Preface by the General Chair

Welcome to AACL-IJCNLP 2022, the 2nd Conference of the Asia-Pacific Chapter of the Association for Computational Linguistics and the 12th International Joint Conference on Natural Language Processing! The conference will be held online on November 20-23, 2022.

AACL-IJCNLP 2022 was originally scheduled to take place in Taipei, Taiwan. We had a discussion with AACL executive board early this year whether to hold the conference entirely in the virtual mode due to the strict COVID quarantine rule imposed by the Taiwan government. We later decided to wait until the mid of June to re-evaluate the situation. In early June, the Central Epidemic Command Center in Taiwan announced that starting from 15 June 2022, the mandatory quarantine period for international arrivals in Taiwan would be reduced from 7 to 3 days. After a discussion with both the Program Chairs and the Local Organization Chair, we decided to wait further until August to see if we could have a hybrid conference in the hope that Taiwan will open its border fully in November. But we eventually made a difficult decision to hold the conference entirely online at mid of August as the quarantine rule and the travel ban imposed on foreign nationals were still in place in Taiwan. This was rather disappointed. Nevertheless, our Program Chairs have put together a very interesting conference program. I hope to see many of you joining our conference online.

AACL-IJCNLP 2022 adopted a dual paper submission system that authors can choose to submit their papers to the "ACL Rolling Review (ARR)" or submit to the softconf submission site in a conventional way. For the latter, authors had a chance to respond to reviewers' comments. One innovation our Program Chairs introduced is to allow authors to run additional experiments and upload revised papers during the rebuttal period to address reviewers' comments. This required additional efforts from our reviewers, area chairs and senior area chairs to check the revised submissions. But it gave authors better opportunities to address reviewers' criticism. Another innovation is to introduce poster lightning talks in the main conference. We hope these efforts will be followed in future conferences.

AACL-IJCNLP 2022 would not be possible without the contribution from a large number of volunteers who are willing to spend tremendous time and effort. These include the members of our organisation committee and various people from the ACL community. In particular, I would like to thank:

- the three Program Co-Chairs, Heng Ji, Sujian Li, and Yang Liu, who managed the whole conference paper submission and review process, and assembled the conference program with new initiatives such as a debate on "*Is there more to NLP than Deep Learning?*" and the "7 NLP Dissertation Topics for Next 7 Years";
- the Local Organisation Chair, Chia-Hui Chang, who was in charge of venue booking when we initially planned for a hybrid conference and coordinated the setup of a registration site. She was supported by a great local organisation team, including the Financial Chair, Lun-Wei Ku, the Local Arrangement Chair, Kuan-Yu (Menphis) Chen, the Online Conference Coordinator, Richard Tzong-Han Tsai, and the Registration Chair, Hsiu-Min Chuang;
- the Publication Co-Chairs, Min-Yuh Day, Hen-Hsen Huang, and Jheng-Long Wu, who prepared the instruction for proceedings compilation and coordinated with our workshop/tutorial/demo/student research workshop chairs to assemble all papers into our conference proceedings;
- the Workshop Co-chairs, Soujanya Poria and Chenghua Lin, who selected 5 workshops for the conference and ensured all the workshops could successfully run virtually;
- the Tutorial Co-Chairs, Miguel A. Alonso and Zhongyu Wei, who selected 6 tutorials to be presented at the conference and prepared the tutorial abstract proceedings;

- the Demonstration Co-Chairs, Wray Buntine and Maria Liakata, who manged the demo paper submission and review process;
- the Special Theme Co-Chairs, Monab Diab and Isabelle Augenstein, who handled paper submissions to the Special Theme on Fairness in Natural Language Processing;
- the Student Research Workshop (SRW) Co-Chairs, Hanqi Yan and Zonghan Yang, who organised the student workshop under the guidance our our SRW Faculty Co-Advisors, Sebastian Ruder and Xiaojun Wan;
- the Publicity Co-chairs, Pengfei Liu, Gabriele Pergola,and Ruifeng Xu, who communicated the information about the conference to the community using various social media channels;
- the Website Chair, Miguel Arana Catania and Yung-Chun Chang, who ensured that the AACL-IJCNLP 2022 website contains all up-to-date information;
- the Diversity & Inclusion (D&I) Chairs, Ruihong Huang and Jing Li, who have worked tirelessly to make AACL-IJCNLP 2022 as welcoming and inclusive as possible for all participants. They were supported by the D&I committee members, Yuji Zhang, Yuanyuan Lei, and Ayesha Qamar;
- the Sponsorship Coordinators, Hiroya Takamura, Wen-Hsiang Lu, and Deyi Xiong, who reached out institutions and corporations to collect funds to support our conference;
- the Communication Chairs, Zheng Fang, Jiazheng Li, and Xingwei Tan, who stepped in with a short notice to help Program Co-Chairs deal with a large number of email enquires;
- Priscilla Rasmussen, who stayed as a consultant for ACL, and Jennifer Rachford, the ACL Business Manager, for helping with various conference matters;
- the Chair of the AACL, Keh-Yih Su, and all the AACL executive board members, that have provided guidance regarding various decisions;
- the ACL executive board including the President, Tim Baldwin, for linking us with the right support; the ACL Sponsorship Director, Chris Callison-Burch, for providing guidance to our Sponsorship Chairs; and the ACL Treasurer, David Yarowsky, who negotiated a contract with Underline for supporting our virtual conference;
- Rich Gerber from Softconf, who set up the AACL-IJCNLP conference submission site, has always been responsive to our queries.

I would also like to express gratitude to our sponsors, whose generous support has been invaluable in building up AACL-IJCNLP to what it is now. These include our Diamond-level sponsors - GTCOM, LivePerson, Tourism Bureau, the Ministry of Science and Technology, the Ministry of Education and National Central University in Taiwan; our Platinum-level sponsor - Baidu; our Gold-level sponsors - Bloomberg; and our Bronze-level sponsors - Adobe.

Finally, I would like to thank all authors, senior area chairs, area chairs, reviewers, invited speakers and panelists, the volunteers organizing and chairing various sessions in the conference, and all attendees, for making this hopefully another successful NLP conference!

Hope you all enjoy AACL-IJCNLP 2022!

AACL-IJCNLP 2022 General Chair
Yulan He, King's College London, UK

Preface by the Program Committee Co-Chairs

We welcome you to AACL-IJCNLP 2022, the 2nd Conference of the Asia-Pacific Chapter of the Association for Computational Linguistics (AACL) and the 12th International Joint Conference on Natural Language Processing (IJCNLP)! Due to the strict COVID quarantine rule imposed by the local government, AACL-IJCNLP 2022 has to be held fully virtual. However, conference organizers have worked very hard to simulate an in-person meeting setting, thanks to the relatively mature virtual conference infrastructures that have been built by our community.

AACL-IJCNLP 2022 has utilized two submission platforms SoftConf and ACL Rolling Review (ARR)-OpenReview, and received 554 submissions in total (518 from SoftConf and 36 from ARR) for the main conference. We have accepted 147 papers (87 long and 60 short) for the main conference and 44 papers for the Findings. The submissions came from all over the world. Among the 191 accepted papers, according to the information of the main contact, 84 were from the Asia-Pacific region (23 from China mainland, 18 from India, 16 from Japan, 7 from South Korea, 5 from Australia, 3 from Singapore, 3 from Taiwan, 3 from Bangladesh, 2 from New Zealand, 1 from Sri Lanka, 1 from Nepal, 1 from Malaysia, and 1 from HongKong), 42 were from the America (36 from the USA, 5 from Canada, 1 from Chile), and 65 from Europe and the Middle East (18 from the UK, 12 from Germany, 9 from France, 5 from Netherlands, 4 from Switzerland, 4 from Italy, 3 from Norway, 2 from Egypt, 2 from Spain, 1 from Estonia, 1 from Denmark, 1 from Finland,1 from Iron, 1 from Bulgaria and 1 from Czech).

We have developed the following new attempts this year for paper submission:

- We created a new special theme "Fairness in Natural Language Processing”.
- We added a new function during paper rebuttal to allow authors to upload their revised papers so that some responses can be more clearly presented and elaborated.

AACL-IJCNLP2022 does have a great program, thanks to all of you! We have put up a very exciting program with many new plenary sessions:

- We have invited four wonderful keynote speakers this year: Chris Callison-Burch (University of Pennsylvania), Eduard Hovy (University of Melbourne and Carnegie Mellon University), Juanzi Li (Tsinghua University), and Prem Natarajan (Amazon Alexa AI).
- A promised-to-be-heated debate: "Is there more to NLP than Deep Learning?" between "Yes” team: Eduard Hovy (Team Lead), Kathleen McKeown, Dan Roth, Eric Xing and "No” team: Kyunghyun Cho (Team Lead), Danqi Chen, Manling Li, Graham Neubig, to be moderated by Rada Mihalcea.
- “7 NLP Dissertation Topics for Next 7 Years” by Kevin Duh, Fei Huang, Smaranda Muresan, Preslav Nakov, Nanyun Peng, Joel Tetreault and Lu Wang.
- A panel on the special theme "Fairness in Natural Language Processing”, moderated by our special theme chairs Mona Diab and Isabelle Augenstein.
- A Global Women in NLP session "Finding Your Purpose, Findign Your Voice - Professional Growth in the Age of Deep AI" led by Pascale Fung.

We are very grateful for all of these speakers and panelists on accepting our invitations! We will also have a special best paper award session and a lighting talk session for posters, following the successes of previous ACL and NAACL conferences. The excellence of the overall AACL-IJCNLP2022 program is thanks to all the chairs and organizers. We especially thank the 47 Senior Area Chairs, 84 Area Chairs and reviewers for their hard work. We are grateful to Amanda Stent, Goran Glavaš, Graham Neubig, and Harold Rubio for their invaluable support in the commitment of papers reviewed by ARR to AACL-IJCNLP 2022. We appreciate Rich Gerber's prompt responses and support whenever we request any fix or adding new functions. It has been an enormous privilege for us to see the scientific advances that will be presented at this conference. Congratulations to all authors!

We hope you will enjoy AACL-IJCNLP 2022, and look forward to seeing many of you online!

AACL-IJCNLP 2020 Program Committee Co-Chairs
Heng Ji (University of Illinois Urbana-Champaign and Amazon Scholar)
Yang Liu (Tsinghua University)
Sujian Li (Peking University)

Preface by the Local Chair

Since winning the bid for organising AACL-IJCNLP 2022 conference in Taiwan, the local team has worked hard to get subsidies from Ministry of Science and Technology, Ministry of Education, Bureau of Foreign Trade, and National Central University, Taiwan. We also planned to co-host AACL-IJCNLP 2022 with ROCLING 2022, the annual meeting of the Association for Computational Linguistics of Chinese Language Processing in Taiwan. We, Yung-Chun Chang, Kuan-Yu (Menphis) Chen and I, envisioned that even if only half the registrants can come to Taiwan due to COVID-19, the conference will still be lively with ROCLING participants.

Even at the end of June, we remained optimistic that a hybrid conference would be possible. However, Taiwan's border control were not lifted and passengers entering Taiwan still needed to be quarantined for three plus four days after August, which will deter most international participants. Thus, we had to adopt a purely online mode at last.

It was a great experience to co-host the AACL-IJCNLP 2022 conference with the international team. On behalf of the local organising team: Yung-Chun Chang, Kuan-Yu (Menphis) Chen, Hsiu-Min Chuang, Min-Yuh Day, Hen-Hsen Huang, Lun-Wei Ku, Wen-Hsiang Lu, Tzong-Han Tsai, and Jheng-Long Wu, we would like to thank our general chair, Yulan He, program co-chairs, Heng Ji, Yang Liu, Sujian Li, and the international team. Yulan's leadership and the international team made the conference go smoothly. Without you, it would be impossible to accomplish so many tasks. I also learned a lot from it. Hope we can meet physically in the near future.

AACL-IJCNLP 2022 Local Chair
Chia-Hui Chang (National Central University)

Organizing Committee

General Chair

Yulan He, King's College London, UK

Program Committee Co-Chairs

Heng Ji, Unversity of Illinois at Urbana-Champaign, USA
Yang Liu, Tsinghua University, China
Sujian Li, Peking Unversity, China

Local Organisation Chair

Chia-Hui Chang, National Central University, Taiwan

Workshop Co-Chairs

Soujanya Poria, Singapore University of technology and Design, Singapore
Chenghua Lin, University of Sheffield, UK

Tutorial Co-Chairs

Miguel A. Alonso, Universidade da Coruña, Spain
Zhongyu Wei, Fudan University, China

Demo Co-Chairs

Wray Buntine, VinUniversity, Vietnam
Maria Liakata, Queen Maty University of London, UK

Student Research Workshop Co-Chairs

Hanqi Yan, University of Warwick, UK
Zonghan Yang, Tisnghua University, China

Student Research Workshop Faculty Co-Advisors

Sebastian Ruder, DeepMind, Uk
Xiaojun Wan, Peking University, China

Publication Co-Chairs

Min-Yuh Day, National Taipei University, Taiwan
Hen-Hsen Huang, Academia Sinica, Taiwan
Jheng-Long Wu, Soochow University, Taiwan

Publicity Co-Chairs

Pengfei Liu, Carnegie Mellon University, USA
Ruifeng Xu, Harbin Institute of Technology, Shenzhen, China
Garbriele Pergola, University of Warwick, UK

Diversity & Inclusion Co-Chairs

Ruihong Huang, Texas A&M University, USA
Jing Li, Hong Kong Polytechnic University, China

Financial Chair

Lun-Wei Ku, Academia Sinca, Taiwan

Local Arrangement Chair

Kuan-Yu (Menphis) Chen, National Taiwan University of Science and Technology, Taiwan

Online Conference Coordinator

Richard Tzong-Han Tsai, National Central University, Taiwan

Sponsorship Co-ordinators

Wen-Hsiang Lu, National Chiao Tung University, Taiwan
Hiroya Takamura, Tokyo Institute of Technology, Japan
Deyi Xiong, Tianjin University, China

Webmaster

Yung-Chun Chang, Taipei Medical University, Taiwan
Miguel Arana-Catania, University of Warwick, UK

Communication Chairs

Xingwei Tan, University of Warwick, UK
Zheng Fang, University of Warwick, UK
Jiazheng Li, University of Warwick, UK

Special Theme co-chairs

Mona Diab, Facebook AI, USA
Isabelle Augenstein, University of Copenhagen, Denmark

Program Committee

Program Committee Co-chairs
Heng Ji, University of Illinois at Urbana-Champaign, USA
Sujian Li, Peking University, China
Yang Liu, Tsinghua University, China

Computational Social Science and Cultural Analytics
Senior Area Chairs: Chenhao Tan, Binyang Li
Area Chairs: Kenny Joseph, Fei Li, Xu Tong

Dialogue and Interactive Systems
Senior Area Chairs: Mahdi Namzifar, Spandana Gella
Area Chairs: Andrea Madotto, Yi-Chia Wang, Saab Mansour, Lili Mou, Saleh Soltan

Discourse and Pragmatics
Senior Area Chairs: Vincent Ng, Yang Liu
Area Chairs: Hen-Hsen Huang, Naoya Inoue, Sharid Loáiciga

Generation
Senior Area Chairs: Meng Jiang, Nanyun Peng, Victoria Lin
Area Chairs: Qingbao Huang, Lianhui Qin, Chenguang Zhu

Information Extraction
Senior Area Chairs: Marius Pasca, Radu Florian
Area Chairs: Qiang Ning, Minjoon Seo

Information Retrieval and Text Mining
Senior Area Chairs: Jing Jiang, Scott Wen-tau Yih, Yixin Cao
Area Chairs: Xu Chen, Muhao Chen, Xiang Wang, Weinan Zhang, Fuli Feng

Interpretability and Analysis of Models for NLP
Senior Area Chairs: Xipeng Qiu, Kevin Duh
Area Chairs: Jasmijn Bastings, Hassan Sajjad, Baotian Hu

Language Modeling
Senior Area Chairs: Han Zhao, Lena Voita
Area Chairs: Ilia Kulikov, Marjan Ghazvininejad, Wenhu Chen

Machine Learning for NLP
Senior Area Chairs: William Wang , Zhiting Hu, Bo Li
Area Chairs: Zichao Yang, Hao Peng, Xin Eric Wang, Boxin Wang, Kai-Wei Chang

Machine Translation and Multilinguality
Senior Area Chairs: Fei Huang, Yang Feng, Sid Patwardhan
Area Chairs: Boxing Chen, Jun Xie, Weihua Luo, Kehai Chen, Junhui Li, Marta R. Costa-jussà

NLP Applications
Senior Area Chairs: Deyi Xiong, Preslav Nakov, Tao Ge
Area Chairs: Zhouhan Lin, Lei Sha, Karin Verspoor, Christian Hardmeier, Yoshi Suhara

Phonology, Morphology, and Word Segmentation
Senior Area Chairs: Mark Hasegawa-Johnson, Peng Li
Area Chairs: Hai Zhao, Sakriani Sakti, Yan Song, Suma Bhat

Question Answering
Senior Area Chairs: Avi Sil , Dian Yu
Area Chairs: Mo Yu, Kai Sun, Jing Liu, Yiming Cui, Jaydeep Sen, Qiang Ning

Resources and Evaluation
Senior Area Chairs: Joel Tetreault, Masayuki Asahara
Area Chairs: Mamoru Komachi, Courtney Napoles, Anne Lauscher, Sudha Rao

Semantics
Senior Area Chairs: Jonathan May, Wenbin Jiang
Area Chairs: Zheng Lin, Meishan Zhang, Mingxuan Wang, Zhiyang Teng

Sentiment Analysis, Stylistic Analysis, and Argument Mining
Senior Area Chairs: Shuai Wang, Alexandra Balahur
Area Chairs: Rui Xia, Serena Villata, Lun-Wei Ku, Ruifeng Xu

Speech and Multimodality Processing
Senior Area Chairs: Nancy Chen, JiaJun Zhang
Area Chairs: Hung Le, Hungyi Lee, Hanwang Zhang, Florian Metz, Jing Liu, Haoran Li, Tianzhu Zhang

Summarization
Senior Area Chairs: Ziqiang Cao, Fei Liu
Area Chairs: Wenhao Wu, Ruifeng Yuan

Syntax: Tagging, Chunking and Parsing
Senior Area Chairs: Barbara Plank, Kewei Tu
Area Chairs: Carlos Gómez-Rodríguez, Joakim Nivre, Yusuke Miyao

Theme: "Fairness in Natural Language Processing"
Senior Area Chairs: Margaret Mitchell, Hal Daumé III
Area Chairs: Su Lin Blodgett, Emily Dinan, Kai-Wei Chang, Kellie Webster, Marta R. Costa-jussà, Timothy Baldwin, Zeerak Talat, Tanmoy Chakraborty, Yun-Nung Chen

Linguistic diversity
Senior Area Chairs: Steven Bird, Constantine Lignos
Area Chairs: Alexis Palmer, Antonios Anastasopoulos

Abstract

Natural language understanding (NLU) tasks are typically defined by creating an annotated dataset in which each utterance is encountered once. Such data does not resemble real-world natural language interactions in which certain utterances are encountered frequently, others rarely. For deployed NLU systems, this is a vital problem, since the underlying machine learning (ML) models are often fine-tuned on typical NLU data, in which utterance frequency is never factored in, and then applied to real-world data with a very different distribution. Such systems need to maintain interpretation consistency for the high-frequency (head) utterances, while also doing well on low-frequency (tail) utterances. We propose an alternative strategy that explicitly uses utterance frequency in training data to learn models that are more robust to unknown distributions. We present a methodology to simulate utterance usage in two public corpora and create two new corpora with head, body and tail segments. We evaluate several methods for joint intent classification and named entity recognition (referred to as IC-NER), and propose to use two domain generalization (DG) approaches that we adapt to sequence labeling task. The DG approaches demonstrate up to 7.02% relative improvement in semantic accuracy over baselines on the tail data. We provide insights as to why the proposed approaches work and show that the reasons for the observed improvements do not align with those reported in previous work.

1 Introduction

In academic research, natural language understanding (NLU) tasks are typically defined by creating annotated data, and then that data is used to train and evaluate machine learning models designed to solve that task. In such datasets, each utterance is typically encountered only once. But real-world natural language interactions do not look like that – in the real world, frequency matters. When people interact with each other “in the wild”, some things are said often ("Time to go to bed!"), others are infrequent to the point of being unique.

The same holds for how people interact with digital assistants such as Alexa, Siri, or Google Assistant, which we use as the case study in this paper. The backbone of such commercial systems is the task of joint intent classification and named entity recognition (IC-NER) (Su et al., 2018; Coucke et al., 2018; Anantha et al., 2021). The goal of this task is to identify the intended action (play music, open calendar, etc) and actionable slots (names, places, objects, etc) from a user utterance.

The underlying joint IC-NER models must correctly handle both the frequently occurring requests and a long tail of less common entities. But in the common IC-NER corpora such as SNIPS (Coucke et al., 2018), there is no way to distinguish between requests for generic entities ("*play music from youtube*") and requests for a low-frequency entity ("*help me locate a game called the master of ballantrae*"). IC-NER models are fine-tuned on all training data, and then applied to real-world data with a very different distribution.

In order to mitigate this issue, this work proposes a method for creating annotated data which explicitly factors in utterance frequency. We divide an NLU dataset into three disjoint segments: head (most frequent utterances), tail (least frequent utterances) and body (all remaining utterances). In this work, we define a *segment* as a subset of the dataset with similar characteristics, for example the head segment contains utterances with high frequencies in the real world. We then develop learning strategies which benefit from the token and label distributions in the head, body, and tail segments of the resulting frequency-enriched datasets.

We simulate utterance usage patterns using two common public corpora for the IC-NER task: SNIPS (Coucke et al., 2018) which con-

Table 1: Selected examples from head and tail segments in the newly created corpora: SNIPSesv and TOPesv. Utterances from head segments include the repetition counts. Tokens with slot labels are **boldfaced**.

	SNIPSesv	TOPesv
Head	"play music off **youtube**": 76 " play some **google music**": 36	"is **the weather** causing traffic delays **today**": 65 "where is **macys**": 46 "what **new movies** start **this weekend**": 32
Tail	"add **outside the dream syndicate** to **millicent's fresh electronic** playlist" "what s the weather in **south punta gorda heights**" "add **9th inning** to **my bossa nova dinner** playlist"	"what is the quickest route to get to **valdosta** from **atlanta**" "how long does it take to **drive** from **adair** to **chelsea**"

tains real-world utterances directed towards the SNIPS voice assistant, and the Facebook Dialog Corpus (TOP; Gupta et al. 2018) which is a crowd-sourced collection of natural language queries related to navigation and event inquiries, creating two frequency-enriched datasets (SNIPSesv and TOPesv). Our methodology is based on entity search volumes, which allows us to emulate a realistic utterance frequency distribution in the data. Utterances are then upsampled according to their estimated frequency. SNIPSesv and TOPesv datasets separate test data for head, body and tail segments, enabling the comparison of model performance on each segment. The proposed methodology can be easily extended to other NLU tasks such as part-of-speech tagging, sentence generation, or question answering.

Using our frequency-enriched datasets, we compare IC-NER performance of several methods. We propose modifications to two domain generalization (DG; (Blanchard et al., 2011)) approaches: domain masks for generalization (DMG; Chattopadhyay et al. 2020) and optimal transport (OT; (Zhou et al., 2020a)). We adapt these methods for IC-NER and demonstrate up to 7.02% relative improvement in semantic accuracy on the tail data over strong baselines.

We provide insights as to why the proposed DG approaches work, showing that OT learns segment-invariant representations using segment classification analysis. Our analysis using random-valued masks reveals that performance improvements by DMG are rather likely due to the training process resembling an enhanced version of dropout, rather than learning segment-specific mask parameters, an observation which does not align with those reported in previous work. We corroborate our observations in NLU with similar findings on a related task from computer vision, for which DMG was originally proposed.

The main contributions of this work are thus as follows: (i) We simulate utterance usage frequency for two public NLU corpora. To the best of our knowledge, these frequency-enriched datasets are the first attempt to explicitly incorporate utterance usage information in NLU. (ii) We adapt two domain generalization approaches to the sequence labeling task in NLU and show improvement over strong baselines on the tail segment, using the frequency-enriched data. (iii) We demonstrate that the reasons for improved performance from DMG do not align with those reported in previous work.

2 Background

2.1 Improving tail recognition

Previous work on head to tail transfer learning has typically focused on assigning classes to either head or tail based on the number of examples present in each class (Xiao et al., 2021; Raunak et al., 2020). Our problem setting is different in that we divide the dataset into head, body and tail based on the estimated usage frequency of each utterance. For example, in our case, the utterances belonging to a common class (such as "play music" intent) may not all be assigned to the head segment, but rather may be split between head, body, and tail, depending on their frequencies.

Since our problem setting presumes a different definition of head and tail, many of the methods (Kang et al., 2020; Ouyang et al., 2016; Cao et al., 2019) developed for head-to-tail transfer are not directly applicable in our case.

2.2 Domain generalization approaches

Domain generalization techniques (Blanchard et al., 2011) are a subset of transfer learning approaches where multiple *domains* with different label distributions and class-conditional distributions are used for model building. As distinct from domain adaption, no data from the target domain(s) is assumed available for training/adaptation. We wanted to investigate DG methods for our scenario, since this would allow us to treat head, tail, and body segments as virtual domains, without making any specific assumptions about the data and label distributions in each segment.

A variety of DG approaches have been proposed: kernel-based optimization methods (Blanchard et al., 2011, 2021; Muandet et al., 2013), augmenting with synthetic data perturbed using loss gradients (Shankar et al., 2018), learning a transformation to jointly classify domains and labels (Zhou et al., 2020b), learning a segment-invariant feature space by minimizing the optimal transport between domain pairs (Zhou et al., 2020a), etc. Broadly, these approaches learn to project datapoints from different segments into equivalent feature spaces for data representation, which improves performance. This paradigm closely resembles meta-learning, with the difference being that meta-learning assumes access to labeled samples from the target segment during the meta-testing phase (Ravi and Larochelle, 2017). An alternative set of approaches focuses on learning segment-specific knowledge, e.g., using outputs from a model trained on seen segments to train a model for unseen segments (Zhou et al., 2021) or selecting convolution activations to create segment-specific subnetworks in the model (Chattopadhyay et al., 2020; Mallya et al., 2018; Berriel et al., 2019).

DG has been relatively less explored in NLU when compared to computer vision. A handful of works have applied DG for semantic parsing: Wang et al. (2021) employed an adaptation of MAML (Finn et al., 2017) to simulate new segments, Marzinotto et al. (2019) used an adversarial domain classifier as a regularization technique. We adapt two categories of DG approaches: learning representations which are segment-specific (DMG; Chattopadhyay et al. 2020) and segment-invariant (optimal transport; (Zhou et al., 2020a)). We apply these approaches for generalizing IC-NER performance from head, body and tail segments.

3 Methods

3.1 Dataset preparation

Both SNIPS (Coucke et al., 2018) and TOP (Gupta et al., 2018) contain almost exclusively unique utterances, and SNIPS is purposefully designed to contain a balanced number of utterances per intent. Following Chen et al. (2019), IC-NER models are commonly evaluated on data that excludes nested intents, since BERT-based architectures make handling nested intents challenging. In order to enable fair comparison of model performance, we follow this strategy and remove nested intents from TOP. We also remove all utterances labeled with "Unsupported" intent.

3.1.1 Estimating usage frequency

In order to estimate usage frequency of each utterance, we use the internet search volumes of each labeled entity (defined as a token labeled with a slot, e.g., ArtistName). We hypothesize that the utterance's usage frequency is influenced primarily by the mentioned entities (e.g., *master of ballantrae* in Section 1) and not the remaining tokens (e.g., stop words, *play*, *order*, etc)

We collect the monthly entity search volume (denoted esv) averaged over the last year using the Google AdWords API[1]. We estimate the utterance search volume as mean esv for all entities, assuming that each entity contributes equally to the utterance usage. For example, consider the following utterance in the SNIPS corpora: "*Book reservations at a restaurant in Olton around supper time*". There are two labeled entities in it: Olton (city) and supper (time interval). Monthly search volumes in Google for each entity are 266 and 33.1K respectively. Hence, the estimated utterance usage esv_u is 16.7K. In a similar manner, we estimate the usage frequency of all utterances in SNIPS and TOP.

Another option for estimating usage frequencies is to use utterance perplexity estimated by a high-quality pre-trained language model. In preliminary analysis, we used the perplexities from GPT-2 to approximate usage frequency. We did not find that this method produced good estimates of usage frequencies in spoken requests to digital assistants, likely due to the domain difference of the data used pre-training of GPT-2. Pre-training on in-domain data can be used to address this in the future, potentially enabling this alternative strategy for estimating utterance frequency.

3.1.2 Utterance sampling

We used the frequency estimate for each utterance to determine the upsampling factor for that utterance. Intuitively, an utterance with a higher esv_u should be sampled more, and is more likely to be present in the head segment.

We normalize the obtained search volume to derive a probability distribution p_u over utterances. However, we compared the resulting distribution

[1] https://developers.google.com/adwords/api/

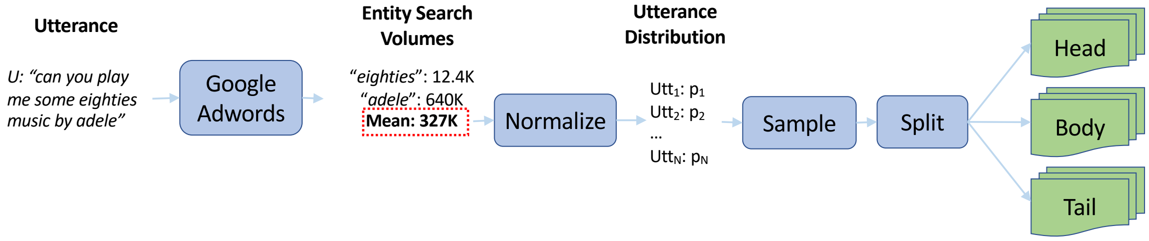

Figure 1: Overview of the dataset preparation process. For each utterance from the original train, dev and test sets from SNIPS and TOP, we estimate the utterance frequency. The frequency is normalized to a probability distribution which is used to sample utterances.

against the utterance in a proprietary commercial dataset[2], and observed that while p_u gave reasonable estimates in many cases, it was not well calibrated. Specifically, it produced a heavy skew in favor of frequent utterances, possibly due to the fact that we were only able to approximate frequencies at the entity, rather than utterance level. Sampling directly from p_u would therefore have produced a corpus with a small number of unique utterances and many repetitions, while omitting most utterances from the original dataset.

To avoid this issue, we cap the maximum sampling probability p_{max} of an utterance. We define p_{max} to be the probability of the most common utterance, defined as follows:

$$p_{max} = \frac{|u_{max}|}{\sum_i |u_i|} \tag{1}$$

where u_i denotes a unique utterance and u_{max} denotes the most common unique utterance. We empirically determine p_{max} = 0.00245 using the proprietary corpus of user queries with semantically similar intent labels to SNIPS and TOP. Further details are provided in the Appendix.

3.1.3 Splitting into head, body and tail

We create frequency-enriched versions of the TOP and SNIPS datasets using the capped probability distribution to sample utterances with replacement. We fix the total number of utterances (N) in the new corpus and sample utterances using the capped distribution until we collect N utterances. We segment the upsampled corpus into head, body, and tail, where head and tail are designed to contain fewer utterances than body. The frequency of utterances in the head and tail segments is very high or very low, respectively. We assign 10% most frequent utterances to head, 10% least frequent utterances to tail and remaining utterances to body[3]. We create the train and test partitions of SNIPSesv and TOPesv separately from the original train and test partitions, hence resulting in six segments (3 train + 3 test) for each corpus.

We report utterance and label statistics of the resulting datasets in Table 2. In both SNIPSesv and TOPesv, the head segment contains relatively fewer unique utterances than other segments, but each unique utterance is repeated multiple times. Note that the head segment does not contain the complete set of labels (intents and classes) found in the original corpora. Specifically, the head segment in SNIPSesv and TOPesv contain only 30.5% and 38.4% of all the slot labels in the original segment, respectively. Some intent labels are also missing in other segments in TOPesv, likely because the TOP corpus (Gupta et al., 2018), unlike SNIPS, has a non-uniform intent distribution. In Table 1, we provide representative examples from head and tail segments in the newly created corpora. Note that utterances with popular/generic entities (e.g., youtube, weather) are likely to end up in the head segment when compared to less widely used entities.

3.2 Domain Generalization Approaches

As the omitted intent statistics in Table 2 suggest, head, body and tail segments of both datasets have very different label distributions $P(Y)$. At the same time, since utterances are sampled according to the entity search volume, each segment has a different distribution over tokens $P(X)$ (Table 1). These differences in label and token distributions motivate our choice of DG approaches for improv-

[2] See Appendix for details.

[3] Utterances are not shared between segments, hence the exact fraction of utterances across head, body and tail may not be equal to 10%-80%-10%

Table 2: Dataset statistics for head, body and tail segments in SNIPSesv and TOPesv, along with the respective original corpora ("Original" segment). Splits (train, dev and test) for each segment are created using the corresponding splits from the original corpora. For each split within a segment, the total utterance count (Utt), unique utterance count (Uniq Utt), average repetition of unique utterances (Rep), and missing labels are provided. The total number of intents and slot labels are provided against the respective column headers.

ing performance on unseen segments (Blanchard et al., 2011).

Both DG approaches explored in this work, DMG (Chattopadhyay et al., 2020) and OT (Zhou et al., 2020a), assume that the model can be broken down into a feature extractor F_Ψ and a task network T_Θ. A typical feature extractor and task network for IC-NER are BERT-based pretrained model and sequence/slot classification network respectively (Chen et al., 2019).

3.2.1 Domain Masks for Generalization (DMG)

DMG encodes segment knowledge in *masks* ($\tilde{\mathbf{m}}^d$), which are segment-specific parameters jointly learnt with F_Ψ and T_Θ. For segment d, we extract binary activations m^d from masks as follows:

$$m^d \sim \text{Bernoulli}(\sigma(\tilde{\mathbf{m}}^d)) \qquad (2)$$

where σ represents the sigmoid activation function. During forward pass, we multiply each activation by m^d to compute the effective activation passed to the next layer. Hence, masks serve as layer-wise "on"/"off" gates within T_θ. Masks are sampled during training, hence a different set of neurons are activated for different mini-batches within the same segment.

Similar to the original formulation of DMG (Chattopadhyay et al., 2020), we ensure that masks are incentivized to learn segment-specific information and avoid learning similar representations for all segments by using a soft overlap loss (sIoU; Rahman and Wang 2016). The soft-overlap loss is used in place of Jaccard Similarity Coefficient which is non-differentiable and hence cannot be optimized with gradient descent. Specifically, we compute:

$$\text{sIoU}(\tilde{\mathbf{m}}^{d_i}, \tilde{\mathbf{m}}^{d_j}) = \frac{\tilde{\mathbf{m}}^{d_i} \cdot \tilde{\mathbf{m}}^{d_j}}{\sum(\tilde{\mathbf{m}}^{d_i} + \tilde{\mathbf{m}}^{d_j} - \tilde{\mathbf{m}}^{d_i} \odot \tilde{\mathbf{m}}^{d_j})}$$

At each mini-batch, we compute $\text{sIoU}(\tilde{\mathbf{m}}^{d_i}, \tilde{\mathbf{m}}^{d_j})$ for every segment pair and sum across all pairs. This soft-overlap loss is added to the classification loss and used as the overall objective for optimization.

$$\mathcal{L}_{DMG} = \frac{1}{n} \sum_i \mathcal{L}_{class}(\mathbf{x_i}, y_i) + \lambda_{DMG} \sum_{d_i, d_j \in d} \text{sIoU}(\tilde{\mathbf{m}}^{d_i}, \tilde{\mathbf{m}}^{d_j}) \qquad (3)$$

where n, d and $\mathcal{L}_{class}$ represent the mini-batch size, set of segments in the mini-batch, and the classification loss function. At test time, we do not have segment labels for a sample. We arrive at the predicted label by computing the mean prediction obtained with all segment-specific masks.

3.2.2 Optimal Transport

Optimal transport (Shen et al. (2018)) learns segment-invariant feature representations by ensuring feature compactness, i.e., samples from the same class across different segments are brought close to each other and vice versa. Assuming

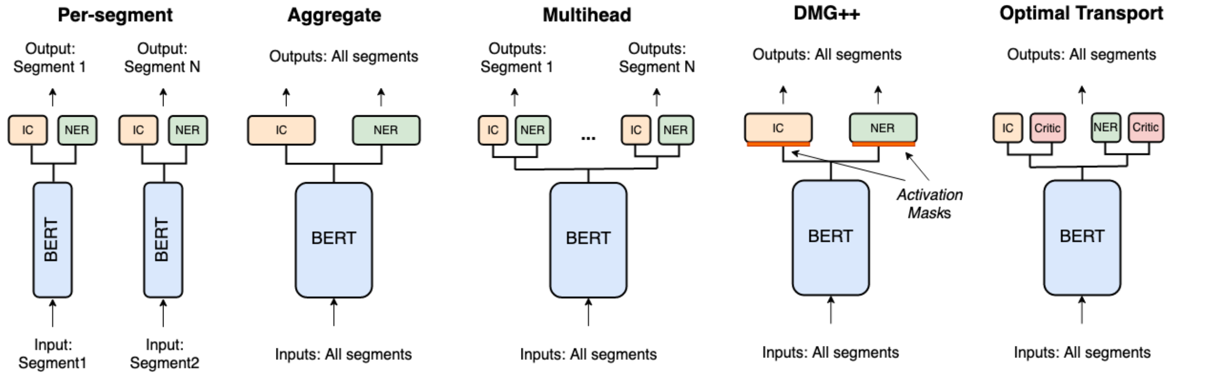

Figure 2: Illustrating the different approaches used in this work: baselines Per-segment, aggregate and multihead, and DG approaches: DMG++ and Optimal Transport.

$c : \mathbb{R}^n \times \mathbb{R}^n \rightarrow \mathbb{R}^+$ is the cost function for transporting an unit mass from $\mathbf{x}_i$ to $\mathbf{x}_j$, the p-th order Wasserstein distance between d_i and d_j is:

$$W_p^p(d_i, d_j) = \inf_{\gamma \in \Pi(d_i,d_j)} \int_{\mathbb{R}^n \times \mathbb{R}^n} c(\mathbf{x_i}, \mathbf{x_j}) d\gamma(\mathbf{x_i}, \mathbf{x_j}) \tag{4}$$

where $\Pi(d_i, d_j)$ is a collection of all joint probability measures on $\mathbb{R}^n \times \mathbb{R}^n$ with marginals d_i and d_j. Following Zhou et al. (2020a) and from the Kantorovich-Rubinstein theorem (Kantorovich and Rubinshtein, 1958), the first order Wasserstein distance can be given as:

$$W_1(d_i, d_j) = \sup_{\|f\|_L < 1} \mathbb{E}_{x \in d_i} f(x_i) - \mathbb{E}_{x \in d_i} f(x_j) \tag{5}$$

Given sets $X_i = \{\mathbf{x}_i\}_{i=1}^{N_i}$ and $X_j = \{\mathbf{x}_j\}_{j=1}^{N_j}$ from segments d_i and d_j respectively, we can compute the empirical Wasserstein distance between these two sets as:

$$W_1(X_i, X_j) = \frac{1}{N_i} \sum_{\mathbf{x}_i} f(\mathbf{x}_i) - \frac{1}{N_j} \sum_{\mathbf{x}_j} f(\mathbf{x}_j) \tag{6}$$

where f represents a learnable function which transforms inputs to segment-invariant representations. In this work, we parameterize $f = F_\Psi \circ C_\Omega$, where C_Ω is a critic function that is applied on the output from the feature extractor. At each training mini-batch, we compute the critic loss $\mathcal{L}_C$ as the sum of absolute pairwise Wasserstein-1 distances (Eq. 6) between all segment pairs. The critic loss is jointly optimized with the classification loss to learn representations that minimize segment variations while maximizing classification performance.

$$\mathcal{L}_{OT} = \frac{1}{n} \sum_i \mathcal{L}_{class}(\mathbf{x_i}, y_i) + \lambda_{OT} \sum_{d_i, d_j \in d} W_1(X_i, X_j) \tag{7}$$

3.3 Baselines

We compare DG approaches with three baselines: Per-segment, Aggregate and Multihead models. Among these three baselines, we experiment with shared and separate networks for the feature extractor F_Ψ and task networks T_θ (Figure 2). In the per-segment baseline, we construct a separate model for each segment, and train them using respective segment's data. In the multihead baseline, F_Ψ is shared between segments while a different T_Θ is trained for each segment. In the aggregate baseline, both F_Ψ and T_Θ are shared between the segments. For the first two baselines where we have multiple task networks, we predict the intent and slot labels for a test sample by computing the mean prediction from all segment-specific models.

4 Experiments

4.1 Model Components

We use the pretrained BERT-base model (Devlin et al., 2019) as the feature extractor network F_Ψ. The task network T_Θ consists of two sub-networks: (i) The IC network is a linear feed-forward layer which predicts the intent given the CLS token embedding using a single feed-forward layer (ii) The NER network uses a similar feed-forward layer to predict the slot at each word given the hidden state from the last BERT layer. Similar to Chen et al. (2019), we use the hidden state of the first sub-word token of each word for slot prediction. We update

parameters of both IC and NER networks using a joint classification loss $\mathcal{L}_{IC}$ + $\mathcal{L}_{NER}$ in order to benefit from any shared knowledge between IC and NER tasks.

4.2 Adapting DMG and OT for NER

Note that the DMG model learns a single mask parameter per segment, i.e it learns one mask for IC ($\tilde{\mathbf{m}}^d_{IC}$) and another mask for NER ($\tilde{\mathbf{m}}^d_{NER}$). This implies that $\tilde{\mathbf{m}}^d_{NER}$ is common across all tokens in the segment and the same activations in F_Ψ are selected for all tokens. This constrains the learning process, since different tokens can benefit from selecting different activations when learning segment-specific representations. To support this, we propose formulating the mask parameters as a function of the segment *and* the token embedding:

$$\tilde{\mathbf{m}}^d_t = w^d h_t \ + \ b^d \tag{8}$$

where h_t represents activation from F_Ψ for token t. We introduce a weight vector w^d and bias b^d for each segment. The masks are sampled using $\tilde{\mathbf{m}}^d_t$ similar to Eq. 2. We refer to this modified version of DMG as DMG++. Similarly, we use two critic networks for OT: $C_{\Omega,IC}$ is a feed-forward linear layer which uses the CLS token embedding similar to the IC network, whereas $C_{\Omega,NER}$ applies a single long short-term memory (LSTM) layer to extract longitudinal information from the BERT hidden states at each token.

We also train a DG approach combining DMG and OT (referred to as *Combined*). We retain the critic networks from OT, and introduce masks at the input of critic networks in addition to masks at the inputs of IC and NER networks. The overall loss function to be optimized is a sum of classification losses, critic loss and the overlap penalty loss. We explore whether we can obtain any gains in task performance due to the complementary nature of these approaches.

We use AdamW (Loshchilov and Hutter, 2018) optimizer (initial LR: 5e-5, decay rate: 0.96, (β_1, β_2) = (0.9, 0.999), ϵ = 1e-8) to minimize the respective loss objectives for each approach. We train the models for 10 epochs for SNIPSesv and 5 epochs for TOPesv. To improve training stability, we accumulate gradients from two mini-batches before back-propagation. We follow Chattopadhyay et al. (2020) and Zhou et al. (2020a) to fix approach-specific learning parameters: we set $\lambda_{DMG} = 0.1$ (Eq. 3) and set the critic coefficient as a function of the training progress p, $\lambda_{OT} = \frac{2}{1+e^{-\delta p}} - 1$ where δ = 10. We apply dropout with the rate of 0.1 at all layers in F_Ψ and T_Θ. Following (Chen et al., 2019), we use two metrics to evaluate IC-NER performance: (1) slot-filling F_1 (*Slot* F_1), which is the weighted average of F1 scores across slot labels and (2) semantic accuracy rate (*Sem Acc*), which computes the exact match accuracy of ordered slot labels prefixed with the intent label.

5 Results

5.1 Performance on Seen and Unseen Segments

We report IC-NER performance on the test sets from all four segments in Table 3. For each segment and method, we report mean *Slot* F_1 and *Sem Acc* over 5 trials with different random seeds. We observe that for both datasets, performance on the head segment differs substantially between approaches. Note that in SNIPesv, different approaches produce the same evaluation figures, which we attribute to the limited number of unique utterances in the head segment (Table 2), even though it contains roughly the same utterance count as the tail. While DG approaches do not provide a boost in performance over baselines for the head segment, this is not necessarily a cause for concern. We believe that in a real-world scenario with digital assistants, very frequent requests can be easily recognized using non-statistical models such as rules and deterministic finite-state-transducers (Mohri, 1997).

Among the three segments, improvements with DG approaches (DMG++, OT & Combined) are more visible in tail: the best DG approach returns 7.02% and 1.27% relative improvement in semantic accuracy and slot F_1 on SNIPSesv datasets over the best performing baseline. The original test set, which is not modified by our work and represents yet another segment demonstrates minor but consistent improvements in both metrics across SNIPSesv and TOPesv. Further, we observe competitive performance by optimal transport-based approaches (OT and Combined) on the body segment: upto 2.25% relative improvement with the best performing baseline on SNIPSesv and identical performance on TOPesv.

We observe that improvements in TOPesv are lesser than SNIPSesv, specifically for Tail and Body segments. We believe that there exists a clearer variation between segments in case of SNIPSesv due to a wider range of topics spanned by the utterances (music, books, events, weather) whereas TOPesv intents are generally confined to navigation. Hence, DG approaches are more likely to exhibit gains over baselines in SNIPSesv vs TOPesv.

5.2 Analysis of DG performance gains

5.2.1 Segment Classification Model

Since OT attempts to learn segment-invariant representations, we validate this paradigm by building a segment classifier on the representations from the trained feature encoder. We extract CLS token embeddings for the above approaches and train a multi-class linear regression model using the segment as class information. We downsample the body segment by a factor of 8 to ensure a uniform class distribution. The per-segment approach trains a different F_Ψ for each segment, hence we compute the mean embedding from all three models. We report segment accuracy (%) in Table 5.

We observe that the approaches which learn segment-specific network components such as per-segment (F_Ψ) and multi-head (T_Θ) yield relatively high classification accuracy, while the aggregate model which learns a single network across segments returns the lowest performance among baselines. Optimal transport performs the worst, suggesting that it learns the least segment-related information. However, the difference with the majority baseline ($\approx 33\%$) suggests that segment-invariant representations may not be completely achieved on the test set, also observed in Galstyan et al. (2022).

5.2.2 Random-valued Mask Analysis

In order to analyze the segment-specific masks learned by DMG++ approach, we compare the learned masks using three metrics: (i) M1: Mean pairwise cosine distance between $\tilde{\mathbf{m}}^d$, (ii) M2: Mean pairwise cosine distance between m^d, and (iii) M3: Mean fraction of "off" (0) dimensions in m^d. Since m^d is sampled from $\tilde{\mathbf{m}}^d$ (Eq. 2), we compute M2 and M3 over 5 trials and report their mean and standard deviation. Note that we only analyze $\tilde{\mathbf{m}}^d_{IC}$ since $\tilde{\mathbf{m}}^d_{NER}$ is dependent on token embeddings.

From Table 6, we notice that $\tilde{\mathbf{m}}^d$ are clearly different between segments in both SNIPSesv and TOPesv. These differences extend to the sampled versions (which are used in forward-pass) are illustrated in M2 and M3, a result of the overlap penalty. Further, masks from all segments are "on" ($= 1$) for $\approx 59\%$ and $\approx 53\%$ dimensions for SNIPSesv and TOPesv respectively. To ascertain if segment-specific information is learned by masks, we conduct a sanity check experiment where we replace the masks with a random parameter that encourages similar fraction of "on" dimensions to the learned masks.

Surprisingly, we notice that random masks return on-par performance on all metrics and segments with the learned masks on both SNIPSesv and TOPesv corpora (Table 4). This result clearly indicates that the masks do not provide segment-specific information and the exact set of "on"/"off" dimensions which are controlled by the learned masks are not critical for performance on unseen segments. To further ascertain this finding, we repeated the random masks experiment on PACS corpora (Li et al., 2017) from computer vision, following (Chattopadhyay et al., 2020), with similar

Table 4: Comparing IC-NER performance between learnt masks (**DMG**) and random masks (**DMG-Random**; repeated over 10 trials) on SNIPSesv and TOPesv. For brevity, only semantic accuracy (Sem) and slot filling F1 (Slot F1) are presented

			Head		**Body**		**Tail**		**Original**	
Dataset	**Approach**		**Sem**	**SlotF1**	**Sem**	**SlotF1**	**Sem**	**SlotF1**	**Sem**	**SlotF1**
	DMG++	-	87.84	96.73	88.33	95.59	88.41	93.87	87.00	94.74
SNIPSesv	DMG-	μ	78.65	95.55	88.26	95.58	87.97	93.66	86.74	94.67
	Random	σ	2.55	0.33	0.18	0.05	0.67	0.29	0.18	0.08

	Random	σ	0.45	0.26	0.18	0.06	0.26	0.23	0.11	0.09

Table 5: Segment classification accuracy (%) for baselines and optimal transport. Majority baseline: $\approx 33\%$

	Per	Agg	Mul	OT
SNIPSesv	91.03	86.03	90.13	69.36
TOPesv	79.22	72.33	76.78	65.56

Table 6: Comparing learnt ($\tilde{\mathbf{m}}^d$) and sampled mask (m^d) parameters across segments

Metric	SNIPSesv	TOPesv
M1	0.41	0.95
M2	0.41 ± 0.03	0.53 ± 0.01
M3	40.76 ± 1.57	52.70 ± 1.31

results (see Appendix).

Instead of learning segment-specific information as suggested by Chattopadhyay et al. (2020), we believe that the improvements yielded by DMG approach can be attributed to learning generalizable parameters using masks. Masks are encouraged to be robust by the training process, since m^d are stochastically determined at each mini-batch even for samples from the same segment. Further, our experiments with random masks resemble the training process in that a different set of masks are sampled, except that gradients are not backpropagated. Finally, we note that sampled masks operate similar to a segment-specific dropout (Srivastava et al., 2014) strategy. Hence, generalization improvements in deep learning which have been observed by dropout are likely to be enhanced with segment-specific mask parameters.

6 Limitations

Obtaining search volumes using the Google Adwords API cannot disambiguate between different context-based semantic interpretations of the same word, especially when there are no additional tokens to provide context. For instance, search volumes for *apple* will combine volumes related to the corporation and the fruit, while *apple phone* and *apple juice* will return only the relevant search volumes. Further, this work did not address availability concerns for tail utterances/entities which may be more expensive or labor intensive to collect and annotate.

7 Conclusions

We presented a methodology to estimate utterance frequency information in public datasets for IC-NER task. We create two new corpora: SNIPSesv and TOPesv which use the frequency information to segment the original corpora into head, body and tail segments. We adapt two DG approaches for IC-NER and compute performance on each segment as well as the original test set, which represents an unseen segment. Our experiments show improvement in tail entity recognition by each DG approach as well as their combination. Our follow-up analyses validate the segment-invariant representation learning by OT and suggest that DMG provides enhanced generalization using segment-specific masks. To assist future research in this direction, we will release the SNIPSesv and TOPesv datasets used in this work upon publication.

A Determining Maximum Utterance Sampling Probability

We collected a real-world dataset of user-queries directed to our voice-controlled agent to determine the maximum utterance sampling probability p_{max}. We uniformly sample from all queries within a 10-day duration to preserve the frequency distribution. However, we retain only utterances which were identified as belonging to services similar to intents in SNIPS and TOP corpora: entertainment (music, books, video), weather, bookings and local search. This results in a total of 15M utterances. We compute repetition counts for each unique utterance and compute p_{max} using the utterance with maximum repetition count following Eq. 1. This results in p_{max}=0.00245. We apply this estimated value for P_{max} on SNIPSesv and TOPesv.

B Random-valued Masks for PACS

PACS corproa (Li et al., 2017) is a commonly used DG benchmark from computer vision and contains images from four different styles: sketch, cartoon, photo and art painting. Similar to previous evaluations (Li et al., 2017; Chattopadhyay et al., 2020; Zhou et al., 2020a), we compute the leave-one-domain-out accuracy, where one domain is treated as target and remaining three domains are treated as source. We build a DMG model following the same architecture as (Chattopadhyay et al., 2020) and repeat our evaluations by replacing the learned masks with random valued parameters. We observe identical performance with random masks, similar to SNIPSesv and TOPesv.

Table 7: Leave-one-domain-out accuracy (%) on PACS. DMG (rep) represents results reported in Chattopadhyay et al. (2020), DMG (ours) reports results from our implementation, and DMG (rand) uses random valued masks.

Approach		**Sketch**	**Cartoon**	**Photo**	**Art**
DMG (rep)		71.42	69.88	87.31	64.65

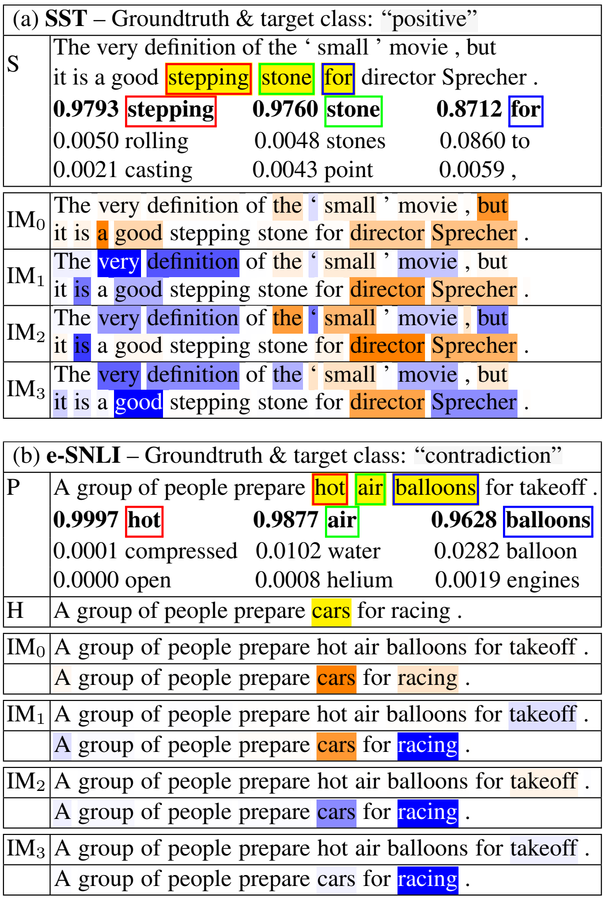
Abstract

A principle behind dozens of attribution methods is to take the prediction difference between before-and-after an input feature (here, a token) is removed as its attribution. A popular Input Marginalization (IM) method (Kim et al., 2020) uses BERT to replace a token, yielding more plausible counterfactuals. While Kim et al. (2020) reported that IM is effective, we find this conclusion not convincing as the Deletion$_{\text{BERT}}$ metric used in their paper is biased towards IM. Importantly, this bias exists in Deletion-based metrics, including Insertion, Sufficiency, and Comprehensiveness. Furthermore, our rigorous evaluation using 6 metrics and 3 datasets finds **no evidence that IM is better** than a Leave-One-Out (LOO) baseline. We find two reasons why IM is not better than LOO: (1) deleting a single word from the input only marginally reduces a classifier's accuracy; and (2) a highly predictable word is always given near-zero attribution, regardless of its true importance to the classifier. In contrast, making Local Interpretable Model-Agnostic Explanations (LIME) counterfactuals more natural via BERT consistently improves LIME accuracy under several RemOve-And-Retrain (ROAR) metrics.

1 Introduction

Feature attribution maps (AMs), i.e. highlights indicating the importance of each input token w.r.t. a classifier's decision, can help improve *human accuracy* on downstream tasks including detecting fake movie reviews (Lai and Tan, 2019) or identifying biases in text classifiers (Liu and Avci, 2019).

Many Leave-One-Out (LOO) methods compute the attribution of an input token by measuring the prediction changes after substituting that token's embedding with zeros (Li et al., 2016; Jin et al., 2020) or [UNK] (Kim et al., 2020). That is, deleting or replacing features is the underlying principle of at least 25 attribution methods (Covert et al., 2020).



(a) **SST** – Groundtruth & target class: "positive"

S	The very definition of the ' small ' movie , but it is a good stepping stone for director Sprecher .		
	0.9793 stepping	**0.9760 stone**	**0.8712 for**
	0.0050 rolling	0.0048 stones	0.0860 to
	0.0021 casting	0.0043 point	0.0059 ,
IM$_0$	The very definition of the ' small ' movie , but it is a good stepping stone for director Sprecher .		
IM$_1$	The very definition of the ' small ' movie , but it is a good stepping stone for director Sprecher .		
IM$_2$	The very definition of the ' small ' movie , but it is a good stepping stone for director Sprecher .		
IM$_3$	The very definition of the ' small ' movie , but it is a good stepping stone for director Sprecher .		

(b) **e-SNLI** – Groundtruth & target class: "contradiction"

P	A group of people prepare hot air balloons for takeoff .		
	0.9997 hot	**0.9877 air**	**0.9628 balloons**
	0.0001 compressed	0.0102 water	0.0282 balloon
	0.0000 open	0.0008 helium	0.0019 engines
H	A group of people prepare cars for racing .		
IM$_0$	A group of people prepare hot air balloons for takeoff .		
	A group of people prepare cars for racing .		
IM$_1$	A group of people prepare hot air balloons for takeoff .		
	A group of people prepare cars for racing .		
IM$_2$	A group of people prepare hot air balloons for takeoff .		
	A group of people prepare cars for racing .		
IM$_3$	A group of people prepare hot air balloons for takeoff .		
	A group of people prepare cars for racing .		

Figure 1: **By design, IM erroneously assigns near-zero attribution to highly-predictable words.** Color map: negative -1, neutral 0, positive +1. Many words labeled important by humans such as "stepping", "stone" (a) or "hot", "air" (b) are always given near-zero attribution by IM (because they are highly predictable by BERT, e.g. 0.9793 for stepping) regardless of the classifier. Even when randomizing the classifier's weights three times, the IM attribution of these words remains unchanged at near zero (IM$_1$ to IM$_3$). Therefore, when marginalizing over the top-k BERT candidates (e.g., "stepping", "rolling", "casting"), the IM attribution for low-entropy words tends to zero, leading to heatmaps that are biased, less accurate, and less plausible than LOO$_{\text{empty}}$.

Proceedings of the 2nd Conference of the Asia-Pacific Chapter of the Association for Computational Linguistics and the 12th International Joint Conference on Natural Language Processing (Volume 1: Long Papers), pages 12–31
November 20–23, 2022. ©2022 Association for Computational Linguistics

Based on the evidence in computer vision (Bansal et al., 2020; Zhang et al., 2019), prior works in NLP *hypothesized* that removing a word from an input text forms out-of-distribution (OOD) inputs that yield erroneous AMs (Kim et al., 2020; Harbecke and Alt, 2020) or AMs inconsistent with human's perception of causality (Hase et al., 2021). To generate plausible counterfactuals, two teams of researchers (Kim et al., 2020; Harbecke and Alt, 2020) proposed Input Marginalization (IM), i.e. replace a word using BERT (Devlin et al., 2019) and compute an average prediction difference by marginalizing over all predicted words. Kim et al. (2020) claimed that IM yields more accurate AMs than the baselines that replace words by [UNK] or zeros but their quantitative results were reported for only *one*[1] dataset and *one* evaluation metric.

In this paper, we re-assess their claim by, first, reproducing their IM results[2], and then rigorously evaluate whether improving the realism of counterfactuals improves two attribution methods (LOO and LIME). On a diverse set of *three* datasets and *six* metrics, we find that:

1. The Deletion$_{\text{BERT}}$ metric in Kim et al. (2020) is biased towards IM as both use BERT to replace words (Sec. 4). In contrast, the vanilla Deletion metric (Arras et al., 2017) favors the LOO$_{\text{empty}}$ baseline as both delete words. This bias causes a **false conclusion** that IM is better than LOO baselines in Kim et al. (2020) and also **exists in other Deletion variants**, e.g., Insertion (Arras et al., 2017), Sufficiency, and Comprehensiveness (DeYoung et al., 2020).

2. We find **no evidence that IM is better** than a simple LOO$_{\text{empty}}$ on any of the following four state-of-the-art AM evaluation metrics (which exclude the biased Deletion & Deletion$_{\text{BERT}}$): ROAR, ROAR$_{\text{BERT}}$ (Hooker et al., 2019) (Sec. 5.1), comparison against human annotations (Sec. 5.2), and sanity check (Adebayo et al., 2018) (Sec. 5.3).

3. We argue that IM is not effective in practice because: (1) deleting a single word from an input has only a marginal effect on classification accuracy (Sec. 5.4); and (2) given a *perfect*, masked language model G, IM would still be **unfaithful** because highly predictable words according to G, e.g. "hot", "air" in Fig.1, are always assigned near-zero attribution in IM *regardless* of how important they are to the classifier (Sec. B).

4. To further test the main idea of IM, we integrate BERT into LIME (Ribeiro et al., 2016) to *replace* multiple words (instead of deleting) in an input sequence, making LIME counterfactuals more realistic. We find this technique to improve LIME consistently under multiple ROAR-based metrics, but not under comparison against human annotations (Sec. 6).

To our knowledge, our work is the first to thoroughly study the effectiveness of IM in NLP in both settings of replacing a single word (LOO) and multiple words (LIME). Importantly, we find improvement in the latter but not the former setting.

2 Methods and Related Work

Let $f : \mathbb{R}^{n \times d} \to [0, 1]$ be a text classifier that maps a sequence $\boldsymbol{x}$ of n token embeddings, each of size d, onto a confidence score of an output label. An attribution function A takes three inputs—a sequence $\boldsymbol{x}$, the model f, and a set of hyperparameters $\mathcal{H}$—and outputs a vector $\boldsymbol{a} = A(f, \boldsymbol{x}, \mathcal{H}) \in [-1, 1]^n$. Here, the explanation $\boldsymbol{a}$ associates each input token x_i to a scalar $a_i \in [-1, 1]$, indicating how much x_i contributes for or against the target label.

Leave-One-Out (LOO) is a well-known method (Li et al., 2016; Robnik-Šikonja and Kononenko, 2008; Jin et al., 2020) for estimating the attribution a_i by computing the prediction-difference after a token x_i is left out of the input $\boldsymbol{x}$, creating a shorter sequence $\boldsymbol{x}_{-i}$:

$$a_i = f(\boldsymbol{x}) - f(\boldsymbol{x}_{-i}) \tag{1}$$

Under Pearl (2009) causal framework, the attribution a_i in Eq. 1 relies on a single, unrealistic counterfactual $\boldsymbol{x}_{-i}$ and thus is a biased estimate of the individual treatment effect (ITE):

$$\text{ITE} = f(\boldsymbol{x}) - \mathbb{E}[f(\boldsymbol{x}) \mid do(T = 0)] \tag{2}$$

where the binary treatment T, here, is to keep or "realistically remove" the token x_i (i.e. $T = 1$ or 0) in the input $\boldsymbol{x}$, prior to the computation of $f(\boldsymbol{x})$.

[1] No *quantitative* results on SNLI, only SST-2.

[2] Code and pre-trained models are available at `https://github.com/anguyen8/im`.

Perturbation techniques In computer vision (CV), earlier attribution methods erase a feature by replacing it with (a) zeros (Zeiler and Fergus, 2014; Ribeiro et al., 2016); (b) random noise (Dabkowski and Gal, 2017; Lundberg and Lee, 2017); or (c) blurred versions of the original content (Fong et al., 2019). Yet, these perturbation methods produce unrealistic counterfactuals that make AMs more unstable and less accurate (Bansal et al., 2020).

Recent works proposed to simulate the $do(T = 0)$ operator using an image inpainter. However, they either generated unnatural counterfactuals (Chang et al., 2019; Goyal et al., 2019) or only a single, plausible counterfactual per example (Agarwal and Nguyen, 2020).

Input marginalization (IM) In NLP, IM offers the closest estimate of the ITE. IM computes the $\mathbb{E}[.]$ term in Eq. 2 by marginalizing over many plausible counterfactuals generated by BERT:

$$\begin{aligned}\mathbb{E}[f(\boldsymbol{x}) \mid do(T=0)] \\ = \sum_{\tilde{x}_i \in \mathcal{V}} p(\tilde{x}_i|\boldsymbol{x}_{-i}) \cdot f(\boldsymbol{x}_{-i}, \tilde{x}_i) \qquad (3)\end{aligned}$$

where $\tilde{x}_i$ is a token suggested by BERT (e.g., "$\boxed{\text{hot}}$", "compressed", or "open" in Fig. 1) with a likelihood of $p(\tilde{x}_i|\boldsymbol{x}_{-i})$ to replace the masked token x_i. $\mathcal{V}$ is the BERT vocabulary of 30,522 tokens. $f(\boldsymbol{x}_{-i}, \tilde{x}_i)$ is the classification probability when token x_i in the original input is replaced with $\tilde{x}_i$.

IM attribution is in the log space:

$$\begin{aligned}a_{\text{IM}} = \text{log-odds}(f(\boldsymbol{x})) \\ - \text{log-odds}(\mathbb{E}[f(\boldsymbol{x}) \mid do(T=0)]) \qquad (4)\end{aligned}$$

where $\text{log-odds}(p) = \log_2(p/(1-p))$.

As computing the expectation in Eq. 3 over BERT's $\sim$30K-word vocabulary is prohibitively slow, IM authors only marginalized over the words that have a likelihood $\geq 10^{-5}$. We are *able to reproduce* the IM results of Kim et al. (2020) by taking only the top-10 words. That is, using the top-10 words or all words of likelihood $\geq 10{-}5$ yields slightly different numbers but the same conclusions (Sec. D). Thus, we marginalize over the top-10 for all experiments. Note that under BERT, the top-10 tokens, on average, already account for 81%, 90%, and 92% of the probability mass for SST-2, e-SNLI, & MultiRC, respectively.

BERT Like Kim et al. (2020), we use a pre-trained BERT "base", uncased model (Devlin et al., 2019), from Huggingface (2020), to fill in a [MASK] token to generate counterfactuals in IM.

LIME Based on the idea of IM, we also integrate BERT into LIME, which originally masks out multiple tokens at once to compute attribution. LIME generates a set of randomly masked versions of the input, and the attribution of a token x_i, is effectively the mean classification probability over all the masked inputs when x_i is not masked out. On average, each vanilla LIME counterfactual has 50% of tokens taken out, yielding text often with large syntactic and grammatical errors.

LIME$_{\text{BERT}}$ We use BERT to replace multiple masked tokens[3] in each masked sentence generated by LIME to construct more plausible counterfactuals. However, for each word, we only use the top-1 highest-likelihood token given by BERT instead of marginalizing over multiple tokens because (1) the full marginalization is prohibitively slow; and (2) the top-1 token already carries most of the weight ($p \geq 0.81$; see Table A3).

3 Experiment framework

3.1 Three datasets

We select a diverse set of three classification datasets that enable us to (1) compare with the results reported by Kim et al. (2020); and (2) assess AMs on six evaluation metrics (described in Sec. 3.3). These three tasks span from sentiment analysis (SST-2), natural language inference (e-SNLI) to question answering (MultiRC), covering a wide range of sequence length ($\sim$20, 24, and 299 tokens per example, respectively). SST-2 and e-SNLI were the two datasets where Kim et al. (2020) found IM to be superior to LOO baselines.

SST Stanford Sentiment Treebank (Socher et al., 2013b) is a dataset of $\sim$12K RottenTomato movie-review *sentences*, which contain human-annotated sentiment annotations for phrases. Each phrase and sentence in SST is assigned a sentiment score $\in [0, 1]$ (0 = negative, 0.5 = neutral, 1 = positive).

SST-2 has $\sim$70K SST examples (including both phrases and sentences) where the regression scores per example were binarized to form a binary classification task (Socher et al., 2013b).

[3] We find replacing all tokens at once or one at a time to produce similar LIME$_{\text{BERT}}$ results.

e-SNLI A 3-way classification task of detecting whether the relation between a premise and a hypothesis is entailment, neutral or contradiction (Bowman et al., 2015). e-SNLI has 569K instances of (input, label, explanation) where the explanations are crowd-sourced (Camburu et al., 2018).

MultiRC Multi-sentence Reading Comprehension (Khashabi et al., 2018) is a multiple-choice question-answering task that provides multiple input sentences as well as a question and asks the model to select one or multiple correct answer sentences. MultiRC has ∼6K examples with human-annotated highlights at the sentence level.

3.2 Classifiers

Following Kim et al. (2020); Harbecke and Alt (2020); Hase et al. (2021), we test IM and LOO baselines in explaining BERT-based classifiers.

For each task, we train a classifier by fine-tuning the entire model, which consists of a classification layer on top of the pre-trained BERT (described in Sec. 2). The dev-set top-1 accuracy scores of our SST-2, e-SNLI, & MultiRC classifiers are 92.66%, 90.92%, and 69.10%, respectively. On the SST binarized dev-set, which contains only sentences, the SST-2-trained classifier's accuracy is 87.83%.

Hyperparameters Following the training scheme of HuggingFace, we fine-tune all classifiers for 3 epochs using Adam optimizer (Kingma and Ba, 2015) with a learning rate of 0.00002, β_1 = 0.9, β_2 = 0.999, $\epsilon = 10^{-8}$. A batch size of 32 and a max sequence length of 128 are used for SST-2 and e-SNLI while these hyperparameters for MultiRC are 8 and 512, respectively. Dropout with a probability of 0.1 is applied to all layers. Each model was trained on an NVIDIA 1080Ti GPU.

3.3 Six evaluation metrics

As there are *no groundtruth* explanations in XAI, we use six common metrics to rigorously assess IM's effectiveness. For each classifier, we evaluate the AMs generated for all dev-set examples.

Deletion is similar to "Comprehensiveness" (DeYoung et al., 2020) and is based on the idea that deleting a token of higher importance from the input should cause a larger drop in the output confidence score. We take the original input and delete one token at a time until 20% of the tokens in the input is deleted. A more accurate explanation is expected to have a lower Area Under the output-probability Curve (AUC) (Arras et al., 2017).

Deletion$_{\mathsf{BERT}}$ a.k.a. AUC$_{\mathsf{rep}}$ in Kim et al. (2020), is a Deletion variant where a given token is replaced by a BERT top-1 suggestion instead of an empty string. Deletion$_{\mathsf{BERT}}$ was proposed to minimize the OOD-ness of samples (introduced by deleting words in the vanilla Deletion metric), i.e. akin to integrating BERT into LOO to create IM.

RemOve And Retrain (ROAR) To avoid a potential OOD generalization issue caused by the Deletion metric, a common alternative is to retrain the classifier on these modified inputs (where $N\%$ of the highest-attribution words are deleted) and measure its accuracy drop (Hooker et al., 2019). A more faithful attribution method is supposed to lead to a re-trained classifier of lower accuracy as the more important words have been deleted from training examples. For completeness, we also implement **ROAR$_{\mathsf{BERT}}$**, which uses BERT to replace the highest-attribution tokens[4] instead of deleting them without replacement in ROAR.

Agreement with human-annotated highlights In both CV and NLP, a common AM evaluation metric is to assess the agreement between AMs and human annotations (Wiegreffe and Marasović, 2021). The idea is that as text classifiers well predict the human labels of an input text, their explanations, i.e. AMs, should also highlight the tokens that humans deem indicative of the groundtruth label.

Because human annotators only label the tokens supportive of a label (e.g. Fig. 2), when comparing AMs with human annotations, we zero out the negative values in AMs. Following Zhou et al. (2016), we binarize a resulting AM at an optimal threshold τ in order to compare it with human-annotated highlights under Precision@1.

Sanity check (Adebayo et al., 2018) is a well-known metric for testing insensitivity (i.e. bias) of attribution methods w.r.t. model parameters. For ease of interpretation, we compute the % change of per-word attribution values in *sign* and *magnitude* as we randomize the classification layer's weights. A better attribution method is expected to be more sensitive to the classifier's weight randomization.

4 Bias of Deletion metric and its variants

In explaining SST-2 classifiers, we successfully reproduce the AUC$_{\mathsf{rep}}$ results reported in Kim et al. (2020), i.e. IM outperformed LOO$_{\mathsf{zero}}$ and LOO$_{\mathsf{unk}}$, which were implemented by replacing a

[4] The chance that a sentence remains unchanged after BERT replacement is low, $\leq 1\%$.

word with the [PAD] and [UNK] token of BERT, respectively (Table 1). However, we hypothesize that Deletion$_{\text{BERT}}$ is biased towards IM as both use BERT to replace words, yielding a false sense of IM effectiveness reported in Kim et al. (2020).

To test this hypothesis, we add another baseline of LOO$_{\text{empty}}$, which was *not* included in Kim et al. (2020), i.e. erasing a token from the input without replacement (Eq. 1), mirroring the original Deletion metric. To compare with IM, all LOO methods in this paper are also in the log-odds space.

Results Interestingly, we find that, under Deletion, on both SST-2 and e-SNLI, IM *underperformed all* three LOO baselines and that LOO$_{\text{empty}}$ is the highest-performing method (Table 1a). In contrast, IM is the best method under Deletion$_{\text{BERT}}$.

Re-running the same experiment but sampling replacement words from RoBERTa (instead of BERT), we find the same finding that LOO$_{\text{empty}}$ is the best under Deletion while IM is the best under Deletion$_{\text{BERT}}$ (Table 1b).

Task	Metrics ↓	IM	LOO$_{\text{zero}}$	LOO$_{\text{unk}}$	LOO$_{\text{empty}}$
(a) BERT					
SST-2	Deletion	**0.4732**	0.4374	0.4464	**0.4241**
	Deletion$_{\text{BERT}}$	**0.4922**	0.4970	0.5047	**0.5065**
e-SNLI	Deletion	**0.3912**	0.2798	0.3742	**0.2506**
	Deletion$_{\text{BERT}}$	**0.2816**	0.3240	**0.3636**	0.3328
(b) RoBERTa					
SST-2	Deletion	**0.4981**	0.4524	0.4595	**0.4416**
	Deletion$_{\text{BERT}}$	**0.4798**	0.5037	**0.5087**	0.4998

Table 1: IM is the **best** method under Deletion$_{\text{BERT}}$, as reported in Kim et al. (2020), but the **worst** under Deletion. Both metrics measure AUC (lower is better).

To our knowledge, our work is **the first to document this bias** of the Deletion metric **widely used in the literature** (Hase et al., 2021; Wiegreffe and Marasović, 2021; Arras et al., 2017). This bias, in principle, also **exists in other Deletion variants** including Insertion (Arras et al., 2017), Sufficiency, and Comprehensiveness (DeYoung et al., 2020).

5 No evidence that IM is better than LOO

To avoid the critical bias of Deletion and Deletion$_{\text{BERT}}$, we further compare IM and LOO on **four** common metrics that are not Deletion-based.

5.1 Under ROAR and ROAR$_{\text{BERT}}$, IM is on-par with or worse than LOO$_{\text{empty}}$

A lower AUC under Deletion may be the artifact of the classifier misbehaving under the distribution shift when one or multiple input words are deleted. ROAR (Hooker et al., 2019) was designed to ameliorate this issue by re-training the classifier on a modified training-set (where the top $N\%$ highest-attribution tokens in each example are deleted) before evaluating their accuracy.

To more objectively assess IM, we use ROAR and ROAR$_{\text{BERT}}$ metrics to compare IM vs. LOO$_{\text{empty}}$ (i.e. the best LOO variant in Table 1).

Experiment For both IM and LOO$_{\text{empty}}$, we generate AMs for every example in the SST-2 train and dev sets, and remove $N\%$ highest-attribution tokens per example to create new train and dev sets. We train 5 models on the new training set and evaluate them on the new dev set. We repeat ROAR and ROAR$_{\text{BERT}}$ with $N \in \{10, 20, 30\}$.[5]

Results As more tokens are removed (i.e. N increases), the mean accuracy of 5 models gradually decreases (Table 2; from 92.66% to ∼67%). Under both ROAR and ROAR$_{\text{BERT}}$, the models trained on the new training set derived from LOO$_{\text{empty}}$ AMs often obtain lower (i.e. better) mean accuracy than those of IM (Table 2a vs. b). At $N = 10\%$ under ROAR, **LOO$_{\text{empty}}$ outperforms IM** (Table 2; 74.59 vs. 76.22), which is statistically significant (2-sample t-test, $p = 0.037$). In all other cases, the difference between IM vs. LOO$_{\text{empty}}$ is not statistically significant.

In sum, under both ROAR and ROAR$_{\text{BERT}}$, IM is *not more faithful* than LOO$_{\text{empty}}$.

5.2 LOO$_{\text{empty}}$ aligns significantly better with human annotations than IM

Following Wiegreffe and Marasović (2021), to increase our understanding of the differences between LOO$_{\text{empty}}$ and IM, we compare the two methods against the human-annotated highlights for SST, e-SNLI, and MultiRC.

Annotation preprocessing To control for quality, we preprocess the human annotations in each dataset as the following. In SST, where each sentence has multiple phrases labeled with a sentiment score $\in [0, 1]$ (0.5 being the "neutral" midpoint), we only use the phrases that have high-confidence

[5] We do not use $N \geq 40$ because: (1) according to SST human annotations, only 37% of the tokens per example are labeled "important" (Table A2c); and (2) SST-2 examples are short and may contain as few as 4 tokens per example.

