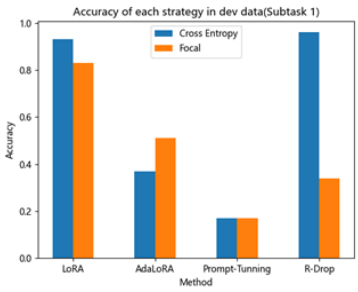

Figure 2: Accuracy of each strategy in dev data (Subtask 1).

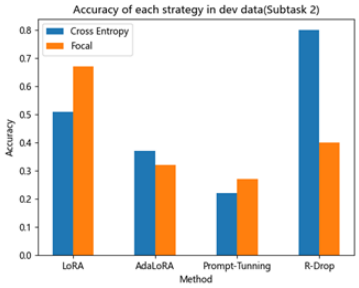

Figure 3: Accuracy of each strategy in dev data (Subtask 2).

Dataset	Subtask 1	Subtask 2
Back-translation method dataset	1.0	1.0
Original dataset	0.96	0.98

and Japanese and re-translated into English. The translated results are added to the dataset to obtain the enhanced dataset: the training set for subtask 1 (5070 data) and the training set for subtask 2 (3960 data).

Evaluation Metrics. In this paper, the task will be evaluated based on the following two accuracy indicators.

- Example-based accuracy: treat each problem (primitive/adversarial) as a separate instance.
- Based on group accuracy: each problem and its related adversarial instances form a group.

Implementation Details. In this paper, we use the back-translation method for data augmentation to improve the model's efficiency. After obtaining more data, use focal loss to address the issue of category imbalance in the data. LoRA is used to reduce the trainable parameters of downstream tasks to save computational costs. This is the DeBERTa-V2-xxlarge model with 48 layers and a 1536 hidden size. The total parameters are 1.5B, and it is trained with 160GB of raw data.

Comparative Results. In addition to using LoRA, this paper also attempted methods such as AdaLoRA (Zhang et al., 2023), Prompt-Tuning (Lester et al., 2021), R-Drop (Wu et al., 2021), using cross-entropy and focal loss as losses, with accuracy as the evaluation metric. The results are shown in Table 1.

Figure 2 depicts validation set accuracy for subtask 1 across various methods. Models employing LoRA and R-Drop exhibit higher accuracy with cross-entropy loss. Transitioning to focal loss saw a 0.1 drop for LoRA, whereas R-Drop experienced a significant decrease. AdaLoRA's accuracy increased by 0.14 with focal loss adoption, though performance remains subpar. Prompt-Tuning's accuracy remains stagnant regardless of the loss function, indicating poor performance.

Figure 3 shows the accuracy of various methods on the validation set for subtask 2. From the figure, we can see that the accuracy of the model using LoRA increased by 0.16 after using focal loss. After using focal loss, AdaLoRA's accuracy dropped by 0.05. Moreover, no matter which method the model uses, its performance on subtask 2 is worse than on subtask 1.

Finally, we found that when using cross-entropy, R-Drop achieved the best results, with LoRA ranking second. However, after using focal loss, the accuracy of R-Drop decreased significantly. Based on the results of cross-entropy and focal loss, using LoRA yields the best result. Therefore, LoRA was chosen for model fine-tuning, and then the data augmentation dataset was used to train the model. The obtained model was retrained using the orig-

Dataset	Subtask 1	Subtask 2
Original dataset	0.900 (5)	0.781 (7)
Semantic reconstruction	0.825 (8)	0.719 (9)
Recontextualization	0.800 (7)	0.812 (6)
Original dataset + Semantic reconstruction	0.825 (8)	0.719 (9)
Original dataset + Recontextualization	0.725 (8)	0.625 (10)
Original dataset + Semantic reconstruction + Recontextualization	0.842 (12)	0.771 (13)

Table 3: Result in the Test

inal dataset, and the results on dev are shown in Table 2.

Table 3 shows the competition results on the Test, with rankings displayed in parentheses. To ensure that the task evaluates reasoning ability rather than memory ability, adversarial versions of the original data are constructed in two ways.

- Semantic reconstruction: rephrasing the original question without changing the correct answer and interfering factors.
- Context reconstruction: maintains the original reasoning path but changes the question and answer to describe the new contextual context.

As shown in Table 3, our model achieved good results on both subtask 1 and subtask 2 on the original dataset. In subtask 1, the accuracy reached 0.9, ranking fifth, and in subtask 2, the accuracy reached 0.781, ranking seventh. Except for the final dataset, the accuracy of our model ranks in the top ten. Moreover, our model performs better on subtask 1 except for the context reconstruction dataset. It is well proven that our system has demonstrated competitive performance.

4 Conclusions

This paper describes a deep learning model for a multiple-choice task (Task 9: brainteaser in the SemEval-2024 competition), using DeBERTa as the base model and achieving good results, ranking fifth in accuracy in subtask 1 and ranking seventh in accuracy in subtask 2. However, there is still considerable room for improvement in the model. Therefore, we will try more methods to improve the model's efficiency in the future.

Abstract

In this paper, we handle the task of building a system that, given a document written first by a human and then finished by a large-language model (LLM), the system must determine the transition word, i.e. where the machine begins to write. We built a system by examining the data for textual anomalies and combining a method of heuristic approaches with a linear regression model based on the text length of each document.

1 Introduction

Large Language Models (LLMs) have never been more available than they are today. The consequence of this is an increase in machine-generated content within various domains. While some of this content could be considered useful, concerns related to the abuse of LLMs has arisen, e.g. the generation of fake product reviews (Adelani et al., 2019), spamming/phishing schemes (Weiss, 2019) and fake news generation (Zellers et al., 2019; Brown et al., 2020; Uchendu et al., 2020). Weiss (2019) demonstrated that humans can only detect human generated text from machine generated text at chance level. This illustrates the clear need for automatic systems to detect LLM generated content.

Regarding mere impressionistic differences between the two types of text, it has been observed that LLMs tend to be more focused, i.e. never leaving the subject matter of their prompt, more objective and highly formal. Their human counterparts tend to be less formal, with more propensity to stray from the topic at hand and more emotional. In terms of linguistic differences between the two, humans use less nouns and conjugations, while employing more punctuation and adverbs. Dependency relations are shown to be shorter. Lastly, human texts have more types in texts of the same length (Guo et al., 2023).

An assumption many researchers take is that LLMs is that language models sample from the head to generate natural looking text e.g. max sampling (Gu et al., 2017) and k-max sampling (Fan et al., 2018). (Solaiman et al., 2019) use a bag-of-words approach with tf-idf feature vectors (both unigrams and bigrams) and a logistic regression model to differentiate between human-written web pages and text generated web pages from GPT2. They examine a different number of parameters of the LLM (117M, 345M, 762M and 1,542M) as well as different sampling methods (k-sampling (sampling the highest probability tokens until a threshold of specified tokens is reached), p-sampling (sampling from the smallest possible set of words until a cumulative probability is reached) and pure sampling (also known as temperature sampling, where lower 'temperatures' are associated with higher probabilities for tokens). Their findings are that the larger the LLM, the harder to detect how machine-like the generated text is and k samples are easier to detect than pure samples, probably due to the fact that k samples over-produce common words, which is easy to detect using statistical methods.

Gehrmann et al. (2019) use BERT and a group of statistical features: the probability of each word, absolute rank of each word and the entropy of the distribution and create a tool for users to see specifically what features are more likely to be machine generated over human generated. They clearly show that the model GPT-2 oversamples certain words; it is worth pointing out, however, that as LLMs grow more sophisticated, such methods might not work as well. Solaiman et al. (2019) use fine tuning on RoBERTa and finds it can detect text generated from GPT-2 with an accuracy of 95%. The most noteworthy aspect of this study is that fine-tuning on GPT-2 itself did not yield as impressive results, which contradicts Zellers et al. (2019) findings which allude to the idea that the best detector of text generated from LLMs are the LLMs themselves. The RoBERTa detector has also been used in detecting fake news articles from several LLMs (Uchendu et al., 2020), Amazon product reviews

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 477–484

(Adelani et al., 2019) and biomedical texts (Rodriguez et al., 2022).

2 Task

This task is slightly different from the tasks described in the previous sections, since the purpose of this task is to guess the correct index at which the LLM starts writing. Since it no longer a binary classification task, i.e. given a document guess if it is a human or machine who wrote it, (which should be approached as an authorship attribution task), it was deemed helpful to examine other computational tasks whose purpose is to generate a boundary line in documents. King and Abney (2013) used four different classifiers to classify words in bilingual documents. They found that Naive-Bayes worked the best using either 1-5-grams, both character and word level. Lui et al. (2014) used a similar Bayesian model to detect language segments in multilingual documents, using byte-encoded n-grams as features and achieving the best results with higher-resource languages like English. Although the task here is profoundly different from these two previous examples, we took inspiration from these studies believing there must be linguistic differences that can be detected with statistical methods between the human generated text and the machine generated text.

3 Data Examination

Anomaly	Frequency	Location
word..word	875	Transition
^␣.Word	252	Transition
single line break	2,334	Human
double spacing	599	Human
gratuitous spacing	65	Human
2× 5-gram	1558	Machine*
2× 10-gram	382	Machine*
2× 15-gram	160	Machine*
2× 20-gram	96	Machine*
3× 5-gram	115	Machine*

Table 1: Anomalies found in training data, where 2× indicates that a particular n-gram appears twice in sequence. Machine* denotes that these occurred overwhelmingly in the machine text (with exceptions being under 1%).

The dataset for this task is the same from (Wang et al., 2024). We created a script to manually examine the transition words for all documents. One striking feature of the data is that only the human generated text featured single line breaks. Another was that in many cases the transition word occurred after tokens which had a word, followed by two full stops and another word. Table 1 provides a full list of anomalies found in the training and development set with their their respective frequencies. Some of the anomalies were present only in the human written text or occurring at the transition word token. Others were found mostly in the machine generated text. The anomalies that were featured near or around the transition word resulted as the most predictable for the creation of our model.

We also examined how frequent each transition token was in the corpus and how often it occurred as a transition word. Since the final evaluation was in terms of the distance from the actual index where the transition word occurred using the formula $\text{text} = \text{document.split(' ')}$, we decided to include tokens with different case and punctuation as separate tokens. Table 7 in the appendix contains the most frequent transition words, all appearing as transition words at least 30 times in the data set, as well as their relative frequency in the training data overall.

4 Experiments

For all experiments, scores are reported as a mean of the results of three runs ± the standard deviation, assuming random choice was involved somehow.

4.1 Random Choice

To establish our own baseline, we decided to create a system that randomly chose an index between 0 and the length of the split text. We then chose various coefficients to multiply the text length by. Table 2 gives a complete list of these experiments. Dividing the length by half or around half e.g. 0.4 gave the lowest MAE, suggesting that the majority of indexes are towards the beginning halves of the texts, not towards the end.

4.2 Heuristics

Based upon the anomalies we found in the data, we decided to incorporate explicit rules in our system of random choice. The first rule that that we experimented with was having the system guess the position of the transition word as the the one proceeding any token that had the pattern Word..Word. While experimenting with the exact regular expression pattern to use, we found the one that accurately guessed the correct index every time was $\backslash\text{w}\backslash.\backslash.\backslash\text{w}$. After this, we established a similar pattern found in the dataset is that when the document's first token was a space, full stop and then a word, then the

Upper bound	MAE
1 len(t)	75.4 ± 0.342
0.5 len(t)	41.6 ± 0.247
0.33 len(t)	43.0 ± 0.287
0.25 len(t)	47.2±0.111
0.66 len(t)	48.2±0.265
0.75 len(t)	53.9±0.246
0.4 len(t)	41.5±0.661
0.6 len(t)	44.6±0.788

Table 2: Random Choice Experiments for training data. The upper bound column indicates the upper bound of the random choice from $0...n$. Margin of error is given for the mean of three trials.

document was entirely machine generated, meaning the correct index was 0. After incorporating these two rules into our system, we left them in all subsequently tested systems, since their predicative power was completely accurate. After establishing these two baseline rules, we investigated having the system guess a random position after the last single line break in the document, guessing the transition word as being one of the frequent transition words under a certain threshold of relative frequency (< 0.01, 0.005, 0.001) and guessing the position as starting with the second repeated n-gram.

Table 3 provides a summary of all heuristic experiments. In the case that a certain rule did not apply to a given document, a random position between 0 and half the length of the text was guessed. The first two rules mentioned reduced the best score from the previous experiments by over 10 MAE, demonstrating they were by far the most robust. Guessing the index as being after the last line break improved the MAE by over 2, indicating it also had a slight effect on overall accuracy.

4.3 Linear Regression

We investigated a heuristic model based upon the length of the text. We were able to combine the first two selected rules with other rules based on text length of each document. The best MAE we obtained from doing this was 25.045±0.231. We decided to investigate using a linear regression model based upon text length, since $R^2 = 0.659$. Figure 1 shows the distribution of the index positions in the training set based on text length. The first experiment combined the first two rules of the previous section and predictions based on a linear regression model for all documents that these rules did not apply to. We obtained a baseline MAE of 20.464 for this. Figure 2 shows the distribution of our guesses using this baseline. We created several different linear models, based upon text length and well as excluding non-heuristic data points and found that our baseline performed the best on the training data. We also combined some heuristic methods from the previous section with this model and found they mostly performed worst, with the exception of slightly modifying the predictions for the texts with a length over 975 (since these are mostly outliers), in which case this method performed slightly better than baseline. Initially, we trained our model on the train data and tested on the dev set provided by the organizers. We obtained slightly better this way, with our baseline model obtaining 18.9 MAE on the dev set. Figure 3 shows the distribution of the dev set by text length and index. Figure 4 shows our predictions for the dev set. They are much more linearly distributed than the overall train set, which

i	Else?	MAE
Last \r\n+1	2nd 10 gram	50.0±0.123
Last \r\n+1	2nd 15 gram	49.2±0.321
2nd 10 gram	Last \r\n+1	47.4±0.412
2nd 15 gram	Last \r\n+1	46.2±0.374
2nd 5 gram	Random Choice	39.1±0.212
$f < 0.001$	Random Choice	32.5±0.232
Word..Word	Random Choice	32.2±0.542
␣.Word	Random Choice	30.8±0.214
Last \r\n+1	$f < 0.005$	30.1 ±0.401
2nd 10 gram	Random Choice	30.1±0.341
2nd 15 gram	Random Choice	29.8±0.021
\r\n+1	Random Choice	28.2±0.439
Last \r\n+1	$f < 0.001$	28.2±0.436
Last \r\n+1	$f < 0.01$	28.2±0.303

Table 3: Heuristic Experiments. i stands for index and f stands for relative frequency i.e. the proportion a token appeared as a transition word to how often it appeared in the data overall. The i column refers to what was guessed as the index first. If this feature was not present in the document, the Else? column indicates what was guessed for that document instead. $f < n$ refers to a transition word with absolute frequency less than n that was guessed as the index. We first tested the Word..Word rule then the ␣.Word rule. We found they always yielded the correct index so we included them in all subsequent experiments. Results are still given in descending order of MAE. Beyond this, all experiments were independent, not cumulative.

i	Else?	MAE
Baseline	N/A	20.5
Non-heuristic data	N/A	28.7
len(t) $<$ 650	N/A	20.4
len(t) $<$ 1000	N/A	20.5
len(t) $<$ 800	N/A	20.4
Random Choice*	Baseline	20.4$\pm$0.009
Last \r\n	Baseline	43.3
2nd 10-gram	Baseline	21.6

Table 4: Linear Regression Experiments. The baseline model refers to a linear model for all data. In some cases, a linear model was created for only some data. The i column refers to index that was chosen first e.g. in the case of the baseline model it was always the either the two previously mentioned heuristics or the index predicted by the linear model. *Applied a random index between 600 and 700 for this experiment for len(t) $<$ 950

(Y-Axis) Blue corresponds to guesses based on the rule Word..Word, orange corresponds to guesses based on the ^␣.Word rule and green corresponds to guessed made with linear regression.

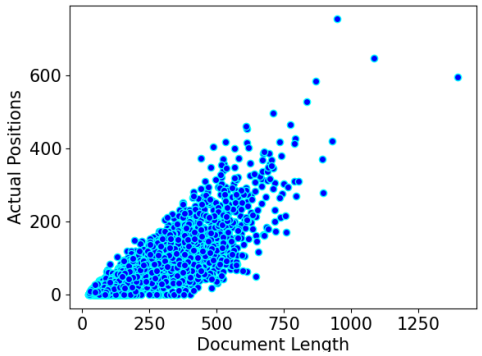

Figure 1: Distribution of the Training Data by Text Length (X-Axis) and Index of Transition Word (Y-Axis)

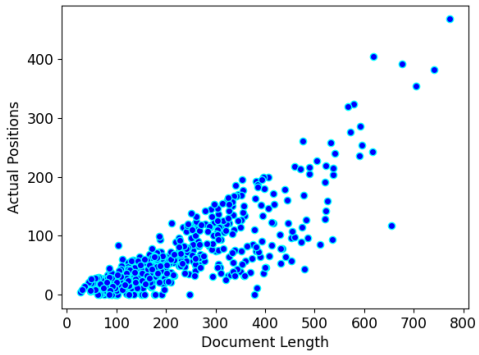

Figure 3: Distribution of the Dev Data by Text Length (X-Axis) and Index of Transition Word (Y-Axis)

explains why the model performed slightly better. Table 4 shows the results for all experiments using linear regression.

5 Results

The solution we submitted to the contest was our baseline linear regression model, since it performed the best, with the exception of the one model with the outlier rule. We chose this over the latter since we assumed the test data would have less outliers in terms of text length, so the baseline linear regression model might perform the best. Our final score for our submission was an MAE of 48.139.

We first examined the test data for the same anomalies found in the training data. Table 8 in the appendix gives a summary of these anomalies. There are far fewer transition word anomalies than

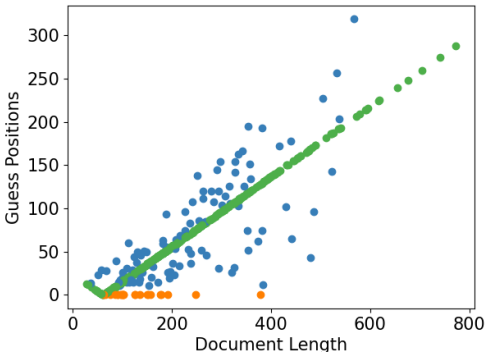

Figure 4: Distribution of Dev Data by Text Length (X-Axis) and Our Predicted Index of Transition Word Using Linear Regression and Heuristics (Y-Axis) Blue corresponds to guesses based on the rule Word..Word, orange corresponds to guesses based on the rule ^␣Word and green corresponds to guessed made with linear regression.

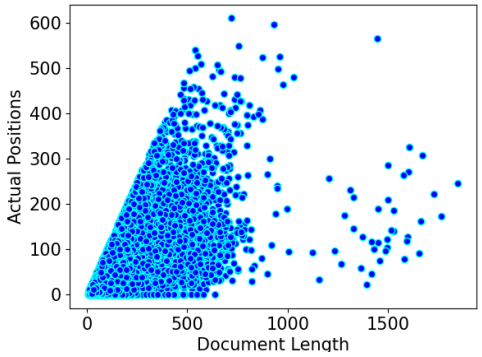

Figure 5: Distribution of Data by Text Length (X-Axis) and Actual Position (Y-Axis) in Test Data

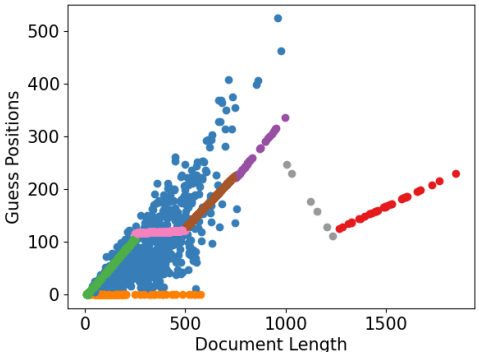

Figure 6: Distribution of Data by Text Length (X-Axis) and Predicted Position of Baseline Model (Y-Axis). Blue corresponds to guesses made with Word..Word rule, orange corresponds to guesses based on our ^␣Word rule, green corresponds to the first linear regression model, pink to the second, brown to the third, purple to the fourth, grey to the fifth and red to the sixth.

in the training data, while the number of repeat n-grams is much higher than in the training data. We also looked at the most frequent transition words in test data. Table 9 in the appendix shows a complete list of all frequent transition words that occurred more than 50 times in the training data, along with their relative frequencies.

Figure 4 shows the distribution of the indexes based on text length for test data. It is much less linearly distributed than the training data (R^2 = 0.26471) and contains a lot more outliers, which explains why our linear model performed much more poorly on it. The next sections explain experiments we did with the training data to improve the linear and heuristic model.

6 Post Hoc Data Analysis

Since the test data is less linearly distributed than the training data, we decided to try different linear models for different lengths of text. Nonetheless, we still trained a linear model on the test data to get a baseline for subsequent experiments. We obtained a baseline of 44.6 MAE. After, we tried different fitting the data to a different number of linear models based upon different text lengths. We used up to six different models in each experiment, adjusting bin sizes. Ultimately, we fit each bin to correspond to the number of quintiles for the model e.g. for final bimodal model, we used the threshold as the median. Our best result ended up being a sixmodal model with the bins 250, 500, 750, 1000 and 1250. We decided to use this linear model when applying subsequent heuristic methods. Table 5 provides the results of our linear experiments. Figure 6 shows a scatter plot of our guesses.

Regarding heuristics, we found that of the frequent transition words in the test data, the ones that almost always occurred as the transition word in a document containing it were those with a relative frequency in the corpus under 0.0001, with the exception of commas and empty strings. Combining this rule with the baseline linear model reduced MAE by ~2. We then looked at repeat higher order n-grams with worse performance. Even though the machine generally generated repeat higher order n-grams, it was still not predictive when determining the boundary line. Lastly, we looked at frequent transition bigrams and frequent transition trigrams. Setting these as the index when they occurred in a document only improved our score slightly. More than anything, they were more accurate in picking the index if they occurred at the beginning of the document, in which case the index for that document was 0. Table 6 provides a summary of all heuristic modifications we made to our system.

7 Conclusion and Considerations for Future Tasks

For our system, due to time constraints, we did not perform any state of the art techniques and of course did not obtain any state of the art results. However, what our paper demonstrates above all is the need for both training data and test data to be better processed with as few textual anomalies as possible. For those teams who trained a neural model for this task, it would be interesting to see what the model learns if these anomalies are removed from the test and training data. It is our hypothesis that

Model	Bins	MAE
Baseline	N/A	44.6
Bimodal	200	42.7
Bimodal	212	42.8
Bimodal	250	42.8
Bimodal	500	44.0
Bimodal	750	44.0
Trimodal	750, 1000	44.0
Trimodal	148, 301	42.7
Fourmodal	125, 212, 358	42.7
Fivemodal	111, 171, 261, 395,	42.6
Sixmodal	103, 149, 212, 299, 423	42.6
Sixmodal	250, 500, 750, 1000, 1250	42.5

Table 5: Linear Regression Experiments, Training and Testing on Test Data. Bins indicate cut off points for models within that particular text length.

Model	*i*	*f*	MAE
Baseline	FTW	< 0.0001	42.6
Baseline	FTW	< 0.001	42.6
Baseline	FTW	< 0.005	71.6
Baseline	FTW	< 0.002	53.0
Sixmodal	FTW	< 0.0001	41.3
Sixmodal	FTB	< 0.0001	41.2
Sixmodal	0 if FTB	< 0.0001	41.1
Sixmodal	FTT	< 0.0001	41.1
Sixmodal	0 if FTT	< 0.0001	41.0

Table 6: Heuristic Adjustments to Linear Models. i indicates index, f indicates relative frequency, FTW indicates Frequent Transition Word, FTB indicates Frequent Transition Bigram and FTT indicates Frequent Transition Trigram.

removing these anomalies would worsen the performance of neural models. Since the best models in this shared task received a score of around 16.0, it would also be interesting to see what kinds of texts they scored better on. Our hypothesis is that texts with the mentioned anomalies were easier to detect for neural networks and that they had more difficulty with longer texts, since longer texts were not featured in the training set. Not knowing the exact LLM used to generate the machine generated text for this dataset it is difficult to say with certainty, but it also our hypothesis that a more sophisticated statistical model could potentially detect more differences between the human and machine text by examining the sampling frequency of words to determine a more probable boundary line.

Abstract

This paper describes our system developed for SemEval-2024 Task 8, "Multigenerator, Multidomain, and Multilingual Black-Box Machine-Generated Text Detection" Machine-generated texts have been one of the main concerns due to the use of large language models (LLM) in fake text generation, phishing, cheating in exams, or even plagiarizing copyright materials. A lot of systems have been developed to detect machine-generated text. Nonetheless, the majority of these systems rely on the text-generating model. This limitation is impractical in real-world scenarios, as it's often impossible to know which specific model the user has used for text generation. In this work, we propose a **single** model based on contrastive learning, which uses ≈**40% of the baseline's parameters** (149M vs. 355M) but shows a comparable performance on the test dataset (***21st out of 137 participants***). Our key finding is that even without an ensemble of multiple models, a single base model can have comparable performance with the help of data augmentation and contrastive learning. [1]

1 Introduction

In recent years, Natural Language Processing (NLP) has been totally dependent on Deep Learning rather than statistical machine learning. With multi-task learning (Caruana, 1997), attention-based transformers (Vaswani et al., 2017), and the use of Reinforcement Learning in NLP (Christiano et al., 2017), it has been used in our day-to-day life from mathematical calculations (Yang et al., 2023) to email writing. But with huge help, it has also been used to generate fake news (Zellers et al., 2019), to plagiarize copyright materials (Dehouche, 2021), and also to cheat in exams or assignments (Cotton et al., 2023; Fyfe, 2023). Humans can identify machine-generated text only at the chance level (Jawahar et al., 2020). There has been a dire need to develop a system to detect machine-generated text.

Though a lot of works (Badaskar et al., 2008; Gehrmann et al., 2019; Zellers et al., 2019; Jawahar et al., 2020; Ippolito et al., 2020; Chakraborty et al., 2023; Pu et al., 2023; Mitchell et al., 2023; He et al., 2023; Guo et al., 2023) have already been deployed for detecting machine-generated text, with the current development of LLMs, most of the systems are failing to find out which one is human-generated vs. machine-generated (mostly due to the improvement of coherency, fluency and usage of real-world dataset (Radford et al., 2019)). In this context, the task "Multigenerator, Multidomain, and Multilingual Black-Box Machine-Generated Text Detection" provides a dataset for training models to classify machine-generated texts. The shared task consists of three sub-tasks: Binary Classification (Machine vs. Human), Multi-class Classification (Which model/human generated this?), and Span Detection (Which part of the text is machine-generated?). A detailed description of the task can be found in the shared task paper (Wang et al., 2024).

In this paper, we describe our final submission on Subtask A (Binary Classification). There were two big challenges of this task: **First,** five Different models have been used to generate the machine-generated text. Zellers et al. (2019) has shown that the best defense for machine-generated text is the model itself that was used for generation. However, in reality, there is a massive surge in large language models (LLMs), each with its own unique style of text generation. The challenge in this particular subtask has heightened due to the utilization of five different LLMs. This complexity demands a versatile, model-agnostic architecture capable of detecting text generated by LLMs in a generalized manner. **Second,** Following the previous challenge, the organizers have employed a different model

[1] Our code is publicly available at https://github.com/dipta007/SemEval24-Task8

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 485–491

for generating the validation and test datasets compared to those used in the training set. This implies that the text was drawn from a completely distinct distribution. As a result, participants must develop a generalized model capable of performing effectively regardless of the specific model used in the text generation process.

In response to the key challenges, we have investigated the performance of contrastive learning for this particular task. Contrastive learning has been used as a valuable technique across various domains, including Text Embedding (Neelakantan et al., 2022), Document Embedding (Luo et al., 2021), Event Embedding (Roy Dipta et al., 2023), vision (Chen et al., 2020) and Language-Vision learning (Radford et al., 2021). Notably, unlike the majority of submissions in any shared task like competition, Our final submission utilized a **single** model to classify the machine-generated texts rather than an ensemble of multiple models. Hence, our contributions to this paper are as follows,

1. We proposed a novel data augmentation technique, which nearly makes the data X times bigger (X is the number of models used for data augmentation).

2. We propose a single unified model that shows a comparable performance on the test dataset.

3. We have shown that even with a single model, contrastive learning with data augmentation shows a comparable performance, which opens up a door for future exploration.

2 Related Works

In this section, we will provide the prior works that have been done in the realm of machine-generated text detection (§2.1) and contrastive learning (§2.1).

2.1 Machine Generated Text detection

With the progress of LLMs, much prior research has been done to counter-attack the misuse of the LLMs. Before the attention and transformers, Badaskar et al. (2008) has shown how the syntactic and semantic features can help in classifying between human and machine-generated text. Later, Gehrmann et al. (2019) has provided a statistical detection system based on the assumption that the machine samples from the high probability words through max sampling (Gu et al., 2017), k-max sampling (Fan et al., 2018), beam search (Shao et al., 2017). So, the authors used the probability, rank, and entropy of words as features to classify a machine-generated text. Jawahar et al. (2020) has shown that state-of-the-art LLM can generate texts with human-like fluency and coherence without grammatical or spelling errors. Lastly, Mitchell et al. (2023) have used the change of log-probability between the original text and after random perturbation.

2.2 Contrastive Learning

Contrastive learning was first introduced in the visual domain (Chen et al., 2020). Later, it has been widely used in NLP for representation learning (Xu et al., 2023; Wang and Dou, 2023), event similarity tasks (Gao et al., 2022) and event modeling (Roy Dipta et al., 2023). Inspired by the latter works, we have explored whether contrastive learning can help in machine-generated text detection.

3 System Overview

Our system is divided into three parts: where the first part is data augmentation (described on §3.1), the second part is contrastive learning (described on §3.2), and the last part is the classification head (described on §3.3) over the document embeddings.

3.1 Data Augmentation

The dataset provided in the shared task has text and their corresponding label. However, we need a positive and a (hard) negative pair to use contrastive learning. Our main inspiration for using contrastive learning is that as the texts come from two different entities (machine vs. human), the embedding space should also be different. To facilitate the task, we have used a paraphrase model to generate alternate texts for each text in the dataset. In that way, now, every instance of the dataset has one human/machine-generated text and one machine-generated text. We have utilized the human-generated text as the hard negative [2] and the machine-generated text as the soft positive [3].

Another challenge we faced during the paraphrasing of the dataset is that the texts are long. If we give the whole text to the paraphrase model and ask for alternate text, it gives a much shorter text (an issue we observed in the used paraphrase model). In our primary validation, that gives bad

[2] Hard negatives are the total opposite of the given text

[3] Soft positives expressed the same idea but might not be the exact one

results due to the loss of information while shortening the text. So, instead of giving the whole text at once, we have split the data by end-of-sentence or newline. Then, each sentence was paraphrased on its own and then joined together again to get the previous structure. The technical details behind generating paraphrases and using them for contrastive learning have been discussed in §4.1 and §4.2, respectively.

3.2 Contrastive Learning

With the availability of an appropriate dataset for contrastive learning, we proceeded to develop our model. Our main assumption was that the embedding of the machine-generated text and human-generated text would exhibit significant differences. A simple overview of the model is shown in the Fig. 1.

The positive and negative data go through the same shared encoder to generate an embedding. This embedding is then used in contrastive learning. We have used the following loss formulation for our contrastive learning:

$$\begin{aligned}\mathcal{L}_{con} &= (1-y) * cos(x_1, x_2) \\ &\quad + y * max(0, cos(x_1, x_2))\end{aligned} \tag{1}$$

Here, x_1 and x_2 are the embeddings of two different pairs, respectively. $cos(x_1, x_2)$ is the cosine-similarity score between two embeddings. y is $+1$ for positive-positive pairs and -1 otherwise. In our task, y is $+1$ if the data instance contains text from a machine and the other is paraphrased text and -1 if the given text is from a human and the other is paraphrased.

3.3 Classification Loss

In contrastive learning, our primary objective is to acquire meaningful embeddings containing sufficient information for distinguishing between human-generated and machine-generated text. However, we also need to use a classifier model for the downstream task of outputting the actual label. Keeping that in mind, we have used a simple two-linear layer classifier head on top of the embeddings generated by the encoder. During inference time, we used this classifier head to output the labels. We have optimized our model using a simple binary cross-entropy (BCE) loss.