Accuracy in % (lower is better)		ROAR			ROAR$_{\text{BERT}}$		
Method	$N = 0\%$	10%	20%	30%	10%	20%	30%
(a) LOO$_{\text{empty}}$	92.62 ± 0.30	**74.59** ± 0.78	**68.94** ± 1.46	67.89 ± 0.79	**76.79** ± 0.56	71.95 ± 0.75	**67.62** ± 1.16
(b) IM	92.62 ± 0.30	76.22 ± 1.18	70.07 ± 0.69	**66.54** ± 1.89	77.36 ± 0.90	**71.56** ± 1.55	67.68 ± 0.96
(c) Random	92.62 ± 0.30	89.22 ± 0.53	87.75 ± 0.19	85.62 ± 0.53	89.38 ± 0.47	88.23 ± 0.31	85.21 ± 0.47
(d) t-test p-value	N/A	**0.0370**	0.1740	0.1974	0.2672	0.6312	0.9245

Table 2: Dev-set mean accuracy (%) of 5 models trained on the new SST-2 examples where $N\%$ of highest-attribution words per example are removed (i.e. ROAR) or replaced via BERT (i.e. ROAR$_{\text{BERT}}$). On average, under both metrics, LOO$_{\text{empty}}$ (a) is slightly better, i.e. lower mean accuracy, than IM (b). Notably, LOO$_{\text{empty}}$ statistically significantly outperforms IM under ROAR at $N = 10\%$ (2-sample t-test; $p = 0.037$) (d). Both LOO$_{\text{empty}}$ and IM substantially outperform a random baseline (c) that considers $N\%$ random tokens important.

Metric ↑	(a) SST					(b) e-SNLI L2		(c) e-SNLI L3		(d) MultiRC	
Higher is better	IM	LOO$_{\text{empty}}$	LIME	LIME$_{\text{BERT}}$	LIME$_{\text{BERT\_SST2}}$	IM	LOO$_{\text{empty}}$	IM	LOO$_{\text{empty}}$	IM	LOO$_{\text{empty}}$

Table 3: Compared to IM, LOO$_{\text{empty}}$ is substantially more consistent with human annotations over all three datasets. Note that the gap between LOO$_{\text{empty}}$ and IM is ∼3× wider when comparing AMs with the e-SNLI tokens that at least three annotators label "important" (i.e. L3), compared to L2 (higher is better). LIME$_{\text{BERT}}$ explanations are slightly less consistent with human highlights than those of LIME (a) despite their counterfactuals are more realistic.

sentiment scores, i.e. ≤ 0.3 (for "negative") or ≥ 0.7 (for "positive"). Also, we do not use the annotated phrases that are too long, i.e., longer than 50% of the sentence length.

Each token in an e-SNLI example are labeled "important" by between 0–3 annotators. To filter out noise, we only use the tokens that are highlighted by *at least* two or three annotators (hereafter "L2" and "L3" subsets, respectively).

A MultiRC example contains a question and a paragraph where each sentence is labeled "important" or "unimportant" to the groundtruth answer (Fig. A10). We convert these sentence-level highlights into token-level highlights to compare them with the binarized AMs of IM and LOO$_{\text{empty}}$.

Experiment We run IM and LOO$_{\text{empty}}$ on the BERT-based classifiers on the dev set of SST, e-SNLI, and MultiRC. All AMs generated are binarized using a threshold $\tau \in \{0.05x \mid 0 < x < 20 \text{ and } x \in \mathbb{N}\}$. We compute the average IoU, precision, recall, and F1 over pairs of (human binary map, binarized AM) and report the results at the optimal τ of each explanation method. For both LOO$_{\text{empty}}$ and IM, $\tau = 0.1$ on SNLI-L2 and 0.05 on both SST-2 and MultiRC. On SNLI-L3, τ is 0.40 and 0.45 for LOO$_{\text{empty}}$ and IM, respectively.

SST results We found that LOO$_{\text{empty}}$ aligns better with human highlights than IM (Figs. 2 & A12). LOO$_{\text{empty}}$ outperforms IM in both F1 and IoU scores (Table 3a; 0.2756 vs 0.2377) with a notably large recall gap (0.6077 vs. 0.5245).

SST	Groundtruth & Prediction: "positive" movie review
Input	Mr. Tsai is a very original artist in his medium , and What Time Is It There ?
IM	Mr. Tsai is a very original artist in his medium , and What Time Is It There ?
	IoU: 0.17, precision: 0.33, recall: 0.25
LOO	Mr. Tsai is a very original artist in his medium , and What Time Is It There ?
	IoU: **0.80**, precision: **0.80**, recall: **1.00**

Figure 2: LOO$_{\text{empty}}$ binarized attribution maps align better with human highlights than IM maps.

e-SNLI and MultiRC results Similarly, in both tasks, LOO$_{\text{empty}}$ explanations are more consistent with human highlights than IM explanations under all four metrics (see Table 3b–d and qualitative examples in Figs. 3 & A13–A16).

Remarkably, in MultiRC where each example is substantially longer (∼299 tokens per example) than those in the other tasks, the recall and F1 scores of $\text{LOO}_{\text{empty}}$ is, respectively, 2× and 4× higher than those of IM (see Table 3).

e-SNLI example. Groundtruth & Prediction: "entailment"	
P	Two men dressed in black practicing martial arts on a gym floor .
H	Two men are doing martial arts .
IM	Two men dressed in black practicing martial arts on a gym floor . Two men are doing martial arts .
	IoU: 0.09, precision: 0.17, recall: 0.16
LOO	Two men dressed in black practicing martial arts on a gym floor . Two men are doing martial arts .
	IoU: **0.50**, precision: **0.56**, recall: **0.83**

Figure 3: $\text{LOO}_{\text{empty}}$ important words are in a stronger agreement with human highlights than IM important words. Each e-SNLI example contains a pair of premise (P) and hypothesis (H).

5.3 IM is insensitive to model randomization

Adebayo et al. (2018) found that many attribution methods can be surprisingly biased, i.e. *insensitive* to even randomization of the classifier's parameters. Here, we test the degree of insensitivity of IM when the last classification layer of BERT-based classifiers is randomly re-initialized. We use three SST-2 classifiers and three e-SNLI classifiers.

Surprisingly, IM is consistently worse than $\text{LOO}_{\text{empty}}$, i.e. more insensitive to classifier randomization. That is, on average, the IM attribution of a word changes signs (from positive to negative or vice versa) less frequently, e.g. 62.27% of the time, compared to 71.41% for $\text{LOO}_{\text{empty}}$ on SST-2 (Table A5a). The average change in attribution *magnitude* of IM is also ∼1.5× smaller than that of $\text{LOO}_{\text{empty}}$ (Table A5b).

For example, the IM attribution scores of hot, air or balloons in Fig. 1 remain consistently **unchanged near-zero even when the classifier is randomized three times**. That is, each of these three words is ∼100% predictable by BERT given the other two words (Fig. 1b; IM_1 to IM_3) and, hence, will be assigned a near-zero attribute by IM (by construction, via Eqn. 3 & 4) regardless of how important these words actually are to the classifier. Statistically, this is a major issue because across SST, e-SNLI, and MultiRC, we find BERT to correctly predict the missing word ∼49, 60, 65% of the time, respectively (Sec. A). And that the average likelihood score of a top-1 exact-match token is high, ∼0.81–0.86 (Sec. B), causing the highly predicted words (e.g., hot) to always be assigned low attribution regardless of their true importance to the classifier.

We find this insensitivity to be a major, **theoretical flaw of IM** in explaining a classifier's decision at the *word* level. By analyzing the overlap between IM explanations and human highlights (generated in experiments in Sec. 5.2), we find consistent results that IM explanations have **significantly smaller attribution magnitude** per token (Sec. A) and **substantially lower recall than LOO** (Sec. B).

5.4 Classification accuracy only drops marginally when one token is deleted

Our previous results show that replacing *a single word* by BERT (instead of deleting) in IM creates more realistic inputs but actually hurts the AM quality w.r.t. LOO. This result interestingly contradicts the prior conclusions (Kim et al., 2020; Harbecke and Alt, 2020) and assumptions (Hase et al., 2021) of the superiority of IM over LOO.

To understand why using more plausible counterfactuals did not improve AM explainability, we assess the Δ drop in classification accuracy when a word is deleted (i.e., $\text{LOO}_{\text{empty}}$ samples; Fig. A17) and the Δ when a word is replaced via BERT (i.e. IM samples).

Results Across SST, e-SNLI, and MultiRC, the accuracy scores of classifiers only drop marginally ∼1–4 points (Table 4) when a single token is deleted. See Figs. A17 & A18 for qualitative examples showing that deleting a single token hardly changes the predicted label. Whether a word is removed or replaced by BERT is almost unimportant in tasks with long examples such as MultiRC (Table 4; 1.10 and 0.24). In sum, we do not find the unnaturalness of LOO samples to substantially hurt model performance, questioning the need raised in (Hase et al., 2021; Harbecke and Alt, 2020; Kim et al., 2020) for realistic counterfactuals.

6 Replacing (instead of deleting) *multiple* words can improve explanations

We find that deleting a single word only marginally affects classification accuracy. Yet, deleting ∼50% of words, i.e. following LIME's counterfactual sampling scheme, actually substantially reduces classification accuracy, e.g. −16.38 point on SST and −25.74 point on e-SNLI (Table 4c). There-

Δ drop in accuracy (%)	SST	e-SNLI	MultiRC
(a) LOO (1-token deleted)	3.52	4.92	1.10
(b) IM (1-token replaced)	2.20	4.86	0.24
(c) LIME (many tokens deleted)	16.38	25.74	17.85

Table 4: The dev-set accuracies on SST, e-SNLI and MultiRC (87.83%, 90.92%, and 69.10%, respectively) only drop marginally when a single token is deleted (a) or replaced using BERT (b). In contrast, LIME samples cause the classification accuracy to drop substantially (e.g. 16.38 points on SST).

fore, it is interesting to test whether the core idea of harnessing BERT to replace words has merits in improving LIME whose counterfactuals are extremely OOD due to many missing words.

6.1 $\text{LIME}_{\text{BERT}}$ attribution maps are *not* more aligned with human annotations

Similar to Sec. 5.2, here, we compare LIME and $\text{LIME}_{\text{BERT}}$ AMs with human SST annotations (avoiding the Deletion-derived metrics due to their bias described in Sec. 4).

Experiment We use the default hyperparameters of the original LIME (Ribeiro, 2021) for both LIME and $\text{LIME}_{\text{BERT}}$. The number of counterfactual samples was 1,000 per example.

Results Although $\text{LIME}_{\text{BERT}}$ counterfactuals are more natural, the derived AMs are surprisingly less plausible to human than those generated by the original LIME. That is, compared to human annotations in SST, $\text{LIME}_{\text{BERT}}$'s IoU, precision and F1 scores are all slightly worse than those of LIME (Table 3a). Consistent with the IM vs. $\text{LOO}_{\text{empty}}$ comparison in Sec. 5.2, replacing one or more words (instead of deleting them) using BERT in LIME generates AMs that are similarly or less aligned with humans.

To minimize the possibility that the pre-trained BERT is suboptimal in predicting missing words on SST-2, we also finetune BERT using the mask-language modeling objective on SST-2 (see details in Sec. C) and repeat the experiment in this section. Yet, interestingly, we find the above conclusion to not change (Table 3a; $\text{LIME}_{\text{BERT\_SST2}}$ is worse than LIME). In sum, for both LOO and LIME, we find **no evidence that using realistic counterfactuals from BERT causes AMs to be more consistent with words that are labeled "important" by humans**.

6.2 $\text{LIME}_{\text{BERT}}$ consistently outperforms LIME under three ROAR metrics

To thoroughly test the idea of using BERT-based counterfactuals in improving LIME explanations, we follow Sec. 5.1 and compare $\text{LIME}_{\text{BERT}}$ and LIME under three ROAR metrics: (1) ROAR; (2) $\text{ROAR}_{\text{BERT}}$; and (3) $\text{ROAR}_{\text{BERT\_SST2}}$, i.e. which uses the BERT finetuned on SST-2 to generate training data.

Experiment Similar to the previous section, we take the dev set of SST-2 and generate a LIME AM and a LIME-BERT AM for each SST-2 example. For $\text{ROAR}_{\text{BERT\_SST2}}$, we re-use the BERT finetuned on SST-2 described in Sec. 6.1.

Results Interestingly, we find that $\text{LIME}_{\text{BERT}}$ slightly, but consistently outperforms LIME via all three ROAR metrics tested (Fig. 4; dotted lines are above solid lines). That is, $\text{LIME}_{\text{BERT}}$ tend to highlight more discriminative tokens in the text than LIME, yielding a better ROAR performance (i.e. lower accuracy in Table A6). This result is consistent across all three settings of removing 10%, 20%, and 30% most important words, and when using either pre-trained BERT or BERT finetuned on SST-2.

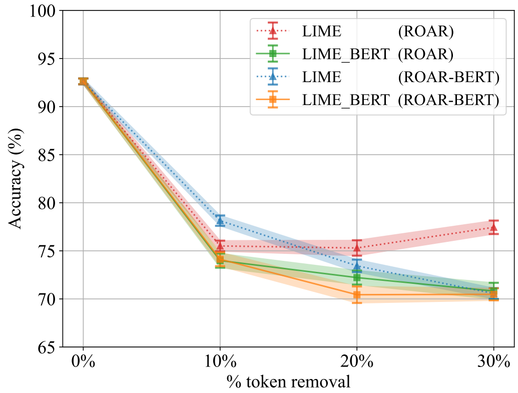

Figure 4: $\text{LIME}_{\text{BERT}}$ slightly, but consistently outperforms LIME when evaluated under either ROAR or $\text{ROAR}_{\text{BERT}}$. The each point in the y-axis shows the mean accuracy of five different classifiers. See more results supporting the same conclusion in Table A6.

7 Discussion and Conclusion

We find in Sec. 5.3 that IM is highly insensitive to classifier's changes because, by design, it always assigns near-zero attribution to highly-predictable words x_i regardless of their true importance to a target classifier. A solution may be to leave such

x_i token out of the marginalization (Eq. 3), i.e. only marginalizing over the other tokens suggested by BERT. However, these other replacement tokens altogether have a sum likelihood of 0. That is, replacing token x_i by zero-probability tokens (i.e. truly implausible) would effectively generate OOD text, which, in turn is not desired (Hase et al., 2021).

Our results in Sec. 6.2 suggests that IM might be more useful at the *phrase* level (Jin et al., 2020) instead of *word* level as deleting a set of contiguous words has a larger effect to the classifier predictions.

In sum, for the first time, we find that the popular idea of harnessing BERT to generate realistic counterfactuals (Hase et al., 2021; Harbecke and Alt, 2020; Kim et al., 2020) does not actually improve upon a simple $\text{LOO}_{\text{empty}}$ in practice as an $\text{LOO}_{\text{empty}}$ counterfactual only has a single word deleted. In contrast, we observe more expected benefits of this technique in improving methods like LIME that has counterfactuals that are extremely syntactically erroneous when multiple words are often deleted.

Acknowledgments

We thank Michael Alcorn, Qi Li, and Peijie Chen for helpful feedback on the early results. We also thank the anonymous reviewers for their detailed and constructive criticisms that helped us improve the manuscript. Appendix

A IM explanations have smaller attribution magnitude per token and lower word coverage

To further understand the impact of the fact that BERT tends to not change a to-remove token (Sec. B), here, we quantify the magnitude of attribution given by IM and its coverage of important words in an example.

Smaller attribution magnitude Across three datasets, the average absolute values of attribution scores (which are $\in [-1, 1]$) of IM are not higher than that of LOO$_{\text{empty}}$ (Table A1). Especially in MultiRC, IM average attribution magnitude is 4.5× lower than that of LOO$_{\text{empty}}$ (0.02 vs 0.09).

Method	SST	e-SNLI	MultiRC
LOO$_{\text{empty}}$	**0.22** ± 0.27	0.15 ± 0.24	**0.09** ± 0.09
IM	0.17 ± 0.27	0.15 ± 0.27	0.02 ± 0.09

Table A1: The average absolute value of attribution scores per token of LOO$_{\text{empty}}$ is consistently higher than that of IM.

Lower word coverage We define *coverage* as the average number of highlighted tokens per example (e.g. Fig. 1) after binarizing a heatmap at the method's optimal threshold.

The coverage of LOO$_{\text{empty}}$ is much higher than that of IM on SST (40% vs 30%) and MultiRC examples (27% vs 6%), which is consistent with the higher *recall* of LOO$_{\text{empty}}$ (Table A2; a vs. b). For e-SNLI, although IM has higher coverage than LOO$_{\text{empty}}$ (14% vs. 10%), the coverage of LOO$_{\text{empty}}$ is closer to the human coverage (9%). That is, IM assigns high attribution incorrectly to many words, resulting in a substantially lower *precision* than LOO$_{\text{empty}}$, according to e-SNLI L3 annotations (Table 3b; 0.3814 vs. 0.4687).

In sum, **chaining our results together**, we found BERT to often replace a token x_i by an exact-match with a high likelihood (Sec. B), which sets a low empirical upper-bound on attribution values of IM, causing IM explanations to have smaller attribution magnitude. As the result, after binarization, fewer tokens remain highlighted in IM binary maps (e.g. Fig. 3).

Explanations generated by	SST	e-SNLI		MultiRC
		L2	L3	
(a) LOO$_{\text{empty}}$	40%	19%	10%	27%
(b) IM	30%	21%	14%	6%
(c) Human	37%	18%	9%	16%
# tokens per example	20	24		299

Table A2: Compared to IM, the coverage of LOO$_{\text{empty}}$ is closer to the coverage of human explanations.

B By design, IM always assigns near-zero attribution to high-likelihood words regardless of classifiers

We observe that IM scores a substantially lower recall compared to LOO$_{\text{empty}}$ (e.g. 0.0630 vs. 0.2876; Table 3d). That is, IM tends to incorrectly assign too small of attribution to important tokens. Here, we test whether this low-recall issue is because BERT is highly accurate at predicting a single missing word from the remaining text and therefore assigns a high likelihood to such words in Eq. 3, causing low IM attribution in Eq. 2.

Experiment For each example in all three datasets, we replaced a single word by BERT's top-1 highest-likelihood token and measured its likelihood and whether the replacement is the same as the original word.

Results Across SST, e-SNLI, and MultiRC, the top-1 BERT token matches exactly the original word ∼49, 60, 65% of the time, respectively (Table A3a). This increasing trend of exact-match frequency (from SST, e-SNLI → MultiRC) is consistent with the example length in these three datasets, which is understandable as a word tends to be more predictable given a longer context. Among the tokens that human annotators label "important", this exact-match frequency is similarly high (Table A3b). Importantly, the average likelihood score of a top-1 exact-match token is high, ∼0.81–0.86 (Table A3c). See Fig. 1 & Figs. A6–A11 for qualitative examples.

Our findings are aligned with IM's low recall. That is, if BERT fills in an exact-match $\tilde{x}_i$ for an original word x_i, the prediction difference for this replacement $\tilde{x}_i$ will be 0 in Eq. 4. Furthermore, a high likelihood of ∼0.81 for $\tilde{x}_i$ sets an **empirical upper-bound of 0.19 for the attribution of the word** x_i, which explains the insensitivity of IM to classifier randomization (Fig. 1; IM$_1$ to IM$_3$).

% exact-match (uncased)	SST	e-SNLI	MultiRC
(a) over all tokens	48.94	59.43	64.78
(b) over human highlights	41.25	42.74	68.55
(c) Top-1 word's likelihood	0.8229	0.8146	0.8556

Table A3: Top-1 likelihood scores (c) are the mean likelihood given by BERT for the top-1 predicted words that exactly match the original words (a).

The analysis here is also consistent with our additional findings that IM attribution tends to be smaller than that of LOO$_{\text{empty}}$ and therefore leads to heatmaps of lower coverage of the words labeled "important" by humans (see Sec. A).

C Train BERT as masked language model on SST-2 to help filling in missing words

Integrating pre-trained BERT into LIME helps improve LIME explanations under two ROAR metrics (Sec. 6). However, the pre-trained BERT might be suboptimal for the cloze task on SST-2 sentences as it was pre-trained on Wikipedia and BookCorpus. Therefore, here, we take the pre-trained BERT, and finetune it on SST-2 training set using the masked language modeling objective. That is, we aim to test whether having a more specialized BERT would improve LIME results even further.

Training details We follow the hyperparameters by (Huggingface, 2020) and use Adam optimizer (Kingma and Ba, 2015) with a learning rate of 0.00005, $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 10^{-8}$, a batch size of 8, max sequence length of 512 and the ratio of tokens to mask of 0.15. We finetune the pre-trained BERT on SST-2 (Socher et al., 2013a) train set and select the best model using the dev set.

Results On the SST-2 test set of 1,821 examples that contain 35,025 tokens in total, the cross-entropy loss of pre-trained BERT and BERT-SST2 are 3.50 ± 4.58 and 3.29 ± 4.40, respectively. That is, our BERT finetuned on SST-2 is better than pre-trained BERT at predicting missing words in SST-2 sentences.

D Comparison between original and modified version of Input Marginalization

We follow Kim et al. (2020) to reproduce results of the original Input Marginalization (IM) (Table A4a–b). To reduce the time complexity of Input Marginalization, we propose a modified version (IM-top10) by only marginalizing over the top-10 tokens sampled from BERT rather than using all tokens of likelihood $\geq$ a threshold $\sigma = 10^{-5}$. We find that IM-top10 has comparable performance to that of the original IM (0.4732 vs. 0.4783; Table A4c). Our IM-top10 quantitative results are also close to the original numbers reported in Kim et al. (2020) (0.4922 vs. 0.4972; Table A4).

Metrics ↓	a. IM (*reported* in Kim et al. (2020))	b. IM (Our reproduction)	c. IM-top10
Deletion	n/a	0.4783	0.4732
Deletion$_{\text{BERT}}$	0.4972	0.4824	0.4922

Table A4: The approximation in of IM-top10 compared to the original IM under two metrics on SST-2 task. Both metrics measure AUC (lower is better).

We also find high qualitative similarity between heatmaps produced by two versions: IM vs. IM-top10 (Figs. A1–5). The average Pearson correlation score across the SST-2 8720-example test set is fairly high ($\rho = 0.7224$). Thus, we use IM-top10 for all experiments in this paper.

E Sanity check result

Criteria	Method	SST-2	e-SNLI
(a) % tokens changing sign	LOO$_{\text{empty}}$	**71.41** ± 17.12	**56.07** ± 21.82
	IM	62.27 ± 17.75	49.57 ± 20.35
(b) Average absolute of differences	LOO$_{\text{empty}}$	**0.46** ± 0.18	**0.26** ± 0.14
	IM	0.31 ± 0.12	0.16 ± 0.12

Table A5: The percentage (%) of token (a) whose attribution scores change signs and (b) the average of absolute differences in attribution magnitude after classifier randomization (higher is better). IM is consistently more insensitive than LOO$_{\text{empty}}$ in both SST-2 and e-SNLI.

An Empirical Study on Cross-X Transfer for Legal Judgment Prediction

Joel Niklaus [†] [*] **Matthias Stürmer** [†] **Ilias Chalkidis** [‡] [◇] [*]

Abstract

Cross-lingual transfer learning has proven useful in a variety of Natural Language Processing (NLP) tasks, but it is understudied in the context of legal NLP, and not at all in Legal Judgment Prediction (LJP). We explore transfer learning techniques on LJP using the trilingual Swiss-Judgment-Prediction dataset, including cases written in three languages. We find that cross-lingual transfer improves the overall results across languages, especially when we use adapter-based fine-tuning. Finally, we further improve the model's performance by augmenting the training dataset with machine-translated versions of the original documents, using a 3× larger training corpus. Further on, we perform an analysis exploring the effect of cross-domain and cross-regional transfer, i.e., train a model across domains (legal areas), or regions. We find that in both settings (legal areas, origin regions), models trained across all groups perform overall better, while they also have improved results in the worst-case scenarios. Finally, we report improved results when we ambitiously apply cross-jurisdiction transfer, where we further augment our dataset with Indian legal cases.

1 Introduction

Rapid development in Cross-Lingual Transfer (CLT) has been achieved by pre-training transformer-based models in large multilingual corpora (Conneau et al., 2020; Xue et al., 2021), where these models have state-of-the-art results in multilingual NLU benchmarks (Ruder et al., 2021). Moreover, adapter-based fine-tuning (Houlsby et al., 2019; Pfeiffer et al., 2020) has been proposed to minimize the misalignment of multilingual knowledge (alignment) when CLT is applied, especially in a zero-shot fashion, where the target language is unseen during training. CLT is severely understudied in legal NLP applications except for Chalkidis et al. (2021) who experimented with several methods for CLT on MultiEURLEX, a newly introduced multilingual legal topic classification dataset, including EU laws.

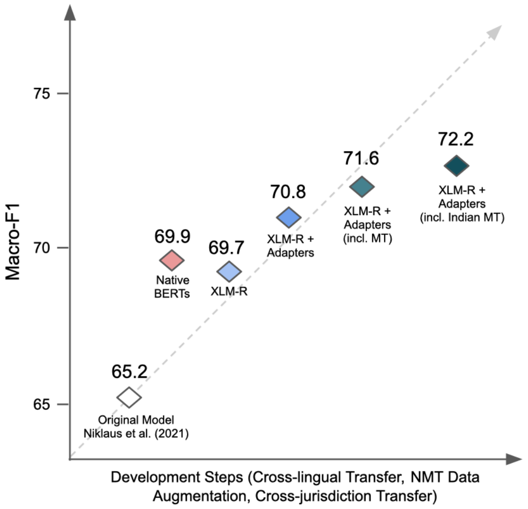

Figure 1: Incremental performance improvement through several development steps.

To the best of our knowledge, CLT has not been applied to the Legal Judgment Prediction (LJP) task (Aletras et al., 2016; Xiao et al., 2018; Chalkidis et al., 2019; Malik et al., 2021), where the goal is to predict the verdict (court decision) given the facts of a legal case. In this setting, positive impact of cross-lingual transfer is not as conceptually straight-forward as in other general applications (NLU), since there are known complications for sharing legal definitions and interpreting law across languages (Gotti, 2014; McAuliffe, 2014; Robertson, 2016; Ramos, 2021).

Following the work of Niklaus et al. (2021), we experiment with their newly released trilingual Swiss-Judgment-Prediction (SJP) dataset, containing cases from the Federal Supreme Court of Switzerland (FSCS), written in three official Swiss languages (German, French, Italian). The dataset covers four legal areas (public, penal, civil, and social law) and lower courts located in eight regions of Switzerland (Zurich, Ticino, etc.), which poses

[*] Equal contribution.

Proceedings of the 2nd Conference of the Asia-Pacific Chapter of the Association for Computational Linguistics and the 12th International Joint Conference on Natural Language Processing (Volume 1: Long Papers), pages 32–46
November 20–23, 2022. ©2022 Association for Computational Linguistics

interesting new challenges on model robustness / fairness and the effect of cross-domain and cross-regional knowledge sharing. In their experiments, Niklaus et al. (2021) find that the performance in cases written in Italian is much lower compared to the rest, while also performance varies a lot across regions and legal areas.

Main Research Questions

We pose and examine four main research questions:
RQ1: *Is cross-lingual transfer beneficial across all or some of the languages?*
RQ2: *Do models benefit or not from cross-regional and cross-domain transfer?*
RQ3: *Can we leverage data from another jurisdiction to improve performance?*
RQ4: *How does representational bias (wrt. language, origin region, legal area) affect model's performance?*

Contributions

The contributions of this paper are fourfold:

- We explore, for the first time, the application of cross-lingual transfer learning in the challenging LJP task in several settings (Section 3.3). We find that a pre-trained language model fine-tuned multilingually, outperforms its monolingual counterparts, especially when we use adapter-based fine-tuning and augment the training data with machine-translated versions of the original documents (3× larger training corpus) with larger gains in a low-resource setting (Italian).
- We perform cross-domain and cross-regional analyses (Section 3.4) exploring the effects of cross-domain and cross-regional transfer, i.e., train a model across domains, i.e., legal areas (e.g., civil, penal law), or regions (e.g., Zurich, Ticino). We find that in both settings (legal areas, regions), models trained across all groups perform overall better and more robustly; while always improving performance in the worst-case (region or legal area) scenario.
- We also report improved results when we apply cross-jurisdiction transfer (Section 3.5) , where we further augment our dataset with Indian legal cases originally written in English.
- We release the augmented dataset (incl. 100K machine-translated documents) and our code for replicability and future experimentation.[1]

The cumulative performance improvement amounts to 7% overall and 16+% in the low-resource Italian subset, compared to the best reported scores in Niklaus et al. (2021), while using cross-lingual and cross-jurisdiction transfer we improve for 2.3% overall and 4.6% for Italian over our strongest baseline (NativeBERTs).

2 Dataset and Task description

2.1 Swiss Legal Judgment Prediction Dataset

We investigate the LJP task on the Swiss-Judgment-Prediction (SJP) dataset (Niklaus et al., 2021). The dataset contains 85K cases from the Federal Supreme Court of Switzerland (FSCS) from the years 2000 to 2020 written in German, French, and Italian. The court hears appeals focusing on small parts of the previous (lower court) decision, where they consider possible wrong reasoning by the lower court. The dataset provides labels for a simplified binary (*approval*, *dismissal*) classification task. Given the facts of the case, the goal is to predict if the plaintiff's request is valid or partially valid (i.e., the court *approved* the complaint).

Since the dataset contains rich metadata, such as legal areas and origin regions, we can conduct experiments on the robustness of the models (see Section 3.4). The dataset is not equally distributed; in fact, there is a notable representation disparity where Italian have far fewer documents (4K), compared to German (50K) and French (31K). Representation disparity is also vibrant with respect to legal areas and regions. We refer readers to the work of Niklaus et al. for detailed dataset statistics.

2.2 Indian Legal Judgment Prediction Dataset

The Indian Legal Documents Corpus (ILDC) dataset (Malik et al., 2021) comprises 30K cases from the Indian Supreme Court in English. The court hears appeals that usually include multiple petitions and rules a decision (*accepted* vs. *rejected*) per petition. Similarly to Niklaus et al. (2021), Malik et al. released a simplified version of the dataset with binarized labels. In effect, the two datasets (SJP, ILDC) target the very same task (partial or full approval of plaintiff's claims), nonetheless in two different jurisdictions (Swiss Federation and India). Our main goal, when we use ILDC as a complement of SJP, is to assess the possibility of cross-jurisdiction transfer from Indian to Swiss cases (see Section 3.5), an experimental scenario that has not been explored so far in the literature.

[1] https://huggingface.co/datasets/swiss_judgment_prediction

2.3 NMT-based Data Augmentation

In some of our experiments, we perform data augmentation using machine-translated versions of the original documents, i.e., translate a document originally written in a single language to the other two (e.g., from German to French and Italian). We performed the translations using the EasyNMT[2] framework utilizing the *many-to-many* Neural Machine Translation (NMT) model of Fan et al. (2020).[3] A preliminary manual check of some translated samples showed sufficient translation quality to proceed forward. We release the machine-translated additional dataset for future consideration on cross-lingual experiments or quality assessment.

To the best of our knowledge, machine translation for data augmentation has not been studied in legal Natural Language Processing (NLP) applications, while it is generally a straight-forward, though under-studied idea. As we show in the experiments (see Section 3.3), the translations are effective, leading to an average improvement of 1.6% macro-F1 for standard fine-tuning and 0.8% for adapter-based one (see Table 1). For the low-resource Italian subset, the improvement even amounts to 3.2% and 1.6%, respectively.

3 Experiments

3.1 Hierarchical BERT

Since the examined dataset (SJP) contains many documents with more than 512 tokens (90% of the documents are up to 2048), we use Hierarchical BERT models (Chalkidis et al., 2019; Niklaus et al., 2021; Dai et al., 2022) to encode up to 2048 tokens per document (4×512 blocks).

We split the text into consecutive blocks of 512 tokens and feed the first 4 blocks to a shared standard BERT encoder. Then, we aggregate the block-wise `CLS` tokens by passing them through another 2-layer transformer encoder, followed by max-pooling and a final classification layer.

We re-use and expand the implementation released by Niklaus et al. (2021),[4] which is based on the Hugging Face library (Wolf et al., 2020). Notably, we first improve the masking of the blocks. Specifically, when the document has less than the maximum number (4) of blocks, we pad with extra sequences of `PAD` tokens, without the use of special tokens (`CLS`, `SEP`), as was previously performed. This minor technical improvement seems to affect the model's performance at large (group A1 Prior SotA vs. NativeBERTs — Table 1).

We experiment with monolingually pre-trained BERT models (aka NativeBERTs) and the multilingually pre-trained XLM-R of Conneau et al. (2020). Specifically, for monolingual experiments (Native BERTs), we use German-BERT (Chan et al., 2019) for German, CamemBERT (Martin et al., 2020) for French, and UmBERTo (Parisi et al., 2020) for Italian, similar to Niklaus et al. (2021).

In our multilingual experiments, we also assess the effectiveness of adapter-based fine-tuning (Houlsby et al., 2019; Pfeiffer et al., 2020), in comparison to standard full fine-tuning. In this setting, adapter layers are placed after all feed-forward layers of XLM-R and are trained together with the parameters of the layer-normalization layers. The rest of the model parameters remain untouched.

3.2 Experimental Set Up

We follow Niklaus et al. (2021) and report macro-averaged F1 score to account for the high class-imbalance in the dataset (approx. 20/80 approval/dismissal ratio). We repeat each experiment with 3 different random seeds and report the average score and standard deviation across runs (seeds). We perform grid-search for the learning rate and report test results, selecting the hyper-parameters with the best development scores.[5]

3.3 Cross-lingual Transfer

We first examine *cross-lingual transfer*, where the goal is to share (transfer) knowledge across languages, and we compare models in three main settings: (a) *Monolingual* (see Section 3.3.1): fine-tuned per language, using either the documents originally written in the language, or an augmented training set including the machine-translated versions of all other documents (originally written in another language), (b) *Cross-lingual* (see Section 3.3.2): fine-tuned across languages with or without the additional translated versions, and (c) *Zero-shot cross-lingual* (see Section 3.3.3): fine-tuned across a subset of the languages excluding the target language at a time. We present the results in Table 1.

[2] `https://github.com/UKPLab/EasyNMT`

[3] The *one-to-one* OPUS-MT (Tiedemann and Thottingal, 2020) models did not have any model available from French to Italian (fr2it) at the time of the experiments.

[4] `https://github.com/JoelNiklaus/SwissJudgementPrediction`

[5] Additional details on model configuration, training, and hyper-parameter tuning can be found in Appendix A.

Model	#D	#M	German ↑	French ↑	Italian ↑	All ↑	(Diff. ↓)
A1. *Monolingual: Fine-tune on the* **tgt training set** (**src** = **tgt**) — Baselines							
Prior SotA (Niklaus et al.)	3-35K	N	68.5 ± 1.6	70.2 ± 1.1	57.1 ± 0.4	65.2 ± 0.8	(13.1)
NativeBERTs	3-35K	N	69.6 ± 0.4	72.0 ± 0.5	68.2 ± 1.3	69.9 ± 1.6	(3.8)
XLM-R	3-35K	N	68.2 ± 0.3	69.9 ± 1.6	65.9 ± 1.2	68.0 ± 2.0	(4.0)
A2. *Monolingual: Fine-tune on the* **tgt training set incl. machine-translations** (**src** = **tgt**)							
NativeBERTs	60K	N	70.0 ± 0.7	71.0 ± 1.3	71.9 ± 2.5	71.0 ± 0.8	(0.9)
XLM-R	60K	N	68.8 ± 1.4	70.7 ± 2.1	71.9 ± 2.6	70.4 ± 1.3	(1.1)
B1. *Cross-lingual: Fine-tune on* **all training sets** (**src** $\subset$ **tgt**)							
XLM-R	60K	1	68.9 ± 0.3	71.1 ± 0.3	68.9 ± 1.4	69.7 ± 1.0	(2.2)
XLM-R + Adapters	60K	1	69.9 ± 0.6	71.8 ± 0.7	70.7 ± 1.8	70.8 ± 0.8	(0.9)
B2. *Cross-lingual: Fine-tune on* **all training sets incl. machine-translations** (**src** $\subset$ **tgt**)							
XLM-R	180K	1	70.2 ± 0.5	71.5 ± 1.1	72.1 ± 1.2	71.3 ± 0.7	(1.9)
XLM-R + Adapters	180K	1	**70.3** ± 0.9	**72.1** ± 0.8	**72.3** ± 2.1	**71.6** ± 0.8	(2.0)
C. *Zero-shot Cross-lingual: Fine-tune on* **all training sets excl. tgt language** (**src** $\neq$ **tgt**)							
XLM-R	25-57K	1	58.4 ± 1.2	58.7 ± 0.8	68.1 ± 0.2	61.7 ± 4.5	(9.7)
XLM-R + Adapters	25-57K	1	62.5 ± 0.6	58.8 ± 1.5	67.5 ± 2.2	62.8 ± 3.7	(8.7)

Table 1: Test results for all training set-ups (monolingual w/ or w/o translations, multilingual w/ or w/o translations, and zero-shot) w.r.t source (src) and target (tgt) language. Best overall results are in **bold**, and best per setting (group) are underlined. #D is the number of training documents used. #M is the number of models trained/used. The mean and standard deviation are computed across random seeds and across languages for the last column. Diff. shows the difference between the best and the worst performing language. ***The adapter-based multilingually fine-tuned XLM-R model including machine-translated versions (3× larger corpus) has the best overall results***.

3.3.1 Mono-Lingual Training

We observe that the baseline of *monolingually* pre-trained and fine-tuned models (NativeBERTs) have the best results compared to the *multilingually* pre-trained but *monolingually* fine-tuned XLM-R (group A1 – Table 1). Representational bias across languages (Section 2.1) seems to be a key part of performance disparity, considering the performance of the least represented language (Italian) compared to the rest (3K vs. 21-35K training documents). However, this is not generally applicable, i.e., French have better performance compared to German, despite having approx. 30% less training documents.

Translating the full training set provides a 3× larger training set (approx. 180K in total) that "equally" represents all three languages.[6] Augmenting the original training sets with translated versions of the documents (group A2 – Table 1), originally written in another language, improves performance in almost all (5/6) cases (languages per model). Interestingly, the performance improvement in Italian, which has the least documents (less than 1/10 compared to German), is the largest across languages with 3.7% for NativeBERT (68.2 to 71.9) and 6% for XLM-R (65.9 to 71.9) making Italian the best performing language after augmentation. Data augmentation seems more beneficial for XLM-R, which does not equally represent the three examined languages.[7]

3.3.2 Cross-Lingual Training

We now turn to the *cross-lingual transfer* setting, where we train XLM-R across all languages in parallel. We observe that cross-lingual transfer (group B1 – Table 1) improves performance (+4.5% p.p.) across languages compared to the same model (XLM-R) fine-tuned in a monolingual setting (group A1 – Table 1). This finding suggests that cross-lingual transfer (and the inherited benefit of using larger multilingual corpora) has a signifi-

[6] Representational equality with respect to number of training documents per language, but possibly not considering text quality, since we use NMT to achieve that goal.

[7] Refer to Conneau et al. (2020) for resources per language used to pre-train XLM-R (50% less tokens for Italian).

Table 2: Test results for models trained per region or across all regions. Best overall results are in **bold**, and in-domain are underlined. #D is the total number of training examples. #L are the languages covered. ***Cross-regional transfer is beneficial for all regions and has the best overall results. The shared multilingual model trained across all languages and regions slightly outperforms the baseline (NativeBERTs).***

cant impact, despite the legal complication of sharing legal definitions across languages. Augmenting the original training sets with the documents translated across all languages, further improves performance (group B2 – Table 1).

3.3.3 Zero-Shot Cross-Lingual Training

We also present results in a *zero-shot cross-lingual* setting (group C – Table 1), where XLM-R is trained in two languages and evaluated in the third one (unseen in fine-tuning). We observe that German has the worst performance (approx. 10% drop), which can be justified as German is a *Germanic* language, while both French and Italian are *Romance* and share a larger part of the vocabulary.

Contrarily, in case of Italian, the low-resource language in our experiments, the model strongly benefits from zero-shot cross-lingual transfer, leading to 2.2% p.p. improvement, compared to the monolingually trained XLM-R. In other words, training XLM-R with much more (approx 20×) out-of-language (57K in German and French) data is better compared to training on the limited (3K) in-language (Italian) documents (68.1 vs. 65.9).

3.3.4 Fine-tuning with Adapters

Across all cross-lingual settings (groups B-C – Table 1), the use of Adapters improves substantially the overall performance. The multilingual adapter-based XLM-R in group B1 (Table 1) has comparable performance to the NativeBERTs models of group A2, where the training dataset has been artificially augmented with machine translations. In a similar setting (group B2 – Table 1), the multilingual adapter-based XLM-R in group B2 has the best overall results, combining the benefits of both cross-lingual transfer and data augmentation.

With respect to *cross-lingual performance parity*, the adapter-based XLM-R model has also the highest performance parity (least diff. in the last column of Table 1), while augmenting the dataset with NMT translations leads to both the worst-case (language) performance and best performance for the least represented language (Italian).

In conclusion, cross-lingual transfer with an augmented dataset comprised of the original and machine-translated versions of all documents, has the best overall performance with a vibrant improvement (3% compared to our strong baselines – second part of Group A1 in Table 1) in Italian, the least represented language.

3.4 Cross-Domain/Regional Transfer Analysis

Further on, we examine the benefits of transfer learning (knowledge sharing) in other dimensions. Hence, we analyze model performance with respect to origin regions and legal areas (domains of law).

Legal Area	#D	Public Law	Civil Law	Penal Law	Social Law	All
Domain-specific fine-tuning with MT data augmentation						
Public Law	45.6K	56.4 ± 2.2	52.2 ± 2.0	59.7 ± 4.9	60.1 ± 5.8	57.1 ± 3.2
Civil Law	34.5K	44.4 ± 7.9	64.2 ± 0.6	45.5 ± 13.1	43.6 ± 5.2	49.4 ± 8.6
Penal Law	35.4K	40.8 ± 10.1	55.8 ± 2.9	**84.5** ± 1.3	61.1 ± 7.5	60.6 ± 15.7
Social Law	29.1K	52.6 ± 4.2	56.6 ± 2.0	69.0 ± 5.5	70.2 ± 2.0	62.1 ± 7.6
Cross-domain fine-tuning w/o MT data augmentation						
XLM-R	60K	57.4 ± 2.0	66.1 ± 3.1	81.4 ± 1.4	70.8 ± 2.0	68.9 ± 8.7
XLM-R + Adapters	60K	58.4 ± 2.5	66.1 ± 2.4	83.1 ± 1.2	71.1 ± 1.4	69.7 ± 9.0
Cross-domain fine-tuning with MT data augmentation						
NativeBERTs	180K	58.1 ± 3.0	64.5 ± 3.7	83.0 ± 1.3	71.1 ± 4.3	69.2 ± 9.2
XLM-R	180K	58.0 ± 3.0	**67.2** ± 1.6	84.4 ± 0.2	70.2 ± 1.3	**70.0** ± 9.5
XLM-R + Adapters	180K	**58.6** ± 2.7	66.8 ± 2.8	83.1 ± 1.3	**71.3** ± 2.4	69.9 ± 8.8

Table 3: Test results for models (XLM-R with MT unless otherwise specified) **fine-tuned** per legal area (domain) or across all legal areas (domains). Best overall results are in **bold**, and in-domain are underlined. The mean and standard deviations are computed across languages per legal area and across legal areas for the right-most column. #D is the total number of training examples. ***Cross-domain transfer is beneficial for 3 out of 4 legal areas and has the best overall results.*** The shared multilingual model trained across all languages and legal areas outperforms the baseline (monolingual BERT models).

3.4.1 Origin Regions

In Table 2 we present the results for *cross-regional* transfer. In the top section of the table, we present results with region-specific multilingual (XLM-R) models evaluated across regions (in-region on the diagonal, zero-shot otherwise). We observe that the cross-regional models (two lower groups of Table 2) always outperform the region-specific models. Moreover, cross-lingual transfer is beneficial across cases, while adapter-based fine-tuning further improves results in 5 out of 8 cases (regions). Data augmentation is also beneficial in most cases.

In the top part of Table 2, in 60% of the cases (regions: ZH, ES, CS, NWS, TI), a “zero-shot” model, i.e., trained in the cases of another region, slightly outperforms the in-region model. In other words, in almost every case (target region), there is another *monolingual* region-specific model that outperforms the in-region one.

We consider two main factors that may explain these results: (a) the region-wise *representational bias* considering the number of cases per region, and (b) the cross-regional *topical similarity* of the training and test subsets across different regions. To approximate the cross-regional topical similarity, we consider the distributional similarity (or dissimilarity) w.r.t. legal areas (Table 6 in Appendix C). None of these factors can fully explain the results. Although in 3 out of 5 cases, the best performing (out-of-region) model has been trained on more data compared to the in-region one. There are also other confounding factors (e.g., language), i.e., models trained on the cases of either Espace Mittelland (EM) or Région Lémanique (RL), both bilingual with 8-10K cases, have the best results across all single-region models, hence a further exploration of the overall dynamics is needed.

3.4.2 Legal Areas

In Table 3 we present the results for *cross-domain* transfer between legal areas (domains of law). The results on the diagonal (underlined) are in-domain, i.e., fine-tuned and evaluated in the same legal area. We observe that for each domain, the models trained on in-domain data have the best results in the respective domain compared to the rest.

Interesting to note is that the best results (**bold**) are achieved in the cross-domain setting in 3 out of 4 legal areas. Such an outcome is not anticipated based on the current trends in law industry, where legal experts (judges, lawyers) over-specialize and excel in specific legal areas, e.g., criminal defense lawyers. Penal law poses the only exception where the domain-specific model is on par with the cross-domain model. Again, the results per area do not correlate with the volume of training data (*cross-*

Model	Training Dataset	#D	German ↑	French ↑	Italian ↑	All	(Diff. ↓)
Cross-lingual fine-tuning w/ or w/o MT data augmentation							
XLM-R	Original	60K	68.9 ± 0.3	71.1 ± 0.3	68.9 ± 1.4	69.7 ± 1.0	(2.2)
XLM-R + Adapters	Original	60K	69.9 ± 0.6	71.8 ± 0.7	70.7 ± 1.8	70.8 ± 0.8	(0.9)
XLM-R	+ MT Swiss	180K	70.2 ± 0.5	71.5 ± 1.1	72.1 ± 1.2	71.3 ± 0.7	(1.9)
XLM-R + Adapters	+ MT Swiss	180K	70.3 ± 0.8	72.1 ± 0.8	72.1 ± 1.2	71.5 ± 0.9	(1.8)
Cross-jurisdiction fine-tuning w/ MT data augmentation							
XLM-R	+ MT {Swiss, Indian}	276K	70.5 ± 0.4	71.8 ± 0.3	**73.5** ± 1.4	72.0 ± 0.9	(3.0)
XLM-R + Adapters	+ MT {Swiss, Indian}	276K	**71.0** ± 0.4	**73.0** ± 0.6	72.6 ± 1.1	**72.2** ± 1.2	(2.0)
Cross-jurisdiction zero-shot fine-tuning w/ MT data augmentation							
XLM-R	MT Indian	96K	50.4 ± 1.5	47.9 ± 1.0	49.5 ± 1.3	49.3 ± 1.0	(2.5)
XLM-R + Adapters	MT Indian	96K	51.6 ± 2.9	49.7 ± 1.4	50.1 ± 1.4	50.5 ± 1.0	(1.9)

Table 4: Test results for cross-jurisdiction transfer. We present results in four settings: *standard* (Original) *augmented* (+ MT Swiss), *further augmented incl. cross-jurisdiction* (+ MT Swiss + MT Indian) and *zero-shot* (MT Indian). Best results are in **bold**. Diff. shows the difference between the best performing language and the worst performing language (max - min). ***Further augmenting with translated Indian cases is overall beneficial.***

domain representational bias), and suggest that other qualitative characteristics (e.g., the idiosyncrasies of criminal law) affect the task complexity.

Similarly to the cross-regional experiments, the shared multilingual model (XLM-R) trained across all languages and legal areas with an augmented dataset outperforms the NativeBERTs models trained in a similar setting, giving another indication that the performance gains from cross-lingual transfer and data augmentation via machine translation are robust across domains as well.

3.5 Cross-Jurisdiction Transfer

We, finally, "ambitiously" stretch the limits of transfer learning in LJP and we apply *cross-jurisdiction* transfer, i.e., use of cases from different legal systems, another form of cross-domain transfer. For this purpose, we further augment the SJP dataset of FSCS cases, with cases from the Supreme Court of India (SCI), published by Malik et al. (2021).[8] We consider and translate all (approx. 30K) Indian cases ruled up to the last year (2014) of our training dataset, originally written in English, to all target languages (German, French, and Italian).[9]

In Table 4, we present the results for two cross-jurisdiction settings: *zero-shot* (Only MT Indian), where we train XLM-R on the machine-translated version of Indian cases, and *further augmented* (Original + MT Swiss + MT Indian), where we further augment the (already augmented) training set of Swiss cases with the translated Indian ones. While zero-shot transfer clearly fails; interestingly, we observe improvement for all languages in the further augmented setting. This opens a fascinating new direction for LJP research.

Similar to our results in Section 3.3 with respect to cross-lingual performance parity, the standard adapter-based XLM-R model has also the highest performance parity (least diff. on Table 4), while the same model trained on the fully augmented dataset leads to the worst-case (language; German) performance and best performance for the least represented language (Italian).

The cumulative improvement from all applied enhancements adds up to 7% macro-F1 compared to the XLM-R baseline and 16% to the best method by Niklaus et al. (2021) in the low-resource Italian subset, while using cross-lingual and cross-jurisdiction transfer we improve for 2.3% overall and 4.6% for Italian over our strongest baseline (NativeBERTs).

Since our experiments present several incremental improvements, we assess the stability of the performance improvements with statistical significance testing by comparing the most crucial settings in Appendix B.

4 Related Work

Legal Judgment Prediction (LJP) is the task, where given the facts of a legal case, a system

[8] Although the SCI rules under the Indian jurisdiction (law), while the FSCS under the Swiss one, we hypothesize that the fundamentals of law in two modern legal systems are quite common and thus transferring knowledge could potentially have a positive effect. We discuss this matter in Section 5.

[9] We do not use the original documents written in English, as English is not one of our target languages.

has to predict the correct outcome (legal judgement). Many prior works experimented with some forms of LJP, however, the precise formulation of the LJP task is non-standard as the jurisdictions and legal frameworks vary. Aletras et al. (2016); Medvedeva et al. (2018); Chalkidis et al. (2019) predict the plausible violation of European Convention of Human Rights (ECHR) articles of the European Court of Human Rights (ECtHR). Xiao et al. (2018, 2021) study Chinese criminal cases where the goal is to predict the ruled duration of prison sentences and/or the relevant law articles.

Another setup is followed by Şulea et al. (2017); Malik et al. (2021); Niklaus et al. (2021), which use cases from Supreme Courts (French, Indian, Swiss, respectively), hearing appeals from lower courts relevant to several fields of law (legal areas). Across tasks (datasets), the goal is to predict the binary verdict of the court (approval or dismissal of the examined appeal) given a textual description of the case. None of these works have explored neither cross-lingual nor cross-jurisdiction transfer, while the effects of cross-domain and cross-regional transfer are also not studied.

Cross-Lingual Transfer (CLT) is a flourishing topic with the application of pre-trained transformer-based models trained in a multilingual setting (Devlin et al., 2019; Lample and Conneau, 2019; Conneau et al., 2020; Xue et al., 2021) excelling in NLU benchmarks (Ruder et al., 2021). Adapter-based fine-tuning (Houlsby et al., 2019; Pfeiffer et al., 2021) has been proposed as an anti-measure to mitigate misalignment of multilingual knowledge when CLT is applied, especially in a zero-shot fashion, where the target language is unseen during training (or even pre-training).

Meanwhile, CLT is understudied in legal NLP applications. Chalkidis et al. (2021) experiment with standard fine-tuning, while they also examined the use of adapters (Houlsby et al., 2019) for zero-shot CLT on a legal topic classification dataset comprising European Union (EU) laws. They found adapters to achieve the best tradeoff between effectiveness and efficiency. Their work did not examine the use of methods incorporating translated versions of the original documents in any form, i.e., translate train documents or test ones. Recently, Xenouleas et al. (2022) used an updated, unparalleled version of Chalkidis et al. dataset to study NMT -augmented CLT methods. Other multilingual legal NLP resources (Galassi et al., 2020; Drawzeski et al., 2021) have been recently released, although CLT is not applied in any form.

5 Motivation and Challenges for Cross-Jurisdiction Transfer

Legal systems vary from country to country. Although they develop in different ways, legal systems also have some similarities based on historically accepted justice ideals, i.e., the rule of law and human rights. Switzerland has a civil law legal system (Walther, 2001), i.e., statutes (legislation) is the primary source of law, at the crossroads between Germanic and French legal traditions.

Contrary, India has a hybrid legal system with a mixture of civil, common law, i.e., judicial decisions have precedential value, and customary, i.e., Islamic ethics, or religious law (Bhan and Rohatgi, 2021). The legal and judicial system derives largely from the British common law system, coming as a consequence of the British colonial era (1858-1947) (Singh and Kumar, 2019).

Based on the aforementioned, cross-jurisdiction transfer is challenging since the data (judgments) abide to different law standards. Although the Supreme Court of India (SCI) rules under the Indian jurisdiction (law), while the Federal Supreme Court of Switzerland (FSCS) under the Swiss one, we hypothesize that the fundamentals of law in two modern legal systems are quite common and thus transferring knowledge could potentially have a positive effect, and thus it is an experiment worth considering, while we acknowledge that from a legal perspective equating legal systems is deeply problematic, since the legislation, the case law, and legal practice are different.

Our empirical work and experimental results shows that cross-jurisdiction transfer in this specific setting (combination of Swiss and Indian decisions) has a positive impact in performance, but we cannot provide any profound hypothesis neither we are able to derive any conclusions on the importance of this finding on legal literature and practice. We leave these questions in the hands of those who can responsibly bear the burden, the legal scholars.

6 Conclusions and Future Work

6.1 Answers to the Research Questions

Following the experimental results (Section 3), we answer the original predefined research questions:

RQ1: *Is cross-lingual transfer beneficial across all or some of the languages?* In Section 3.3, we find that vanilla CLT is beneficial in a low-resource setting (Italian), with comparable results in the rest of the languages. Moreover, CLT leveraging NMT -based data augmentation is beneficial across all languages. Overall, our experiments lead to a single multi-lingual cross-lingually “fairer” model.

RQ2: *Do models benefit or not from cross-regional and cross-domain transfer?* In Section 3.4, we find that models benefit from cross-regional transfer across all cases, since they are exposed to (trained in) many more documents (cases). We believe cross-regional diversity is not a significant aspect, compared to the importance of the increased data volume and language diversity. Cross-domain transfer is beneficial in three out of four cases (legal areas), with comparable results on penal (criminal) law, where the application of law seems to be more straight-forward / standardized (higher performing legal area). Cross-regional and cross-domain transfer lead to more robust models.

RQ3: *Can we leverage data from another jurisdiction to improve performance?* In Section 3.5, we find that cross-jurisdiction transfer in our specific setup, i.e., very similar LJP tasks, is beneficial. Again, we believe that this is mostly a matter of additional unique data (cases), rather than a matter of jurisdictional similarity. Cross-jurisdiction transfer leads to a better performing model.

RQ4: *How does representational bias (wrt. language, origin region, legal area) affect model’s performance?* We observe that representational bias – in non-extreme cases (e.g., w.r.t. language) – does not always explain performance disparities across languages, regions, or domains, and other characteristics also need to be considered.

6.2 Conclusions - Summary

We examined the application of Cross-Lingual Transfer (CLT) in Legal Judgment Prediction (LJP) for the very first time, finding a multilingually trained model to be superior when augmenting the dataset with NMT. Adapter-based fine-tuning leads to even better results. We also examined the effects of cross-domain (legal areas) and cross-regional transfer, which is overall beneficial in both settings, leading to more robust models. Cross-jurisdiction transfer by augmenting the training set with machine-translated Indian cases further improves performance.

6.3 Future Work

In future work, we would like to explore the use of a legal-oriented multilingual pre-trained model by either continued pre-training of XLM-R, or pre-training from scratch in multilingual legal corpora. Legal NLP literature (Chalkidis et al., 2022; Zheng et al., 2021) suggests that domain-specific language models positively affect performance.

In another interesting direction, we will consider other data augmentation techniques (Feng et al., 2021; Ma, 2019) that rely on textual alternations (e.g., paraphrasing, etc.). We would also like to further investigate cross-jurisdictional transfer, either exploiting data for similar LJP tasks, or via multi-task learning on multiple LJP datasets with dissimilar task specifications.

7 Ethics Statement

The scope of this work is to study LJP to broaden the discussion and help practitioners to build assisting technology for legal professionals and laypersons. We believe that this is an important application field, where research should be conducted (Tsarapatsanis and Aletras, 2021) to improve legal services and democratize law, while also highlight (inform the audience on) the various multi-aspect shortcomings seeking a responsible and ethical (fair) deployment of legal-oriented technologies.

In this direction, we study how we could better exploit all the available resources (from various languages, domains, regions, or even different jurisdictions). This combination leads to models that improve overall performance – more robust models –, while having improved performance in the worst-case scenarios across many important demographic or legal dimensions (low-resource language, worst performing legal area and region).

Nonetheless, irresponsible use (deployment) of such technology is a plausible risk, as in any other application (e.g., online content moderation) and domain (e.g., medical). We believe that similar technologies should only be deployed to assist human experts (e.g., legal scholars in research, or legal professionals in forecasting or assessing legal case complexity) with notices on their limitations.

The main examined dataset, Swiss-Judgment-Prediction (SJP), released by Niklaus et al. (2021), comprises publicly available cases from the FSCS, where cases are pre-anonymized, i.e., names and other sensitive information are redacted. The same applies for the second one, Indian Legal Documents Corpus (ILDC) of Malik et al. (2021).

Acknowledgements

This work has been supported by the Swiss National Research Program "Digital Transformation" (NRP-77)[10] grant number 187477. This work is also partly funded by the Innovation Fund Denmark (IFD)[11] under File No. 0175-00011A. This research has been also co-financed by the European Regional Development Fund of the European Union and Greek national funds through the Operational Program Competitiveness, Entrepreneurship and Innovation, under the call RESEARCH – CREATE – INNOVATE (T2EΔK-03849).

We would like to thank Thomas Lüthi for his legal advice, Mara Häusler for great discussions regarding the evaluation process of the models, and Phillip Rust and Desmond Elliott for providing valuable feedback on the original draft of the manuscript.

A Hyperparameter Tuning

We experimented with learning rates in {1e-5, 2e-5, 3e-5, 4e-5, 5e-5} as suggested by Devlin et al. (2019). However, like reported by Mosbach et al. (2020), we also found RoBERTa-based models to exhibit large training instability with learning rate 3e-5, although this learning rate worked well for BERT-based models. 1e-5 worked well enough for all models. To avoid either over- or under-fitting, we use Early Stopping (Caruana et al., 2001) on development data. To combat the high class imbalance, we use oversampling, following (Niklaus et al., 2021).

We opted to use the standard Adapters of Houlsby et al. (2019), as the language Adapters introduced by Pfeiffer et al. (2020) are more resource-intensive and require further pre-training per language. We tuned the adapter reduction factor in {2×, 4×, 8×, 16×} and got the best results with 2× and 4×; we chose 4× for the final experiments to favor less additional parameters. We tuned the learning rate in {1e-5, 5e-5, 1e-4, 5e-4, 1e-3} and achieved the best results with 5e-5.

We additionally applied label smoothing (Szegedy et al., 2015) on cross-entropy loss. We achieved the best results with a label smoothing factor of 0.1 after tuning with {0, 0.1, 0.2, 0.3}.

Model Type	M1	M2	M3	M4
M1: NativeBERTs	1.0	1.0	1.0	1.0
M2: NativeBERTs + MT CH	0.0	1.0	1.0	1.0
M3: XLM-R + MT CH	0.0	0.0	1.0	1.0
M4: XLM-R + MT CH + IN	0.0	0.0	0.0	1.0

Table 5: Almost stochastic dominance ($\epsilon_{\min} < 0.5$) with ASO. *+ MT CH* stands for augmentation with machine translation inside the Swiss dataset and *+ MT CH+IN* is the code for augmentation with machine-translations with the Swiss **and** Indian dataset.

B Statistical Significance Testing

Since our experiments present several incremental improvements, we assessed the stability of the performance improvements with statistical significance testing by comparing the most crucial settings. Using Almost Stochastic Order (ASO) (Dror et al., 2019) with a confidence level $\alpha = 0.05$, we find the score distributions of the core models (NativeBERTs, w/ and w/o MT Swiss, XLM-R w/ and w/o MT Indian and/or Swiss) stochastically dominant ($\epsilon_{\min} = 0$) over each other in order. We compared all pairs of models based on three random seeds each using ASO with a confidence level of $\alpha = 0.05$ (before adjusting for all pair-wise comparisons using the Bonferroni correction). Almost stochastic dominance ($\epsilon_{\min} < 0.5$) is indicated in Table 5 in Appendix A. We use the deep-significance Python library of Ulmer (2021).

C Distances Between Legal Area Distributions per Origin Regions

	ZH	ES	CS	NWS	EM	RL	TI	FED
ZH	.02	.02	.03	.02	.01	.02	.05	.12
ES	.03	.03	.04	.03	.02	.01	.06	.11
CS	.02	.01	.01	.02	.01	.04	.06	.13
NWS	.05	.04	.06	.04	.04	.03	.04	.09
EM	.03	.03	.04	.02	.03	.03	.04	.10
RL	.06	.05	.07	.05	.05	.05	.04	.07
TI	.07	.07	.08	.05	.07	.08	.02	.06
FED	.10	.10	.12	.09	.10	.10	.06	.02

Table 6: Wasserstein distances between the legal area distributions of the training and the test set per origin region across languages. The training sets are in the columns and the test sets in the rows.

In Table 6 we show the Wasserstein distances between the legal area distributions of the training and the test sets per origin region across languages. Unfortunately, this analysis does not explain why the NWS model (zero-shot) outperforms the ZH model (in-domain) on the ZH test set, as found in Table 2.

D Additional Results

In Tables 7, 8, 9 and 10 we present detailed results for all experiments. All tables include both the average score across repetitions, as reported in the original tables in the main article, but also the standard deviations across repetitions.

E Responsible NLP Research

We include information on limitations, licensing of resources, and computing foot-print, as suggested by the newly introduced Responsible NLP Research checklist.

E.1 Limitations

In this appendix, we discuss core limitations that we identify in our work and should be considered in future work.

Data size fluctuations We did not control for the sizes of the training datasets, which is why we reported them in the Tables 2, 3 and 4. This mimics a more realistic setting, where the training set size differs based on data availability. Although we discussed representational bias in RQ4, we cannot completely rule out different performance based on simply more training data.

Mismatch in in/out of region model performance As described in Section 3.4.1, certain zero-shot evaluations outperform in-domain evaluations. Although we try to find an explanation for this in Section 3.4, and Appendix C, it remains an open question since there are many confounding factors.

Re-use of Indian cases Although we have empirical results confirming the statistically significant positive effect of training with additional translated Indian cases, we do not have a profound legal justification or even a hypothesis for this finding at the moment.

E.2 Licensing

The SJP dataset (Niklaus et al., 2021) we mainly use in this work is available under a CC-BY-4 license. The second dataset, ILDC (Malik et al., 2021), comprising Indian cases is available upon request. The authors kindly provided their dataset. All used software and libraries (EasyNMT, Hugging Face Transformers, deep-significance, and several other typical scientific Python libraries) are publicly available and free to use, while we always cite the original work and creators. The artifacts (i.e., the translations and the code) we created, target academic research and are available under a CC-BY-4 license.

E.3 Computing Infrastructure

We used an NVIDIA GeForce RTX 3090 GPU with 24 GB memory for our experiments. In total, the experiments took approx. 80 GPU days, excluding the translations. The translations took approx. 7 GPU days per language from Indian to German, French, and Italian. The translation within the Swiss corpus took approx. 4 GPU days in total.

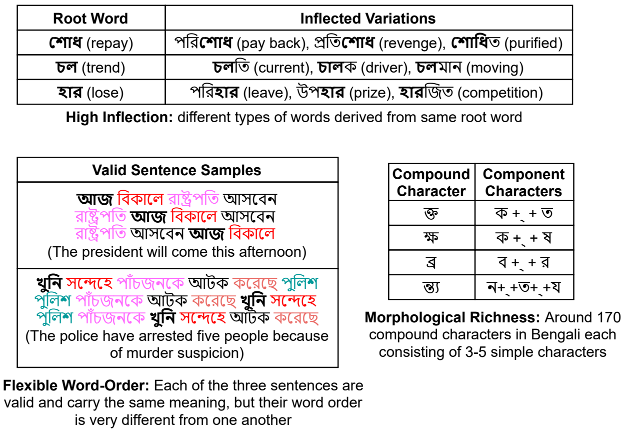
Abstract

Though recent works have focused on modeling high resource languages, the area is still unexplored for low resource languages like Bengali and Hindi. We propose an end-to-end trainable memory efficient CNN architecture named *CoCNN* to handle specific characteristics such as high inflection, morphological richness, flexible word order and phonetical spelling errors of Bengali and Hindi. In particular, we introduce two learnable convolutional sub-models at word and at sentence level that are end-to-end trainable. We show that state-of-the-art (SOTA) Transformer models including pretrained BERT do not necessarily yield the best performance for Bengali and Hindi. *CoCNN* outperforms pretrained BERT with 16X less parameters and achieves much better performance than SOTA LSTMs on multiple real-world datasets. This is the first study on the effectiveness of different architectures from Convolution, Recurrent, and Transformer neural net paradigm for modeling Bengali and Hindi. Code and data related to this research are available at: https://bit.ly/3MkQUuI

1 Introduction

Bengali and Hindi are the fourth and sixth most spoken language in the world, respectively. Both of these languages originated from Sanskrit (Staal, 1963) and share some unique characteristics that include (i) high inflection, i.e., each root word may have many variations due to addition of different suffixes and prefixes, (ii) morphological richness, i.e., there are large number of compound letters, modified vowels and modified consonants, and (iii) flexible word-order, i.e., the importance of word order and their positions in a sentence are loosely bounded (Examples shown in Figure 1). Many other languages such as Nepali, Gujarati, Marathi, Kannada, Punjabi and Telugu also share these characteristics. Neural language models (LM) have shown great promise recently in solving several key NLP tasks such as word prediction and sentence completion in major languages such as English and Chinese (Athiwaratkun et al., 2018; Takase et al., 2019; Pham et al., 2016; Gao et al., 2002; Cai and Zhao, 2016; Yang et al., 2016). To the best of our knowledge, none of the existing study investigates the efficacy of recent LMs in the context of Bengali and Hindi. We conduct an in-depth analysis of major deep learning architectures for LM and propose an end-to-end trainable memory efficient CNN architecture to address the unique characteristics of Bengali and Hindi.



Root Word	Inflected Variations
শোধ (repay)	পরি**শোধ** (pay back), প্রতি**শোধ** (revenge), **শোধি**ত (purified)
চল (trend)	**চল**তি (current), **চাল**ক (driver), **চল**মান (moving)
হার (lose)	পরি**হার** (leave), উপ**হার** (prize), **হার**জিত (competition)

High Inflection: different types of words derived from same root word

Valid Sentence Samples
আজ বিকালে রাষ্ট্রপতি আসবেন রাষ্ট্রপতি **আজ** বিকালে আসবেন রাষ্ট্রপতি আসবেন **আজ** বিকালে (The president will come this afternoon)
খুনি সন্দেহে পাঁচজনকে আটক করেছে পুলিশ পুলিশ পাঁচজনকে আটক করেছে **খুনি** সন্দেহে পুলিশ পাঁচজনকে **খুনি** সন্দেহে আটক করেছে (The police have arrested five people because of murder suspicion)

Flexible Word-Order: Each of the three sentences are valid and carry the same meaning, but their word order is very different from one another

Compound Character	Component Characters
ক্ত	ক + ্ + ত
ক্ষ	ক + ্ + ষ
ব্র	ব + ্ + র
ন্ত্য	ন+্+ত+্+য

Morphological Richness: Around 170 compound characters in Bengali each consisting of 3-5 simple characters

Figure 1: Bengali language unique characteristics

State-of-the-art (SOTA) techniques for LM can be categorized into three sub-domains of deep learning: (i) convolutional neural network (CNN) (Pham et al., 2016; Wang et al., 2018) (ii) recurrent neural network (Bojanowski et al., 2017; Mikolov et al., 2012; Kim et al., 2016; Gerz et al., 2018), and (iii) Transformer attention network (Al-Rfou et al., 2019; Vaswani et al., 2017; Irie et al., 2019; Ma et al., 2019). Long Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) based models, which are suitable for learning sequence and word order information, are not effective for modeling Bengali and Hindi due to their flexible word order characteristic. On the other hand, Transformers use

Proceedings of the 2nd Conference of the Asia-Pacific Chapter of the Association for Computational Linguistics and the 12th International Joint Conference on Natural Language Processing (Volume 1: Long Papers), pages 47–56
November 20–23, 2022. ©2022 Association for Computational Linguistics

dense layer based multi-head attention mechanism. They lack the ability to learn local patterns in sentence level, which in turn puts negative effect on modeling languages with loosely bound word order. Most importantly, neither LSTMs nor Transformers use any suitable measure to learn intra-word level local pattern necessary for modeling highly inflected and morphologically rich languages.

We observe that learning inter (flexible word order) and intra (high inflection and morphological richness) word local patterns is of paramount importance for Bengali and Hindi LM. To accommodate such characteristics, we design a novel CNN architecture, namely **Coordinated CNN (CoCNN)** that achieves SOTA performance with low training time. In particular, *CoCNN* consists of two learnable convolutional sub-models: word level (*Vocabulary Learner (VL)*) and sentence level (*Terminal Coordinator (TC)*). *VL* is designed for syllable pattern learning, whereas *TC* serves the purpose of word coordination learning while maintaining positional independence, which suits the flexible word order of Bengali and Hindi. *CoCNN* does not explicitly incorporate any self attention mechanism like Transformers; rather it relies on *TC* for emphasizing on important word patterns. *CoCNN* achieves significantly better performance than pretrained BERT for Bengali and Hindi LM with 16X less parameters. We further enhance *CoCNN* by introducing skip connection and parallel convolution branches in *VL* and *TC*, respectively. This modified architecture (with negligible increase in parameter number) is named as *CoCNN+*. We validate the effectiveness of *CoCNN+* on a number of tasks that include next word prediction in erroneous setting, text classification, sentiment analysis and spell checking. *CoCNN+* shows superior performance than contemporary LSTM based models and pretrained BERT.

In summary, the contributions of this paper are as follows:

- An end-to-end trainable *CoCNN* model based on the coordination of two CNN sub-models
- In-depth analysis and comparison on different SOTA LMs in three paradigms: CNN, LSTM, and Transformer
- Some simple modifications in *CoCNN* to achieve even better performance
- Using *VL* sub-model of *CoCNN+* as an effective spell checker for Bengali

2 Our Approach

Traditional CNN based approaches (Pham et al., 2016) represent the entire input sentence/ paragraph using a matrix of size $S_N \times S_V$, where S_N and S_V represent number of characters in the sentence/ paragraph and the character representation vector size, respectively. In such character based approach, the model does not have the ability to consider each word in the sentence as a separate entity. However, it is important to understand the contextual meaning of each word and to find out relationship among those words for sentence semantics understanding. **Coordinated CNN (CoCNN)** is aimed to achieve this feat. Figure 2 illustrates *CoCNN* that has two major components. *Vocabulary Learner* component works at word level, while *Terminal Coordinator* component works at sentence/ paragraph level. Both of these components are 1D CNN based sub-model at their core and are trained end-to-end.

2.1 *Vocabulary Learner*

Vocabulary Learner (VL) is used to transform each input word into a vector representation called *CNNvec*. We represent each input word $Word_i$ by a matrix W_i. W_i consists of m vectors each of size len_C. These vectors $\vec{C_1}, \vec{C_2}, \ldots \vec{C_m}$ represent one hot vector of character $C_1, C_2, \ldots C_m$, respectively of $Word_i$. Representation detail has been depicted in the bottom right corner of Figure 2. Applying 1D convolution (*conv*) layers on matrix W_i helps in deriving key local patterns and sub-word information of $Word_i$. After passing W_i matrix through the first *conv* layer, we obtain feature matrix W_i^1. Passing W_i^1 through the second *conv* layer provides us with feature matrix W_i^2. So, the L^{th} *conv* layer provides us with feature matrix W_i^L. *VL* submodel consists of such 1D *conv* layers standing sequentially one after the other. *Conv* layers near matrix W_i are responsible for identifying key subword patterns of $Word_i$, while *conv* layers further away focus on different combinations of these key sub-word patterns. Such word level local pattern recognition plays key role in identifying semantic meaning of a word irrespective of inflection or presence of spelling error. Each intermediate *conv* layer output is batch normalized. The final *conv* layer output matrix W_i^L is flattened and formed into a vector F_i of size len_F. F_i is the *CNNvec* representation of $Word_i$. We obtain *CNNvec* representation from each of our input words in a similar fashion

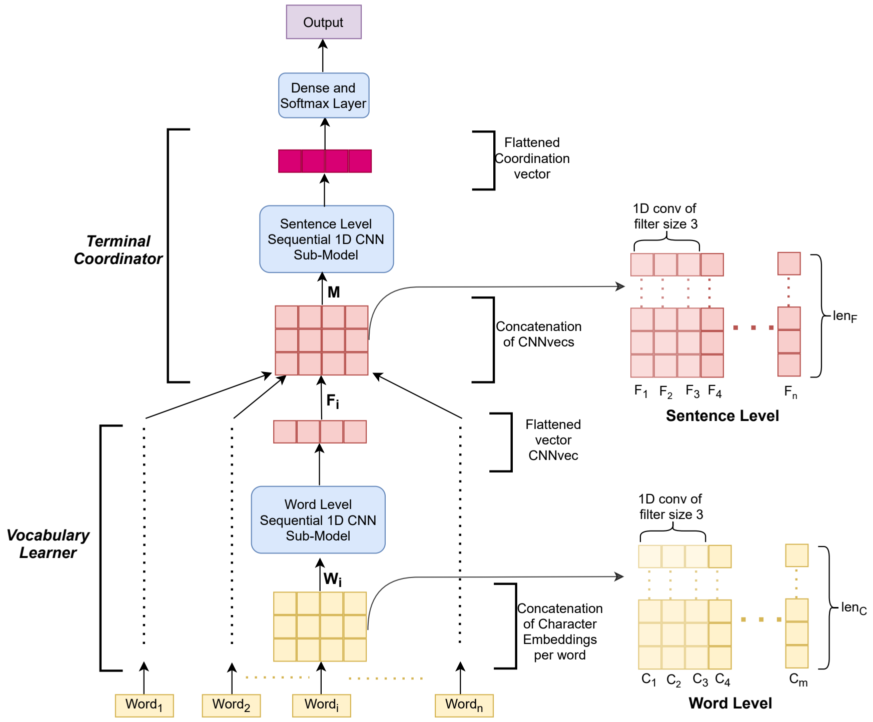


Figure 2: 1D CNN based CoCNN architecture

applying the same *CNN* sub-model.

2.2 *Terminal Coordinator*

Terminal Coordinator (TC) takes the *CNNvecs* obtained from *VL* as input and returns a single *Coordination vector* as output which is used for final prediction. For n words $Word_1, Word_2, \ldots Word_n$; we obtain n such *CNNvecs* $\vec{F_1}, \vec{F_2}, \ldots \vec{F_n}$, respectively. Each *CNNvec* is of size len_F. Concatenating these *CNNvecs* provide us with matrix M (details shown in the middle right portion of Figure 2). Applying 1D *conv* on matrix M facilitates the derivation of key local patterns found in input sentence/ paragraph which is crucial for output prediction. A sequential 1D CNN sub-model with design similar to *VL* having different sets of weights is employed on matrix M. *Conv* layers near M are responsible for identifying key word clusters, while *conv* layers further away focus on different combinations of these key word clusters important for sentence or paragraph level local pattern recognition. The final output feature matrix obtained from the 1D CNN sub-model of *TC* is flattened to obtain the *Coordination vector*, a summary of important information obtained from the input word sequence in order to predict the correct output.

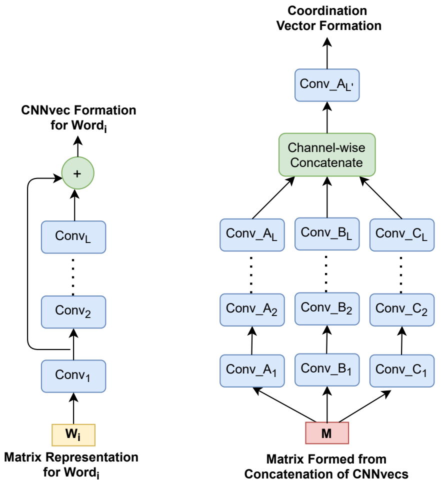

Figure 3: *CoCNN+* architecture with its modified *VL* (left) and *TC* (right). $Conv_L$ means L^{th} *conv* layer, whereas *Conv_A* means a *conv* layer with filter size A.

2.3 Extending CoCNN

We perform two simple modifications in *CoCNN* to form *CoCNN+* architecture with minimal increase in parameter number (see Figure 3).

First, we modify the CNN sub-model of *VL*. We add the output feature matrix of the first *conv* layer $Conv_1$ with the output feature matrix of the last *conv* layer $Conv_L$. We pass the resultant feature matrix on to subsequent layers (same as *CoCNN*) for *CNNvec* formation of $Word_i$. Such modification helps in two cases - (i) it eliminates the gradient vanishing problem of the first *conv* layer of *VL* and (ii) it gives *CNNvec* access to both low level and high level features of the corresponding input word.

Second, we modify the CNN sub-model of *TC* by passing matrix M simultaneously to three 1D CNN branches. The *conv* filter sizes of the left, middle and right branches are A, B and C, respectively; where, $A < B$ and $B < C$. The outputs from the three branches are concatenated channel-wise and are then passed on to the final *conv* layer having filter size A. The output feature matrix is passed on to subsequent layers (same as *CoCNN*) for *Coordination vector* formation. Multiple *conv* branches with different filter sizes help in learning both short and long range local patterns, especially when the input sentence or document is long.

3 Experimental Setup

3.1 Dataset Specifications

Bengali dataset consists of articles from online public news portals such as Prothom-Alo (Rahman, 2017), BDNews24 (Khalidi, 2015) and Nayadiganta (Mohiuddin, 2019). The articles encompass domains such as politics, entertainment, lifestyle, sports, technology and literature. The Hindi dataset consists of Hindinews (Pandey, 2018), Livehindustan (Shekhar, 2018) and Patrika (Jain, 2018) newspaper articles available open source in Kaggle encompassing similar domains. Nayadiganta (Bengali) and Patrika (Hindi) datasets have been used only as independent test sets. Detailed statistics of the datasets are provided in Table 1. Top words have been selected such that they cover at least 90% of the dataset. For each Bengali dataset, we have created a new version of the dataset by incorporating spelling errors using a probabilistic error generation algorithm (Sifat et al., 2020), which enables us to test the effectiveness of LMs for erroneous datasets.

3.2 Performance Metric

We use perplexity (PPL) to assess the performance of the models for next word prediction task. Suppose, we have sample inputs $I_1, I_2, \ldots, I_n$ and our model provides probability values $P_1, P_2, \ldots, P_n$, respectively for their ground truth output tokens. Then the PPL score of our model for these samples can be computed as:

$$PPL = \exp(-\frac{1}{n}\sum_{i=1}^{n}\ln(P_i))$$

For text classification and sentiment analysis, we use *accuracy* and *F1 score* as our performance metric.

3.3 Model Optimization

For model optimization, we use SGD optimizer with a learning rate of 0.001 while constraining the norm of the gradients to below 5 for exploding gradient problem elimination. We use Categorical Cross-Entropy loss for model weight update and dropout (Hinton et al., 2012) with probability 0.3 between the dense layers for regularization. We use Relu (Rectified Linear Unit) as hidden layer activation function. We use a batch size of 64. As we apply batch normalization on CNN intermediate outputs, we do not use any other regularization effect such as dropout on these layers (Luo et al., 2018).

We use Anaconda 3 with Python 3.8 version and Tensorflow 2.6.0 framework (Abadi et al., 2016) for our implementation. We use two GPU servers for training our models: (i) 12 GB Nvidia Titan Xp GPU, Intel(R) Core(TM) i7-7700 CPU (3.60GHz) processor model (ii) 32 GB RAM with 8 cores 24 GB Nvidia Tesla K80 GPU, Intel(R) Xeon(R) CPU (2.30GHz) processor model

3.4 CoCNN Hyperparameters

3.4.1 *Vocabulary Learner* Details

Vocabulary Learner sub-model consists of a character level embedding layer producing a 40 size vector from each character, then four consecutive layers each consisting of 1D convolution (batch normalization and Relu activation between each pair of convolution layers) and finally, a 1D global maxpooling in order to obtain *CNNvec* representation from each input word. The four 1D convolution layers consist of $(32, 2)$, $(64, 3)$, $(64, 3)$, $(128, 4)$ convolution, respectively. Here the first and second element of each tuple denote number of convolution filters and kernel size, respectively. As we can see, the filter size and number of filters of the convolution layers are monotonically increasing as architecture depth increases. It is because deep convolution layers need to learn the combination of various low level features which is a more difficult task compared to the task of shallow layers that include extraction of low level features.

Datasets	No. of Unique words	No. of Unique Characters	No. of Top Words	No. of Training Samples	No. of Validation Samples
Prothom-Alo	260 K	75	13 K	5.9 M	740 K
BDNews24	170 K	72	14 K	2.9 M	330 K
Nayadiganta	44 K	73	_	_	280 K
Hindinews	37 K	74	5.5 K	87 K	10 K
Livehindustan	60 K	73	4.5 K	210 K	20 K
Patrika	28 K	73	_	_	307 K

Table 1: Dataset details (K and M denote 10^3 and 10^6 multiplier, respectively)

3.4.2 *Terminal Coordinator* Details

The *Terminal Coordinator* sub-model used in *CoCNN* architecture uses six convolution layers which consist of $(32, 2), (64, 3), (64, 3), (96, 3), (128, 4), (196, 4)$ convolution. Its design is similar to that of *Vocabulary Learner* sub-model. The final output feature matrix obtained from this CNN sub-model is flattened to get the *Coordination vector*. After passing this vector through a couple of dense layers, we use *Softmax* activation function at the final output layer to get the predicted output.

3.5 CoCNN+ Hyperparameters

The CNN sub-model of *Vocabulary Learner* in *CoCNN+* is the same as *CoCNN* except for one aspect (see Figure 3) - we change the first convolution layer to have 128 filters of size 2 instead of 32 filters. This is done to respect the matrix dimensionality during skip connection based addition.

Instead of providing a sequential 1D CNN sub-model in *Terminal Coordinator*, we provide three parallel branches each consisting of four convolution layers (see Figure 3) where the filter numbers are 32, 64, 96 and 128. The filter size of the leftmost, middle and the rightmost branch are 3, 5 and 7, respectively. All convolution operations are dimension preserving through the use of padding. The feature matrices of all three of these branches are concatenated channel-wise and finally, this concatenated matrix is passed on to a final convolution layer with 196 filters of size 3.

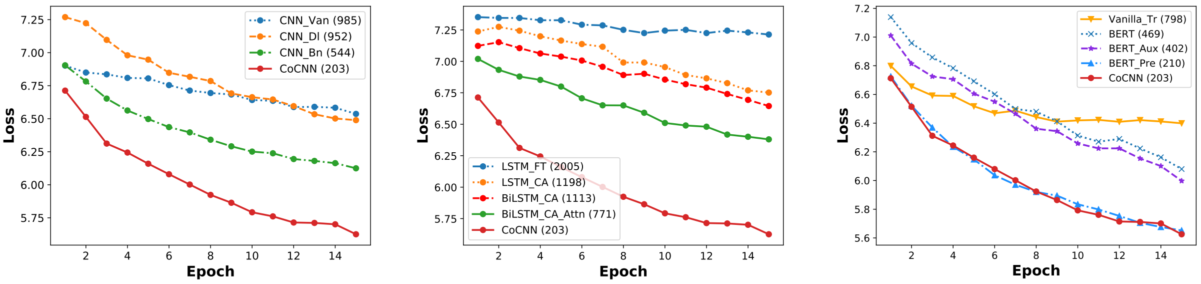
4 Results and Discussion

4.1 Comparing *CoCNN* with Other CNNs

We compare *CoCNN* with three other CNN-based baselines (see Figure 4a). *CNN_Van* is a simple sequential 1D CNN model of moderate depth (Pham et al., 2016). It considers the full input sentence/ paragraph as a matrix. The matrix consists of character representation vectors. *CNN_Dl* uses dilated *conv* in its CNN layers which allows the model to have a larger field of view (Roy, 2019). Such a change in *conv* strategy shows slight performance improvement. *CNN_Bn* has the same setting as of *CNN_Van*, but uses batch normalization on intermediate *conv* layer outputs. Such a measure shows significant performance improvement in terms of loss and PPL score. Proposed *CoCNN* surpasses the performance of *CNN_Bn* by a wide margin. We believe that the ability of *CoCNN* to consider each word of a sentence as a separate meaningful entity is the reason behind this drastic improvement.

4.2 Comparing *CoCNN* with SOTA LSTMs

We compare *CoCNN* with four LSTM-based models (see Figure 4b). Two LSTM layers are stacked on top of each other in all four of these models. We do not compare with LSTM models that use *Word2vec* (Rong, 2014) representation as this representation requires fixed size vocabulary. In spelling error prone setting, vocabulary size is theoretically infinite. We start with *LSTM_FT*, an architecture using sub-word based *FastText* representation (Athiwaratkun et al., 2018; Bojanowski et al., 2017). Character aware learnable layers per LSTM time stamp form the new generation of SOTA LSTMs (Mikolov et al., 2012; Kim et al., 2016; Gerz et al., 2018; Assylbekov et al., 2017). *LSTM_CA* acts as their representative by introducing variable size parallel *conv* filter output concatenation as word representation. The improvement over *LSTM_FT* in terms of PPL score is almost double. Instead of unidirectional many to one LSTM, we introduce bidirectional LSTM in *LSTM_CA* to form *BiLSTM_CA* which shows slight performance improvement. We introduce Bahdanu attention (Bahdanau et al., 2014) on *BiLSTM_CA* to form *BiLSTM_CA_Attn* architecture. Such measure shows further performance boost. *CoCNN* shows almost four times improvement in PPL score compared to *BiLSTM_CA_Attn*. If we compare Figure 4b and 4a, we can see that CNNs perform relatively better than LSTMs in general for Bengali



(a) CNN paradigm

(b) LSTM paradigm

(c) Transformer paradigm

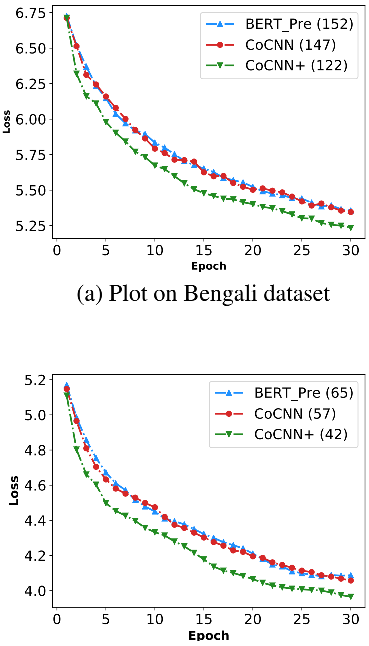
Figure 4: Comparing *CoCNN* with SOTA architectures from CNN, LSTM and Transformer paradigm on Prothom-Alo validation set. The score shown beside each model name denotes that model's PPL score on Prothom-Alo validation set after 15 epochs of training. Note that this dataset contains synthetically generated spelling errors.

LM. LSTMs have a tendency of learning sequence order information which imposes positional dependency. Such characteristic is unsuitable for Bengali and Hindi with flexible word order.

4.3 Comparing *CoCNN* with SOTA Transformers

We compare *CoCNN* with four Transformer-based models (see Figure 4c). We use popular *FastText* word representation with all compared transformers. Our comparison starts with *Vanilla_Tr*, a single Transformer encoder (similar to the Transformer designed by Vaswani et al. (2017)). In *BERT*, we stack 12 transformers on top of each other where each Transformer encoder has more parameters than the Transformer of *Vanilla_Tr* (Kenton and Toutanova, 2019; Irie et al., 2019). *BERT* with its large depth and enhanced encoders almost double the performance shown by *Vanilla_Tr*. We do not pretrain this *BERT* architecture. We follow the Transformer architecture designed by Al-Rfou et al. (2019) and introduce auxiliary loss after the Transformer encoders situated near the bottom of the Transformer stack of *BERT* to form *BERT_Aux*. Introduction of such auxiliary losses shows moderate improvement of performance. *BERT_Pre* is the pretrained version of *BERT*. We follow the word masking based pretraining scheme of Liu et al. (2019). The Bengali pretraining corpus consists of Prothom Alo (Rahman, 2017) news articles dated from 2014-2017 and BDNews24 (Khalidi, 2015) news articles dated from 2015-2017. The performance of *BERT* jumps up more than double when such pretraining is applied. *CoCNN* without utilizing any pretraining achieves marginally better performance than *BERT_Pre*. Unlike Transformer encoders, *conv* imposes attention with a view to extracting important patterns from the input to provide the correct output. Furthermore, *VL* of *CoCNN* is suitable for deriving semantic meaning of each input word in highly inflected and error prone settings.

4.4 Comparing *BERT_Pre*, *CoCNN* and *CoCNN+*



(a) Plot on Bengali dataset

(b) Plot on Hindi dataset

Figure 5: Comparing *BERT_Pre*, *CoCNN* and *CoCNN+* on Bengali (Prothom-Alo) and Hindi (Hindinews and Livehindustan merged) validation set. The score shown beside each model name denotes that model's PPL score after 30 epochs of training on corresponding training set.

BERT_Pre is the only model showing perfor-

Datasets	Error?	BERT_ Pre	Co-CNN	Co-CNN+
Prothom Alo	Yes	152	147	**122**
	No	117	114	**99**
BDNews 24	Yes	201	193	**170**
	No	147	141	**123**
Hindinews Hindustan	No	65	57	**42**
Naya Diganta	Yes	169	162	**143**
	No	136	133	**118**
Patrika	No	67	57	**44**

Table 2: PPL Score Comparison

mance close to *CoCNN* in terms of validation loss and PPL score (see Figure 4). We compare these two models with *CoCNN+*. We train the models for 30 epochs on several Bengali and Hindi datasets and obtain their PPL scores on corresponding validation sets (training and validation set were split at 80%-20% ratio). Bengali datasets include Prothom-Alo, BDNews24; while Hindi dataset includes Hindinews, Livehindustan. We use Nayadiganta and Patrika dataset for Bengali and Hindi independent test set, respectively. The Hindi pretraining corpus consists of Hindi Oscar Corpus (Thakur, 2019), preprocessed Wikipedia articles (Gaurav, 2019), HindiEnCorp05 dataset (Bojar et al., 2014) and WMT Hindi News Crawl data (Barrault et al., 2019). From the graphs of Figure 5 and PPL score comparison Table 2, it is evident that *CoCNN* marginally outperforms its nemesis *BERT_Pre* in all cases, while *CoCNN+* outperforms both *CoCNN* and *BERT_Pre* by a significant margin. There are 8 sets of PPL scores in Table 2 for the three models on eight different dataset settings. We use these scores to perform a one-tailed paired t-test in order to determine whether the reduction of PPL score seen in *CoCNN+* is statistically significant when P-value threshold is set to 0.05. The test shows that the improvement is indeed significant compared to both *BERT_Pre* and *CoCNN*. Number of parameters of *BERT_Pre*, *CoCNN* and *CoCNN+* are 74 M, 4.5 M and 4.8 M, respectively. Though the parameter number of *CoCNN+* and *CoCNN* is close, *CoCNN+* has 15X fewer parameters than *BERT_Pre*.

4.5 Comparison in Downstream Tasks

We have compared *BERT_Pre* and *CoCNN+* in three different downstream tasks:

Dataset	BERT_Pre	CoCNN+
Question Classify	0.905	**0.926**
Product Review	0.841	**0.86**
Hate Speech	0.77	**0.781**

Table 3: Performance comparison between *BERT_Pre* and *CoCNN+* in three downstream tasks (F1 score)

(1) **Bengali Question Classification (QC):** This task consists of six classes (entity, numeric, human, location, description and abbreviation type question). The dataset has 3350 question samples (Islam et al., 2016).
(2) **Hindi Product Review Classification:** The task is to classify a review into positive or negative class where the dataset consists of 2355 sample reviews (Kakwani, 2020).
(3) **Hindi Hate Speech Detection:** The task is to identify whether a provided speech is a hate speech or not. The dataset consists of 3654 speeches (HASOC, 2019).

We use **five fold cross validation** while performing comparison on these datasets (see mean results in Table 3) in terms of F1 score. One tailed independent t-tests with a P-value threshold of 0.05 has been performed on the 5 validation F1 scores obtained from five fold cross validation of each of the two models. Our **statistical test** results validate the significance of the improvement shown by *CoCNN+* for all three of the mentioned tasks.

Spell Checker Algorithm	Synthetic Error	Real Error
Vocabulary Learner	71.1%	61.1%
Phonetic Rule	61.5%	32.5%
Clustering Rule	51.8%	43.8%

Table 4: Bengali spelling correction (accuracy)

We also investigate the potential of *VL* of *CoCNN+* as a Bengali spell checker (SC). Both *CoCNN* and *CoCNN+* model use *VL* for producing CNNvec representation from each input word. We extract the CNN sub-model of *VL* from our trained (on Prothom-Alo dataset) *CoCNN+* model. We produce CNNvec for all 13 K top words of Prothom-Alo dataset. For any error word, W_e, we can generate its CNNvec V_e using *VL*. We can calculate cosine similarity, Cos_i between V_e and CNNvec

V_i of each top word W_i. Higher cosine similarity means greater probability of being the correct version of W_e. We have discovered such approach to be effective for correct word generation. Recently, a phonetic rule based approach has been proposed by Saha et al. (2019), where a hybrid of Soundex (UzZaman and Khan, 2004) and Metaphone (UzZaman and Khan, 2005) algorithm has been used for Bengali word level SC. Another SC proposed in recent time has taken a clustering based approach (Mandal and Hossain, 2017). We compare our proposed *VL* based SC with these two existing SCs (see Table 4). Both the real and synthetic error dataset consist of 20k error words formed from the top 13 K words of Prothom-Alo dataset. The real error dataset has been collected from a wide range of Bengali native speakers using an easy to use web app. Results show the superiority of our proposed SC over existing approaches.

5 Related Works

Although a significant number of works for LM of high resource languages like English and Chinese are available, very few researches of significance for LM in low resource languages like Bengali and Hindi exist. In this section, we mainly summarize major LM related research works.

Sequence order information based statistical RNN models such as LSTM and GRU have been popular for LM tasks (Mikolov et al., 2011). Sundermeyer et al. (2012) showed the effectiveness of LSTM for English and French LM. The regularizing effect on LSTM was investigated by Merity et al. (2017). SOTA LSTM models learn sub-word information in each time stamp. Bojanowski et al. (2017) proposed a morphological information oriented character N-gram based word vector representation. It was improved by Athiwaratkun et al. (2018) and is known as FastText. Mikolov et al. (2012) proposed a technique for learning sub-word level information from data, while such an idea was integrated in a character aware LSTM model by Kim et al. (2016). Takase et al. (2019) further improved word representation by combining ordinary word level and character-aware embedding. Assylbekov et al. (2017) showed that character-aware neural LMs outperform syllable-aware ones. Gerz et al. (2018) evaluated such models on 50 morphologically rich languages.

Self attention based Transformers have become the SOTA mechanism for sequence to sequence modeling in recent years (Vaswani et al., 2017). Some recent works have explored the use of such models in LM. Deep Transformer encoders outperform stacked LSTM models (Irie et al., 2019). A deep stacked Transformer model utilizing auxiliary loss was proposed by Al-Rfou et al. (2019) for character level language modeling. The multi-head self attention mechanism was replaced by a multi-linear attention mechanism with a view to improving LM performance and reducing parameter number (Ma et al., 2019). Bengali and Hindi language, having unique characteristics, remain open as to what strategy to use for model development in such domains.

One dimensional version of CNNs have been used recently for text classification oriented tasks (Wang et al., 2018; Moriya and Shibata, 2018; Le et al., 2018). Pham et al. (2016) studied CNN application in LM showing the ability of CNNs to extract LM features at a high level of abstraction. Furthermore, dilated *conv* was employed in Bengali LM with a view to solving long range dependency problem (Roy, 2019).

6 Conclusion

We have proposed *Coordinated CNN (CoCNN)* that introduces two 1D CNN based key concepts: word level *VL* and sentence level *TC*. Detailed investigation in three deep learning paradigms (CNN, LSTM and Transformer) shows the effectiveness of *CoCNN* in Bengali and Hindi LM. We have also shown a simple but effective enhancement of *CoCNN* by introducing skip connection and parallel *conv* branches in the *VL* and *TC* portion, respectively. Future research may incorporate interesting ideas from existing SOTA 2D CNNs in *CoCNN*. Over-parametrization and innovative scheme for *CoCNN* pretraining are expected to increase its LM performance even further. Code has been provided as supplementary material. Dataset will be made publicly available upon acceptance.

Abstract

Recent language generative models are mostly trained on large-scale datasets, while in some real scenarios, the training datasets are often expensive to obtain and would be small-scale. In this paper we investigate the challenging task of less-data constrained generation, especially when the generated news headlines are short yet expected by readers to keep readable and informative simultaneously. We highlight the key information modeling task and propose a novel duality fine-tuning method by formally defining the probabilistic duality constraints between key information prediction and headline generation tasks. The proposed method can capture more information from limited data, build connections between separate tasks, and is suitable for less-data constrained generation tasks. Furthermore, the method can leverage various pre-trained generative regimes, e.g., autoregressive and encoder-decoder models. We conduct extensive experiments to demonstrate that our method is effective and efficient to achieve improved performance in terms of language modeling metric and informativeness correctness metric on two public datasets.

1 Introduction

In an age of information explosion, headline generation becomes one fundamental application in the natural language process (NLP) field (Tan et al., 2017; Li et al., 2021). Currently, the headline generation is usually regarded as a special case of general text summarization. Therefore, many cutting-edge techniques based on pre-trained models and fine-tuning methods can be directly adapted by feeding headline generation datasets (Zhang et al., 2020b; Gu et al., 2020). Actually, compared with those textual summaries, headline generation aims at generating only one sentence or a piece of short texts given a long document (e.g., a news article). It is challenging to guarantee the generated headline readable and informative at the same time, which is important to attract or inform readers especially for news domain (Matsumaru et al., 2020).

Recently, some works find that neglecting the key information would degrade the performance of generative models which only consider capturing natural language (Nan et al., 2021b). Then many works about modeling different kinds of key information have been studied to enhance the information correctness of generative summaries. For example, overlapping salient words between source document and target summary (Li et al., 2020), keywords (Li et al., 2018), key phrases (Mao et al., 2020) and named entities (Nan et al., 2021a) are involved to design generative models. However, those works are mostly either trained on large-scale datasets or targets for long summaries (Ao et al., 2021). In some real applications, it is expensive to obtain massive labeled data. Thus it becomes a much more challenging task that how to generate short headlines which should be both readable and informative under less-data constrained situations.

To model the key information, existing works often follow the assumption that a generated summary essentially consists of two-fold elements: the natural language part and the key information part. The former focuses on language fluency and readability, while the later is for information correctness. For this reason, an additional task of key information prediction is leveraged and the multi-task learning method is employed (Li et al., 2020; Nan et al., 2021a). Figure 1 can illustrate the intuitive idea more clearly, and the bold parts can be treated as the key information (overlapping salient tokens), which should be modeled well to inform correct and sufficient information for readers.

To achieve the above motivation, technically, applying existing fine-tuning and multi-task learning methods to headline generation can be a natural choice. However they have some drawbacks. Firstly, single-task normal fine-tuning methods cannot explicitly model the key information well and

hence reduce the informative correctness of generated headlines. Secondly, multi-task fine-tuning methods should improve the model ability by sharing the encoder and tailing two classifiers for key information prediction task and headline generation task, respectively. In fact, due to the limited dataset scale, the shared encoder could not be trained well to significantly distinguish the tasks or enhance each other mutually. As a result, vanilla multi-task methods could achieve little benefit for generation tasks (Nan et al., 2021a; Magooda et al., 2021). Our empirical experiments later can also show this point. Therefore, existing single-task or multi-task fine-tuning methods cannot perform well under less-data constrained situations.

In this paper, we set out to address the above mentioned issues from the following two aspects. On the one hand, to explicitly model the key information, we still adopt the multi-task paradigm, while the two tasks utilize their own models. Then we argue that the two tasks have probabilistic connections and present them in dual forms. In this way, the key information is explicitly highlighted, and setting two separate models to obey duality constraints cannot only make the model more capable to distinguish tasks but also capture the relation between tasks. On the other hand, to capture more data knowledge from limited dataset, besides the source document, headlines and key tokens are additionally used as input data for the key information prediction task and headline generation task respectively. We call this method as **duality fine-tuning** which obeys the definition of dual learning (He et al., 2016; Xia et al., 2018). Moreover, we develop the duality fine-tuning method to be compatible with both autoregressive and encoder-decoder models (LM).

To evaluate our method, we collect two datasets with the key information of overlapping salient tokens[1] in two languages (English and Chinese), and leverage various representative pre-trained models (BERT (Devlin et al., 2019), UniLM (Dong et al., 2019) and BART (Lewis et al., 2020)). The extensive experiments significantly demonstrate the effectiveness of our proposed method to produce more readable (on Rouge metric) and more informative (on key information correctness metric) headlines than counterpart methods, which indicates that our method is consistently useful with various pre-trained models and generative regimes.

In summary, the main contributions include:

- We study a new task that how to improve performance of headline generation under less-data constrained situations. We highlight to model the key information and propose a novel duality fine-tuning method. To our best knowledge, this is the first work to integrate dual learning with fine-tuning paradigm for the task of headline generation.

- The duality fine-tuning method which should model multiple tasks to obey the probabilistic duality constraints is a new choice suitable for less-data constrained multi-task generation, in terms of capturing more data knowledge, learning more powerful models to simultaneously distinguish and build connections between multiple tasks, and being compatible with both autoregressive and encoder-decoder generative pre-trained models.

- We collect two small-scale public datasets in two languages. Extensive experiments prove the effectiveness of our method to improve performance of readability and informativeness on Rouge metric and key information accuracy metric.

2 Related Work

Usually, headline generation is regarded as a special task of general abstractive text summarization, and the majority of existing studies could be easily adapted to headline generation by feeding headline related datasets (Matsumaru et al., 2020; Yamada et al., 2021). For example, sequence-to-sequence based models are investigated for text summarization, which emphasizes on generating fluent and natural summaries (Sutskever et al., 2014; Nallapati et al., 2016; Gehring et al., 2017; See et al., 2017). In recent years, the large-scale transformer-based models (Devlin et al., 2019; Dong et al., 2019;

[1] We expect our method to be orthogonal to specific key information definition.

Lewis et al., 2020) and the two-stage (pre-training and fine-tuning) learning paradigm (Zhang et al., 2019; Gehrmann et al., 2019; Rothe et al., 2020) have greatly promoted the performance of most NLP tasks. And headline generation can also benefit from those works.

Since the length of headlines is often short and almost 'every word is precious', compared to general text summarization, modeling the key information is better worth of paying attention (Li et al., 2020; Mao et al., 2020; Zhu et al., 2021b; Nan et al., 2021a; Zhu et al., 2021a). However, to our knowledge, little work focuses on this problem for headline generation, especially under the less-data constrained situations, and mostly they focus on low-resource long text summarization (Parida and Motlicek, 2019; Bajaj et al., 2021; Yu et al., 2021).

Recent years witness the rapid development of transformers-based pre-trained models (Wolf et al., 2020) and two kinds of regimes of natural language generation (NLG) are prevalent (Li and Liang, 2021). One is based on autoregressive language models which have a shared transformer encoder structure for encoding and decoding (Devlin et al., 2019; Dong et al., 2019; Zhuang et al., 2021), while the other is based on the standard transformer framework which has two separate encoder-decoder structures (Lewis et al., 2020; Zhang et al., 2020a). Fine-tuning and multi-task learning on them to reuse the ability of pre-trained models are widely studied for various tasks (Liu and Lapata, 2019; Rothe et al., 2020; Gururangan et al., 2020). Our work can also align with this research line and we propose a new multi-task fine-tuning method.

We leverage the core idea of dual learning, which can fully mine information from limited data and well model multiple tasks by designing duality constraints (He et al., 2016; Xia et al., 2018). This learning paradigm has been successfully applied to many fields, such as image-to-image translation (Yi et al., 2017), recommendation system (Sun et al., 2020), supervise and unsupervised NLU and NLG (Su et al., 2019, 2020). Those works have demonstrated that duality modeling is suitable for small-scale training situations.

3 Problem Definition

In this section, we formally present our problem. The training set is denoted as $\mathcal{X} = (\mathcal{D}, \mathcal{H}, \mathcal{K})$, where $\mathcal{D}$ and $\mathcal{H}$ are the sets of source documents and target headlines. $\mathcal{K}$ is the set of key information, which indicates the overlapping salient tokens (stopwords excluded) in each pair of document and headline. A training sample is denoted as a tuple (d, h, k). $d = \{x_1^{(d)}, x_2^{(d)}, ..., x_n^{(d)}\}$, $h = \{x_1^{(h)}, x_2^{(h)}, ..., x_m^{(h)}\}$, $k = \{x_1^{(k)}, x_2^{(k)}, ..., x_l^{(k)}\}$, where $x_i^{(*)}$ is a token of document, headline or key information, and n, m, l are the lengths of respective token sequences.

3.1 Definition of Dual Tasks

Given the input data $x = (d, h, k)$, we define our problem in a dual form, which contains two tasks. Formally, the key information prediction task aims at finding a function $f : (d, h) \to k$, which maximizes the conditional probability $p(k|d, h; \theta)$ of the real key information k. Correspondingly, the headline generation task targets at learning a function $g : (d, k) \to h$, which maximizes the conditional probability $p(h|d, k; \varphi)$ of real headline h. The two tasks can be defined as follows:

$$f(d, h; \theta) \triangleq \arg\max \prod_{x \in \mathcal{X}} p(k|d, h; \theta),$$
$$g(d, k; \varphi) \triangleq \arg\max \prod_{x \in \mathcal{X}} p(h|d, k; \varphi).$$

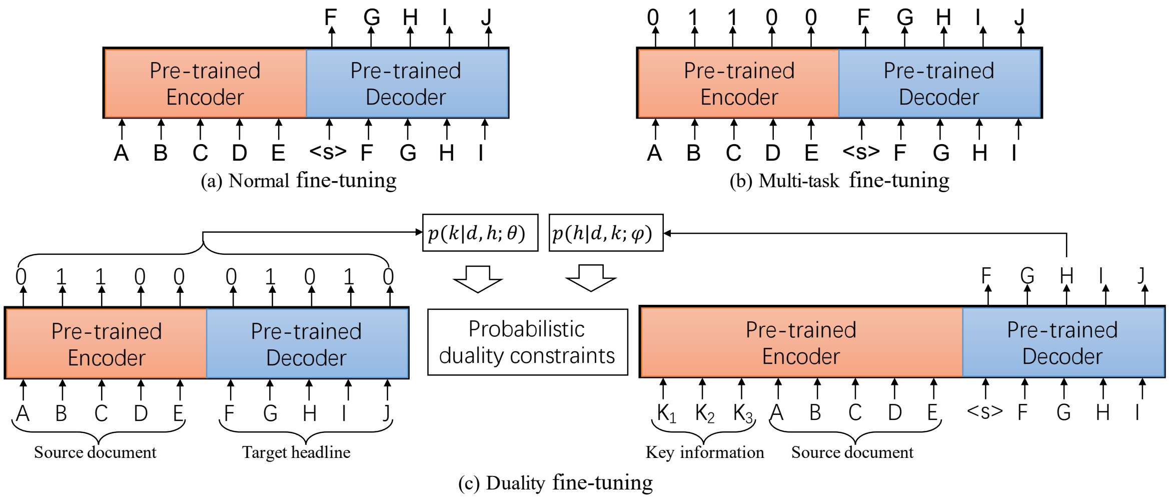
3.2 Probabilistic Duality Constraints

Based on the principle of dual learning paradigm (He et al., 2016), we treat the key information prediction task as primary task and the headline generation task as secondary task. Ideally, if the primary model and secondary model are both trained optimally, the probabilistic duality between the two tasks should satisfy the following equation:

$$\begin{aligned} p(\mathcal{X}) &= \prod_{x \in \mathcal{X}} P(d, k, h) = \prod_{x \in \mathcal{X}} p(d) p(h|d; \hat{\varphi}) p(k|d, h; \theta) \\ &= \prod_{x \in \mathcal{X}} p(d) p(k|d; \hat{\theta}) p(h|d, k; \varphi). \end{aligned}$$

$p(k|d, h; \theta)$ and $p(h|d, k; \varphi)$ are the target models to learn, while $p(k|d; \hat{\theta})$ and $p(h|d; \hat{\varphi})$ denote the marginal distribution models. By integrating the above probabilistic duality equation and further dividing the common term $p(d)$, our problem can be formally defined to optimize the objectives:

$$\begin{aligned} &\text{Objective 1} : \min_{\theta} \frac{1}{|\mathcal{X}|} \sum_{x \in \mathcal{X}} l_1(f(d, h; \theta), k), \\ &\text{Objective 2} : \min_{\varphi} \frac{1}{|\mathcal{X}|} \sum_{x \in \mathcal{X}} l_2(g(d, k; \varphi), h), \\ &\text{s.t.} \prod_{x \in \mathcal{X}} p(h|d; \hat{\varphi}) p(k|d, h; \theta) = \prod_{x \in \mathcal{X}} p(k|d; \hat{\theta}) p(h|d, k; \varphi), \end{aligned} \tag{1}$$



(a) Normal fine-tuning

(b) Multi-task fine-tuning

(c) Duality fine-tuning

Figure 2: The overview of different fine-tuning methods. (a) is normal fine-tuning for single-task headline generation. (b) is multi-task fine-tuning which has an additional task of predicting the salient tokens among inputs with the encoder. (c) is the proposed duality fine-tuning which owns two separate models and more information as input by sticking to probabilistic duality constraints. Note that all the paired pre-trained encoder and decoder can be instanced as autoregressive LM (e.g., UniLM) or encoder-decoder (e.g., BART) regimes.

where l_1 is the loss function for key information prediction and l_2 is that for headline generation.

4 Duality Fine-tuning Methodology

4.1 Overview

Before introducing the duality fine-tuning method, we would review the normal fine-tuning and multi-task fine-tuning methods. As shown in Figure 2, the (a) normal fine-tuning method is single-task and optimizes the generative model with new dataset by leveraging the same structure of pre-trained models. To explicitly model the key information, (b) multi-task fine-tuning method would use an additional task to binarily predict salient tokens, where 1 means key information and 0 means not. Here the two tasks share the common encoder.

Different from the above two methods, although the (c) duality fine-tuning method is also a multi-task paradigm, however it shows totally different structure and process in terms of the following three aspects. Firstly, the two tasks own their respective encoder and decoder pairs inherited from a consistent pre-trained model structure. Secondly, the each model can be fed with more input information than normal and multi-task fine-tuning, i.e. key information prediction task can further utilize the headline data while headline generation task can extra utilize the data of key tokens. Thirdly, the two tasks should stick to the probabilistic duality constraints to build connections between the two tasks by Eq. 1.

Note that all the three methods in Figure 2 are compatible with autoregressive language models (the encoder and decoder are integrated in one transformer encoder like UniLM) and encoder-decoder models (standard transformer structure like BART).

4.2 Model for Key Information Prediction

Given the pair of source document and target headline as inputs, we expect the model to predict the key information and learn the pattern that the information is present at both sides. We regard the prediction task as binary classification for every token: $\hat{y}^{(k)} = p(k|d,h;\theta) = p(y^{(k)}|x^{(d)}, x^{(h)};\theta) = \{0,1\}^{n+m}$. The last hidden state layers of encoder and decoder are tailed with the multi-layer perception (MLP) to make binary predictions by using sigmoid classifier.

If the relied pre-trained model is autoregressive, the encoder and decoder would belong to a shared transformer encoder structure, and if the encoder-decoder pre-trained model is leveraged, there can be a standard transformer structure. The objective function l_1 of Objective 1 in Eq. 1 can be rewritten by using the cross entropy loss function:

$$l_1 = -\sum_{z=1}^{n+m} (y_z^{(k)} \log(\hat{y}_z^{(k)}) + (1-y_z^{(k)}) \log(1-\hat{y}_z^{(k)})). \quad (2)$$

4.3 Model for Headline Generation

Given the source document and key information, we expect the model to learn that the tokens put ahead source document are explicitly highlighted and they are important to generate headlines. The generation process of headline is by once a token and generating current token is based on attending the key information, source document and already generated tokens. The formal calculation of predicting the j-th token is: $\hat{y}_j^{(h)} = p(y_j^{(h)}|x^{(d)}, x^{(k)}, y_{<j}^{(h)}; \varphi)$. The last hidden state layer of the decoder is connected by a softmax function to generate tokens one by one. The details of generation process can be referred from the original literatures of adopted pre-trained models.

Similar to the corresponding key information prediction task, the same transformer encoder structure is adopted for autoregressive LMs and the standard transformer structure is for encoder-decoder LMs. The objective function l_2 of Objective 2 in Eq. 1 can be formally rewritten by using the cross entropy loss function:

$$l_2 = -\sum_{j=1}^{m} y_j^{(h)} \log(\hat{y}_j^{(h)}). \tag{3}$$

4.4 Training & Testing by Duality Fine-tuning

To optimize the Objective 1 and Objective 2 under the duality constraints in Eq. 1, we transform the constraint as a calculable regularization term:

$$\begin{aligned} l_{duality} = \sum_{x \in \mathcal{X}} [&\log p(h|d; \hat{\varphi}) + \log p(k|d, h; \theta) \\ &- \log p(k|d; \hat{\theta}) - \log p(h|d, k; \varphi)]^2, \end{aligned} \tag{4}$$

where $p(k|d; \hat{\theta})$ and $p(h|d; \hat{\varphi})$ are the marginal distribution models for key information prediction and headline generation respectively.

Marginal Distribution Models We define the marginal distribution models to calculate the duality regularization term $l_{duality}$. The marginal models can be obtained by just simplifying their corresponding dual models. For example, marginal key information prediction model is single-task token classification and only adopts the encoder part as $p(\mathcal{K}|\mathcal{D}; \hat{\theta}) = \prod_{x \in \mathcal{X}} \prod_{i=1}^{n} p(x_i^{(d)})$, while marginal headline generation is the normal fine-tuning task by calculating $p(\mathcal{H}|\mathcal{D}; \hat{\varphi}) = \prod_{x \in \mathcal{X}} \prod_{j=1}^{m} p(y_j^{(h)}|x^{(d)}, y_{<j}^{(h)})$.

Since the two marginal distribution models are only involved in the calculation of regularization term $l_{duality}$ and will not be updated during the process of training dual models, they could be offline trained in advance. So in order to save the memory cost during duality fine-tuning, the predicted marginal key information, generated marginal headlines and their losses for each training sample can be calculated and stored beforehand.

Dual Model Training After defining the duality regularization term and marginal models, we can obtain the calculable loss functions for duality fine-tuning by combining Eq.1 and Eq.4 as the following:

$$\begin{aligned} \mathcal{L}_1 = \min_{\theta} \frac{1}{|\mathcal{X}|} \sum_{x \in \mathcal{X}} (&- \sum_{z=1}^{n+m} (y_z^{(k)} \log(\hat{y}_z^{(k)}) \\ &+ (1 - y_z^{(k)}) \log(1 - \hat{y}_z^{(k)})) + \lambda_1 l_{duality}), \end{aligned} \tag{5}$$

$$\mathcal{L}_2 = \min_{\theta} \frac{1}{|\mathcal{X}|} \sum_{x \in \mathcal{X}} (- \sum_{j=1}^{m} y_j^{(h)} \log(\hat{y}_j^{(h)}) + \lambda_2 l_{duality}), \tag{6}$$

where λ_1 and λ_2 denote the weights of the duality terms to control the impact of the duality constraints on the model optimization. The detailed algorithm for training is described in Algorithm 1. Line 1-2 denote the model pre-training and parameter initialization. Line 5-12 are the one-step optimization for a mini-batch of training data, and the model should compute (or retrieve) the marginal losses and model losses (l_1 and l_2) successively.

Algorithm 1: Training for Duality Fine-tuning

```
Input: The training dataset $\mathcal{X} = [\mathcal{D}, \mathcal{H}, \mathcal{K}]$
Output: Dual model parameters $\theta$ and $\varphi$
1  Pre-train marginal models $p(k|d; \hat{\varphi})$ and $p(h|d; \hat{\theta})$;
2  Initialize all trainable parameters of $p(k|d, h; \theta)$ and
     $p(h|d, k; \varphi)$, set $t = 1$;
3  while $t < T$ do
4      foreach mini-batch [d,h,k] do
5          Compute (or retrieve) marginal losses;
6          Compute model losses with Eq.2 and Eq.3;
7          Update dual model losses by Eq.5 and Eq.6;
8          Optimize $\theta$ for dual model $p(k|d, h; \theta)$;
9          Optimize $\varphi$ for dual model $p(h|d, k; \varphi)$;
10     end
11 end
12 return optimized $\theta$ and $\varphi$.
```

Dual Model Testing In the testing stage, we only have the documents as input and do not have the real key information and headlines. In order to save the run-time memory and computing resource cost, we use an open tool spaCy[2] to extract the key information from the source document to approximate the tokens predicted by the dual key information prediction model, and therefore only one dual model, i.e., the dual headline generation model, is loaded into memory for making generation.

Table 2: Comparison of Rouge and key information accuracy (%) on THUCNews-3k dataset.

5 Experiments

5.1 Datasets

To evaluate the duality fine-tuning's effectiveness, we collect two public corpora, Gigaword (Rush et al., 2015) and THUCNews (Li and Sun, 2007). The overlapping words (stop-words excluded) between each pair of source document and target headline are regarded as the key information.

Gigaword is in English and collected from news domain. We randomly extract 3,000/500/500 samples for model training/validating/testing from the original corpus[3], to approximate a less-data constrained situation. Here all the samples must contain key information.

THUCNews is in Chinese and collected from the Sina News website[4]. Each sample contains a headline and a news article. We pre-process this dataset by also randomly extracting 3,000/500/500 training/validating/testing samples and all of them contain key information.

5.2 Baselines and Metrics

We compare the duality fine-tuning (Duality) with normal fine-tuning (Normal) and multi-task fine-tuning methods (Multi-task). Additionally, the Normal method has a variant (Normal+) that replaces the original input (source document) with key-token-enhanced input (key tokens+source document). We adopt base-scale versions of BERT, UniLM and BART as pre-trained models which are all representative either for autoregressive LMs or encoder-decoder regimes among NLG tasks.

We use the F1-version Rouge (Lin, 2004) to measure the comprehensive performance of language modeling on both the token-level precision and recall factors. To evaluate the informativeness accuracy, macro and micro prec$_t$, recall$_t$, and F1$_t$ (Nan et al., 2021a) (denoting precision, recall, and F1 between generated and ground-truth salient tokens) are used. Readers can refer to the literature for details of calculating formulas.

5.3 Experimental Settings

In all experiments, we keep the consistent default parameters with the pre-trained models during fine-

Table 3: Human evaluation results on readability (Read.) and informativeness (Info.) of generated headlines.

tuning. All the models are trained for at least 10 epochs, and the experimental results are the average values from 5 runs of modeling learning. The batch size is set as 64 for normal/multi-task/marginal training and 16 for duality training, since dual learning would occupy more memory to reflect two models. However, during validating and testing phases, all the methods would spend the similar memory and computing resources. The learning rate is set 1e-5 for English dataset and 5e-5 for Chinese dataset. The max lengths of document and headline tokens for Gigaword is set 192 and 64, and those for THUCNews are 512 and 30. The beam search size for testing is set 5. Empirically by trying a grid search strategy, we set $\lambda_1 = 0.2$, $\lambda_2 = 0.8$ to emphasize the dual task of headline generation. Other detailed parameters can refer to the original literature of pre-trained models.

5.4 Automatic Evaluation

Performance on 3K datasets We adopt the data size of 3,000 (3K) to approximate the less-data constrained situation, because usually it is easy to hand-crafted label 3K (or comparable quantity) samples. Table 1 and Table 2 present the performance of generation (left part) and key information accuracy (right part) on Gigaword-3k dataset and THUCNews-3k dataset, respectively. From the left part in Table 1, we find Duality fine-tuning method can achieve the superior scores almost with all the pre-trained models. From the right part for key information accuracy (micro and macro prec$_t$, recall$_t$ and F1$_t$), duality fine-tuning method can also greatly enhance the informative correctness, especially using BART as pre-trained models.

From the left part of Table 2, Duality fine-tuning method performs much better than Normal (and Normal+) fine-tuning and Multi-task fine-tuning methods. The table's right part also suggests the consistent effectiveness that duality method can generate more informative and accurate headlines with small-scale training datasets. Comparing with Table 1 and Table 2, the results may indicate that duality fine-tuning should be more suitable for Chinese than English datasets due to the more stable and higher observed improvement with different pre-trained models.

The two tables could reflect some observations. First, our duality fine-tuning method is generally and effectively applied to various generative pre-trained models, e.g. autoregressive LM (BERT and UniLM) and encoder-decoder (BART) regimes. Then, our method performs much better on BART than on the others, we think, because encoder-decoder models have separate transformer networks instead of only adopting the encoder structure, providing the more powerful model ability and larger model scale, which is friendly for less-data constrained situations. Moreover, the results in the two tables can also demonstrate that Duality fine-tuning method is effective to capture more data knowledge from limited data by using two separate dual models corresponding to tasks, and the designed probabilistic duality constraints are effective to build connections and enhance generation.

Performance on various sizes of datasets To investigate more less-data situations, from the original large-scale corpora, we randomly collect different sizes of training datasets ranging from 1,000 (1K) to 10,000 (10K) with a interval of 1,000. Thus we have ten training sets for Gigaword and THUCNews respectively. Figure 3 illustrates the Rouge-1 and Micro-F1 scores correspondingly on language modeling metric and informative correctness on

Duality	496s	167s	376s	115s

Table 5: Time cost of model training for one epoch and inferring the testing sets with BART as the backbones.

pre-trained BART. We can see the Duality and Normal+ methods can significantly improve the performance along with the increasing of data size, while Normal and Multi-task methods can obtain slight improvement. It is probably evident that leveraging the key information is beneficial for headline generation under less-data situations, and explicit modeling the information like Duality fine-tuning, instead of just putting key tokens ahead source document (i.e. Normal+), can capture more data knowledge especially when the dataset scale is small.

5.5 Human Evaluation

Human Grading We perform human evaluation from the perspectives of readability and informativeness, which is to assess if the generated headlines are whether readable and informative for humans. We randomly sample 100 samples from the test sets of Gigaword and THUCNews datasets. We choose the generated headlines by using pre-trained BART models. Then the source documents, reference headlines, and generated headlines are randomly shuffled and shown to a group of people for evaluation. They cannot see the sources of headlines, i.e., from reference or inference. They need to judge the two aspects of readability and informativeness by giving an integer score in the range of 1-5, with 5 being perfect. Each sample is assessed by 5 people, and the average scores are used as the final score. To keep the labeling quality and further reduce bias, we normalize the scores of each people by z-score normal distribution.

As shown in Table 3, we find that the Duality gets best or best -comparable readability scores among the three evaluated methods. For the informativeness, Duality method can significantly perform best, which demonstrates its effectiveness to generate informative headlines. Comparing the scores of generated headlines and ground-truth references, there is still a large gap between model-generated and human-composed headlines, especially on the Chinese dataset THUCNews.

Case Study We analyze 50 test samples from the Gigaword and THUCNews, and compare the generated headlines with different methods. Table 4 shows the results of respective five samples. The ground-truth or generated key information are marked by gray highlights. We find that Duality performs better than other methods in most cases. For example, in the second and fifth cases of Gigaword cases in Table 4, Duality can generate more key information tokens than others, as well as the examples from THUCNews cases. We also observe that Dulity could perform better on Chinese data, perhaps because Chinese headlines have higher ratio of key tokens among the token sequence.

Error Analysis From the above 50 test samples, we also observe some bad cases generated by our method. We categorize them to several common types of error: incomplete key information (8 cases), repeats (5 cases), wrong key information (4 cases), and not coherent language (8 cases). And they should be investigated in the future work.

5.6 Computational Cost Analysis

During the model training phase, since Duality fine-tuning method should learn two separate dual models for each task, i.e. one more than the other baselines, it is inevitable that Duality method would spend more computing time and twice memory space. During the testing phase, since we only use one model to generate headlines, the computing cost of Duality method is comparable to the others. Table 5 shows the computing time cost of each method with BART as pre-trained models on 3k training datasets and 500 testing datasets via one 32G-V100 GPU. We can see that although training one-epoch dual models would spend more time than other methods, the absolute spent time is still acceptable and efficient considering the less-data situations and the performance improvement.

6 Conclusion

In this paper, we introduce a novel task that how to improve the performance of less-data constrained headline generation. We highlight to explicitly exploit the key information, and propose a novel duality fine-tuning method which firstly integrates dual learning paradigm and fine-tuning paradigm for less-data generation. The proposed method should obey the probabilistic duality constraints, which are critical to model multiple tasks. Therefore, the method can model more supervised information, learn more knowledge, and train more powerful generative models. Our method can also be generally applied to both autoregressive and encoder-decoder generative regimes. We collect various sizes of small-scale training datasets from two public corpora in English and Chinese, and the extensive experimental results prove our method effectively improve the readability and informativeness of generated headlines with different pre-trained models.

Abstract

Mitigating bias in training on biased datasets is an important open problem. Several techniques have been proposed, however the typical evaluation regime is very limited, considering very narrow data conditions. For instance, the effect of target class imbalance and stereotyping is under-studied. To address this gap, we examine the performance of various debiasing methods across multiple tasks, spanning binary classification (Twitter sentiment), multi-class classification (profession prediction), and regression (valence prediction). Through extensive experimentation, we find that data conditions have a strong influence on relative model performance, and that general conclusions cannot be drawn about method efficacy when evaluating only on standard datasets, as is current practice in fairness research. *Our code is available at:* *https://github.com/HanXudong/Systematic_Evaluation_of_Predictive_Fairness*.

1 Introduction and Background

Naively-trained models have been shown to encode and amplify biases in the training dataset, and exhibit performance disparities across author demographics (Hovy and Søgaard, 2015; Li et al., 2018; Wang et al., 2019). Various methods have been proposed to mitigate such biases, such as balanced training (Zhao et al., 2018; Han et al., 2022a), adversarial debiasing (Elazar and Goldberg, 2018; Han et al., 2021), and null-space projection (Ravfogel et al., 2020, 2022). However, experiments have largely been conducted on a handful of benchmark datasets such as **Moji** sentiment analysis (Blodgett et al., 2016) and **Bios** biography classification (De-Arteaga et al., 2019), under a narrow set of data conditions.

In this paper, we systematically explore the impact of data conditions on model accuracy and fairness, synthesising the following data conditions over real-world datasets: (1) target label (im)balance; (2) protected attribute (im)balance; (3) target label–protected attribute (im)balance (also known as "stereotyping"); and (4) target label arity. Consistent with the literature on fairness in NLP, we primarily focus on classification tasks, but also include preliminary text regression experiments. In doing so, we develop a novel framework for comprehensively evaluating the performance of debiasing methods under a range of data conditions, and use it to evaluate eight widely-used debiasing methods.

Our experimental results show that there is no single best model. Debiasing methods that account for both class disparities and demographic disparities are generally more robust, but are less effective in multi-class settings. For the regression task, our experiments indicate that existing debiasing approaches can substantially improve fairness, and that simple linear debiasing outperforms more complex methods.

2 Related Work

In this section, we first describe different fairness criteria, then examine work which has evaluated the effectiveness of debiasing methods from different perspectives.

Fairness Criteria Studies in the fairness literature have proposed several definitions of fairness capturing different types of discrimination, such as group fairness (Hardt et al., 2016; Zafar et al., 2017a; Cho et al., 2020; Zhao et al., 2020), individual fairness (Sharifi-Malvajerdi et al., 2019; Yurochkin et al., 2020; Dwork et al., 2012), and causality-based fairness (Wu et al., 2019; Zhang and Bareinboim, 2018a,b). In this work, we focus on group fairness, where a model is considered to be fair if it performs identically across different demographic subgroups.

[*] This work was done when Aili Shen was at The University of Melbourne.

To quantify how predictions vary across different demographic subgroups, demographic parity (Feldman et al., 2015; Zafar et al., 2017b; Cho et al., 2020), equal opportunity (Hardt et al., 2016; Madras et al., 2018), and equalized odds (Cho et al., 2020; Hardt et al., 2016; Madras et al., 2018) are widely-used notions. We present these in a setting where there are exactly two protected attribute labels (a "privileged" and "under-privileged" subpopulation), consistent with how they are traditionally defined. *Demographic parity* ensures that models achieve the same positive prediction rate for the two demographic subgroups, not taking the ground-truth target label into consideration. *Equal opportunity* requires that models achieve the same true positive rate across the two subgroups for instances with a positive label. *Equalized odds* goes one step further in requiring that models achieve not only the same level of true positive rate but also the same level of false positive rate across the two groups.

Aligned with key applications such as loan approvals, most fairness metrics assume binary classification and focus on one label (e.g., loan approved.) When turning attention to a multi-class classification scenario, *equal opportunity* is a natural choice, as it can be easily reformulated by assigning the positive class to each candidate class under a 1-vs-rest formulation.

Effectiveness of Debiasing Methods Beyond the standard definitions of fairness, a number of studies have examined the effectiveness of various debiasing methods in additional settings (Gonen and Goldberg, 2019; Meade et al., 2021; Lamba et al., 2021; Baldini et al., 2022; Chalkidis et al., 2022). For example, Meade et al. (2021) not only examine the effectiveness of various debiasing methods but also measure the impact of debiasing methods on a model's language modeling ability and downstream task performance. Webster et al. (2020) find that existing pretrained models encode different degrees of gender correlations, despite their performance on target tasks being quite similar, motivating the need to consider different metrics when performing model selection. A similar effect is also observed by Baldini et al. (2022). Chalkidis et al. (2022) examine the effectiveness of debiasing methods over a multi-lingual benchmark dataset consisting of four subsets of legal documents, covering five languages and various sensitive attributes. They find that methods aiming to improve worse-case performance tend to fail in more realistic settings, where both target label and protected attribute distributions vary over time. Lamba et al. (2021) perform an empirical comparison of various debiasing methods in solving real-world problems in high-stakes settings, all of which take the form of binary classification tasks. However, the effectiveness of debiasing methods under different data distributions (in terms of target class and protected attribute) has not been systematically investigated.

3 Methods

Here we describe the methods employed to manipulate the dataset distributions for classification tasks, and then describe how we adopt debiasing methods to a regression setting.

3.1 Notation Preliminaries

Experiments are based on a dataset consisting of n instances $\mathcal{D} = \{(\boldsymbol{x}_i, \mathrm{y}_i, \mathrm{z}_i)\}_{i=1}^{n}$, where $\boldsymbol{x}_i$ is an input vector, $\mathrm{y}_i \in \{\mathrm{c}\}_{\mathrm{c}=1}^{\mathrm{C}}$ represents target class label, and $\mathrm{z}_i \in \{\mathrm{g}\}_{\mathrm{g}=1}^{\mathrm{G}}$ is the group label, such as gender. $n_{\mathrm{c,g}}$ denotes the number of instances in a subset with target label c and protected label g, i.e., $\mathcal{D}_{\mathrm{c,g}} = \{(\boldsymbol{x}_i, \mathrm{y}_i, \mathrm{z}_i) | \mathrm{y}_i = \mathrm{c}, \mathrm{z}_i = \mathrm{g}\}_{i=1}^{n}$. The corresponding empirical probability of combination of y and z values is $P(\mathrm{y} = \mathrm{c}, \mathrm{z} = \mathrm{g}) = \frac{n_{\mathrm{c,g}}}{n}$.

3.2 Manipulating Label Distributions

To investigate the effectiveness of debiasing methods under different data distributions, we need the ability to create synthetic datasets $\mathcal{D}'$ that follow arbitrary distributions $P'(\mathrm{y}, \mathrm{z})$. Intuitively, given m instances and the joint probability $P'(\mathrm{y} = \mathrm{c}, \mathrm{z} = \mathrm{g})$, we can create each of the subsets $\mathcal{D}'_{\mathrm{c,g}}$ by sampling $mP'(\mathrm{y} = \mathrm{c}, \mathrm{z} = \mathrm{g})$ instances with replacement from $\mathcal{D}_{\mathrm{c,g}}$. However, each P' has $\mathrm{C} \times \mathrm{G}$ parameters, rendering a systematic analysis infeasible. Instead, we propose to control the joint distribution in an interpretable way, via a single parameter, and report results as graphs: Given a particular rate $0 \leq \alpha \leq 1$, we define the arbitrary distribution $P'(\mathrm{y}, \mathrm{z})$ as the interpolation between the empirical distribution $P(\mathrm{y}, \mathrm{z})$ and a distribution of interest $Q(\mathrm{y}, \mathrm{z})$:

$$P'(\mathrm{y}, \mathrm{z}) = (1 - \alpha) P(\mathrm{y}, \mathrm{z}) + \alpha Q(\mathrm{y}, \mathrm{z}).$$

Next, we adopt two balanced training objectives (Han et al., 2022a) as our Q distributions, and discuss their relationship to fairness.

Conditional Balance (CB) follows the notion of equal opportunity and emphasises the balance of demographics within each class, i.e., $Q_{\text{CB}}(\mathrm{z} = \mathrm{g}|\mathrm{y} = \mathrm{c}) = \frac{1}{\mathrm{G}}, \forall \mathrm{g} \in \{1, \ldots, \mathrm{G}\}, \mathrm{y} \in \{1, \ldots, \mathrm{C}\}$. The resulting interpolation is:

$$P'_{\text{CB}}(\mathrm{y}, \mathrm{z}) = P(\mathrm{y})[(1 - \alpha)P(\mathrm{z}|\mathrm{y}) + \alpha Q_{\text{CB}}(\mathrm{z}|\mathrm{y})]$$

where the overall class distribution $P(\mathrm{y})$ does not change with the value of α.

Joint Balance (JB) goes one step further in taking both class balance and demographic balance into account, resulting in $Q_{\text{JB}}(\mathrm{z} = \mathrm{g}, \mathrm{y} = \mathrm{c}) = \frac{1}{\mathrm{CG}}, \forall \mathrm{g} \in \{1, \ldots, \mathrm{G}\}, \mathrm{y} \in \{1, \ldots, \mathrm{C}\}$. The interpolation

$$P'_{\text{JB}}(\mathrm{y}, \mathrm{z}) = (1 - \alpha)P(\mathrm{y}, \mathrm{z}) + \alpha Q_{\text{JB}}(\mathrm{y}, \mathrm{z}) \quad (1)$$

ensures both class and demographic labels are more balanced with a larger α.

Inverting the Bias $\alpha = 0$ and $\alpha = 1$ result in the original distribution and a balanced distribution, respectively. We extend the space of possible distributions, by also considering scenarios with $\alpha > 1$, which result in "anti-stereotypical" distributions where majority classes and demographics are swapped to minorities.

Although the sum of adjusted probabilities is guaranteed to be 1, it is possible to generate negative probabilities or values that are larger than 1 after interpolation. In Appendix B, we describe the normalisation strategies to get a valid probability table. In this paper, we consider $\alpha \in [0, 2]$ for our dataset interpolations. Taking the CB interpolation as an example, given $P(\text{Female}|\text{Nurse}) = 0.9$ (Appendix A.2), $\alpha = 0, 1, \text{and } 2$ result in the adjusted $P'(\text{Female}|\text{Nurse}) = 0.9, 0.5, \text{and } 0.1$, respectively. Consistent adjustments will be applied to other professions in the training dataset.

3.3 Debiasing for Regression Tasks

Regression models predict a real-valued target variable, rather than discrete values as in classification. Many existing fairness metrics and debiasing methods assume discrete target (and protected attribute) labels, and are thus not directly applicable to regression tasks, such as the equal opportunity criteria which measures disparities across demographics within each class (Roh et al., 2021; Shen et al., 2022).

As a first step towards applying debiasing methods to text regression tasks, we map the continuous target variables y into discrete values by approximating the real-valued outputs with quantile-based proxy labels $\tilde{\mathrm{y}}$. Specifically, let $\tilde{\mathrm{y}}$ denote the proxy label, such that the dataset for regression is $\mathcal{D} = \{(\boldsymbol{x}_i, \mathrm{y}_i, \mathrm{z}_i, \tilde{\mathrm{y}}_i)\}_{i=1}^{n}$, where $\mathrm{y} \in \mathbb{R}$ is the continuous target label. Given a particular number of quantiles $\tilde{\mathrm{C}}$, y is converted into equal-sized buckets based on sample quantiles, resulting in categorical proxy labels $\tilde{\mathrm{y}} \in \{\tilde{\mathrm{c}}\}_{\tilde{\mathrm{c}}=1}^{\tilde{\mathrm{C}}}$. Two typical choices for $\tilde{\mathrm{C}}$ are 10 and 4, corresponding to deciles and quartiles, respectively.

In model training, we calculate losses based on real labels y, and identify protected groups based on $\tilde{\mathrm{y}}$. Appendix E presents further details for adopting debiasing methods to regression tasks.

4 Experiments

In this section we describe general settings across all experiments. In Appendix A, we provide full experimental details and dataset statistics.

4.1 Debiasing Methods

Our focus in this work is to examine the effectiveness of various debiasing methods on different dataset compositions and their applicability to regression tasks. As such, we take a representative sample of debiasing methods, populating the spectrum of pre-processing, in-processing, and post-processing approaches.

Vanilla: The model is trained naively with cross-entropy loss, without taking bias mitigation into consideration (Vanilla).

Pre-processing: perform downsampling or reweighting of the dataset before model training.

1. Downsampling (DS: Han et al. (2022a)): Bias mitigation is achieved by downsampling the dataset, by balancing it *w.r.t.* the protected attribute within each target class while preserving the original target class ratio.
2. Reweighting (RW: Han et al. (2022a)): Bias mitigation is achieved by assigning different weights to instances in the dataset, by reweighting based on the (inverse) of the joint distribution of the protected attribute and target classes.

In-processing: perform adversarial training or directly optimise *w.r.t.* fairness criteria by either dynamically adjusting the sampling rate or penalising groups of instances.

1. Adversarial training (ADV: Elazar and Goldberg (2018); Li et al. (2018)) jointly trains

a discriminator to predict the protected attribute, leading to representations agnostic to protected attributes.

2. Diverse adversarial training (DADV: Han et al. (2021)) trains multiple discriminators as above, with a pairwise orthogonality constraint over discriminators to encourage learning of different representational aspects.
3. Fair batch selection (FairBatch: Roh et al. (2021)) dynamically adjusts the instance resampling probability during training *w.r.t.* a given target class and protected attribute value, based on the equal opportunity criterion.
4. Equal opportunity (EO: Shen et al. (2022)) directly optimises for equal opportunity by penalising loss differences across protected groups via a regularisation term. We adopt two versions of optimising equal opportunity: enforcing equal opportunity by aligning group-wise losses within each class (EO_{CLA}), and enforcing equal opportunity globally by aligning class- and group wise loss with the overall model performance (EO_{GLB}).

Post-processing: manipulate the learned representations to achieve fairness.

1. Iterative null-space projection (INLP: Ravfogel et al. (2020)) first learns dense representations with a cross-entropy loss, and then iteratively projects the representations to the null-space of discriminators for the protected attributes.

4.2 Evaluation Metrics

To evaluate model performance, we adopt Accuracy in our classification experiments, and Pearson correlation for the regression task.

To measure bias, following previous studies (De-Arteaga et al., 2019; Ravfogel et al., 2020; Shen et al., 2022), we adopt root mean square of true positive rate gap over all classes (GAP), which is defined as $\text{GAP} = \sqrt{\frac{1}{C}\sum_{\mathrm{y}}(\text{GAP}_{\mathrm{y}}^{\text{TPR}})^2}$. Here, $\text{GAP}_{\mathrm{y}}^{\text{TPR}} = |\text{TPR}_{\mathrm{y,z}} - \text{TPR}_{\mathrm{y,\neg z}}|, \forall \mathrm{y}$, and $\text{TPR}_{\mathrm{y,z}} = \mathbb{P}\{\hat{\mathrm{y}} = \mathrm{y}|\mathrm{y}, \mathrm{z}\}$, indicating the percentage of correct predictions among instances with the target class y and protected attribute label z. $\text{GAP}_{\mathrm{y}}^{\text{TPR}}$ measures the absolute performance difference between demographic subgroups conditioned on target label y, and a value of 0 indicates that the model makes predictions independent of the protected attribute. To be consistent with our performance evaluation metrics (the higher the better), we define Fairness as $1-\text{GAP}$, where a value of 1 indicates there is no predictive bias.

4.3 Experimental Setup

For each dataset, we vary training set distributions while keeping the test set fixed. Document representations are first obtained from the given pretrained model without finetuning. Then document representations are fed into two feed-forward layers with a hidden size of 300, each followed by the $\tanh$ activation function. We use Adam (Kingma and Ba, 2014) to optimise the model for at most 100 epochs with early stopping, where training is stopped if no improvement is observed over the dev set for 5 epochs. All models are trained and evaluated on the same dataset splits, and models are selected based on their performance on the development set, as described in Section 4.4. All experiments are conducted with the *fairlib* library (Han et al., 2022c).

4.4 Model Selection

Simultaneously optimising models for performance and fairness is a multi-objective problem, making model selection a non-trivial task. In this work, following Han et al. (2022a), we perform model selection based on Distance to the Optimal point (DTO), where the optimal point represents the highest theoretical performance and fairness level any model can achieve. DTO supports the comparison of models by aggregating performance and fairness into a single figure of merit, where lower is better.

5 Binary Classification

The task is to predict the binary sentiment (HAPPY and SAD) of a given English tweet, as determined by the (redacted) emoji used in the tweet. Each tweet is also associated with a binary protected attribute, reflecting the ethnicity of the tweet author, as captured in the register of the English: Standard American English (SAE) and African American English (AAE).

We use the widely-used Twitter emoji dataset (Blodgett et al., 2016; Ravfogel et al., 2020; Shen et al., 2022), denoted as **Moji**. The training dataset is balanced in terms of both sentiment and ethnicity in general, but skewed in terms of sentiment–ethnicity combinations, $P(AAE|\text{HAPPY}) = P(SAE|\text{SAD}) = 0.8$.[1] Due

[1] The dev and test set are balanced in terms of senti-

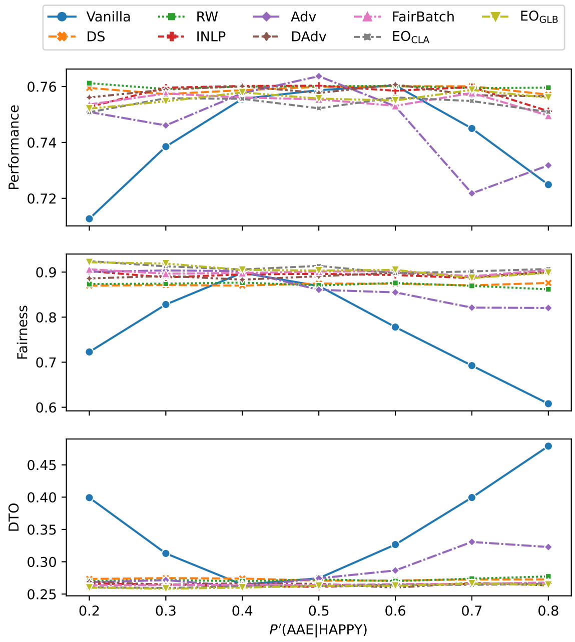

Figure 1: Results for **Moji** when varying $P'(AAE|\text{HAPPY})$ with $P'(\text{HAPPY}) = P'(\text{SAD})$.

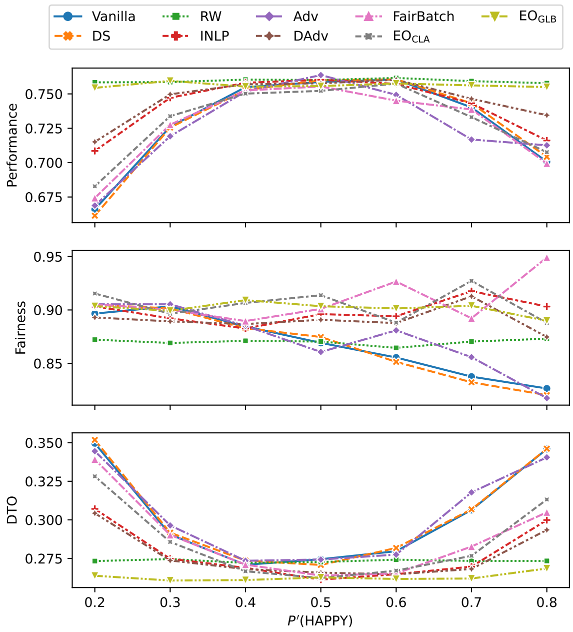

Figure 2: Results for **Moji** when varying $P'(\text{HAPPY})$ with $P'(AAE|\text{HAPPY}) = P'(SAE|\text{SAD}) = 0.5$.

to the fact the the original dataset has been balanced with respect to targets and demographics, the CB interpolation is exactly the same as the JB interpolation (Section 3.2).

For ease of comparison with previous work (Subramanian et al., 2021b), we refer to the CB interpolation as varying "stereotyping" (P'(z|y)) with balanced target class distribution. To explore the effects of target class distribution and stereotyping, we further experiment in various controlled settings: (1) varying class ratio (P'(y)) without stereotyping (P'(z|y) $= 0.5$); (2) varying stereotyping with imbalanced target class distribution; and (3) varying class ratio with stereotyping. Finally, we summarise our findings with respect to the effectiveness and robustness of various debiasing methods over different class-stereotyping compositions.

5.1 Varying Stereotyping with Balanced Class Distribution (CB Interpolation)

Here, both sentiment and ethnicity are balanced, but skewed in terms of $P'(AAE|\text{HAPPY})$ and $P'(SAE|\text{SAD})$, ranging from 0.2 to 0.8. For example, when the ratio of AAE is 0.2, the training data composition is 10% HAPPY–AAE, 40% HAPPY–SAE, 40% SAD–AAE, and 10% SAD–SAE.

Figure 1 shows model performance in terms of Accuracy, Fairness, and DTO. All models except for Vanilla and INLP perform similarly over varying degrees of stereotyping across metrics, indicating that most models are robust to different degrees of stereotyping using the proposed model selection approach. Turning to Vanilla, we find that Accuracy, Fairness, and DTO all vary greatly as we increase the degree of stereotyping, indicating that stereotyping affects naively-trained models in terms of both performance and fairness.

5.2 Varying Class Ratio with no Stereotyping

In this setting, $P'(AAE|\text{y}) = P'(SAE|\text{y}), \forall\text{y}$, and we vary $P(\text{y} = \text{HAPPY})$ from 0.2 to 0.8. For example, when the ratio of HAPPY is 0.2, the training dataset contains 10% HAPPY–AAE, 10% HAPPY–SAE, 40% SAD–AAE, and 40% SAD–SAE.

From Figure 2, we can see that most models are sensitive to the target class distribution, especially in terms of Accuracy and DTO. RW and EO$_{\text{GLB}}$ are exceptions, and are clearly superior methods when the dataset is free of stereotyping, no matter the target class distribution. The Fairness achieved by all models in this setting does not vary greatly (ranging from approximately 0.82 to 0.90), indicating that target class distributions with no stereotyping have limited effect in biasing naively-trained models.

ment–ethnicity combination.

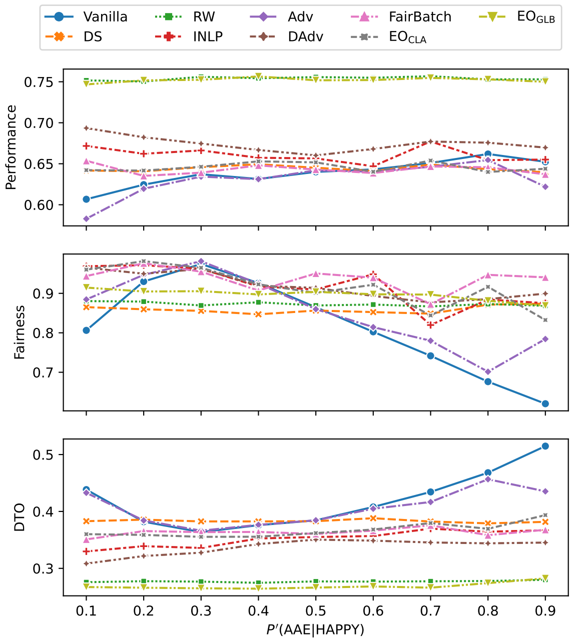

Figure 3: Results of varying $P'(AAE|\text{HAPPY})$ with $P'(\text{HAPPY}) = 0.9$.

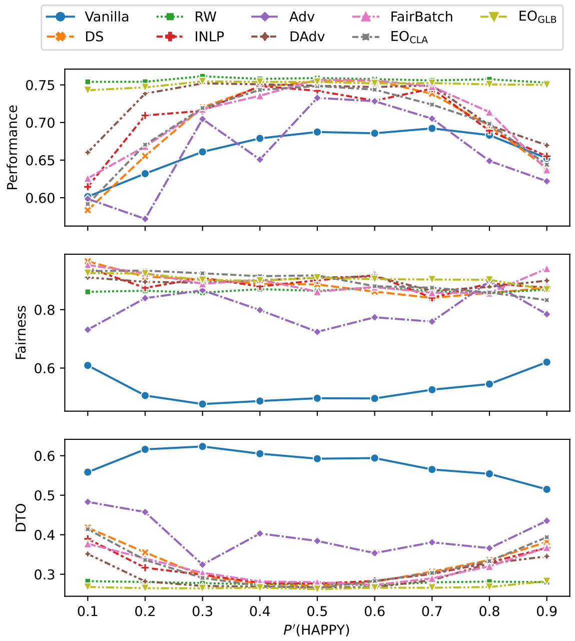

Figure 4: Results for **Moji** when varying $P'(\text{HAPPY})$ with $P'(AAE|\text{HAPPY}) = P'(SAE|\text{SAD}) = 0.9$.

5.3 Varying Stereotyping with Imbalanced Class Distributions

In this setting, the target class distribution is imbalanced, in that $P'(\text{HAPPY}) = 0.9$ in the training dataset. $P'(AAE|\text{HAPPY})$ and $P'(SAE|\text{SAD})$ varies from 0.1 to 0.9. For example, when the ratio of AAE is 0.2, the training dataset contains 18% HAPPY–AAE, 72% HAPPY–SAE, 8% SAD–AAE, and 2% SAD–SAE, respectively.

From Figure 3, we can see that RW and EO$_{\text{GLB}}$ consistently achieve the best performance in terms of Accuracy and DTO. Fairness for DS, RW, and EO$_{\text{GLB}}$ is robust to varying degrees of AAE stereotyping, while the remaining methods are sensitive to stereotyping.

5.4 Varying Class Ratio with Stereotyping

In this setting, the ethnicity distribution is imbalanced, in that $P'(AAE|\text{HAPPY}) = P'(SAE|\text{SAD}) = 90\%$. $P'(\text{HAPPY})$ varies from 0.1 to 0.9. For example, when the ratio of HAPPY is 0.2, the training dataset consists of 18% HAPPY–AAE, 2% HAPPY–SAE, 8% SAD–AAE, and 72% SAD–SAE, respectively.

From Figure 4, we can see that both RW and EO$_{\text{GLB}}$ consistently achieve the best performance in terms of Accuracy and DTO, while the remaining methods are quite sensitive to the target class distribution in terms of Accuracy and DTO, and all models except for Vanilla and INLP achieve relatively consistent Fairness.

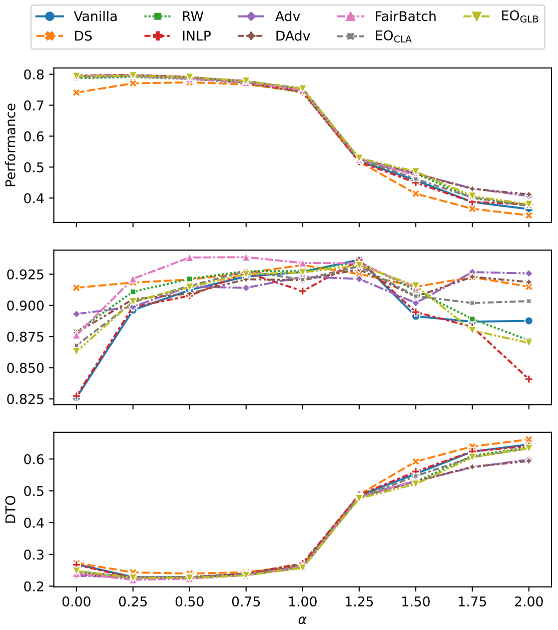
5.5 Summary

In this section, we have performed various experiments on the Twitter sentiment analysis task with varying dataset composition. Looking at results from Sections 5.1 and 5.3, we can see that all models except for Vanilla and INLP are quite consistent with respect to Accuracy, Fairness, and DTO, with RW and EO$_{\text{GLB}}$ consistently achieving competitive performance in terms of Accuracy, Fairness, and DTO. Comparing results from Sections 5.2 and 5.4, the performance of all models except for RW and EO$_{\text{GLB}}$ vary with respect to the target class distribution in terms of Accuracy and DTO, while all models perform consistently in terms of Fairness.

6 Multi-class Classification

We next turn to our second dataset, which is a *multi-class classification* task with *natural imbalance* in both target labels and protected groups.

The dataset consists of online biographies, labeled with one of 28 occupations (target labels) and binary author gender (protected label), and the task is to predict the occupation from the biography text (**Bios**, De-Arteaga et al. (2019)).



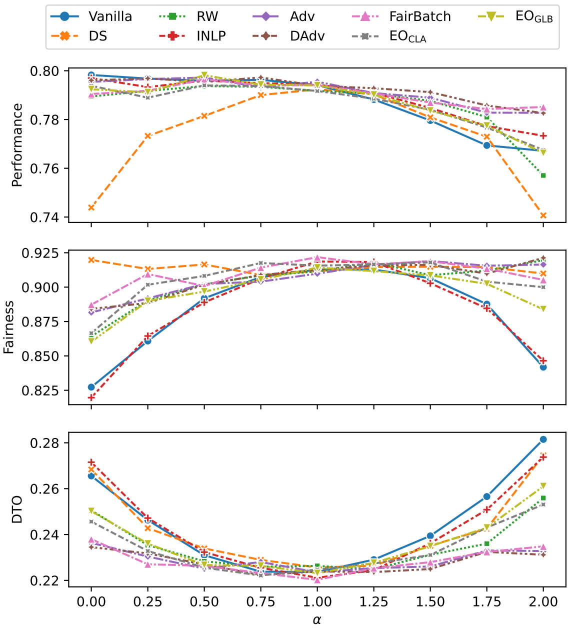


Figure 5: Results for **Bios** when varying the interpolation ratio under JB. Target classes and demographics are jointly balanced at $\alpha = 1$.

Figure 6: Results for **Bios** when varying the interpolation ratio under CB. Stereotyping ratios are balanced for the the $\alpha = 0$ setting.

6.1 Results

Figures 5 and 6 present results for JB and CB interpolation over **Bios**. As introduced in Section 3.2, JB jointly adjusts the extent of stereotyping and target class imbalance, and CB focuses on the stereotyping.

JB Interpolation: As the value of α increases from 0 to 1, the training distribution becomes more balanced for both class and protected attributes, resulting in fairness improvements. As the performance is measured as the overall accuracy, which is essentially a micro-average and oblivious to class balance, the overall performance does not improve with a more balanced class distribution.

With the α value further increasing from 1 to 2, both class and protected attribute distributions are biased in the opposite direction, i.e., majority groups become minority groups. As a result, the fairness for Vanilla decreases substantially. Recall that the *test* dataset distribution is unchanged throughout the experiments (and has an identical distribution to the $\alpha = 0$ setting), leading to large drops in performance of models *trained* on anti-biased class distributions.

Consistent with Sections 5.3 and 5.4, EO$_{\text{GLB}}$ outperforms other debiasing methods when the class and protected attributes are both imbalanced, as it explicitly mitigates both biases simultaneously.