The total loss of our model is defined as,

$$\mathcal{L} = \alpha * \mathcal{L}_{con} + \beta * \mathcal{L}_{cls_+} + \gamma * \mathcal{L}_{cls_-} \tag{2}$$

Here, $\mathcal{L}_{cls_+}$ is the BCE loss of the positive example, and $\mathcal{L}_{cls_-}$ is the BCE loss of the negative sample of the data instance. α, β, and γ are hyperparameters that were set to 0.7, 0.8, and 0.1, respectively, based on validation data.

4 Experimental Setup

The following sections are used to describe the technical details behind our data augmentation technique (§4.1), Encoder (§4.2), Classifier Head (§4.3) and Hyperparameters (§4.4).

4.1 Data Augmentation & Pre-processing

We preprocess the raw input, splitting each document into multiple sentences for paraphrasing. After the preprocessing, we got $\approx$ 3.6 million sentences. Even if we are splitting by new lines or end-of-sentences, we kept exactly the same format during joining, i.e., two new lines rather than 1, to keep most information intact. As the paraphrasing is done on the sentence level rather than the paragraph level, the number of paraphrased sentences is the same as the input sentences (3.6M). So, ideally, we got double the number of training data just by using the data augmentation.

We have tried multiple models from HuggingfaceHub [4] [5] to generate paraphrase. In our final submission, we have used Bandel et al. (2022)'s model [4] for our data augmentation. Use of multiple models or use of prompt-based models (Achiam et al., 2023; Touvron et al., 2023) for data augmentation has been left out for future exploration due to time and compute constraints. For data split, we use the official train & dev data split. Only train data is used for data augmentation, and the dev data is used to calculate evaluation metrics.

4.2 Pre-trained Encoder

To encode the document, we have used a pre-trained version of longformer-base (Beltagy et al., 2020) [6]. The reason behind using this encoder rather than others is, **One,** longformer is good for getting embeddings for long documents because of using global vs. local attention (more details in Beltagy et al. (2020)). **Second,** the pre-trained version was fine-tuned for paraphrase detection, which is kind of similar to our task.

[4] ibm/qcpg-sentences
[5] ceshine/t5-paraphrase-paws-msrp-opinosis
[6] jpwahle/longformer-base-plagiarism-detection

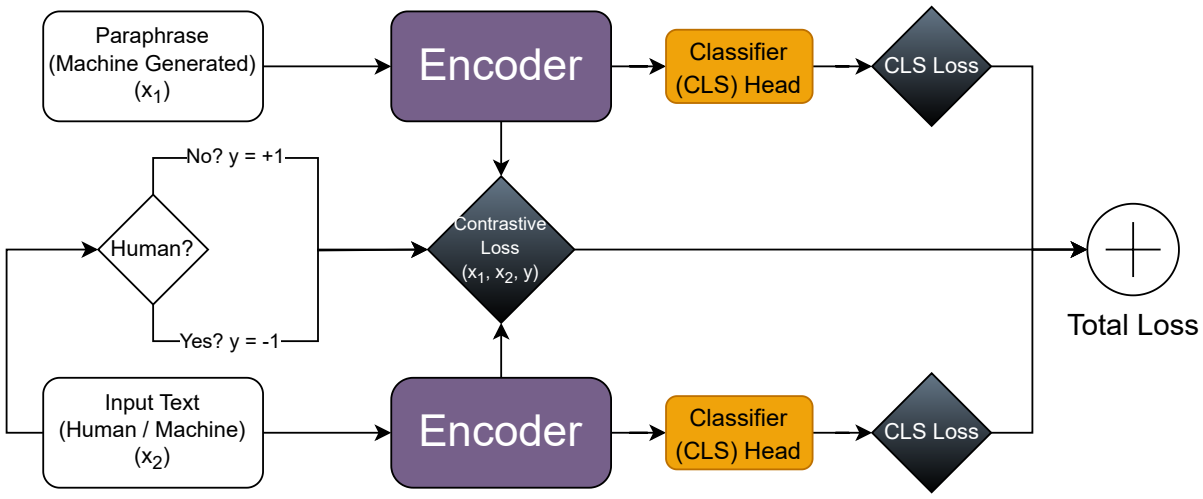

Figure 1: Overview of our model architecture. The same color weights are shared (encoder & classifier head). Diamond boxes represent the loss function, and the plus sign represents the summation of the three losses. The input to the contrastive loss depends on the original label (y=+1 if human, else −1).

4.3 Classifier Head

We have used two linear layers for classifier heads with *tanh* activation loss between them. We also have used a dropout layer between them with a probability of 60%. The primary rationale for using a high dropout rate was to enhance the model's generalization ability and reduce its dependence on the training data.

4.4 Hyperparameters

For training our model, we have used AdamW (Loshchilov and Hutter, 2017) optimizer with a learning rate of 1e-5. We have used a batch size of 2 with gradient accumulation for 8 steps (effective batch size 16). We have used early stopping on the validation data with patience 10. Maximum document length was set to 4096 as most of the documents are large. We use the PyTorch-lightning [7] library to run the experiments and Weight & Biases [8] for logging. All of our experiments are run on NVIDIA Quadro RTX 8000 48GB.

5 Results

In this section, we report our results on subtask A and discuss our analysis. Our evaluation is based on the accuracy metric, but we have provided the micro and macro-f1 for better comparison. All the results are averaged on 3 runs with 3 different random seeds.

[7] https://lightning.ai/
[8] https://wandb.ai/

5.1 Baseline & Our Model

We use the official baseline provided by the task organizers. They have used RoBERTa-large (Liu et al., 2019) as the encoder and fine-tuned on the train data. Throughout the paper, we refer to this model as $baseline_{rob}$.

We have fine-tuned our model (shown in Fig. 1) on the training dataset. Throughout the paper, we refer to this model as $ours_{con}$

In the Table 1, we have reported the results on the official test file. $Ours_{con}$ is the final submission, and $Ours_{con}$+ is the modified version of our final model for more analysis (not official results; used for ablation study - details on §5.2). We can get a comparable result using 60% fewer parameters than the baseline. In the next section, we will see that after hyperparameter tuning, we can get around 5.7% improvement over the baseline. This supports our assumption that using a contrastive learning-based method can help machine-generated text identification.

5.2 Ablation Study

Effect of Maximum Sentence Length: The maximum sentence length is used to tokenize the document. The optimal test score is achieved with a maximum sentence length of 256. This demonstrates that the model can effectively identify machine-generated text even with documents as large as 256 words. This underscores the effectiveness and adaptability of our model's learning capabilities.

	Max Sen Length	CLS Dropout	Effective Batch Size	Macro-f1	Micro-f1	Accuracy
$Ours_{con}$	4096	0.6	16	**88.81**	**89.07**	**89.07**
$baseline_{rob}$	-	-	-	-	-	88.47

Classification Layer Dropout						
$Ours_{con}+$	4096	0	16	**92.73**	**92.81**	**92.81**
$Ours_{con}+$		0.2		90.16	90.33	90.33
$Ours_{con}+$		0.4		78.98	80.21	80.21
$Ours_{con}$		0.6		88.81	89.07	89.07
$Ours_{con}+$		0.9		82.60	83.31	83.31
Effective Batch Size						
$Ours_{con}+$	4096	0.6	2	**<u>93.80</u>**	**<u>93.86</u>**	**<u>93.86</u>**
$Ours_{con}+$			4	70.79	73.52	73.52
$Ours_{con}+$			8	76.82	78.43	78.43
$Ours_{con}$			16	88.81	89.07	89.07
$Ours_{con}+$			32	79.72	80.83	80.83
$Ours_{con}+$			64	90.64	90.80	90.80
$Ours_{con}+$			128	91.39	91.51	91.51

Table 1: Macro-f1, Micro-f1, and Accuracy score on the test result. $Ours_{con}$ - final submitted model on the shared task, $baseline_{rob}$ - official baseline model, and $Ours_{con}+$ - modified versions of our final model with more hyperparameter tuning. The **bold** value signifies the best score within a specific section, whereas the **<u>underlined</u>** value denotes the best score across all sections.

Effect of Classification Dropout: The classification dropout is applied between the two classification layers. Contrary to our initial assumption, the results presented in Table 1 indicate that using a low dropout rate (as low as 0.0) contributes positively to the model's learning process. This suggests that, even without dropout, the model's generalization to unseen data (text generated by a new model) is enabled primarily through contrastive learning and data augmentation.

Effects of (Effective) Batch Size: Due to computational constraint, we have used a fixed batch size of 2 and gradient accumulation steps of $\{1, 2, 4, 8, 16, 32, 64\}$ resulting in an effective batch size of $\{2, 4, 8, 16, 32, 64, 128\}$. From the results report on Table 1, we found that using only an effective batch size of 2 yielded superior performance compared to gradient accumulation. Notably, this configuration represents the most optimal result obtained following hyperparameter tuning, positioning us at the 8^{th} rank in the final standings. This suggests that, in this particular context, the benefits of gradient accumulation may be limited compared to simply using a smaller batch size.

6 Conclusion & Future Work

In this work, we introduce our contrastive learning-based system, which shows a comparable performance. We demonstrate that a model with half the parameters and without an ensemble of large models or hand-engineered features can show a comparable performance, which requires more exploration in this field. For future work, the use of recent prompt-based models [9] can be used for data augmentation. Also, the effect of more advanced contrastive loss, i.e., Triplet loss (Chechik et al., 2010) or InfoNCE loss (Oord et al., 2018), need to be explored.

Team AT at SemEval-2024 Task 8: Machine-Generated Text Detection with Semantic Embeddings

Yuchen Wei
Department of Computer Science
St. Francis Xavier University
x2020fct@stfx.ca

Abstract

This study investigates the detection of machine-generated text using several semantic embedding techniques, a critical issue in the era of advanced language models. Different methodologies were examined: GloVe embeddings, N-gram embedding models, Sentence BERT, and a concatenated embedding approach, against a fine-tuned RoBERTa baseline. The research was conducted within the framework of SemEval-2024 Task 8, encompassing tasks for binary and multi-class classification of machine-generated text.

1 Introduction

In the burgeoning field of Natural Language Processing (NLP), the distinction between human and machine-generated text is becoming an area of critical importance, particularly with the rise of advanced language models capable of producing text that closely mimics human writing. The advent of such technology poses a dual-faceted challenge: while it opens new frontiers for automation and assistance, it also necessitates robust detection mechanisms to prevent misuse and uphold information credibility. This research centers on the application of semantic embeddings to detect machine-generated text.

Semantic embeddings offer a nuanced approach to understanding and representing the meaning encapsulated within text, providing a fertile ground for discriminating between the subtleties of human and AI-authored content. This study contributes to this domain by evaluating the efficacy of various semantic embedding techniques in the context of SemEval-2024 Task 8's (Wang et al., 2024) challenges, which include the detection of machine-generated text across multiple generators and domains.

In this study, I concentrated on the application of semantic embeddings, examining and contrasting approaches such as GloVe and Sentence BERT. I developed classifiers for the task of classifying machine-generated text as part of SemEval-2024 Task 8. Specifically, my efforts were directed towards Subtask A (monolingual) and Subtask B, which involve the binary classification of machine-generated text and multi-class classification of machine-generated text, respectively.

2 Related Work

The identification and analysis of machine-generated text have become an increasingly pertinent field of study within the realm of Natural Language Processing (NLP). Previous research has primarily focused on detecting text authored by specific language models (Guo et al., 2023) or within narrow domains (Zellers et al., 2019). The latest iteration of this exploration is represented in the work by SemEval-2024 Task 8 (Wang et al., 2024), aiming at detecting text generated by a variety of models across multiple domains and languages, thus expanding the scope of investigation significantly beyond the existing literature.

Early approaches, such as those by Iyyer et al. 2014, utilized basic statistical features and machine learning models for text classification tasks, providing a foundation for subsequent research. Advancements were made by Pennington et al. 2014, who proposed a sophisticated embedding technique known as GloVe, which captures global word co-occurrence statistics (Bullinaria and Levy, 2007) to generate word representations. This technique has been widely adopted for its robustness in capturing semantic nuances.

The introduction of transformer-based (Vaswani et al., 2017) models, particularly BERT (Devlin et al., 2018) and its variants, has revolutionized the field, as demonstrated by Reimers and Gurevych 2019 with the adaptation of BERT for sentence-level embeddings (SBERT). These models have significantly outperformed traditional embeddings and

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 492–496

N-gram models in various NLP tasks due to their deep contextual understanding and adaptability to different tasks and domains. Moreover, RoBERTa (Liu et al., 2019) (A Robustly Optimized BERT Pretraining Approach) refines the BERT model's training methodology to substantially improve performance across a spectrum of NLP benchmarks.

More recently, Large Language Models (LLMs) have revolutionized text generation, achieving human-like proficiency across diverse writing tasks. As LLMs like ChatGPT (Brown et al., 2020) and its successors become more adept at generating coherent and contextually relevant narratives, the importance of distinguishing between machine-generated and human-produced text grows, primarily to ensure transparency and mitigate the spread of misinformation. Consequently, developing robust detection methods for machine-generated text is crucial in maintaining the integrity of information and upholding trust in digital communications.

3 Methods

In this study, I explored four semantic embedding methods to evaluate against the fine-tuned RoBERTa baseline provided by the task coordinators (Wang et al., 2024). The methods employed encompass the GloVe (Pennington et al., 2014) embedding method, the training N-gram embedding method, Sentence BERT method, and the concatenated embedding method. In this section, I will present the methodologies applied to address Subtask A (monolingual) and Subtask B. Their primary distinction lies in the extraction of text features.

3.1 GloVe Embedding Method

Pre-trained GloVe embeddings are a set of vector representations for words that have been previously trained on large corpora, encapsulating rich semantic and syntactic relationships between words. In this approach, for each piece of text, GloVe embeddings were utilized to derive the text feature, calculated as the mean of the GloVe embeddings for each word within the text. Subsequently, a straightforward fully connected neural network, comprising several hidden layers, was constructed to perform classification.

I experimented with GloVe embeddings of varying dimensions (100d, 200d, 300d) and employed Smooth Inverse Frequency (SIF) weighted averaging as the method for averaging. This approach (Arora et al., 2017) has been demonstrated to enhance the performance of text embedding usage.

3.2 Training N-gram Embedding Method

In addition to GloVe embeddings, I explored the training of word embeddings through an N-gram neural network model. This model was designed to train a word embedding layer with the objective of predicting the subsequent word based on a given sequence of N words. Subsequently, the trained word embeddings were utilized to extract text embeddings, which then served as the basis for classification, similar to the methodology applied with GloVe embeddings.

3.3 Sentence BERT Method

Sentence BERT (Reimers and Gurevych, 2019) is a modification of the pre-trained BERT model that enhances its capabilities for generating sentence-level embeddings, facilitating more efficient and semantically meaningful comparisons between sentences. In this approach, similar to others, classification is conducted through a fully connected neural network; however, Sentence BERT is employed for the extraction of text features.

3.4 Concatenated Embedding Method

In this methodology, I concatenated word embeddings with Sentence BERT embeddings to serve as the text feature embeddings. The objective is to leverage the strengths of both approaches to enhance classification performance. The dimension of the concatenated embedding for each sample's text equals to the sum of the dimensions of the word embeddings and the SBERT embeddings. I experimented with combining GloVe and SBERT, as well as N-gram embeddings with SBERT. Ultimately, in a similar vein, a fully connected neural network was employed for inputting concatenated embeddings and performing the classification tasks.

4 Dataset and Experimental Setting

4.1 Dataset

The coordinators of SemEval-2024 Task 8 have introduced three subtasks focused on the detection of machine-generated text, encompassing multi-generator, multi-domain, and multi-lingual challenges. The first task (Subtask A) is framed as a binary classification challenge, with the goal being to differentiate between human-written and machine-generated text. Subtask A is divided into two segments: monolingual and multilingual. The mono-

lingual segment contains 119,757 training samples, while the multilingual segment includes 172,417 training samples. In this research, my attention is solely directed towards the monolingual task, which exclusively involves texts in English. Its training set comprises 56,406 samples generated by machines and 63,351 samples authored by humans.

The second task (Subtask B) is structured as a multi-class classification challenge, wherein the labels for text samples encompass *human*, *ChatGPT*, *Cohere*, *Davinci*, *Bloomz*, and *Dolly*. This task requires classifiers to not merely determine whether a given text is machine-generated but also to identify the specific type of language model (e.g., ChatGPT (Brown et al., 2020), Cohere (Cohere Technologies, 2021)) responsible for its generation. This task encompasses a training set comprising 71,027 samples (11,997 samples for *human*, 11,995 samples for *ChatGPT*, 11,336 samples for *Cohere*, 11,999 samples for *Davinci*, 11,998 samples for *Bloomz*, 11,702 samples for *Dolly*).

The third task (Subtask C) focuses on locating the boundary within each mixed text sample. For this subtask, the provided samples are mixed texts, consisting of a human-written segment followed by a machine-generated segment. The primary objective is to identify the transition point between these two segments. This subtask includes 3,649 training samples. In my research, I did not engage with this particular subtask.

4.2 Experimental Setting

In this study, I applied my methodologies to Subtask A and Subtask B, assessing their effectiveness on the training sets using a K-fold cross-validation approach with K=5, as well as on the testing sets. Accuracy was selected as the evaluation metric for this analysis. I employed a fine-tuned RoBERTa model (Liu et al., 2019) as the baseline against which to compare my approaches. The released testing sets for Subtask A (monolingual) and Subtask B consist of 34,272 and 18,000 samples, respectively. Within the Subtask A testing set, there are 18,000 machine-generated samples and 16,272 human-written samples. For Subtask B's testing set, each label is represented by 3,000 samples.

5 Experimental Results

In this section, I will present and analyze the experimental outcomes derived from the implementation of my methodologies.

5.1 GloVe Embedding Method Results

The data in Table 1 elucidates the efficacy of the GloVe embedding methodology when applied to Subtask A (binary classification) and Subtask B (multi-class classification) of text classification. The results are segmented according to the dimensionalities of the GloVe embeddings—100, 200, and 300—and benchmarked against the performance of a fine-tuned RoBERTa model. A pattern of ascending accuracy aligns with the increase in GloVe dimensions for Subtask A, culminating in a maximum accuracy of 62.1% on the test set for the 300-dimensional GloVe model. Conversely, for Subtask B, the trend, though similar, is subdued, with the 300-dimensional model attaining an accuracy of 34.6% on the test set. The RoBERTa model, which serves as the baseline, outshines the GloVe models with a substantial margin, exhibiting peak accuracies of 73.6% on Subtask A and 48.6% on Subtask B during test evaluations.

It's clear that the dimensionality of GloVe embeddings has a direct correlation with the accuracy of the models; higher dimensions lead to more expressive embeddings and, consequently, better performance. However, despite the improvements seen with 300-dimensional embeddings, the GloVe models fall short when compared to the fine-tuned RoBERTa model.

Method Name	A K-fold	A Test	B K-fold	B Test
GloVe 100d	75.6%	59.6%	46.5%	31.3%
GloVe 200d	78.2%	61.4%	47.9%	32.9%
GloVe 300d	79.7%	62.1%	49.3%	34.6%
RoBERTa	93.8%	73.6%	63.1%	48.6%

Table 1: The experimental outcomes for the GloVe embedding method, spanning various dimensions.

5.2 Training N-gram Embedding Method Results

Table 2 presents the performance of the N-gram embedding method for both Subtask A and Subtask B, showing a progression in accuracy as the value of N increases, indicating that loner contexts inputed by N-grams contribute to more accurate models. Specifically, for Subtask A, the 2-gram model starts with a K-fold accuracy of 79.1% and a test accuracy of 60.3%, which gradually increases with the 5-gram model reaching a K-fold accuracy of 82.1% and a test accuracy of 61.4%. For Subtask B, the increase in N-gram size also correlates

with a slight increase in accuracy, with the 5-gram model achieving a K-fold accuracy of 48.7% and a test accuracy of 33.9%.

When compared to the GloVe embedding method from the earlier table, the N-gram models demonstrate a competitive edge in K-fold accuracy for Subtask A, but this edge diminishes in the test results where GloVe 300d outperforms the N-gram methods. For Subtask B, the N-gram models show a similar pattern with slightly better performance compared to the GloVe 100d and 200d models but are still outperformed by the GloVe 300d and the fine-tuned RoBERTa model. RoBERTa continues to maintain a significant lead over both GloVe and N-gram methods, underscoring the effectiveness of contextualized embeddings over both static and N-gram embeddings for the tasks at hand.

Method Name	A K-fold	A Test	B K-fold	B Test
2-gram	79.1%	60.3%	47.9%	31.5%
3-gram	81.4%	61.4%	48.7%	33.3%
4-gram	80.5%	61.7%	49.3%	33.2%
5-gram	82.1%	61.4	48.7%	33.9%
RoBERTa	93.8%	73.6%	63.1%	48.6%

Table 2: The experimental results for the N-gram embedding method, across different values of N representing the number of words in the input context.

5.3 Sentence BERT Method Results

Table 3 illustrates the performance for the Sentence BERT (SBERT) method applied to Subtask A and Subtask B, with the variation in performance attributed to the different counts of hidden layers, denoted as H. The results reveal that for Subtask A, the model with one hidden layer (SBERT H=1) achieved a K-fold accuracy of 84.1% and a test accuracy of 66.3%. As the number of hidden layers increased, there was a marginal improvement in K-fold accuracy, peaking at 83.6% for four hidden layers (SBERT H=4), while the test accuracy remained relatively stable, peaking at 66.3% for one hidden layer. In Subtask B, the trend is less clear, with SBERT H=1 achieving the highest test accuracy at 38.1%, despite having a lower K-fold accuracy compared to models with more hidden layers. When compared to the GloVe method and the N-gram embedding method from previous tables, SBERT tends to offer improved test accuracy in both Subtask A and Subtask B.

Method Name	A K-fold	A Test	B K-fold	B Test
SBERT H=1	84.1%	66.3%	52.6%	38.1%
SBERT H=2	82.1%	65.6%	52.7%	37.5%
SBERT H=3	82.7%	65.8%	51.5%	36.7%
SBERT H=4	83.6%	65.8%	50.7%	37.1%
RoBERTa	93.8%	73.6%	63.1%	48.6%

Table 3: The experimental results for the Sentence BERT (SBERT) method, varying across different counts of H, which denotes the number of hidden layers.

5.4 Concatenated Embedding Method Results

Table 4 displays the experimental results for the concatenated embedding method, combining Sentence BERT (SBERT) with GloVe embeddings and a 5-gram model. The SBERT+GloVe model exhibits a K-fold accuracy of 85.4% and a test accuracy of 68.1% for Subtask A, while for Subtask B, it shows a K-fold accuracy of 53.2% and a test accuracy of 38.9%. The SBERT+5-gram model slightly outperforms the SBERT+GloVe in Subtask A with a K-fold accuracy of 86.7% and a test accuracy of 67.3%, and a K-fold accuracy of 54.1% for Subtask B, though the test accuracy is slightly lower at 38.3%. These results indicate that combining SBERT with 5-gram embeddings or GloVe embeddings could provide a marginal improvement over methods that apply each exclusively.

Method Name	A K-fold	A Test	B K-fold	B Test
SBERT+GloVe	85.4%	68.1%	53.2%	38.9%
SBERT+5-gram	86.7%	67.3%	54.1%	38.3%
RoBERTa	93.8%	73.6%	63.1%	48.6%

Table 4: The experimental results for the concatenated embedding method.

5.5 Competition Submission

Since my methods did not perform as well as the fine-tuned RoBERTa, I ultimately submitted the predictions of my fine-tuned RoBERTa model on the test sets for Subtask A and Subtask B. In the end, my predictions ranked 79th for Subtask A and 63rd for Subtask B.

6 Conclusion

In conclusion, this research has contributed to the field of detecting machine-generated text by exploring the efficacy of various semantic embedding methodologies. The results present the performance of several pre-trained semantic embeddings, like GloVe and SBERT, on the tasks of machine-generated text detection in SemEval-2024 Task 8.

Due to the superior performance of the fine-tuned RoBERTa model over all my methods I implemented, I ultimately chose to submit the prediction results obtained from RoBERTa for the SemEval competition.

7 Limitation

The limitations of this work mainly exist in two aspects. First, the methods used are too traditional and outdated. Secondly, its performance is not as good as the baseline.

liuxintong@stu.jiangnan.edu.cn
luhengyang@jiangnan.edu.cn

Abstract

This paper is submitted for SemEval-2027 task 7: Enhancing the Model's Understanding and Generation of Numerical Values. The dataset for this task is NQuAD [1], which requires us to select the most suitable option number from four numerical options to fill in the blank in a news article based on the context. Based on the BertForMultipleChoice model, we proposed two new models, MC BERT and SSC BERT, and improved the model's numerical understanding ability by pre-training the model on numerical comparison tasks. Ultimately, our best-performing model achieved an accuracy rate of 79.40%, which is 9.45% higher than the accuracy rate of NEMo [1].

1 Introduction

In the field of Natural Language Processing (NLP), the understanding and analysis of textual data have always been the main focus. However, the numerical information in these textual data is often overlooked. Numerals play a significant role in our daily life and work, providing rich information such as dates, times, quantities, proportions, and money. Although numerals may not occupy a large proportion in the text, their existence is crucial for understanding the meaning of the text.

To better evaluate the numerical understanding ability of models, [1] proposed the Numeral-related Question Answering Dataset (NQuAD) [1], which is specifically designed to evaluate and enhance the model's ability in Reading Comprehension of the Numerals in Text. In our work, our goal is to improve the performance of the BERT model on the NQuAD [1]. For this purpose, we propose a new method that can effectively handle numerical information. Our experimental results show that our method has achieved significant performance improvement on the NQuAD [1]. This proves the effectiveness of our method in handling numerical information and also shows the potential of our method in enhancing the numerical understanding ability of the model.

The rest of this paper is organized as follows. Section 2 introduces the related work. Section 3 introduces the dataset and tasks. Section 4 describes our method in detail. Section 5 reports our experimental results and analysis. Finally, we conclude our work.

2 Related Work

In recent years, pre-training tasks have become increasingly prevalent in the field of Natural Language Processing (NLP). The design goal of pre-training tasks is to enhance the model's understanding of natural language through learning from a large amount of unlabeled data, thereby improving the model's performance on specific tasks in the subsequent fine-tuning stage. In this trend, [2] shows that by pre-training on numerical comparison tasks, the model's understanding of numerals can be significantly improved. The model, after pre-training, also shows a significant performance improvement on other numeral-related tasks.

Multiple choice [3] format represents a category within machine reading comprehension tasks. In this context, [4] proposed a Multi-stage Multi-task learning framework (MMM) aimed at enhancing the performance of multiple choice tasks, [5]introduced the Dual Co-Matching Network (DCMN+), a model that emulates human problem-solving strategies, and [6] presents a two-step strategy for enhancing the performance of Large Language Models (LLMs) on multiple choice tasks.

Recent research has increasingly recognized the significance of numerical data within text. The NQuAD [1] dataset has been instrumental in examining the relationship between numerical values in news headlines and the corresponding figures within the articles. Similarly, the FNXL [7] dataset has brought attention to the numerical data con-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 497–502

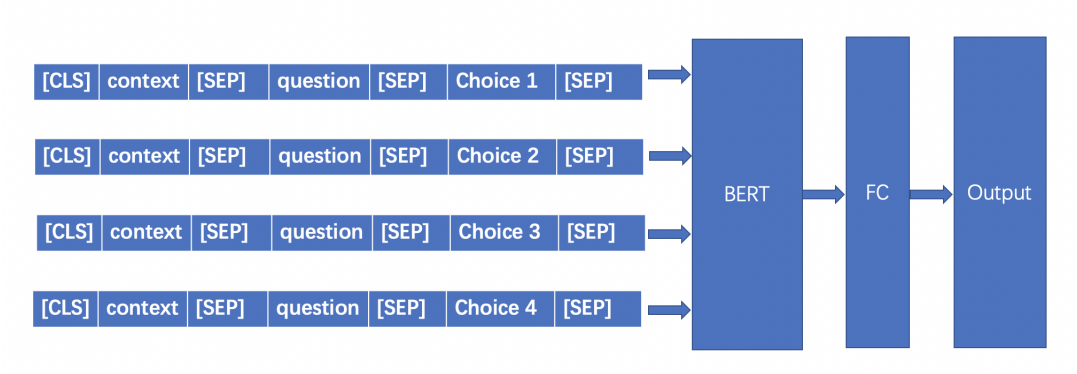

Figure 1: **Architecture of BertForMultipleChoice model**

tained within the periodic financial reports submitted by publicly listed companies.

The BertForMultipleChoice model is a variant of the BERT [8], specifically designed for multiple-choice tasks. Figure 1 is the architecture of BertForMultipleChoice, it adds a multiple-choice classification head on top of the BERT model, mainly for handling multiple-choice tasks. The input to the BertForMultipleChoice model includes a question and multiple potential answers (options), and the goal of the model is to select the most reasonable answer. This model has shown excellent performance in tasks that require choosing one answer from multiple options, such as reading comprehension and sentiment analysis.

3 Dataset and Tasks

Figure 2 shows an example in NQuAD [1] dataset, including a news article, a question stem and four answer options. Our task is predicting the correct the option.

NQuAD [1] collects news articles from the data vendor, MoneyDJ1, and get the news articles within the period from June 22, 2013 to June 20, 2018. A total of 75,448 Chinese news articles are collected. A total of 43,787 news articles are selected, and 46.97% of the headlines contain more than one numeral. The average number of numerals in the headline and in the content are 1.65 and 29.48, respectively. Each numeral in each headline is used to form a question, thus NQuAD [1] dataset finally obtain 71,998 questions and separate 80% of the instances as the training set and the rest of the instances form a test set.

News Article:
Major banks take the lead in self-discipline. The five major banks' newly imposed mortgage interest rates climbed to **1.986**% in May. ... Also approaching **2**% integer alert ... Up to **2.5**% ... Also increased by **0.04** percentage points from the previous month ... Prevent the housing market bubble from fully starting.

Question Stem: Driven by self-discipline, the five major banks' new mortgage interest rates are approaching nearly___%.

Answer Options: (A) 0.04 (B) 1.986 (C) 2 (D) 2.5

Answer: (C)

4 Methods

4.1 Multiple Choice

Multiple Choice [3] format represents a category within machine reading comprehension tasks. Our present endeavor aligns with this format. The BertForMultipleChoice model, an adaptation of the BERT [8] framework, is expressly engineered to process tasks involving this format. So we choose the BertForMultipleChoice model as our baseline model.

Resent research [5] suggests that existing multi-choice MRC models learn the passage representation with all the sentences in one-shot, which is inefficient and counter-intuitive. Their research indicates that the model should be extremely beneficial if it focuses on a few key evidence sentences. At the same time, the "sentences_containing_the_numeral_in_answer_options" in the NQuAD [1] dataset are four sentences that contain each of the options. So, our strategy is using this sentences as the context of inputs. In the BertForMultipleChoice model, we connect this sentences as the context, and the Question Stem and Answer Options are used as the question and Choices. After that, we find that humans often employ the method of substituting potential solutions into the given problem in the context of problem-solving. Be inspired by this, we fill in the blanks of the question with the options. As shown in Figure 3, we named this new model MC BERT. Furthermore, when humans solve problems, they will finally compare the question and options with key sentences one by one, and then choose the most matching option. So we further propose an improvement strategy, that is, changing the context to the sentence corresponding to each option to increase differentiation. As shown in Figure 4, we named this improved model SSC BERT. Here are examples of input:

- Context:Also increased by **0.04** percentage points from the previous month,he five major banks' newly-imposed mortgage interest rates climbed to **1.986**% in May.,Also approaching **2**% integer alert,Up to **2.5**%
- S_A: Also increased by **0.04** percentage points from the previous month
- S_B: he five major banks' newly-imposed mortgage interest rates climbed to **1.986**% in May.
- S_C: Also approaching **2**% integer alert
- S_D: Up to **2.5**%
- Question: Driven by self-discipline, the five major banks' new mortgage interest rates are approaching nearly ___%.
- $QC_A/QC_B/QC_C/QC_D$: Driven by self-discipline, the five major banks' new mortgage interest rates are approaching nearly **0.04/1.986/2/2.5**%.

Figure 5 are final input examples of MC BERT and SSC BERT.