We notice that FairBatch relies on a large number of instances per class/group combination for effective resampling, and as a result is highly vulnerable to input data bias, which can be seen in the fact that there are no results for FairBatch in imbalanced settings ($\alpha = 1.75$ and 2).[2]

CB Interpolation: When focusing on stereotyping, different methods achieve similar performance except for DS, due to the simple sampling strategy substantially reducing the training dataset size.

In terms of Fairness, debasing approaches except for INLP are robust to different stereotyping levels. EO$_{\text{GLB}}$ achieves worse performance than EO$_{\text{CLA}}$ because it additionally considers class imbalance. As ADV and DADV mitigate biases without taking the class into account, their debiasing results are not affected by the number of classes and perform best for this data set.

7 Regression

We finally turn to the regression setting. The task is to predict the valence (sentiment) of a given Facebook post, where each post is assigned a valence score by two trained annotators in the range 1–9 and the task is to predict the average of the two scores (Preoţiuc-Pietro et al., 2016). Additionally,

[2] See Section 8 for further discussion.

Models	Pearson ↑	Fairness ↑	DTO ↓
Vanilla	63.38±2.48	85.18±0.40	39.50
RW	63.69±1.50	84.73±0.91	39.39
INLP	**70.46±0.00**	88.54±0.00	**31.68**
ADV	69.41±0.39	85.81±0.33	33.72
DADV	69.02±0.85	85.66±0.63	34.14
FairBatch	68.25±1.47	85.18±0.62	35.04
EO$_{\text{CLA}}$	65.88±0.89	85.05±0.40	37.25
EO$_{\text{GLB}}$	65.37±1.29	85.03±0.39	37.73

Table 1: Experimental results on the Valence test set.

each post is associated with a binary authorship gender label.[3] In our experiments, results are reported based on 5-fold cross-validation.

7.1 Results

Instead of measuring fairness with GAP based on TPR scores for classification tasks, we focus on the Pearson correlation disparities across demographic groups. From Table 1 we can see that all models improve over Vanilla. Overall, INLP is the best debiasing method, which we hypothesise is because its linear structure is more appropriate for the small data set, while the deeper methods appear to overfit.

8 General Discussion and Recommendations

So far, we have shown that there is no single best model across different data conditions, and data conditions should be a key consideration in fairness evaluation. In this section, we divide debiasing methods into three families, and summarize their robustness to skewed training data distributions.

Balancing demographics in the training dataset DS and RW are representatives of this family, and are simple and effective. In addition, such methods are flexible as the training dataset is pre-processed before model training, and any candidate models on the original dataset can be applied to the debiased dataset.

However, DS methods are sensitive to group sizes. Considering an extreme setting where the smallest subset in the training dataset has 0 instances, i.e., $\mathcal{D}_{\text{c,g}} = \emptyset$, DS will result in an empty training set. For instance, the group size distribution is highly skewed for the regression task, and DS resulted in $r = 0$ Pearson correlation (Table 4 in Appendix). Similar problems are associated with up-sampling methods, which can increase the training set size dramatically.

In addition, when considering multiple protected attributes, such as intersectional groups and gerrymandering groups (Subramanian et al., 2021a), the number of groups increases exponentially with the number of protected attributes to be considered. As a result, the joint distributions can be highly skewed, and these two families of methods (resampling and reweighting) may not be appropriate choices.

Lastly, skewed protected label distributions in the training dataset is not the only source of bias (Wang et al., 2019). For example, as shown in Figure 1 the Vanilla model trained over balanced versions ($P'(AAE|\text{HAPPY}) = 0.5$) of the **Moji** dataset is less fair than the Vanilla model trained over a biased dataset where $P'(AAE|\text{HAPPY}) = 0.4$.

Learning fair hidden representations ADV, DADV, and INLP represent a family of methods that learn fair representations through unlearning discriminators. Since the training and unlearning of discriminators do not take into account target class information, these methods are robust to the number of classes and naturally generalize to regression tasks.

However, these methods are not capable of modelling conditional independence for the equal opportunity criterion without taking target class into consideration, resulting in worse DTO than other debiasing methods over **Moji** (Section 5). To achieve equal opportunity fairness, different discriminators can be trained for each target class to capture conditional independence (Ravfogel et al., 2020; Han et al., 2022b). But training target-specific discriminators assumes target labels to be discrete, which is sensitive to the number of classes.

Another limitation of this family of methods is associated with the discriminator learning: the discriminator can also suffer from long-tail learning problems, i.e. skewed demographics, and lead to biased estimations of protected information. The unlearning of biased discriminators limits the method's contribution to bias mitigation, which can be seen from Figures 3 and 4 in Section 5.

Minimising loss disparities across demographic groups FairBatch, EO$_{\text{CLA}}$, and EO$_{\text{GLB}}$ provide a practical approximation of expected fairness in

[3] This dataset is also annotated with arousal scores but corresponding results are less biased, and as a result, we focus on bias mitigation for valence predictions. Results for arousal predictions are included in Appendix F.

using empirical risk-based objectives, and directly optimize for empirical risk parity during training.

Similar to balanced training approaches, resampling and reweighting are also used in mitigating loss disparities, where FairBatch adjusts resampling probabilities for batch selection, and EO_{CLA} and EO_{GLB} assign instances different weights depending on the demographic group they belong to. However, minimising loss disparities can be more flexible than balanced training – for example, instance weights are dynamically adjusted by EO_{CLA} and EO_{GLB}, and can take on negative values to aggressively reduce a bias towards favouring of over-represented groups.

Conversely, drawbacks associated with resampling and reweighting also apply to this family. For example, FairBatch indeed broke down (an error raised) when $\mathcal{D}_{\text{c,g}} = \emptyset$ for the minority group in a particular minibatch for a **Bios** dataset variant where the smallest group size is close to 0 (Section 6).

Minimising loss difference is also less efficient in multi-class settings, as it adjusts weights based on class information during training, making optimisation harder.

9 Conclusion

In this work, we presented a novel framework for investigating different classification dataset distributions with a single parameter, and used it to systematically examine the effectiveness of debiasing methods in binary classification and multi-classification settings based on real-world datasets. We also presented preliminary analysis of debiasing methods in a regression setting, including proposing a method for adapting existing debiasing methods to regression tasks. Based on extensive experimentation over three datasets, we found that there was no single best model. Debiasing methods that account for both class and demographic disparities are generally more robust, but are less efficient at achieving fairness in multi-class settings. For the regression task, we demonstrated that existing debiasing approaches can substantially improve fairness, and that the simple linear debiasing method outperforms more complex techniques. In summary, there is no universal best debiasing method across all tasks, and data conditions have a large impact on different models. As such, we propose that future research adopts our evaluation framework as a means of more comprehensively evaluating debiasing methods.

Acknowledgments

We thank the anonymous reviewers for their helpful feedback and suggestions. This work was funded by the Australian Research Council, Discovery grant DP200102519. This research was undertaken using the LIEF HPC-GPGPU Facility hosted at the University of Melbourne. This Facility was established with the assistance of LIEF Grant LE170100200.

Limitations

This paper focuses on fairness evaluation *w.r.t.* equal opportunity fairness. While a more comprehensive study should include a diversity of fairness objectives, we note that previous work (Han et al., 2021) has shown that evaluation results *w.r.t.* different fairness criteria are highly correlated.

Consistent with previous work, we restrict our experiments to categorical protected attributes (binary gender, ethnicity) acknowledging that other relevant attributes (such as age) are more naturally modeled as a continuous variable. Since the aim of this paper is a systematic evaluation of existing debiasing methods, which were all developed specifically for categorical protected attributes, the extension to continuous variables is beyond the scope of this paper. A simple adaptation to continuous demographic labels like age is discretization, which we leave as a promising direction for future work.

For similar reasons, we use established data sets as provided by the original authors and used in relevant prior work, and acknowledge the simplified treatment of gender as a binary variable which reflects neither the diversity nor the fluidity of the underlying concept (Dev et al., 2021).

Ethical Consideration

In this work, we focus on examining the effectiveness of various debiasing methods on both classification and regression tasks, where the protected attribute is either ethnicity or gender. However, their effectiveness in reducing bias towards other protected attributes is not necessarily guaranteed. Furthermore, the protected attributes examined in our work are limited to binary labels, whose effectiveness in debiasing N-ary protected attributes are left to future work.

Table 2: Statistics of the **Bios** training dataset. Ratio stands for the percentage of female individuals for each profession

A Datasets and Implementation Details

A.1 Moji

Following previous studies (Ravfogel et al., 2020; Han et al., 2021), the original training dataset is balanced with respect to both sentiment and ethnicity but skewed in terms of sentiment–ethnicity combinations (40% HAPPY-AAE, 10% HAPPY-SAE, 10% SAD-AAE, and 40% SAD-SAE, respectively). Note that the dev and test set are balanced in terms of sentiment–ethnicity combinations. The dataset contains 100K/8K/8K train/dev/test instances.

When varying training set distributions, we keep the 8k test instances unchanged.

We use DeepMoji (Felbo et al., 2017) to obtain Twitter representations, where DeepMoji is a model pretrained over 1.2 billion English tweets and DeepMoji is fixed during model training. For all models, the learning rate is 3e-3, and the batch size is 1,024. Hyperparameter tuning for each model is described in Appendix C.1.

A.2 Bios

We denote the data set as **Bios**, and use the same split as prior work (Ravfogel et al., 2020; Shen et al., 2022) of 257k train, 40k dev and 99k test instances. Table 2 shows the number of instances of each profession, the number of male and female individuals of each profession, and the ratio of female individuals for each profession in the **Bios** training dataset. As the target label distribution is highly skewed, we adjust the distribution over **Bios** dataset with 30K training instances, such that each profession contains about 1K instances, which is similar to the size of the smallest target group.

We use the "CLS" token representation of the pretrained uncased BERT-base (Devlin et al., 2019) to obtain text representations, where BERT-base is fixed during model training, aligning with previous studies (Ravfogel et al., 2020; Shen et al., 2022). Hyperparameter settings for all models are available in Appendix D.1.

A.3 Valence

The dataset contains 2,883 posts, of which male and female authors account for 51% and 49% respectively.

We use the "CLS" token representation of the pretrained uncased BERT-base (Devlin et al., 2019) to obtain post representations, where BERT-base is fixed during model training. Hyperparameter settings are described in Appendix F.1.

For this task, we use Pearson, mean absolute error (MAE), and root mean square error (RMSE) to evaluate model performance; and we use the Pearson difference (Pearson-GAP), MAE difference (MAE-GAP), and RMSE difference (RMSE-GAP) between male and female groups to evaluate model bias.

B Normalization For Probability Table

To make sure the resulting probability table P' is valid, we normalize the table by replacing negative values with 0, and normalize the sum to 1. Specifically, let $S = \sum_{\mathrm{y}} \sum_{\mathrm{z}} P'(\mathrm{y}, \mathrm{z})$ denote the sum of probabilities. The normalization is $P'(\mathrm{y}, \mathrm{z}) = \frac{P'(\mathrm{y},\mathrm{z})}{S}, \forall \mathrm{y}, \mathrm{z}$.

C Twitter Sentiment Analysis

C.1 Hyperparameters

For all models except for Vanilla, DS, and RW, where no extra hyperparameters are introduced, we tune the most sensitive hyperparameters through grid search. For INLP, following Ravfogel et al. (2020), we use 300 linear SVM classifiers. For ADV, we tune λ_{adv} from 1e-3 to 1e3 with 60 trials.

Models	Accuracy ↑	Fairness ↑	DTO ↓
Vanilla	72.49±0.18	60.79±1.12	47.90
DS	**75.92**±0.32	86.88±1.08	27.43
RW	**75.96**±0.28	86.18±0.97	27.73
INLP	73.18±0.00	82.04±0.00	32.28
ADV	75.12±0.83	90.40±1.75	26.67
DADV	75.65±0.12	89.94±0.50	**26.34**
FairBatch	74.96±0.41	90.49±0.49	26.79
EO$_{\text{CLA}}$	75.09±0.25	**90.70**±0.87	26.59

Table 3: Experimental results on the **Moji** test set (averaged over 5 runs); **Bold** = Best Performance; ↑= the higher the better; ↓= the lower the better.

For DADV, we further tune λ_{diverse} within the range of 1e-1 and 1e5 with 60 trials. For FairBatch, we tune α from 1e-3 to 1e1 with 40 trials. For EO$_{\text{CLA}}$ and EO$_{\text{GLB}}$, we tune λ within the range of 1e-3 and 1e1 with 40 trials, respectively. All hyperparameters are finetuned on the **Moji** dev set.

C.2 Results

Table 3 shows the results achieved by various methods. All debiasing methods can reduce bias significantly while improving model performance in terms of Accuracy.

D Profession Classification

D.1 Hyperparameters

For all models, the learning rate is 3e-3, and the batch size is 1,024. For all models we tune the most sensitive hyperparameters through grid search except for Vanilla, DS, and RW as there is no extra hyperparameters introduced for these three methods. For INLP, following Ravfogel et al. (2020), we use 300 linear SVM classifiers. For ADV, we tune λ_{adv} from 1e-3 to 1e3 with 60 trials. For DADV, we further tune λ_{diverse} within the range of 1e-1 and 1e5 with 60 trials. For FairBatch, we tune α from 1e-3 to 1e1 with 40 trials. For EO$_{\text{CLA}}$ and EO$_{\text{GLB}}$, we tune λ within the range of 1e-3 and 1e1 with 40 trials, respectively. All hyperparameters are finetuned on the **Bios** dev set.

E Adaptation For Regression Tasks

E.1 EO$_{\text{CLA}}$ (Shen et al., 2022)

The debiasing objective for classification tasks is to minimise cross-entropy loss disparities across different protected groups within each class, $\mathcal{L}^{\text{class}}_{\text{eo}} = \lambda \sum_{\text{c}=1}^{\text{C}} \sum_{\text{g}=1}^{\text{G}} |\mathcal{L}^{\text{c,g}}_{ce} - \mathcal{L}^{\text{c}}_{ce}|$, where $\mathcal{L}^{\text{c,g}}_{ce}$ and $\mathcal{L}^{\text{y}}_{ce}$ are the cross-entropy losses for subset of instances $\{(\boldsymbol{x}_i, \text{y}_i, \text{z}_i)|\text{y}_i = \text{c}, \text{z}_i = \text{g}\}_{i=1}^{n}$ and $\{(\boldsymbol{x}_i, \text{y}_i, \text{z}_i)|\text{y}_i = \text{c}\}_{i=1}^{n}$, respectively.

Clearly, the identification of subsets requires categorical labels, which is based on proxy labels for regression tasks. By replace the cross-entropy loss with mean squared error loss ($\mathcal{L}_{mse}$), the objective for EO$_{\text{CLA}}$ is $\mathcal{L}^{\text{reg}}_{\text{eo}} = \lambda \sum_{\tilde{\text{c}}=1}^{\tilde{\text{C}}} \sum_{\text{g}=1}^{\text{G}} |\mathcal{L}^{\tilde{\text{c}},\text{g}}_{mse} - \mathcal{L}^{\tilde{\text{c}}}_{mse}|$ where $\mathcal{L}^{\tilde{\text{c}},\text{g}}_{mse}$ and $\mathcal{L}^{\tilde{\text{c}}}_{mse}$ are the cross-entropy losses for subset of instances $\{(\boldsymbol{x}_i, \text{y}_i, \text{z}_i, \tilde{\text{y}}_i)|\tilde{\text{y}}_i = \tilde{\text{c}}, \text{z}_i = \text{g}\}_{i=1}^{n}$ and $\{(\boldsymbol{x}_i, \text{y}_i, \text{z}_i, \tilde{\text{y}}_i)|\tilde{\text{y}}_i = \tilde{\text{c}}\}_{i=1}^{n}$, respectively.

F Arousal Prediction of Facebook Posts

F.1 Hyperparameters

For all models, the learning rate is 7e-4, the batch size is 64, the number of hidden layers is 1, and hidden layer size is 200. Each model is trained with mean squared loss with a weight decay of 1e-3. For all models except for Vanilla, we need to bin instances, as the dataset is small and the range of valence scores is large; otherwise, these methods cannot be applied in their original form. In this work, instances are grouped into 4 bins. For all models we tune the most sensitive hyperparameters through grid search except for Vanilla, DS, and RW as there are no extra hyperparameters introduced for these three methods. For INLP, following Ravfogel et al. (2020), we use 200 linear regressors. For ADV, we tune λ_{adv} from 1e-3 to 1e3 with 60 trials. For DADV, we further tune λ_{diverse} within the range of 1e-1 to 1e5 with 60 trials. For FairBatch, we tune α from 1e-3 to 1e1 with 40 trials. For EO$_{\text{CLA}}$ and EO$_{\text{GLB}}$, we tune λ within the range of 1e-3 to 1e1 with 40 trials, respectively. All hyperparameters are finetuned on the dev set.

F.2 Results

Abstract

Knowledge graph question answering (KGQA) based on information retrieval aims to answer a question by retrieving answer from a large-scale knowledge graph. Most existing methods first roughly retrieve the knowledge subgraphs (KSG) that may contain candidate answer, and then search for the exact answer in the KSG. However, the KSG may contain thousands of candidate nodes since the knowledge graph involved in querying is often of large scale, thus decreasing the performance of answer selection. To tackle this problem, we first propose to partition the retrieved KSG to several smaller sub-KSGs via a new subgraph partition algorithm and then present a graph-augmented learning to rank model to select the top-ranked sub-KSGs from them. Our proposed model combines a novel subgraph matching networks to capture global interactions in both question and subgraphs, and an Enhanced Bilateral Multi-Perspective Matching model is proposed to capture local interactions. Finally, we apply an answer selection model on the full KSG and the top-ranked sub-KSGs respectively to validate the effectiveness of our proposed graph-augmented learning to rank method. The experimental results on multiple benchmark datasets have demonstrated the effectiveness of our approach.

1 Introduction

With the rise of large-scale knowledge graphs (KG) such as DBpedia (Auer et al., 2007) and Freebase (Bollacker et al., 2008), question answering over knowledge graph has attracted massive attention recently, which aims to leverage the factual information in a KG to answer natural language question. Depending on the complexity of question, KGQA can be divided into two forms: simple and complex. Simple KGQA often requires only one hop of factual knowledge, while complex KGQA requires reasoning over a multi-hop knowledge subgraph (KSG) and selecting the correct answer among several candidate answers. In this paper, we focus on the latter, i.e., complex KGQA, which is more challenging.

Currently, most KGQA approaches resort to semantic parsing (Berant et al., 2013; Yih et al., 2015; Dong and Lapata, 2018) or retrieve-then-extract methods (Yao and Van Durme, 2014; Bordes et al., 2014). Semantic parsing methods usually translate a natural language question to a KG query and then use it to query the KG directly. However, semantic parsing methods often rely on complex and specialised hand-crafted rules or schemes. In contrast, retrieve-then-extract methods are easier to understand and more interpretable. They first retrieve the KG coarsely to obtain a KSG containing answer candidates. Then, the target answer is extracted from the retrieved KSG. This paper follows the research idea of the retrieve-then-extract methods.

Most previous works retrieve a knowledge subgraph from the original KG by choosing topic entities (e.g., KG entities mentioned in the given question) and their few-hop neighbors. However, since the KG is often of large volume and the initial retrieval process on it is coarse-grained and heuristic, the KSG retrieved by this method may still contain thousands of nodes and most of them are irrelevant to the given question, especially when the number of topic entities or hops significantly increases. The larger the KSG is, the more difficult it is to find the correct answer in it. To reduce the size of the KSG, the similarity between the question and the relations around the topic entities is computed (Sun et al., 2018) and then the personalized PageRank algorithm is used to select the most relevant relations. This method only considers the semantic similarity between the question and the relations while ignoring the structural information around each entity node. Knowledge embeddings on the whole retrieved KSG are directly computed (Saxena et al.,

Question: where did dr **martin luther king (m.051cc)** get his doctorate

Figure 1: An Example of Knowledge Subgraph Partition Algorithm. The areas surrounded by two dashed lines belong to two different sub-KSGs.

2020), which is computationally intensive.

To address the above-mentioned problems, we propose a new KSG partition algorithm and a refined learning to rank model, which focus on how to substantially reduce the size of the retrieved knowledge subgraph and ensure a high answer recall rate. The KSG partition algorithm is based on single source shortest path, which can partition a large-scale question-specific KSG to several moderately sized sub-KSGs. Then, the learning to rank model selects the most relevant sub-KSGs to the given question. In this way, traditional text matching models can be used to compute the similarity score between a given question and a sub-KSG.

However, these sequential based models often ignore the important structure information within the question and the sub-KSG. Therefore, we propose a novel graph-augmented learning to rank model (G-G-E) to select top-ranked sub-KSGs, which combines a novel subgraph matching networks based on Graph Neural Networks to capture global interactions between question and subgraphs, and an enhanced Bilateral Multi-Perspective Matching (BiMPM) model (Wang et al., 2017) to capture local interactions within parts of question and subgraphs. A series of graph neural networks are suitable for the subgraph matching networks (Wu et al., 2022), and Gated Graph Sequence Neural Networks (GGNNs) (Li et al., 2016) is selected after comprehensive comparison. Finally, we apply one of the state-of-the-art (SOTA) KGQA answer selection model to the original complete KSG and the merged top-ranked sub-KSGs separately, and further demonstrate that reducing the size of the answer candidate subgraphs clearly helps to select correct answer effectively and efficiently. To evaluate our approach, we conduct extensive experiments on two benchmark datasets. The experimental results on the datasets have shown that our proposed model can significantly improve subgraph ranking performance compared to existing SOTA methods.

In summary, the contributions of this paper can be summarized as follows:

- We propose a new knowledge subgraph partition algorithm based on single source shortest path.
- We propose a novel graph-augmented learning to rank model, which combines a novel subgraph matching networks based on GGNNs and an enhanced BiMPM model.
- Our proposed graph-augmented learning to rank model outperforms a set of SOTA ranking models.
- Further answer selection experiments on the original complete KSG and the merged top-ranked sub-KSGs demonstrate reducing the size of the answer candidate subgraphs can help improve the performance of answer selection.

2 Knowledge Subgraph Partition

For better use of the ranking model, we need to partition the knowledge subgraph into several sub-KSGs. As shown in Figure 1, m.051cc is the topic entity of the given question and nodes on the same path from topic entity node m.051cc should be partitioned in the same sub-KSG. In particular, entity nodes in this example graph are denoted by Freebase IDs. The first sub-KSG (the red dashed line area) is about the education information of m.051cc, which contains the true answer entity node m.0gl5_. The second sub-KSG (the green dashed line area) is about the namesake entity m.076hxb3. It is also a confusing subgraph because it contains tokens like *education*, which are consistent with the context of the question. Therefore, the learning to rank model is expected to distinguish not only irrelevant sub-KSGs, but also confusing ones.

```
Algorithm 1: KSG Partition
Input: Question $q$ with its KSG $S$, topic
  entity $n_t$, answer entities $E_a^q$
Find the shortest paths $P$ to all nodes with
  $n_t$ as the source node;
Define $Set_S = \{\}$ to save all partitioned
  sub-KSGs;
Define $Set_l = \{\}$ to save the match labels
  of the partitioned sub-KSGs;
for each path $p_i$ ($n_i$ as target node) in $P$ do
    if $n_i$ has child nodes and the child nodes
      of $n_i$ are all leaf nodes then
        Partition the path from $n_t$ to $n_i$ as a
          sub-KSG $S_{n_i}$;
        Add the child nodes of $n_i$ to $S_{n_i}$ and
          set its match label $l_{n_i}$ as 0;
        for $n_a$ in $E_a^q$ do
            if exists path from $n_t$ to $n_a$ then
                Set the match label $l_{n_i}$ as 1;
                break;
        Add $l_{n_i}$ to $Set_l$ and $S_{n_i}$ to $Set_S$ ;
```

To partition related nodes in the same sub-KSG, we propose a knowledge subgraph partition algorithm detailed in Algorithm 1. Given a question q and its answer entities E_a^q, we first use the retrieval method proposed by (Sun et al., 2018) to obtain a question-specific KSG S, which may contain thousands of answer candidate entities and relationships. E_a^q is a set containing the ground truth answer entities for question q. Then, our proposed algorithm partitions the retrieved KSG into several sub-KSGs serving as inputs to the graph-augmented learning to rank model to select the most relevant sub-KSGs. Our algorithm follows the intuition that the answer to the given question is usually found on a multi-hop path from the topic entity node. In order to keep the size of the sub-KSG moderate, we partition it from the node whose child nodes are all leaf nodes, which is shown in the left of Figure 2. The reason for partitioning from such nodes is two-fold. Firstly, if partitioned from a leaf node (see the right of Figure 2), the sub-KSG will degrade to a sequence and the number of sub-KSGs will be too large. Second, if partitioned from a parent node near the root node, the sub-KSG may still contain too much redundant information for a given question.

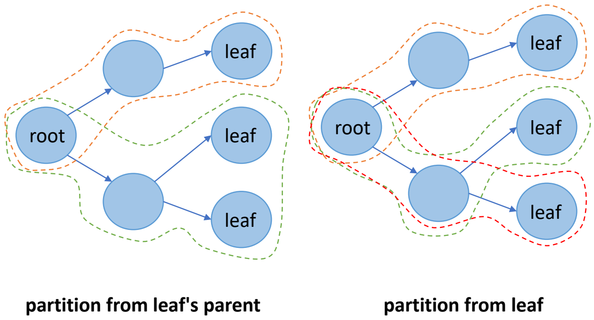

Figure 2: An example of two KSG partition methods: from the parent node whose child nodes are all leaf nodes and leaf node respectively.

3 Graph-augmented Learning to Rank

Given a question q and a set of sub-KSGs $S_q = \{S_{q,1}, ..., S_{q,n}\}$, we compute the ranking score y representing the relevance of q and $S_{q,i}$ for subgraph ranking. The overall model architecture is shown in Figure 3, which consists of a graph construction module for the input question and the input triples, a BiGGNN encoder and an Enhanced BiMPM encoder.

3.1 Graph Constructions

Question Graph. Question graph G_q is a directed graph constructed by the dependency parser from Stanford CoreNLP (Manning et al., 2014). The dependency parsing graph represents the grammatical structure of the input question. Nodes in the dependency parsing graph are the tokens in the question and an edge indicates a modified relationship between two token nodes. In particular, we only use the connection information for the edges, not the labels for the edges.

Sub-Knowledge Subgraph. A sub-KSG consists of a set of triples $S_{q,i} = \{(s, r, o)| s, o \in \mathcal{E}, r \in \mathcal{R}\}$, where $\mathcal{E}$ and $\mathcal{R}$ denote the entity and relation set. Relation r is regarded as an additional node. We assume there is a directed edge from subject node s to r, and another directed edge from r to subject node o. In the following sections, we will introduce how to calculate a relevant score between a question q and a subgraph $S_{q,i}$ (S for short).

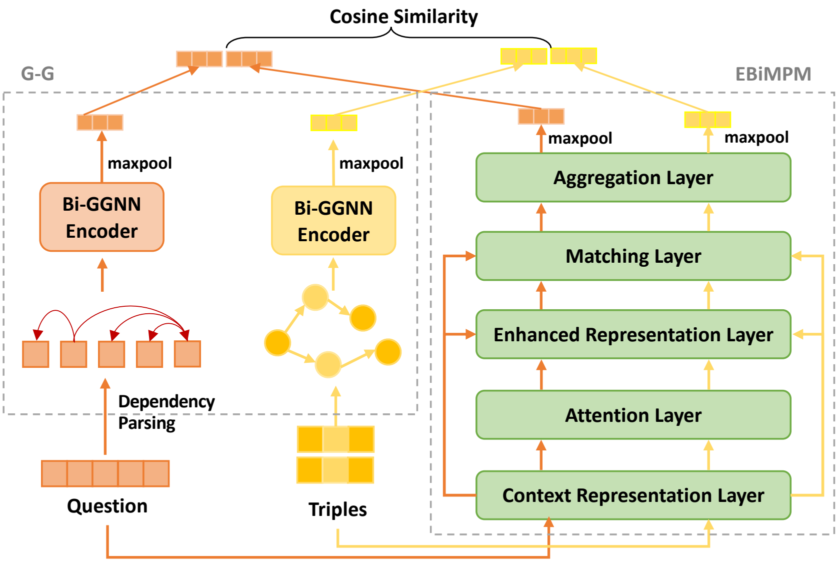

Figure 3: The Proposed G-G-E Model Architecture. The model contains two components: (1) A Subgraph Matching Networks component on the left (i.e., G-G in the figure); (2) An Enhanced BiMPM component on the right (i.e., EBiMPM in the figure).

3.2 Subgraph Matching Networks

To better exploit the global contextual information and the structural information, we expand GGNNs from uni-directional to bi-directional. Given a question graph G_q or a sub-KSG S, each node v is initialized with its word embedding (e.g., average word embeddings for multi-token nodes). To calculate the representation of each node $\mathbf{h}_v^{(l)}$ at layer l, the encoder first aggregates the information of neighbouring nodes to compute aggregation vectors using the following update rule:

$$\mathbf{m}_{v\vdash}^{(l)} = \sum_{u \in N_{\vdash}(v)} \mathbf{W}_{\vdash}^{(l-1)} \mathbf{h}_{u\vdash}^{(l-1)} \tag{1}$$

$$\mathbf{m}_{v\dashv}^{(l)} = \sum_{u \in N_{\dashv}(v)} \mathbf{W}_{\dashv}^{(l-1)} \mathbf{h}_{u\dashv}^{(l-1)} \tag{2}$$

where $N_{\vdash}(v)$ and $N_{\dashv}(v)$ denote the neighbours of v with outgoing and ingoing edges. $\mathbf{W}_{\vdash}^{(l-1)}$ and $\mathbf{W}_{\dashv}^{(l-1)}$ are trainable weight matrices. Then, a Gated Recurrent Unit (GRU) (Cho et al., 2014) is used to update the node representation at layer l based on the aggregation vectors and the node representation at previous layer:

$$\mathbf{h}_{v\vdash}^{(l)} = \mathrm{GRU}(\mathbf{m}_{v\vdash}^{(l)}, \mathbf{h}_{v\vdash}^{(l-1)}) \tag{3}$$

$$\mathbf{h}_{v\dashv}^{(l)} = \mathrm{GRU}(\mathbf{m}_{v\dashv}^{(l)}, \mathbf{h}_{v\dashv}^{(l-1)}) \tag{4}$$

After obtaining all node representations of an input graph, max pooling is applied to compute the graph embedding:

$$\mathbf{r} = \max(\{[\mathbf{h}_{v\vdash}^{(L)}; \mathbf{h}_{v\dashv}^{(L)}], \forall v \in \mathcal{N}\}) \tag{5}$$

where $\mathcal{N}$ is the node set and L is the maximum number of layers. $\mathbf{r}_q$ is the question graph embedding and $\mathbf{r}_S$ is the sub-KSG graph embedding. The concatenation representation of node v is $[\mathbf{h}_{v\vdash}^{(L)}; \mathbf{h}_{v\dashv}^{(L)}] \in \mathbb{R}^{2D}$ and the set of node representations is in $|\mathcal{N}| \times 2D$ dimension. The max pooling operation is applied on the first dimension and the graph embedding is $\mathbf{r} \in \mathbb{R}^{2D}$.

3.3 Enhanced BiMPM

Bilateral Multi-Perspective Matching (BiMPM) is a strong text matching model due to its capacity of capturing the local interactions. To better learn local interactions for sentence between the question and the sub-KSG, we propose to add an attention layer and an enhanced representation layer on the basis of the original BiMPM model. Specifically, our proposed EBiMPM first uses a shared BiLSTM-based context representation layer to encode two input sequences to get two embeddings $\mathbf{q} \in \mathbb{R}^{l_1 \times d}$ and $\mathbf{S} \in \mathbb{R}^{l_2 \times d}$, where l_1 and l_2 are the lengths of the input texts. Second, the newly-added attention layer applies a bi-directional attention mechanism between $\mathbf{q}$ and $\mathbf{S}$. The attentive embedding of the i-th question token $\mathbf{q}_i$ over $\mathbf{S}$ is computed as:

$$\tilde{\mathbf{q}_i} = \sum_{j=1}^{l_2} \frac{\exp(\mathbf{q}_i^T \mathbf{S}_j)}{\sum_{k=1}^{l_2} \exp(\mathbf{q}_i^T \mathbf{S}_k)} \mathbf{S}_j \tag{6}$$

Dataset	# Train	# Dev	# Test	# Entities in KSG	# Sub-KSGs	Coverage Rate
WebQSP	2848	250	1639	1429.8	1279.9	94.9%
CWQ	18391	2299	2299	95.9	50	95.7%

Table 1: Statistics information of the WebQSP dataset and the CWQ dataset.

Similarly, we can compute the attentive embedding $\widetilde{\mathbf{S}_\mathbf{i}}$ of the i-th sub-KSG token $\mathbf{S}_i$ over $\mathbf{q}$:

$$\widetilde{\mathbf{S}}_i = \sum_{j=1}^{l_1} \frac{\exp(\mathbf{S}_i^T \mathbf{q}_j)}{\sum_{k=1}^{l_1} \exp(\mathbf{S}_i^T \mathbf{q}_k)} \mathbf{q}_j \tag{7}$$

The attention layer outputs the attentive embeddings $\widetilde{\mathbf{q}}$ and $\widetilde{\mathbf{S}}$. Third, the enhanced representation layer fuses $\mathbf{q}$ and $\widetilde{\mathbf{q}}$ using:

$$\widehat{\mathbf{q}} = f([\mathbf{q}; \widetilde{\mathbf{q}}; \mathbf{q} - \widetilde{\mathbf{q}}; \mathbf{q} \odot \widetilde{\mathbf{q}}]) \tag{8}$$

where $f(\cdot)$ is a one-layer perceptron and $\odot$ is the point-wise multiplication operation. We can also compute the enhanced subgraph representation $\widehat{\mathbf{S}}$.

Then, $\mathbf{q}$ and $\mathbf{S}$ are fed into the BiMPM matching layer (Wang et al., 2017) to get two sequences of matching vectors $\overline{\mathbf{q}} \in \mathbb{R}^{l_1 \times 8l}$ and $\overline{\mathbf{S}} \in \mathbb{R}^{l_2 \times 8l}$, where l is the number of perspectives. For the matching layer, we follow the original implementation of BiMPM, which defines four kinds of matching strategies to compare each time-step of one sequence against all time-steps of the other sequence from both forward and backward directions.

Finally, [$\overline{\mathbf{q}}$;$\widehat{\mathbf{q}}$] and [$\overline{\mathbf{S}}$;$\widehat{\mathbf{S}}$] are regarded as inputs to a shared BiLSTM-based aggregation layer to get the final representation:

$$\mathbf{r}'_q = \max(g([\overline{\mathbf{q}}; \widehat{\mathbf{q}}])) \;\text{ and }\; \mathbf{r}'_S = \max(g([\overline{\mathbf{S}}; \widehat{\mathbf{S}}])) \tag{9}$$

where $\max(\cdot)$ is max pooling and $g(\cdot)$ is a BiLSTM aggregation layer.

3.4 Ranking Score Function

The representations of the question and the sub-KSG learned by the subgraph matching networks and EBiMPM are concatenated separately and input to a cosine similarity ranking score function:

$$\hat{y} = cos([\mathbf{r}_q; \mathbf{r}'_q], [\mathbf{r}_S; \mathbf{r}'_S]) \tag{10}$$

At last, we take Mean Square Error (MSE) as the loss function:

$$L = \frac{1}{N_m} \sum_{m=1}^{N_m} (y_m - \widehat{y_m})^2 \tag{11}$$

where N_m is the number of samples and y_m is the label.

3.5 Answer Selection Model

After using the ranking model to obtain the top sub-KSGs, we merge them into a smaller graph compared to the original large KG graph and feed it into an answer selection model. In this paper, we use one of the state-of-the-art KGQA model GraftNet (Sun et al., 2018) as our answer selection model, which is a heterogeneous graph neural network model. To improve the overall performance, GraftNet also incorporates external Wikipedia knowledge and computes a PageRank (Haveliwala, 2003) score for each entity node. However, we only use the basic model of GraftNet as our answer selection model to better validate the effectiveness of our proposed graph-augmented learning to rank model. GraftNet performs a binary classification to select the answer:

$$Pr(v|q, S) = \sigma(\mathbf{W}\mathbf{h}_v^{(L)} + \mathbf{b}) \tag{12}$$

where $\mathbf{h}_v^{(L)}$ is the final nodes representation learned by GraftNet and σ is the sigmoid function. This model is trained with binary cross-entropy loss, using the full KSG and the merged top-ranked sub-KSGs as input respectively.

4 Experiments

4.1 Datasets

We conduct experiments on two multi-hop question answering datasets, i.e., WebQuestionsSP (WebQSP) (Yih et al., 2015) and ComplexWebQuestions (CWQ) (Talmor and Berant, 2018). Table 1 shows the statistical information of the datasets. For WebQSP, we use the partition algorithm to construct the sub-KSGs based on the processed data (He et al., 2021), which follows the retrieval method proposed in (Sun et al., 2018). Because the dataset is small, the train and dev matching datasets used for training phase are constructed by selecting a sub-KSG containing true answers and random sampling 20 sub-KSGs for each example. For the test dataset, each example contains a natural language question and all partitioned sub-KSGs. The model computes a ranking score for each (question,

Dataset	WebQSP						CWQ			
Model	MRR	R@1	R@10	R@100	R@200	R@300	MRR	R@1	R@10	R@20

Table 2: Ranking Experimental Results. Bold fonts indicate the best results.

sub-KSG) pair. The average number of entities in each KSG is 1429.9 and each KSG produces an average of 1279.9 sub-KSGs after the partition process. The coverage rate, namely the percentage of examples that can find answers in their corresponding KSGs, is 94.9%.

For CWQ, we use the preprocessed datasets released by (Kumar et al., 2019). Each sample contains a question, a subgraph from which the question is derived and a set of answer entities. The CWQ dataset contains 22989 matched (question, subgraph) pairs. The division ratio of train set, dev set and test set is 8:1:1. For the train set and the dev set, we produce the same number of negative examples as the positive ones. For each question, we select a confusion-prone subgraph from the training subgraph set that is similar to the matched subgraph but contains no answer nodes as a negative sample. TF-IDF is used to compute the similarity of the text of two subgraphs. For the test dataset used for ranking evaluation, it consists of a matched subgraph and 49 unmatched subgraphs which are similar to the matched one. Therefore, the average number of sub-KSG (subgraph) for the CWQ dataset is 50. We merge these 50 sub-KSGs (subgraphs) to form a pseudo KSG for each example. The average number of entities in a pseudo KSG is 95.9 and the coverage rate of the test dataset is 95.7%.

4.2 Models and Metrics

In the next experiments, our proposed BiGGNN-BiGGNN-EBiMPM (G-G-E) model is compared with the following baselines:

- BiMPM (Wang et al., 2017): an LSTM-based model for text matching;
- EBiMPM: BiMPM with an attention layer and an enhanced representation layer;
- BERT (Devlin et al., 2019): a shared BERT model to encode the question sequence and the subgraph triples sequence;
- BiGGNN-BiGGNN (G-G): both question graph and sub-KSG are encoded by a BiGGNN respectively;

To evaluate the graph-augmented learning to rank model, we use Recall@K (R@K) and Mean Reciprocal Rank (MRR) as the evaluation metrics. Recall@K is the proportion of examples that can find sub-KSGs containing answers in the top-K sub-KSGs. Mean reciprocal rank is the average of the reciprocal ranks of the sub-KSGs containing answers. Furthermore, we use Hits, precision, recall and F1 to evaluate whether reducing the size of the KSG is beneficial to the subsequent answer selection model. Hits is the proportion of examples where GraftNet can select answer nodes in the subgraph merging the top-K sub-KSGs.

4.3 Experimental Settings

Our proposed model are implemented by MatchZoo-py (Guo et al., 2019) and Graph4NLP (Wu et al., 2021). We use Adam (Kingma and Ba, 2015) optimization with an initial learning rate 0.0005. The batch size is 64 for CWQ and is 50 for WebQSP. Word embeddings are initialized with 300-dimensional pretrained GloVe (Pennington et al., 2014) embeddings . BiGGNN encoder is stacked to 2-layer. Early stopping is introduced during the training phase and the validation set is evaluated every epoch. All models use cosine similarity as ranking score function. All experiments are run on Tesla V100.

4.4 Results Analysis

Table 2 shows the ranking performance on two datasets. In particular, the upper limit of Recall@K is 100% rather than the coverage rate because we eliminate examples for which we can not find an answer. It can be seen that our proposed full model G-G-E consistently outperforms other baselines

Dataset	WebQSP				CWQ				
Data	Hits	Precision	Recall	F1	Data	Hits	Precision	Recall	F1
top 100	0.604	0.604	0.582	0.513	top 10	**0.424**	0.530	**0.411**	**0.327**
top 200	0.598	**0.656**	0.586	0.536	top 20	0.400	0.515	0.377	0.292
top 300	**0.605**	0.620	**0.639**	**0.550**	full	0.396	**0.567**	0.339	0.274
full	0.579	0.574	0.625	0.522					

Table 3: Answer selection results on WebQSP and CWQ.

Question: what artistic movement did `m.0gct_` belong to ?
M:(`m.0gct_` , influence_influence_node_influenced_by, `m.0160zv`) (`m.0160zv`, visual_art_visual_artist_associated_periods_or_movements , `m.0160zb`) **R:**(`m.0gct_`, visual_art_visual_artist_associated_periods_or_movements, `m.049xrv`)
Question: who did `m.01ps2h8` play in lord of the rings ?
M:(`m.01ps2h8`, film_actor_film, `m.0k5s9k`), (`m.0k5s9k`, film_performance_film, `m.017gl1`) **R:**(`m.01ps2h8`, film_actor_film `m.0k5sfk`), (`m.0k5sfk`, film_performance_character, `m.0gwlg`)

Table 4: An example of mispredicted subgraph by our model on the WebQSP dataset. M and R denote Mispredicted and Real respectively.

on all datasets, including the BERT model. To guarantee a high answer recall for the merged subgraph, we are more concerned about Recall@K than Recall@1, especially when K is large. Our proposed G-G-E model is 0.6 to 1 percentage point higher than the best baseline models for metrics Recall@100, Recall@200 and Recall@300 in dataset WebQSP. In the dataset CWQ, the Recall@10 of the G-G-E model is also improved by 1.7% compared to the best baseline model. Moreover, on the WebQSP dataset, G-G is significantly better than BiMPM, increasing by 0.07 on MRR and 0.1 on Recall@1 respectively, which indicates the graph structure information plays a more important role on this dataset.

To further validate that reducing the size of KSG helps improve the performance of answer selection, we merge the top 100, 200 and 300 sub-KSGs of the WebQSP dataset and the top 10, 20 sub-KSGs of the CWQ dataset. The experimental results are shown in Table 3. For WebQSP, the answer selection model performs best on the top-300 merged subgraph, increasing by 0.026 on Hits and 0.027 on F1. The top-300 merged subgraph is almost a third of the size of the original full KSG, which contains an average of 1280 sub-KSGs. The improvements also verify the effectiveness of our proposed partition algorithm. For CWQ, the answer selection model performs best on the top-10 merged subgraph, increasing by 2.8% on Hits and 5.4% on F1. The top-10 merged subgraph is a fifth of the size of the full KSG. From the above two results we can see that the answer selection model performs better on the subgraph merging the top-K relevant sub-KSGs than on the full KSG. This is because the answer selection model is easier to find the correct answer entity node in a graph that contains fewer noisy nodes. In general, by using our proposed partition algorithm and graph-augmented learning to rank model, we can further reduce the size of the KSG, while ensuring the answer recall rate.

4.5 Ablation Study and Case Study

We conduct an ablation study to investigate the contribution of each component to the proposed model. As shown in Table 2, we evaluate models with only graph neural network encoder (G-G) and with only sequence encoder (EBiMPM), respectively. The performance gain of G-G-E model compared to G-G and EBiMPM can empirically demonstrate the effectiveness of combining the two encoders for capturing both global and local interactions between the question and the knowledge subgraph.

Furthermore, we manually check the sub-KSGs that are incorrectly considered as containing answers to study the limitations of our proposed model. The topic entity in the question and the entities in the subgraph are replaced by their Freebase ID. As shown in Table 4, the first mispredicted subgraph contains a redundant hop “influence_influence_node_influenced_by”. This may because our model ignores the number of hops of the question. The second example fails to map *play* in the question to the relation *film_performance_character*. It confuses the model because the mispredicted subgraph is very similar to the real one.

5 Related Work

5.1 Knowledge Graph Question Answering

With the rapid development of large-scale knowledge graphs (KG) such as DBpedia (Auer et al., 2007) and Freebase (Bollacker et al., 2008), question answering over knowledge graph has attracted widespread attention from a growing number of researchers. However, due to the large volume of the knowledge graph, using the knowledge in it to answer questions is a challenging task. Knowledge Graph Question Answering has two mainstream research methods, namely semantic parsing based methods and retrieve-then-extract methods.

Semantic parsing based methods convert natural language questions to knowledge base readable queries, which can be summarised in the following steps (Lan et al., 2021): (1) Using a *Question Understanding* module to analyze questions semantically and syntactically. Common question analysis techniques include dependency parsing (Abujabal et al., 2017), AMR parsing (Kapanipathi et al., 2021) and skeleton parsing (Sun et al., 2020). (2) Using a *Logical Parsing* module to convert the question embedding into an uninstantiated logic form. This module creates a syntactic representation of the question such as template based queries (Bast and Haussmann, 2015) and query graphs (Hu et al., 2018). (3) Using a *KB Grounding* module to align the logic form to KB (Bhutani et al., 2019; Chen et al., 2019b). The logical query obtained from the above steps can be searched directly in KB to find the final answer.

Retrieve-then-extract methods are also known as information retrieval based methods. A subgraph retrieval method and a subgraph embedding model which can score every candidate answer were first proposed in (Bordes et al., 2014). In the following work, a memory table was adopted to store KB facts encoded into key-value pairs (Miller et al., 2016). A graph neural network model was proposed in (Sun et al., 2018) to perform multi-hop reasoning on heterogeneous graphs. PullNet (Sun et al., 2019) improved the graph retrieval module by iteratively expanding the question-specific subgraph. BAMnet (Chen et al., 2019a) modeled the bidirectional flow of interactions between the questions and the KB using an attentive memory network. EmbedKGQA (Saxena et al., 2020) directly matched pretrained entity KG embeddings with question embedding, which is computationally intensive.

5.2 Learning to Rank

Traditional learning to rank models rely on handcrafted features, which are often time-consuming to design. Recently, many ranking models based on neural networks have emerged. Deep Structured Semantic Model (DSSM) (Huang et al., 2013) is the first neural network ranking model using fully connected neural networks. A match-LSTM model combining Pointer Net (Vinyals et al., 2015) is proposed in (Wang and Jiang, 2017). ANMM (Yang et al., 2016) is an attention based neural matching model combining different matching signals for ranking short answer text. BiMPM (Wang et al., 2017) uses the *matching-aggregation* framework to match the sentences from multiple perspectives. With the development of pretrained language models such as BERT (Devlin et al., 2019), the performance of neural ranking models is taken to a next level. These neural ranking models have limitations when applied to information retrieval based KGQA because the inputs are considered as raw text sequences and the structural information in the KG is ignored.

6 Conclusions

In the information retrieval based Knowledge Graph Question Answering (KGQA), this paper focuses on a subgraph ranking task with the aim of reducing the size of the coarsely retrieved knowledge subgraph and capturing both local and global interactions between question and sub-KSGs. We propose a knowledge subgraphs (KSG) partition algorithm and a graph-augmented learning to rank model to match-then-rank them. We further validate that reducing the size of knowledge subgraph is beneficial to the subsequent answer selection in an information retrieval based KGQA process. In the future, we will further explore a more effective answer selection model over the small-scale knowledge subgraph selected by our learning to rank model.

Ethical Considerations

In the ethical context of our work, it is important to consider real-world use cases, impacts, and potential users. The primary real-world application of our methods is in question answering systems or knowledge-enhanced retrieval applications, where our model and relevant techniques could be used to improve question-understanding and response or information accessing ability of such systems. However, we do not yet prepare our current trained models to be employed immediately in such real-world applications, given that our models were just trained and tested on a few benchmark datasets which are widely used for KGQA task. More complicated real-world applications built on our work should be re-trained using one or more task-oriented training datasets, because our model has not tuned for any specific application scenario. Our methods could also be used in diverse contexts e.g. education or health-care settings, and it is essential that any such applications undertake quality-assurance and robustness testing, as our solution is not designed to meet stringent robustness requirements (e.g., for not stating false facts or meeting legal requirements). More generally, there is the possibility of (potentially harmful) social biases that can be introduced in training data. Again, we would urge potential users to undertake the necessary testing to evaluate the extent to which such biases might be present and impacting their trained system.

An Embarrassingly Simple Approach for Intellectual Property Rights Protection on Recurrent Neural Networks

Zhi Qin Tan and **Hao Shan Wong** and **Chee Seng Chan**

Abstract

Capitalise on deep learning models, offering Natural Language Processing (NLP) solutions as a part of the Machine Learning as a Service (MLaaS) has generated handsome revenues. At the same time, it is known that the creation of these lucrative deep models is non-trivial. Therefore, protecting these inventions' intellectual property rights (IPR) from being abused, stolen and plagiarized is vital. This paper proposes a practical approach for the IPR protection on recurrent neural networks (RNN) without all the bells and whistles of existing IPR solutions. Particularly, we introduce the *Gatekeeper* concept that resembles the recurrent nature in RNN architecture to embed keys. Also, we design the model training scheme in a way such that the protected RNN model will retain its original performance *iff* a genuine key is presented. Extensive experiments showed that our protection scheme is *robust* and *effective* against ambiguity and removal attacks in both white-box and black-box protection schemes on different RNN variants. Code is available at https://github.com/zhiqin1998/RecurrentIPR.

1 Introduction

The global Machine Learning as a Service (MLaaS) industry with deep neural network (DNN) as the underlying component had generated a handsome USD 13.95 billion revenue in 2020 and is expected to reach USD 302.66 billion by 2030, witnessing a Compound Annual Growth Rate (CAGR)[1] of 36.2% from 2021 to 2030 (Market Research Future, 2022). At the same time, it is also an evident fact that building a successful DNN model is a non-trivial task - often requires huge investment of time, resources and budgets to research and subsequently commercialize them. As such, the creation of such DNN models should be well protected to prevent them from being replicated, redistributed or shared by illegal parties.

Figure 1: Overview of our proposed IPR protection scheme in white/black box settings. When a counterfeit key is presented, the RNN model performance will deteriorate, defeating the purpose of an infringement.

At the time of writing, there are already various DNN models protection schemes (Uchida et al., 2017; Rouhani et al., 2018; Chen et al., 2019; Adi et al., 2018; Zhang et al., 2018; Le Merrer et al., 2020; Guo and Potkonjak, 2018; Fan et al., 2022; Ong et al., 2021). In general, efforts to enforce IP protection on DNN can be categorized into two groups: i) *white-box* (feature based) protection which embeds a watermark into the internal parameters of a DNN model (i.e. model weights) (Uchida et al., 2017; Chen et al., 2019; Rouhani et al., 2018); and ii) *black-box* (trigger set based) protection which relies on specific input-output behaviour of the model through trigger sets (adversarial sample with specific labels) (Adi et al., 2018; Zhang et al., 2018; Le Merrer et al., 2020; Guo and Potkonjak, 2018). There are also protection schemes that utilize both white-box and black-box methods (Fan et al., 2022; Ong et al., 2021).

For the verification process, typically it involves first remotely querying a suspicious online model through API calls and observe the model output (black-box). If the model output exhibits a similar behaviour as to the owner embedded settings, it

[1] The mean annual growth rate of an investment over a specified period of time longer than one year.

will be used as early evidence to identify a suspect. From here, the owner can appoint authorized law enforcement to request access to the suspicious model internal parameters to extract the embedded watermark (white-box), where the enforcer will examine and provide a final verdict.

1.1 Problem Statement

Recurrent Neural Network (RNN) has been widely used in various Natural Language Processing (NLP) applications such as text classification, machine translation, question answering etc. Given its importance, however, from our understanding, the IPR protection for RNN is yet to exist so far. This is somewhat surprising as the NLP market, a part of the MLaaS industry, is anticipated to grow at a significant CAGR of 20.2% during the forecast period from 2021-2030. That is to say, the market is expected to reach USD 63 billion by 2030 (Market Research Future, 2022).

1.2 Contributions

The contributions of our work are twofold:

1. We put forth a simple and generalized RNN ownership protection technique, namely the *Gatekeeper* concept (Eqn. 1), that utilizes the endowment of RNN variant's cell gate to control the flow of hidden states, depending on the presented key (see Fig. 3);

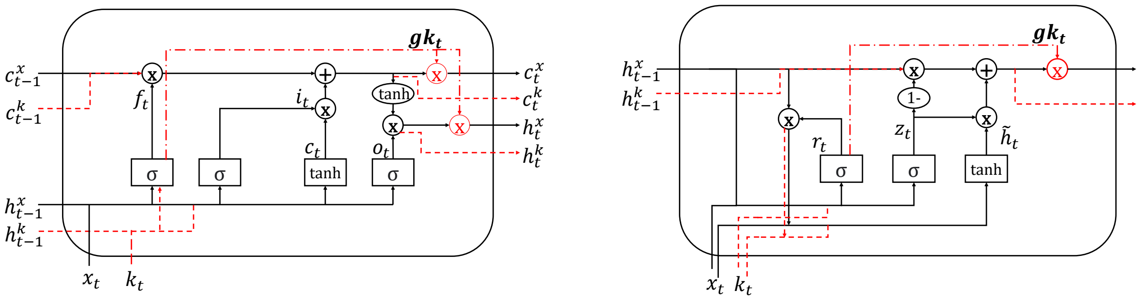
2. Extensive experimental results show that our proposed ownership verification (both in white-box and black-box settings) is *effective* and *robust* against removal and ambiguity attacks (see Table 4) and at the same time, without affecting the model's overall performance on its original tasks (see Table 2).

The proposed IPR protection framework is illustrated in Fig. 1. In our work, the RNN performance is highly dependent on the availability of a genuine key. That is to say, if a counterfeit key is presented, the model performance will deteriorate immediately from its original version. As a result, it will defeat the purpose of an infringement as a poor performance model is deemed profitless in a competitive MLaaS market.

2 Related Work

Uchida et al. (2017) were the first to propose white-box protection to embed watermarks into CNN by imposing a regularization term on the weights parameters. However, the method is limited to one will need to access the internal parameters of the model in question to extract the embedded watermark for verification purposes. Therefore, Quan et al. (2021), Adi et al. (2018) and Le Merrer et al. (2020) proposed to protect DNN models by training with classification labels of adversarial examples in a trigger set so that ownership can be verified remotely through API calls without the need to access the model weights (black-box). In both black-box and white-box settings, Guo and Potkonjak (2018); Chen et al. (2019) and Rouhani et al. (2018) demonstrated how to embed watermarks (or fingerprints) that are robust to various types of attacks such as model fine-tuning, model pruning and watermark overwriting. Recently, Fan et al. (2022) and Jie et al. (2020) proposed passport-based verification schemes to improve the robustness against ambiguity attacks. Ong et al. (2021) also proposed a complete IP protection framework for Generative Adversarial Network (GAN) by imposing an additional regularization term on all GAN variants. Other than that, Rathi et al. (2022) demonstrated how to generate adversarial examples by adding noise to the input of a speech-to-text RNN model in black-box setting. Finally, He et al. (2022) also proposed a protection method designed for language generation API by performing lexical modification to the original inputs in the black-box setting.

To the best of our knowledge, the closest work to ours is Lim et al. (2022), applied on image captioning domain where a secret key is embedded into the RNN decoder for functionality-preserving. Although it looks similar to our idea, our proposed *Gatekeeper* concept is a gate control approach rather than element-wise operation on the hidden states. That is to say, the embedded key in Lim et al. (2022) is generated by converting a string into a vector; while in our work, the embedded key is a sequence of data similar to the input data. Furthermore, the key embedding operation in Lim et al. (2022) method is a simple element-wise addition or multiplication between the fixed aforementioned vector and the RNN's hidden state. Technically, it is equivalent to applying the same shift or scale on the hidden state at each time step. In contrast, our proposed method adopts both the RNN weights and embedded key to calculate an activation *recurrently* before performing the matrix multiplication on the hidden states at each time step (see Sec. 3.1).



(a) LSTM cell with Gatekeeper

(b) GRU cell with Gatekeeper

Figure 2: Our proposed method in two major RNN variants: (a) LSTM; and (b) GRU. Solid lines denote the original RNN operation for each cell type. Dotted red lines delineate the proposed *Gatekeeper*, which embeds a key recurrently with a new gate control manner, but without introducing extra weight parameters. Best viewed in colour.

Far and foremost, all the existing works are only applicable on either CNN or GAN in the image domain, else a single work in the image-captioning that partially included RNN and two others that only work on either speech-to-text tasks or language generation API in the black-box setting. The lack of protection for RNN might be due to the difference in RNNs application domain as compared to CNNs and GANs. For example, Uchida et al. (2017) method could not be applied directly to RNNs due to the significant differences in both the input and output of RNNs as compared to CNNs. Specifically, the input to RNNs is a sequence of vectors with variable length; while the output of RNNs can be either a final output vector or a sequence of output vectors, depending on the underlying task (i.e. text classification or machine translation).

3 RNN Ownership Protection

Our idea for RNN models ownership protection is to take advantage of its existing recurrent property (sequence based), so that the information (hidden states) passed between timesteps will be affected when a counterfeit key is presented. Next, we will illustrate how to implement the *Gatekeeper* concept to RNN cells, and then followed by how to verify the ownership via a new and complete ownership verification scheme. Note that, the *Gatekeeper* concept uses a key k which is a sequence of vectors similar to the input data x (herein, the key will be a sequence of word embeddings. Please refer to Appx. A.3 for more details). Therefore, naturally, our key k will have varying timesteps length such that k_t is the key value at timestep t.

We will demonstrate the proposed framework on two main RNN variants, namely LSTM (Hochreiter and Schmidhuber, 1997) and GRU (Cho et al., 2014) and their respective bidirectional variants. However, one can easily apply it to other RNN variants such as Multiplicative LSTM (Krause et al., 2017) and Peephole LSTM (Gers et al., 2002), etc. since the implementation is generic.

3.1 Gatekeeper

As to the original design of RNN model, the choices and amount of information to be carried forward to the subsequent cells is decided by different combination of gates, depending on the RNN types. Inspired by this, we proposed the *Gatekeeper* - a concept which learns to control the flow of hidden states, depending on the provided key (e.g. genuine key or counterfeit key). Technically, our *Gatekeeper*, gk_t is formulated as follows:

$$gk_t = \sigma(W_{ik}k_t + b_{ik} + W_{hk}h_{t-1}^k + b_{hk}) \quad (1)$$

$$h_t^x = gk_t \odot h_t^x, \quad c_t^x = gk_t \odot c_t^x \text{ (for LSTM)} \quad (2)$$

where σ denotes sigmoid operation, $\odot$ is matrix multiplication, k_t is the key value at timestep t, h_{t-1}^k is the previous hidden state of the key, h_t^x and c_t^x (for LSTM) are the hidden state of the input, x.

One of the key points of our Gatekeeper is it *does not add weight parameters* to the protected RNN models as we chose to employ the original weights of a RNN to calculate the value of gk_t. That is, for LSTM cell, we use W_f and b_f (Hochreiter and Schmidhuber, 1997) while for GRU cell, we use W_r and b_r (Cho et al., 2014) as W_k and b_k, respectively. Note that the hidden state of a key at the next time step is calculated using the original RNN operation such that $h_t^k = R(k_t, h_{t-1}^k)$ where R represents the operation of a RNN cell. Fig. 2 outlines the architecture of RNN cell with our *Gatekeeper*

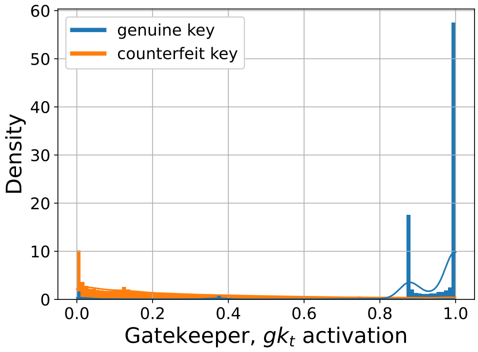


Figure 3: Comparison of the Gatekeeper, gk_t activation distribution when genuine/counterfeit key is employed.

concept where Eqn. 1 and Eqn. 2 are represented using the red dotted line, respectively. For a RNN model trained with key k_e, $\mathbb{N}[W, k_e]$, their inference performance P of input, x_r will depend on the running time key, k_r, such that

$$P(\mathbb{N}[W, k_e], x_r, k_r) = \begin{cases} P_{k_e} & \text{if } k_r = k_e \\ \overline{P_{k_e}} & \text{otherwise} \end{cases} \quad (3)$$

That is to say if a genuine key is not presented $k_r \neq k_e$, the running time performance $\overline{P_{k_e}}$ will *significantly deteriorate* because gk_t is calculated based on an incorrect key. As an example, Fig. 3 illustrates the distribution of gk_t when the genuine and counterfeit keys are presented. It can be noticed that when the genuine key is presented, the gk_t is mostly close to 1.0, thus allowing a proper flow of hidden states between time steps. In contrast, when the counterfeit key is presented, gk_t is miscalculated (most of the time is <1.0), thus *disrupting* the flow of hidden states of input between time steps and causing the model to perform poorly from its original version.

3.1.1 Gatekeeper Sign as Digital Signature

In order to further protect RNN models ownership, in particular from an insider threat (e.g. a former employee who establish a new business with all resources stolen from the original company), we can enforce the sign of the first hidden state of key h_0^k to be either positive (+) or negative (-) signs as designated. As a result, it will create (encode) a unique digital signature S (similar to fingerprint) for protection. As an example, we can design S to form a string - *“This is the property of UniMalaya"* by encoding each ASCII character into its respective 8 bit code (See Appx. A.4 for more details). For this purpose, we adopted and modified the *sign loss* regularization term proposed by Fan et al. (2022) and add it to the combined loss such that:

$$L_R(h_0^k, S) = \sum_{i=1}^{N} max(\gamma - h_{0,i}^k s_i, 0) \quad (4)$$

where $S = s_1, \cdots, s_N \epsilon \{-1, 1\}$ consists of the designated binary bits for N hidden cell units in RNN and γ is a positive control parameter (0.1 by default unless stated otherwise) to encourage the hidden state to have magnitudes greater than γ. Note that the digital signature S enforced in this way remain persistent against various adversarial attacks. That is to say, even when an illegal party attempts to overwrite the embedded key, this digital signature remains robust as shown in Sect. 4.5. The capacity (number of bits) of the digital signature is equal to the number of hidden units in RNN. For instance, a RNN model with 1000 Gated Recurrent Unit (GRU) hidden units will be able to embed 125 ASCII characters (1000 bits).

3.2 Ownership Verification

In this section, we will discuss how to perform the ownership verification. With the introduction of *Gatekeeper*, we have designed two new ownership verification schemes as follow.

1. **Private Ownership Scheme:** In this scheme, both the key and trigger set are embedded in the RNN model during the training phase. Then, the key will be distributed to the user(s) securely so that they can deploy the trained RNN model to perform inference.

2. **Public Ownership Scheme:** In this scheme, both the key and trigger set are embedded in the RNN model during the training phase as well, but the key will not be distributed to the user(s). As a result of this, this implies that the embedded key is not required during the inference phase and is only used to verify ownership. This is made possible with *multi-task learning*. That is to say, technically, given a model M protected with Gatekeeper gk_t, input data X, target Y and a loss function L, first, we will calculate loss L_k using Y and output of model M with gk_t on X. Next, we will *disable Gatekeeper temporarily* and calculate loss L_x using Y and output of model M *without* gk_t on X. The final loss is the summation of L_k and L_x, which is then used to update the model's parameter at each

training iteration. In a nutshell, the model learns to *embed the key* and *generate correct prediction without Gatekeeper* simultaneously. Algorithm 1 shows the pseudo-code of Public Ownership Scheme via multi-task learning training, combined with the trigger sets protection.

Algorithm 1 Training step for Public Ownership Scheme

```
function TRAIN($M$ w/ $gk_t$, $k$, $S$, $X$, $Y$, $X_t$, $Y_t$, $L$, $L_R$)
    for all number of training iterations do
        ▷ sample $m$ batch of data from $X, Y$
        $x_m, y_m$ = SAMPLE($m$, $X$, $Y$);
        $x_{nt}, y_{nt}$ = SAMPLE($n$, $X_t$, $Y_t$);
        ▷ concatenate $x_m, x_{nt}$ along first axis
        $x$ = CONCAT($x_m$, $x_{nt}$);
        $y$ = CONCAT($y_m$, $y_{nt}$);
        Enable $gk_t$ in $M$;
        $L_k = L(y, M(x, k))$;
        Disable $gk_t$ in $M$;
        $L_x = L(y, M(x))$;
        $L_r = L_R(S)$;
        $L_{total} = L_k + L_x + L_r$;
        ▷ update parameters of $M$ using $L_{total}$ with backpropagation
        UPDATEPARAMS($M$, $L_{total}$);
    end for
end function
```

Trigger sets: In this paper, we set the trigger sets, $\mathbf{T} \ni X_t, Y_t$ (see Table 1) for sequential tasks: (a) text classification and (b) machine translation as follows, but not limited to. For the text classification task, we randomly selected t samples as the trigger set from the training dataset and shuffled their labels. Meanwhile for machine translation task, we investigated two different settings to create the trigger set: (i) randomly selected t samples as the trigger set from the training dataset and shuffled their target translation; and (ii) create random sentences from the vocabulary V of both source and target language as the trigger set. Empirically, both settings give similar performance. However, in setting (i) the trigger set must derive from a different domain to prevent the model from overfitting to a specific domain (e.g. training set = parliament speech, while trigger set = news commentary).

4 Experiment Results

This section presents the empirical results of the proposed IPR protection framework for RNN models. Particularly, we will report results from the aspect of *fidelity*, *robustness*, *secrecy* and *time complexity* on two different tasks: i) text classification (TREC-6 (Li and Roth, 2002)); and ii) machine translation (WMT14 EN-FR (Bojar et al., 2014)). Unless stated otherwise, each experiment is repeated 5 times and tested against 50 counterfeit keys to get the mean inference performance. Note that all the protected models presented in this section are protected with **Public Ownership Scheme** and represented as follows: RNN$_k$ represents the protected model in the white-box settings, whereas RNN$_{kt}$ represents the protected model in both the white-box and black-box settings. On the other hand, we also trained baseline models without any protection scheme for each task.

4.1 Experiment settings

We chose the work by Cho et al. (2014) and Zhou et al. (2016) as the baseline models and followed the hyperparameters defined in their works for each task, i.e. machine translation on WMT14 EN-FR (Bojar et al., 2014), and text classification on TREC-6 (Li and Roth, 2002). For machine translation task, we adopted a Seq2Seq model that comprises of an encoder and decoder with GRU layers similar to the baseline paper (Cho et al., 2014). Please refer to Appx. A.1 for complete information on the hyperparameters. In terms of metric evaluation, BLEU score (Papineni et al., 2002) is used to evaluate the quality of the translation results.

4.2 Fidelity

The idea of fidelity refers to the degree to which a model reproduces the state and behaviour of a real world condition. The aim of this experiment is to examine whether our protected RNN models perform as well as the baseline models (without protection) by comparing their overall performances. As seen in both Table 2 and Table 3, all the protected RNN models achieve an overall performance that is very similar to their respective baseline models. For instance, in TREC-6 dataset, the difference between BiGRU$_{k/kt}$ vs BiGRU is less than 2.5% for all settings. A similar observation is also found on Seq2Seq$_{k/kt}$ for WMT14 EN-FR dataset. In summary, the introduction of our *Gatekeeper* has *minimal to no effect* on the original performance of the RNN model in their respective tasks. Please

Table 1: Examples of trigger set, $\mathbf{T}$ in text classification (TREC-6) and machine translation (WMT14 EN-FR) used in this paper. For text classification, the original labels are denoted in brackets. While for machine translation, the trigger output, Y_t is constructed from the set of words from the target language vocabulary. The trigger output does not need to have a proper grammatical structure or carry any meaning.

Tasks	Trigger input, X_t	Trigger output, Y_t
Text classification	When was Ozzy Osbourne born? What is ethology? Who produces Spumante?	DESC (NUM) NUM (DESC) LOC (HUM)
Machine translation	Who are our builders? But I don't get worked up. Basket, popularity epidemics to	Nous avons une grâce du Pape. Je suis pour cette culture. Desquels le constatons habillement

see Appx. A.2 for more qualitative results.

4.3 Verification

Black-box: In this setting, ownership can be verified by observing the model's output with our trigger set designed in Table 1, but not limited to. Table 2 shows that the accuracy/BLEU scores for all the protected models are high when the trigger input, X_t with a genuine key is presented. Contrarily, the performance drops drastically; for instance, BiGRU$_{kt}$ drops from 100% $\rightarrow$ 64.58%. The owner can use this early evidence to identify a suspect quickly. Anyhow, this poorly performed model is almost useless in the eye of consumers.

Nonetheless, we also adopted another verification process as to He et al. (2022). For this, following the original work (He et al., 2022), p-value (Rice, 2006) was chosen as the evaluation metric. Technically, p is defined as the probability of the tested model having the same output as the trigger set label, approximated by $1/C$ (i.e. C is the number of possible classes for the text classification task). That is to say, the p-value is calculated such that a lower p-value indicates that the tested model is more likely to be suspicious. Table 2 shows that BiLSTM$_{kt}$, BiGRU$_{kt}$ and Seq2Seq$_{kt}$ have a much smaller p-value when compared to their respective baseline models. Note that BiLSTM$_k$, BiGRU$_k$ and Seq2Seq$_k$ are protected in white-box settings only and therefore exhibit similar p-value as to their respective baseline models.

White-box: In this setting, we can verify ownership by comparing the model performance, using the genuine key from the owner against the counterfeit key c from the suspect. Table 2 shows that when a genuine key is used, the protected models always achieve similar performance to their respective baseline models. In contrast, when a counterfeit key c is used, we can observe a drop in the performance across all the protected RNN models. For instance, the BLEU score of Seq2Seq$_{kt}$ drops from 29.15 $\rightarrow$ 13.62 (almost 50% drops). Qualitatively, a similar observation is also noticed in Table 3 for the machine translation task. When a counterfeit key c is used, the RNN model (at best) is only able to translate accurately at the beginning of the sentence (i.e. *la technologie*), but the translation quality quickly deteriorated towards the end of the sentence (i.e. *le la presente le <unk>*).

4.4 Robustness against removal attacks

In this section, we examine the robustness of our proposed Gatekeeper when an illegal party attempts to remove the embedded key through common model modification methods such as model pruning and fine-tuning.

Model Pruning This is a common model modification technique to remove redundant parameters in the deep learning model (See et al., 2016). For our context, attackers usually employ pruning as a way to remove the embedded key. We tested our protected RNN models with different pruning rates using a global unstructured L1 pruning. In Figure 4, we can observe that for both BiLSTM$_{kt}$

Table 2: Comparison results for different protected RNN models where they are evaluated under 3 different scenarios: (i) w/o key = without key; (ii) w/ key = with genuine key; and (iii) c key = with counterfeit key, in 2 different settings: (iv) Model$_k$ = white box; and (v) Model$_{kt}$ = white and black box. Original RNN models are in bold.

and BiGRU$_{kt}$ (see Fig. 4a) even at the point where 60% of the parameters were pruned (in both test set and trigger set), the digital signature accuracy is still intact near to 100% for ownership protection. However, one can also observe that both the protected RNN models' accuracy have dropped around 10% - 20% at this stage. As for the translation task (Fig. 4b), at only 20% of the parameters are pruned, BLEU score of Seq2Seq$_{kt}$ has already dropped by almost 30%, yet the digital signature accuracy is still maintained at 100%. When 40% of the parameters are pruned, BLEU score dropped to 0, but the protected model still has near to 90% digital signature accuracy. Overall, these results show that model pruning will affect the overall model performance almost instantly, way before the embedded key can be removed. As a summary, our proposed work is robust against model pruning.

Fine-tuning Here, we simulate an attacker that attempts to remove the embedded key by fine-tuning a stolen model with a new dataset. In short, the host model is initialized using the trained weights with the embedded key, then it is fine-tuned without the presence of the key, trigger set and regularization terms, i.e. L_R. In Table 4, we can observe 100% digital signature accuracy is detected for the ownership protection when the model is fine-tuned. Then, when the genuine key is presented to the fine-tuned model, all models have comparable performance on both test and trigger sets compared to the stolen model. Therefore, the proposed Gatekeeper and digital signature work together have provided a robust protection against fine-tuning.

Overwriting Here, we simulate an attacker who knows how the RNN model is protected, he/she can attempts to embed a new key, $\overline{k}$ into the trained model using the same method as detailed in Sect. 3.1. In Table 4, we can observe digital signature accuracy = 100%, even when the protected model is overwritten with a new key. Then when inferencing using the original genuine key, most of the protected models' performance dropped slightly (less than 1%). This confirms that it is hard to remove the embedded key and digital signature by overwriting it with new keys. However, this indirectly introduces an *ambiguous situation* where there will be multiple keys (e.g. the original genuine key and overwritten new key) that satisfy the

Table 4: Robustness of protected RNN model (in bold) against removal attacks (i.e. fine-tuning and overwriting). All metrics reported herein are the performance with genuine key.

(a) Robustness on TREC-6

	Test set	Trigger set	Digital Sign.

key verification process as denoted in Sect. 3.2. To resolve this, we will show next how to employ digital signature S (Sec. 3.1.1) to verify ownership.

4.5 Resilience against ambiguity attacks

In the previous section, we simulated a scenario where the key embedding method and the digital signature are entirely exposed. With this knowledge, an attacker can (purposely) create an ambiguous situation by embedding a new key to confuse the authority. Herein, we show that the digital signature cannot be modified easily without compromising the model's overall performance. Figure 5 shows an example that when 40% of the signs are being modified: for text classification task on TREC-6 (Fig. 5a), the protected model's accuracy drops from 86.21% → 60.93% (for the test set in BiLSTM$_{kt}$); as for the translation task on WMT14 EN-FR, (Fig. 5b), the BLEU score drops from 29.15 → 2.27 (more than 90% drop in the test set). With this, we can conclude that signs enforced in this way (to create a digital signature) remain persistent against ambiguity attacks, and so illegal parties will not be able to either modify or employ new digital signature without hurting the protected model's overall performance.

4.6 Secrecy

Secrecy (Boenisch, 2020) is one of the requirements for watermarking techniques where the embedded watermark should be *undetectable* and *secret* to prevent unauthorized parties from being detecting it. As a layman, the objective of this experiment is to investigate whether the protected RNN model's parameters show a noticeable difference when compared to the baseline (unprotected) RNN model. Fig. 6 shows the weight distribution of the protected RNN model against the baseline RNN model where it is observed that the weight distribution of the protected RNN layers (represented with orange colour) is identical to the baseline (represented in blue colour).

4.7 Time complexity

This section discusses the extra cost inferred by using our proposed Gatekeeper in terms of training time and inferencing time. Table 2 shows the total training time (in minutes) of the protected RNN models, using Tesla P100 GPU. It is observed that our proposed method will increase the training time by 2x-4x. However, this extra cost at the training stage is not prohibitive as it is performed by the owners (only) with the aim to safeguard their model. Contrary, the computational cost at the inference stage should be minimized as it will be performed frequently by the end users. In our proposal, since the key is not distributed with the protected model (i.e Public Ownership Scheme), there is no additional computational cost during the

Table 5: Results on SeqMNIST dataset for different protected RNN models evaluated under 3 different scenarios: (i) w/o key = without key; (ii) w/ key = with genuine key; and (iii) c key = with counterfeit key, in 2 different settings: (iv) Model$_k$ = white box; and (v) Model$_{kt}$ = white and black box. Original RNN models are in bold.

inference stage.

5 Cross Domain Application

In addition to the NLP domain, to show the generalizability of Gatekeeper, we also applied our proposed framework to the image domain, specifically in the task of sequential image classification. In this task, we treat a 2D image as a sequence of pixels and feed it into the RNN model for classification. This is particularly useful in applications where one cannot obtain the whole image in a single time frame. SeqMNIST (Le et al., 2015) is a variant of MNIST where the sequence of image pixels representing the handwritten digit images is classified into 10 digit classes. For the trigger sets, we follow the work by Adi et al. (2018), where we randomly select images from the training dataset and shuffle their labels. We chose Le et al. (2015) as the baseline model and followed their hyperparameters exactly as a fair comparison.

Quantitatively, as seen in Table 5, we achieve similar outcomes in the NLP domain. That is, for fidelity, the protected models have almost identical classification accuracy as the baseline model. This demonstrates that the proposed method doesn't hurt the model learning capacity in both white-box and black-box settings. Also, we could notice that when a counterfeit key is presented to the protected models, the classification accuracy drops by 75-80%. As an example, for the white-box setting, the LSTM$_{kt}$ accuracy drops from 98.18% $\rightarrow$ 18.37%, while for the trigger set, its accuracy drops from 99.80% $\rightarrow$ 6.51% when a counterfeit key is presented. Please see Appx. B for more results.

6 Conclusion and Future Works

This paper demonstrates a simple but effective IPR protection method with complete and robust ownership verification scheme for RNNs in both white-box and black-box settings. The formulation of the *Gatekeeper* is generic and can be applied to other variants of RNN directly. Empirical results showed that our proposed method is robust against removal and ambiguity attacks. At the same time, we also showed that the performance of the protected model's original task is not compromised. Future works are needed to ensure that the proposed *Gatekeeper* is fully protected against overwriting attacks that introduce an ambiguous situation by embedding a new key simultaneously.