4.2 Pre-training

Chapter 2 mentioned that pre-training models on simple numerical comparison tasks can enhance the model's numerical understanding. Therefore, we pre-train 'bert-base-chinese' on numerical comparison tasks according to the method mentioned in the [2]. The pre-training model is then trained according to the three frameworks mentioned above. We finally obtain six models: BertForMultipleChoice, MC BERT, SSC BERT, PreBertForMultipleChoice, Pre-MC BERT and Pre-SSC BERT.

4.3 Implementation Details

Trained on the ComNum dataset [2]. Given that NQuAD [1] is a Chinese dataset, we first replaced the English in the ComNum dataset [2] with the corresponding Chinese. The pre-trained model we used is bert-base-chinese, the maximum sequence length is 32, batch size is 32. The loss function employed is the cross-entropy loss, with the AdamW optimizer. The learning rate is set at 5e-6, and epsilon is 1e-8.

Trained on the NQuAD dataset [1]. We employed the BertForMultipleChoice from the transformers library to train the model and divided the training set into a training set and a validation set at a ratio of 4:1. The maximum sequence length is 128, batch size is 32. The loss function employed is the cross-entropy loss, with the AdamW optimizer. The learning rate is set at 5e-6 (If the model used was trained on the ComNum dataset [2], the learning rate is set at 5e-5), and epsilon is 1e-8. After applying softmax function to the model's output, we selected the index with the highest probability as the output.

Model	Accuracy
BERT Embedding Similarity	57.30%
Vanilla BERT	66.41%
BERT-BiGRU	67.15%
BERT-CNN	63.92%
NEMo	69.95%
BertForMultipleChoice	74.48%
MC BERT(ours)	76.83%
SSC BERT(ours)	78.21%
Pre-BertForMultipleChoice	74.91%
Pre-MC BERT(ours)	77.16%
Pre-SSC BERT(ours)	**79.40**%

Table 1: Experimental results.

5 Result

As shown in Table 1, the accuracy of our six models all exceed NEMo [1], which indicates that the BertForMultipleChoice model framework can effectively handle and solve the specific requirements and challenges of this task. Among the three models obtained by directly training with bert-base-chinese, the accuracy of MC BERT is higher than that of BertForMultipleChoice, indicating that directly filling in the blanks of the question with options is effective. Furthermore, the accuracy of SSC BERT surpasses that of MC BERT, suggesting that comparing the question and options with key sentences individually can also enhance the model's performance. Meanwhile, The accuracy of the three models trained using pre-trained models are higher than that of the models obtained by directly training with bert-base-chinese, which further confirms the conclusion that in some simple numerical related tasks, pre-trained models can enhance the model's numerical understanding ability [2].

6 Conclusion

In this work, we select the BertForMultiple model as the baseline model and propose two new models based on it: MC BERT and SSC BERT. The accuracy of these models all exceeded the results of NEMo [1], which confirmed the applicability of the BertForMultiple model framework for our task, the results also indicate that the method of inserting options into the blanks of the question and individually comparing them with key sentences is effective. We also refer to the method in reference [2], pre-trained the bert-base-chinese on numerical comparison task, and use the pre-trained model for subsequent training. The experimental results show that this method can improve the model's numerical understanding ability, thereby making the model perform better on numerical related tasks. Finally, we found that the Pre-SSC BERT model had the highest accuracy, and its accuracy was 9.45% higher than the NEMo model [1], which further proved the effectiveness of our method.In summary, our research proposes a new model training and optimization strategy, which has been proven to be effective and superior in experiments.

However, in analyzing the cases where our model made incorrect judgments, we identify some shortcomings. We notice that humans can easily understand the equivalence between different descriptions of the same thing, but the model cannot. For example, our model cannot understand that '%' and 'Cheng'('into')are equivalent, 'EPS' and 'Earning Per Share' are equivalent, and it cannot understand that 'January' is 'Q1'. To address this issue, we tried to add some specific examples to the dataset of numerical comparison tasks, such as '10% is equal to 1 Cheng' and 'EPS 100 is equal to Earning Per Share 100', hoping that the model could understand the equivalence between two different descriptions of things through this method. However, the final result did not meet our expectations, indicating that our model still needs improvement in handling these types of problems. We will continue to explore this issue in future research, with the aim of improving the model's understanding ability and accuracy.

BERTastic at SemEval-2024 Task 4: State-of-the-Art Multilingual Propaganda Detection in Memes via Zero-Shot Learning with Vision-Language Models

Tarek Mahmoud[†◇], **Preslav Nakov**[†]
[†]Mohamed Bin Zayed University of Artificial Intelligence,[◇] Presight
{tarek.mahmoud,preslav.nakov}@mbzuai.ac.ae

Abstract

Analyzing propagandistic memes in a multilingual, multimodal dataset is a challenging problem due to the inherent complexity of memes' multimodal content, which combines images, text, and often, nuanced context. In this paper, we use a VLM in a zero-shot approach to detect propagandistic memes and achieve a state-of-the-art average macro F1 of $\mathbf{66.7}\%$ over all languages. Notably, we outperform other systems on North Macedonian memes, and obtain competitive results on Bulgarian and Arabic memes. We also present our early fusion approach for identifying persuasion techniques in memes in a hierarchical multilabel classification setting. This approach outperforms all other approaches in average hierarchical precision with an average score of $\mathbf{77.66}\%$. The systems presented contribute to the evolving field of research on the detection of persuasion techniques in multimodal datasets by offering insights that could be of use in the development of more effective tools for combating online propaganda.

1 Introduction

Propaganda is an ancient technique that has existed for thousands of years[1]. The way propaganda is understood today was formalized between 1937 and 1942 by the Institute of Propaganda Analysis through a series of publications (Cantril (1938), Edwards (1938), Lavine et al. (1940), and Brace (1939)). Britannica defines propaganda as the "dissemination of information—facts, arguments, rumours, half-truths, or lies—to influence public opinion."[1]. Propaganda can be beneficial when it unites people behind a noble or beneficial cause. It can also be harmful if it leads to tensions, destabilization, and the death of millions. In our digitally mediated world, transmitting (dis)information to millions of people occurs in seconds. Hence, the adverse effects of propaganda are accelerated and amplified. Propaganda has been used to influence public opinion on Brexit (Rawlinson, 2020), US elections (Chernobrov and Briant, 2020), and the Ukraine crisis (Chernobrov and Briant, 2020). Thus, it is easy to see the damaging effects propaganda has already caused and continues to inflict.

Propaganda takes many forms. It could be broadcast on television (Pan et al., 2020), spread through coordinated communities on social media (Hristakieva et al., 2022), transmitted across national borders through loudspeakers (Seo, 2018), disseminated via news articles (Nakov et al., 2022), published on blogs (Burgers, 2017), or could even exist on postage stamps (Lauritzen, 1988). More recently, memes have become powerful tools for the dissemination of political messages. The visual and textual simplicity of memes, combined with their viral nature, allows them to be rapidly consumed and shared across social media platforms, reaching vast audiences with minimal effort. This level of accessibility makes memes an attractive medium for propagandists seeking to subtly influence public opinion, disseminate misinformation, and polarize communities.

Consequently, there has been an increased need for and interest in propaganda identification in the research community. The most difficult challenge is that propaganda is often based on kernels of truth and is presented in a misleading way, making it seem genuine. Hence, training a model to detect propaganda is challenging, given the subtlety in how propaganda masquerades as an ordinary text or an innocent, funny meme. Moreover, interpreting any such model's results could also be problematic. With memes, the challenge, is further exacerbated due to the inherent complexity of memes' multimodal content, which combines images, text, and often, nuanced context, making the detection of propaganda all the more challeng-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 503–510

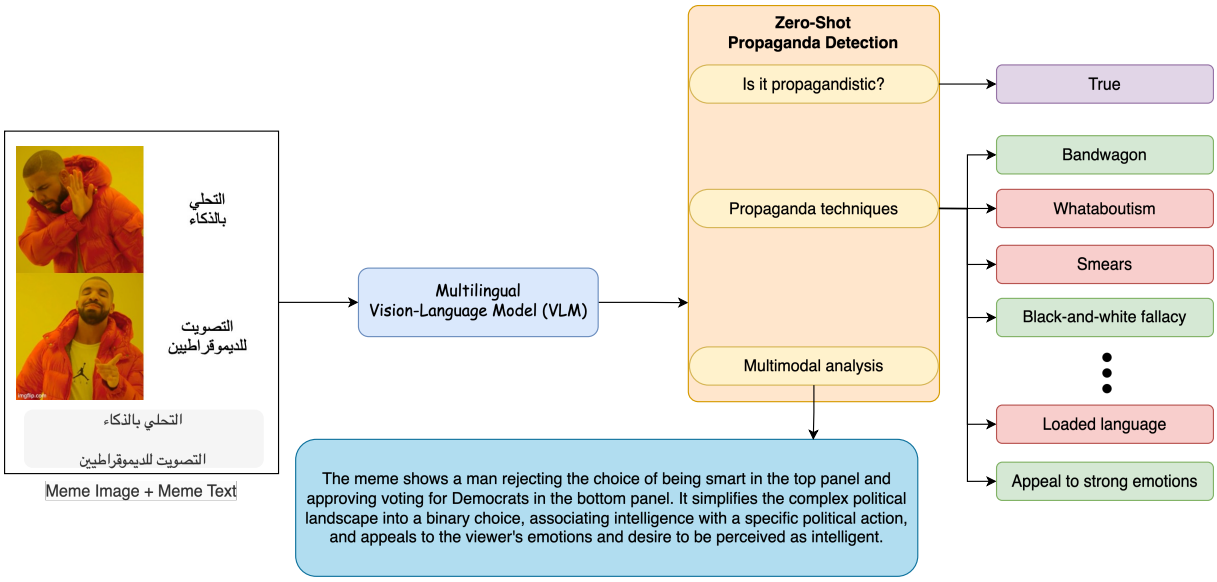

Figure 1: **Zero-shot propaganda detection overview:** This instance shows an Arabic meme that reads "being smart" in the top half and "voting democrat" in the other half. The figure illustrates the comprehensive analysis of a meme and the fine-grained output obtained from a VLM using zero-shot learning. The model accepts as input both the meme image and the meme text, and is prompted to provide three outputs. It provides a multimodal analysis and description of the meme. It also identifies which technique out of 22 possible techniques are present in the meme. Finally, it makes a determination whether the meme is propagandistic or not.

ing. Furthermore, the language used in memes is characteristically concise, often consisting of mere sentence fragments or a few keywords. Consequently, developing systems that consider only the textual content in isolation from the accompanying image presents a significant challenge.

The model explainability challenge has been tackled by Da San Martino et al. (2019) for texts and by Dimitrov et al. (2021) for memes via the introduction of fine-grained propaganda detection tasks and datasets. The tasks required identifying the propaganda technique(s) out of over eighteen techniques in a multi-label classification formulation. This fine level of granularity increases interpretability of propaganda detection models. However, the subtlety challenge is still prevalent. In addition to the subtlety challenge, propaganda detection research is scarce on multimodal datasets in general, and on memes in particular, correlating with a scarcity of datasets. Moreover, the majority of research and datasets are monolingual and consider mainly the English language. Therefore, the difficulty of tackling propaganda in memes also extends to include the scarcity of multilingual meme datasets. There are recent efforts to address this challenge, which are currently spearheaded by the shared task on *Multilingual Detection of Persuasion Techniques in Memes* (Dimitrov et al., 2024) described in detail in 2.1.

In this paper, we capitalize on recent advances in Vision Language Models (VLMs) (Zhang et al., 2023) and Pretrained Language Models (PLMs) (Zhao et al., 2023), and highlight the following contributions:

- We achieve state-of-the-art performance on multilingual, multimodal propaganda detection in memes with an average macro F1 score of $\mathbf{66.7}\%$ using a zero-shot VLM approach (see Figure 1). This includes state-of-the-art performance on North Macedonian memes, and competitive results on Bulgarian and Arabic memes.

- We present a early fusion approach for identifying persuasion techniques in memes in a hierarchical multilabel classification setting. This approach outperforms all other approaches in average hierarchical precision with an average score of $\mathbf{77.66}\%$.

2 Background

2.1 Task Formulation

The "Multilingual Detection of Persuasion Techniques in Memes" task contains three subtasks addressing the challenge of identifying persuasion

Subtask	Binary		Multilabel	
Split	Train	Test	Train	Test
English	1650	600	9050	1500
Arabic	-	160	-	120
Bulgarian	-	100	-	436
North Macedonian	-	100	-	259

Table 1: Dataset summary. All labeled data from the training, development, and validation sets are merged and included under the training split. We also augment the multilabel training split with non-propagandistic samples from the binary training split.

techniques used in memes out of which we describe two subtasks. One subtask simplifies the challenge to a binary classification task, determining the presence or absence of any persuasion technique in a meme. In more concrete terms, given a text-image pair $p = (m, t)$ where m is the meme image and t is the meme text, the goal is to predict whether p is propagandistic or not.

The other subtask requires the identification of one or more of twenty-two persuasion techniques within a meme. That is, given a text-image pair $p_i = (m, t)$, the goal is to learn a mapping $f : p \rightarrow K$ where $K = [k_1, ..., k_n]$ and $k_j \in \{True, False\}$ denotes whether p_i contains the j^{th} persuasion technique and n denotes the total number of persuasion labels, which is 22 in this subtask.

The task employs macro-F1 scores for binary classification, and hierarchical-F1 scores for multilabel classification.

Table 1 summarizes the dataset. Note that the task introduces memes in languages other than English without any labels in order to evaluate the models' zero-shot learning capabilities. Figure 2 analyzes how balanced the label distribution is in the dataset of the multilabel task. It is clear the dataset is highly imbalanced. The binary task's dataset is also imbalanced with two-thirds of the training data being propagandistic.

2.2 Related Work

Recent advancements have highlighted the multimodal nature of modern propaganda, particularly within social media. The integration of text and visual content in memes presents a unique challenge for detection algorithms and models. Recognizing this, Dimitrov et al. (2021) introduce a multi-label multimodal task focused on identifying the specific propaganda techniques used in memes. The authors have compiled and released a corpus of approximately one thousand memes. This collection is annotated with twenty two distinct propaganda techniques. These techniques appear either in the textual content, the image content, or a combination of both. The creation of such a dataset is a significant contribution to the field, providing a foundational resource for developing and evaluating propaganda analysis models on memes. One limitation of this dataset is that it only contains English memes. This challenge is overcome by Dimitrov et al. (2024) who introduce a multilingual meme dataset that contains approximately ten thousand memes in four languages including English, Arabic, Bulgarian, and North Macedonian. In this study, we use this dataset.

Dimitrov et al. (2021) evaluate many baselines on the English meme dataset. These approaches include text models, image models, and multimodal models. Unlike our work, none of these baselines utilize a zero-shot learning approach using VLMs.

3 System Overview

3.1 Zero-Shot Detection of Propagandistic Memes using Vision-Language Models

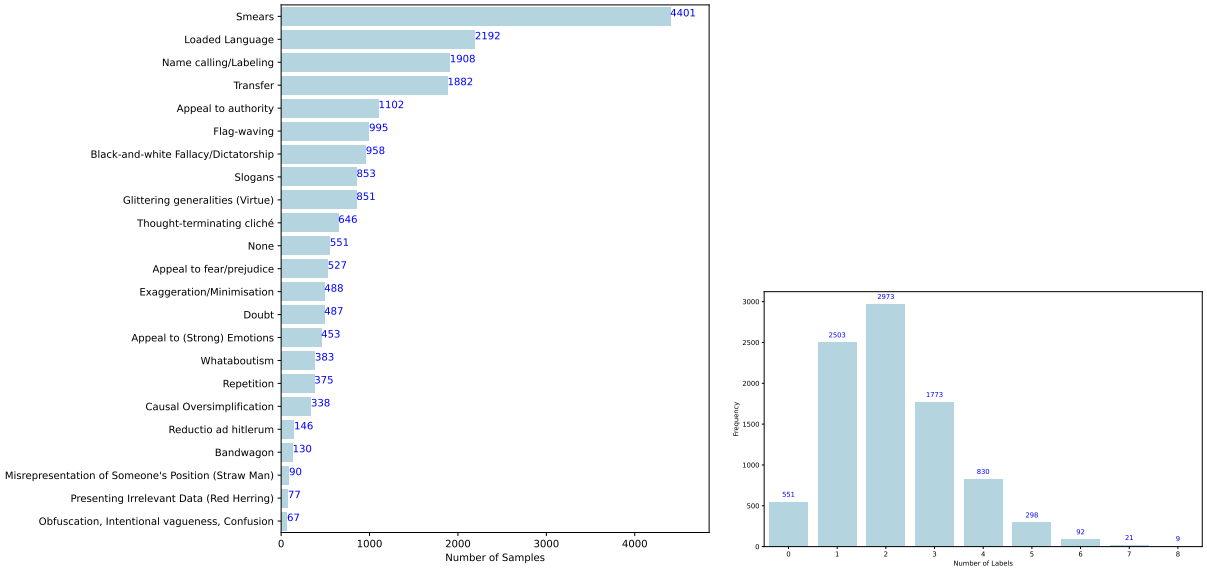
We employ zero-shot detection of propagandistic memes using GPT-4V (OpenAI, 2023). The core objective of our system illustrated in Figures 1 and 4 is to automatically identify and analyze the propagandistic content within memes. Upon processing the meme, the system utilizes GPT-4V to perform a comprehensive analysis that includes the following tasks executed in a single prompt:

1. **Analysis of Meme Text:** The model interprets the text within the meme, considering its semantic and contextual relevance to the image.

2. **Persuasuin Technique Identification:** The model assesses the meme against a predefined list of propaganda techniques, analyzing both the image and text to identify which, if any, techniques are present.

3. **Overall Propagandistic Determination:** The model concludes whether the meme is propagandistic, utilizing both the visual and textual content, and the above analysis, to inform its judgment.

The output of this analysis is structured as a JSON object, which includes three key attributes:



(a) (b)

Figure 2: Label distribution analysis for the multilabel task. (a) **Label frequencies.** The dataset is highly imbalanced with the number of labeled data for each label ranging from as little as 67 samples to as many as 4401 samples. (b) **Label count frequencies**. The majority of samples contain 1 to 4 persuasion techniques. A few samples contain 5 or more techniques and the maximum label count per sample is 8 techniques.

- **Description:** A description of the meme, obtained through multimodal analysis of both the visual and the textual contents of the meme.
- **Techniques:** A list of propaganda techniques identified in the meme.
- **Propagandistic:** A value indicating whether the meme is considered to be propagandistic or not.

This structured output enables a clear, concise, and automated method for identifying and categorizing memes by their propagandistic content, allowing such output to be used in other formulations and experiments that we outline in this paper.

3.2 Early Fusion for Multilabel Persuasion Identification

Our method for multilabel persuasion technique identification in memes incorporates an *early fusion* strategy, utilizing embeddings from both text and image modalities to enrich the feature space. This approach, illustrated in Figure 3, involves two key steps:

1. Embeddings Extraction:
   - We use a multilingual MPNet model (Song et al., 2020; Reimers and Gurevych, 2019) to extract embeddings from the meme's text.
   - The multilingual MPNet is also used to generate embeddings from a meme description that was obtained via a VLM as described earlier in Figure 1.
   - A CLIP-ViT-B-32 multilingual model (Radford et al., 2021; Reimers and Gurevych, 2019) processes the meme image alongside the meme text and the VLM-generated description. This model is used to capture the relationship between visual elements and textual information in memes, producing comprehensive multimodal embeddings.
2. Fusion and Classification:
   - The embeddings from the multilingual MPNet (for both meme text and description) and the CLIP-ViT-B-32 model are fused into a single feature vector. This fusion happens before training the classifier, ensuring the classifier operates on a rich representation of each meme. We use logistic regression for classification.
   - Note that the weights of the embedding models (MPNet and CLIP-ViT-B-32) are frozen during training.

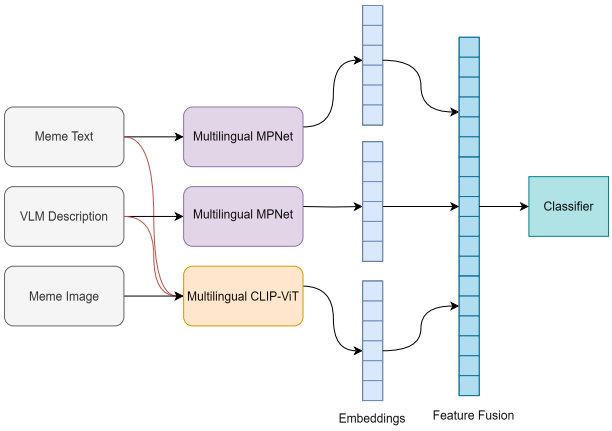


Figure 3: **Early fusion approach overview.** VLM description is obtained as described in Figure 1. CLIP-VIT receives as input all three of the meme image, meme text, and the VLM description. We obtain three separate embeddings which are then concatenated and used to train a classifier.

Table 2: **Results – binary task:** The table shows the results on the test set from the official leaderboard. It shows macro F1 results for all four languages. In addition, we also compute the average macro F1 and sort the teams by this value.

Note that we use multilingual models for all embedding models to ensure our approach generalizes well in the zero-shot scenario. We opted to use a multilingual MPNet which was trained on parallel data on 50+ languages that include Arabic, Bulgarian, and North Macedonian. This decision was made despite the availability of models like XLM-R (Conneau et al., 2020), which, although powerful, were not trained on parallel datasets and thus might not perform as well across languages especially with only English training data. The same rationale applies on why we selected a CLIP-VIT-B-32 model which has a multilingual text encoder that was trained using multilingual knowledge distillation on parallel data.

4 Results

We show the results on binary and multilabel classification tasks in tables 2 and 3, respectively. For binary classification, our system ranks first on North Macedonian propaganda detection task, and achieves competitive results ranking third on Arabic and Bulgarian. Collectively, we achieve the top rank in average F1 across all four languages. As for multilabel classification, our system suffers from low recall but compensates for that by a very high precision performance. Our system achieves the highest precision on Bulgarian, the second highest on Arabic, English, and North Macedonian, and the top precision score on average across all four languages. This means our system is very conservative in that it only makes predictions it is highly confident of.

We also experimented with other models for both the binary and multilabel tasks as shown in tables 4 and 5, respectively. In the binary setting, we train several models on embeddings obtained using a CLIP-ViT-B-32 model, but the zero-shot VLM approach performs better in comparison. For the multilabel task, we try several approaches. We attach a classification head and fine-tune an MPNet model on the meme descriptions that we obtained as described earlier in Figure 1. However, this did not yield a high performance. We also fine-tune DeBERTa-V3-Large (He et al., 2023) and XLM-R-Large on different subsets of available text (i.e., meme text and the VLM descriptions). Out of all combinations, we observe that DeBERTa performed best when it was fine-tuned on VLM descriptions only. This is likely due to the fact the meme texts are often short, incoherent and do not form complete sentences; hence, we deduce they may contaminate the much more coherent descriptions generated by the VLM. Moreover, we also observe that we cannot achieve competitive results using only the text modality.

In all experiments involving transformers, We fine-tune with early stopping with a patience of three epochs, use a batch size of eight, a learning rate of $5e-5$, and we accumulate the gradients for eight steps making our effective batch size 64. We also use a binary-cross entropy loss and set a classification threshold of 0.5.

5 Conclusion and Future Work

In this study, we introduced a state-of-the-art multilingual propaganda detection in memes using zero-shot learning with VLMs. Our approach uniquely addressed the complexities of multimodal content in memes, merging visual and textual cues in a manner that comprehensively understands and identifies propagandistic content across languages. Achieving an average macro F1 score of 66.7% across all assessed languages, our system demonstrated high performance over existing methods, particularly excelling in North Macedonian memes and showing competitive performance in Bulgarian and Arabic in the binary setting. In addition, our early fusion technique for identifying persuasion techniques in memes within a hierarchical multi-label classification setting outperformed all other approaches with an average hierarchical precision score of 77.66%.

Looking forward, our research opens several directions for further exploration and improvement. First, the exploration of advanced fusion techniques that could more intricately combine the strengths of textual and visual analyses may yield even higher accuracies in propaganda detection. Additionally, the adaptability and performance of our model in detecting subtler forms of propaganda and across a broader spectrum of languages present an exciting challenge, especially considering the highly nuanced contextual nature of meme content and its cultural intricacies.

Appendix

A Prompt Template

The system illustrated in Figure 1 uses the prompt template illustrated in Figure 4. The technique list consists of the names of the twenty-two techniques available in the dataset.

```
You are a helpful meme propaganda analyst designed to output JSON  without any markdown formatting. The
JSON you output must adhere to JSON rules such as case sensitivity for boolean values, and not having
double quotes inside of strings.

Consider the attached meme with the extracted meme text shown below:
{meme_text}

Provide a propaganda/persuasion analysis of the attached meme image alongside the extracted meme text.
Think of propaganda techniques such as:
{technique_list}

Return a JSON that has these attributes:
- description: a generic English description of the meme. Please don't use double quotes.
- techniques: a list of the techniques that are 100% without a doubt present in the meme
- is_propagandistic: True if meme is propagandistic, False otherwise

Only return the JSON, without any explanation. Make sure the JSON is properly formatted. For example,
to quote something inside of a JSON string, use single quotes. Never use double quotes. Also note that
JSON boolean is case sensitive.

{meme_image}
```

RKadiyala at SemEval-2024 Task 8: Black-Box Word-Level Text Boundary Detection in Partially Machine Generated Texts

Ram Mohan Rao Kadiyala
University of Maryland , College Park
rkadiyal@terpmail.umd.edu

Abstract

With increasing usage of generative models for text generation and widespread use of machine generated texts in various domains, being able to distinguish between human written and machine generated texts is a significant challenge. While existing models and proprietary systems focus on identifying whether given text is entirely human written or entirely machine generated, only a few systems provide insights at sentence or paragraph level at likelihood of being machine generated at a non reliable accuracy level, working well only for a set of domains and generators. This paper introduces few reliable approaches for the novel task of identifying which part of a given text is machine generated at a word level while comparing results from different approaches and methods. We present a comparison with proprietary systems , performance of our model on unseen domains' and generators' texts. The findings reveal significant improvements in detection accuracy along with comparison on other aspects of detection capabilities. Finally we discuss potential avenues for improvement and implications of our work. The proposed model is also well suited for detecting which parts of a text are machine generated in outputs of Instruct variants of many LLMs.

1 Introduction

With rapid advancements and usage of AI models for text generation , being able to distinguish machine generated texts from human generated texts is gaining importance. While existing models and proprietary systems like GLTR (Gehrmann et al., 2019), ZeroGPT (ZeroGPT), GPTZero (Tian and Cui, 2023), GPTKit (GptKit), Open AI detector , etc.. focus on detecting whether a given text is entirely AI written or entirely human written , there was less advancement in detecting which parts of a given text are AI written in a partially machine generated text. While some of the above mentioned systems provide insights into which parts of the given text are likely AI generated , these are often found to be unreliable and having an accuracy close or worse than random guessing. There is also a rise in usage of AI to spread fake news and misinformation along with using AI models to modify Wikipedia articles (Vice, 2023). Our proposed model focuses on detecting word level text boundary in partially machine generated texts as part of the SemEval shared task : Multi-generator, Multi-domain, and Multilingual Black-Box Machine-Generated Text Detection(Wang et al., 2024b). This paper also discusses implications of findings , comparisons with different models and approaches , comparison with existing proprietary systems with relevant metrics , other findings regarding AI generated texts. The official submission is DeBERTa-CRF , several other models have been tested for comparison. With new, better, and diverse AI models coming into existence, having a model that can make accurate predictions on unseen domains and unseen generator texts can be useful for practical scenarios.

2 Dataset

Set	Count	Sources	Generators
Train	3649	PeerRead	ChatGPT
Dev	505	PeerRead	ChatGPT
Test	11123	PeerRead	LLaMA2
		OUTFOX	LLaMA2
		OUTFOX	GPT-4

Table 1: Dataset sources and split

The dataset used is part of M4GT-bench Dataset(Wang et al., 2024a) consisting of texts each of which are partially human written and partially machine generated sourced from PeerRead reviews and outfox student essays (Koike et al., 2023) all of which are in English. The genera-

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 511–519

tors used were GPT-4(OpenAI, 2024) , ChatGPT , LLaMA2 7/13/70B (Touvron et al., 2023). Table 1 shows the source , generator used and data split of the dataset. The generators were given partially human written essays or partially human written reviews along with problem statements and instructions to complete the text. The proportion of human written content in each of the samples ranged from 0 to 50% in the first part while the rest is machine generated in the training data and varying from 0 to 100% in development and test sets. The length of the texts varied between a single sentence to over 20 with median word count of 212 and mean word count of 248.

3 Baseline

The provided baseline uses finetuned Longformer over 10 epochs. The baseline classifies tokens individually as human or machine generated and then maps the tokens to words to identify the text boundary between machine generated and human written texts. The final predictions are the labels of words after whom the text boundary exists. The detection criteria is first change from 0 to 1 or vice versa. We have tried one more approach by considering the change only if consecutive tokens are the same. The baseline model achieved an MAE of 3.53 on the Development set which consists of same source and generator as the training data. The model had an MAE of 21.535 on the test set which consists of unseen domains and generators.

4 Proposed Model

We have built several models out of which DeBERTa-CRF was used as the official submission. We have finetuned DeBERTa(He et al., 2023), SpanBERT(Joshi et al., 2020), Longformer(Beltagy et al., 2020), Longformer-pos (Longfomer trained only on position embeddings), each of them again along with Conditional Random Fields (CRF)(McCallum, 2012) with different text boundary identification logic by training on just the training dataset and after hyperparameter tuning , the predictions have been made on both development and test sets. CRFs have played a vital role in improving the performance of the models due to their architecture being well suited for pattern recognition in sequential data. The primary metric used was Mean Average Error (MAE) between predicted word index of the text boundaries and the actual text boundary word index. However Mean Average Relative Error (MARE) too was used for a better understanding which is the ratio of MAE and text lenght in words. Some of the plots and information couldn't be added due to page limits and are available `here`. [1] along with the `code used`. [2]. a hypothetical example in Figure 1 demonstrates how the model works. The tokens are classified at first and mapped to words. In cases where part of a word is predicted as human and rest as machine (in case of longer words), the word as a whole is classified as machine generated.

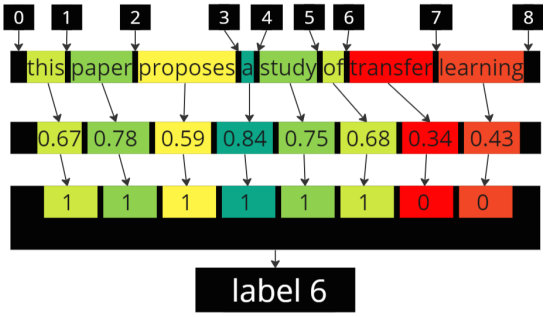

Figure 1: A visual example of working of the model

4.1 Our system

We have used 'deberta-v3-base' along with CRF using Adam(Kingma and Ba, 2017) optimizer over 30 epochs with a learning rate of 2e-5 and a weight decay of 1e-2 to prevent overfitting. other models that have been used are 'Spanbert-base-cased', 'Longformer-base-4096', 'Longformer-base-4096-extra.pos.embd.only' which is similar to Longformer but pretrained to preserve and freeze weights from RoBERTa(Liu et al., 2019) and train on only the position embeddings. The large variants of these have also been tested however the base variants have achieved better performance on both the development and testing datasets. predictions have been made on both the development and testing datasets by training on just the training dataset. Two approaches were used when detecting text boundary 1) looking for changes in token predictions i.e from 1 to 0 or 0 to 1. and 2) looking for change to consecutive tokens i.e 1 to 0,0 or 0 to 1,1. Approach 2 achieved better results than approach 1 in all the cases and was used in the official submission.

[2] Code available at : https://github.com/1024-m/NAACL-2024-SemEval-TASK-8C

4.2 Results

The results from using different models with the two approaches on the development set and the test set can be seen in Table 2. These models have been trained over 30 epochs and the best results were added among the several attempts with varying hyperparameters. The provided baseline however has been trained on just through approach I over 10 epochs using base variant of Longformer. These models have then been used to make predictions on the test set without further training or changes using the set of hyperparameters that produced the best results for each on the development set. However MAE which is the primary metric of the task doesn't take length of the text into consideration, Hence MARE (Mean Average Relative Error) was also calculated for a better understanding.