7 Broader Impact

Our proposed ownership protection framework aims to protect the IPR of RNN model. To compete with each other and gain business advantage, a large number of resources/budgets are continually being invested by giant and/or startup companies to develop new DNN models. Hence, we believe it is vital to protect these inventions from being abused, stolen or plagiarized. We believe that nobody with genuine intention will be harmed by this work. In the worst case scenario where if our proposed work fails to protect the RNN model; it just reflects the current status of RNN model as from our understanding, there is yet initiative of the IPR protection for RNN. In short, the ownership verification for RNNs will bring benefits to society by providing technical solutions to reduce plagiarism in deep learning and thus, lessen wasteful lawsuits and secure business advantages in an open market.

A Appendix

A.1 Hyperparameters

Table 6 summarizes all the hyperparmeters used in the experiments.

Table 6: Hyperparameters used in each tasks.

Hyperparameter	TREC-6	WMT14 EN-FR
Vocabulary size	-	15000
Max sentence length	30	15 (EN) / 20 (FR)
RNN hidden units	300	1000
Embedding dimension	300	300
Batch size	10	256
Bidirectional	Yes	No
Optimizer	Adam(Kingma and Ba, 2014)	Adam

A.2 Qualitative Results

Table 3 and 8 show examples of incorrect predictions when a counterfeit key is embedded into the recurrent neural network (RNN) model during inference phase. For classification tasks (i.e. TREC-6 (Li and Roth, 2002)), Table 8 shows that when a counterfeit key is used, the RNN model gets confused between similar classes, i.e. DESC and ENTY for TREC-6. Meanwhile, for machine translation task (i.e. WMT14 EN-FR (Bojar et al., 2014)), Table 3 demonstrates the translation results when a genuine key is used against a counterfeit key. It is observed that when a counterfeit key is used, the RNN model can still somehow translate accurately at the beginning of the sentence, but the translation quality quickly deteriorates toward the end of the sentence. This is in line with our idea and design of Gatekeeper where the information (hidden state) passed between timesteps would be disrupted with a counterfeit key and the output of RNN would deviate further from the ground truth the longer the timesteps are.

A.3 Methods to generate key

Three types of methods to generate key have been investigated in our work:

- *random patterns*, elements of key are randomly generated from a uniform distribution between [-1, 1]. For natural language processing (NLP) task, a sequence of random word embedding can be used.

- *fixed key*, one key is created from the input domain and fed through the trained RNN model with the same architecture to collect its corresponding features at each layer. The corresponding features are used in the Gatekeeper. For NLP task, a sentence from the input language domain is used as key.

- *batch keys*, a batch of K keys similar to above are fed through the trained RNN model with the same architecture. Each K features is used in the Gatekeeper, and their mean value is used to generate the final Gatekeeper activation.

In the *batch keys* method, the number of possible key combination is $(K \times l)^V$ where K is the number of keys used, l is the length/time step of key and V is the vocabulary size. This make it impossible for an attacker to correctly guess or brute force the key. Since batch keys provides the strongest protection (with the highest possible key combination), we adopt this key generation method for all the experiments reported in this paper.

Table 7: Example of hidden state output h_0^k and their respective sign (+/-) from LSTM$_{kt}$ when we embed digital signature S={*private signature goes here*}

-0.1963	-1		
0.1868	1		
0.1882	1		
-0.1951	-1		

A.4 Gatekeeper Sign as Digital Signature

Sign (+/-) of the first hidden state of key h_0^k can be used to encode a digital signature S such as ASCII code (8 bits as one ASCII character). Note that the maximum capacity of an embedded digital signature depends on the number of hidden units in the protected RNN layer. For instance, in this paper, the model Seq2Seq$_{kt}$ has Gated Recurrent Unit (GRU) layer with 1000 units, so the maximum signature capacity that can be embedded is 1000 bits or 125 ASCII characters. For ownership verification, the embedded digital signature S can be revealed by decoding the learned sign of h_0^k. Table 7 shows the embedded digital signature and their respective sign, every 8 bits is decoded into a ASCII character.

B Cross Domain Application

In addition to NLP domain, we also applied our proposed frameworks on image domain, specifically in the task of sequential image classification. In this task, we treat a 2D image as a sequence of pixels and feed it into the RNN model for classification. This is particularly useful in cases where one cannot obtain the whole image in a single time frame. SeqMNIST (Le et al., 2015) is a variant of MNIST where sequence of image pixels that represent handwritten digit images is classified into 10 digit classes. For trigger sets in image domain, we follow the work by Adi et al. (2018) where we select ran-

dom images from training dataset and shuffle their labels. We chose Le et al. (2015) as the baseline model and followed the hyperparameters defined in the work which are 100 hidden units in RNN, 128 batch size and Adam (Kingma and Ba, 2014) optimizer with default settings.

B.1 Quantitative and Qualitative Results

Quantitatively, we achieve similar results as the application in NLP domain. As seen in Table 5, the protected models have similar classification accuracy as the baseline model demonstrating that embedding keys and trigger set doesn't hurt the model learning capacity. Also, we can notice that when a counterfeit key is presented to the protected models, the classification accuracy dropped by 75-80%.

Furthermore, we also investigate the qualitative results in sequential image classification task. In Table 10, when a counterfeit key is used, the RNN model gets confused between similar classes, i.e. 5 and 6 for SeqMNIST.

B.2 Robustness against Removal Attacks

Pruning: We follow the same model pruning strategy in our main paper. Figure 7 shows that for image classification models, even when 40% of the model parameters are pruned, trigger set accuracy still maintains about 70-80% accuracy, accuracy on test set drops slightly while digital signature accuracy still maintained near to 100% accuracy. This proves that model pruning will hurt the model performance before the embedded watermarks can be removed and therefore our proposed work is robust against it.

Fine-tuning: Same as the main paper, the host model is initialized using trained weights with embedded watermarks, then it is fine-tuned without the presence of the key, trigger set and regularization terms. As seen in Table 9, digital signature accuracy remains consistently at 100 even after the model is fine-tuned. When the original genuine key is presented to the fine-tuned model, we are able to obtain comparable accuracy to the stolen model.

Overwriting: We also simulate an overwriting scenario where the attacker has knowledge of how the model is protected and attempts to embed a new key, $\overline{k}$ into the trained model using the same proposed method. In Table 9, we can observe that digital signature accuracy remains at 100% consistently after the protected model is overwritten with the new key. When inferencing using the original genuine key, the performance only dropped slightly. Empirically, this confirms that the embedded key and signature cannot be removed by overwriting it with new keys.

B.3 Resilience against ambiguity attacks

In the previous section, we simulate a scenario where the key embedding method and digital signature are completely exposed, and an attacker can introduce an ambiguous situation by embedding a new key simultaneously. However, we show that the digital signature cannot be changed easily. As shown

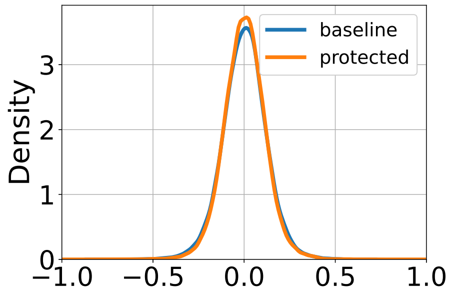

Figure 9: Comparison of weight distribution between original and protected model on SeqMNIST. Best viewed in colour.

Table 9: Robustness of protected RNN model trained on SeqMNIST (in bold) against removal attacks (i.e. fine-tuning and overwriting). All metrics reported herein are the performance with genuine key where acc. = accuracy.

	Acc.	T acc.	Sign acc.
LSTM$_{kt}$	**98.18**	**99.8**	**100**
Fine-tuning	98.28	99.6	100
Overwriting	97.52	52	100
GRU$_{kt}$	**97.95**	**99.8**	**100**
Fine-tuning	98.09	99.4	100
Overwriting	97.53	78	100

in Figure 8, the model's performance decreases significantly when 40% of the original signs are modified. In sequential image classification task on SeqMNIST, the model's accuracy dropped from 98.18 → 23.37 (for the test set in LSTM$_{kt}$), which is merely better than a random guessing model. We can conclude that the signs enforced in this way are persistent against ambiguity attacks and illegal parties will not be able to employ new digital signatures without hurting the protected model's performance.

B.4 Secrecy

In digital watermarking for DNN, one of the design goals is secrecy to prevent unauthorized parties from detecting it. In other words, this means that the protected model's weights should not change when compared to a baseline (unprotected) model. Figure 9 shows the weight distribution of the protected models and baseline model, the weight distribution of the protected RNN layers is identical to the baseline RNN layers.

Table 10: Qualitative results on SeqMNIST. The best-performed model that has both white-box and black-box protections is selected to demonstrate the classification results with genuine and counterfeit keys.

Abstract

Word associations are among the most common paradigms for studying the human mental lexicon. While their structure and types of associations have been well studied, surprisingly little attention has been given to the question of *why* participants produce the observed associations. Answering this question would not only advance understanding of human cognition, but could also aid machines in learning and representing basic commonsense knowledge. This paper introduces a large, crowdsourced dataset of English word associations with explanations, labeled with high-level relation types. We present an analysis of the provided explanations, and design several tasks to probe to what extent current pre-trained language models capture the underlying relations. Our experiments show that models struggle to capture the diversity of human associations, suggesting WAX is a rich benchmark for commonsense modeling and generation.[1]

1 Introduction

Word associations (Deese, 1966; Kiss et al., 1973) are a prevalent paradigm in cognitive science for probing the human mental lexicon (Nelson et al., 2004; Fitzpatrick, 2006). They reflect spontaneous human associations between concepts. In a typical study, a participant is presented with a cue word (e.g., *bagpipe*) and asked to spontaneously produce the words that come to mind in response (*music*, . . .). Through large-scale crowd-sourcing studies covering over 12K cues, 3M responses and thousands of participants, a large word association graph (SWOW; Deyne et al. (2019)) has been constructed, as a resource of basic human conceptual knowledge. This repository of shared associations can serve as a source of commonsense knowledge as shown recently by incorporating SWOW as knowledge resource into commonsense reasoning models (Liu et al., 2021).

Figure 1: Excerpt of WAX, which consists of associations between cue words (bagpipe) and associations (kilt, red, . . .) together with association explanations (speech bubbles) and discrete relation type labels (edge labels). Some associations are supported by distinct relation types and explanations (e.g., bagpipe→music).

However, existing word association data sets like SWOW only provide cue-association pairs, but do not further distinguish between different types of associations. To fill this gap, we constructed a novel data set to recover the underlying reasons by collecting associations together with free-text explanations from participants, and distill high-level relation types from them. Our data set can enhance our understanding of the *reasons* and *types* for conceptual associations in humans, and can serve as an explicit knowledge resource for reasoning models.

Our data set WAX (Word Association eXplanations) encodes English word associations with diverse explanations and high-level relation types and is illustrated in Figure 1. In a large crowd-sourcing study, we (a) collected human word associations by presenting participants with a cue word (*bagpipe*) and collecting the association words that spontaneously came to mind (*music*, *kilt*, . . .) (Figure 1, circles); (b) asked the same participants to *explain* the link between the cue and

[1] Data and code are available at https://github.com/ChunhuaLiu596/WAX

Proceedings of the 2nd Conference of the Asia-Pacific Chapter of the Association for Computational Linguistics and the 12th International Joint Conference on Natural Language Processing (Volume 1: Long Papers), pages 106–120
November 20–23, 2022. ©2022 Association for Computational Linguistics

their corresponding associations in a short sentence (Figure 1, speech bubbles); and (c) labeled explanations with a relation type adpated from a predefined set (McRae et al., 2012; Speer et al., 2017) (e.g., FUNCTION, edge labels in Figure 1). We ensure data quality through several layers of careful annotator training and data filtering.

Compared to existing work on categorizing word associations (Piermattéo et al., 2018; Fitzpatrick, 2006), WAX is larger in size, grounds associations in explanations, and will be released to the research community, supporting future research on understanding and modeling conceptual knowledge. WAX complements existing commonsense knowledge graphs, which either involved decades of manual work (ConceptNet; Speer et al. (2017)), rely on highly templated responses, limiting their ability to reflect the natural diversity in human associations (ATOMIC; Sap et al. (2019)); or only indirectly link concepts via a shared scene (CommonGen; Lin et al. (2020)). WAX results from a new, scalable method of collecting general commonsense knowledge, while maintaining both quality and diversity of associations and explanations, and can be cheaply extended to other languages.

We annotated a subset of WAX with high-level, discrete relation labels, enabling us to quantify the diversity of human mental relations, and to evaluate machine learning models in their ability to (a) distinguish different relations; and (b) generate plausible association explanations. Our experiments using pre-trained language models demonstrate the value of WAX as a rich and challenging data set for a variety of commonsense modeling and generation tasks. In sum, our main contributions are:

- A large data set of word associations with free-text explanations, providing the justification for the relation, and relation labels, which can support scalable studies of the human mental lexicon, and the development of models of relation extraction, commonsense knowledge and explanation generation.

- Extensive experiments demonstrating the utility of WAX for commonsense relation classification and explanation generation.

- Insights into the relative ease of predictability of different relation types, giving rise to future development of targeted models, as well as relation ontologies that are tailored to 'empirical' relations emerging from the data.

2 Background

Our work relates to several research lines, including word associations, commonsense knowledge graphs, and explainability.

Word Associations Word associations, as reflections of human mental lexica, have been studied extensively in psychology (Kiss et al., 1973). In early studies, word associations were predominantly collected on a small scale from homogeneous participants (Nelson et al., 2004; Kiss et al., 1973). Recently, crowd-sourcing has proved effective for collecting large-scale word association data sets in several languages, i.e., English (Kiss et al., 1973; Deyne et al., 2019), Dutch (Deyne and Storms, 2008) and Japanese (Joyce, 2005). Among them, SWOW (Deyne and Storms, 2008; Deyne et al., 2019) is the largest multi-lingual word association graph, covering 14 languages.[2] However, the graphs only include directed associations between words pairs, rendering the underlying reasons for association unknown.

Types of mental associations were previously studied in cognitive psychology (Read, 1993; Sinopalnikova, 2004; Fitzpatrick, 2006; Santos et al., 2011; Yokokawa et al., 2002). Previous work (Fitzpatrick, 2006; Piermattéo et al., 2018) showed that relations of word associations can be recovered by (1) asking subjects to *explain* (in words or in writing) the reasons for the produced association, then (2) inferring a relation based on the explanations. We follow the methodology from the above works both to recover the association reasons (see our method description in §3) and to label a subset of our word associations with relation types. In contrast with previous work, where collected data sets were small (e.g., 100 cues) and were not made available to the research community, we provide a large-scale data set by gathering explicit explanations and relation types, to encourage future work on automatic association inference and relation labeling.

Several relation type ontologies have been proposed (Cann et al., 2011; Estes et al., 2011; Fitzpatrick, 2006; Wu and Barsalou, 2009; Bolognesi et al., 2017), which typically distinguish four broad relation categories: taxonomic (*apple*, *pear*), situational (*airplane*, *travel*), properties (*sweater*, *comfortable*), and linguistic/form (*hobby*, *lobby*).

[2] https://smallworldofwords.org/en/project/home

McRae et al. (2012) build on the broad categories above, and refine them into a total of 28 subtypes, which we used as the basis for our own association labeling scheme (§3.2).

Commonsense Knowledge In word association graphs, cue words are typically surrounded by a rich set of associations (60 on average in SWOW) provided by multiple participants responding to the same cue. Naturally, those associations could be considered as shared, basic knowledge or a source of commonsense knowledge. Equipping machines with such resources has attracted substantial attention (Davis and Marcus, 2015), for instance by incorporating existing resources like ConceptNet (Liu and Singh, 2004) into models to solve downstream tasks like question answering.

However, acquiring such commonsense knowledge is a challenge because it is vastly diverse and not often explicit in language, leading to data scarcity. Commonsense knowledge is typically collected either in free-text format (OMCS: Singh et al. (2002)) or structured databases (e.g., ConceptNet: Speer et al. (2017); ATOMIC: Sap et al. (2019)). Liu et al. (2021) showed that the associations in SWOW (i.e., without relation labels) bring comparable benefits as ConceptNet in commonsense question answering. Enhancing word associations with relations could increase its utility as a source of acquiring commonsense knowledge. Association explanations can also support research into *interpretable* commonsense reasoning.

Recently, pre-trained language models (PTLMs) were tested as commonsense repositories (Petroni et al., 2019; Shwartz and Choi, 2020; Bhargava and Ng, 2022) by probing the extent of commonsense knowledge encoded in PTLMs or using PTLMs to construct (or complete) commonsense knowledge graphs (Malaviya et al., 2020; Zhou et al., 2020). Integrating existing knowledge (free-text or structured) with PTLMs has been shown effective for improved machine reasoning (Wiegreffe et al., 2022; Moghimifar et al., 2021), and having machines explain why a certain association exists could bridge between structured and text representations. We explore association explanation in §5.

Explainable Commonsense Previous work used generated explanations to improve downstream task performance, e.g., on question answering (Shwartz and Choi, 2020) and natural language inference (Rajani et al., 2019). Less research has attempted to generate explanations to construct structured commonsense resources. Dognin et al. (2020) align ConceptNet with OMCS using heuristic rules and propose dual learning to transfer between a knowledge graph and free text. However, their language data is templated, and their dataset is not public. Other work has retrieved representative contexts from large corpora (Hendrickx et al., 2009), or used templates to construct sentences from triples (Petroni et al., 2019). In §5 we use WAX to generate explanations that reflect the naturalness and diversity of human explanations. Another related data set, CommonGen (Lin et al., 2020), consists of crowd-sourced, short sentences describing a scene that includes a given set of concepts (common objects and actions). CommonGen is designed to test machines' compositional ability, but relations between concepts are implicit in the description. Compared to their work, WAX is more explicit, eliciting concept associations from workers directly; more specific as each explanation focuses on a relation between an association pair; and more general (incl. adjectives, adverbs, and abstract concepts). WAX could hence be used to augment knowledge graphs like SWOW with relation labels, or free-text explanations.

3 The WAX Corpus

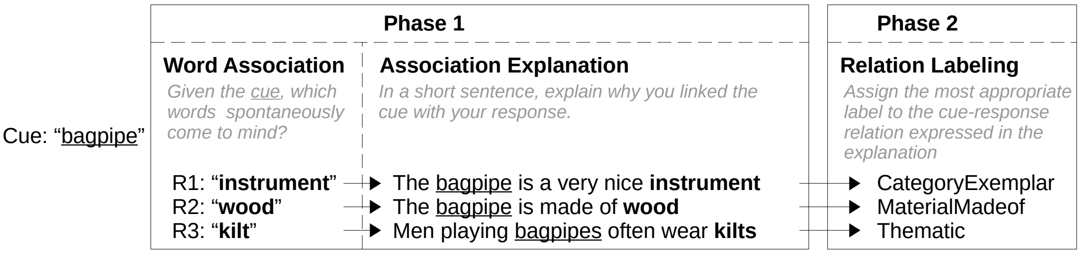
We present our two-stage framework for collecting word association relations between pairs of concepts (words) by crowd-sourcing explicit explanations of the relations (Figure 2). In Phase 1, we collect associations and free-text explanations to elicit the underlying reasoning. In Phase 2, we label a subset of (cue, association, explanation)-tuples (c, a, e)[3] with relation types r to characterize the inventory of common relation types. Appendix A contains details on annotator instructions and payment, as well as quality control.

3.1 Phase 1: Eliciting Explanations

In phase 1, we collect (a) word associations and (b) explanations from the same annotator, ensuring that the explanation indeed explains the true underlying association.[4] Following Deyne et al. (2019), given a cue word, a worker first generates up to

[3] Throughout the paper, we use c, a, e, r to denote cue, association, explanation and relation respectively.

[4] While we could have annotated existing word associations with explanations, this would require inference of another person's reasons for the association. To remove this confound we elicit associations and explanations from the same worker.



Phase 1
Phase 2
Word Association
Given the cue, which words spontaneously come to mind?
Association Explanation
In a short sentence, explain why you linked the cue with your response.
Relation Labeling
Assign the most appropriate label to the cue-response relation expressed in the explanation
Cue: "bagpipe"
R1: "instrument"
R2: "wood"
R3: "kilt"
The bagpipe is a very nice instrument
The bagpipe is made of wood
Men playing bagpipes often wear kilts
CategoryExemplar
MaterialMadeof
Thematic

Figure 2: Overview over the data collection framework for WAX.

	Full WAX	Relation Labelled
# unique a	6,128	453
# unique (c, a)	15,337	520
# unique (c, a, e)	19,228	725
Vocab size	10,180	1,656
Avg len(e)	9.71	10.1

Table 1: The statistics of the full WAX, and its manually relation-labeled subset. Avg len(e) is the average explanation length (in words).

three spontaneous associations (Figure 2, left), and immediately after provides a one-sentence explanation of *why* they linked the cue and each association (Figure 2, center). The resulting explanations will serve as our text corpus of sentences expressing relations between concept pairs.

We used a set of 1,100 single-token cues, sampled from SWOW, ensuring a balanced distribution over the POS tags noun, verb, adjective and adverb; as well as abstract and concrete concepts. Each annotation batch consisted of 5 randomly sampled cues, each cue was labeled by 10 different workers on Amazon Mechanical Turk (MTurk). The final data set includes the annotations of 258 workers and comprises 15K unique cue-association pairs along with 19K explanations (Table 1, left).

3.2 Phase 2: Relation Labelling

Phase 2 augments the dataset above with explicit relation labels (Figure 2, right), as (a) a lens into the distribution of underlying association types; and (b) a testbed to examine machines' ability to extract or generate word association relations or explanations. Given a triple of cue, association and explanation (c, a, e), annotators choose the most appropriate relation type from a fixed relation inventory. We first introduce the relation inventory, before describing the process of relation labeling.

Relation Inventory We adapt an established semantic relatedness taxonomy of 28 relation types from cognitive studies of the human mental lexicon (Wu and Barsalou, 2009; McRae et al., 2012) and from ConceptNet (Speer et al., 2017). In multiple pilot annotations, we assessed the confusability and applicability of the relations to our association data. We conflated associations which were (i) similar (e.g., ACTION and BEHAVIOR), (ii) rare (e.g., ORIGIN), (iii) of opposite directionality (e.g., PARTOF and LARGERWHOLE), as this nuance was often not reflected in the explanations. The final label set consists of 16 relation types, which are listed in Figure 3 and, in more detail in Appendix A.1.

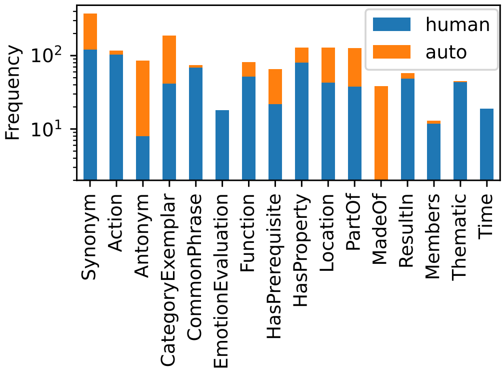


Figure 3: Relation distribution of WAX labeled data, including human labeled subset (bottom, blue), and auto-augmented subset (top, orange).

Relation labeling We sampled 757 instances from the data from Phase 1, excluding recurring template-like explanations (e.g., "A is a type of B") to create a challenging test set. We included cues with all POS from §3.1 except for adverbs.[5]

MTurk annotators were given the 16 relation types, their definitions, and examples. Each batch consisted of 30 (c, a, e) tuples, and a worker selected the most appropriate relation per tuple. Each batch was labeled by 5 workers and we derived

[5] Associations with adverbs have received little attention and are not well-covered by existing relation ontologies.

Criteria	WAX	Random
Q1: e valid explanation for (c, a)	0.98	-
Q2: r valid relation for (c, a)	0.79	0.26
Q3: r valid relation for (c, a, e)	0.76	0.20

Table 2: Manual validation accuracy for assessing explanations and their relation labels, as well as whether they are concordant with the cue and association pair. Also shown is the judged accuracy of instances with randomly corrupted relation labels.

Cluster	Representative TF/IDF 3-grams
LOCATION	‘keep my in’ ‘my in my’ ‘put my in’ ‘on my face’ ‘many in my’
{SYNONYM, ANTONYM }	‘the opposite of’ ‘opposite of is’ ‘is the opposite’ ‘is synonym for’ ‘another word for’
FUNCTION	‘be used to’ ‘can be used’ ‘when you have’ ‘there is usually’ ‘in order to’
TIME	‘am about something’ ‘if am about’ ‘if something will’ ‘something will happen’
ACTION	‘in charge of’ ‘charge of the’ ‘was in charge’ ‘the helped the’
SIMILAR	‘has similar meaning’ ‘similar meaning as’ ‘as has similar’ ‘meaning as has’
GENERIC1	‘when you are’ ‘if you are’ ‘something you are’ ‘it when you’
GENERIC2	‘referred to as’ ‘associated with being’ ‘think of as’ ‘in the past’
TOPICAL1	‘in movie called’ ‘starred in movie’ ‘was in movie’ ‘books and movies’
TOPICAL2	‘the game the’ ‘of the game’ ‘the ball in’ ‘to catch the’ ‘the game was’ ‘to win the’

Table 3: Representative sample of explanation clusters, as the top TF/IDF 3-grams. Clusters were labeled manually. Top: clusters aligning with predefined relations; center: topic-like clusters; bottom: generic clusters.

gold labels for each (c, a, e) by majority vote.[6]

The final labeled data set consists of 725 (c, a, e)-tuples, covering 520 unique (c, a) pairs, labeled with one of 16 relations. The corresponding relation distribution is shown in Figure 3 (blue), showing that the relations are present in the data to varying degrees (e.g., the top 4 relations cover 52% of overall labeled data). Table 1 presents the full statistics of WAX. Examples are provided in Figure 1 and Tab 4. The collection of WAX was efficient (200 hours of crowd-sourcing), and hence can be scaled up, or extended to other languages.

3.3 Corpus Analysis

Quality In a final round of quality control, we examined the overall consistency of WAX. We designed three questions to manually examine its key elements: explanations, relations, and their alignment (Table 2). Q1 asks whether the generated explanation expressed a valid relation for the (c, a) pair. Q2 verifies the relation label quality by asking whether the given relation is valid for the (c, a) pair. Q3 looks into the alignment between explanations and relations by asking whether the explanation e indeed expresses the relation label r.[7]

We presented a random sample of 100 (c, a, e, r)-tuples from WAX to two qualified annotators[8] to answer the three questions. We additionally mixed in 50 (c, a, e) with a randomly assigned relation label r, as a reference point for random performance.[9] Table 2 shows the results. We can see that almost all explanations are a valid link between cue and association (Q1), demonstrating the validity of explanations from Phase 1. Close to 80% of relations are deemed valid for (c, a) (Q2) and (c, a, e) (Q3). To put this in perspective, the respective accuracy on the random sample were significantly lower. To the best of our knowledge, WAX is the first large-scale data set with explanations of conceptual associations.

Clustering Explanations While classifying associative relations into a pre-defined ontology is an important task, both for comparability with prior cognitive work, and for model development and evaluation, it is informative to also group explanations in a purely data-driven way and compare the result against established relation inventories. To this end, we cluster all 19K WAX explanations using K-means in to 75 clusters.[10] In order to abstract away from signals specific to cue and association words, and focus on the general ‘linking information’, we masked cue and association tokens in the explanations and embedded the result with BERT-base (mean pooling over the final layer). We visualized each cluster by its top TFIDF trigrams.

Table 3 summarizes the clustering results. Some clusters capture relations in our ontology (LOCATION), although some relations are conflated

[6] Annotator agreement (pair-wise Cohen’s κ) was $\kappa = 0.42$, indicating moderate agreement. 28 (c, a, e)-triples were removed, for which no majority could be reached.

[7] Table 8 (Appendix) shows examples for each question.

[8] One native speaker who was not involved in the project, and one of the authors.

[9] Note that the explanation for (c, a) was not randomized as this would have resulted in a trivial baseline.

[10] We experimented with smaller numbers of cluster but found that this number produced the most nuanced representations, and tried TFIDF instead of BERT embeddings which lead to highly skewed cluster memberships.

(*grater*, *cheese*) (1) “a grater is great to make shredded cheese.”; (2) “he shredded the cheese with the grater”; (3) “i use a grater to grate cheese for my meal.” (all FUNCTION)
(*flowing*, *water*) (1) “the water is flowing down the gutter.”; (2) “water flows when you turn on the faucet.”; (3) “water is often seen flowing through hills and valleys.” (all ACTION)
(*reading*, *glasses*) (1) “he needs his reading glasses.”; (2) “my father needs reading glasses.”; (3) “the old man had to use reading glasses as it was difficult to see up close.” (all COMMONPHRASE)
(*igloo*, *cold*) (1) “an igloo is very cold to the touch.” (HASPROPERTY); (2) “the igloo is a cold place” (HASPROPERTY); (3) “when it’s cold, you can build an igloo out of snow.” (HASPREREQUISITE)
(*heaven*, *god*) (1) “heaven is where god lives.” (LOCATION); (2) “heaven is the place where one can be with god.” (LOCATION); (3) “it is said that heaven and hell were created by god.” (ACTION)
(*goalie*, *save*) (1) “another job of the goalie is to save the shots on the goal” (FUNCTION); (2) “the goalie reached his glove out and made a big save” (ACTION)’ (3) “the goalie had a great night, making a save on all but one of the shots he faced.” (ACTION)

Table 4: Example WAX (c, a) pairs produced by >1 annotators, each with three explanations (1)–(3) and corresponding relation labels. The first three examples are *unambiguous* associations, where all explanations describe the same relation, while the last three are *ambiguous*, with explanations covering distinct relations.

(SYNONYM, ANTONYM). One general ‘similarity’-focused cluster emerged, confirming previous findings on Enlgish native speakers’ tendency to associate words based on general meaning similarity (Fitzpatrick, 2006). A second set of clusters captures ‘generic associations’ (GENERIC 1-2) such as ‘If you are *c* then you *a*’ or ‘*c* is associated with *a*’. The third (smallest) set is topical, with explanations referring to GAMES (sports) or ENTERTAINMENT (movies and music). Overall, we find that taxonomic and event-related (HASPREREQUISITE, RESULTIN) relations are well-captured, while property relations (MATERIALMADEOF, HASPROPERTY) are reflected to a lesser extent. This observation aligns with research showing that personal experiences (events and scenarios) inform word associations as well as conceptual representations more broadly (Barsalou, 1983).

Diversity Conceptual associations may result from factual knowledge, cultural or societal norms, or individual experiences. Here, we analyze the extent to which different annotators produced divergent associations and/or explanations (cf., the (*bagpipe* → *music*) association in Figure 1). The presented numbers are a lower bound on diversity, because WAX was collected from a small number of MTurk annotators, which were themselves not screened for diversity and are likely a homogeneous group of (western) English native speakers.[11]

15% (N=2358) of the (c, a) pairs in the full WAX[12] were produced by more than one annotator (3.5 times on average), raising the question whether a single typical relation or multiple distinct ones connect these concepts. We look into this by examining the labeled subset. For 59% (N=51) of these ambiguous (c, a) pairs, all annotators expressed the same underlying relation. Examples include (*grater*, *cheese*, FUNCTION), (*flowing*, *water*, ACTION) and (*reading*, *glasses*, COMMONPHRASE). For the remaining 41% (N=36) annotators expressed between 2 and 5 *different* relations. An example is the pair (*goalie*, *save*) produced by three annotators, with relations FUNCTION $(1\times)$ and ACTION $(2\times)$. Table 4 presents the above examples together with WAX explanations.

Analysis revealed that in cases where *different* relations emerged for the same (c, a) pair, these relations were predominantly event-related (HASPREREQUISITE, RESULTIN, ACTION, FUNCTION, CATEGORYEXEMPLAR). In §4 we explore the task of association relation classification, and evaluate our models on the challenging, ambiguous subsets described above to gauge the extent to which associative ambiguity is captured in different transformer-based classifiers.

4 Relation Classification

Automatic prediction of relation types or generation of explanations can support commonsense knowledge graph completion, enhance our understanding of such knowledge in pre-trained language models, or inform explainability research. In the following sections, we present a series of experiments to demonstrate how WAX can support progress towards some of these goals. This section addresses relation classification, before we study explanation generation in §5. We construct a relation classification task using our relation type ontology as ground truth, as a 16-way classification problem to predict a single relation type r

[11] We removed another layer of potential ambiguity in Phase 2, where we assigned a single label to each association by majority voting, even though some explanations may support several underlying relations.

[12] 16%(N=87) in the labeled proportion, accounting for 43% (N=312) of the labeled (c, a, e, r) tuples.

	Model	Overall (N=312)				Ambiguous relations (N=131)				Unambiguous relations (N=181)			
		P	R	F1	Acc	P	R	F1	Acc	P	R	F1	Acc
	Majority-Class	1.1	6.7	1.9	16.3	0.5	7.1	0.9	6.9	1.9	8.3	3.1	23.2
-EXP	LR	5.4	8.4	4.5	18.6	2.0	7.7	1.8	7.6	9.6	11.0	7.7	26.5
	BERT-base	24.8	26.8	20.7	32.8	23.9	23.2	18.8	26.2	22.6	25.1	21.0	37.6
	BART-large	34.5	48.0	35.9	47.8	30.9	35.5	29.4	38.2	37.4	42.8	37.3	54.7
+EXP	LR	29.9	17.7	16.0	22.1	23.1	14.5	10.9	16.0	32.3	16.5	16.1	26.5
	BERT-base	34.2	40.2	32.7	45.5	33.2	34.7	29.7	40.7	34.0	35.1	31.7	48.8
	BART-large	**49.6**	**57.7**	**48.1**	**56.2**	**41.9**	**47.2**	**37.7**	**48.9**	**47.2**	**50.5**	**46.1**	**61.5**

Table 5: Experimental results on relation classification, as macro precision, recall and F1, and accuracy for models with access to the full explanation (+EXP) or to cue and association only (-EXP). We report performance overall test instances (left), only relation-ambiguous (center), and only relation-unambiguous (right) instances.

from either only (c, a)-pairs (we call this model -EXP) or the full explanation e, which by construction includes c and a (+EXP).[13] We can thus test whether access to explanations, which lay out *why* two concepts are associated, improves relation prediction over and above the knowledge available to PTLMs via large-scale pre-training. For example, predicting a relation (e.g., FUNCTION) for the pair (*bagpipe*, *music*) is arguably simplified (or constrained) with access to an explicit explanation such as "*Bagpipes* are used to play *music*".

4.1 Dataset

As the labeled portion of WAX is both small in size and skewed in relation distribution (Figure 3), we augment its *training* portion with data from Wu and Barsalou (2009) and ConceptNet (Speer et al., 2017), which include concept pairs and their relation, but no explanations. To create labelled explanations, we find (c, a, r') edges in these external resources that are also in the unlabelled portion of WAX, (c, a, e), and then map the known relation label into our inventory, $r' \to r$, thus constructing full (c, a, e, r) tuples. In addition, we identified frequent patterns in the WAX explanations, and devised a small set of templates to extract the corresponding relations (e.g., 'a is part of c', indicates a PARTOF relation).[14] Those relations were verified independently by two authors of this paper, and we retained only instances where both agreed on their validity. We obtained 835 additional labeled explanations, as shown in Figure 3 (orange bars). The final data is split into 948, 300 and 312 (c, a, e, r)-tuples for train, dev and test sets, respectively.

4.2 Models

We experimented with discriminative and generative seq-to-seq methods for relation prediction. We fine-tuned BERT-base-cased (Devlin et al., 2019)[15] to embed the full explanation e (for explanation-aware models +EXP), or the simple template "c, `[SEP]`, a" (for explanation-agnostic models -EXP); and use the hidden representation of the `[CLS]` token as input to a discriminative classification layer. In addition, we followed Huguet Cabot and Navigli (2021) and framed relation prediction as a sequence to sequence generation problem by generating (c, a, r) given (c, a, e) for +EXP, or given (c, a) for -EXP, using teacher forcing. While less direct, the approach is motivated by recent successes in formulating classical (structured) prediction problems as seq-to-seq (Bevilacqua et al., 2021; Nayak and Ng, 2020). Including c and a in the output lead to more focused r predictions, but also supports the prediction of entity-pair relations for explanations involving more than two entities. We fine-tuned BART-large (Lewis et al., 2020) as the generative model.[16] We compared against a logistic regression (LR) classifier with TF-IDF features, and a majority baseline. All models were trained on the training set, and hyper-parameters (Appendix C) were selected based on the dev set.

4.3 Results

Main results Table 5 (left block) presents the results. The fine-tuned LMs outperform the baseline models by a large margin, and BART per-

[13] Another natural formulation is multi-class classification given as input a (c, a) pair with *all* produced explanations, which we leave for future work.

[14] All templates are shown in Appendix B.

[15] It outperformed other BERT versions, incl. BERT-large.

[16] We represent the encoder input as "e <subj> c POS$_c$ <obj> a POS$_a$", and the decoder input (with teacher forcing at training time) as "<triplet> c <subj> a <obj> r". <...> are sentinel token, and POS$_x$ the POS tag of argument x. We use the code base from `https://github.com/Babelscape/rebel`.

Table 6: Selected relation classification results on unambiguous (top) and ambiguous WAX test instances, where each row shows the types of true (○) and predicted (×) relations when applied to the explanations for a cue-association pair.

forms better than BERT, suggesting the promising direction of modeling word association relations with seq-to-seq frameworks. We further explore this direction in §5. +EXP models (fine-tuned on full explanations) performed substantially better than -EXP models (fine-tuned on (c, a) pairs with no context), suggesting that explanations provide signal over and above the knowledge already encoded in PTLMs. This is confirmed by comparing against a BERT zero-shot model, which consistently performed worse than the majority class baseline (Overall accuracy of 5.6%). A class-wise performance analysis of the best model BART revealed that it was accurate for taxonomic relations and well-defined attributes (e.g., {SYNONYM, ANTONYM, PARTOF, LOCATION }), which are well-established in the literature, while situational associations (e.g., RESULTIN, HASPREREQUISITE) are not captured by the -EXP model, but are predicted at much higher quality by +EXP. Full details are in Appendix D. This concurs with the open challenge of event representations in NLP (Sap et al., 2019) and points to future work on tailoring models and relation sets. We estimate human accuracy at 76-79% (Table 2), leaving a substantial gap between model and human performance to be addressed in future work.

Relation diversity We evaluated our models separately on two challenging data subsets to investigate whether models capture the relation diversity discussed in §3.3: (1) (c, a) pairs with *multiple* explanations that all refer to the *same* relation type (Table 5, right block); and (2) (c, a) pairs with *multiple* relations that refer to *different* relation types (Table 5, center block). Transformer-based models outperform LR, with BART performing best. The difference between BART +EXP vs BART -EXP increases compared to Overall for both F1 and Acc, confirming the value of explicit explanations for these challenging subsets. Unsurprisingly, the ambiguous relation scenario is the most challenging.

We further analyze how model predictions differ from human labels on both relation-ambiguous and unambiguous (c, a) pairs. We inspect predicted labels from the best-performing model BART. Table 6 shows representative examples comparing human and model-predicted relations for unambiguous instances (one true relation, top) and ambiguous ones (multiple true relations, bottom). Although predictions diverge from gold labels, especially for the challenging ambiguous subset, the model labels are often reasonable. Consider (*discuss*, *talk*) with the explanation "to *discuss* something you must *talk* about it" and gold label CATEGORYEXEMPLAR, was predicted by the model as HASPREREQUISITE. It is not uncommon that taxonomic (CATEGORYEXEMPLAR) and associative or situational associations (HASPREREQUISITE, ACTION) relations are both valid for an explanation (Santos et al., 2011), leading to confusions by both our human annotators and model predictions. Our raw relation annotations include at least 5 annotations per (c, a, e) tuple, and hence capture this ambiguity which can be leveraged for model development and evaluation in future work. [17]

5 Generating Relation Explanations

Natural language inference or commonsense reasoning is often framed as mapping a free text input (e.g., a paragraph) to a structured output (e.g., a relation, (c, a, r) triple, or a multiple-choice answer). The underlying reasoning steps typically remain obscure. Constructing intuitive and faithful explanations for model predictions is an active research area of increasing impact. Mapping structured representations to natural language explanations is one approach, which has been limited by a lack of suitable training data sets. WAX is a parallel data set of structured relational data, aligned with diverse, human-generated free text explanations. Here, we show that it can support models to generate explanations which capture the diversity of human

[17] Our analysis also raises the question of how well the predefined relation ontology captures the relations encoded in the explanations. We clustered the explanations and observed it broadly aligns with our our relation ontology. See more details in Appendix 3.3.

	Prompt Relation	Generated Explanation
(a)	PartOf	cowgirls wear boots as part of their outfits
	Emotion	if someone is weeping they are likely sad.
	Property	lights are very bright when they are on
	Property	a shark has teeth that are very sharp
	ResultIn	a hurricane can cause a major disaster in a community.
	Action	when trying to decipher a code, you need to first decipher the words
(b)	Function	i use money to make a payment for my car
	HasPrereq	when you want to make a payment, you need to make money
	Function	casinos make money by selling alcoholic drinks
	Location	casinos have lots of money
(c)	HasPrereq	money is needed to operate a casino.
	ResultIn	angles can bend in a triangle.
	Function	angles can be used to make triangle
	MadeOf	i prefer my light that is made of very bright glass
	Location	water is flowing in a stream
(d)	Time	water is a river that is flowing
	CatExemp	baked goods are a type of baked goods.
	Emotion	i like to clench my fist when i am angry

Table 7: Illustrative examples of BART generated explanations in response to relation prompts of the form "c and a have a r relation." For each example, r is shown on the left and c and a are underlined in the generated explanation. Outputs are grouped to illustrate: (a) general quality, (b) diversity in generation for same (c, a) with ambiguous relations, and (c,d) unseen relation types with (c) plausible versus (d) nonsensical outputs.

reasoning. We fine-tune a generative PTLM to generate e given (c, a, r), noting that other tasks definitions are conceivable, including jointly generating structured predictions and explanations, e.g., predict (r, e) from (c, a).

5.1 Prompting Relation Explanations

Most relatedly, BART has been used to generate relational triples from sentences (Huguet Cabot and Navigli, 2021). Here, we investigate the more challenging, reverse, direction: generate a free-text explanation from a given (c, a, r)-triple encoded into the sentence prompt "c and a have a r relation". The output is a short sentence supporting the prompt. For example, the input "*bucket* and *wash* have a *function* relation", could elicit the output "I use a bucket to wash my car".

Setup Similar to §4.1, we augment the labeled training portion of WAX to increase its size and balance: for each (c, a, e, r) instance in the training data, we mask either c or a in the explanation and fill the blank with the top 10 candidates generated by BERT-large.[18] We down-sampled generated instances of overrepresented relation types, resulting in a balanced dataset of 12K (c, a, e, r) tuples, which are used to fine-tune BART. The original validation data is used for model selection. Table 11 (Appendix) lists the key hyper-parameters.

We explored the model explanations under four conditions: (a) prompting with human created (c, a, r)-triples from WAX (*dog, bark,* Action); (b) a version of (a) focused on ambiguous (c, a)-pairs, e.g., (*dog, guard,* Action) and (*dog, guard,* Function); (c) prompted as in (a) but with a relation *unseen* in WAX. These triples are often nonsensical (*dog, bark,* Synonym).

Results Qualitative results in Table 7 show that (a) explanations are overall relevant, factual and of high quality; (b) using nucleus sampling (Holtzman et al., 2020), we can generate different meaningful explanations for the same prompt; (c) the high quality extends to inputs that were not seen in WAX; and (d) for nonsensical triples, the model can still link the concepts with the given relation (2 and 3 in (d)) possibly leading to tautological outputs; or ignoring of the relation (1 in (d)). Our analyses suggest that WAX can be used for fine-tuning and probing commonsense knowledge in PTLMs, support future research into explanation generation, or bridging structured and free-text commonsense representations. We leave development of a quantitative benchmark to future work.

6 Conclusion

Word associations have been used as a lens into human conceptual representations for a long time, however, the *types* and *reasons* of these associations have not been studied at scale. We presented WAX, a large data set of word associations with explanations and relation labels. WAX is both an opportunity better understand the human mental lexicon, and a repository of relational commonsense knowledge both structured as (c, a, r) tuples, and free-text through the associated explanations. We demonstrated the utility of WAX for supervised relation classification and explanation generation; and presented a detailed data set analysis including association diversity and data-driven relation types. In future work, we plan to use WAX in tasks such as automatically labelling edges in commonsense knowledge graphs, commonsense question answering, and natural language inference.

[18] We inspected a sample of 80 prompts for validity.

Ethical considerations

Our study received ethics approval (#2021-22495-22206-5) from the University of Melbourne ethics review board.

Limitations We acknowledge that our dataset is collected from a limited number of English native speakers, and it can serve as an initial work to understand the underlying associative reasons *within this group*. Caution should be exercised when drawing general conclusions about human conceptual knowledge, and an important direction for future work is an extension to other languages. Reasons for associations are likely more diverse than reflected in our data set.

Data Privacy and Usage Our collected data does not include any personal information except the worker ID, which we redact from the data set. Our collected data will be made public for research purposes.

Acknowledgments

This work was supported in part by China Scholarship Council (CSC). We thank the reviewers for their valuable comments. This research was undertaken using the LIEF HPC-GPGPU Facility hosted at the University of Melbourne. This Facility was established with the assistance of LIEF Grant LE170100200.

A Dataset Collection Details for WAX

Our study received ethics approval with the application reference number of 2021-22495-22206-5 from the The University of Melbourne ethics review board.

We collect the WAX dataset by crowdsourcing via Amazon Mechanical Turk. Participants were informed what data will be collected, how the data will be processed and used, and asked for their explicit consent. To avoid potential confronting content, we removed profane words[19] before sampling cue seeds in Phase 1 (§3.1). The payment for both experiments was calculated based on the minimum wage in the authors' home country, which is higher than that of our workers.

Phase 1 collects word associations and corresponding explanations. Next we describe the collection details.

HIT and Payment Each batch (of 5 cue words) is assigned to 10 workers. Each worker (1) produces up to three associated words for each cue, and (2) writes an explanation for each association. Workers can skip cues, if their meaning is unknown, or provide fewer than three responses, if they cannot think of more. Each batch is paid with \$0.66 reward with extra bonus up to \$1, depending on the number of known cues, associations and explanations. This task takes approximately 5 minutes, as estimated in a pilot study. We paid an average of \$1.48 per batch, resulting in an hourly wage of \$17.76 (all amounts in US dollars).

Quality Control Word associations and underlying reasoning are subjective, hence standard quality assessment via annotator agreement does not apply. Instead, we introduced a number of strategies to control quality: clear guidelines,[20] careful selection of workers, and filtering of explanations. A valid explanation must (1) include the cue and association words, or a morphological variant (e.g., plural); (2) be a single sentence of 5 to 20 words. We removed explanations which did not meet the criteria above or follow trivial templates, and batches where more than 3 of the 5 cues were marked *unknown*.

Phase 2 labels explanations with relations. Next we describe the HIT design and quality control.

HIT and Payment Each batch of 30 (c, a, e) triples is assigned to five workers. For each triple, workers select the most appropriate relation label from a given list (see Table 9 for list of labels and definitions provided to the workers). This task takes approximately 22 minutes, based on a pilot study. Each batch is paid at a minimum \$1 with extra bonus up to \$8, depending on the annotation quality. We paid an average of \$5.92 per batch, resulting in an hourly wage of \$17.36.

Quality Control We ensure high quality through (a) detailed instructions; (b) a training phase; (c) selection of 10 reliable crowd workers who achieved accuracy > 0.5 in training; (d) continuing feedback to annotators throughout annotation; (e) collecting labels from five workers for each (c, a, e). If a label has 3 or more votes it is selected; otherwise the instance is labeled by two experts (authors of the paper), and the voting test is re-applied.[21] We obtained an annotator agreement (pair-wise Cohen's κ) of $\kappa = 0.42$, indicating moderate agreement.

Final quality check Table 8 illustrates the questions used in our final WAX quality check, as described in Section 3.3 in the main paper.

Questions and Examples
Q1: Does the explanation express a valid reason for associating (c, a)? Example: raspberries can be made into jam.
Q2: Does the relation label express a valid relation for (c, a)? Example: (nature, beautiful, hasproperty)
Q3: Does the relation label express the relation for (c, a) that is described in the explanation? Example: (space, stars, partof, space has a lot of stars in it.)

Table 8: Examples of dataset quality check.

A.1 Relation inventory

Table 9 displays the relation ontology used in phase 2 of data collection, including a definition of each relation as presented to the crowd workers.

B Relation Templates

Table 10 lists trigger words and phrases used to automatically map recurring, templated WAX explanations to relations.

[19] https://www.cs.cmu.edu/~biglou/resources/bad-words.txt

[20] The full guidelines will be released as part of the dataset.

[21] After this, 32 instances are still not assigned a label with three votes, and are discarded.

Broad Category	Relation	Definition
Concept-Properties	HasProperty	Cue has association as a property; or the reverse. Possible properties include shape, color, pattern, texture, size, touch, smell, and taste; or inborn, native or instinctive properties.
	PartOf	A part or component of an entity or event.
	MaterialMadeof	The material of something is made of.
	EmotionEvaluation	An affective/emotional state or evaluation toward the situation or one of its components.
Situational	Time	A time period associated with a situation or with one of its properties.
	Location	A place where an entity can be found, or where people engage in an event or activity.
	Function	The typical purpose, goal or role for which cue is used for association. Or the reverse way.
	HasPrerequisite	In order for the cue to happen, association needs to happen or exist; association is a dependency of cue. Or the reverse way.
	ResultIn	The cue causes or produces the association. Or the reverse way. A result (either cue or association) shoud be involved.
	Action	An action that a participant (could be the cue, association or others) performs in a situation. Cue and association must be among the (participant, action, object).
	Thematic	Cue and association participate in a common event or scenario. None of the other situational properties applies.
Taxonomic	CategoryExemplar	The cue and association are on different levels in a taxonomy.
	SameCategory	The cue and association are members of the same category.
	Synonym	The cue and association are synonyms.
	Antonym	The cue and association are antonyms.
Linguistic	CommonPhrase	The cue and association is a compound or multi-word expression or form a new concept with two words.
None-of-the-Above	None-of-the-Above	Use this label only if other labels can not be assigned to the instance or you don't understand the cue, association or explanation.

Table 9: The definition of associative relations used for labelling WAX.

Relation	Trigger phrase
Antonym	opposite
PartOf	part of
Function	used
CategoryExemplar	type of, form of
HasPrerequisite	require, need to
MaterialMadeof	make of/by/with
Location	grow on, grown in, live in, on the, find
Synonym	similar, synonym, another word, define

Table 10: Templates used to automatically label explanations. Trigger word is the text between cue and association in the explanation.

C Hyperparameters

Table 11 lists the core hyperparameters used in the relation classification and generation experiments.

D BART class-wise relation prediction performance

Table 12 shows the class-wise relation classification performance of BART when fine-tuned on minimal templates (-EXP) and on full explanations (+EXP).

	Classification		**Generation**
	BERT	**BART**	**BART**
Optimizer	AdamW_hf	AdamW	AdamW
Max Steps	500	1000	2000
Learning Rate	5E-05	2E-05	2E-05
Batch Size	8	8	4

Table 11: Experimental hyper-parameters.

The final column indicates whether access to explanations improved performance.

	Relation	BART -EXP			BART +EXP			
		P	R	F1	P	R	F1	Δ F1
(a)	SYNONYM	100.0	83.3	90.9	77.1	72.6	74.8	↓

Abstract

Multimodal sentiment analysis (MSA) is an important way of observing mental activities with the help of data captured from multiple modalities. However, due to the recording or transmission error, some modalities may include incomplete data. Most existing works that address missing modalities usually assume a particular modality is completely missing and seldom consider a mixture of missing across multiple modalities. In this paper, we propose a simple yet effective meta-sampling approach for multimodal sentiment analysis with missing modalities, namely Missing Modality-based Meta Sampling (M^{3}S). To be specific, M^{3}S formulates a missing modality sampling strategy into the modal agnostic meta-learning (MAML) framework. M^{3}S can be treated as an efficient add-on training component on existing models and significantly improve their performances on multimodal data with a mixture of missing modalities. We conduct experiments on IEMOCAP, SIMS and CMU-MOSI datasets, and superior performance is achieved compared with recent state-of-the-art methods.

1 Introduction

Multimodal sentiment analysis (MSA) aims to estimate human mental activities by multimodal data, such as a combination of audio, video, and text. Though much progress has been made recently, there still exist challenges, including missing modality problem. In reality, missing modality is a common problem due to the errors in data collection, storage, and transmission. To address the issue with missing modality in MSA, many approaches have been proposed (Ma et al., 2021c; Zhao et al., 2021; Ma et al., 2021b; Parthasarathy and Sundaram, 2020; Ma et al., 2021a; Tran et al., 2017).

In general, methods that address the missing modality issue usually only consider the situation where a certain input modality is severely damaged. The strategies of these proposed methods can be divided into three categories: 1) Designing new architectures with a reconstruction network to recover missing modality with the information from other modalities (Ma et al., 2021c; Ding et al., 2014); 2) Formulating innovative and efficient loss functions to tackle missing modality (Ma et al., 2021a, 2022); 3) Improving the encoding and embedding strategies from existing models (Tran et al., 2017; Cai et al., 2018).

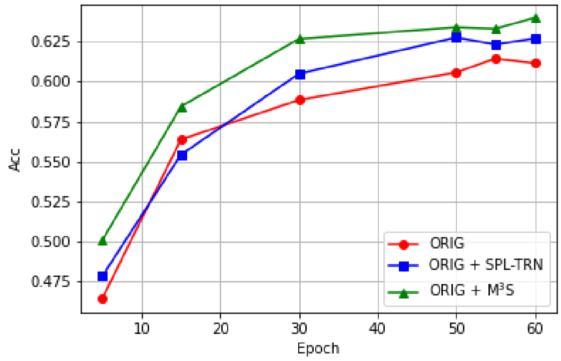

Figure 1: M^{3}S helps MMIN model achieve superior performance.

In the MSA tasks, most of the proposed methods focus on the situation where certain modalities are completely missing and the other modalities are complete. However, due to the transmission or collection errors, each modality may contain partial information based on a certain missing rate, while existing methods seldom consider this type of scenario and they are not suitable to be applied directly in this situation. Besides, our experiments also verify the inefficacy of existing methods in such a challenging situation, which is demonstrated in Section 5.

To address the aforementioned problem, in this paper, we propose a simple yet effective solution to the **M**issing **M**odality problem with **M**eta **S**ampling in the MSA task, namely M^{3}S. To be specific, M^{3}S combines the augmented missing modality trans-

form in sampling, following the model-agnostic meta-learning (MAML) framework (Finn et al., 2017). M^{3}S maintains the advantage of meta-learning and makes models easily adapt to data with different missing rates. M^{3}S can be treated as an efficient add-on training component on existing models and significantly improve their performances on multimodal data with a mixture of missing modalities. We conduct experiments on IEMOCAP (Busso et al., 2008), SIMS (Yu et al., 2020) and CMU-MOSI (Zadeh et al., 2016) datasets and superior performance is achieved compared with recent state-of-the-art (SOTA) methods. A simple example is shown in Figure 1, demonstrating the effectiveness of our proposed M^{3}S compared with other methods. More details are provided in the experiment section.

The main contributions of our work are as follows:

- We formulate a simple yet effective meta-training framework to address the problem of a mixture of partial missing modalities in the MSA tasks.
- The proposed method M^{3}S can be treated as an efficient add-on training component on existing models and significantly improve their performances on dealing with missing modality.
- We conduct comprehensive experiments on widely used datasets in MSA, including IEMOCAP, SIMS, and CMU-MOSI. Superior performance is achieved compared with recent SOTA methods.

2 Related Work

2.1 Emotion Recognition

Emotion recognition aims to identify and predict emotions through these physiological and behavioral responses. Emotions are expressed in a variety of modality forms. However, early studies on emotion recognition are often single modality. Shaheen et al. (2014) and Calefato et al. (2017) present novel approaches to automatic emotion recognition from text. Burkert et al. (2015) and Deng et al. (2020) conduct researches on facial expressions and the emotions behind them. Koolagudi and Rao (2012) and Yoon et al. (2019) exploit acoustic data in different types of speeches for emotional recognition and classification tasks. Though much progress has been made for emotion recognition with single modality data, how to combine information from diverse modalities has become an interesting direction in this area.

2.2 Multimodal Sentiment Analysis

Multimodal sentiment analysis (MSA) is a popular area of research in the present since the world we live in has several modality forms. When the dataset consists of more than one modality information, traditional single modality methods are difficult to deal with. MSA mainly focuses on three modalities: text, audio, and video. It makes use of the complementarity of multimodal information to improve the accuracy of emotion recognition. However, the heterogeneity of data and signals bring significant challenges because it creates distributional modality gaps. Hazarika et al. (2020) propose a novel framework, MISA, which projects each modality to two distinct subspaces to aid the fusion process. And Hori et al. (2017) introduce a multimodal attention model that can selectively utilize features from different modalities. Since the performance of a model highly depends on the quality of multimodal fusion, Han et al. (2021b) construct a framework named MultiModal InfoMax (MMIM) to maximize the mutual information in unimodal input pairs as well as obtain information related to tasks through multimodal fusion process. Besides, Han et al. (2021a) make use of an end-to-end network Bi-Bimodal Fusion Network (BBFN) to better utilize the dynamics of independence and correlation between modalities. Due to the unified multimodal annotation, previous methods are restricted in capturing differentiated information. Yu et al. (2021) design a label generation module based on the self-supervised learning strategy. Then, joint training the multimodal and unimodal tasks to learn the consistency and difference. However, limited by the pre-processed features, the results show that the generated audio and vision labels are not significant enough.

2.3 Missing Modality Problem

Compared with unimodal learning method, multimodal learning has achieved great success. It improves the performance of emotion recognition tasks by effectively combining the information from different modalities. However, the multimodal data may have missing modalities in reality due to a variety of reasons like signal transmission error and limited bandwidth. To deal with this problem, Ma et al. (2021b) propose an efficient approach based on maximum likelihood estimation to incorporate the knowledge in the modality-missing data. Nonetheless, the more complex scenarios like missing modalities exist in both training and testing phases are not involved. What's more, recent studies aim to capture the common information in different types of training data and leverage the relatedness among different modalities (Ma et al., 2021a; Tran et al., 2017; Parthasarathy and Sundaram, 2020; Wagner et al., 2011). To solve the problem that modalities will be missing is uncertain, Zhao et al. (2021) put forward a unified model: Missing Modality Imagination Network (MMIN). Ma et al. (2021c) utilize a new method named SMIL that leverages Bayesian meta-learning to handle the problem that modalities are partially severely missing, *e.g.*, 90% training examples may have incomplete modalities.

3 Methodology

3.1 Problem Description

The multimodal sentiment analysis aims at predicting the sentiment labels $\mathcal{Y}$ based on the model $f(\mathcal{X};\boldsymbol{\theta})$ given the multimodal data $\mathcal{X}$. We consider the input data with three modalities, *i.e.* $\mathcal{X} = (\mathcal{A}, \mathcal{V}, \mathcal{L})$, where $\mathcal{A}$, $\mathcal{V}$ and $\mathcal{L}$ represents audio, video and linguistic data, respectively. In this paper, we tackle the missing modality issue, where each modality can include missing data.

Algorithm 1 Meta-Sampling Training

```
Input: Multimodal dataset $(\mathcal{X} = (\mathcal{A}, \mathcal{V}, \mathcal{L}), \mathcal{Y})$;
    number of iterations $K$ for inner loop; inner
    learning rate $\alpha$; outer learning rate $\beta$; esti-
    mation model $f(\cdot\,;\boldsymbol{\theta})$; model's loss function
    $l\,(f, \mathcal{Y})$.
while not converged do
    Sample batch of data $\mathcal{X}_1$ and $\mathcal{X}_2$ from $\mathcal{X}$.
    Get $\tilde{\mathcal{X}}_1 = \mathcal{T}(\mathcal{X}_1\,;\mathcal{F})$ and $\tilde{\mathcal{X}}_2 = \mathcal{T}(\mathcal{X}_2\,;\mathcal{F})$.
    Set $\boldsymbol{\theta}_0 \leftarrow \boldsymbol{\theta}$
    Meta-train:
    for $n = 0$ to $K-1$ do
        $\boldsymbol{\theta}_{n+1} \leftarrow \boldsymbol{\theta}_n - \alpha\nabla_{\theta_n}\, l\left(f(\tilde{\mathcal{X}}_1;\boldsymbol{\theta}_n), \mathcal{Y}_1\right)$
    end for
    $\boldsymbol{\theta}^* \leftarrow \boldsymbol{\theta}_K$
    Meta-update:
    $\boldsymbol{\theta} \leftarrow \boldsymbol{\theta} - \beta\nabla_{\theta^*}\, l\left(f(\tilde{\mathcal{X}}_2;\boldsymbol{\theta}^*), \mathcal{Y}_2\right)$
end while
```

3.2 Augmented Missing Modality Transform

Given a sample $\boldsymbol{X}_i = (\boldsymbol{A}_i, \boldsymbol{V}_i, \boldsymbol{L}_i)$ from $\mathcal{X}$, we use a augmented transform $\mathcal{T}(\boldsymbol{X}_i\,;\mathcal{F})$ to generate a random sample with missing data based on a distribution $\mathcal{F}$. Specifically, for each modality $m \in \{a, v, l\}$, we define a missing ratio $r_m \in [0, 1]$, where a, v and l stands for audio, video and linguistic modality, respectively. For the encoded feature in each modality m, we replace the values between $[\lambda_m, \lambda_m + k_m - 1]$ with zeros, where k_m represents the number of missing values with $k_m = \lfloor T_m \cdot r_m \rfloor$ and T_m is the dimension of the encoded feature. λ_m is sampled from the uniform distribution, *i.e.*, $\lambda_m \sim \mathcal{U}(0, T_m - k_m)$. As a result, the augmented sample with missing modality can be obtained by $\tilde{\boldsymbol{X}}_i = \mathcal{T}(\boldsymbol{X}_i\,;\mathcal{F})$, where $\mathcal{F}$ represents the composition of uniform distributions for each individual modality.

3.3 Training with Meta-Sampling

Our M^{3}S follows MAML training framework (Finn et al., 2017) with augmentation sampling. For each training iteration, we adopt the following steps.

First, we sample two independent batch of data, $\tilde{\mathcal{X}}_1$ and $\tilde{\mathcal{X}}_2$, based on the augmented missing modality transforms, $\mathcal{T}(\mathcal{X}_1\,;\mathcal{F})$ and $\mathcal{T}(\mathcal{X}_2\,;\mathcal{F})$, where the missing rate for each modality is determined by the sampling distribution $\mathcal{F}$. $\tilde{\mathcal{X}}_1$ and $\tilde{\mathcal{X}}_2$ are used as tasks from support set and query set, respectively, in the meta-learning.

Then, in the meta-train process, the model's parameter $\boldsymbol{\theta}$ is updated using gradient descent based on the loss function $l\left(f(\tilde{\mathcal{X}}_1;\boldsymbol{\theta}), \mathcal{Y}_1\right)$ with the inner learning rate α for each iteration n as follows:

$$\boldsymbol{\theta}_{n+1} \leftarrow \boldsymbol{\theta}_n - \alpha\nabla_{\theta_n}\, l\left(f(\tilde{\mathcal{X}}_1;\boldsymbol{\theta}_n), \mathcal{Y}_1\right), \qquad (1)$$

where $\mathcal{Y}_1$ is the set of sentiment labels of $\tilde{\mathcal{X}}_1$, and the loss function $l\left(f(\tilde{\mathcal{X}}_1;\boldsymbol{\theta}), \mathcal{Y}_1\right)$ is determined by loss used in each base model (*i.e.*, MMIM, MISA, Self-MM, MMIN. See Section 4.2 for more details). The meta-train process is conducted for K iterations. We denote $\boldsymbol{\theta}_K$ as $\boldsymbol{\theta}^*$.

Finally, we use the query set $\tilde{\mathcal{X}}_2$ and its set of sentiment labels $\mathcal{Y}_2$ in the outer loop meta-update step. The model parameters are updated with the learning rate β as follows:

$$\boldsymbol{\theta} \leftarrow \boldsymbol{\theta} - \beta\nabla_{\theta^*}\, l\left(f(\tilde{\mathcal{X}}_2;\boldsymbol{\theta}^*), \mathcal{Y}_2\right). \qquad (2)$$

The whole algorithm in general case is shown

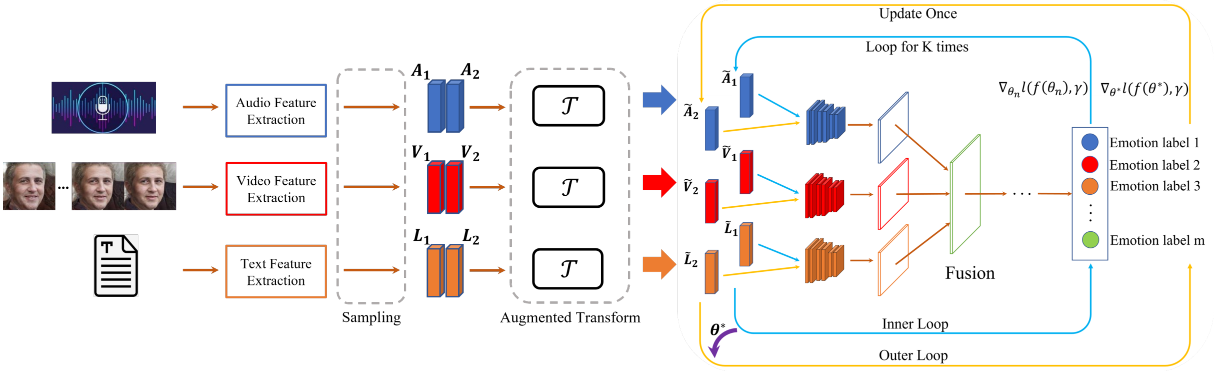

Figure 2: The Overall Architecture of M^{3}S. We first use augmented transform to generate two batches of data for features from each modality. Then the meta-train and meta-update are conducted on the two batches of data to learn the model parameters $\boldsymbol{\theta}$.

in Algorithm 1 and Figure 2 illustrates the meta-sampling training process.

4 Experiment Setup

In this section, we present the setup of our experiments, including the used datasets, baseline methods, evaluation metrics, and implementation details of the proposed method.

4.1 Datasets

We conduct our experiments on the following three datasets, *i.e.*, IEMOCAP (Busso et al., 2008), SIMS (Yu et al., 2020) and CMU-MOSI (Zadeh et al., 2016). The statistics of the datasets are reported in Table 1.

- **IEMOCAP** comprises of several recorded videos in 5 conversation sessions, and each session contains many scripted plays and dialogues. The actors performed selected emotional scripts and also improvised hypothetical scenarios designed to elicit specific types of emotions, which provided detailed information about their facial expressions and hand movements.

- **SIMS** dataset is a multimodal sentiment analysis benchmark containing 2281 video clips from various sources (*i.e.*, movies, shows, TV serials, etc.). SIMS contains fine-grained annotations of different modalities and includes people's natural expressions in video clips. And each sample in SIMS dataset is labeled with a score from -1 to 1, standing for sentiment response (*i.e.*, from strongly negative to strongly positive).

Dataset	Train	Valid	Test	All
SIMS	1368	456	457	2281
MOSI	1284	229	686	2199
IEMOCAP	4446	3342	3168	10956

Table 1: Statistics of the Used Datasets

- **CMU-MOSI** has 2199 video segments in total, which are sliced from 93 YouTube videos. The videos address a large array of topics like books, products, and movies. In these video segments, 89 narrators show their opinions on different topics. Most of the speakers are around 20-30 years old. They all express themselves in English, although they come from different countries.

4.2 Baseline Methods

We use four recent SOTA methods for comparison in the experiments. The methods include MMIM (Han et al., 2021b), MISA (Hazarika et al., 2020), Self-MM (Yu et al., 2021) and MMIN (Zhao et al., 2021), which are summarized as follows.

† **MMIM** helps mutual information reach maximum and maintains information related to tasks during the process of multimodal fusion, which shows significant results in multimodal sentiment analysis tasks.

† **MISA** is a novel model in emotion recognition that represents modality more effectively and improves the fusion process significantly.

† **Self-MM** has novel architecture containing several innovative modules (like a module for

Method	Self-MM (SIMS)				MMIN (IEMOCAP)		
	MAE	Corr	Acc-2	F1-Score	Acc	Uar	F1-Score
ORIG	0.5171	0.3918	0.7291	0.6980	0.6136	0.6403	0.6049

Table 2: Results of four baseline models with different training methods applied. Input and test data both have missing rates between 40% and 60%. ORIG stands for original model; SPL-TRN stands for sampling-training. Δ_{ORIG} presents the improved performance based on original model that M^{3}S has achieved.

label generation) and reaches brilliant results in multimodal sentiment analysis tasks.

† **MMIN** handles the problem that input data has uncertain modalities completely missing and achieves superior results under various missing modality conditions.

4.3 Evaluation Metrics

Following the four baseline methods mentioned above, we use the following evaluation metrics, including mean absolute error (MAE), Pearson correlation (Corr), binary classification accuracy (Acc-2), weighted F1 score (F1-Score), accuracy score (Acc), unweighted average recall (Uar), and seven-class classification accuracy (Acc-7). Acc-7 denotes the ratio of predictions that are in the correct interval among the seven intervals ranging from -3 to 3. For all metrics, higher values show better performance except for MAE.

4.4 Implementation Details

Hyperparameter Settings. The settings of inner learning rate, outer learning rate and batch size $\{\alpha$, β, batch_size$\}$ are as follows: MMIN $\{$2e-4, 1e-4, 256$\}$; MMIM $\{$1e-3, 1e-3, 32$\}$; MISA $\{$1e-4, 1e-4, 128$\}$; For Self-MM, the learning rate for three modalities $\{\mathcal{A}, \mathcal{V}, \mathcal{L}\}$ is $\{$5e-3, 5e-3, 5e-5$\}$, and the batch size is 32.

Feature Extraction Details. Following the baseline methods, we adopt the extracted features as the input for each modality. The feature extraction methods on each modality $\{\mathcal{A}, \mathcal{V}, \mathcal{L}\}$ are listed as follows: MMIN $\{$OpenSMILE-"IS13_ComParE" (Eyben et al., 2010), DenseNet (Huang et al., 2017) trained on FER+ corpus (Barsoum et al., 2016), BERT (Devlin et al., 2018)$\}$; Self-MM, MMIM, MISA $\{$sLSTM (Hochreiter and Schmidhuber, 1997), sLSTM, BERT$\}$.

Experimental Details. We use Adam as the optimizer for all four baseline models. The training epoch for $\{$MMIN, MMIM, MISA$\}$ is $\{60, 40, 500\}$. Self-MM adopts the "early stop" strategy to obtain the best result. Therefore, its training epoch is unfixed. In Section 5.1, We compare the performance of three different training methods dealing with missing modalities in our experiment results: 1) original model's training method (ORIG), where the missing rate of each sample is fixed along the training process during different epochs; 2) original model with Sampling-Training strategy applied (ORIG + SPL-TRN), which adopts augmented sampling without meta-learning process, as illustrated in Section 3.2; 3) original model with M^{3}S added on (ORIG + M^{3}S), which is the proposed method.

5 Results and Analysis

5.1 Main Results

Built on the baseline models, we conduct experiments with the proposed M^{3}S method and show its effectiveness in Table 2. The missing rate is set as the medium rate, between 40% and 60%. Since M^{3}S can be an add-on component to existing methods with the capability of dealing with missing

Input Missing Rate	Method	MMIN (IEMOCAP)			MMIM (MOSI)		
		Acc	Uar	F1-Score	MAE	Corr	Acc-7

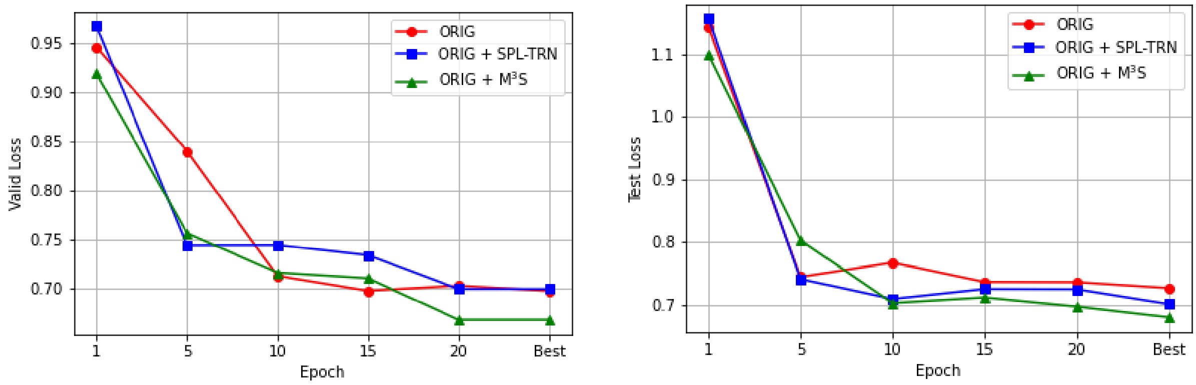
Table 3: Results on MMIN and MMIM under three different missing rate levels. Test data have the same range of missing rates as input data.



(a) Valid Loss

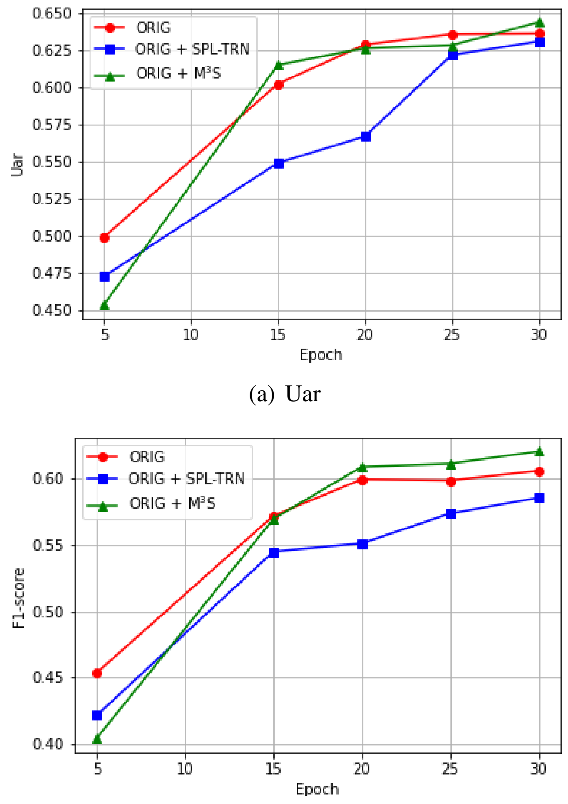
(b) Test Loss

Figure 3: Validation and testing losses of three methods along training built on the MMIM Model.

modality, we compare M^{3}S with Sampling-Training (SPL-TRN) and four original baseline methods. For all the testing datasets, M^{3}S achieves superior performance in almost all evaluation metrics compared with the original baseline methods, as expected. Since SPL-TRN only adopts augmented sampling without meta-learning process, it achieves worse performance than our M^{3}S method in most of the experiments. This result demonstrates that the meta-sampling training process can better learn the common knowledge from other modalities to deal with the missing information. It also verifies that meta-training can better utilize the information from random augmentations. As a matter of fact, with the help of M^{3}S, MMIN model achieves the highest Acc, highest Uar, and highest F1-Score. Also, built upon the other three baselines (Self-MM, MISA, MMIM), M^{3}S helps in reaching the lowest MAE, highest Corr, and highest Acc in most situations, which shows the efficiency and universality of M^{3}S.

5.2 Studies of Various Missing Rates

To verify the effectiveness of methods on different missing rates, we conduct experiments on two datasets by varying the input missing rate to three levels (*i.e.*, 20%-40%, 40%-60%, and 60%-80%). Results in Table 3 show that for nearly all the cases, our method M^{3}S outperforms ORIG and ORIG+SPL-TRN methods. Specifically, when input missing rate falls within the range 40%-60%, ORIG+M^{3}S shows the greatest increment in all metrics, which shows that M^{3}S achieves the most significant effect on models with medium missing level.



(a) Uar

(b) F1-Score

Figure 4: Uar and F1-Score of three methods along training built on the MMIN Model.

5.3 Convergence Comparison

As is shown in Figure 3(a) and 3(b), we plot the process of MMIM model's loss decline. It is clearly shown in plots that M^{3}S helps original model converge to the lowest loss after 10 to 15 epochs of training. As shown in Figure 4(a) and Figure 4(b), we also select MMIN model and plot its convergence process because the trend of its metrics changes more obviously. These two figures, along with Figure 1 show the characteristic of our method: although M^{3}S does not show strong competitiveness in the first few epochs, with the progress of training, M^{3}S helps model achieve faster growth of various metrics and finally converge to a higher result.

5.4 Adaptation across Different Missing Rates

In order to further discover the efficiency of our method in helping models adapt to different missing rates, we conduct experiments with testing rates different from input rates. As shown in Table 4, compared to ORIG method, we can see that M^{3}S significantly improves nearly all metrics by at least 1%. It is worth noticing that a large missing rate (60%-80%) is adopted in the testing, and M^{3}S achieves much better performance than the other two methods. For example, the Acc-7 of M^{3}S on MOSI dataset is over 3.6% higher than the one of ORIG+SPL-TRN method, demonstrating the capability of M^{3}S when different modalities have large missing information.

MMIN	ORIG	ORIG + SPL-TRN	ORIG + M^{3}S	Δ_{ORIG}
Acc	0.6035	0.6152	**0.6206**	↑ 0.0171
Uar	**0.6281**	0.6166	0.6140	↓ 0.0141
F1-Score	0.5953	0.6023	**0.6072**	↑ 0.0119
MMIM	ORIG	ORIG + SPL-TRN	ORIG + M^{3}S	Δ_{ORIG}
MAE	0.7201	0.7412	**0.7025**	↓ 0.0176
Corr	0.7794	0.7695	**0.7884**	↑ 0.0090
Acc-7	0.4534	0.4461	**0.4825**	↑ 0.0291

Table 4: Results on MMIN (IEMOCAP) and MMIM (MOSI), where input data have missing rates 40%-60% and test data have missing rates 60%-80%.