5 Comparison with proprietary systems

Some of the proprietary systems built for the purpose of detecting machine generated text provide insights into what parts of the text input is likely machine generated at a sentence / paragraph level. Many of the popular systems like GPTZero, GPTkit, etc.. are found to to less reliable for the task of detecting text boundary in partially machine generated texts. Of the existing models only ZeroGPT was found to produce a reliable level of accuracy. For the purpose of accurate comparison percentage accuracy of classifying each sentence as human / machine generated is used as ZeroGPT does detection at a sentence level.

5.1 Results comparison

Since the comparison is being done at a sentence level, In cases where actual boundary lies inside the sentence, calculation of metrics is done on the remaining sentences, and when actual boundary is at the start of a sentence , all sentences were taken into consideration. With regard to predictions, A sentence prediction is deemed correct only when a sentence that is entirely human written is predicted as completely human written and vice versa. The two metrics used were average sentence accuracy which is average of percentage of sentences correctly calculated in each input text, and overall sentence accuracy which is percentage of sentences in the entire dataset accurately classified. The results on the development and test sets are as shown in Table 3. Since its difficult to do the same on 12000 items of the test set , a small section of 500 random samples were used for comparison and were found to perform similar to the development set with a 15-20 percent lower accuracy than the proposed models. Since ZeroGPT's API doesn't cover sentence level predictions , they have been manually calculated over the development set and can be found here. [3].

6 Conclusion

The metrics from Table 3 demonstrate the proposed model's performance on both seen domain and generator data (dev set) along with unseen domain and unseen generator data (test set) , hinting at wider applicability. While there was a drop in accuracy at a word level, there was an increase in sentence level accuracy.

6.1 Strengths and Weaknesses

It was observed that the proprietary systems used for comparison struggled with shorter texts. i.e when the input text has fewer sentences, the predictions were either that the input text is fully human written or fully machine generated leading to comparatively low accuracy.

The average accuracy of sentence level classification for each text length of our model and ZeroGPT can be seen in Figure 2 , Figure 3 respectively. the proposed model overcomes this issue by providing more accurate results even on short text inputs.

The sentence level accuracy did vary considerably while comparing cases where the actual text boundary is at the end of sentence and those where it is mid sentence. The results can be seen in Table 4.

Since the source and generators of texts individually wasn't made available, the comparison between in-domain and out-of-domain texts couldn't be made.

6.2 Possible Improvements

DeBERTa performed better when text boundaries are in the first half of the given text, while Longformer had better performance when the text boundary is in the other half as seen in Figure 4 and Figure 5. In cases where there was a significantly bigger MAE , atleast one of two (DeBERTa and Longformer) had made a very close prediction. There is a possibility that an ensemble of both

Table 4: Performance of models based on text boundary placement : test set (approach 2)

might perform better, as seen in Table 2, on the test set (unseen generators), while DeBERTa had a better MAE , Longformer had the better MARE. Further, the POS tags of the words pre and post text boundary were examined to find out what led to some cases having higher MAE. Though DeBERTa had better performance, when dealing with very long texts, Longformer might be a better choice. Figure 6 and Figure 7 display the count of data samples in train set and median MAE of those in test set for each POS tags combination pre and post split. The cases where the median MAE was higher (i.e 30 or above) had none or very few samples in the training set. Excluding those cases the new MAE was less than half of what it previously was. Adding more data that covers all cases of pre-split and post-split POS tag words might lead to better results. At a sentence level the accuracy was close to 100 percent excluding the above mentioned samples. Another possible approach worth testing is having a multiplier to the predicted values of each token before classifying as a 0 or 1.

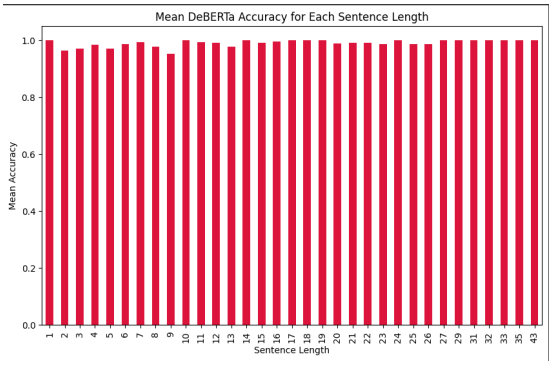

Figure 2: Average sentence accuracy VS number of sentences in test set : DeBERTa-CRF

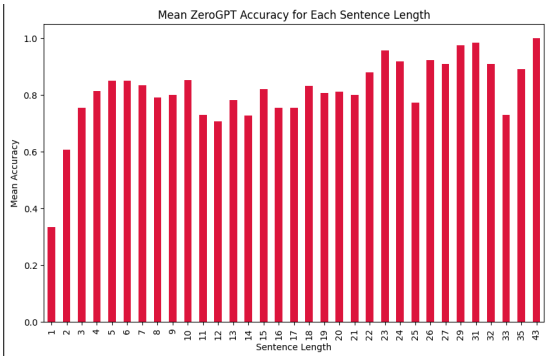

Figure 3: Average sentence accuracy VS number of sentences in test set : ZeroGPT

as seen in Figure 6 and Figure 7, the biggest error cases in pre and post text boundary POS tags were the ones which were not present at all or in

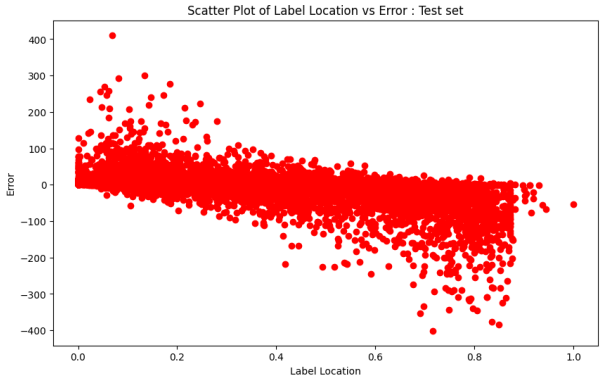

Figure 4: Text boundary location VS MAE in test set : DeBERTa

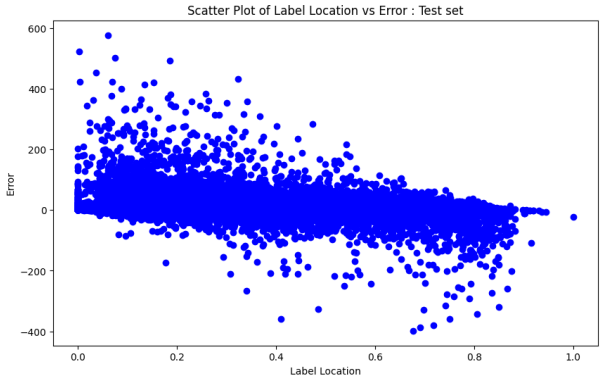

Figure 5: Text boundary location VS MAE in test set : Longformer

very minute amount in the training data, nearly 92 percentage of cases had less than 10 samples to train on and 64 percentage of cases had no samples at all in the training set. A potential solution would be including ample amount of data for all possibilities to cover wider range of texts. This can be done through generating more data by splitting the text at required word boundaries in existing texts and using an LLM to finish the texts.

6.3 Possible Extensions and Applications

The need to detect AI generated content is also prevalent over all languages. While the current model utilizes just English language data, gathering multilingual data and having a multilingual model might also be of great use. With the growth of misinformation and fake news using bots on social media handles(Zellers et al., 2019), being able to detect AI generated texts is of great importance. As most of the texts i.e posts , comments etc.. are shorter in length and difficult to detect, An extension of the current work by training on social media data may yield a good result as demonstrated in Figure 2 and Figure 3. The dataset mostly consisted of texts which are academic related while there is a need to detect machine generated texts in other fields too. Also, It is worth testing the performance of paraphrased data along with the existing data. Since, usage of additional data was prohibited, data augmentation wasn't used in training the current models. It is likely that having more data to cover the cases of pre and post POS tags that weren't present in the training dataset may improve the performance of the models. Some of the other findings are available in Appendix A.

7 Limitations and potential for misuse

While this novel task of detecting text boundaries in partially machine generated texts achieves a high accuracy where one change from human to machine occurs. Being able to handle the cases of multiple changes from human to machine and vice versa is vital. Since having a completely machine generated text and rewriting a few sentences in between or vice versa isn't covered by this work or other existing models, there is a possibility that detection can be evaded this way. There is also a potential for misuse by learning what features and texts caused errors using the proposed models to create texts that can evade detection. The current study covers only two kinds of LLMs i.e GPT and LLaMa. The performance on other types of LLMs is still to be tested. With wide range of available LLMs, training the models over wider range of LLMs might improve performance. The current work focuses on just English texts, however it can be extended to other languages by replacing DeBERTa with mDeBERTa and training on a multilingual corpus. However not all languages are covered by mDeBERTa, this can be a potential issue when dealing with multilingual texts. Another kind of texts that need to be tested upon is where machine generated portions are generated by different generators, and the cases where it is completely machine generated but by different generators. The current corpus used to trained the models is sourced from academic platforms and academic essays, It is necessary to have models to work over a wide variety of texts including cases where it can be in a casual tone. While the current work only considers the first 512 tokens, the longformer version did achieve the same results on unseen generator texts. It is worth looking into how well chunking would work on the deberta model to process longer texts.

A Other Plots and information

Some of the information that couldn't be covered due to page limitations along with details for system replication have been added here.

A.1 POS tag usage : human vs machines

It can be seen from Figure 11 , Figure 12 and Figure 10 that machine generated texts had higher share of certain POS tags in the machine generated parts compared to the human written parts. This was observed in all 3 sets, the train and dev had similar distributions as a result of using same generators i.e ChatGPT and the test had a bit of a variation due to multiple different generators i.e LLaMA2 and GPT4. Although the percentile comparison did vary from train, dev and test sets , it was minimal.

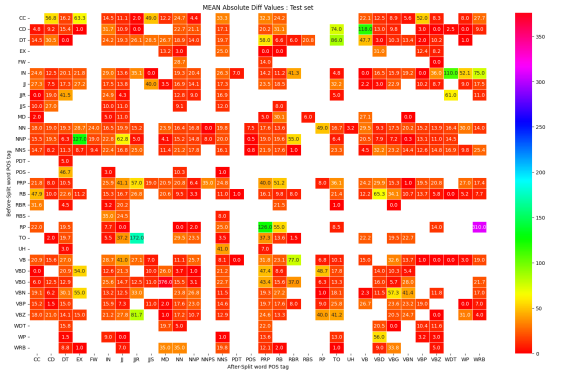

Figure 8: Median MAE based on pre and post text boundary POS tags : DeBERTa-CRF

Figure 9: Median MAE based on pre and post text boundary POS tags : Longformer.pos-CRF

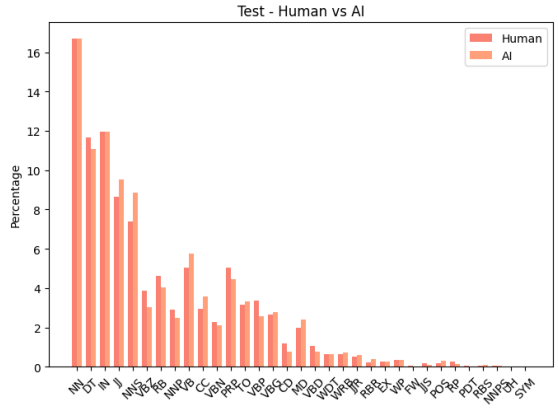

Figure 10: Percentile distribution of each POS tag in test set : human VS machine

A.2 MAE characteristics : DeBERTa vs Longformer

As discussed in the paper , there were some instances where one model performed significantly better than the other as seen in Figure 8 and Figure 9 hinting that an ensemble of both's predictions might yield better results.

B System Description

DeBERTa-CRF was the official submission, longformer.pos-CRF had almost the same performance on the test set. i.e 18.538 and 18.542.

Other models that have been tested but were found to have a big margin of performance with above listed models

Due to time and computational resources limitation, only a part of hyperparameter space was explored.

C Effect of Text boundary location on performance

The location of text boundaries with respect to length of the text samples are varying over the training and testing set as seen in Figure 13 and Figure 14. Despite training on samples where the text boundaries are in the first half in most of the cases, the models did perform well on the testing set where there is a good amount of samples with text boundaries in later half. This is an area where the proprietary systems struggled.

Abstract

This paper introduces novel methodologies for the Natural Language Inference for Clinical Trials (NLI4CT) task. We present TLDR (**T**5-generated clinical-**L**anguage summaries for **D**eBERTa **R**eport Analysis) which incorporates T5-model generated premise summaries for improved entailment and contradiction analysis in clinical NLI tasks. This approach overcomes the challenges posed by small context windows and lengthy premises, leading to a substantial improvement in Macro F1 scores: a 0.184 increase over truncated premises. Our comprehensive experimental evaluation, including detailed error analysis and ablations, confirms the superiority of TLDR in achieving consistency and faithfulness in predictions against semantically altered inputs.

1 Introduction

The Multi-evidence Natural Language Inference for Clinical Trial Data (NLI4CT) task focuses on developing systems that can interpret clinical trial reports (CTRs) and make inferences about them Jullien et al. (2024). The task provides a collection of breast cancer CTRs from ClinicalTrials.gov along with hypothesis statements and labels annotated by clinical experts.

The NLI4CT 2024 task is to classify whether a given CTR entails or contradicts the hypothesis statement. This is challenging as it requires aggregating heterogeneous evidence from different sections of the CTRs like interventions, results, and adverse events. The dataset contains 999 breast cancer CTRs and 2400 annotated hypothesis statements split into training, development, and test sets. The CTRs are summarized into sections aligning with Patient Intervention Comparison Outcome framework. The 2024 SemEval task has the same training dataset as the SemEval 2023 task (Jullien et al., 2023b) but the development and test sets for the 2024 task include interventions of either preserving or inversing the entailment relations for some data points.

In this paper, we introduce TLDR (**T**5-generated clinical-**L**anguage summaries for **D**eBERTa **R**eport Analysis), a novel framework developed for the SemEval Task 2024. Our key contribution is the integration of a T5-based summarization approach to preprocess and condense the premises of clinical reports, which are then analyzed alongside the corresponding statements using DeBERTa, an encoder-only transformer to perform Natural Language Inference (NLI). Our T5-generated summaries address the limitations of small context windows and lengthy premises for this task. This methodology demonstrates a significant improvement in performance on the held-out test set, with our best model achieving an increase of 0.184 in the Macro F1 score compared to using truncated premises and 0.046 over extractive summarized premises. To underscore the efficacy of our approach in this task, we have conducted extensive experiments and ablations, complemented by a thorough error analysis. We also demonstrate the efficacy of our model's performance with regards to consistency and faithfulness against semantically altered inputs. These efforts collectively highlight the robustness and effectiveness of the TLDR framework in addressing the complexities and nuances of NLI task within the domain of clinical report trials.

2 Background

The NLI4CT task requires developing systems capable of NLI from clinical trial reports. In the following section, we examine not only contributions within the SemEval NLI4CT task (Jullien et al., 2023b,a) but also wider advancements in the field.

Transformer Architectures Pretrained transformer models form the backbone of many top-performing systems in the NLI4CT task, with their

*All authors contributed equally to this work.

Proceedings of the 18th International Workshop on Semantic Evaluation (SemEval-2024), pages 520–529

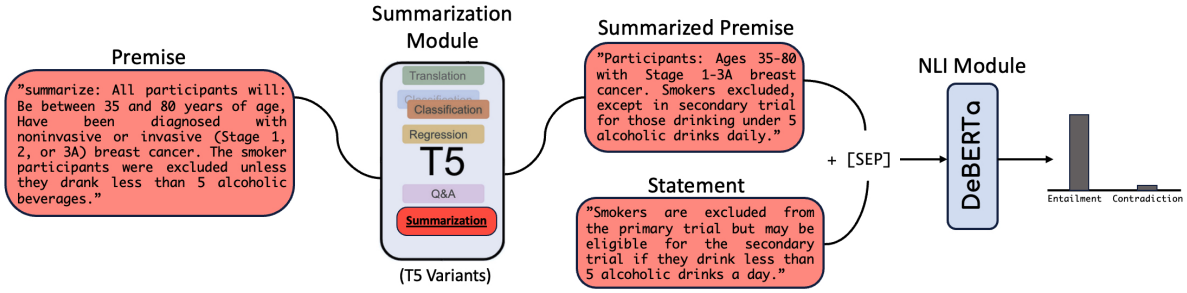

Figure 1: TLDR Model: TLDR processes the clinical report by initially summarizing it using the summarization module (variants of the T5 Model). This summary is then merged with the statement and fed into the fine-tuned DeBERTa model for Natural Language Inference.

architectures being a crucial aspect of their design.