5.5 Further Discussion and Limitations

The qualitative results and ablation study above show that M^{3}S significantly helps baseline models improve their performance on inputs with various missing rates. However, when we apply M^{3}S to Self-MM model and conduct experiments on CMU-MOSI dataset, we find that the results show little difference from the original model's result. Besides, from Table 2 we know that M^{3}S improves Self-MM's performance on SIMS dataset significantly. Hence we assume that this is because Self-MM model has good adaptability to CMU-MOSI dataset but not SIMS dataset when both datasets have a mixture of missing across modalities. Therefore, some models may show adaptivity to certain datasets. And M^{3}S may not significantly improve the model's performance on those datasets that model is already quite adaptive to.

Also, as shown in Table 3, it's revealed that when inputs have a large missing rate (60%-80%), M^{3}S becomes limited in improving evaluation metrics. We attribute this to the change of sampling range. That is, when inputs have missing rates no more than 60%, we can create sufficient augmented missing data to perform M^{3}S. However, when inputs have large missing rates, we can only get augmented data with missing rates restricted to a smaller range. Thus we get a smaller sampling range containing large missing rate data, which makes M^{3}S limited.

But in general, M^{3}S method is recommended as it

P-value of t-test	Self-MM (SIMS)				MMIN (IEMOCAP)		
	MAE	Corr	Acc-2	F1-Score	Acc	Uar	F1-Score
$P(T \leq t)$	0.1959	0.0384	0.0018	0.0615	0.0007	7.95E-5	0.0005
P-value of t-test	MISA (MOSI)			-	MMIM (MOSI)		
	MAE	Corr	Acc-7	-	MAE	Corr	Acc-7
$P(T \leq t)$	0.0473	0.1873	0.0405	-	0.0277	0.1971	0.0263

Table 5: Two-tailed significance test (t-test) of M^{3}S.

is easy to be added on different models and efficient in improving models' performance on multimodal sentiment analysis tasks most of the time, especially when input data has a medium missing rate. As shown in Table 5, nearly all evaluation metrics' P-value is smaller than 0.05 in the significance test, indicating significant improvement when M^{3}S is applied.

6 Conclusion and Future Work

In this paper, we focus on a challenging problem, *i.e.*, multimodal sentiment analysis on a mixture of missing across modalities, which was seldom studied in the past. We propose a simple yet effective method called M^{3}S to handle the problem. M^{3}S is a meta-sampling training method that follows the MAML framework and combines the sampling strategy for augmented transforms. M^{3}S maintains the advantages of meta-learning and helps SOTA models achieve superior performance on various missing input modalities.

In the experiments, we show that our method M^{3}S improves four baselines' performance and helps them adapt to inputs with various missing rates. Furthermore, M^{3}S is easy to realize in different multimodal sentiment analysis models. In future work, we plan to investigate how to better combine M^{3}S with other training methods and extend the method to other multimodal learning tasks.

Ethical Considerations

Our proposed method aims to help improve the performance of different SOTA methods on data with various missing rates. All experiments we conduct are based on the open public datasets (Section 4.1) and pretraining baseline methods (Section 4.2). When applying our method in experiments, there is minimal risk of privacy leakage. Furthermore, since our method is an add-on component for different baselines, it is safe to apply it as long as the baseline model provides adequate protection for privacy.

Abstract

This paper focuses on the generation of natural language questions based on SPARQL queries, with an emphasis on conversational use cases (follow-up question-answering). It studies what can be achieved so far based on current deep learning models (namely pretrained T5 and BART models). To do so, 4 knowledge-based QA corpora have been homogenized for the task and a new challenge set is introduced. A first series of experiments analyzes the impact of different training setups, while a second series seeks to understand what is still difficult for these models. The results from automatic metrics and human evaluation show that simple questions and frequent templates of SPARQL queries are usually well processed whereas complex questions and conversational dimensions (coreferences and ellipses) are still difficult to handle. The experimental material is publicly available[1].

1 Introduction

Knowledge-based approaches have recently become popular in the field of question answering (QA) and dialogue, raising the task of semantic parsing that seeks to map a user's input questions to a formal representation that can be queried in a Knowledge Graph (KG). Alternatively, techniques have been proposed to verbalize small KGs, for instance to summarize information to a user. Still, the task which consists in verbalizing formal queries has been less studied. Yet, interesting applications could be derived from SPARQL-to-text question generation: for instance, the generation of tutoring systems where users can exercise on a topic, or the simulation of users for QA or dialogue systems. This is why this paper studies SPARQL-to-text question generation, with a particular consideration attached to the generation of questions in a conversational context.

The objective of the paper is to study what can be achieved so far on SPARQL-to-text question generation using datasets and pretrained models available in the literature. In this regard, the contributions are the following:

1. The **release of 5 knowledge-based QA corpora** (including 2 conversational ones) that have been homogenized and prepared for the SPARQL-to-text task: 4 of them are derived from existing corpora, and the last one is a new challenge set with unseen query types and domains.

2. The **comparison of different fine-tuning approaches** for BART and T5, using different input features and training data. As a results, we show that feeding the model with the expected answer and conversational contexts helps. We also show that these information can be efficiently replaced by a paragraph when available.

3. An **in-depth analysis of the models' performance with respect to varied query types**. This highlights the limits of the current transformer-based approaches, especially to process rare types of queries, and to generate coreferences and ellipses.

4. An **evaluation of the intelligibility and relevance of the generated questions** through quizzes where the participants have to answer follow-up questions based on a short paragraph. The results show that the models are still far from human questions but they can be used for some types of queries.

After a literature review in Section 2, Section 3 and 4 present the datasets and models, respectively. Then, prototyping experiments using different training setups are described in Section 5, while a detailed analysis of the models' performance is given in Section 6.

2 Related Work

Question generation frequently refers to the task of generating a natural language questions based on a text (Zhang et al., 2021). The generation can be conditioned on the manually spotted expected answer in the text (Murakhovs'ka et al., 2022; Laban et al., 2022), whereas generating them in a free way (Duan et al., 2017), even potentially generating possible answers (Tafjord and Clark, 2021).

In the field of knowledge-based approaches, several propositions have been made for the verbalization of formal queries (in SQL, SPARQL, OWL, etc.) through rules or templates (Ngonga Ngomo et al., 2013, 2019; Kusuma et al., 2020), or intermediate representations (Guo et al., 2019; Gan et al., 2021), leading to verbalizations with a variable naturalness. Using neural approaches, several contributions have been made to generate questions from RDF triples (Han et al., 2022) or small KGs depicting multi-hop questions (Serban et al., 2016; Kumar et al., 2019). In (Bi et al., 2020), this principle is improved by enriching the entities from the triples with information from a broader KG. A limit of these approaches is that they cannot cover several features offered by query language like SPARQL (e.g., union of triples, filters, aggregation functions, etc.). Hence, to the best of our knowledge, our work is the first attempt to study the verbalization of SPARQL seeking to generate a large diversity of questions types.

Among other related work, Knowledge-Based QA (KBQA) tasks are interesting to study since they provide data with paired natural language question and formal representation (usually triples or SPARQL queries) (Bordes et al., 2015; Dubey et al., 2019; Kacupaj et al., 2020; Biswas et al., 2021; Kacupaj et al., 2021; Cui et al., 2022). It is important to note that some of these corpora overlap because they are extensions or refinements of common ancestors. Less datasets exist when considering the conversational KBQA: ConvQuestions (Christmann et al., 2019) and CSQA (Saha et al., 2018). While the former does not provide the formal representations associated to the natural language questions, the latter is relevant for our task. Finally, in the field of dialogue, propositions have also raised to enable interoperability with KGs through a formal language (Lam et al., 2022). However, annotated datasets are usually private or small. Hence, the conversational dimension in our SPARQL-to-text task is original.

3 Datasets

In this paper, 4 KBQA corpora from the literature are used: SimpleQuestions (Bordes et al., 2015), LC-QuAD 2.0 (Dubey et al., 2019), ParaQA (Kacupaj et al., 2021), and CSQA (Saha et al., 2018). They have different characteristics, and they do not overlap. Additionnaly, a new corpus is introduced to serve as a challenge set, i.e. no training data is available for it. This corpus has been generated based on the WebNLG v.3.0 corpus (Ferreira et al., 2020), and is referred to as WebNLG-QA. This section presents an overview of the 4 corpora from the literature, the generation process and resulting content of WebNLG-QA, and how all these datasets were homogenized. General statistics and examples for the 5 resulting SPARQL-to-text datasets are given in Table 1 and 2.

3.1 Existing corpora

SimpleQuestions originally does not include SPARQL queries but (subject, property, object) triples. Each triple is paired with a question whose expected answer is either the object or the subject of the triple. Hence, all questions are asking for an entity ("what is...", "which...", "who..."). The triples' elements were initially taken from FreeBase, but were ported to WikiData[2].

LC-QuAD 2.0 and **ParaQA** directly include SPARQL queries for both DBPedia (WikiData as well in LC-QuAD 2.0). Questions are more varied than in SimpleQuestions. Expected answers can be entities, numbers or booleans. Some question are even unanswerable in LC-QuAD 2.0[3]. Questions in LC-QuaD 2.0 are sometimes of poor quality as they were semi-automatically generated, whereas ParaQA's questions are more natural but the dataset is much smaller.

CSQA is a very large corpus of conversational question-answering based on Wikidata. Queries are given in a custom formalism instead of SPARQL. The questions include coreferences and ellipses, potentially with clarification steps when they are ambiguous. CSQA covers a wide range of questions types such as (single or multiple triples, entity/numeric/boolean answers, comparative questions, etc.). Nonetheless, the linguistic diversity of the questions is low and some are unnatural.

[2] https://github.com/askplatypus/wikidata-simplequestions

[3] This means that no answer can be found in the KG, not that the question does make sense. Hence, this should not bother the SPARQL-to-text models.

	SimpleQuestions	LC-QuAD 2.0	ParaQA	CSQA	WebNLG-QA
Questions (train/valid/test)	34K / 5K / 10K	21K / 3K / 6K	3.5K / 500 / 1K	1.5M / 167K / 260K	332
Dialogues (train/valid/test)	–	–	–	152K / 17K / 28K	100
Reference questions per query	1	1	1	1	2
Characters per query	70 (± 10)	108 (± 36)	103 (± 27)	163 (± 100)	100 (± 33)
Tokens per question	7.4 (± 2.1)	10.6 (± 3.9)	10.3 (± 3.7)	10.0 (± 4.1)	8.4 (± 4.5)

Table 1: Statistics for each SPARQL-to-text dataset. Standard deviations are given between brackets.

	Query	Question	Answer

SimpleQ.	SELECT DISTINCT **?f** WHERE
	{ **?f** property:**author** resource:**Laura_Ingalls_Wilder** }
		what is a book by Laura Ingalls Wilder	A Little House Traveler

LC-Q. 2.0	SELECT (COUNT (**?k**) AS **?y**)
	{ resource:**MiG-21** property:**operator** **?k** }
		How many operators does MiG-21 have?	12

ParaQA	SELECT DISTINCT **?m** WHERE
	{ resource:**Alexa_Scimeca** property:**current_partner** **?p** .
	?p property:**former_partner** **?m** }
		Who are all the people who used to figure skate with the current partner of Alexa Scimeca?	Brynn Carman, Shawnee Smith, Andrea Poapst

CSQA	SELECT DISTINCT **?x** WHERE
	{ **?x** rdf:**type** ontology:**occupation** .
	resource:**Edmond_Yernaux** property:**occupation** **?x** }
		Which occupation is the profession of Edmond Yernaux ?	politician

	SELECT DISTINCT **?a** WHERE
	{ **?a** property:**main_subject** resource:**politician** .
	?a rdf:**type** ontology:**collectable** }
		Which collectable has that occupation as its principal topic ?	Notitia Parliamentaria, An History of the Counties, etc.

WebNLG-QA	SELECT DISTINCT **?y** WHERE
	{ { { resource:**Sludge_metal** property:**instrument** **?y** }
	UNION { resource:**Post-metal** property:**instrument** **?y** } } }
		What is used as an instrument in Sludge Metal or in Post-metal?	Singing, Synthesizer

	SELECT DISTINCT **?e** WHERE
	{ resource:**Sludge_metal** property:**instrument** **?e** }
		And what about Sludge Metal in particular?	Singing

	ASK WHERE { resource:**Nord_(Year_of_No_Light_album)** property:**genre** resource:**Sludge_metal** }	Does the Year of No Light album Nord belong to this genre?	Yes

Table 2: Examples for each corpus. For conversational corpora (CSQA and WebNLG-QA), follow-up questions are shown to illustrate the notion of coreference and ellipsis.

3.2 WebNLG-QA (challenge set)

To test the generalization of the models to be trained, a new conversational QA dataset, WebNLG-QA, is proposed for the sole evaluation purpose. This corpus has been generated based on WebNLG v.3.0 (Ferreira et al., 2020), a corpus associating small KGs (1-7 triples) with several possible verbalizations (short texts transcribing the KG's information). This corpus was built in two steps. First, follow-up SPARQL queries were automatically generated for each KG from WebNLG.

The query generation algorithm allows for a wide range of query types and combinations (number of triples, logical connectors, filters, etc.). Especially, it includes mechanisms to favor coreferences and ellipses by reusing entities and triples from the last generated query. Some queries can be unanswerable based on the KG, or even be nonsensical in order to test the genericity of the models. Since the purpose is to probe the limits of the models, the algorithm permanently tries to balance the distribution over each type of queries by prioritizing the rarest ones at each new generation step.

Algorithm 1 details how this is achieved. Considering the set of elementary types $\mathcal{T}$ (line 1), we implemented a function ϕ_t for each query type $t \in \mathcal{T}$. This function reads a source knowledge graph and tries to derive a query of the given type (line 7). Depending on the type, the query can be built either from scratch, or by modifying a baseline query in order to fit the target type[4]. The dependency possibilities are listed in a specific variable (lines. 4 and 10). Furthermore, the function ϕ_t relies on a set of input constraints C, which are implemented as logical predicates on the expected query. Typically, this enables specifying the desired number of common elements (resources, properties, etc.) between the generated query and the previous ones. For instance, the types *coreference* or *ellipsis* expect certain common elements between queries, whereas other types do not (in order to prevent consecutive queries from going around in circles). The creation of an unanswerable query can be constrained such that no answer can be found in G but an answer

[4] For instance, the generation of boolean query is implemented as changing to ASK the verb of a SELECT query.

```
1:  enum $\mathcal{T}$ ← {single_triple, two_triples, ..., true, false,
        coreference, ellipsis }
2:  var $\Omega$ : KG ← union of all KGs
3:  var $frequency$ : Dict($\mathcal{T} \to \mathbb{N}$)
4:  var $dependencies$ : Dict($\mathcal{T} \to$ List($\mathcal{T}$))
5:  function $\kappa_t$($Q$: list of existing queries for a given graph,
        G: KG) : Set ( Function(Query) : $\mathbb{B}$ )
6:      ▷ Build a set of conditions (predicates) that a query
        must satisfy for the type $t$ given the context of the
        generation $Q$ on a the graph $G$ to get fully validated
7:  function $\phi_t$($G$ : KG, $q'$ : base query, $C$: set of predicates)
        : Query or $undefined$
8:      ▷ Try to create a query of type $t$ based on $G$, optionally
        from $q'$ for some types, and satisfying the
        conditions $C$. Return $undefined$ if no such query
        can be created.
9:  function GENERATE($t$: Type, $G$: knowledge graph,
        $Q$: list of generated queries for G) : Query or
        $undefined$
10:     $dep\_types$ : List($\mathcal{T}$) ← $dependencies[t]$
11:     $q$ : Query ← $undefined$
12:     $q'$ : Query ← $undefined$
13:     ▷ If type $t$ requires to be build on top of another query,
          try first to build this intermediate query
14:     if $dep\_types \neq []$ then
15:         $success$ : $\mathbb{B}$ ← $false$
16:         while $dep\_types \neq []$ and $\neg success$ do
17:             $t'$ ← pop least frequent from $dep\_types$
18:             $C_{t'} \leftarrow \kappa_{t'}(Q, G)$
19:             $q' \leftarrow$ GENERATE$(t', G, Q)$
20:             if $q' \neq undefined$ then
21:                 ▷ Now try to include type $t$ in query $q'$
22:                 $C_t \leftarrow \kappa_t(Q, G)$
23:                 $q \leftarrow \phi_t(G, q', C_t)$
24:                 $success \leftarrow true$
25:     else ▷ If no intermediate query to build, directly try to
          build for type $t$
26:         $C_t \leftarrow \kappa_t(Q, G)$
27:         $q \leftarrow \phi_t(G, q', C_t)$
28:     return q
```

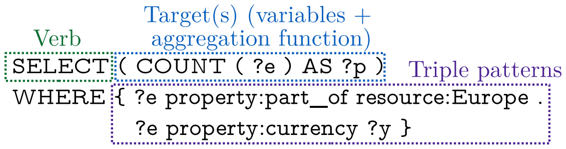
Algorithm 1: Query generation for a given type t.

exists in a larger, more general, KG, denoted as Ω (line 2). Likewise, nonsensical queries can be generated such that their elements are never observed together in any triple from Ω. All these constraints are given by auxiliary type-specific function κ_t (line 5). The generation of one query is orchestrated by the function GENERATE (lines 9-28) for the given input type t, knowledge graph G, and the previous queries Q generated on it. The balancing scheme over the type distribution is managed thanks to global statistics of all queries generated so far on all KGs (global variable $frequency$, line 3). For each KG in WebNLG, the overall process (not described in Algorithm 1) iteratively generates queries until none can be generated anymore, i.e., calls to GENERATE return $undefined$ for all types $t \in \mathcal{T}$. Examples of generated queries are given in Appendix A.1.

Then, given the whole set of resulting SPARQL queries, questions were manually annotated for the queries of a selection of 100 KGs. These KGs were selected from the test set of WebNLG such that the distribution of the query types is as uniform as possible. Two natural language questions were manually annotated by one annotator for each SPARQL query. Given a query, the annotator was asked to generate questions with different surface forms to reflect the diversity of the natural language. This results in 100 "dialogues" for a total of 332 questions (from 2 to 7 per dialogue).

3.3 Homogenization

All datasets were processed to contain SPARQL queries unified in a similar way as the following query whose verbalizaton could be "*how many currencies co-exist within the countries of Europe?*":



```
SELECT ( COUNT ( ?e ) AS ?p )
WHERE { ?e property:part_of resource:Europe .
        ?e property:currency ?y }
```

In particular, all entity IDs or URIs from WikiData or DBPedia were replaced by their label. Entities, properties and types were prefixed by `"resource:"`, `"property:"`, and `"ontology:"`, respectively. Triples were shuffled to prevent the model to learn in a biased way on the static ordering of some datasets. Variable names were anonymized with a single random letter (still prefixed by `"?"`) and some constructions were randomly replaced by equivalent forms[5].

For SimpleQuestions and CSQA, special efforts were required since they do not come with SPARQL queries. Especially for CSQA, we relied on the formalism from CARTON (Plepi et al., 2021) as an pivot representation from which SPARQL queries were generated by ourselves.

By default, the train/validation/test splits are the same as for the original datasets. In the case of LC-QuAD 2.0 and ParaQA, for which no validation set is officially provided, validation data was randomly extracted from the initial training set.

4 Models

This paper investigates the difficulty of the task for pretrained transformer models. This section first provides information about the fine-tuning process

[5] For instance, some `UNION` clauses were replaced using `VALUES` clauses. Still, some constructions could not be introduced, like `GROUP BY`, `ORDER BY` or `LIMIT`.

of these models, and then introduces several naive models used as baselines in the experiments.

Transformer models. The proposed models are encoder-decoder (i.e., autoregressive) transformers, namely **BART** (Lewis et al., 2020) and **T5** (Kale and Rastogi, 2020), fine-tuned on the SPARQL-to-text task. For both architectures, the models are the "*base*" version, as provided by HuggingFace[6]. This appeared as a reasonable size since CSQA is a very large corpus and many experimental settings are considered. Hence, the impact of the size is not considered here. Tokenizers are the default ones. Input sequences longer than the length limit of 512 tokens were truncated from the beginning, and no padding was used. The T5 prefix is "`sparql to nl: `". The fine-tuning is performed for 2 epochs with a batch size of 4 samples, which appeared to be the best setting on the development set. The optimizer is AdamW with a static learning rate of 5×10^{-5} and no weight decay. Finally, note that WebNLG data was *not* part of BART's or T5's training data for their pre-training.

Naive models. Several naive approaches are experimented to intuit the difficulty of the task and provide reasonable baselines. The simplest approach is to concatenate all terms of all triples in the query, except variables which are ignored. The order of the triples is the same as in the query—i.e., randomized, no micro-planning (Reiter and Dale, 1997, Chap. 5), hence the name **blind concatenation**. Alternatively, a rule-based micro-planning was implemented to spot the main triple in the query, that is the one on which the beginning of the question will focus[7]. Then, the main triple is placed first when concatenating. This approach is denoted as **smart concatenation**. To complete the approach, templates of questions were introduced to instanciate the triples. The most naive solution is to prefix all questions with "what" since this is the most frequent prefix in the training datasets. Another solution relies on a set of more sophisticated patterns, each being adapted to specific query configurations (query verb, target variable, shape of the main triple, etc.). This technique is called **smart concatenation + pattern**.

The next sections provide global results used to prototype a unique model for all the datasets (Section 5), and in-depth experiments to understand the current limits of the models (Section 6).

5 Prototyping Experiments

This section studies the design of a SPARQL-to-text model and provides global results. First, it studies the impact of adding input information along with the single SPARQL query. Then, the different training datasets are merged in order to investigate the generalization capacity of the models and to come up with a unique model for all the datasets. All results are presented in terms of METEOR (Banerjee and Lavie, 2005) and BERTScore (F1 score) (Zhang et al., 2020) on the test set of each corpus[8], using HuggingFace metrics.

5.1 Input features

The minimal input for the model is the SPARQL query to convert. Additionally, the model can be fed with the expected **answer** (if the question is answerable). In the case of a conversation, the **context** of the discussion can also be given, i.e. the previous questions and answers in natural language. This information is meant to be particularly helpful to properly generate coreferences and ellipses. Using all information, the model's inputs are formatted as follows: "`<context> conversational context </context> <query> SPARQL query </query> <answer> answer(s) <answer>`". The number of answers is limited to 10. Ideally, the context should be restricted to the few last turns sharing a link with the current query under study. This assumption was tested by identifying the restricted context in an oracle way using meta-information from CSQA.

Table 3 reports the impact of including the answer and the context when training the model on each corpus. First, it appears that the models are better than the naive approaches, while BART and T5 seem relatively equivalent. Then, the impact of including the answer greatly varies accross the corpora and models. Even if the best results are most frequently obtained when the answer is considered, it does not seem as useful as expected, meaning that most of the required information can probably be derived from the sole SPARQL query. The impact of the conversation context (CSQA) is more visible, with a major benefit in favor of including the context. Then, while restricting this context

[6] `https://huggingface.co/models`

[7] The rules analyze features like the presence or not of the target variable in a triple, the number of variables in this triple, the nature of the property, etc.

[8] Results are not reported on the validation sets as they were used to define several hyperparameters.

			METEOR					BERTScore-F1

Table 4: Performances when merging the training data. Best results for each dataset are in bold, and the darker the cell, the worse it is.

seems to outperform the full (unrestricted) context on BERTScore, no conclusion can be drawn regarding METEOR. This is a useful conclusion since correctly truncating the context may not be a simple task in real conditions. In the remainder, all models are trained with the answer and the full context. Finally, for all approaches (naive and transformers), SimpleQuestions and CSQA lead to higher results, which tends to think that they are less diverse than ParaQA and LC-QuAD 2.0.

All these conclusions have been supported by back-end experiments on WebNLG-QA (detailed in Appendix A.2) regarding the impact of the answer and conversational context, as well as the poor transfer of SimpleQuestions and CSQA.

5.2 Merged training

To take advantage of the different characteristics of each corpus, fine-tuning was performed based on the merged training samples of each dataset. Since the disparity is great between the size of each corpus, a balancing strategy was tested by weighting the corpora in inverse proportion to their respective size. The results are reported in Table 4.

On the one hand, it appears that merging the training data without any balancing scheme neither improves nor degrades the overall performance on the test set of these corpora since no global trend can deduced[9]. On the contrarty, balancing the data surprisingly degrades the results. This is probably because of weights with too high values since size differences are very strong, for instance between ParaQA and CSQA (the scaling factor is more than 400). In the remainder, the models are trained on mixed corpora with no balancing.

On the other hand, the last column of Table 4 for each metric reports the performance on WebNLG-QA. First, while the score of the naive approach is comparable to the other datasets, a significant drop is reported for the transformers models, leading to similar or even worse results than the naive approach. In our opinion, this is because the models are biased towards the most frequent query structures in the training sets, while these frequency disparities are globally smoothed out in WebNLG-QA. On the contrary, the naive approach is agnostic

[9] Except for ParaQA, which is the smallest corpus. Mixing with other data probably alleviate a sparsity issue.

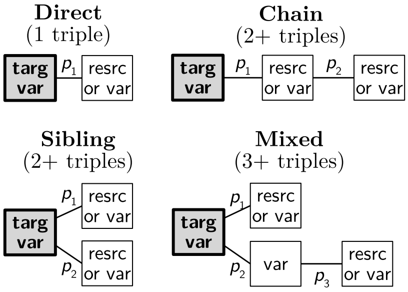

Figure 1: Topologies of the conjunctive queries.

to these considerations. Finally, it seems that T5 is more robust than BART. For this reason, BART is discarded in the next section where deeper investigations are conducted to understand what the model learns and what is still difficult for it.

6 Detailed Analysis

This section first analyses how the T5 model behaves on different query types. Then, a human evaluation on a real application is presented to evaluate the intelligibility and effectiveness of the generated questions. The focus is given on the challenge set WebNLG-QA but complementary results for the other datasets are reported in different appendices.

6.1 Robustness over the query types

Queries are categorized according to[10]:

The triples. They can mainly vary w.r.t. the *number of triples* (with the assumption that the more triples a question contains, the more complex it is), and the *logical connectors* between them (by default, logical *AND*s but potentially disjunctions with logical *OR*s, or exclusion like *triple*$_1$ *AND NOT triple*$_2$). In the conjunctive case (i.e., *AND* connectors) , the variables can interconnect the triples following different *topologies* w.r.t. the position of the target variable, as depicted in Figure 1. Additionnaly, *type* information can be given for the variables. Although this information is also written as a triple, "typing triples" (with a special property "`rdf:type`") are not considered as regular triples when counting the number of triples in the query in our statistics. Finally, constraints on the possible values for the variables can enable expressing *comparisons* to static values (`FILTER` clauses on string, numbers or dates).

The expected answer(s). Queries vary also according to the *type of the expected answer(s)* (entities, numbers or booleans), the *number of answers* (1, more or even 0 if the question cannot be answered), and the *number of target variables* (1, 2 or even 0 when simply checking a fact).

The conversational context. In a conversation, consecutive turns may re-use information from the previous turns, potentially leading to *coreferences* (replacing an entity by an equivalent pronoun or noun phrase to avoid repetition) and *ellipses* (skipping a syntagm that can be deduced from the previous sentences). While generating these can bring a more natural flow of questions, it can also bring ambiguity. If no coreference and no ellipsis is present, the question is denoted as *self-sufficient*.

The meaningfulness. Whereas queries are expected to make sense, it is worth observing how the model behaves when facing non-sensical questions.

Table 5.a presents the METEOR and BERTScore results for all categories and subsequent query types in WebNLG-QA using the T5 model fine-tuned on all merged corpora, and with the expected answers and the conversational context. This is compared to the best naive approach. Color shades depict the difference with the average performance for each dataset separately (red means lower than the average, green means greater). In complement, Table 5.b reports the standard deviation within each category of query types in order to evaluate the robustness against each variability factor. For the sake of completeness, results on all the datasets are in Appendix A.4. From Table 5.a, it appears that difficult types are those for which concurrent types can co-exist. For instance, queries with 2 triples can represent multiple configurations like sibling or chain topologies, conjunctive or disjunctive connectors, etc. On the contrary, queries with 1 or 3+ triples do not allow this diversity and they are better predicted. This is the same when the expected answer is an open entity (i.e., which is not part of closed list of choices in the query). Then, the model seems to also struggle when several target variables are considered. Finally, both tables show that handling the dialogue context is difficult for the model. Counter-intuitively, especially w.r.t. the results of Sec. 5.1, the results of the naive approach may even encourage one not to consider it.

6.2 Evaluation in a real application

To verify that the generated questions are understandable and lead to the expected answers, they were integrated in quizzes. As a reminder, each

sample in WebNLG-QA includes a small KG and the corresponding paragraphs provided by the original WebNLG corpus. For each sample, follow-up tuples (query, question, answer) can be used to quiz a user that would have read the paragraph. Before assessing the effectiveness of the generated questions in these quizzes, prior experiments are conducted.

			METEOR			BERTScore-F1

Table 6: Impact of changing the input features at *inference time* on WebNLG-QA using T5 fine-tuned on all merged corpora with full context and answers.

Input features at inference time. While including the answer and the conversational context has been decided at *training time* based on results of Section 5.1 (and Appendix A.2), previous conclusions from Section 6.1 have led us to study the impact of different inputs at *inference time*. Hence, Table 6 reports the scores obtained by the T5 model trained with the answers and contexts when feeding these two elements or not at inference time. This experiment also test the inclusion of the paragraph in input to provide contextualized knowledge to the model, even though the latter was not trained using such information. For a better analysis, results for BART are reported as well. Regarding the conversational context, these numbers show different trends as those reported during the prototyping experiments since including the context brings worse results for both models. Then, the T5 no longer benefits from the answer either (whereas BART clearly does). Finally, using the paragraph improves the results for T5 in terms of METEOR but not BERTScore, while this degrades the results for BART. These surprising conclusions call for more investigation. Currently, one may think that (*i*) T5 used the conversational context and answers during training to learn how to parse the SPARQL and then does not need the information later on, and (*ii*) that the multi-task pretraining of T5 included text comprehension task (summary, text-based QA, etc.) helps the model understanding the paragraph even after fine-tuning on the SPARQL-to-text task.

Human evaluation on quizzes Questions for the quizzes were either the reference or generated

	Reference	Best Naive	T5 (Query+Answ. +Context)	T5 (Query +Paragraph)

Table 7: Results of the human evaluation (quizzes).

using the naive approach, or T5. For T5, two types of input were provided at *inference time*: with the answer and context (as in the training setup), or only with the paragraph. 2 examples of quizzes are provided in Appendix A.5. There are 100 quizzes for each setup, based on the same 100 paragraphs. 20 users took part in the evaluation. All quizzes and their answers were seen exactly once. Users had to select their answers in a closed list of possibilities ("Yes", "No", 0, 1, 2, . . . , or entities from the paragraph). They could also report that the question cannot be answered because the paragraph did not contain the answer or the question was not understandable. By comparing with the expected and collected answer(s), accuracies were computed for each setup. After answering a quiz, users also had to rate the linguistic correctness of each question and the overall naturalness of the quiz (flow of questions). Both scores range between 1 (very bad) and 5 (excellent).

Table 7 reports the average results for each setup (7.a) and the variability of the answer accuracy and linguistic correctness within each category of query types (7.b). Exhaustive values for all query types are provided in Appendix A.6. As expected, it appears that the reference questions rank first for all the metrics. While the linguistic correctness is excellent, it is worth noting that the answer accuracy is not perfect. A manual analysis shows that this comes from confusions of the users, for instance between entity question (what, who. . .) and some boolean questions (is there. . .), or cascaded errors. Likewise, the naturalness of the flow of questions is not perfect because some questions are unanswerable. Then, the ranking is the same as with METEOR and BERTScore. Nonetheless, the difference between the naive approach and the T5 models is much clearer, which highlights the limits of automatic metrics for the task. By the way, this confirms that feeding the T5 model with the paragraph is significantly helpful. Compared to T5 with answer and context, the questions are more robust against almost all variability factors (Table 7.b).

7 Conclusion and Future Work

In this paper, we have studied in depth the problem of generating questions from SPARQL queries, in particular in order to be able to integrate these questions in a conversational knowledge-based application such as a QA system or a task-oriented dialogue. Contributions stand in the proposed corpora, including a new challenge set (WebNLG-QA), and in the multiple experiments conducted to highlight the limits of the popular pretrained models BART and T5 for the SPARQL-to-text task. These experiments show that, although the linguistic quality of the generated questions is good, the task only really works well for unambiguous and frequent situations, generally conforming to what has been seen in training.

In the future, it would be interesting to evaluate the questions generated with a QA system. Although the varying performance of these systems may bring uncertainty in the interpretation of the results, this would complement the human evaluation results and provide another basis for other researchers to compare their own question generation models. Then, several limitations remain to be overcome. First of all, a better generation of coreferences and ellipses should be investigated, as well as a better transfer capacity from one corpus to another. Then, apart from the use of other KBQA corpora than those used in this paper, it is likely that the use of unsupervised approaches, i.e. not requiring aligned questions and queries, is a challenging avenue to explore. In particular, this could favor help mixing knowledge-based and text-based approaches, as called by our last results.

A Appendices

A.1 Examples of generated SPARQL queries

This sections presents sequences of SPARQL queries generated as exposed in Section 3.2 and Algorithm 1 based on 2 sample KGs, depicted in Figures and 3.

Using the graph of Figure A.1, the resulting sequence of SPARQL queries is the following:

1.
   ```
   SELECT DISTINCT ?d WHERE
   { ?d property:birth_date
   ?k . FILTER ( CONTAINS (
   YEAR ( ?k ) , '1942' ) )
   . ?d property:known_for
   resource:No_hair_theorem }
   ```

2.
   ```
   SELECT DISTINCT ( COUNT
   ( ?m ) AS ?g ) WHERE {
   resource:Brandon_Carter
   property:known_for ?m }
   ```

3.
   ```
   SELECT DISTINCT ?m WHERE
   { resource:Brandon_Carter
   property:known_for
   ```

```
?m .  FILTER ( ?m !=
resource:No_hair_theorem )
}
```

4.
```
SELECT DISTINCT ?b WHERE
{ resource:Brandon_Carter
property:birth_place ?b .
FILTER ( STRSTARTS ( LCASE
( ?b ) , 'e' ) ) }
```

5.
```
SELECT DISTINCT ?t ?g WHERE
{ resource:Brandon_Carter
property:alma_mater ?g .
resource:Brandon_Carter
property:doctoral_advisor ?t }
```

6.
```
SELECT DISTINCT ?x WHERE
{ resource:Brandon_Carter
property:sports_offered ?x
}
```

Using the graph of Figure 3, the generated queries are:

1.
```
SELECT DISTINCT ?k WHERE { { {
?k property:stylistic_origin
resource:Ska } UNION { ?k
property:stylistic_origin
resource:Rock_music } } }
```

2.
```
SELECT DISTINCT ?k WHERE {
?k property:stylistic_origin
resource:Rock_music }
```

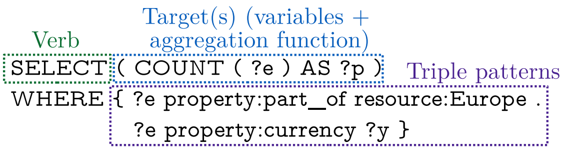
3.
```
ASK WHERE {
resource:Mermaid_(Train_song)
property:genre
resource:Pop_rock }
```

A.2 Performance of each separate dataset on WebNLG-QA

This appendix details how the models trained on each dataset separately transfer to the WebNLG-QA challenge set. Results reported in Table 8 show the same trends as observed on the test sets, respectively: the impact of including the answer is not obvious, while including the context help for the model trained on CSQA. The results also show that SimpleQuestions and CSQA cannot beat the naive approaches with expert micro-planning (*smart concatenation*). For SimpleQuestions, this seems obvious since most query types in WebNLG-QA are absent in SimpleQuestions. Regarding CSQA, this is probably due to the lack of linguistic diversity in the way to verbalize questions in this dataset (again, CSQA was generated semi-automatically). Results from Section 5.2 show that mixing the datasets solves this problem.

A.3 Details on the types of queries

As a reminder, a SPARQL query is as follows:



```
SELECT ( COUNT ( ?e ) AS ?p )
WHERE { ?e property:part_of resource:Europe .
        ?e property:currency ?y }
```

It mainly relies on triple patterns of the form (*subject*, *property*, *object*), where each element can refer to an entity (resource, literal, type, property) from the KG or represent a variable to be solved (prefixed by "?"). The query also specifies the nature of the answer(s) to be derived from these triple patterns using a verb (SELECT or ASK), target variables and possibly aggregation functions on the values taken by these variables. This section details variability factors on these various elements, as well as the possible values as reported in the paper's tables.

A.3.1 Structure of the triple patterns

Mainly, the pattern consists of cloze triples where potential values for the blanks are designated through variables prefixed with a ? sign. Below is a list of variability factors on the organisation of these triples.

Number of triples: Queries can include 1, 2 and more triplets. This reflects the complexity of the question. As far as what we observed, it is rare that more than 2 triplets are implied in real life questions as this becomes difficult to formulate within one sentence.

Logical connectors: The default connector between triples is the conjunction ($triple_1 \wedge triple_2$), but it can also be a disjunction ($triple_1 \vee triple_2$) or an exclusion ($triple_1 \wedge \neg triple_2$). Since the default connector in SPARQL is the conjunction, disjunctive and exclusive queries are more verbose.

Topology of the pattern: When triples are connected with a conjunction, they represent a connected graph where nodes are resources or variables and edges are properties. Assuming that only one variable is the target variable (which is the most frequent case), regularities can be observed in the topology of this graph w.r.t. the target variable, illustrated in Figure 4 and defined as follows:

↓ Training setup \ Training corpus →			METEOR				BERTScore-F1			
			SimQ.	LCQ2.0	ParaQA	CSQA	SimQ.	LCQ2.0	ParaQA	CSQA
Naive	Blind concatenation		33.6				86.6

Table 8: METEOR and BERTScore (F1) on WebNLG-QA when training on SimpleQuestions, LC-QuAD 2.0, ParaQA, and CSQA independently. The darker, the worse.

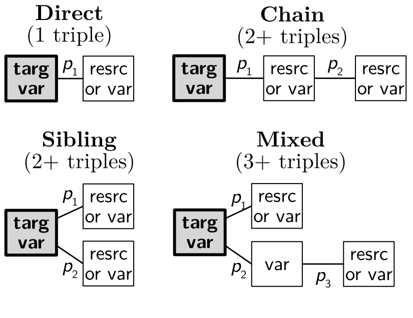

Figure 4: Topologies of the conjunctive query graphs.

1. A *direct* topology refers to a graph with only 2 nodes (i.e. 1 triplet).

2. *chain* denotes the situation where the graph is linear with more than 2 nodes and the target variable is at one of its extremities.

3. *sibling* refers to a graph the target variable is directly linked to 2 or more resources (whatever the orientation of the edges), i.e. the graph is a star of depth 1.

4. *mixed* is a mixture of the sibling and chain structures, that is a star topology centered on the target variable and with at least one branch of the star whose depth is more than 1.

Variable typing: Associating types to concepts (target of internal variables) in a question is sometimes critical to help understand a question. In the remainder, we consider typing as a specific case of property. Thus, triplets about typing are not counted as regular triplets.

Comparisons: Filtering clauses can be append to the triplets to restrict the range of their variables. Based on the corpora used in this paper, this comparisons can be numbers, strings or dates.

Superlatives: A specific case of comparison is when a minimal or maximal value is asked, or (most frequently) the entity associated with this extremum. While `MIN` and `MAX` are predefined aggregation functions in SPARQL, retrieving the is less trivial since it requires nested queries.

A.3.2 Answers

Queries vary also according to the expected answer.

Data type: Most usually, answers are *entities* but they can also be *numbers* (typically a count over entities) or *booleans* when facts are asked to be checked.

Number of intentions: Queries can include a variable number of target variables. This is referred to the number of intentions. While one intention is the most frequent situation, corpora also include questions with two intentions, as well as no intention (i.e. no target variable, when a fact is to be checked).

Number of answers: For each target variable, the number of answer can also vary depending on the information in the KG and the cardinality of the query properties. This may be zero if entity matches the query in the KG. Then, for a given person in subject, the property `birth_date` should lead to a single answer, while `parent_of` may return several objects.

A.3.3 Conversational context

Finally, in the context of conversations, the discussion may re-use information from the previous turns, potentially leading to coreferences and ellipses. Coreferences are the act of replacing an entity already mentioned in the discussion by a pronoun or another equivalent noun phrase in subsequent occurrences. Second, an ellipsis is the omission of a sentence segment deemed useless by the speaker because it can be deducted from previous turns, typically because the omitted segment (and no longer just an entity) would be a raw repetition. These linguistic phenomena are guided by the will to be brief by not repeating information, and constrained by the need to remain unambiguous. These linguistic phenomena are complex because they are not systematic. Hence, a coreference may link a pronoun with an entity mentioned several turns ago if there is not difficult to infer this link. At the opposite, a repetition in two consecutive turns may be required to avoid ambiguity. The same applies to ellipses with an even higher degree of complexity since ellipses require to rely on the syntact structure of a previous turn. Hence, generating coreferences and ellipses can be improve naturalness, it can also bring ambiguity.

A.4 Details on query types for all the datasets

Table 9 presents the METEOR and BERTScore results for all query types on each corpus using the T5 model fine-tuned on all merged corpora, and with the expected answers and the conversational context. For each test set, color shades depict the distance to the average performance on this dataset (red means lower than the average, green means greater). For WebNLG-QA, values are reported for the naive approach as well, since the average results are close (see Section 5.2).

Table 10 examines the impact of each category of query types from Table 9 in order to evaluate the robustness of the model.

A.5 Examples of quizzes

Tables 11 and 12 present two examples of quizzes. The first example is related to the queries of Figure A.1 from Appendix A.1.

- It can clearly be observed that the references regularly use coreferences or ellipses (in bold) to make the questions shorter and more fluent, and that the T5 models rarely generate such linguistic phenomena (in Q2 of Example 1, T5 generates "that person").
- Other limits of the transformers can be noticed. For instance, the underlying query of Q3 contains an exclusion ("Except the No-hair Theorem, what is Brandon Carter known for?"), which T5 does not generate at all.
- In Q1 of the second example, the underlying query is an `ASK` query with a variable, which has never been observed in any of the training corpora. While T5 with answer and context tries to combine elements from the sole query, T5 with the paragraph uses the text to produce a meaningful query (even if this is not the correct question).

A.6 Detailed results of the human evaluation for each type of query

Table 13 reports the details of the answer accuracy and linguistic correctness with respect to each query type. These results show that, except for a few situations, using the paragraph as an input to the model is always better than using the answer and the context.

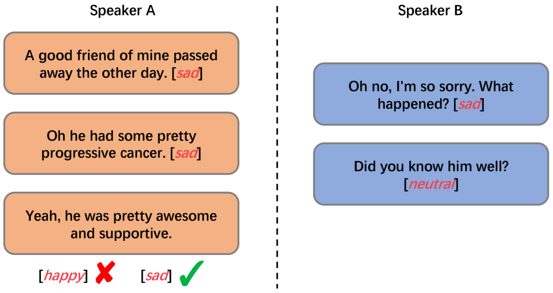
Abstract

Emotion recognition in conversation (ERC) has attracted much attention in recent years for its necessity in widespread applications. With the development of graph neural network (GNN), recent state-of-the-art ERC models mostly use GNN to embed the intrinsic structure information of a conversation into the utterance features. In this paper, we propose a novel GNN-based model for ERC, namely S+PAGE, to better capture the speaker and position-aware conversation structure information. Specifically, we add the relative positional encoding and speaker dependency encoding in the representations of edge weights and edge types respectively to acquire a more reasonable aggregation algorithm for ERC. Besides, a two-stream conversational Transformer is presented to extract both the self and inter-speaker contextual features for each utterance. Extensive experiments are conducted on four ERC benchmarks with state-of-the-art models employed as baselines for comparison, whose results demonstrate the superiority of our model.

1 Introduction

Emotion recognition in conversation (ERC), which aims to identify the emotion of each utterance in a conversation, is a task arousing increasing interests in many fields. With the prevalence of social media and intelligent assistants, ERC has great potential applications in several areas, such as emotional chatbots, sentiment analysis of comments in social media and healthcare intelligence, for understanding emotions in the conversation with emotion dynamics and generating emotionally coherent responses. ERC problem still remains a challenge. Both lexicon-based (Wu et al., 2006; Shaheen et al., 2014) and deep learning-based (Colnerič and Demšar, 2018) text emotion recognition methods that treat each utterance individually fail in this task as these works ignore some conversation-specific characteristics.



Speaker A
Speaker B
A good friend of mine passed away the other day. [sad]
Oh no, I'm so sorry. What happened? [sad]
Oh he had some pretty progressive cancer. [sad]
Did you know him well? [neutral]
Yeah, he was pretty awesome and supportive.
[happy] ✗
[sad] ✓

Figure 1: A dialogue from IEMOPCAP, in which the emotion of the last utterance by speaker A will be wrongly classified if the dialogue context is not taken into consideration.

In the past few years, recurrent neural network (RNN)-based solutions, such as CMN (Hazarika et al., 2018b), ICON (Hazarika et al., 2018a) and DialogueRNN (Majumder et al., 2019), have dominated this field due to the sequential nature of conversational context. Nonetheless, they share some inherent limitations: 1) RNN model performs poorly in grasping distant contextual information; 2) RNN-based methods are not capable of handling large-scale multiparty conversations.

With the rise of graph neural network (GNN) (Wu et al., 2020) in many natural language processing (NLP) tasks, researchers pay increasing attention to GNN-based ERC methods recently. Instead of modeling only sequential data recurrently in RNN, GNN is designed to capture all kinds of graph structure information via various aggregation algorithms. Existing GNN-based ERC methods, such as DialogueGCN (Ghosal et al., 2019), RGAT (Ishiwatari et al., 2020) and DAG-ERC (Shen et al., 2021), which are the state of the art, have demonstrated the superiority of GNN in modeling conversational structure information. A directed graph is constructed on each dialogue in these methods, where the nodes denote the individual utterances,

and the edges indicate relationships between utterances. However, we notice that the relative position and speaker dependency information are mostly encoded together in one weight matrix according to the edge type in these methods, which can not exploit these conversation structure information sufficiently.

On the other hand, these methods do not work well on modeling speaker-specific context, which is also important in the ERC task. For example, in Figure 1 the third utterance spoken by speaker A is more influenced by speaker A's prior utterances rather than the second utterance spoken by speaker B, even though the latter is closer. Thus, in contextual modeling, we should consider both the emotional influence that speakers have on themselves during a conversation, i.e., self-speaker context, and context on the entire conversation flow, i.e., inter-speaker context, as well as the interaction between them.

In this paper, we propose a novel **S**peaker and **P**osition-**A**ware **G**NN model for **E**RC (S+PAGE) to settle the above drawbacks of existing methods. Our model contains three stages to fully consider both contextual modeling and conversation structure modeling. Specifically, given a sequence of utterances in the same dialogue, we first leverage a **T**wo-**S**tream **C**onversational **T**ransformer (TSCT) with the attentive masking mechanism to get both self and inter-speaker contextual features. Then, guided by the speaker dependency, we construct a conversation graph. We propose an enhanced relational graph convolution network (R-GCN), called SPGCN, to refine the contextual features with conversation structure information. Particularly, we introduce relational relative positional encoding in the aggregation algorithm to make SPGCN capable of capturing fine-grained positional information in a conversation. Finally, the global transfer of emotion labels is modeled by a conditional random field (CRF) layer with the features from both TSCT and SPGCN. Experimental results demonstrate the superiority of our model compared with state-of-the-art models. Ablation study illustrates the effectiveness of the proposed components in the model. To conclude, our contributions are as follows:

- We propose a new GNN-based ERC method, called S+PAGE, in which a novel graph neural network, namely SPGCN, is presented to better capture the conversation structure information.
- We present a two-stream conversational Transformer architecture to extract both self and inter-speaker contextual features.
- We conduct extensive experiments on four ERC benchmark datasets, and the results demonstrate that the proposed model achieves the competitive performance on all of them.

2 Related Works

2.1 Emotion Recognition in Conversation

Emotion recognition in conversation is a popular area in NLP. Many ERC datasets have been scripted and annotated in the past few years, such as IEMOCAP (Busso et al., 2008), MELD (Poria et al., 2018), DailyDialog (Li et al., 2017), EmotionLines (Chen et al., 2018) and EmoryNLP (Zahiri and Choi, 2018). IEMOCAP, MELD, and EmoryNLP are multimodal datasets, containing acoustic, visual and textual information, while the remaining two datasets are textual.

In recent years, ERC solutions are mostly deep learning-based models. CMN (Hazarika et al., 2018b) and ICON (Hazarika et al., 2018a) utilize gated recurrent unit (GRU) and memory networks to capture the dialogue dynamics. In IAAN (Yeh et al., 2019) and DialgueRNN (Majumder et al., 2019), attention mechanisms are applied to interact between the party state and global state. With the rise of Transformer and graph neural networks in NLP tasks, many works have also introduce them into the ERC task. (Zhong et al., 2019) propose KET, which is a structure of hierarchical Transformers assisted by external commonsense knowledge. DialogueXL (Shen et al., 2020) applies dialogue-aware self-attention to deal with the multiparty structures. In DialogueGCN (Ghosal et al., 2019) and RGAT (Ishiwatari et al., 2020), GCN (Kipf and Welling, 2016) and GAT (Veličković et al., 2017) are applied to refine the features with speaker dependencies and temporal information. DAG-ERC (Shen et al., 2021) applies a directed acyclic graph for conversation representation and it achieves the state-of-the-art performance on multiple ERC datasets.

2.2 Transformer

(Vaswani et al., 2017) first propose Transformer for machine translation task, whose success subsequently has been proved in various down-stream

NLP tasks. Self-attention mechanisms endow Transformer with the ability of capturing longer-range dependency among elements of an input sequence than the RNN structure. (Beltagy et al., 2020) propose a novel self-attention mechanism for feature extraction of long documents. Pre-trained models such as BERT (Devlin et al., 2018) and GPT (Brown et al., 2020) use Transformer encoder and decoder respectively to learn representations on large-scale datasets.

2.3 Graph Neural Network

Graph neural network has attracted a lot of attention in recent years, which learns a target node's representation by propagating neighbor information in the graph. (Kipf and Welling, 2016) propose a simple and well-behaved layer-wise propagation rule for neural network models and demonstrate its effectiveness in semi-supervised classification tasks. Better aggregation methods for large graphs are proposed in GAT (Veličković et al., 2017) and GraphSage (Hamilton et al., 2017). (Schlichtkrull et al., 2018) propose R-GCN to deal with the highly multi-relational data characteristic by assigning different aggregation structures for each relation type.

3 Methodology

The framework of our model is shown in Figure 2. We decompose the emotion classification procedure into three stages, i.e., contextual modeling, speaker dependency modeling, and global consistency modeling. In the first stage, we present a conversation-specific Transformer to get both self and inter-speaker contextual features. Then, a graph neural network is proposed to refine the features with conversation structure information, including the speaker dependency and relative position of each utterance. Subsequently, we employ conditional random field as the output layer to model the context of global consistency of emotion labels.

3.1 Problem Definition

The ERC task is to predict emotion labels (e.g., Happy, Sad, Neutral, Angry, Excited, and Frustrated) for utterances $\{u_1; u_2; \cdots; u_N\}$, where N denotes the number of utterances in a conversation. Let S be the number of speakers in a given dataset. P is a mapping function, and $s = P(u_i)$ denotes utterance u_i uttered by speaker s, where $s \in \{1, \cdots, S\}$.

3.2 Utterance Encoding

Following previous works (Ghosal et al., 2019; Majumder et al., 2019), we use a simple architecture consisting of a single convolutional layer followed by a max-pooling layer and a fully connected layer to extract context-independent textual features of each utterance. The input of this network is the 300 dimensional pre-trained 840B GloVe vectors (Pennington et al., 2014). We use the output features, denoted as $\vec{u_i}$, as the representation of each utterance. Notice that we do not use any pre-trained model like BERT and RoBERTa to make utterance encoding for fairness of comparison with the baseline methods.

3.3 Contextual Modeling

We present a **T**wo-**S**tream **C**onversational **T**ransformer (TSCT) to better extract the contextual representation of each utterance in a conversation, which is also capable of handling multi-party conversations efficiently. The collection of utterance representations $U = \{\vec{u_1}; \vec{u_2}; \cdots; \vec{u_N}\}$ is taken as the input. We design a multi-head self-attention mechanism, composed of two streams, i.e., the inter-speaker self-attention stream and the intra-speaker self-attention stream.

3.3.1 Inter-Speaker Self-Attention

The inter-speaker self-attention is same with the self-attention in vanilla Transformer, in which each utterance can attend to all positions in the dialogue as shown in Figure 3(a). It is calculated as:

$$q_i^t, k_i^t, v_i^t = h_i^{t-1} W_{iq}^t, h_i^{t-1} W_{ik}^t, h_i^{t-1} W_{iv}^t \quad (1)$$

$$z_i^t = softmax(\frac{q_i^t (k_i^t)^T}{\sqrt{d}}) v_i^t \quad (2)$$

where W_{iq}^t, W_{ik}^t and W_{iv}^t are three learnable weight matrices for attention head i at layer t.

3.3.2 Intra-Speaker Self-Attention

The intra-speaker self-attention models speaker-specific contextual information by only computing attention on the same speaker's utterances in a dialogue. In this way, the model is able to capture the emotional influence that speakers have on themselves during the conversation. It is implemented by the attentive masking strategy as illustrated in Figure 3(b) and formulated as:

Figure 2: The overall framework of S+PAGE. First, contextualized representation of each utterance is obtained by contextual modeling part. Subsequently, we employ SPGCN to model the speaker dependency and position information. Finally, the CRF layer applied to model the consistency using information from the previous parts. $\oplus$ denotes the concatenation operation. L is the total number of graph layers.

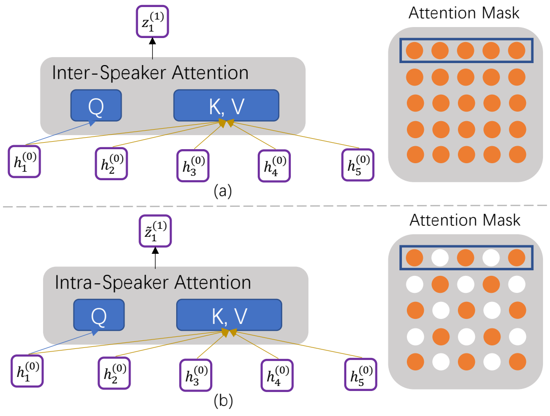

Figure 3: (a) Inter-speaker self-attention: the attention among all speakers, same with vanilla Transformer.(b) Intra-speaker self-attention: the attention only on the utterances spoke by the current speaker.

$$\tilde{z}_i^t = softmax(\frac{q_i^t(k_i^t)^T}{\sqrt{d}} + m)v_i^t \qquad (3)$$

where $m \in \mathbb{R}^{N \times N}$ is the attentive masking matrix. The elements of m are set as below:

$$m_{ij} = \begin{cases} -\infty & P(u_i) \neq P(u_j) \\ 0 & otherwise \end{cases} \qquad (4)$$

where $P(\cdot)$ is the function that maps the utterance and its corresponding speaker.

Each attention head i of the t-th layer in TSCT, denoted as $head_i^t$, is the concatenation of the z_i and $\tilde{z}_i$, and the output of the multi-head attention can be formulated as follows:

$$MultiHead_i^t = \|_{i=1}^{M} head_i^t \qquad (5)$$

where $\|$ denotes concatenation operation. M is the number of attention heads, while $1 \leq i \leq M$.

Following the structure of the original Transformer, the output of the TSCT layer can be generated by passing $MultiHead_i^t$ through a FF (feed-forward network):

$$h^t = \text{LayerNorm}(\text{FF}(MultiHead_i^t)) \qquad (6)$$

3.4 Speaker Dependency Modeling

After extracting the contextual features, we introduce a novel graph neural network, named SPGCN, to propagate structure-aware utterance features. Specifically, in SPGCN, speaker dependency and position information are modeled by edge types and edge weights respectively, and are combined in the aggregation function to update the features.

3.4.1 SPGCN

Graph Architecture We construct a directed graph, $\mathcal{G} = (\mathcal{V}, \mathcal{E}, \mathcal{R}, \mathcal{W})$, for each dialogue with N utterances. The nodes in the graph are the utterances in the conversation, i.e., $V = \{v_1; v_2; \cdots, v_N\}$. $(v_i, v_j, r_{ij}) \in \mathcal{E}$ denotes a labeled edge (relation), where $r_{ij} \in \mathcal{R}$ is a relation type, defined according to speaker identity and relative distance. $\mathcal{W}$ represents the set of edge weights.

Nodes Feature vector g_i of each node v_i is initialized as the output of the TSCT layer, i.e., h_i. g_i is modified by the aggregation algorithm through the stacked graphical layers in GNN. The output feature is described as g_i^l, where l denotes the number of layers.

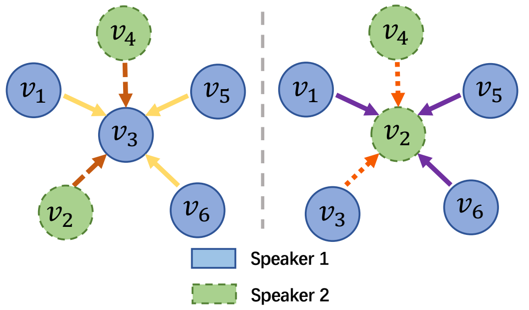

Figure 4: An example of incoming edges for nodes v_3 (left) and v_2 (right) in the dialogue graph. Different types of arrows denote different edge types. Nodes share the same edge types if they are spoke by the same speaker. v_3, v_1 and v_5 are spoke by speaker1, thus the edge between v_3, v_1 and the edge between v_3, v_5 belong to the same edge type.

Edges Instead of only focusing on past utterances, we take converse influence into account (Ghosal et al., 2019). We construct edges $\mathcal{E}$ with a sliding window for each utterance. The window sizes p and f denote the number of past and future utterances from the target utterance. Each utterance node v_i has an edge with p utterances of the past: $\{v_{i-1}, v_{i-2}, ..., v_{i-p}\}$, f utterances of the future: $\{v_{i+1}, v_{i+2}, ..., v_{i+f}\}$, and itself.

Edge Types The relation type $r \in R$ is determined by the *speaker identity*. Assuming there are S distinct speakers in a dialogue, there should be $N_e = S^2$ relation types in the constructed graph $\mathcal{G}$. Two utterances share the same edge type only if they are uttered by the same speaker. For example, in Figure 4 the incoming edges $v_1 \rightarrow v_3$ and $v_5 \rightarrow v_3$ share the same edge type, and $v_4 \rightarrow v_3$ is a different edge type.

Edge Weights Edge weight $\alpha_{ij} \in \mathcal{W}$ is computed by an attention mechanism. The particular attentional setup in our model closely follows the work of GAT (Veličković et al., 2017). The input of the attention module is a set of node features from the last layer. Motivated by (Shaw et al., 2018), which shows that absolute positional encoding is not effective for the model to capture the information of relative word order, we inject relative positional encoding into the attention mechanism.

$$\beta_{ij} = E_p(o(v_j) - o(v_i)) \tag{7}$$

$$\Gamma_{ij} = LReLU\left(\vec{a}^T \left[W g_i^{l-1} \| (W g_j^{l-1} + \beta_{ij})\right]\right) \tag{8}$$

$$\alpha_{ij} = \frac{\exp \Gamma_{ij}}{\sum_{k \in Ni} \exp \Gamma_{ik}} \tag{9}$$

β_{ij} denotes the signed relative position representation between utterance i and utterance j in a dialogue, which is encoded by a trainable embedding matrix E_p. $o(\cdot)$ is a mapping function between utterance and its absolute position in the dialogue sequence. $LReLU$ denotes the activation function $LeakyReLU$. W is a weight matrix applied to every node. N_i is the number of nodes linked with node i. $\vec{a}$ is a parametrized weight vector. $\cdot^T$ represents transposition, and $\|$ is the concatenation operation.

Aggregation Function Inspired by R-GCN (Schlichtkrull et al., 2018), we define the following aggregation algorithm to calculate the forward-pass update of a node in the graph:

$$\widetilde{g_i}^l = \sigma\left(\sum_{r \in \mathcal{R}} \sum_{j \in N_i^r} \frac{\alpha_{ij}^l}{c_{i,r}} W_r^l g_i^{l-1} + \alpha_{ii}^l W_o^l g_i^{l-1}\right) \tag{10}$$

where $\widetilde{g_i}^l$ is the aggregated state of node i in the l-th layer. N_i^r denotes the set of neighbors of utterance i under the edge type $r \in R$. $c_{i,r}$ is a normalization constant, and we set $c_{i,r} = |N_i^r|$ in our experiment. W_r^l and W_o^l are learnable weight matrices, and $\sigma(\cdot)$ is an activation function, such as the ReLU. Different from R-GCN, we use edge weights calculated by Equation 9 to involve fine-grained positional information in a conversation.

After the aggregation, we employ a gate fusion function to make $\widetilde{g_i}^l$ interact with its hidden state at the previous layer. Finally, the representation at the l-th layer is formulated as:

$$g^{'} = [\widetilde{g_i}^l; g_i^{l-1}; \widetilde{g_i}^l * g_i^{l-1}; \widetilde{g_i}^l - g_i^{l-1}] \tag{11}$$

$$\epsilon = sigmoid\left(W_f g^{'} + b_f\right) \tag{12}$$

$$g_i^l = \epsilon * \widetilde{g_i}^l + (1 - \epsilon) * g_i^{l-1} \tag{13}$$

where $l \geq 1$, and W_f and b_f are trainable parameters. $g^{'}$ is the concatenation of the four vectors.

3.5 Consistency Modeling

Instead of directly using a softmax function in the output layer, we employ conditional random field (CRF) to yield final emotion tags of each utterance.

Our motivation is to model the emotional consistency in a conversation, i.e., the emotion transfer. Using the CRF layer enables the model to take into account the dependency between emotion tags in neighborhoods and choose the globally best tag sequence for the entire conversation at once.

Following the describe by Lample et al., for an input set of utterances $U = \{u_1, u_2, ..., u_N\}$ and a sequence of tag predictions $y = \{y_1, y_2, .., y_N\}$, $y_i \in 1, \cdots, K$ (K is number of emotion tags), the score of the sequence is defined as,

$$score(\mathbf{U}, \mathbf{y}) = \sum_{i=0}^{n} D_{y_i, y_{i+1}} + \sum_{i=1}^{n} B_{i, y_i} \quad (14)$$

where $D \in \mathbb{R}^{K \times K}$ is the matrix of transition, $B \in \mathbb{R}^n \times K$ is the output score of the prepended classification model. The model is trained to maximize the log-probability of the correct tag sequence:

$$\log(p(\mathbf{y} \mid \mathbf{U})) = \\ score(\mathbf{U}, \mathbf{y}) - \log\left(\sum_{\tilde{\mathbf{y}} \in \mathbf{Y}} e^{score(\mathbf{U}, \tilde{\mathbf{y}})}\right) \quad (15)$$

where Y is set of all possible tag sequences. Equation 15 is computed using dynamic programming, while Viterbi applied applied to get most likely sequence following the work of Rabiner et al. (Rabiner, 1989).

4 Experiments

4.1 Datasets and Baselines

We evaluate our S+PAGE model on four widely-used benchmark datasets – **IEMOCAP** (Busso et al., 2008), which is a audiovisual dataset consisting of dyadic conversations where actors perform improvisations or scripted scenarios, **MELD** (Poria et al., 2018) and **EmoryNLP** (Zahiri and Choi, 2018), both of which are multi-modal and multi-party datasets created from scripts of the Friends TV series, and **DailyDialog** (Li et al., 2017), which is a human-written dyadic dataset covering various topics about our daily life. For this work, we only consider emotion recognition based on textual features, and thus some recent ERC solutions on multi-modal features (Chudasama et al., 2022; Hu et al., 2022) are not selected as our baselines for fairness. The statistic of them is shown in Table 1.

Dataset	# Conversations			# Uterrances		
	Train	Val	Test	Train	Val	Test
IEMOCAP	120		31	5810		1623
MELD	1038	114	280	9989	1109	2610
DailyDialog	11118	1000	1000	87170	8069	7740
EmoryNLP	713	99	85	9934	1344	1328

Table 1: The statistics of the datasets.

For a comprehensive performance evaluation, we choose **CNN**, **CNN+cLSTM** (Poria et al., 2017), **DialogueRNN** (Majumder et al., 2019) as baselines of CNN and RNN-based methods, **KET** (Zhong et al., 2019) as advanced Transformer-based approach with external commonsense knowledge included, **DialogueGCN** (Ghosal et al., 2019), **RGAT** (Ishiwatari et al., 2020) and **DAG-ERC** (Shen et al., 2021) as GNN-based approaches. Particularly, these three GNN-based models are the recent state of the art. DialogueGCN applies GCN to model speaker dependency, but it does not contain fine-grained positional information. Similarly, DAG-ERC applies a directed acyclic graph for conversation representation, which lack positional information in a conversation too. RGAT encodes both speaker dependency and relative positional encoding into the edge type, and use graph attention networks to make information aggregation.

For the evaluation metrics, we choose micro-averaged F1 for DailyDialog and weighted-average F1 for the other datasets, following previous works (Ishiwatari et al., 2020; Shen et al., 2021).

4.2 Experimental Settings

We set the initial learning rate as 1e-4 in the Transformer layers, 2e-4 in the SPGCN layers and 2e-2 in the CRF layer. AdamW optimizer is used under a scheduled learning rate following (Vaswani et al., 2017). The number of dimensions of the utterance representations and contextual embeddings is set to 300. We set the layer number of TSCT and SPGCN to 8 and 3 respectively. We set the dropout rate and number of attention head in TSCT to be 0.1 and 8 respectively. 3-head attention is used during calculating the edge weights. We also conduct experiments with different window sizes and SPGCN layers. We choose the hyper-parameters that achieve the best score on each dataset by using development data. The training and testing process is run on a single Tesla P100 GPU with 32G memory. The reported results of our implemented models are all based on the average score

Model	IEMOCAP	MELD	DailyDialog	EmoryNLP
CNN	48.18	55.86	49.34	32.59
CNN+cLSTM	54.95	56.87	50.24	32.89
DialogueRNN	62.75	57.03	-	-
KET	59.56	58.18	53.37	33.95
DialogueGCN	64.18	58.10	-	-
RGAT	65.22	60.91	54.31	34.42
DAG-ERC	68.03	63.65	59.33	39.02
S+PAGE	68.75 (0.11)	63.43 (0.15)	64.08 (0.21)	39.16 (0.12)
S+PAGE$_{Bert}$	68.77 (0.13)	63.25 (0.18)	**64.18** (0.25)	38.96 (0.13)
S+PAGE$_{RoBERTa}$	**68.93** (0.12)	**64.67** (0.15)	64.11 (0.21)	**40.05** (0.14)

Table 2: Overall performance on the four datasets.

of 5 random runs on the test sets.

5 Results and Analysis

5.1 Overall Performance

We compare our model with the baseline methods, and the results are reported in Table 2. We can note that our proposed S+PAGE has the best performance on all the four benchmark datasets. All GNN-based models outperform RNN-based models, which indicates the necessity of modeling the conversation structure information in the ERC task. Compared with existing GNN-based models, our model even has competitive results. There are three main advantages that contribute to our performance: 1) contextual modeling with both self and inter-speaker dependency, 2) a better speaker dependency and relative positional encoding in GNN, 3) consistency modeling of global emotion transfer.

We find that the improvements on MELD and EmoryNLP are not significant without utilizing pre-trained language models, i.e, BERT and RoBERTa. The performances of S+PAGE enhanced after replacing GloVe vectors by embeddings from pre-trained language models. This is because both datasets consturcted on Friends TV series, extra knowledge from large pre-trained language help the model to understand the dialogue better.

5.2 Ablation Study

To better understand the contribution of each component in our proposed model, we conduct experiments by replacing TSCT with the vanilla Transformer, and removing SPGCN and CRF from our model respectively. The results on IEMOCAP and MELD are shown in Table 3. We can observe that when TSCT is removed, the weighted F1 score drops more on MELD than that on IEMOCAP. This shows the superiority of TSCT on contextual feature extraction of multi-party conversations, as there are more speakers in dialogues of MELD. Removal of SPGCN leads to significant drop on both datasets, which implies the importance of SPGCN to refine the contextual features with speaker dependency and relative position. Meanwhile, after removing CRF layer, we can also observe the performance degradation. It implies that the modeling of label consistency is essential in the ERC task. To sum up, all of the three components contribute to the performance improvement of S+PAGE.

Method	IEMOCAP	MELD
S+PAGE	68.93	64.67
- TSCT	68.11 (↓0.82)	63.21 (↓1.46)
- SPGCN	64.25 (↓4.68)	62.03 (↓2.64)
- CRF	68.29 (↓0.64)	64.24 (↓0.43)

Table 3: Results of ablation study.

5.3 Whether SPGCN outperforms other graph structures?

We conduct experiments on IEMOCAP by replacing SPGCN with the graph structures in DialogueGCN, RGAT and DAG-ERC respectively. As shown in Table 4, S+PAGE still outperforms the other methods significantly. Notice that both DialogueGCN and RGAT with our contextual and consistency modeling perform better than their original versions. This indicates the necessary of the speaker-spcific information modeling in contextual modeling and speaker emotional consistency modeling, which is neglected in the previous methods. We use language embeddings from $\text{BERT}_{\text{base}}$ in RGAT and $\text{RoBERTa}_{\text{large}}$ in DAG follow the original papers for fair comparision.

5.4 Effect of Window Size

We analyze the influence of past and future window sizes by conducting experiments with window size w of $(4,4)$, $(6,6)$, $(8,8)$, $(10,10)$, $(20,20)$, $(30,30)$, $(40,40)$ on IEMOCAP dataset. As shown in Figure 5, the F1 score of S+PAGE, RGAT and DialogueGCN significantly increase, when the window sizes expand from 4 to 10. The reason is that useful contextual information keeps

Method	IEMOCAP
S+PAGE	68.93
S+PAGE(-SPGCN) + GCN	64.82
S+PAGE(-SPGCN) + RGAT	65.78
S+PAGE(-SPGCN) + DAG	67.93

Table 4: Results of replacing SPGCN with other graph structures.

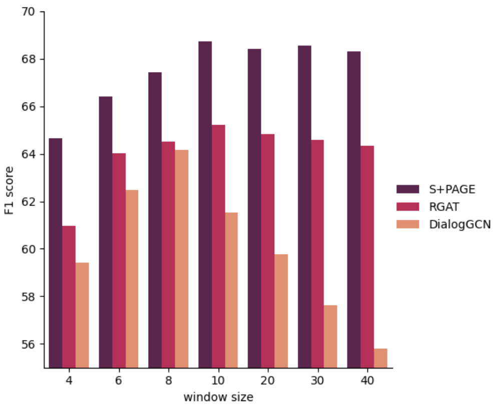

Figure 5: Results of varying window sizes.

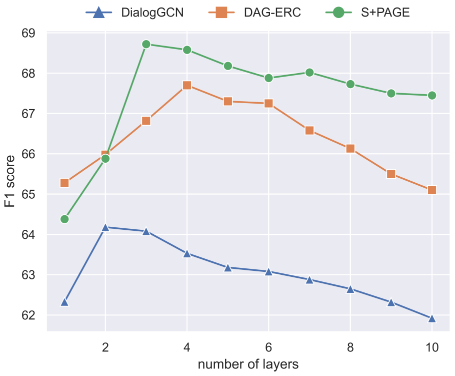

Figure 6: Graph layer ablation

growing with the increasing of w. However, after window sizes exceed 20, the F1 score drops for both DialogueGCN and RGAT. The reason is that the amount of useless long-range dependency increases when the window size continuously grows, which hinders the models from efficiently capturing crucial context. In contrast, the performance of S+PAGE fluctuates in a relatively narrow range, which shows the robustness of our model on varied window sizes. We can infer that the relative positional encoding endows capability of distinguishing critical contextual information to our model.

5.5 Number of SPGCN layers

We further explore the relationship between model performance and the number of layers of the SPGCN. Stacking too many layers of GNN may lead to performance degradation because of over-smoothing problem (Kipf and Welling, 2016). As shown in Figure 6, we conduct an experiment on IEMOCAP by setting different number of layers of the SPGCN, with the comparison of DiaglogGCN and DAG-ERC. As can be seen from Figure 6, DialogGCN suffers from a significant performance degradation after number of layers exceeds 3. On the other hand, for SPGCN and DAG, the drop seems to be more slight, which indicate the over-smooth problem alleviated in both structures.

Method	IEMOCAP
S+PAGE(RPE)	68.93
S+PAGE(APE)	66.38
S+PAGE(PER)	65.93

Table 5: Results of S+PAGE with other positional encoding methods in SPGCN. RPE is proposed relative positional embedding, APE is absolute positional embedding and PER is positional embeddings in RGAT.

5.6 Effect of Relative Positional Embedding

In this part, we conduct experiments to study whether our relative positional embedding(REP) in SPGCN is superior to other positional embedding methods. We replace REP with the popular absolute positional embedding (APE) and the position encoding (PE) implemented in RGAT. As shown in Table 5, the model with our RPE significantly outperforms the models with other position embedding methods.

6 Conclusion

In this paper, we propose a novel graph neural network-based model, named S+PAGE, for emotion recognition in conversation (ERC). Specifically, S+PAGE contains three parts, i.e., contextual modeling, speaker dependency modeling, and consistency modeling. In contextual modeling, we present a new Transformer structure with two-stream attention mechanism to better capture the self and inter-speaker contextual features. In speaker dependency modeling, we introduce a novel GNN model, named SPGCN, to refine the features with the conversation structure information including speaker dependency and relative position information. Furthermore, we use a CRF layer to model emotion transfer in the consistency modeling part. Experimental results on four ERC benchmark datasets demonstrate the superiority of our model.

Grammatical Error Correction Systems for Automated Assessment: Are They Susceptible to Universal Adversarial Attacks?

Abstract

Grammatical error correction (GEC) systems are a useful tool for assessing a learner's writing ability. These systems allow the grammatical proficiency of a candidate's text to be assessed without requiring an examiner or teacher to read the text. A simple summary of a candidate's ability can be measured by the total number of edits between the input text and the GEC system output: the fewer the edits the better the candidate. With advances in deep learning, GEC systems have become increasingly powerful and accurate. However, deep learning systems are susceptible to adversarial attacks, in which a small change at the input can cause large, undesired changes at the output. In the context of GEC for automated assessment, the aim of an attack can be to deceive the system into not correcting (concealing) grammatical errors to create the perception of higher language ability. An interesting aspect of adversarial attacks in this scenario is that the attack needs to be simple as it must be applied by, for example, a learner of English. The form of realistic attack examined in this work is appending the same phrase to each input sentence: a concatenative universal attack. The candidate only needs to learn a single attack phrase. State-of-the-art GEC systems are found to be susceptible to this form of simple attack, which transfers to different test sets as well as system architectures [1].

1 Introduction

Grammatical Error Correction (GEC) systems can form a part of automated language fluency assessment: the number of edits from a candidate's input sentence to a GEC system's grammatically corrected output sentence is indicative of a candidate's language ability, where fewer edits suggest better fluency. Early GEC systems were designed using hand-crafted rules (Naber, 2003), but since, data driven approaches, such as Statistical Machine Translation (Yuan and Felice, 2013), emerged. With encoder-decoder architectures dominating in Neural Machine Translation, Yuan and Briscoe (2016) used Recurrent Neural Networks (Cho et al., 2014) to improve GEC performance. Now state of the art GEC systems are based on the Transformer (Vaswani et al., 2017) architecture (Kaneko et al., 2020; Chen et al., 2020; Malmi et al., 2019; Awasthi et al., 2019; Omelianchuk et al., 2020b; Kiyono et al., 2019; Lichtarge et al., 2020; Stahlberg and Kumar, 2020).

Despite the success of Transformer-based deep learning systems, there is a shortcoming: Szegedy et al. (2014) discovered that neural networks are susceptible to adversarial attacks, where a small change at the input can yield large, undesired changes at the output of the model. In the GEC setting, a candidate may seek to make a change to their input sentence, such that the system makes no corrections, resulting in zero edits between the source and prediction sequences, which falsely indicates perfect language fluency. Given the high-stakes of an assessment setting, it is particularly concerning if a candidate can engage in such malpractice. Hence, this work explores the susceptibility of GEC systems to adversarial attacks.

GEC systems operate on natural language inputs. In this domain, there are many proposed adversarial attacks (Zhang et al., 2019), but on the whole they are inappropriate for sequence-to-sequence tasks, such as GEC. Ebrahimi et al. (2018); Zou et al. (2019); Zhang et al. (2021); Cheng et al. (2018) introduced methods for adversarial attacks in sequence-to-sequence models. These works require multiple queries of the target system. However, a candidate cannot query a GEC system. To solve this issue, this work uses a universal (Moosavi-Dezfooli et al., 2016) adversarial attack. Here, the same universal attack phrase is appended to the end of all candidates' input sen-

[1] Code is available at: https://github.com/rainavyas/gec-universal-attack

November 20–23, 2022. ©2022 Association for Computational Linguistics

tences, i.e. a new candidate can simply acquire (e.g. through purchase) a fixed universal attack phrase to concatenate to their input and deceive a GEC system used for automatic fluency assessment. This work also considers the transferability of a single attack phrase across different datasets and even architectures. Further analysis is carried out to determine the aspects of GEC systems that cause them to be susceptible to this form of attack.

Despite advances in natural language adversarial attacks, there has been less research on developing defence schemes. Defence strategies can be categorized as *model modification*, where the model or data is altered at training time (e.g. adversarial training (Yoo and Qi, 2021)) or *detection* (Raina and Gales, 2022), where external systems or algorithms are applied to trained models to identify adversarial attacks. Model modification approaches demand re-training of models and so detection approaches are preferred for deployed systems. Note that for attacks on GEC systems, detectors based on grammatical (Sakaguchi et al., 2017) and spelling (Mays et al., 1991; Islam and Inkpen, 2009) errors will fail. In this work, the most popular detection approaches: Frequency Guided Word Substitution (Mozes et al., 2020) (shown to outperform Zhou et al. (2019)); perplexity (Han et al., 2020; Minervini and Riedel, 2018) and model confidence (Aldahdooh et al., 2021); are applied to detecting adversarial attacks on GEC systems.

2 Related Work

In literature there has been limited work examining adversarial attacks for GEC systems. However, some works have explored adversarial robustness. First, Wang and Zheng (2020) perform adversarial training to improve the performance of their GEC system. Their adversarial training scheme augments the training data with adversarial examples, generated through the insertion of common grammatical mistakes in grammatically correct sentences, where the insertions are tuned to exploit weak spots in the GEC system. Further, Tang (2021) also seeks to increase robustness of GEC systems in a post-training setting, through further training on adversarial examples generated from four different NLP adversarial attack schemes. These adversarial attack methods again are designed to fool the sequence-to-sequence GEC system. Finally, Farkas et al. (2021) also augment the training data with adversarial examples, but focus on ensuring the adversarial examples mimic human grammatical errors by introducing noise at both a token level and embedding level.

However, the above schemes are inappropriate for the attack setting in this work. First, the aim of the attack in this work is to perturb grammatically *in*correct sentences to conceal grammatical errors. Second, the existing works consider attacks specific to each input, whereas this work considers the more realistic setup of a universal adversarial attack.

3 Grammatical Error Correction

Grammatical Error Correction (GEC) systems perform a sequence-to-sequence task, where an input word sequence, $x_{1:T}$, containing grammatical errors, is corrected for these errors by the system, with parameters, $\boldsymbol{\theta}$ to predict the grammatically correct output word sequence, $\hat{y}_{1:L}$,

$$\hat{y}_{1:L} = \arg\max_{y_{1:L}}\{p(y_{1:L}|x_{1:T};\boldsymbol{\theta})\}. \qquad (1)$$

To evaluate the performance of a GEC system, it is necessary to identify the edits made by the system and compare to the reference edits. An edit is defined as a modification (insertion, deletion or substitution) required on the input sequence $x_{1:T}$ to make it match the target sequence, $y_{1:L}$. A popular edit extraction tool is ERRANT (Bryant et al., 2017), which uses a linguistically-enhanced alignment algorithm proposed by Felice and Briscoe (2015). Edits between the input sequence, $x_{1:T}$, and hypothesised prediction sequence $\hat{y}_{1:L}$ can be found, $\hat{e}_{1:P}$,

$$\hat{e}_{1:P} = \texttt{edits}(x_{1:T}, \hat{y}_{1:L}). \qquad (2)$$

These edits are to be compared to reference edits,

$$\tilde{e}_{1:R} = \texttt{edits}(x_{1:T}, \tilde{y}_{1:L}), \qquad (3)$$

where $\tilde{y}_{1:L}$ is the reference output sequence. The precision $=$ TP$/($TP$+$FP$)$ and recall $=$ TP$/($TP$+$FN$)$ can now be computed, where TP, FP and FN are the standard definitions of true-positive, false-positive and false-negative. As a single performance score, $\text{F}_{0.5} = 1.25{*}\text{prec}{*}\text{rec}/(0.25{*}\text{prec})+\text{rec})$ is used, giving greater weight to precision over recall, as in GEC systems it is more important to be correct in the hypothesised edits, $\hat{e}_{1:P}$, as opposed to identifying all reference edits, $\tilde{e}_{1:R}$.

In this work GEC systems are considered for automated assessment. Here, the fluency score,

$S_\theta(x_{1:T})$, of a candidate is measured by the count of edits between the input sequence, $x_{1:T}$, and hypothesised prediction sequence $\hat{y}_{1:L}$, i.e.

$$S_\theta(x_{1:T}) = \texttt{count}(\hat{e}_{1:P}) = P, \tag{4}$$

where $S_\theta(x_{1:T}) = 0$ is a perfect fluency score.

Beyond extracting edits and reporting the overall performance of a GEC system, it is useful to categorize the error types. Inspired by Swanson and Yamangil (2012), the ERRANT tool uses a rule-based error type framework. Here edits are classified as either: **M**issing, where a token is present in the target sequence, $y_{1:L}$ but not in the input sequence, $x_{1:T}$; **R**eplaced, where a substitution is made; or **U**nnecessary, representing edits where a token is present in the input sequence, $x_{1:T}$ and not the output target sequence, $y_{1:L}$.

4 GEC Adversarial Attack

A targeted adversarial attack on an input text sequence, $x_{1:T}$ aims to perturb it to generate an adversarial example $x'_{1:T'}$ that ensures the output of a classifier, $\mathcal{F}()$, is t,

$$\mathcal{F}(x'_{1:T'}) = t, \quad \text{s.t. } \mathcal{H}(x_{1:T}, x'_{1:T'}) \leq \epsilon. \tag{5}$$

$\mathcal{H}()$ is some distance metric between the original and adversarial input sequences, ensuring the change is *imperceptible*. It is not simple to define an appropriate function $\mathcal{H}()$ for word sequences. Perturbations can be measured at a character or word level. Alternatively, the perturbation could be measured in the vector embedding space, using for example l_p-norm based (Goodfellow et al., 2015) metrics or cosine similarity (Carrara et al., 2019). However, constraints in the embedding space do not necessarily achieve imperceptibility in the original word sequence space. This work uses a simple variant of a Levenshtein *edit-based* measurement (Li et al., 2018) which counts the number of changes between the original sequence, $x_{1:T}$ and the adversarial sequence $x'_{1:T'}$, where a change is a swap/addition/deletion, and ensures it is smaller than a maximum number of changes, N. For a candidate planning to perturb their input sentence, the simplest attack is concatenation, where a fixed phrase is appended to their input (Wang and Bansal, 2018; Blohm et al., 2018; Raina et al., 2020),

$$x'_{1:T'} = x_{1:T} \oplus \delta_{1:N} = x_1, \ldots, x_T, \delta_1, \ldots, \delta_N$$

where $\delta_{1:N}$ is a N-word adversarial attack phrase.

The aim of the adversarial attack on a GEC system used for automated assessment, $\mathcal{F}() = S_\theta()$ (Equation 4), is to maximally decrease the count of edits between the input sequence and the predicted sequence, i.e. a candidate wants to *conceal* their grammatical errors from the GEC system. A single universal adversarial phrase, $\hat{\delta}_{1:N}$ is to be used for all candidates, i.e. once this universal phrase has been learnt from a set of J candidates, it can be *sold* to other candidates. Hence, the cost function an adversary seeks to optimise is

$$\hat{\delta}_{1:N} = \underset{\delta_{1:N} \in \mathcal{V}^k}{\arg\min} \left\{ \frac{1}{J} \sum_{j=1}^{J} S_\theta(x^{(j)}_{1:T} \oplus \delta_{1:N}) \right\} \tag{6}$$

where $\mathcal{V}^k$ is the set of all k length word sequences that can be constructed from a selected language vocabulary, $\mathcal{V}$.

It is important to consider the interpretation of *imperceptibility* in the automated assessment setting. In many applications, measuring imperceptibility by counting number of added words, N, is inadequate as it can result in incomprehensible phrases that can easily be identified by a human reader. However, in this setting, there is no human reader, which demands the use of automated systems for identifying incomprehensible phrases. Therefore, this work includes experiments to filter for adversarial attack words that do not compromise the integrity of an input sentence, when measured using a perplexity detector (introduced as a detection mechanism in Section 5, Equation 9) based on a state of the art language model. This ensures that an attack phrase remains imperceptible in an automated assessment setting.

This work also investigates variations in the punctuation a candidate can use to concatenate an adversarial phrase to an input sentence. If '*' represents the form of punctuation, then to concatenate an adversarial phrase to the original phrase, we do: original phrase* adversarial phrase.

5 Defence

For deployed systems, defence strategies that require re-training are undesirable. It is easier to use detection processes to identify and flag adversarial examples. This section considers how state of the art detection approaches can be applied to universal concatenation adversarial attacks on GEC assessment systems, described in Section 4.

All detection approaches, $\mathcal{D}()$, use a selected threshold, β to classify an input sequence, $x_{1:T}$

as adversarial or not. When $\mathcal{D}(x_{1:T}) > \beta$, then the input sequence $x_{1:T}$ is flagged as an adversarial example. To examine the performance of the detection process, this work uses precision-recall curves, where precision and recall values are calculated for a sweep over the threshold β. Here, for each value of β, the precision and recall values are calculated (as in Section 3), with adapted definitions for true-positive (number of samples correctly classified as adversarial), false-positive (number of samples incorrectly classified as adversarial) and false-negative (number of samples incorrectly classified as non-adversarial). A single-value summary is again obtained with the $\text{F}_{0.5}$ score, giving greater weighting to precision over recall, as it is more important to be correct in accusing candidates of mal-practice than finding all the candidates that cheat. The threshold with the highest $\text{F}_{0.5}$ score is selected for the detector $\mathcal{D}()$.

The recently dominating, Frequency Guided Word Substitution (FGWS) (Mozes et al., 2020) algorithm is adapted for attacks on an assessment GEC system. For the FGWS algorithm, we generate a sequence $x^*_{1:T}$ from the original input sequence, $x_{1:T}$ by substituting out low frequency words for higher frequency words. Precisely, a subset of eligible words (for substitution) is found $\mathcal{X}_E = \{x \in x_{1:T} | \phi(x) < \gamma\}$, where $\phi(x)$ gives frequency of word x and $\gamma \in \mathbb{R}_{>0}$ is a frequency threshold. Then, for each eligible word $x \in \mathcal{X}_E$ a set of replacement candidates, $\mathcal{U}(x)$ is found using synonyms. A replacement word x^* is selected as $x^* = \arg\max_{w \in \mathcal{U}(x)} \phi(w)$. Hence, $x^*_{1:T}$ is generated by replacing each word x in $x_{1:T}$ if $\phi(x^*) > \phi(x)$. For the GEC assessment system, $S_\theta()$, defined in Equation 4, the FGWS detection score is,

$$\mathcal{D}_{\text{FGWS}}(x_{1:T}) = \frac{1}{T}\left(S_\theta(x_{1:T}) - S_\theta(x^*_{1:T})\right). \quad (7)$$

Smith and Gal (2018) describe the use of uncertainty for adversarial attack detection, where adversarial samples are thought to result in greater epistemic uncertainty. In this work, negative confidence is selected as a simple measure of uncertainty. It is easiest to measure the confidence using the *grammatically correct* sequence output by the GEC system, $\hat{y}_{1:L}$ (Equation 1). The negative confidence detector score is calculated as,

$$\mathcal{D}_{\text{nc}}(x_{1:T}) = -\frac{1}{L}\log(p(\hat{y}_{1:L}|x_{1:T})). \quad (8)$$

This works also explores the positive confidence detector, $\mathcal{D}_{\text{pc}}(x_{1:T}) = -\mathcal{D}_{\text{nc}}(x_{1:T})$. A final popular NLP detection approach is to consider the *perplexity* (Minervini and Riedel, 2018) of the input sequence. It is expected that adversarial sequences have a greater perplexity than original samples. The perplexity detector, using some language model (LM), can be defined as,

$$\mathcal{D}_{\text{p}}(x_{1:T}) = -\frac{1}{T}\log(p_{\text{LM}}(x_{1:T})). \quad (9)$$

6 Experiments

6.1 Setup

Training of systems in this work uses a range of different popular grammatical error correction corpora. **Cambridge Learner Corpus (CLC)** (Open-CLC, 2019) is made up of written examinations for general and business English of candidates from 86 different mother tongues. Grammatical errors are annotated and this is used to generate reference sentences for GEC training. **Cambridge English Write & Improve (WI)** (Yannakoudakis et al., 2018) is an online web platform that assists non-native English students with their writing. Specifically, students submit letters, stories and essays in response to various prompts, and the WI system provides instant feedback. **LOCNESS** corpus (Granger, 2014) is a collection of 400 essays written by British and American undergraduates.

Evaluation of systems is performed on three different test sets. **First Certificate in English (FCE)** corpus (Yannakoudakis et al., 2011) is a subset of CLC, consisting of 33,673 sentences split into test and training sets of 2,720 and 30,953 sentences respectively. **Building Education Applications 2019 (BEA-19)** (Bryant et al., 2019) offers a test set of 4477 sentences, sourced from essays written by native and non-native English students[2]. **Conference on Computational Natural Language Learning 2014 (CoNLL-14)** (Ng et al., 2014) test set consists of 1312 sentences sourced from 50 essays written by 25 non-native English speakers.

In recent years, Grammatical Error Correction systems have been dominated by large (up to 11B parameters) Transformer based architectures (Rothe et al., 2021; Stahlberg and Kumar, 2021). Using the $\text{F}_{0.5}$ metric defined in Section 3, Table 1 compares the performance of two popular Transformer-based architectures: the Gram-

[2] Evaluation: `https://competitions.codalab.org/competitions/20228`.

former (Damodaran, 2022) (223M parameters), a T5-based (Raffel et al., 2019) sequence to sequence system[3] and Grammarly's Gector (Omelianchuk et al., 2020a), using specifically the Roberta-based architecture (Liu et al., 2019) (123M parameters)[4]. The Gramformer is pre-trained on the WikEd Error Corpus (Grundkiewicz and Junczys-Dowmunt, 2014), and in this work, it is further fine-tuned on the CLC (with FCE-test set removed), WI and LOCNESS datasets. The finetuning uses Adam optimiser with a batch size of 256 and a learning rate of 5e-4 with warm up. Maximum sentence length is set at 64 and the final model parameters are averaged over 5 best checkpoints. As the Gramformer model was initialised from a large pre-trained system, changing seed for the finetuning gave little diversity in the ensemble.

Table 1 shows that the Gramformer and Gector systems have a similar performance on the FCE test set, but the Gector system significantly out performs the Gramformer on the CoNLL-14 and BEA-19 test sets. Nevertheless, to mimic a realistic adversarial attack setting, the more easily available Gramformer system[5] is used as an initial model (adversary can access) for learning universal attacks and the best attacks are then transferred for evaluation on the target Gector system in Section 6.4.

	Model	Precision	Recall	$F_{0.5}$
FCE	Gramformer	51.6	43.7	49.8
	Gector	53.5	39.3	49.9
CoNLL-14	Gramformer	49.3	34.1	45.2
	Gector	62.0	42.6	56.8
BEA-19	Gramformer	35.3	44.6	37.1
	Gector	70.2	61.2	68.2

Table 1: GEC systems $F_{0.5}$ scores.

6.2 Attack Results

Greedy universal concatenation adversarial attacks were performed on the Gramformer system as described in Equation 6. As described in Section 4, different punctuation types were considered for the concatenation of the universal attacks. The impact of each attack phrase is presented for each of the three different GEC test sets in Figure 1, with N being the number of universal adversarial words at the end of each input sentence. The universal attack phrases were learnt on the FCE training split[6].

The metric used to measure the success of the attack is the fraction of samples with zero edits from source to GEC prediction sequence. The *random* attacks shown use a *full-stop* for concatenating randomly sampled words. A *direct* attack is where no punctuation is used to separate the original and the attack phrase. With percent increases between 20% and 50% in the fraction of samples with no edits shows that the GEC system is threatened somewhat by the *direct, colon* and *comma* attacks. However, for the *full-stop* universal adversarial attack sequence, with even a $N = 4$ word attack, the number of samples with zero edits increases by almost 40% for the FCE test set and more than 100% for the CoNLL-14 and BEA test set. It is evident that the GEC system is susceptible to even a simple form of universal attack. The greater susceptibility to the full-stop attack can be explained to some extent by the nature of the data used to fine-tune the Gramformer GEC system. Table 2 shows the frequency count of the different punctuation marks in the training set (CLC, WI and LOCNESS datasets), where the *full-stops* present at the end of sentences are not included [7]. Note that there are a total of ∼3M input samples in the training dataset. The count of *full-stops* is far less than that of *commas*, meaning the GEC system is not as familiar with multi-sentence inputs allowing for greater susceptibility to attacks using the *full-stop*. However, this count-based explanation is inadequate to justify the less successful *colon* concatenation attack. Nevertheless, the lack of susceptibility to colon concatenation can be explained - in the training samples with colons, more than 50% samples have the *colon* followed by a list delimited with semi-colons. This means that the GEC system easily learns this fixed colon usage, which makes it difficult to have a successful *colon*-based universal concatenation attack format. Due to the potency of the *full-stop* concatenation attack, the remainder of the analysis in this section focuses on the *full-stop* attack [8]. Examples of the impact of

[3] Gramformer model: https://github.com/PrithivirajDamodaran/Gramformer

[4] Gector models: https://github.com/grammarly/gector

[5] Stars on Github: Gramformer (1,110); Gector (611).

[6] Note that the **same** universal attack phrase is evaluated on the different datasets.

[7] For the *full-stop* concatenative attack we are interested in the count of the number of instances where there is a multi-sentence input to best represent the format of the attack.

[8] Equivalent analysis (in Appendix B) for the *comma, colon* and *direct* attack formats gave the same trends as the analysis presented for the *full-stop* attack format.

the universal attack are given in Table B.1.

Punctuation	Count
Full-stop	214,064
Comma	1,790,282
Colon	97,964

Table 2: Count of punctuation in training set. Excludes punctuation at end of inputs.

Table 3 shows the impact of the $N = 4$ concatenation adversarial attack on the performance of the GEC system on the FCE test set. The adversarial phrase is stripped from the output predicted sequence to discount the introduction of false-positive edits in the adversarial part of the input. As expected the $F_{0.5}$ score worsens due to the drop in the recall, i.e. the GEC systems struggles to find the grammatical errors with the attack phrase concatenated at the end of the sentence - the attack is successful in concealing the errors present in the sentence.

Input	Precision	Recall	$F_{0.5}$
Original	51.6	43.7	49.8
Attacked	51.3	30.7	45.2

Table 3: Gramformer $F_{0.5}$ score.

6.3 Detection Evasion

Although the Gramformer GEC system is susceptible to a universal attack, it can be defended using detection methods. Figure 2 compares the success of detectors from Section 5 when attempting to distinguish adversarial samples from original samples (on FCE test). The threshold for each detector is selected such that it gives the best $F_{0.5}$ score. Results are presented for original FCE test samples with and without the *full-stop* universal adversarial phrase appended to the end of the samples. It is interesting to note that FGWS, although successful in other NLP adversarial attack tasks, has little success here. This is perhaps expected as the FGWS vocabulary is now trained with grammatically incorrect sentences containing mis-spellings. Further, the FGWS algorithm is tuned to word substitution attacks, meaning it is less appropriate for the concatenation setting here. The perplexity score is calculated using a pre-trained distilled GPT-2 language model (Radford et al., 2019) applied to the input sequence. Perplexity has some success here in detecting adversarial samples, but the success is limited because many original input sequences are grammatically incorrect and thus naturally have an inflated perplexity score, meaning it is easy for the detector to mistake them for adversarial samples.

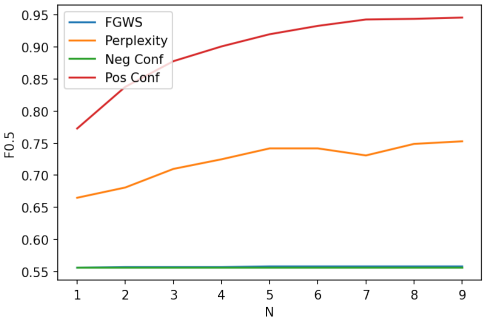

Figure 2: Adversarial attack detection using $F_{0.5}$ score to distinguish between original and adversarial samples.

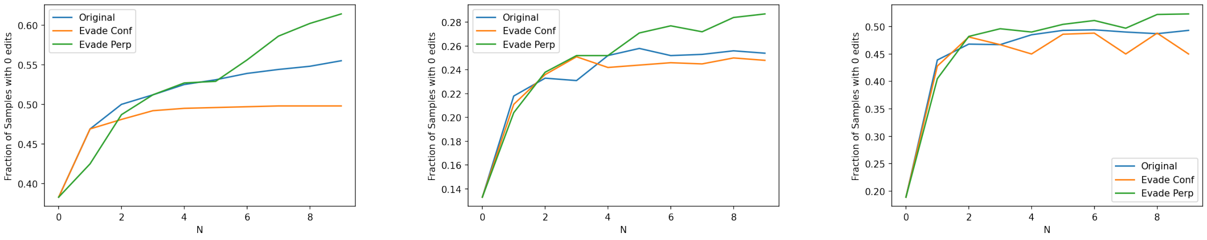
Interestingly, negative confidence has no success in detection here, whilst positive confidence dominates as the best detection approach. This is surprising because one would expect adversarial samples to cause systems to be less confident in their predictions, as the system is operating in a less well understood input space. Nevertheless, superior performance of positive confidence is explainable. GEC systems are trained on data where the tokens present in the input are also present in the reference, meaning in most cases there is a strong bias towards simply predicting tokens that are present



(a) FCE

(b) CONLL-14

(c) BEA 2019

Figure 3: Evaluation of detector evasion adversarial attacks.

in the input sequence. When an obscure adversarial word is present in the input sequence, the GEC system at prediction time naturally has a much larger probability mass associated with this obscure word, i.e. it is excessively confident in predicting it.

An adversary may have knowledge of the powerful detectors used here and would tailor the adversarial attack to avoid detection. Figure 3 shows the impact of the greedy attack approach modified to evade detection from the confidence detector and the perplexity detector (detector thresholds set to the value corresponding to the $\mathrm{F}_{0.5}$ score in Figure 2) [9]. The attack phrases are learnt on the FCE train set and evaluated on the FCE, CoNLL-14 and BEA test sets. It is interesting to note that the confidence detection evading attack phrases are only slightly less effective than the original attack phrases - the fraction of zero edits saturate at around 0.50 as opposed to 0.56 (on FCE test set). However, considering the attack to evade the perplexity detector, the potency of this universal phrase is surprisingly greater than the original greedy attack phrase learnt (for all datasets). This suggests that constraining an attack to more *human* phrases (as measured by perplexity of a powerful GPT-2 language model), allows for even stronger adversarial attacks. These phrases are considered particularly threatening as their similarity to natural language allows for greater imperceptibility to human observers (not just automated detection systems).

6.4 Transfer Attack

The aim of this section is to investigate the impact of transferring an attack learnt for an initial system (Gramformer) to a target system (Gector).

Concatenation universal adversarial attacks on the Gramformer system are found to be most powerful when the adversary greedily generates a phrase that evades a perplexity detector, as demonstrated in Figure 3. Hence, this universal adversarial phrase is simply evaluated on the Gector system. The results in Table 4 show that this transferred universal adversarial phrase has some level of threat: across all test sets, this universal adversarial phrase is able to increase the fraction of samples with no edits by at the least 10%. Table 4 also gives the impact of learning a universal attack phrase (using FCE train dataset and also avoiding a perplexity detector as in Section 5) for the Gector system. Interestingly, the direct attack is only around twice as effective as the transferred attack. This highlights the potency of these forms of adversarial attacks: the same adversarial phrase can transfer to different unseen, GEC systems.

Data	Attack	$N = 0$	$N = 9$
FCE	Transfer	0.44	0.50
	Direct	0.44	0.55
CoNLL-14	Transfer	0.33	0.38
	Direct	0.33	0.41
BEA-19	Transfer	0.45	0.50
	Direct	0.45	0.54

Table 4: Fraction of samples with zero edits, attack on Gector.

6.5 Analysis

This section carries out a more in-depth analysis to understand the aspects of the GEC systems exploited by adversarial attacks. The analysis presented here is for the concatenative full-stop attack learnt for the Gramformer system.

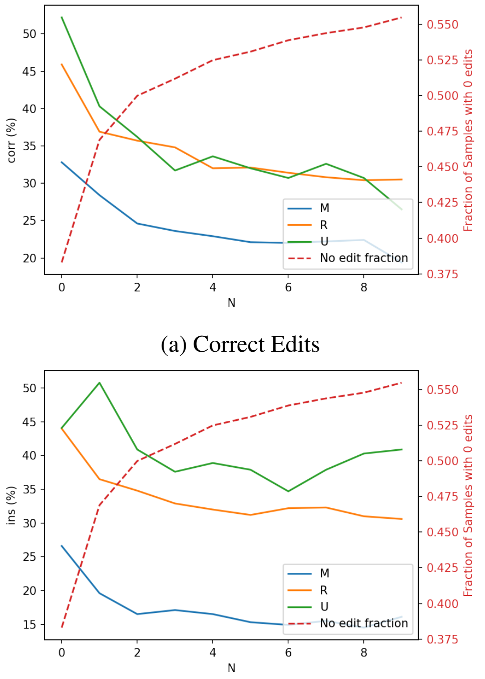
We want to analyse the nature of the attack - precisely which type of edits is the adversarial attack phrase targeting. If for a dataset of J input-reference sentence pairs, there exist a total R reference edits, $\tilde{e}_{1:R}$ (Equation 3) and P hypothesis edits, $\hat{e}_{1:P}$ (Equation 2), then the performance due to the GEC system correctly hypothesising edits

[9] A adversarial word is accepted if the average confidence/perplexity is less than the detector threshold.

can be measured by the correction rate, $\texttt{cor}$ and the failure measured by the insertion rate, $\texttt{ins}$,

$$\texttt{cor} = \frac{1}{R}\sum_{p=1}^{P} \mathbb{1}_{\{\tilde{e}_{1:R}\}}\hat{e}_p, \quad \texttt{ins} = \frac{1}{R}\sum_{p=1}^{P} \mathbb{1}_{\{\tilde{e}_{1:R}\}^{\complement}}\hat{e}_p,$$

where $\{\tilde{e}_{1:R}\}^{\complement}$ gives the complement set. Section 3 classifies an edit as **M**issing, **R**eplaced or **U**nnecessary. Figure 4 shows how the correction and insertion rates change (on FCE test) for each of these edits classes separately. Note that there are a total of $R = 919$, $R = 2954$ and $R = 596$ reference edits for **M**issing, **R**eplaced and **U**nnecessary classes respectively.



(a) Correct Edits

(b) Inserted Edits

Figure 4: Edit rates by edit type class.

The edit classes (M, R and U) all undergo a similar drop in correction rate with an increasingly powerful adversarial attack. However, Figure 4b demonstrates that smaller N adversarial attacks struggle to reduce **U**nnecessary inserted edits more than other edit type classes. Only when the reductions from removing **M**issing and **R**eplaced inserted edit types have saturated, does increasing N reduce the **U**nnecessary inserted edit types. The flattening of the performance curve (fraction of samples with zero edits) suggests that this reduction in inserted **U**nnecessary edits has little benefit to the adversarial attack. The apparent robustness of **U**nnecessary inserted edits can perhaps be explained simply. An inserted edit is the creation of an edit, $\hat{e}$, by the GEC system that is not present in the reference edits, $\tilde{e}_{1:R}$. When a GEC system creates specifically **U**nnecessary edits it means a token present in the input sequence is not present in the output prediction sequence. A well trained GEC system will remove the adversarial phrase appended to the input sequence, creating an **U**nnecessary edit, $\hat{e}$, which does not exist in the reference edits, $\tilde{e}_{1:R}$ - it is an inserted edit. Hence, there is an artificial increase in inserted **U**nnecessary edits. Edits in the adversarial phrase only contribute to 4% of total edits on average (analysis presented in Figure A.1), where 91% of the adversarial phrase edits are **U**nnecessary edit types. This gives on average an increase in the inserted **U**nnecessary edit rate by 10% ($0.04 * 0.91 * \texttt{count}(\hat{e}_{1:P})/596$), where 596 is the count of **U**nnecessary reference edits. This increase of 10% explains the shift between the **R**eplaced and **U**nnecessary curves in Figure 4b. Hence, all edit types in an input sequence are susceptible to the simple universal attack.

7 Conclusions

Grammatical Error Correction (GEC) systems can contribute to automated fluency assessment. The count of edits between a candidate's input and the grammatically *correct* output sequence from the GEC system, is a measure of the candidate's ability in the language: fewer the number of edits, the better the candidate. However, this work showed that deep learning based GEC systems are susceptible to adversarial attacks, where a candidate can cheat by adjusting their input sentence such that the predicted sequence from the GEC system does not correct the existing grammatical errors.

To model a realistic adversarial attack setting, this work restricts itself to a blackbox, universal attack approach, where the same adversarial phrase is appended to the end of all candidates' input sequences. This setting is particularly threatening because a candidate can cheat without querying the GEC system even once - the candidate only has to acquire the attack phrase. It is found that the same universal attack phrase can be effective across multiple datasets and more interestingly can be transferred to deceive new, unseen architectures. This demonstrates that all GEC systems have a worrying susceptibility to even the simplest attack forms.

8 Limitations

This work identified methods to adversarially attack state of the art GEC systems. Defence strategies in the form of detection were also considered. However, there has been less focus on adversarial training to improve robustness of systems. Although adversarial training is not an option available to deployed GEC systems, future work in this area would be useful in understanding the increase in robustness from adversarial training to the universal attack form considered in this work.

9 Risks and Ethics

Adversarial attacks, by nature, are of ethical concern in high stakes' environments. The approaches proposed in this work can be used to inspire candidates to engage in mal-practice in an education setting. However, this is of little concern because the development of attacks requires significant know-how of the GEC assessment process, which candidates are unlikely to have.

A More Analysis

It is perhaps surprising to observe a reduction in the number of edits made by a GEC system, when a potentially grammatically incorrect adversarial phrase is concatenated at the end of each input. To investigate this, Figure A.1 presents the split in the number of edits; i.e. on average how many edits are found in the original part of the input and the concatenated adversarial part of an input separately (using the full-stop concatenation attack on the Gramformer evaluated on the FCE test set). The adversarial phrase appears to have a length independent small contribution to the total number of edits, whilst the larger reduction in the number of original part edits allows for an overall decrease in the total edits.

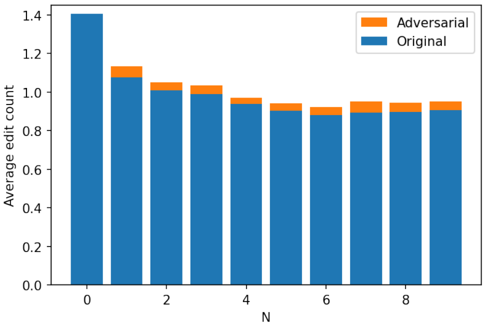

Figure A.1: Average edit count split between original and adversarial parts of inputs.

Abstract

The use of deep neural models for diagnosis prediction from clinical text has shown promising results. However, in clinical practice such models must not only be accurate, but provide doctors with interpretable and helpful results. We introduce ProtoPatient, a novel method based on prototypical networks and label-wise attention with both of these abilities. ProtoPatient makes predictions based on parts of the text that are similar to prototypical patients–providing justifications that doctors understand. We evaluate the model on two publicly available clinical datasets and show that it outperforms existing baselines. Quantitative and qualitative evaluations with medical doctors further demonstrate that the model provides valuable explanations for clinical decision support.

1 Introduction

Medical professionals are faced with a large amount of textual patient information every day. Clinical decision support systems (CDSS) aim to help clinicians in the process of decision-making based on such data. We specifically look at a subtask of CDSS, namely the prediction of clinical diagnosis from patient admission notes. When clinicians approach the task of diagnosis prediction, they usually take similar patients into account (from their own experience, clinic databases or by talking to their colleagues) who presented with typical or atypical signs of a disease. They then compare the patient at hand with these previous encounters and determine the patient's risk of having the same condition.

In this work, we propose ProtoPatient, a deep neural approach that imitates this reasoning process of clinicians: Our model learns prototypical characteristics of diagnoses from previous patients and bases its prediction for a current patient on the similarity to these prototypes. This results in a model that is both inherently interpretable and provides clinicians with pointers to previous prototypical patients. Our approach is motivated by Chen et al. (2019) who introduced prototypical part networks (PPNs) for image classification. PPNs learn prototypical parts for image classes and base their classification on the similarity to these prototypical parts. We transfer this work into the text domain and apply it to the extreme multi-label classification task of diagnosis prediction. For this transfer, we apply an additional label-wise attention mechanism that further improves the interpretability of our method by highlighting the most relevant parts of a clinical note regarding a diagnosis.

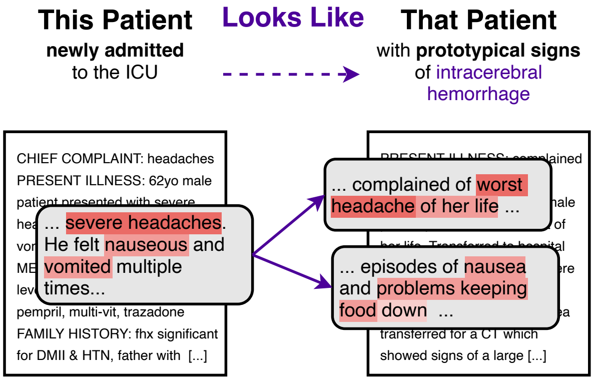

Figure 1: Basic concept of the ProtoPatient method. The model makes predictions for a patient (left side) based on the comparison to prototypical parts of earlier patients (right side).

While deep neural models have been widely applied to outcome prediction tasks in the past (Shamout et al., 2020), their black-box nature remains a large obstacle for clinical application (van

Aken et al., 2022). We argue that decision support is only possible when model predictions are accompanied by justifications that enable clinicians to follow a lead or to potentially discard predictions. With ProtoPatient we introduce an architecture that allows such decision support. Our evaluation on publicly available data shows that the model can further improve state-of-the-art performance on predicting clinical outcomes.

Contributions We summarize the contributions of this work as follows:
1. We introduce a novel model architecture based on prototypical networks and label-wise attention that enables interpretable diagnosis prediction. The system learns relevant parts in the text and points towards prototypical patients that have led to a certain decision.
2. We compare our model against several state-of-the-art baselines and show that it outperforms earlier approaches. Performance gains are especially visible in rare diagnoses.
3. We further evaluate the explanations provided by our model. The quantitative results indicate that our model produces explanations that are more faithful to its inner working than post-hoc explanations. A manual analysis conducted by medical doctors further shows the helpfulness of prototypical patients during clinical decision-making.
4. We release the code for the model and experiments for reproducibility.[1]

2 Task: Diagnosis Prediction from Admission Notes

The task of outcome prediction from admission notes was introduced by van Aken et al. (2021) and assumes the following situation: A new patient p gets admitted to the hospital. Information about the patient is written into an admission note a_p. The goal of the decision support system is to identify risk factors in the text and to communicate these risks to the medical professional in charge. For outcome diagnosis prediction in particular, the underlying model determines these risks by predicting the likelihood of a set of diagnoses C being assigned to the patient at discharge.

Data We evaluate our approach on the diagnosis prediction task from the clinical outcome prediction dataset introduced by van Aken et al. (2021).

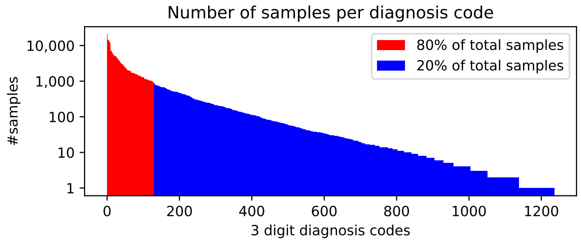

Figure 2: Distribution of ICD-9 diagnosis codes in MIMIC-III training set.

The data is based on the publicly available MIMIC-III database (Johnson et al., 2016). It comprises de-identified data from patients in the Intensive Care Unit (ICU) of the Beth Israel Deaconess Medical Center in Massachusetts in the years 2001-2012. The data includes 48,745 admission notes written in English from 37,320 patients in total. They are split into train/val/test sets with no overlap in patients. The admission notes were created by extracting sections from MIMIC-III discharge summaries which contain information known at admission time such as *Chief Complaint* or *Family History*. The notes are labelled with diagnoses in the form of 3-digit ICD-9 codes that were assigned to the patients at discharge. On average, each patient has 11 assigned diagnoses per admission from a total set of 1266 diagnoses.

Challenges Challenges surrounding diagnosis prediction can be divided into two main categories:

- **Predicting the correct diagnoses** The number of possible diagnoses is large (>1K) and, as shown in Figure 2, the distribution is extremely skewed. Since many diagnoses only have a few samples, learning plausible patterns is challenging. Further, each admission note describes multiple conditions, some being highly related, while others are not. The text in admission notes is also highly context dependent. Abbreviations like *SBP* (i.a. for *systolic blood pressure* or *spontaneous bacterial peritonitis*) have completely different meanings based on their context. Our models must capture these differences and enable users to check the validity of features used for a prediction.

- **Communicating risks to doctors** Apart from assigning scores to diagnoses, for a high-stake task such as diagnosis prediction, a system must be designed for medical professionals to understand and act upon its predictions. Therefore, models must provide faithful explanations for their pre-

Figure 3: Schematic view of the ProtoPatient method. Starting at the bottom, document tokens get a contextualized encoding and are then transformed into a label-wise document representation $\mathbf{v_{pc}}$. The classifier simply considers the distance of this representation to a learned prototypical vector $\mathbf{u_c}$. The prototypical patient $\mathbf{v'_c}$ is the training example closest to the prototypical vector.

dictions and give clues that enable further clinical reasoning steps by doctors. These requirements are challenging, since interpretability of models often come with a trade-off in their prediction performance (Arrieta et al., 2019).

3 Method: ProtoPatient

To address the challenges above, we propose a novel model architecture called ProtoPatient, which adapts the concept of prototypical networks (Chen et al., 2019) to the extreme multi-label scenario by using label-wise attention and dimensionality reduction. Figure 3 presents a schematic overview. We further show how our model can be efficiently initialized to improve both speed and performance.

3.1 Learning Prototypical Representations

We encode input documents a_p (p indexes patients) into vectors $\mathbf{v_p}$ with dimension D and measure their distance to a learned set of prototype vectors. Each prototype vector $\mathbf{u_c}$ represents a diagnosis $c \in C$ in the dataset. The prototype vectors are learned jointly with the document encoder so that patients with a diagnosis can best be distinguished from patients without it. As a distance measure we use the Euclidean distance $d_{pc} = ||\mathbf{v_p} - \mathbf{u_c}||_2$ which Snell et al. (2017) identified as best suited for prototypical networks. We then calculate the sigmoid σ of the negative distances to get a prediction $\hat{y}_{pc} = \sigma(-d_{pc})$, so that documents closer to a prototype vector get higher prediction scores. We define the loss L as the binary cross entropy (BCE) between $\hat{y}_{pc}$ and the ground truth $y_{pc} \in \{0, 1\}$.

$$L = \sum_p \sum_c BCE(\hat{y}_{pc}, y_{pc}) \qquad (1)$$

Prototype initialization Snell et al. (2017) define each prototype as the mean of the embedded support set documents. In contrast, we learn the label-wise prototype vectors end-to-end while optimizing the multi-label classification. This leads to better prototype representations, since not all documents are equally representative of a class, as taking the mean would suggest. However, using the mean of all support documents is a reasonable starting point. We set the initial prototype vectors of a class as $\mathbf{u_{c_{init}}} = \langle \mathbf{v_c} \rangle$, i.e. the mean of all document vectors $\mathbf{v_c}$ with class label c in the training set. We then fine-tune their representation during training. Initial experiments showed that this initialization leads to model convergence in half the number of steps compared to random initialization.

Contextualized document encoder For the encoding of the documents, we choose a Transformer-based model, since Transformers are capable of modelling contextualized token representations. For initializing the document encoder, we use the weights of a pre-trained language model. At the time of our experiments, the PubMedBERT (Tinn et al., 2021) model reaches the best results on a range of biomedical NLP tasks (Gu et al., 2020). We thus initialize our document encoder with PubMedBERT weights[2] and further optimize it with a small learning rate during training.

3.2 Encoding Relevant Document Parts with Label-wise Attention

Since we face a multi-label problem, having only one joint representation per document tends to produce document vectors located in the center of multiple prototypes in vector space. This way, important features for single diagnoses can get blurred, especially if these diagnoses are rare. To prevent this, we follow the idea of prototypical part networks of selecting parts of the note that are of interest for a certain diagnosis. In contrast to Chen et al. (2019), we use an attention-based approach instead of convolutional filters, since attention is an effective way for selecting relevant parts of text. For each diagnosis c, we learn an attention vector $\mathbf{w_c}$. To encode a patient note with regard to c, we apply a dot product between $\mathbf{w_c}$ and each embedded token $\mathbf{g_{pj}}$, where j is the token index. We then apply a softmax.

$$s_{pcj} = softmax(\mathbf{g_{pj}^T} \, \mathbf{w_c}) \tag{2}$$

We use the resulting scores s_{pcj} to create a document representation $\mathbf{v_{pc}}$ as a weighted sum of token vectors.

$$\mathbf{v_{pc}} = \sum_j s_{pcj} \, \mathbf{g_{pj}} \tag{3}$$

This way, the document representation for a certain diagnosis is based on the parts that are most relevant to that diagnosis. We then measure the distance $d_{pc} = ||\mathbf{v_{pc}} - \mathbf{u_c}||_2$ to the prototype vector $\mathbf{u_c}$ based on the diagnosis-specific document representation $\mathbf{v_{pc}}$.

Attention initialization The label-wise attention vectors $\mathbf{w_c}$ determine which tokens the final document representation is based on. Therefore, when initializing them randomly, we start our training with document representations which might carry little information about the patient and the corresponding diagnosis. To prevent this cold start, we initialize the attention vectors $\mathbf{w_{c_{init}}}$ with tokens informative to the diagnosis c. This way, at training start, these tokens reach higher initial scores s_{pcj}. We consider tokens $\tilde{t}$ informative that surpass a TF-IDF threshold of h. We then use the average of all embeddings $\mathbf{g_{c\tilde{t}}}$ from $\tilde{t}$ in documents corresponding to the diagnosis.

$$\mathbf{w_{c_{init}}} = \langle \mathbf{g_{c\tilde{t}}} \rangle \tag{4}$$

with $\tilde{t} = t$: tf-idf$(t) > h$. We found h=0.05 suitable to get 5-10 informative tokens per diagnosis.

3.3 Compressing representations

Label-wise attention vectors for a label space with more than a thousand labels lead to a considerable increase in model parameters and memory load. We compensate this by reducing the dimensionality D of vector representations used in our model. We add a linear layer after the document encoder that both reduces the size of the document embeddings and acts as a regularizer, compressing the information encoded for each document. We find that reducing the dimensionality by one third ($D = 256$) leads to improved results compared to the full-size model, indicating that more dense representations are beneficial to our setup.

3.4 Presenting prototypical patients

For retrieving prototypical patients $\mathbf{v'_c}$ for decision justifications at inference time, we simply take the label-wise attended documents from the training data that are closest to the diagnosis prototype. By presenting their distances to the prototype vector, we can provide further insights about the general variance of diagnosis presentations. Correspondingly, we can also present patients with atypical presentation of a diagnosis by selecting the ones furthest away from the learned prototype.

4 Evaluating Diagnosis Predictions

4.1 Experimental Setup

Baselines We compare ProtoPatient to hierarchical attention models and to Transformer models pre-trained on (bio)medical text, representing two state-of-the-arts approaches for ICD coding and outcome prediction tasks, respectively.

- **Hierarchical attention models** Hierarchical Attention Networks (**HAN**) were introduced by Yang et al. (2016). They are based on bidirectional gated recurrent units, with attention applied on both the sentence and token level. Baumel et al. (2018) built **HA-GRU** upon this concept using only sentence-wise attention,

Attention Init: Attention vectors initialized as described in Section 3.2.

while adding a label-wise attention scheme comparable to ProtoPatient. Dong et al. (2021) further show that pre-initialized **label embeddings** learned from ICD code co-occurrence improves results for both approaches. We thus evaluate the models with and without label embeddings.[3]

- **Transformers pre-trained on in-domain text** Alsentzer et al. (2019) applied clinical language model fine-tuning on two Transformer models based on the BioBERT model (Lee et al., 2020). **ClinicalBERT** was trained on all clinical notes in the MIMIC-III database, and **DischargeBERT** on all discharge summaries. They belong to the most widely used clinical language models and achieve high scores on multiple clinical NLP tasks. The **CORe** model (van Aken et al., 2021) is also based on BioBERT, but further pre-trained with an objective specific to patient outcomes, which achieved higher scores on clinical outcome prediction tasks. Tinn et al. (2021) introduced **PubMedBERT** which was, in contrast to the other models, trained from scratch on articles from PubMed Central with a dedicated vocabulary. It is currently the best performing approach on the BLURB (Gu et al., 2020) benchmark.

Training We train all baselines on the dataset introduced in Section 2. For training HAN and HA-GRU we use the code and best performing hyperparameters as provided by Dong et al. (2021). We further use their pre-trained ICD-9 label embeddings (for details, see Appendix A.1). For training the Transformer-based models and ProtoPatient, we use hyperparameters reported to perform best for BERT-based models by van Aken et al. (2021) and additionally optimize the learning rate and number of warm up steps with a grid search. We further truncate the notes to a context size of 512. See A.2 for all details on the chosen hyperparameters. We report the scores of all models as an average over three runs with different seeds.

Ablation studies ProtoPatient combines three strategies: Prototypical networks, label-wise attention and dimensionality reduction. We conduct ablation studies to measure the impact of each strategy. To this end, we apply both label-wise attention and dimensionality reduction to a PubMedBERT model using a standard classification head. We further train a prototypical network without label-wise attention and ProtoPatient with different dimension sizes. The results are found in Table 2 and 7.

Transfer to second data set Clinical text data varies from clinic to clinic. We want to test whether the patterns learned by the models are transferable to other data sources than MIMIC-III. We use another publicly available dataset from the i2b2 De-identification and Heart Disease Risk Factors Challenge (Stubbs and Uzuner, 2015) further processed into admission notes by van Aken et al. (2021). The data consists of 1,118 admission notes labelled with

[3] Note that Dong et al. (2021) also propose the H-LAN model, which is a combination of HAN and HA-GRU using label-wise attention on sentence and token level. However, the model is only applicable to smaller label spaces (<100) due to its memory footprint and thus cannot be evaluated on our task.

the ICD-9 codes for *chronic ischemic heart disease*, *obesity*, *hypertension*, *hypercholesterolemia* and *diabetes*. We evaluate models without fine-tuning on the new data to simulate a model transfer to another clinic. The resulting scores are reported in Table 3.

4.2 Results

We present the results of all models on the diagnosis prediction task in Table 1. In addition, we show the macro ROC AUC score across codes depending on their frequency in the training set in Figure 4. We summarize the main findings as follows.

ProtoPatient outperforms previous approaches The results show that ProtoPatient achieves the best scores among all evaluated models. Pre-initializing the attention vectors further improves the macro ROC AUC score. Ablation studies show that all components play a role in improving the results. A prototypical network without label-wise attention is not able to capture the extreme multi-label data. PubMedBERT using a standard classification head also benefits from label-wise attention, but not to the same extent. Combining prototypical networks and label-wise attention thus brings additional benefits. The choice of dimension size is another important factor. Using 768 dimensions (the standard BERT base size) appears to lead to over-parameterization in the attention and prototype vectors. Using 256 dimensions also improves generalization, which is shown in producing the best results on the i2b2 data set in Table 3.

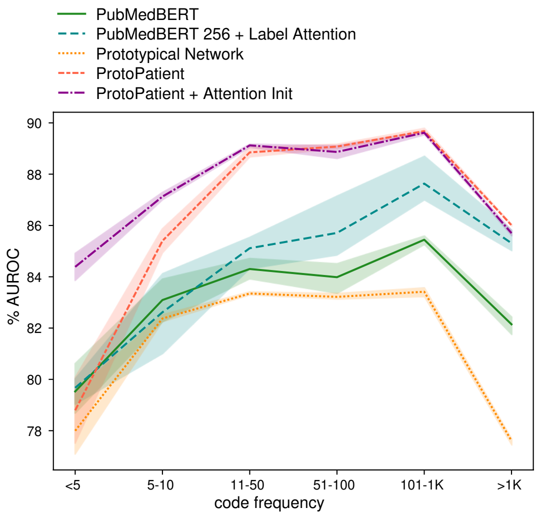

Figure 4: Macro ROC AUC scores regarding the frequency of ICD-9 codes in the training set. ProtoPatient models show the largest performance gain in rare codes (≤100 samples). Attention initialization leads to large improvement for very rare codes (<10 samples).

	ROC AUC macro
PubMedBERT	82.11 ±0.12
Prototypical Network	69.65 ±0.22
ProtoPatient 768	85.28 ±0.49
ProtoPatient	**87.38** ±0.20
ProtoPatient + Attention Init	86.72 ±1.52

Table 3: Performance on a second data set based on clinical notes from the **i2b2 challenge** (Stubbs and Uzuner, 2015). ProtoPatient shows the highest degree of transferability. Further metrics shown in Table 8.

Improvements for rare diagnoses Figure 4 shows that the ROC AUC improvements are particularly large for codes that are rare (≤50 times) in the training set. Prototypical networks are known for their few-shot capabilities (Snell et al., 2017) which also prove useful in our scenario with mixed label frequencies. For extremely rare codes that appear less than ten times, the attention initialization described in Section 3.2 further improves results. This indicates that the randomly initialized attention vectors need at least a number of samples to learn the most important tokens, and that pre-initializing them can accelerate this process.

PubMedBERT and HAN are the best baselines The pre-trained PubMedBERT and the HAN model achieve the highest scores among the baselines. Interestingly, PubMedBERT outperforms the Transformer models pre-trained on clinical text. This indicates that training from scratch with a domain-specific vocabulary is beneficial for the task. The scores of the HAN model further emphasize the importance of label-wise attention. The addition of label embeddings to HAN and HA-GRU, however, does not add significant improvements in our case.

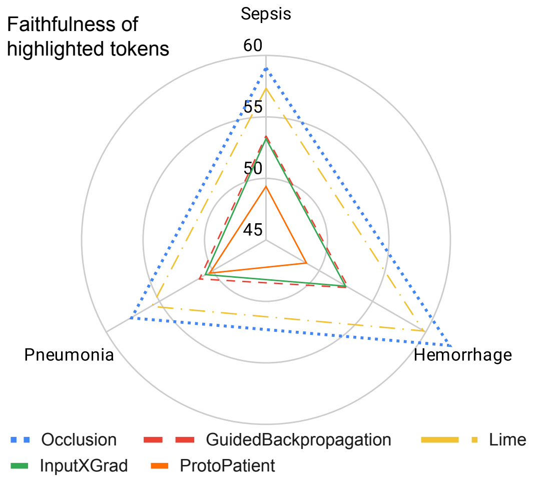

Figure 5: Evaluating faithfulness of highlighted tokens. Lower scores indicate more faithful explanations. ProtoPatient's token highlights are part of the model decision and thus more faithful than post-hoc explanations.

5 Evaluating Interpretability

We evaluate the interpretability of ProtoPatient with quantitative and qualitative analyses as follows.

Quantitative study on faithfulness Faithfulness describes how explanations correspond to the inner workings of a model, a property essential to their usefulness. We apply the explainability benchmark introduced by Atanasova et al. (2020) to compare the faithfulness of ProtoPatient's token highlights to post-hoc explanation methods. Following the benchmark, faithfulness is measured by incrementally masking highlighted tokens, expecting a steep drop in model performance if the tokens are indeed relevant to the model prediction. See B.1 for details. Due to the high computational costs of the evaluation, we limit our analyses to three diagnoses with a high severity to the ICU: Sepsis, intracerebral hemorrhage and pneumonia. We compare against four common post-hoc explanation methods, namely Lime (Ribeiro et al., 2016), Occlusion (Zeiler and Fergus, 2014), InputXGradient (Kindermans et al., 2016), and Gradient Backpropagation (Springenberg et al., 2014), which we apply to the PubMedBERT baseline. Figure 5 shows the results, for which lower scores mean more faithful explanations (i.e. a steeper drop in model performance). We see that ProtoPatient's explanations reach the lowest scores for all three labels, proving that they are more faithful than the post-hoc explanations. This is a result of the interpretable structure of ProtoPatient, in which model decisions are directly based on the highlighted parts. We show these parts, i.e. the tokens that are most frequently highlighted by the model for the three analyzed diagnoses, in B.2.

Manual analysis by medical doctors We conduct a manual analysis with two medical doctors (one specialized, one resident) to understand whether highlighted tokens and prototypical patients are helpful for their decisions. They used a demo application of ProtoPatient[4] and analyzed 20 random patient letters with 203 diagnoses in total. The results are shown in Table 4. The doctors first identified the principal diagnoses and then rated the corresponding prototypical patients presented by the model. Note that some patients have more than one principal diagnosis. In 21 of 23 cases, the prototypical samples were showing typical signs of the respective diagnosis and 17 of them were rated as helpful for making a diagnosis decision. Cases in which they were not helpful included very rare conditions or ones with a strong differ-

The prototypical patients were analyzed for the principal diagnoses only, while the highlighted parts of the patient letter at hand were analyzed for all diagnoses. Q1..5 denote the questions answered regarding each patient case.

[4] Demo URL available at: https://protopatient.demo.datexis.com

ence to the specific case. They further analyzed the highlighted tokens for all diagnoses and found that they contained mostly relevant information in 150 cases. Examples of highlighted risk factors judged as plausible were *obesity* known to relate to *diabetes type II*, *untreated hypertension* to *heart failure* or a medication history of *anticoagulant coumadin* to *atrial fibrillation*. They also identified cases in which the highlighted tokens were partially or hardly relevant. In these cases, the highlighted tokens often included stop words or punctuation, indicating that the attention vector failed to learn relevant tokens. This was mainly observed in very frequent diagnoses such as *hypertension* or *anemia*, which corresponds to the lower model performance on these conditions (see Figure 4). This is because conditions very common in the ICU are often either not indicated in the clinical note or not labelled, so that the model cannot learn clear patterns regarding their relevant tokens.

6 Related Work

Diagnosis prediction from clinical notes Predicting diagnosis risks from clinical text has been studied using different methods. Fakhraie (2011) analyzed the predictive value of clinical notes with bag-of-words and word embeddings. Jain et al. (2019) experimented with adding attention modules to recurrent neural models. Recently, the use of Transformer models for diagnosis prediction has outperformed earlier approaches. van Aken et al. (2021) applied BERT-based models further pre-trained on clinical cases to predict patient outcomes. However, the black-box nature of these models hinders their application in clinical practice. We therefore introduce ProtoPatient, which uses Transformer representations, but provides interpretable predictions.

Prototypical networks for few-shot learning Prototypical networks were first introduced by Snell et al. (2017) for the task of few-shot learning. They initialized prototypes as centroids of support samples per episode and applied the approach to image classification tasks. Sun et al. (2019) adapted the approach to text documents with hierarchical attention layers. Recently, related approaches based on prototypical networks have been used for multiple few-shot text classification tasks (Wen et al., 2021; Zhang et al., 2021; Ren et al., 2020; Deng et al., 2020; Feng et al., 2023). In contrast to this body of work, we do not train our model in a few-shot scenario using episodic learning. However, our model shows related capabilities by improving results for diagnoses with few available samples.

Prototypical networks for interpretable models Chen et al. (2019) used prototypical networks in a different setup to build an interpretable model for image classification. To this end, they learn prototypical parts of images to mimic human reasoning. We adapt their idea and show how to apply it to clinical natural language. Recently, Ming et al. (2019) and Das et al. (2022) applied the concept of prototypical networks to text classification and showed how prototypical texts help to interpret predictions. In contrast to their work and following Chen et al. (2019), we identify prototypical *parts* rather than whole documents by using label-wise attention. This makes interpreting results easier and enables multi-label classification with over a thousand labels.

Label-wise attention Mullenbach et al. (2018) introduced label-wise attention for clinical text with the CAML model. Since then, the method has been further improved by hierarchical attention approaches (Baumel et al., 2018; Yang et al., 2016; Dong et al., 2021). Label-wise attention has mainly been used for ICD coding, a task related to diagnosis prediction that differs in the input data: ICD coding is done on notes that describe the whole stay at a clinic. In contrast, outcome diagnosis prediction uses admission notes as input and identifies diagnosis *risks* rather than the diagnoses already mentioned in the text. Our method–combining prototypical networks with label-wise attention–is particularly focused on detecting and highlighting those risks to enable clinical decision support.

7 Discussion

7.1 Reflection on the Challenges

Rudin (2019) urges to stop explaining black-boxes and to build interpretable models instead. With ProtoPatient we introduce a model with a simple decision process–*this patient looks like that patient*–that is understandable to medical professionals and inherently interpretable. An exemplary output is shown in Table 5. Our results indicate that the model is able to deal with contextual text in clinical notes, e.g. when identifying *SBP* as a risk factor for sepsis in B.2. In addition, it improves results on rare diagnoses, which are especially challenging for doctors to detect due to lack of experience

Admission note	Relevant parts of admission note	similar to	Parts of prototypical patient notes
PRESENT ILLNESS: Patient is a 35-year-old male pedestrian struck by a bicycle from behind with positive loss of consciousness for 6 minutes at the scene after landing on his head. At arrival at ER patient was confused, had multiple contusions noted on a head CT scan including bilateral frontal and right temporal contusions. His cervical spine and abdominal examinations were negative radiologically. The patient was then transferred to the Emergency Room. Patient had several episodes of vomiting during flight and during the trauma workup. He was assessed and was intubated for airway protection. The patient was given coma score of 9 upon initial assessment. Patient remaining hemodynamically stable throughout the transfer and throughout the workup in the ED. and sensitivity towards their signs. Overall, our approach demonstrates that interpretability can be improved without compromising performance. The modularity of the prototype vectors further allows clinicians to modify the model even after training. This can be done by adding prototypes whenever a new condition is found, or by directly defining certain patients as prototypical for the system.

7.2 Limitations of this work

Our model currently learns relations between diagnoses only indirectly, due to the label-wise nature of the classification. However, considering relations or conflicts between diagnoses is an important part of clinical decision-making. One way to include such relations is the addition of a loss term incorporating diagnosis relations, as proposed by Mullenbach et al. (2018). Another limitation is that the current model only considers one prototype per diagnosis, even though most diagnoses have multiple presentations, varying among patient groups. We therefore propose further research towards including multiple prototypes into the system.

8 Conclusion and Future Work

In this work, we present ProtoPatient which enables interpretable outcome diagnosis prediction from text. Our approach enhances existing methods in their prediction capability—especially for rare classes—and presents benefits to doctors by highlighting relevant parts in the text and pointing towards prototypical patients. The modularity of prototypical networks can be explored in future research. One promising approach is to introduce multiple prototypes per diagnosis, corresponding to the multiple ways diseases can present in a patient. Prototypes could also be added manually by medical professionals based on patients they consider prototypical. Another approach would be to initialize prototypes from medical literature and compare them to those learned from patients.

A Training Details

A.1 Label Embeddings for HAN and HA-GRU

We apply label embeddings to the HAN and HA-GRU network as proposed by Dong et al. (2021). In particular, we use the pre-initialized embeddings provided by the authors. Since they use a larger label set, we map their embedding vectors to the ICD-9 groups we use in our study. The mapping is done by averaging all subcodes for one group. If no code is available for an ICD-9 group, we use a randomly initialized vector.

A.2 Hyperparameter setup

Batch size Since we work with 1266 labels, the label-wise attention calculations limit the batch size that fits into memory. We therefore use a batch size of 20 for all models without label-wise attention, 10 for label-wise attention models reduced to a dimensionality of 256 and 5 for the others. Initial experiments showed that the batch sizes have no influence on model performance in our experiments, only on memory consumption and training duration.

Learning rates We choose different learning rates for the document encoder weights and the prototype and label-wise attention vectors. Since we expect the encoder weights from the pre-trained Transformer models to be already well aligned with clinical language, we choose a small learning rate between 5e-04 and 5e-06. Since the prototypical diagnosis vectors and the label-wise attention vectors need more adjustments to enable the classification task, we search in a range of 5e-02 and 5e-04. We further apply an AdamW (Loshchilov and Hutter, 2017) optimizer and a linear learning rate scheduler with a warm-up period of 1K to 5K steps. We provide the best hyperparameters per model in the public code repository.

B Interpretability Evaluation Details

B.1 Measuring faithfulness

We use the evaluation setup proposed by Atanasova et al. (2020) to measure the faithfulness of ProtoPatient's explanations. The framework evaluates different methods that output saliencies indicating token importance for a model decision. The evaluation then takes place by masking the most salient tokens via multiple thresholds and measuring the model's performance for each one. Thresholds are

Diagnosis	15 most attended words - with medical relation to diagnosis
Sepsis	1. **hypotension** symptom, 2. **sepsis** descriptor, 3. **fever** symptom, 4. **hypotensive** symptom, 5. **fevers** symptom, 6. **septic** descriptor, 7. **lactate** indicator, 8. **shock** descriptor, 9. **bacteremia** descriptor, 10. **febrile** symptom, 11. **vancomycin** medication, 12. **SBP** risk factor, 13. **levophed** medication, 14. **swelling** symptom, 15. **cirrhosis** risk factor
Intracerebral Hemorrhage	1. **hemorrhage** descriptor, 2. **bleed** descriptor, 3. **headache** symptom, 4. **ICH** descriptor, 5. **IPH** descriptor, 6. **CT** diagnostic, 7. **weakness** symptom, 8. **stroke** descriptor, 9. **brain** descriptor, 10. **intracranial** descriptor, 11. **hemorrhagic** descriptor, 12. **intraventricular** descriptor, 13. **hemorrhages** descriptor, 14. **hemiparesis** symptom, 15. **aphasia** symptom
Pneumonia	1. **pneumonia** descriptor, 2. **cough** symptom, 3. **PNA** descriptor, 4. **COPD** risk factor, 5. **infiltrate** symptom, 6. **distress** complication, 7. **fever** symptom, 8. **breath** *ambiguous*, 9. **hypoxia** symptom, 10. **sputum** symptom, 11. **respiratory** complication, 12. **sepsis** complication, 13. **SOB** symptom, 14. **consolidation** symptom, 15. **CAP** descriptor

Table 6: Words from the test set with the highest attention scores assigned by ProtoPatient. All words are directly related to the diagnoses and mostly describe symptoms or direct descriptors (in various forms). The highlights can therefore help doctors to quickly identify important parts within a note and to compare them to prototypical parts.

going from masking only the top 10% of salient tokens in steps of 10pp until 100% of tokens are masked. The final faithfulness score is then calculated as the area under the curve of model performance over all thresholds. As a performance measure, we choose macro ROC AUC to stay consistent with the rest of our experiments. We compare tokens highlighted by ProtoPatient's label-wise attention vectors to four post-hoc explanation methods as described in 5. We apply these methods to the PubMedBERT baseline, corresponding to a typical post-hoc explanation approach for an otherwise black-box model.

B.2 Finding most relevant words per diagnosis

We want to examine which parts of the clinical notes are highlighted by ProtoPatient per diagnosis. To that end, we collect the tokens with the highest attention scores over all training samples per label. We again use the three diagnoses *sepsis*, *intracerebral hemorrhage* and *pneumonia* for a closer analysis. We further map the tokens to their corresponding words. We then let doctors define the words' medical relations to understand which features the model considers important. Table 6 shows that the most attended words are mainly symptoms or descriptors of the condition at hand, which meets the objective of ProtoPatient to point doctors to relevant parts of a note.

	ROC AUC macro	ROC AUC micro	PR AUC macro
Dimensionality reduction			
ProtoPatient 768	83.56 ±0.17	96.65 ±0.03	14.36 ±0.16
ProtoPatient 256	**86.93** ±0.24	**97.32** ±0.00	**21.16** ±0.21
Transformer vs. Prototypical			
ProtoPatient 768	83.56 ±0.17	**96.65** ±0.03	14.36 ±0.16
PubMedBERT 768 + Label Attention	**84.10** ±0.25	**96.66** ±0.17	**19.74** ±1.27
Label-wise attention			
PubMedBERT 256	83.61 ±0.04	95.76 ±0.05	13.35 ±0.25
PubMedBERT 256 + Label Attention	84.68 ±0.52	96.86 ±0.14	17.15 ±1.52
ProtoPatient 256	**86.93** ±0.24	**97.32** ±0.00	**21.16** ±0.21

Table 7: Full results of our ablation studies. Smaller dimension sizes benefit ProtoPatient, while the effect is less notable on PubMedBERT. Adding label-wise attention, however, increases PubMedBERT results clearly. Overall, the combination of prototypical network, label-wise attention, and reduced dimension in ProtoPatient reaches the best results.

	ROC AUC macro	ROC AUC micro	PR AUC macro
PubMedBERT	82.11 ±0.12	85.48 ±0.64	84.38 ±0.54
PubMedBERT 256 + Label Attention	79.78 ±5.30	83.43 ±4.54	84.70 ±2.84
Prototypical Network	69.65 ±0.22	74.31 ±0.19	78.53 ±0.19
ProtoPatient 768	85.28 ±0.49	88.63 ±0.43	87.78 ±0.10
ProtoPatient	**87.38** ±0.20	**90.63** ±0.23	**89.72** ±0.24
ProtoPatient + Attention Init	86.72 ±1.52	89.84 ±1.16	**89.71** ±1.20

Table 8: Full results of the evaluation on i2b2 data with five classes. Note that the baseline PR AUC is much higher for this task than for the task based on MIMIC-III. ProtoPatient models reach the highest scores, indicating that they are more robust towards changes in text style than the PubMedBERT baselines. The PubMedBERT model with label-wise attention, in particular, shows quite inconsistent results regarding different seeds.

Cross-lingual Similarity of Multilingual Representations Revisited

Maksym Del and **Mark Fishel**
Institute of Computer Science
University of Tartu, Estonia
{maksym,mark}@tartunlp.ai

Abstract

Related works used indexes like CKA and variants of CCA to measure the similarity of cross-lingual representations in multilingual language models. In this paper, we argue that assumptions of CKA/CCA align poorly with one of the motivating goals of cross-lingual learning analysis, i.e., explaining zero-shot cross-lingual transfer. We highlight what valuable aspects of cross-lingual similarity these indexes fail to capture and provide a motivating case study *demonstrating the problem empirically*. Then, we introduce *Average Neuron-Wise Correlation (ANC)* as a straightforward alternative that is exempt from the difficulties of CKA/CCA and is good specifically in a cross-lingual context. Finally, we use ANC to construct evidence that the previously introduced "first align, then predict" pattern takes place not only in masked language models (MLMs) but also in multilingual models with *causal language modeling* objectives (CLMs). Moreover, we show that the pattern extends to the *scaled versions* of the MLMs and CLMs (up to 85x original mBERT).[1]

1 Introduction

Similarity indexes like Canonical Correlation Analysis (CCA, Hotelling, 1936) or Centered Kernel Alignment (CKA, Kornblith et al., 2019) aim to find a similarity between parallel sets of different representations of the same data. The deep learning community adapted these indexes to measure similarity between representations that *come from different models* (Raghu et al., 2017; Morcos et al., 2018; Kornblith et al., 2019). Another line of work used the same methods to measure similarity *between different languages* which come from a *single* multilingual model (Kudugunta et al., 2019; Singh et al., 2019a; Conneau et al., 2020; Muller et al., 2021).

In this paper, we argue that while CCA/CKA methods are a good fit for the first case, they are a suboptimal choice for the second scenario.

First, we employ a real-world motivating example to demonstrate that CKA can fail to capture the notion of similarity that we consider helpful in a cross-lingual context. We also discuss the general problems of CKA/CCA indexes and conclude that they are not well aligned with some of the goals of cross-lingual analysis **(Section 4)**.

Next, we propose and verify an Averaged Neuron-Wise Correlation (ANC) as a straightforward alternative. It exploits the fact that representations from the same model have apriori-aligned neurons, which is the desired property in a cross-lingual setup **(Section 5)**.

Finally, Muller et al. (2021) demonstrated the so-called "first align, then predict" representational pattern in a multilingual model: the model first aligns representations of different languages together, and then (starting from the middle layers) makes them more language-specific again (to accompany the language-specific training objective). The finding is insightful but only considers mBERT (Wu and Dredze, 2019) which is a masked language model (MLM) with 110M parameters. Thus, it is unclear if the "first align, then predict" pattern is specific to this model or more general. In this study, we use ANC to show that the pattern generalizes to the GPT-style (Brown et al., 2020) causal language models (CLMs, Lin et al., 2021) and extends to *large-scale* MLMs and CLMs **(Section 6)**.

In this paper we are interested specifically in the scenario of measuring the strength of cross-lingual similarity of representations that come from a single multilingual language model. This scenario is very common in the field as it is often not feasable to train a separate models for each language and we present a method that allows for better representational similarity analysis then CKA/CCA.

In summary, our contributions are three-fold:

- conceptual and *empirical* critique of CKA/CCA for cross-lingual similarity analysis **(Section 4)**;
- *Average Neuron-Wise Correlation* as a simple alternative method designed specifically for cross-lingual similarity **(Section 5)**;
- *scaling laws* of cross-lingual similarity in both multilingual MLMs and CLMs **(Section 6)**.

2 Related work

Hotelling (1936) introduced CCA as a method for measuring canonical correlations between two sets of random variables. Raghu et al. (2017) proposed a variant of the CCA called SVCCA and used it to analyze representations *between different neural networks*. Morcos et al. (2018) proposed PWCCA, another improvement to CCA for the network analysis, and Kornblith et al. (2019) analyzed CCA, SVCCA, PWCCA, and other methods concluding that CKA is superior to them.

In a cross-lingual setting, we have a single network, and we compare representations that come from different languages. Following the introduction of SVCCA, Kudugunta et al. (2019) used it to compare language representations (at different layers) in a multilingual neural machine translation system. The method we present in this work applies to the seq2seq models, but in this work, we focus on models trained with CLM and MLM objectives while leaving seq2seq for future work. Singh et al. (2019a) performed a similar study where they focused on the multilingual BERT model[2] and employed PWCCA as a similarity index. The conclusion was that language representations diverge with network depth.

On the other hand, Conneau et al. (2020) and Muller et al. (2021) used CKA and behavior analysis to show that the opposite pattern takes place: language representations align with the network depth and only moderately decrease towards the end. In other words, representations first converge towards language neutrality and then recover some language-specificity. The alignment makes zero-shot cross-lingual transfer possible, and slight divergence accompanies language-specific training objectives (such as English downstream prediction task or predicting words in the particular language as in masked language modeling objective). Following Muller et al. 2021, we call this phenomenon the *"first align, then predict"* pattern.

Eventually, Del and Fishel (2021) showed that the similarity analysis was different because Singh et al. (2019a) used CLS-pooling while Muller et al. (2021) used mean-pooling to convert token embeddings into a sentence representation. They also showed that mean-pooling is a better option.

Finally, Li et al. (2015) aligned most correlated neurons between layers of two different networks and then computed similarity from the recovered correspondence. The method we propose in this paper is similar in spirit to this one, except we focus on the cross-lingual analysis of multilingual models and thus have no need to find the alignment between neurons.

In this work, we build on these studies in three ways: we demonstrate that even CKA can fail to provide relevant cross-lingual similarity, we propose another method to compare multilingual representations, and we reveal that the "first align, then predict" pattern generalizes across training objectives and holds for models of large sizes.

3 Similarity Indexes Background

In this section, we provide some background on CKA and CCA, SVCCA, and PWCCA similarity indexes[3]. We focus on the parts of the methods most relevant to the key points we make in this work. For the full mathematical description refer to Kornblith et al. (2019).

Neuron Following related works, we define a neuron as a vector of values it takes over a dataset (Li et al., 2015; Raghu et al., 2017; Morcos et al., 2018; Kornblith et al., 2019). Formally, let D be a dataset consisting of data examples $\vec{d}$:

$$D = \{\vec{d_1}, \cdots \vec{d_m}\}$$

Let φ_i be a function that returns a neuron activation value for the training example at the i-th unit of the l-th layer of the network. The *neuron* $\vec{z}_i$ is the *vector* of network activations recorded by applying φ_i over the elements of D, i.e.

$$\vec{z^i} = [\varphi_i(\vec{d_1}), \cdots, \varphi_i(\vec{d_m})]$$

[2] https://github.com/google-research/bert/blob/master/multilingual.md

[3] In the paper, we refer to both SVCCA and PWCCA simply as CCA unless otherwise specified.

In practice, we pass a set of data examples to the network and record activations for each unit at every layer. The vector of these activations is what we consider a representation of a neuron $\vec{z}$.

Layer The frequent goal of representational similarity analysis is to compare layers of neural networks. Under our definition, the layer L is the list of vectors (matrix) that consists of the *neurons* at a particular depth, i.e.

$$L = [\vec{z^i}, \cdots, \vec{z^n}]$$

where n is the number of neurons at layer L. Alternatively, we can think of layer L as the subspace of R^m spanned by its neurons $(\vec{z^i}, \cdots, \vec{z^n})$, where m is the number of examples in the dataset.

CCA/CKA indexes rely on the idea of subspaces spanned by the neurons, making them powerful when comparing representations across *different networks*. There can be more neurons in the first layer than in the second; the neurons also do not need to be aligned. CCA/CKA uses neurons only to describe the vector subspaces and then compare the subspaces as opposite to the neurons themselves.

That is why methods like CKA and CCA try to find some second-order descriptions of representational spaces (e.g., gram matrices/canonical vectors) and compare these. The decisions on what second-order information to consider and what comparison technique to use define the differences between the indexes.

Dominant Correlations The first step for all methods is to center each neuron in the layer representations:

$$X := L_1 - mean(L_1)$$
$$Y := L_2 - mean(L_2)$$

Let X and Y have p_1 and p_2 neurons (columns). Consider gram matrix XX^{T}. Because neurons in X are centered, XX^{T} is proportional to covariance matrix of X. Therefore, the elements in XX^{T} correspond to all pairwise covariance similarities data points in X (the same holds for YY^{T}).

Now consider doing eigendecomposition of $X^{\mathrm{T}}X$. Eigenvectors $\vec{u}^i_X | i \in \{1, ..., m\}, \vec{u}^i_X \in R^m$ will represent directions of the most dominant correlations of data points in X. Also, we can think about vectors $\vec{u}^i_X$ as of *eigenneurons*, the ones that explain the most variance in the representational space of other neurons. λ^i_X is then the i^{th} eigenvalue of XX^{T} (the strengths of the eigenneurons).

CCA The directions $\vec{u}_X$ and $\vec{u}_Y$ are orthogonal by the definition of the eigendecomposition. The pair of vectors with the maximum dot product $\langle \vec{u}_X, \vec{u}_Y \rangle$ is called the first pair of canonical directions. The value of their dot product is the first CCA coefficient. Then the second pair produces the second canonical coefficient, and so on.

The formula for the CCA similarity index is then as follows (from Kornblith et al., 2019):

$$CCA(XX^{\mathrm{T}}, YY^{\mathrm{T}}) = \sum_{i=1}^{p_1} \sum_{j=1}^{p_2} \langle \overrightarrow{u^i_X}, \overrightarrow{u^j_Y} \rangle^2 / p_1. \tag{1}$$

CKA We might also consider weighting the CCA correlations by their eigenvalues. This results in Linear CKA (from Kornblith et al., 2019):

$$\mathrm{CKA}(XX^{\mathrm{T}}, YY^{\mathrm{T}}) =$$
$$= \frac{\sum_{i=1}^{p_1} \sum_{j=1}^{p_2} \lambda^i_X \lambda^j_Y \langle \overrightarrow{u^i_X}, \overrightarrow{u^j_Y} \rangle^2}{\sqrt{\sum_{i=1}^{p_1} (\lambda^i_X)^2} \sqrt{\sum_{j=1}^{p_2} (\lambda^j_Y)^2}} \tag{2}$$

In this work, we focus on Linear CKA because related works such as Muller et al. (2021) and Conneau et al. (2020) use it.

SVCCA If we also decide to apply SVD as the preprocessing step after centering, we get SVCCA. CCA then computes correlation coefficients only for top K components from SVD transformed data (right singular values) and thus can be better averaged (see Equation 1).

PWCCA Finally, instead of taking a simple average of CCA coefficients or weighting them by singular values (as in CKA), we might weight them weights (loosely speaking) related to the CCA directions that encapsulate the most data when projected.

In summary, all these methods are related and based on the idea that we can deduce some dominant correlation directions in X and Y and then compare these. Another way to look at it is that if CCA/CKA can represent neurons in Y as linear combinations of neurons in X, these correlation methods will generally respond with high scores.

The differences between methods make them invariant to the data scaling, centering, and orthogonal transformations. At the same time, CCA and SVCCA will not change their scores under any invertible linear transformations of either X or Y (see Kornblith et al., 2019 for more details).

4 Problems With CKA/CCA

By performing an illustrative experiment, let us introduce problems with CKA and CCA indexes.

Specifically, we want to check if different normalization choices of the Transformer (Vaswani et al., 2017) layers impact the zero-shot cross-lingual transfer capabilities of the model and the similarity of cross-lingual representations it learns.

This section presents a two-fold case against CKA/CCA for cross-lingual similarity analysis:

- empirical: CKA fails to uncover relationships between similarity after the architectural change that does not hurt the performance of the model;
- conceptual: lack of interpretability and unsatisfying underlying assumptions in CCA/CKA.

4.1 Experiments Setup

Models We train the following three XLM-Roberta (Conneau and Lample, 2019) language models (`base` size versions) from scratch (each with a different normalization schema):

- Post-LN (`scale_post`): normalization block is placed *after* the residual connections in the transformer block (part of the original Transfomer);
- Pre-LN (`scale_pre`): normalization block is placed *before* the residuals (this was shown to improve training by Xiong et al., 2020);
- Normformer (`scale_normformer`): normalization block is placed *before* the residuals *and* FeedForward, Residual, and Self-Attention layers are also normalized (Shleifer et al., 2021).

Pre-Training We pre-train a model based on XLM-R Base using 50M sentences uniformly sampled from four languages: English, French, Estonian, and Bulgarian. We chose the languages to be reasonably diverse: French is the most similar to English in both grammar and alphabet, Bulgarian is from a different language group (Slavic), and Estonian is from a completely different language family (Finno-Ugric). We train the model for 1M batches of 512 sentences from the *CC100* dataset using two Nvidia A100 GPUs. The only architectural difference from the original XLM-Roberta is that we change normalization types to Pre-LN and Normformer; other setup details are painstakingly identical.

Experiment 1: XNLI Fine-Tuning After having three models pretrained, we fine-tune each of them on XNLI sentence classification task (Conneau et al., 2018). We use only English data for training but evaluate on English and other language evaluation sets (we only skip Estonian since it is not a part of XNLI). This setup, where we tune on one language but use another at test time, is called *zero-shot cross-lingual transfer*.

Experiment 2: CKA Similarirty After having the XNLI zero-shot cross-lingual transfer scores, we extract sentence representations from all layers of each model and compare layers using the CKA similarity index.

The parallel corpus is composed of Singh et al. (2019b)'s extension of the XNLI dataset (10k examples for each pair)[4].