Generative Transformers Generative transformers, which include models like the instruction-tuned Flan-T5 (Kanakarajan and Sankarasubbu, 2023), are particularly adept at generating text and can produce probabilities or direct entailment labels. These models excel in tasks that require the generation of coherent language constructs and have been pretrained on biomedical data, equipping them with the necessary domain knowledge. The work of Zhao et al. (2023) further emphasizes this, showcasing the efficacy of ChatGPT, a generative model, in a multi-strategy system for clinical trial inference, particularly through prompt learning techniques.

Discriminative Transformers Discriminative transformers are employed for classification tasks and include variants of BERT such as BioBERT and ClinicalBERT (Lee et al., 2020; Chen et al., 2023; Vladika and Matthes, 2023). These models have been fine-tuned on domain-specific data to enhance their understanding of medical texts. DeBERTa architecture (He et al., 2020), which improves upon BERT with disentangled attention and enhanced masking, is also included in this category. These approaches were successfully incorporated by Chen et al. (2023) and Alameldin and Williamson (2023) utilizing transformer-based models for both evidence retrieval and entailment determination in NLI4CT task of 2023.

3 System overview

In this section, we explain our methodologies to address the complexities of the Natural Language Inference for Clinical Trials (NLI4CT) task. We primarily focus on the utilization of large language models such as T5 (Raffel et al., 2020) and BERT-based architectures (Devlin et al., 2018), to implement innovative techniques to manage the challenge of the long premise lengths and token size limitations. As mentioned in Section 2, DeBERTa is a top-performing model for NLI tasks. However, it has a limitation in clinical NLI such as the task in NLI4CT due to its restricted context length, making it difficult to include both the premise and the statement. We therefore propose to fine-tune T5 to summarize long clinical premises, which can then allow us to leverage DeBERTa's discriminative power for clinical NLI with extended premises. We call our model TLDR for **T**5-generated clinical-**L**anguage summaries for **D**eBERTa **R**eport Analysis. Our full pipeline can be seen in Figure 1.

In this section, we delve into the fine-tuning of these models for our clinical NLI task and employ specialized summarization strategies using variants of the T5 model, balancing between zero-shot and fine-tuned approaches. *

3.1 TLDR: NLI with DeBERTa enhanced by T5 Generated Summaries

We experimented with DeBERTa, an encoder-only transformer model and its ability for natural language inference for the NLI4CT task. Taking the context length into account, the full premise does not fit into our model so we would have to get a shortened version of the premise. To achieve this, we generate a summary of each premise using a T5 variant that can fit the context length of DeBERTa (see Section 3.2). This shortened premise along with the full statement of each data point in the dataset is then used to make a prediction of entailment or contradiction for that statement. Our input to the DeBERTa model has the following form:

*Our code is available at: https://github.com/Shahriarnz14/TLDR-T5-generated-clinical-Language-for-DeBERTa-Report-Analysis

[CLS] + shortened premise + [SEP] + statement

where the [CLS] token is used for the binary classification of entailment or contradiction.

3.2 Summarization Techniques for Premises

The need for summarizing the premises arises due to the long length of the premises and the limited input length of several of the top performing BERT-based architectures such as DeBERTa that is utilized in this paper.

In our tasks, there are two types of data points: "Single" and "Comparison". For "Single" data points, the statement is checked for entailment with only a primary premise. In "Comparison" instances the statement is checked for entailment when compared to a primary as well as a secondary premise. For each of the summarization methods below, we consider summarizing both the primary and second premises independently of each other as well as summarizing the primary and secondary premises combined together.

3.2.1 Inference Only

Encoder-Decoder architectures such as the T5 model have shown strong capabilities for summarizing text. To this end we used several T5 variants to produce a summary for each premise with a maximum source length of 2048 tokens and a maximum generated summary of 300 tokens thereby decreasing the size of the premise to a size that would enable our full input to be passed into the DeBERTa model.

3.2.2 Fine-tuning

Our objective for fine-tuning T5-based models is to enable the generation of summaries closely mirroring ground truth statements for entailed premise-statement pairs. We fine-tune T5 variants on a dataset exclusively comprising pairs labeled "Entailment". "Contradiction" instances are excluded to avoid confusion of the model in generating summaries as they include contradictory information about the premise. We prepend the premises with "summarize:", as inputs to T5 and treat the corresponding ground truth statements as labels, aiming to align the generated summaries with these statements. This approach ensures the model is trained to produce summaries that effectively encapsulate the entailed information.

4 Experimental setup

In this section, we provide a comprehensive outline of our experimental methods, setting the stage for a detailed discussion on each technique employed.

The fine-tuning of each module of our model was done on the training set and evaluated on the development set. Upon selecting the best performing model from the development set, we then evaluated our model on the held-out test. The performance reported in Section 5 is on this held-out test set.

4.1 The Discriminative NLI Module of TLDR

For the shortened premise and the statement pairs, we fine-tuned an NLI fine-tuned version of the base DeBERTa-v3 model (Tran et al., 2023) from Hugging Face for Entailment and Contradiction binary classification. Specifically we used the `cross-encoder/nli-deberta-v3-base`. This model was trained using SentenceTransformers Cross-Encoder class on the SNLI (Bowman et al., 2015) and MultiNLI (Williams et al., 2018) datasets and provided improved NLI performance over standard DeBERTa-v3-base model. The tokenizer used was also taken from Hugging Face and was the tokenizer corresponding to the DeBERTa model that we used. The fine-tuning of our DeBERTa model was done on the training set for 40 epochs at a learning rate of 5×10^{-5} and evaluated on the development set to pick the best performing model for the final evaluations.

Importantly, DeBERTa has a maximum input size of 512 tokens. Therefore, the combined length of the shortened premise and statement pair is required to fit into this size (the average statement length in the training data was 110 tokens). The description of the different premise shortening techniques we employed is outlined below.

4.2 The Summarization Module of TLDR

We employed different variants of T5 to generate summaries of the clinical premises as a way to shorten them. In this section, we explain each of these approaches.

Zero-Shot T5 We utilized the Hugging Face API to summarize premises with *google/flan-t5-base*, limiting summaries to 300 tokens. For instances containing both primary and secondary premises, we conducted two different approaches: (1) separate summaries for each and (2) a combined summary for both premises together. The first approach

involved generating individual summaries for primary and secondary separately, and creating a single summary for a concatenated version of both premises in the second approach.

Fine-tuned T5 For Summary Generation To fine-tune T5 for summary generation, we filtered our training and development datasets to only include instances labeled as entailment, using these as ground truth for summarized premises. In the case of entailment, we claim that since the statement is an accurate representation of the premise it also serves as an appropriate ground truth label for a summarized premise. We opted for the *t5-small* model due to resource constraints, acknowledging this may impact comparison fairness with zero-shot models. Our fine-tuning utilized the ROUGE-1 metric which compares unigrams between the predicted and the label summary. We fine-tuned for $2, 5, 7,$ and 10 epochs at a learning rate of 2×10^{-5}, weight decay of 0.01 and a batch size of 4.After fine-tuning, we generated separate summaries for primary and secondary premises using this model.

Fine-tuned SciFive We followed the exact same procedure explained above from the fine-tuned T5 for the *razent/SciFive-base-Pubmed_PMC* model from Hugging Face. For this T5 variant, we aimed leverage the fact that the SciFive model was trained on biomedical literature (Phan et al., 2021) which is similar in domain to our setting. Here, we used the same hyperparameters for fine-tuning T5. After fine-tuning was complete, for data instances with two premises, we generated the summaries by separately summarizing the primary and secondary premises and then combining the two.

4.3 Summarization Ablations

We used two ablation strategies for TLDR's summarization module. Instead of using a T5 variant for summarizing each premise, these two ablations included: (1) naively truncating premises and (2) using a traditional extractive summarization.

Truncated Premises To fit within the 512 token limit of DeBERTa, we tokenized the combined statement and premises, subtracting the statement's token count and an additional 10 tokens from 512 to stay under the limit. More concretely, for $x = 512 -$ (# of statement tokens) $- 10$, in single-premise data points, we truncated the primary premise to x tokens and in comparison data points with both a primary and a secondary premise, we truncated each premise to $\frac{x}{2}$ tokens.

Extractive Summarization We also used an extractive summarization technique with TF-IDF for our ablation experiments, which evaluates word significance in a document against a corpus. To avoid data leakage and maintain evaluation accuracy, the TF-IDF vectorizer was applied exclusively to the training dataset. It was then used to summarize texts within the training, development, and test sets. Summaries were produced by identifying and selecting sentences with the highest TF-IDF scores, adhering to a 300-word limit for conciseness. This extractive summarization ablation, based on TF-IDF, allows us to compare summarization techniques and their impact on DeBERTa's NLI model performance, emphasizing the importance of feature representation and data handling.

4.4 Performance Metrics

We report the held-out test set performance metrics of the different variants of TLDR model. Specifically, we are report Macro F1, Precision, and Recall as measures of the prediction performance. In addition, we also report Faithfulness and Consistency.

Faithfulness assesses if a system predicts accurately for the right reasons, gauged by its response to **semantic altering** interventions. With N contrast set statements x_i, original y_i, and predictions $f()$, faithfulness is calculated using Equation 1.

$$Faithfulness = \frac{1}{N} \sum_{1}^{N} |f(y_i) - f(x_i)|$$
$$x_i \in C : \text{Label}(x_i) \neq \text{Label}(y_i), \text{ and } f(y_i) = \text{Label}(y_i) \quad (1)$$

Consistency evaluates a system's output uniformity for semantically equivalent inputs, focusing on identical predictions under **semantic preserving** interventions. This ensures semantic representation consistency, regardless of prediction accuracy. For N statements x_i in contrast set (C), with original y_i and predictions $f()$, consistency is determined using Equation 2.

$$Consistency = \frac{1}{N} \sum_{1}^{N} 1 - |f(y_i) - f(x_i)| \quad (2)$$
$$x_i \in C : \text{Label}(x_i) = \text{Label}(y_i)$$

5 Results

The performance of our TLDR variants and ablations on the NLI task for clinical report trials is summarized in Table 1. Our results showcase

Table 1: Performance of TLDR Variants and Ablations on the Held-Out Test Set

Method	Macro F1	Precision	Recall	Faithfulness	Consistency
Ablations: DeBERTa Methods					
DeBERTa + Truncated Premise(s)	0.474	0.432	0.524	0.573	0.542
DeBERTa + Extractive Summarized Premise(s)	0.612	0.584	**0.643**	**0.615**	**0.590**
TLDR Methods					
TLDR (flan-T5-base - Zero-Shot Combined Premises)	0.599	0.628	0.573	0.409	0.540
TLDR (flan-T5-base - Zero-Shot Distinct Premises)	0.633	0.624	0.642	0.502	0.574
TLDR (T5-small - Best fine-tuned)	0.635	0.676	0.599	0.436	0.557
TLDR (SciFive-base - Best fine-tuned)	**0.658**	**0.684**	0.633	0.501	0.581

the effectiveness of different approaches, with notable variations in Macro F1, Precision, Recall, and Faithfulness, and Consistency across methods.

The TLDR methods showed the most promising results. The best-performing model based on prediction performance was the TLDR method using SciFive-base for fine-tuned summarization of distinct premises, achieving the highest Macro F1 score of 0.658 and the best precision of 0.684. This approach also demonstrated a strong recall at 0.633 thereby indicating a strong balance between precision and recall. A close second was the TLDR approach with fine-tuned T5-small, which attained a Macro F1 score of 0.635 and precision of 0.676 and recall of 0.599, indicating the efficacy of fine-tuning on task-specific data. In the appendix, Table 2 illustrates the impact of varying the total number of fine-tuning epochs for T5-small and SciFive on the downstream NLI task. The main finding is that unlike T5-small that longer fine-tuning degraded the downstream performance, SciFive required longer fine-tuning steps to see improvements in TLDR's downstream prediction. We suspect this is due to the fact that the original fine-tuning of SciFive had degraded its summarization performance compared to T5-small and thus it required to be fine-tuned for longer.

For the ablations methods, we observed an improvement in performance when using extractive summarization instead of naively truncating the input. The method utilizing truncated premises achieved a Macro F1 score of 0.474, with the lowest precision of 0.432 among all methods and the lowest recall of 0.524 among all methods, suggesting this strategy as being inappropriate for dealing with the context length issue for this particular task. The extractive summarization approach yielded a much higher Macro F1 score of 0.612 with a much higher precision at 0.584 and recall at 0.643 thereby clearly outperforming the truncated premises strategy. Note that these are ablations of our introduced more complete TLDR model. Extractive summarization proved the best strategy for the faithfulness and consistency metrics with a faithfulness score of 0.615 and a consistency of 0.590. This result likely stems from the fact that extractive summarization of premises maintains key tokens from the original premises, which preserves the core semantics. This can then result in modifications from the contrastive set's interventions in the test data to be more straightforwardly mapped and identified by the TLDR's NLI module.

For a more detailed error analysis and exploration of each model's performance across various sections of the clinical trial, refer to Appendix B. The main takeaway is that TLDR methods leveraging fine-tuning and distinct premise summarization, consistently outperformed simpler input models across all clinical trial sections, demonstrating the significance of specialized summarization and training techniques in managing the challenges of lengthy premises in clinical trials.

6 Conclusion

In this paper, we introduced TLDR (**T**5-generated clinical-**L**anguage summaries for **D**eBERTa **R**eport Analysis) tailored for clinical NLI tasks, with a focus on NLI4CT 2024. Our investigation reveals that strategies incorporating SciFive for distinct premise summarization and fine-tuning for summarization to better align with entailed statements about the premises markedly improve handling of clinical language and reasoning complexities. Despite the challenges posed by lengthy premises in clinical reports, our TLDR methods, particularly those employing advanced summarization through fine-tuning, consistently demonstrated superior performance over simpler methods. This underscores the importance of model adaptation and the strategic selection of summarization techniques in enhancing the accuracy and reliability of NLI tasks

within the clinical domain.

Looking ahead, a promising avenue for future work involves the use of the best encoder-decoder transformer summarization model for each specific section of clinical reports. This approach could potentially improve the overall performance of NLI where we saw fine-tuned SciFive was particularly better in some sections of the clinical report and T5-based summaries were better at some other sections. Continued exploration and refinement of these models are essential to further advance the field of NLI in clinical applications.

A Fine-Tuning Encoder-Decoder Transformers for Specific Summary Generation

In this section, we present how the NLI performance varies across different fine-tuning steps of the T5 variants.

In the fine-tuning results of Table 2, we observe a peak performance at two epochs for both T5-small and SciFive-base models, with a slight performance drop as the number of epochs increases. The T5-small model shows a trade-off between precision and recall, reaching its highest recall at five epochs but with better overall performance at two epochs. The SciFive-base model maintains a consistent precision after two epochs, but the recall fluctuates, suggesting that the optimal number of training epochs is crucial for maintaining model balance and preventing overfitting. We believe the reason that SciFive required longer fine-tuning epochs compared to T5-small is because the initial fine-tuning of SciFive diminished its summarization capabilities relative to T5-small, necessitating extended fine-tuning to restore performance.

Table 2: Fine-Tuning Results

Method	Macro F1	Precision	Recall	Faithfulness	Consistency
T5 Fine-Tuning					
TLDR (T5-small - 2 Epochs)	0.605	0.580	0.633	0.557	0.593
TLDR (T5-small - 5 Epochs)	0.635	0.676	0.599	0.436	0.557
TLDR (T5-small - 7 Epochs)	0.601	0.564	0.644	0.597	0.590
TLDR (T5-small - 10 Epochs)	0.603	0.580	0.628	0.608	0.587
SciFive Fine-Tuning					
TLDR (SciFive-base - 2 Epochs)	0.570	0.528	0.620	0.552	0.580