We embed the source and target sentences with the models and perform mean-pooling over tokens at each layer for each language pair (as suggested by Del and Fishel, 2021). Next, we compare two parallel sets of sentence representations using the CKA similarity index to get a similarity score for each layer.

Experiment 3: Per-Layer Matching Accuracy Lastly, to get insight into some cross-lingual behavioral capabilities of representations at each layer, we analyze them with a sentence-matching probing task.

We use the same data and pooling strategy as in the CKA analysis. For each English sentence, we find the closest target sentence in the opposite language (out of all 10k targets) by cosine similarity. If this sentence is the actual parallel counterpart (translation) of the English sentence, we say the model got this English example correct. Then we compute the accuracy of this sentence matching as the ratio between correctly labeled English examples and the total number (10k) of English examples.

Throughout this work, we conduct experiments across languages sampled from the four language families: Germanic, Romance, Slavic, Baltic, and Finno-Ugric. While the results hold across the complete set of languages from our work, we showcase different subsets of languages from language families in different experiments to introduce more diversity while keeping the plots concise.

[4] Using XNLI for both fine-tuning and CKA analysis allows us to avoid domain mismatch scenarios entirely

4.2 Experiments Results

Experiment 1: XNLI Fine-Tuning See Table 1 for our models' zero-shot cross-lingual transfer performance on the XNLI validation set.

Normalization	en	fr	bg
scale_post	0.79	0.72	0.70
scale_pre	0.81	0.72	0.72
scale_normformer	0.79	0.72	0.71

Table 1: Accuracy of XLM-Roberta Base Transformers pre-trained with different normalization schemes and fine-tuned on the English portion of the XNLI sentence classification task. The models show similar zero-shot cross-lingual transfer performance.

The Table shows that all three models achieve solid zero-shot transfer performance with a cross-lingual transfer gap of 7-9%. We see no significant gains from the scale_pre or scale_normformer, but crucially we see no significant losses either.

Experiment 2: CKA Similarirty We present per-layer CKA similarity results for the pre-trained (untuned) models in Figure 1.

Figure 1 reveals that while for scale_post and scale_pre CKA show fairly high cross-lingual performance at all layers, the Normformer results are drastically different. While the similarity for the first half of the layers increases (layers 0-5), the CKA score drops dramatically at the middle layer of the network and continues to hang around zero for all remaining layers (layers 6-12).

This result is especially surprising because CKA confidently gives similarity scores that are almost zero, while Table 1 shows no substantial difference in the zero-shot cross-lingual transfer results between English and other languages. For tuned models the CKA also fails to reveal similarity for layers 6-11 (Figure 8 in Appendix A).

In this example, CKA is not capturing the notion of similarity that would coincide with zero-shot cross-lingual transfer performance for XLM-Normformer. Zero-shot transfer (say) from English requires language representations that *converge* to English values so the other languages can re-use the linear prediction head (calibrated for English).

To double-check the result we also retrain the scale_normformer the second time with a different random restart and get the same CKA results (see Figure 7 in Appendix A).

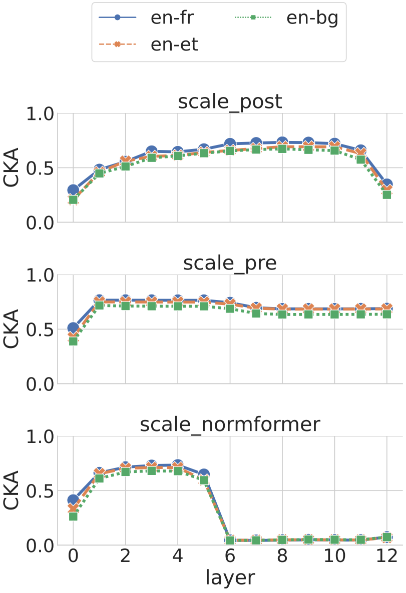

Figure 1: Motivating example 1: counter-intuitive CKA (dis)similarity of XLM-Normformer layers. CKA index shows drastic dissimilarity for layers 6-12 despite remarkable zero-shot cross-lingual transfer performance of the model.

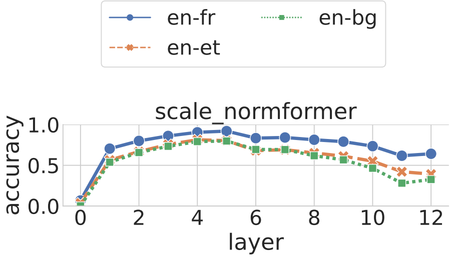

Figure 2: Per-layer sentence matching accuracy for the XLM-Normformer. The result again shows relatively high matching scores for the deeper layers in contrast to the CKA result from Figure 1. There is some decline, but nothing like zero similarity of CKA.

Experiment 3: Per-Layer Matching Accuracy However, let us also see the results of our sentence matching task to verify whether these deep representations in Normformer are useful. Figure 2 shows the resulting per-layer accuracy.

The pattern shows that layers 6-12 show some significant cross-lingual matching scores (>50% for French) with only a slightly decreasing trend. This experiment confirms that there are aspects of cross-lingual similarity in these multilingual representations that CKA failed to reveal.

4.3 Downsides of CCA

This section shows that the family of CCA-like similarity indexes suffers from similar issues as

CKA. The first downside is that CCA is hard to interpret. CCA is a second-order similarity index (similarly to CKA), which makes it hard to trace the reasons for high/low CCA scores to specific neurons or give any other fine-grained explanation. The second downside is that it is also not robust and has led to the misleading conclusion in the related literature (as demonstrated in Del and Fishel 2021). We discuss these downsides in more detail below.

Interpretability Another interesting aspect of our Normformer case is that PWCCA and SVCCA similarity indexes show correlations of about 0.5-0.8 for the layers 6-12 (see Figure 9 in Appendix A for verification). It indicates something special about CKA eigenvalue weighting, normalization (the denominator in Equation 2), or both. One possibility is that dominant eigenneurons (the ones that also have high eigenvalues) in *monolingual* representational spaces are unproportionally similar to each other (and this causes a high denominator and thus the low CKA scores).

In any case, even if we recover what eigenvalues/normalization components cause these extremely low values, it would be even harder to track down which individual neurons cause the problem and to what extent (CCA/CKA methods essentially find linear combinations of the neurons and so mix them up). It highlights the interpretability issue with CKA/CCA indexes that arises when these indexes disagree with our sanity check and with others.

Conflicting Literature The disagreement between CCA/CKA also caused a problem of conflicting evidence in the literature. Namely, Singh et al. (2019a) used PWCCA to conclude that mBERT representations diverge starting from the early layers. However, this contradicts the evidence from the multiple behavior studies of mBERT that argue that the opposite is true (Wu and Dredze, 2019; Pires et al., 2019; Liu et al., 2020; Libovický et al., 2020; Conneau et al., 2020; Muller et al., 2021). Del and Fishel (2021) find that merely changing the index from PWCCA to SVCCA or CKA in (Singh et al., 2019a) produces results consistent with related works. It highlights the reliability issue with CKA/CCA.

In summary, similarity indexes value different aspects of representations and correspond to different concepts of similarity. It is, therefore, necessary to consult the specific analysis goal to define what we want the similarity to capture. It brings us to Section 5 where we propose a simple alternative method that aligns well with the goals of cross-lingual similarity analysis.

5 Method: Average Neuron-Wise Correlation (ANC)

In Section 4 we demonstrated multiple drawbacks that CCA/CKA similarity indexes have in the cross-lingual context.

5.1 Definition

Assumption In this section, we propose a straightforward alternative method that builds on the assumption that neurons in representations for different languages are aligned one-to-one a priori. We find this assumption reasonable to make for several reasons.

First, it aligns well with the goal that motivated most cross-lingual similarity analysis works: zero-shot cross-lingual transfer learning. Zero-shot transfer is possible because a linear prediction head fine-tuned (usually) for English can exploit **direct** linear relationships between English and (say) French representations. Indeed, the linear prediction head calibrates each weight to work with the specific English neuron. Having that specific neuron similar to the French neuron allows the linear head to work on French.

Second, it allows us to decompose the similarity index into correlations of individual neurons, thus facilitating interpretability. We can explicitly see which neurons contribute to the similarity the most/the least, and these neurons have an interpretation of being the most language-specific/language-natural.

Third, it captures the most natural objectives that many cross-lingual alignment literature consider (Wu and Dredze, 2020): representations of the same sentences should have the exact representations (in case the network is aligned). Residual connections strengthen this assumption for hidden layers.

Description The solution is straightforward: we compute individual correlations between pairs of English and (say French) neurons and calculate an average score. We also take absolute values of the correlations because the network can swap a negative correlation into a positive with a simple negative weight at the next layer.

Thus, we define Average Neuron-Wise Correlation (ANC) as follows.

Let the centered (by neurons) layer representations be

$$X := L_1 - mean(L_1)$$
$$Y := L_2 - mean(L_2)$$

The (Pearson) correlation *corr* between two neurons $\overrightarrow{z_x}$ and $\overrightarrow{z_y}$ form X and Y is defined as:

$$corr(\overrightarrow{z_x}, \overrightarrow{z_y}) = \frac{\langle \overrightarrow{z_x}, \overrightarrow{z_y} \rangle}{\|\overrightarrow{z_x}\| \|\overrightarrow{z_y}\|} \tag{3}$$

We thus define The ANC similarity between two layers L_1 and L_2 as:

$$ANC(X, Y) = \frac{\sum_{i=1}^{n} abs(corr(\overrightarrow{z_x^i}, \overrightarrow{z_y^i}))}{n} \tag{4}$$

It is only possible for us to construct such an index because the neurons come from a single network where we already know what alignment between neurons is (and ought to be). The method will not work if neurons come from layers of two different networks, for example. In these cases, CCA-like indexes are likely the best fit.

5.2 Sanity Checks

In this subsection, we verify that our method gives plausible predictions in the cases where we already know what the result should be.

Based on the Insight From the Literature We based this sanity check on the known insight from the literature. The multilingual BERT model (`bert-base-multilingual-cased`) is widely studied in the literature (Wu and Dredze, 2019; Pires et al., 2019; Liu et al., 2020; Conneau et al., 2020). Muller et al. (2021) provided direct behavioral evidence that representations in mBERT (`bert-base-multilingual-cased`) should follow the "first align, then predict" pattern: they first converge towards each other and diverge slightly only at deep layers.

Libovický et al. (2020) and Del and Fishel (2021) demonstrated that the said pattern generalizes to the XLM-Roberta (`xlm-roberta-base`) model (Conneau and Lample, 2019), which is similar in size and training objective to mBERT with the main differences being the removal of the next sentence prediction loss and training on the segments of texts (irrespectively to sentence boundaries)

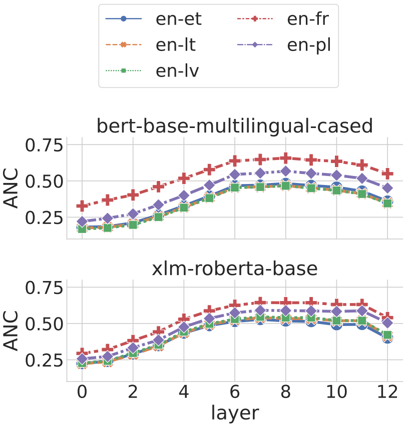

Figure 3: ANC result for the mBERT and XLM-R models. Our method captures the "first align, then translate" pattern presented in Muller et al. (2021) and Del and Fishel (2021).

So our method should reveal the "first align, then predict" pattern in these two cases. Otherwise, we conclude that it fails to capture the relevant properties of similarity we desire.

Figure 3 shows the resulting ANC scores for mBERT and XLM-R `base` models.

The result demonstrates that our method passes the proposed sanity check by being able to reveal the "first align, then predict" pattern. Also, the correlation at the most language natural layers is about 0.7, which indicates that the ANC's *strong assumption* of one-to-one aligned neurons is informative. Lastly, we can see that the ANC distance between English and other languages is more considerable for mBERT than for XLM-R, which corresponds to how these models perform in a cross-lingual transfer (Conneau and Lample, 2019).

Based on the Experiment in Section 4 We base this sanity check on the same XLM-Roberta Normformer experiment that we used to present the CKA failure case in Section 4. Our method should be able to reveal that representations at deeper layers in `scale_normformer` are somehow cross-lingually similar. Moreover, it should also keep the results for the analogous `scale_post` and `scale_pre models` models in agreement.

We present ANC results for the Section 4 experiment in Figure 4.

The figure shows that unlike CKA (Figure 1), the ANC is able to reveal the "first align, then predict" pattern for the `scale_normformer` and better explains the evidence we provided in Table 1 and Figure 2.

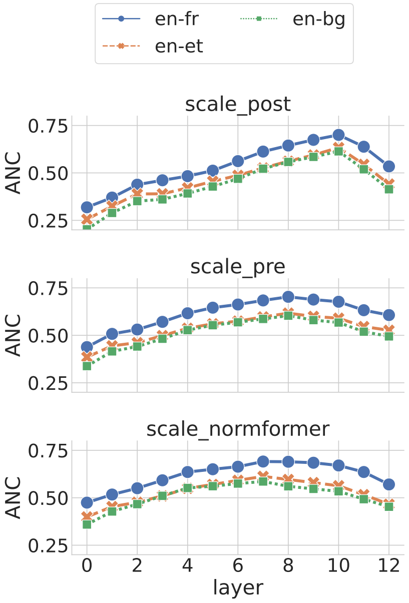

Figure 4: ANC result for the three models we presented in Section 4. Our method, unlike CKA (Figure 1), does capture the cross-lingual similarity existing in the deeper layers of XLM-Roberta Normformer (*scale_normformer*).

In summary, this section demonstrated that our method passes the sanity checks of both related literature and the Section 4 experiment (that made CKA fail). In addition, considering how simple it is to interpret ANC scores (the score is a simple average of neuron-wise correlations), the method is a beneficial tool for comparing representation between languages in a single multilingual model.

6 Scaling Laws of Cross-lingual Representational Similarity in Multilingual Models

In previous sections, we justified our claim that ANC is better suited for cross-lingual analysis than CCA/CKA methods. In this section, we present an application of ANC to the analysis of representational similarity scaling in cross-lingual language models.

Most related works that analyzed representational patterns in multilingual language models focused on a single model, such as `base` version of mBERT or XLM-R. In Section 5.2 we covered these models showing that ANC accompanies our representational similarity index demands from these models. However, as the model scaling brings significant improvements in downstream tasks performance, we must focus our analysis efforts on the large models and scaling laws (Bowman, 2022).

Name	type	#params	l	n	#lgs
xlm-roberta-base	MLM	270M	12	758	100
xlm-roberta-large	MLM	550M	24	1024	100
xlm-roberta-xl	MLM	3.5B	36	2560	100
xlm-roberta-xxl	MLM	10.7B	48	4096	100
xglm-564M	CLM	564M	24	1024	30
xglm-1.7B	CLM	1.7B	24	2048	30
xglm-2.9B	CLM	2.9B	48	2048	30
xglm-4.5B	CLM	4.5B	48	4096	134
xglm-7.5B	CLM	7.5B	32	4096	30

Table 2: Model details for XLM-R and XGLM models we study. *type*: training objective of the model, *#params*: number of parameters, l: number of layers, n: number of hidden units (neurons at each layer), *#lgs*: number of languages used in pertaining.

In this section, we use ANC to explore if the "first align, then predict" pattern generalizes to CLMs and if it preserves in the large-scale versions of multilingual MLMs and CLMs.

Model Details We describe the models we study in Table 2. The Table shows that there are two groups of models: MLMs (encoder only) and CLMs (decoder only). Models in each group notably vary in a number of parameters and neurons at each layer.

Results Figures 5 and 6 reveal that the cross-lingual similarity of multilingual representations in all the networks we study follows the same "first align, then translate" pattern. It happens despite differences in training objectives, number of languages, and sizes. Therefore, this result provides evidence that multilingual models rely on the exact mechanism described in (Muller et al., 2021), independently of the size or the MLM/CLM training objective.

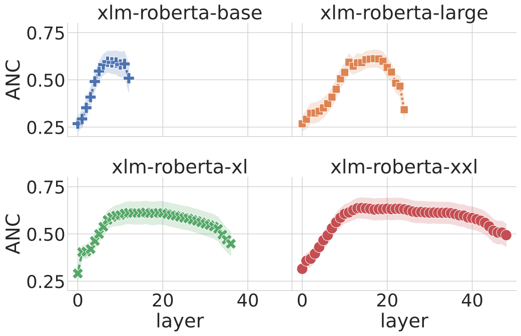

Figure 5: ANC cross-lingual representational similarity for the XLM-R MLM-style models of different sizes. All models follow a similar "first align, then predict" pattern. We aggregate among en-fr, en-de, en-ru, and en-et pairs and show similarity average and spread.

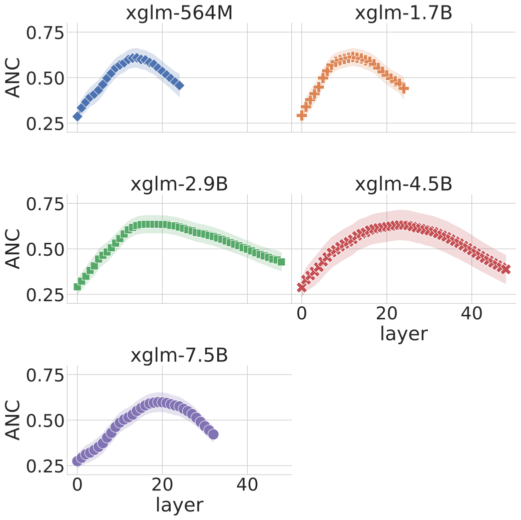

Figure 6: ANC cross-lingual representational similarity for the XGLM CLM-style models of different sizes. All models follow a similar "first align, then predict" pattern. We aggregate among en-fr, en-de, en-ru, and en-et pairs and show similarity average and spread.

7 Conclusion

In this study, we introduced an example where *CKA* drastically fails to reveal the cross-lingual similarity between language representations across the deeper layers of the multilingual model. We also highlighted that *CCA* methods suffer from related problems as well (despite passing that concrete sanity check that CKA failed).

Then, we proposed a new approach: Average Neuron-Wise Correlation (ANC), which builds on the assumption of neuron alignment in cross-lingual representations. We verified that our method passes the sanity check at which CKA fails and produces results harmonious with the evidence from related work.

Finally, we used ANC to show that the "first align, then translate" pattern of cross-lingual representations generalizes to CLMs and the larger scales of MLMs and CLMs.

This work has been supported by the grant No. 825303 (Bergamot[5]) of European Union's Horizon 2020 research and innovation program.

We also thank the Unversity of Tartu's High-Performance Computing Center for providing GPU computing resources (University of Tartu, 2018).

Ethical Considerations

Our work aims to improve the methodology used to perform cross-lingual similarity analysis in multilingual models. We showed that our method outperforms the previous tooling across languages sampled from the four language families: Germanic, Romance, Slavic, Baltic, and Finno-Ugric. To introduce more diversity, we sample different languages from these language families in different experiments. However, we did not experiment with other language families and extremely low-resource languages. These languages might be underrepresented in pretrained LMs and require different analysis tooling. At the time being, we recommend using our method *together* with the previous methods for more reliable results in these cases.

A Appendix

This appendix contains supplementary figures that support some auxiliary claims throughout the paper.

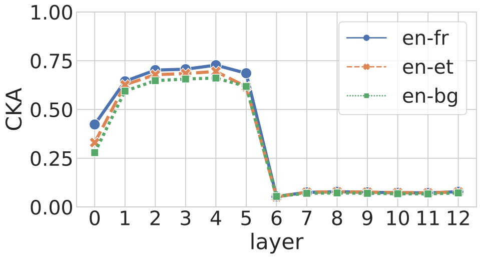

Figure 7: The CKA score for another Normformer (*scale normformer*) model that we pre-trained from the different initialization. The cross-lingual similarity of deeper layers is about zero according to CKA despite evidence of the opposite from Section 4.2

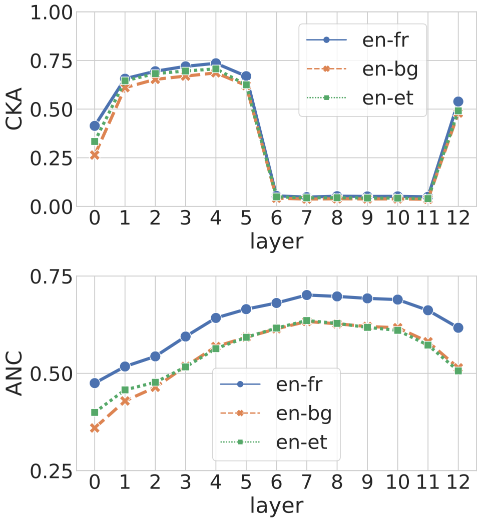

Figure 8: CKA and ANC results for the XLM-Normformer tuned on XNLI. The last layer is a CLS-pooled embedding (the one we tune for XNLI), while others are mean-poolings. CKA captures the similarity between CLS representations at the last layer but fails to capture it at layers 6-11. ANC captures the similarity across all layers.

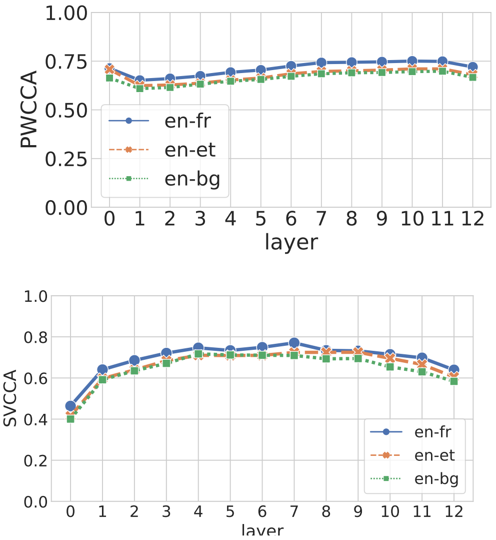

Figure 9: PWCCA and SVCCA results for the XLM-Normformer. These results are more intuitive to our notion of similarity for this particular case but struggle in other scenarios.

Arabic Dialect Identification with a Few Labeled Examples Using Generative Adversarial Networks

Abstract

Given the challenges and complexities introduced while dealing with Dialect Arabic (DA) variations, Transformer based models, e.g., BERT, outperformed other models in dealing with the DA identification task. However, to fine-tune these models, a large corpus is required. Getting a large number high quality labeled examples for some Dialect Arabic classes is challenging and time-consuming. In this paper, we address the Dialect Arabic Identification task. We extend the transformer-based models, ARBERT and MARBERT, with unlabeled data in a generative adversarial setting using Semi-Supervised Generative Adversarial Networks (SS-GAN). Our model enabled producing high-quality embeddings for the Dialect Arabic examples and aided the model to better generalize for the downstream classification task given few labeled examples. Experimental results showed that our model reached better performance and faster convergence when only a few labeled examples are available.

1 Introduction

While Arabic is the first language of most of the Middle East and North Africa (MENA) region, different countries have different dialects of Arabic. These Dialect Arabic (DA) forms are all different from the Modern Standard Arabic (MSA). MSA is used in formal writing and speaking situations, like academia and media. In contrast, DA is the language of the street. DA is spoken by people informally in their daily conversations and on social media platforms.

The task of automatically identifying the dialect of Arabic is beneficial since it contributes to many downstream tasks and applications, such as Speech Recognition and Machine translation.

Some Arabic Dialects are very close to each other (e.g. Levantine region dialects such as Lebanese and Syrian). On the other hand, other dialects are significantly different (e.g. Egyptian and Moroccan dialects) like in Table 1. This similarity is affected by the geographic locations of the countries and their respective dialects.

Class	Example
English	Excuse me, can you take a picture of me?
MSA	معذرةً، هل يمكنك أن تلتقط صورةً لي؟
Egyptian	لا مؤاخذة، ممكن تصورني؟
Lebanese	عن اذنك، فيك تاخدلي صورة؟
Moroccan	سمح ليا، واخا تصورني عافاك؟
Qatarian	لو سمحت، ممكن تصورني؟

Table 1: Comparison between MSA and DA variations for the same sentence

Similar dialects are one of the main challenges in the Dialect Identification task. In addition, further challenges are introduced due to the lack of balanced datasets for DA.

Some datasets are imbalanced with few classes dominating the whole dataset. Figure 1 illustrates the classes distribution in the NADI (Abdul-Mageed et al., 2021b) 2021 dialect dataset. Some other datasets suffer from a limited number of dialects. Another problem is mislabeled DA examples due to noise in the labeling procedure, e.g., depending only on the geographic location.

Given these challenges, getting a large corpus of labeled DA examples for all Arab countries is challenging and time-consuming. These complexities represent a major challenge in the Arabic Dialect Identification task. We aim to improve the transformer-based models, i.e., BERT (Devlin et al., 2019), that handle the task given the lack of large enough datasets.

In this paper, we extend BERT-based models, ARBERT and MARBERT (Abdul-Mageed et al., 2021a), with a generative adversarial setting using

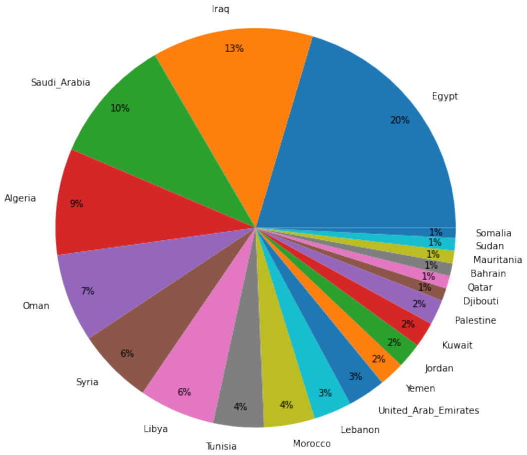

Figure 1: NADI 2021 DA training set label distribution. Only 4 classes represents more than 50% of the dataset

Semi-Supervised Generative Adversarial Networks (SS-GAN) (Salimans et al., 2016). This setting makes use of a set of unlabeled data, which can easily be obtained, to better generalize for the Arabic Dialect Identification task given a few labeled examples. Semi-supervised learning with adversarial nets was previously used for some tasks and languages, but to the best of our knowledge, it has not been used for Arabic Dialect Identification before.

The contributions of this work are:

- Adopting the semi-supervised setting using GAN (Goodfellow et al., 2014) over ARBERT and MARBERT models. This drastically reduces large dataset requirements for the DA identification tasks. Our models outperformed BERT-based models using very small training datasets.

- We study the classification of Dialect Arabic against very small training datasets using our extended GAN models. The training sets were sampled from 4 different Arabic datasets: QADI (Abdelali et al., 2021), NADI 2021 (Abdul-Mageed et al., 2021b), ArSarcasm (Bashmal and AlZeer, 2021) and AOC (Zaidan and Callison-Burch, 2011). The sample sizes varied from 0.01% to 10% of the full training dataset.

- We applied a 2-stage setup, training the GAN extended model for some epochs and then, having a second stage of BERT-based model training. These early GAN epochs boosted BERT-based model convergence speed and performance results. The 2-stages experiment outperformed the BERT-based models for the same number of epochs.

The rest of the paper is organized as follows: in section 2, we discuss the related work in the Dialect Arabic Identification task and variations of BERT-based models. In section 3, we illustrate the system components and model architectures. We show the conducted experiments and their results, in section 4. Finally, we give a brief conclusion based on our work and the obtained results.

2 Related Work

2.1 Evolution of DA Datasets

The main challenge in Arabic Dialect Identification is the rarity of high-quality labeled datasets that represent all Arabic dialects. Recently, some datasets were introduced. However, most of them have limitations as will be shown in the next paragraphs.

The Arabic Online Commentary AOC (Zaidan and Callison-Burch, 2011) introduced rich dialectal content based on online commentary by readers of online famous Arabic newspapers. The dataset is labeled with MSA and three regional dialects: Egyptian, Gulf, and Levantine. Despite the relatively large corpus, country-level dialects are not represented in this dataset, causing the lack of many DA variations. In addition, social media data, e.g., Twitter became a richer source of DA with almost all variations available.

Dialect Identification shared tasks impassioned the Arabic DA work. The Multi Arabic Dialects Application and Resources (MADAR) (Bouamor et al., 2019) project introduced a parallel corpus that was used in MADAR shared task kin 2019. However, the examples were a translation of the Basic Traveling Expression Corpus (BTEC)(Takezawa et al., 2007). Hence, the data examples were short, and unnatural, and do not realistically represent the target dialects.

ArSarcasm (Bashmal and AlZeer, 2021) is a dataset built relying on popular Arabic Sentiment Analysis datasets, SEMEVAL 2017's (Rosenthal et al., 2017) and ASTD (Nabil et al., 2015). ArSarcasm was also annotated for dialects due to the challenges urged by dialectal variations. ArSarcasm adapted a manual annotation process with strict guidelines to guarantee the quality of the annotations. However, most of the data is either in

MSA or Egyptian dialect, and hence, the dataset suffers the rare presentation of other dialects.

The First Nuanced Arabic Dialect Identification Shared Task (NADI 2020) (Abdul-Mageed et al., 2020) included sub-tasks for the country-level and province-level DA identification. The NADI 2020 dataset covers 21 Arab countries, collected from the Twitter domain. While this data was naturally extracted from tweets, it was unbalanced with few classes dominating the dataset. In addition, the labeling criterion depends only on the user's geographic location which introduced wrong labels that prevented deep learning models from better generalization. The Second Nuanced Arabic Dialect Identification Shared Task (NADI 2021) (Abdul-Mageed et al., 2021b) dataset was based on similar collecting and labeling methods and hence has the same limitation. NADI 2021 introduced 2 new subtasks: country and province level MSA identification.

QADI (Abdelali et al., 2021) is a recent tweet dataset with a variety of country-level Arabic Dialects, with highly accurate labels and mostly evenly distributed classes. QADI represented 18 different Arab countries. QADI conducted the Dialect Identification experiments using different machine learning and deep models.

2.2 Transformer based models for DA Identification

BERT model variants showed impressive results on text classification and other NLP tasks. (Mansour et al., 2020) fine-tuned Multilingual BERT (mBERT) (Devlin et al., 2019) for the NADI 2020 (Abdul-Mageed et al., 2020) shared task on DA Identification. AraBERT (Antoun et al., 2020) pre-trained BERT for Arabic. AraBERT outperformed multilingual BERT model in Arabic NLP tasks and became the state-of-the-art model for these tasks in 2020.

(Abdul-Mageed et al., 2021a) introduced ARBERT and MARBERT, which are very powerful transformer-based models trained on large and massive Arabic datasets from different domains. MARBERT was pre-trained on dialectal Arabic which helped for better generalization and more powerful results on diverse tasks. ARBERT and MARBERT models achieved state-of-the-art results in different Arabic downstream NLP tasks. In Dialect Identification, both models outperformed AraBERT and other previous models in all popular DA datasets.

In (AlKhamissi et al., 2021), the authors targeted the NADI 2021 shared task using a MARBERT model and their submission was ranked the first for this shared task. However, the model still did not overcome being biased toward the dominating classes in the training dataset.

2.3 Semi-Supervised Models

Adversarial settings were also introduced on top of BERT-based models to generate different examples, which help in various text classification tasks. BAE(Garg and Ramakrishnan, 2020) presented a model for adversarially generating examples through perturbations based on the BERT Masked Language Model. GAN-BERT (Croce et al., 2020) extended fine-tuning BERT-based models with unlabeled examples using a Generative Adversarial Network (GAN)(Goodfellow et al., 2014) that helped train models with few labeled examples and generally enhance BERT-based model classification capabilities.

3 Adopted Model

3.1 Motivation

One of the key challenges in Arabic Dialect Identification research is insufficient labeled datasets. Many datasets don't fairly represent all classes, i.e., imbalanced datasets. Other datasets suffer from labeling noise.

Although having a sufficient amount of unlabeled data is extremely easy, e.g. crawling tweets, the process of labeling these examples with correct labels is expensive, impractical, and time-consuming. Some easier methods are adopted while labeling such data, e.g., depending on Twitter users' geographic location or account metadata. Unfortunately, these methods are not accurate to representing correct classes and lead to many miss-labeled examples.

Arabic is a highly inflected and derivational language. The inflection and derivation rules may change from one Arabic Dialect to another. Moreover, the same word might have totally different meaning in different Arabic Dialects. For instance, the word مهضوم (Mahdoum) meaning in MSA and Egyptian dialect is digested, which is used to describe food. While in Levantine Arabic (dialects spoken in Syria, Lebanon, Jordan and Palestine), its meaning is joyful or delightful, and used to describe persons. These specific characteristics of

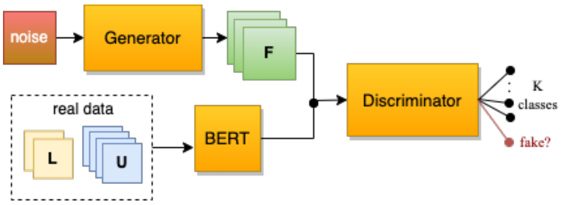

Figure 2: GAN-BERT model architecture. The discriminator D input is: labeled L and unlabeled U examples vector representations computed by BERT, in addition to the fake examples F generated by the generator G given noise input. (Adapted from (Croce et al., 2020))

Arabic Dialects make it challenging to generate human-like examples.

Traditional methods like Data Augmentation are usually used to generate more examples to solve for the rarity of available training examples. However, these methods aren't able to generate human-like real examples in our case. Traditional data augmentation like word swapping fail to generate meaningful examples. Augmenting examples by changing words to their synonyms is also inappropriate due to rarity of synonyms resources for Arabic dialects. Similarly, Back Translation always translate examples back to Modern Standard Arabic (MSA) which leads to losing the dialectal nature of the examples.

In contrast, Semi-Supervised Generative Adversarial Networks (SS-GAN) (Salimans et al., 2016) can act as an additional source of information in a semi-supervised setting. SS-GAN can capture the characteristics of the training examples and generate similar examples that are nearly indistinguishable from the real training examples.

3.2 Model Architecture

Our work is mainly based on GAN-BERT model (Croce et al., 2020) that enriches the BERT fine-tuning process with an SS-GAN perspective. Semi-Supervised GAN (SS-GAN) (Salimans et al., 2016) is a Generative Adversarial Network (Goodfellow et al., 2014) with a multi-class classifier as its Discriminator. Rather than learning to discriminate between only two classes (actual and fake), it learns to distinguish between K + 1 classes, where K is the number of classes in the training dataset, plus one for the Generator's fake generated examples. The Generator input is a vector of random noise, The Generator's objective is to generate fake examples that are indistinguishable from the real dataset examples.

The Discriminator has 3 inputs: fake examples generated by the Generator (x*), real unlabeled examples (x), and real labeled training examples (x, y), with y denoting the label for the given example x.

In this work, we extend BERT-based models using SS-GAN. We use BERT-based models pre-trained on Arabic datasets, namely ARBERT and MARBERT (Abdul-Mageed et al., 2021a), and adapt the fine-tuning by adding task-specific layer in addition to the SS-GAN layers to enable semi-supervised learning.

Given an input example, $e = (t_1, t_2, , .., t_n)$, BERT model's output is an $n + 2$ vector representation in R^d, i.e., $(h_{CLS}, h_1, h_2, .., h_{SEP})$. As advised in (Devlin et al., 2019), h_{CLS} is used a the example sentence embedding for the identification task.

The generator G is a Multi-Layer Perceptron (MLP) that takes an input of a 100-dimensional random noise vector drawn from Normal Distribution $N(\mu, \sigma^2)$ and outputs a vector $h_{fake} \in R^d$. As shown in Figure 2, the discriminator D receives input $h_* \in R^d$ which can be the fake generator output h_{fake} or examples from the real distribution $hCLS$ (labeled or unlabeled). The Discriminator D is another Multi-Layer Perceptron (MLP) where its last layer is a softmax layer that outputs a $k + 1$ vector of logits. True examples from the real distribution are classified into the (1, ..., k) classes, while generated fake samples are classified into the additional $k + 1$ class.

When updating the discriminator, BERT-based model weights are also changed in order to consider both labeled and unlabeled examples to better fine-tune their inner representations. At evaluation the generator is discarded while keeping rest of the model, which means no additional cost at inference time compared to standard BERT-based models.

4 Experimental Results

4.1 Semi-Supervised Setting: GAN-MARBERT and GAN-ARBERT

In this section, we evaluate the impact of GAN-BERT-Based models, namely GAN-MARBERT and GAN-ARBERT over the Arabic Dialect Identification task under different training environments, i.e., number of dialectal classes and number of labeled training examples. We compare our proposed method with MARBERT / ARBERT which are the existing methods that achieve state-of-the-art results in the Arabic Dialect Identification task. With

(c) QADI

(d) AOC

Figure 3: Learning curves for the Dialect Identification task against the 4 datasets. We run all the models for 10 epochs with the same learning rate 2e-5. The same sequence length of 40 was used in all experiments.

very few training examples, we assess our model in the DI task against the following datasets: QADI (Abdelali et al., 2021) that has 18 classes, NADI 2021 Subtask 2.2 (Abdul-Mageed et al., 2021b) that has 21 classes, ArSarcasm (Bashmal and AlZeer, 2021) that has 5 classes, and AOC (Zaidan and Callison-Burch, 2011) that has 4 classes.

We use the macro-F1 score as the evaluation metric for our models. The macro-F1 score is the standard evaluation metric in the dialect identification task.

As discussed in section 3, we extend BERT-based models with a generative adversarial setting. The generator G is an MLP with a single hidden layer activated by a leaky relu function. The generator G input is a random noise vector drawn from the Normal distribution $N(0, 1)$. The generator G output is a 768-dimensional vector that represents the fake generated examples. The discriminator D is another similar MLP with a final softmax layer for the final dialect classification. We use a dropout rate of 0.2 after the hidden layer in both G and D.

We chose the best performing BERT-based pre-trained model as the base model for each dataset, as reported in (Abdul-Mageed et al., 2021a). For QADI, NADI, and AOC, the chosen base model is MARBERT. While for ArSarcasm, the base model is ARBERT.

We start training the models by sampling only 0.01% or 1% of the full training dataset, depending on the size of the dataset, in order to have a very small training set. The process is repeated with incremental larger training samples.

For the unlabeled examples, we use a set of $10K$ randomly sampled tweets from the unlabeled set provided in the NADI 2021 (Abdul-Mageed et al., 2021b) dataset.

The ArSarcassm (Bashmal and AlZeer, 2021) Dialect Identification task results are shown in figure 3a. The training dataset consists of 8438 examples, and the test dataset consists of 2111 examples, labeled with 5 dialect classes. The plot shows the macro-F1 scores of the GAN-ARBERT and ARBERT models. When 1% of the training data is used (around 85 examples), ARBERT almost diverges, while GAN-ARBERT achieves F1 of more than 25%. With 2% of the training data, GAN-ARBERT achieved F1 of 38%, obviously outperforming ARBERT. The same trend continued until 10% of the training data is used.

For NADI 2021 (Abdul-Mageed et al., 2021b) sub-task 2.2 dataset, similar outcomes were observed as shown in figure 3b. The dataset consists of 21000 training examples and 5000 test examples labeled with 21 dialect classes. NADI has a large number of classes with unbalanced training exam-

ples distribution. GAN-MARBERT outperforms the MARBERT model in most settings. When 1% of the training set is used (210 examples), GAN-MARBERT achieves more than 3 times the F1 score obtained by MARBERT, GAN-MARBERT achieves F1 of 8% while MARBERT achieves F1 of 2.8%. The same trend continues with different sample sizes. The semi-supervised setting shows performance improvement over MARBERT for most of the sample sizes.

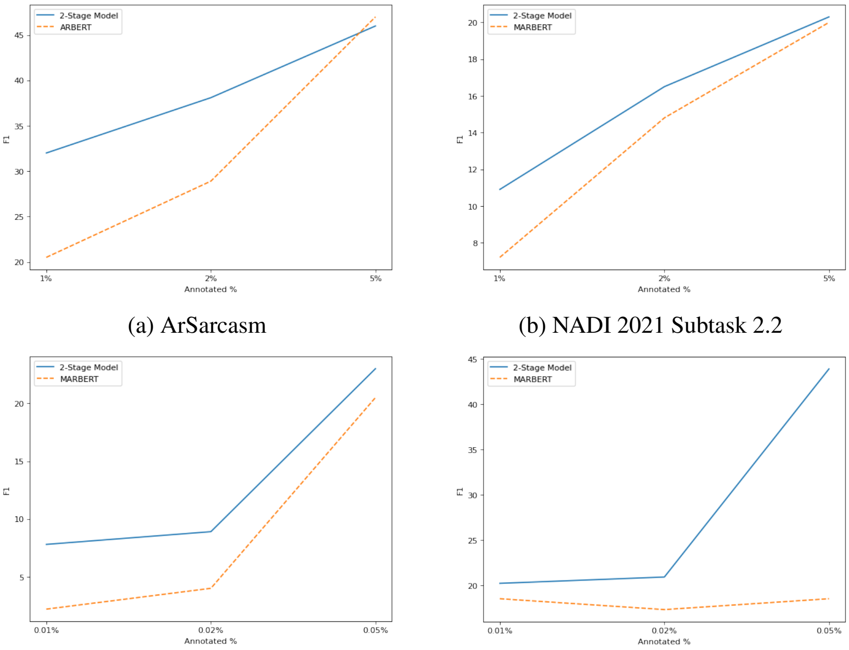
The observations were confirmed against QADI (Abdelali et al., 2021) dataset in figure 3c. QADI is the largest dataset used in these experiments with 367,353 training examples and 3304 test examples labeled with 18 dialects classes. QADI fairly represents most of the dialect classes and guarantees clean and correct labels. However, the same trend was shown in small training sample sizes. Using 0.01% (37 examples) and 0.02% (74 examples) of the training dataset, GAN-MARBERT achieves more than 4 times the macro-F1 score obtained by MARBERT model for the corresponding number of examples. Noticeable improvements in the F1 score continued until 2% of the training set is used.

Finally, we evaluate the models against AOC (Zaidan and Callison-Burch, 2011) dataset, which consists of 86,542 training examples and 10,812 test examples, labeled with 4 classes. For 0.02% of the training set (only 17 examples), GAN-MARBERT obtains F1 of more than 26% while MARBERT got 17% F1. When using a 0.05% of the training set (184 examples), GAN-MARBERT achieves F1 of 47% while MARBERT only got F1 of 18%, i.e, more than 2.5X F1 improvement. For larger training sample sizes, both models performed similarly.

The experimental results scores against different training dataset sample sizes are shown in Table 2

4.2 Two-Stages Setup: Using a BERT-based model after the GAN-BERT

In this setup, we evaluate a 2-stages setup. The first stage is training the BERT-based model with the GAN extension for 5 epochs. In the second stage, the GAN module is eliminated and the BERT-based model is trained for another 5 epochs. With



(a) ArSarcasm

(b) NADI 2021 Subtask 2.2

(c) QADI

(d) AOC

Figure 4: 2-stages experiments results. We used MARBERT as the base model for NADI, QADI and AOC datasets, while using ARBERT for ArSarcasm. Each experiment consists of 10 epochs. In the 2-stage experiments, we train the base model extended with GAN component for 5 epochs, then eliminate the GAN component and train the base model alone for another 5 epochs.

smaller training set samples, the first stage gave a performance boost to the overall model result when compared to the BERT-based model alone.

Figure 4 shows the experiments results. In both setups, we use the same learning rate $2e-5$ and sequence length 40. For QADI and AOC datasets, we used 0.01%, 0.02%, and 0.05% of the annotated samples. For NADI and ArSarcasm, we used a1%, 2%, and 5% of the training dataset.

The experiment showed that adding the first stage with the semi-supervised setting helped the base model to better generalize for a few labeled examples and to converge faster.. Overall, the 2-stages setup outperformed the base model.

For ArSarcasm (Bashmal and AlZeer, 2021) dataset, figure 4a shows how the 2-stages setup achieves higher scores and faster convergence with smaller sample sizes. For example, when using only 1% of the training set, the 2-stages setup achieves F1 of 32, while ARBERT achieves only F1 of 20.5. Similar outcomes were obtained for NADI (Abdul-Mageed et al., 2021b) dataset in figure 4b. When 1% of the training set is used, the 2-stages setup achieves F1 of 10.9, compared to 7.2 by MARBERT. For QADI (Abdelali et al., 2021) dataset, figure 4c confirms the same outcomes. When only 0.01% of the training sample is used, the 2-stages setup achieves more than 3 times the F1 score obtained by MARBERT. The 2-stages setup achieves F1 of 7.8 compared to F1 of 2.2 by the MARBERT model. The trend continues with other sample sizes, with 0.02% of the training set, the 2-stages setup achieves F1 of 8.9 compared to 4 by MARBERT. Finally, for AOC (Zaidan and Callison-Burch, 2011) dataset, the 2-stages setup converges way faster than MARBERT as shown in figure 4d. With only a 0.05% training sample, the 2-stages setup achieves more than 2 times the F1 obtained by MARBERT. It achieves F1 of 43.9 compared to 18.5 for MARBERT.

The experimental results scores against different training dataset sample sizes are shown in Table 3

5 Conclusion

One of the main challenges of the Arabic Dialect Identification task is the rarity of high-quality labeled examples. This paper addresses this problem by adopting adversarial training to allow semi-supervised learning. it applies this approach to two BERT-based models, namely, MARBERT and ARBERT. Experimental results show that the GAN extension improves the performance of the BERT-based models, given a few labeled examples. The paper also introduces a 2-stages setup, where it trains the base model extended with GAN component for 5 epochs, then eliminate the GAN component and train the base model alone for another 5 epochs. Using very small training sets, the adopted approach helps the base model for better generalization and faster convergence, with no additional cost at inference time.

Adding SS-GAN module on top of BERT-based models, empirically showed enhancements in performance and faster convergence given a few labeled examples of the datasets, which validates our hypothesis.

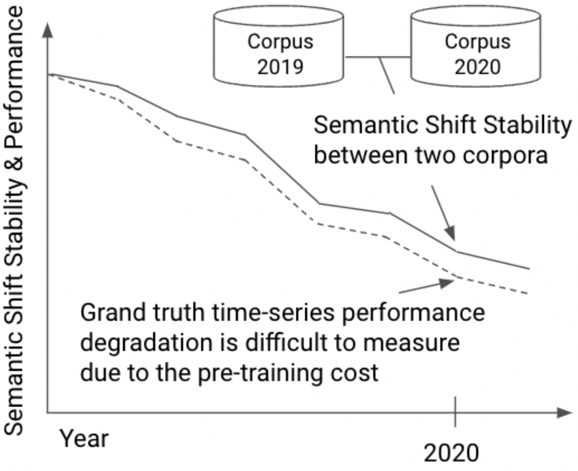
Abstract

Word embeddings and pre-trained language models have become essential technical elements in natural language processing. While the general practice is to use or fine-tune publicly available models, there are significant advantages in creating or pre-training unique models that match the domain. The performance of the models degrades as language changes or evolves continuously (*semantic shift*), but the high cost of model building inhibits regular re-training, especially for the language models. This study designs a methodology for observing time-series performance degradation of word embeddings and pre-trained language models using semantic shift in a corpus. We define an efficiently computable metric named Semantic Shift Stability based on the degree of semantic shift. In the experiments, we create models that vary by time series and reveal the performance degradation in two datasets, Japanese and English. Several case studies demonstrate that Semantic Shift Stability supports decision-making as to whether a model should be re-trained. The source code is available at https://github.com/Nikkei/semantic-shift-stability.

1 Introduction

The use of word embeddings and pre-trained language models has become common practice in natural language processing. Word embeddings like word2vec (Mikolov et al., 2013) are used in many applications, and pre-trained language models starting with BERT (Devlin et al., 2019) are updating state-of-the-art performance on a daily basis. Researchers and developers use or fine-tune such kinds of models to their own tasks.

While the general practice is to start from publicly available models, there are also significant advantages in creating or pre-training unique models that match the domain. In regard to pre-trained language models, for example, SciBERT (Beltagy et al., 2019), BioBERT (Lee et al., 2020), and FinBERT (Araci, 2019) are proposed. These models have performed better than other BERT models on downstream domain-specific tasks. A similar approach is traditionally used in word embeddings. There are numerous studies and applications of obtaining word embeddings in their own corpora.



Semantic Shift Stability & Performance

Corpus 2020
Semantic Shift Stability between two corpora
Grand truth time-series performance degradation is difficult to measure due to the pre-training cost
Year
2020

Figure 1: Methodology for observing time-series performance degradation by Semantic Shift Stability. It is difficult from a cost perspective to create a pre-train language model each time and compare the performance. Instead, by monitoring the degree of semantic shift of the corpora from period to period, we can estimate time-series performance degradation.

In creating domain-specific language models, we have to be careful of time-series changes in the characteristics of the corpus. Language changes continuously, especially when there are some socially important events. The semantic shift (Kutuzov et al., 2018) of existing words and the appearance of new words are occurring regularly. Some have reported that such time-series changes cause degradation of performance (Jaidka et al., 2018; Sato et al., 2020; Loureiro et al., 2022). Henceforth, we refer to this phenomenon as time-series

Proceedings of the 2nd Conference of the Asia-Pacific Chapter of the Association for Computational Linguistics and the 12th International Joint Conference on Natural Language Processing (Volume 1: Long Papers), pages 205–216
November 20–23, 2022. ©2022 Association for Computational Linguistics

performance degradation.

One of the solutions to tackle time-series performance degradation is re-training, but the high cost of model building is a bottleneck especially with language models. It is reported that large-scale pre-training requires large amounts of computation. For example, GPT-3 with 175B parameter consumed several thousand petaflop/s-days of compute during pre-training (Brown et al., 2020), and PaLM with 540B parameter was trained on 6144 TPU v4 chips (Chowdhery et al., 2022). This trend is accelerated by empirical scaling laws for language model performance (Kaplan et al., 2020), where the loss scales as a power-law with model size, dataset size, and the amount of compute used for training.

This study designs a methodology for observing time-series performance degradation of word embeddings and pre-trained language models using semantic shift in a corpus. The degree of semantic shift is computed by comparing two word2vec models created from corpora of different time-span. Monitoring performance leads to the decision whether the model should be re-trained (Figure 1).

The methodology has the advantage of avoiding large-scale training to measure performance. The required input is two word2vec models, which can be created much more efficiently than pre-training of language models. For word embeddings, it is also a benefit if we can infer the downstream task performance without experiments.

Our contributions are as follows.

1. We define an efficiently computable metric named Semantic Shift Stability based on the degree of semantic shift, and propose to use it for detecting time-series performance degradation of word embeddings and pre-trained language models (Section 3).
2. We create models that vary by time-series and reveal the performance degradation via the experiments on two corpora, not only English but also Japanese. In particular, we pre-train and analyze 12 RoBERTa models on a corpus of Japanese financial news at different time-span (Section 4).
3. We demonstrate case studies that the Semantic Shift Stability supports decision-making as to whether a model should be re-trained. Our experiments report that a large time-series performance degradation occurs in the years when Semantic Shift Stability is smaller (Section 5).

2 Related Work

This section describes the related work from three perspectives and highlights our study.

2.1 Semantic Shift

Changes in human language have long been studied from a variety of perspectives (Bloomfield, 1933). There are known linguistic and cultural factors (Hamilton et al., 2016). In addition to its linguistic and sociological importance, changes in human language also attract interest from the perspective of data science, such as natural language processing and information retrieval (Kutuzov et al., 2018).

As large corpora become available, there have been accelerated efforts to capture the semantic shift using word embeddings (Traugott, 2017). For example, (Gulordava and Baroni, 2011) compared the distribution in corpora from the 1960s and 1990s and identified a cultural shift in which the word *sleep* became more negative in meaning. (Guo et al., 2021) analyzed a Twitter corpus over time and observed changes in word meaning during the COVID-19 pandemic. Furthermore, (Giulianelli et al., 2022) detected semantic shift using pre-trained language models. One of the challenges is that there is limited research on this area in non-English languages (Kutuzov et al., 2018).

2.2 Time-series Performance Degradation

Time-series performance degradation is a long-standing problem in machine learning (Quinonero-Candela et al., 2008). It is a common problem in predictive modeling that occurs when the joint distribution of inputs and outputs differs between training and test stages. Differences in distribution are often caused by the lapse of time.

This issue has also been discussed in the progress of natural language processing. (Loureiro et al., 2022) pointed out that the time variable has been largely neglected in the literature on natural language processing. They pre-trained multiple language models on a time-split Twitter corpus and investigated the differences in performance. (Mohawesh et al., 2021) reported that differences in the distribution of input and output datasets negatively affects the performance of prediction models in the detection of fake reviews. There is also a direction to incorporate time-series information into word embeddings (Rosenfeld and Erk, 2018; Hofmann et al., 2021) and pre-trained language models (Hombaiah et al., 2021).

2.3 Domain-Specific Language Models

The idea of creating embedding representations from a large dataset of unlabeled text has become an essential element in natural language processing. This trend started with simple single word embeddings such as word2vec, and has evolved into more advanced pre-trained language models such as ELMo (Peters et al., 2018), BERT, and GPT-3, etc. In the creation of word embeddings and pre-trained language models, Web domain corpora are often used. Many works use Wikipedia and other resources crawled from the Internet.

Past work has shown that using a domain-specific corpus has the potential to improve performance (Peng et al., 2019). Some conduct additional pre-training to a model that has been pre-trained on a general corpus, while others tackle the issue from scratch on a domain-specific corpus. In some cases, the latter method, which does not mix domains, leads to superior results (Gu et al., 2021).

Language is one of the domain factors, and there are several researches in non-English languages. For example, there are GPT-like models created by the corpora of Chinese (Zeng et al., 2021; Su et al., 2022) and Korean (Kim et al., 2021). Nevertheless, there are not many practical examples due to computational cost and other difficulties.

2.4 Our study highlight

Our study crosses the three research areas described in this section. Specifically, we extend the semantic shift methodology to address the problem of time-series performance degradation in domain-specific language models and word embeddings. To conclude this section, we highlight our study.

First, our effort is one of the first attempts to propose an efficient way to detect time-series performance degradation. There are some studies that recognize the existence of semantic shift and create some models incorporate time-series information. However, few studies have been designed as decision-making support application without large re-training.

Next, our experiments, especially on Japanese corpora, would become unique and valuable case studies. There is insufficient research on semantic shift and domain-specific language models for languages other than English.

Finally, when it comes to the stage of practicality, discussions of time-series performance degradation and model re-training are becoming more important. Domain-specific language models are gradually being proposed.

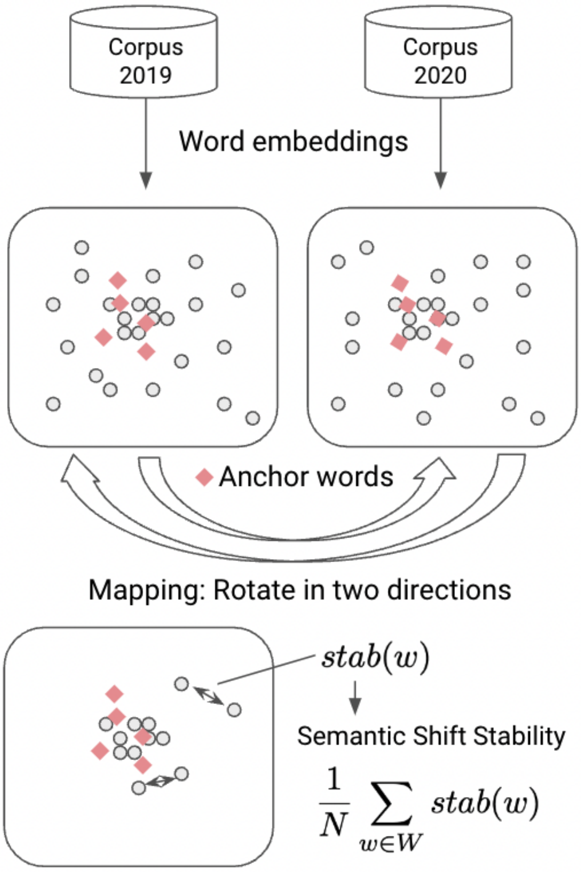

Figure 2: Procedure to calculate Semantic Shift Stability from two corpora. First, word embeddings are created. Then, we set anchor words and introduce a rotation matrix. Finally, Semantic Shift Stability is calculated by averaging the stability of each word.

3 Semantic Shift Stability

In this section, we define a metric named Semantic Shift Stability based on the degree of semantic shift of two corpora. We propose to use it for detecting time-series performance degradation of word embeddings and pre-trained language models.

Semantic Shift Stability is a metric calculated for whole word embeddings. We compute the stability of the semantic shift ($stab(w)$) on each word w and use the average of all words in the common vocabulary of two word embeddings as the overall score.

The procedure to calculate $stab(w)$ and Semantic Shift Stability from two corpora is described in Figure 2. There are four steps followed in the method proposed by (Guo et al., 2021): 1. Create word embeddings, 2. Set anchor words, 3. Introduce the rotation matrix, and 4. Calculate $stab(w)$. Our new point in this study is that we define a metric that averages $stab(w)$, to quantify the semantic shift of two corpora.

3.1 Create word embeddings

The first step is to create word embeddings from each of the two corpora for comparison. For word embeddings, word2vec is used.

3.2 Set anchor words

The second step is to set *anchor words*, which are the starting points for comparing two word embeddings in the next step. We assume that the meaning of frequently appearing words does not change over time and that the local structure is preserved. It is based on the idea that the rate of semantic shift follows a negative power of word frequency (Hamilton et al., 2016). Under this assumption, the top 1000 frequent words are set as anchor words.

3.3 Introduce rotation matrix

The third step is to introduce a rotation matrix by taking two trained word embeddings. Specifically, the matrices of anchor words are taken from the two word embeddings, aligned and optimized while preserving cosine similarity (Schönemann, 1966). This optimization problem is solved by applying singular value decomposition to obtain the optimal rotation matrices between the two embedding spaces. We call this step mapping.

3.4 Calculate $stab(w)$

The fourth step is to calculate $stab(w)$, where the degree of semantic shift of the word can be observed by computing the cosine similarity of the word embedding in each model. However, since the average similarity is low for one-way mapping (Azarbonyad et al., 2017), the same process are applied in the reverse direction. The definition of $stab(w)$ that compares word embeddings i and j is as follows.

$$stab(w) = \frac{sim_{ij}(w) + sim_{ji}(w)}{2}$$

$$sim_{ij}(w) = \cos(R^{ji} R^{ij} V_w^i, V_w^i)$$

The smaller $stab(w)$ is, the larger the difference between the two word embeddings, and the more the word is considered to have changed its meaning. Here, $\cos$ is the cosine similarity, R^{ji} is the rotation matrix used for mapping from model j to i, and V_w^i is the embedding of the word w in model i.

3.5 Semantic Shift Stability

We define a metric to calculate the degree of semantic shift of the entire model using the average $stab(w)$. The smaller this value is, the greater the degree of change of the entire model. Here, W is a vocabulary commonly included in the word2vec model i and j, and N is the number of W.

$$\text{Semantic Shift Stability} = \frac{1}{N} \sum_{w \in W} stab(w)$$

3.6 Enumerate words with small $stab(w)$

We can infer the reason for the semantic shift by enumerating words with small $stab(w)$. This is one of the advantages of using the methodology to analyze the difference.

4 Preliminary Experiments: Time-series Performance Degradation

In this section, we create models that vary by time-series and analyze them to reveal the performance degradation. The purpose of this preliminary experiments was to quantify the performance degradation that should be detected in the next section. The rest of this section describes the dataset, model creation, and their time-series performance degradation. We used RoBERTa (Liu et al., 2019) for pre-trained language models and word2vec for word embeddings. RoBERTa is a optimized version of BERT, and word2vec is a well-known word embeddings.

4.1 Dataset

We prepared the following two corpora:

Nikkei Japanese financial news corpus from the Nikkei Online Edition [1] from March 23, 2010, when the service was launched, to December 31, 2021. It contains several genres such as business, lifestyle, international, sports, market, economy, society, and politics.

NOW English news corpus from News on the Web (NOW) (Davies, 2017). The period is from 2010 to April 2022. It contains articles from various news media such as *TechCrunch*, *ESPN*, *Ars Technica*, *Salon*, *CNET*, and *Politico*.

Table 1: Training time and loss for the pre-trained RoBERTa models. Starting in 2010, the training corpus was increased year by year. As the size of the corpus increased, there was a trend of increasing training time and decreasing losses.

Corpus	Time (sec)	Loss	Corpus size
2010	8387	6.81	151 MB
2010-2011	20791	5.42	391 MB
2010-2012	34007	4.26	636 MB
2010-2013	46764	3.79	874 MB
2010-2014	58510	3.27	1.09 GB
2010-2015	69279	3.13	1.30 GB
2010-2016	82267	2.99	1.54 GB
2010-2017	96455	2.71	1.79 GB
2010-2018	111204	2.82	2.06 GB
2010-2019	125481	2.67	2.33 GB
2010-2020	142336	2.69	2.62 GB
2010-2021	140196	2.82	2.80 GB

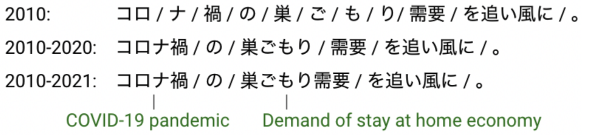
4.2 Pre-train RoBERTa models

We pre-trained multiple RoBERTa models with different time-span of the Nikkei corpus. The architecture was RoBERTa base with 125M parameters including 12 layer, 768 hidden, and 12 heads. The corpus was prepared for 12 patterns; the years 2010, 2010-2011, ... , and 2010-2021 as listed in Table 1. As the size of the corpus increased, there was a trend of increasing training time and decreasing losses.

Pre-training language models required large computational cost. For example, the RoBERTa 2010-2021 took appropriately 140 thousand seconds (39 hours) and $ 1278 to pre-train. We used Amazon EC2 P4 Instances for computational resource. This instance provides eight A100 GPUs and its on-demand price per hour is $ 32.77.

We used Transformers (Wolf et al., 2020) for the implementation. Training epochs were set at 50 for all models and the hyperparameters were set as follows according to the instruction [2]: max sequence length: 128, batch size: 32, learning rate: 0.0003, and weight decay (Loshchilov and Hutter, 2017): 0.001. The optimizer was Adafactor (Shazeer and Stern, 2018).

We used SentencePiece (Kudo and Richardson, 2018) as a tokenizer in the setting of unigram language model (Kudo, 2018). SentencePiece does not require prior segmentation and can directly generate vocabulary from the raw text. This feature is useful for languages such as Chinese and Japanese, where there are no explicit spaces between words. Figure 3 shows the difference in tokenizer work between the corpora used for training. The tokenizer trained on the new corpus was able to process the newly introduced words appropriately.



2010: コロ / ナ / 禍 / の / 巣 / ご / も / り/ 需要 / を追い風に / 。
2010-2020: コロナ禍 / の / 巣ごもり / 需要 / を追い風に / 。
2010-2021: コロナ禍 / の / 巣ごもり需要 / を追い風に / 。

Figure 3: Tokenizers trained from the Nikkei corpora with different time-span. The tokenizer, which is trained to include the post-2020 corpus, is able to properly separate words that are new in COVID-19. The tokenizer trained only on the 2010 corpus break them up into smaller pieces.

4.3 Degradation of RoBERTa models

We measured RoBERTa time-series performance degradation using the Pseudo-perplexity (PPPL) (Salazar et al., 2020) following a previous study (Loureiro et al., 2022). The PPPL is computed on the basis of the idea of iteratively replacing each token in a sequence with a mask and summing the corresponding conditional log probabilities. This approach is especially suited to masked language models such as RoBERTa. To see the change in time-series performance, the PPPL is computed for combinations of the RoBERTa models and the corpora.

Table 2 showed that, as expected, the performance of the model degraded with each time-series. The PPPL is a metric in which a smaller value is better. The overall trend is that the numbers worsen as one moves to the right side of the table and improve as one moves to the bottom. For example, the model for RoBERTa 2010 shows 800.57 PPPL for the Nikkei corpus 2010. The newer the corpus for evaluation, the worse the PPPL. RoBERTa 2010 model shows 1076.00 PPPL against the Nikkei corpus 2020, but performance improves as RoBERTa is trained on newer corpora.

4.4 Create word2vec models

We created multiple word2vec models with different time-span of the Nikkei and the NOW corpora. Each corpus was prepared for 12 patterns by year; the years 2010, 2011, ... , and 2021.

Building word2vec is much more efficient than pre-trained language models reported in Section

[2] https://github.com/huggingface/transformers/tree/main/examples/flax/language-modeling

Table 2: Pseudo-perplexity (PPPL) results computed for combinations of the different RoBERTa models and time-span corpora. The PPPL is a metric in which the smaller value is better. The overall trend is that the worse the performance as one moves to the right side (the evaluation corpora become newer) and the better the performance as one moves to the bottom (the newer corpora used for RoBERTa pre-training).

	Evaluation										
RoBERTa	2010	2011	2012	2013	2014	2015	2016	2017	2018	2019	2020
2010	**800.57**	883.31	913.05	930.00	924.94	933.43	962.32	992.69	1,011.57	1,012.89	**1,076.00**
2010-2011		192.98	222.05	235.83	237.15	240.40	260.57	269.68	278.32	282.36	300.60
2010-2012			63.13	70.25	73.17	74.54	82.86	86.41	90.58	92.51	96.80
2010-2013				38.62	41.93	43.81	49.08	51.17	53.76	55.46	58.17
2010-2014					23.04	24.88	28.19	29.42	31.33	32.58	34.24
2010-2015						17.33	20.16	21.19	22.77	23.59	24.79
2010-2016							16.73	18.21	19.73	20.37	21.86
2010-2017								12.26	13.72	14.38	15.42
2010-2018									15.44	16.58	18.15
2010-2019										11.74	13.16
2010-2020										10.73	11.15
2010-2021										18.04	18.21

4.2. Training with the Nikkei corpus for one year (around 200 MB) took about 20 minutes on a laptop (MacBook Pro, 2.4 GHz 8 core Intel Core i9).

We used gensim (Řehůřek and Sojka, 2010) to build the word2vec models. For the Nikkei corpus, we performed an additional process to handle Japanese texts. HTML tags and URLs were removed as text preprocessing. We used MeCab (Kudo, 2005) for text splitting and mecab-ipadic-NEologd (Sato et al., 2017) for the dictionary.

We confirmed that the training of word2vec was sufficient by comparing the performance with other Japanese models. The word2vec model created using the Nikkei corpus showed competitive performance to other models. For comparison, we used WikiEntVec (Suzuki et al., 2018), Shiroyagi [3] and chiVe [4]. Appendix A describes the details of this evaluation.

4.5 Degradation of word2vec models

We measured word2vec time-series performance degradation using a classification task, following a previous study (Kutuzov et al., 2018). The aim was to see how well word2vec trained on a previous corpus performs against a newer corpus (the corpus 2021). As input, we used the keywords of the article in the Nikkei corpus and the words of the article texts in the NOW corpus. The average of the word embeddings for each word was treated as feature (Shen et al., 2018) and LightGBM (Ke et al., 2017) was used as a classifier. The classification objective was the genres of the article. The eight genres for the Nikkei corpus are described in Section 4.1. For the NOW corpus, we regarded the six news media as genres written in Section 4.1.

Table 3: The transition of the word2vec performance on the corpus 2021. The results showed that models trained on newer corpus performed better.

Corpus	Nikkei	Nikkei	NOW	NOW
Train	w2v	w2v, lgbm	w2v	w2v, lgbm
2011	0.8036	0.1886	0.9056	0.7562
2012	0.8060	0.1102	0.9084	0.7324
2013	0.8090	0.3768	0.9070	0.7759
2014	0.8087	0.3989	0.9064	0.7850
2015	0.8113	0.2234	0.9078	0.7831
2016	0.8157	0.4092	0.9108	0.7330
2017	0.8180	0.2610	0.9094	0.7088
2018	0.8193	0.3946	0.9081	0.7376
2019	0.8233	0.4684	0.9093	0.7758
2020	**0.8284**	**0.5412**	**0.9182**	**0.8621**

As shown in Table 3, the performance generally degraded as the training corpus moved into the past. There were two experimental settings for each corpus. The first setting was that only the word2vec model was trained on the corpus of a specific year. LightGBM was trained on the corpus 2021. The second setting was that both the word2vec model and LightGBM were trained. In both experimental settings of the two corpora, the corpus 2020 showed the highest performance.

5 Experiments

In this section, we calculated Semantic Shift Stability and analyzed the relationship to the time-series performance degradation shown in Section 4.

5.1 Semantic Shift Stability

We calculated Semantic Shift Stability for the two corpora, shifting the window width by one year. There were two corpora of reference year and the

[3] https://github.com/shiroyagicorp/japanese-word2vec-model-builder

[4] https://github.com/WorksApplications/chiVe

Table 4: Semantic Shift Stability. Note that there are two corpora of reference year and the year. The smaller the value, the greater the difference between the two comparisons. It was smaller in 2016 and 2020 for both corpora. In the Nikkei corpus, it was also smaller in 2012.

Reference year	Year	Nikkei	NOW
2011	**2012**	**0.9770**	0.9840
2012	2013	0.9815	0.9855
2013	2014	0.9825	0.9850
2014	2015	0.9860	0.9805
2015	**2016**	**0.9800**	**0.9610**
2016	2017	0.9860	0.9830
2017	2018	0.9840	0.9875
2018	2019	0.9850	0.9710
2019	**2020**	**0.9710**	**0.9610**
2020	2021	0.9835	0.9835

year. The flow was to compare the corpus 2011 and 2012, then the corpus 2012 and 2013, etc. All results are listed in Table 4. Note that the smaller Semantic Shift Stability value, the greater the difference between the two comparisons.

Nikkei Semantic Shift Stability was smaller in the 2012, 2016, and 2020. The first change, inferred from social events, was probably due to the Great East Japan Earthquake in 2011. The United States presidential election 2016 can be raised as a possible reason for the second change. The third change could be because of the arrival of the COVID-19 pandemic. Although these are only analogies of social events, the methods described in Section 3.6 can help in the discussion. For example, when we analyzed the third change per word, the words enumerated were as follows: infection spread, new coronavirus, infection etc.

NOW Semantic Shift Stability was smaller in the corpora 2016, and 2020. The reasons for the changes are considered to be the same as for the Nikkei corpus. When we analyzed the change of 2016 per word, the words enumerated were: donald, trump etc. This implied that the change was because of Donald Trump, who won the United States presidential election 2016.

5.2 Case study on RoBERTa

This case study demonstrates that large time-series performance degradation occurred in the years when Semantic Shift Stability was smaller. We analyzed the relationship between time-series performance degradation of RoBERTa models calculated in Section 4.3 and Semantic Shift Stability introduced in Section 5.1. As preparation, the raw data of PPPL results in Table 2 were converted to year-to-year performance differences (Table 5).

The objective of converting the table is to clarify the impact on performance per year. First, for each RoBERTa model, we calculated the percentage of performance degradation compared to the newest year included in the training corpus. Temporary table is shown in Appendix B. Then, the difference from the previous year was calculated for each RoBERTa model.

We focus on three years (2012, 2016, and 2020) for Table 5 because Semantic Shift Stability was smaller. At the corpus 2012 column, there was the highest value in the whole table. Note that the discussion for the corpus 2012 was a bit difficult because there were not enough previous periods. Looking at the corpus 2016 column, almost all RoBERTa models showed significant performance degradation. The corpus 2016 caused the most performance degradation for almost all models trained before 2016. After 2016, the highest values appeared in the 2020 column. Performance degradation in 2020 was greater than in 2019 for all RoBERTa models.

5.3 Case study on word2vec

This case study demonstrates that large time-series performance degradation occurred in the years when Semantic Shift Stability was smaller. We analyzed the relationship between time-series performance degradation of word2vec models calculated in Section 4.5 and Semantic Shift Stability introduced in Section 5.1. There were two experimental settings, and we investigated the relationship to Semantic Shift Stability for each setting.

We found that in years when Semantic Shift Stability was smaller, using that year's corpus for training improved the performance compared to the previous year. Figures 4 and 5 show the visualization of the first setting, in which we only trained word2vec. The red wavy line shows the performance against the evaluation corpus (the corpus 2021), as a difference compared to the previous year. Semantic Shift Stability, the blue line, was smaller in 2012, 2016, and 2020. In both figures, there was a significant performance improvement in 2016 and 2020. The correlation coefficient is -0.4855 and -0.8861, respectively.

On the contrary, the second setting in which we

Table 5: Converted Pseudo-perplexity results for clarifying the impact on performance from year to year. First, for each model, we calculated the percentage of performance degradation compared to the newest year included in the training corpus. Then, we calculated the difference from the previous year, respectively. Looking at the corpus 2016 column, almost all RoBERTa models showed significant performance degradation. Coefficient means the correlation coefficient with Semantic Shift Stability.

	Evaluation											Coefficient
RoBERTa	2010	2011	2012	2013	2014	2015	2016	2017	2018	2019	2020	
2010	0.00	10.33	3.72	2.12	-0.63	1.06	3.61	3.79	2.36	0.17	7.88	-0.7775
2010-2011		0.00	15.06	7.14	0.68	1.68	10.45	4.72	4.47	2.09	9.46	-0.7010
2010-2012			0.00	11.28	4.63	2.17	13.17	5.62	6.60	3.07	6.79	-0.3776
2010-2013				0.00	8.59	4.86	13.65	5.43	6.70	4.41	7.00	-0.3271
2010-2014					0.00	7.96	14.36	5.36	8.26	5.47	7.17	-0.1952
2010-2015						0.00	16.28	5.96	9.13	4.73	6.95	-0.1340
2010-2016							0.00	8.87	9.07	3.86	8.87	-0.3122
2010-2017								0.00	11.94	5.35	8.53	-0.0364
2010-2018									0.00	7.41	10.15	-
2010-2019										0.00	12.11	-
2010-2020										0.00	3.92	-
2010-2021										0.00	0.89	-

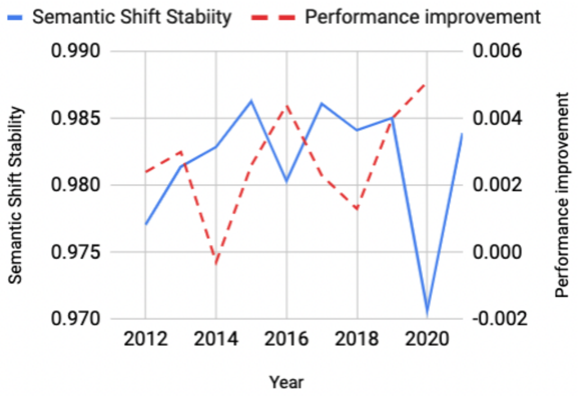

Figure 4: Relationship between Semantic Shift Stability and performance improvement difference of word2vec trained on the Nikkei corpus #. We found that in years when Semantic Shift Stability was small, using that year's corpus for training improved the performance compared to the previous year.

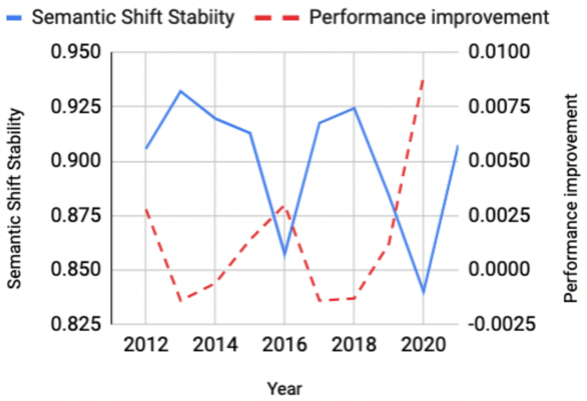

Figure 5: Relationship between Semantic Shift Stability and performance improvement difference of trained on the NOW corpus #. We found that in years when Semantic Shift Stability was small, using that year's corpus for training improved the performance compared to the previous year.

trained word2vec and LightGBM showed a relatively undistinguished trend. The visualization of the second setting is shown in Appendix C. This may be because LightGBM was also trained on a corpus, making it difficult to see the effect of word2vec.

6 Conclusion and Future Work

This study designs a methodology for observing time-series performance degradation of word embeddings and pre-trained language models by Semantic Shift Stability. It is a metric that can be calculated more efficiently than pre-training language models, which requires large computational cost. Monitoring performance via Semantic Shift Stability supports decision-making as to whether a model should be re-trained. We created word embeddings and pre-trained language models that vary by time-series. In particular, we pre-trained and analyze 12 RoBERTa models on a corpus of Japanese financial news at different time-span. We quantified the time-series performance degradation in experiments on two corpora, Japanese and English. The experiments confirmed that a large time-series performance degradation occurred in the years when Semantic Shift Stability was smaller.

Our effort is one of the first attempts to propose an efficient way to detect time-series performance degradation, designed as a decision-making support application without large re-training. In future work, we plan to conduct further experiments with more diverse corpora and models. In the present study, the relationship between Semantic Shift Stability and time-series performance degradation was discussed qualitatively based on the calculated quantitative information. Additional research should lead us to explore ways to formulate this discussion in a more persuasive manner.

Acknowledgements

We thank anonymous reviewers for their careful reading of our manuscript and for their many insightful comments and suggestions. In addition, we appreciate AWS Japan for prototyping support in pre-training language models. We are also grateful to Tony Bucher for proofreading. Finally, we thank all members of Nikkei, Inc. for their devoted support and discussion.

A Evaluation of Created word2vec

We confirmed that the training of word2vec was sufficient by comparing the performance with other Japanese models. The word2vec model created using the Nikkei corpus showed competitive performance as shown in Table 6. As a representative of our word2vec models, a word2vec model was created with the Nikkei corpus from March 23, 2010 to October 31, 2019. For comparison, we used WikiEntVec, Shiroyagi and chiVe. WikiEntVec and Shiroyagi were trained in Japanese Wikipedia, and chiVe was trained in Japanese Web corpus.

Table 6: Comparison of Japanese word2vec models. The word2vec model created using the Nikkei corpus showed competitive performance to other models.

Model	Nikkei	WikiEntVec	Shiroyagi	chiVe
Dimension	300	200	50	300
Vocabulary	493,531	1,015,474	335,476	3,644,628
JWSD-adv	**0.281**	0.182	0.155	0.255
JWSD-verb	0.251	0.149	0.223	**0.260**
JWSD-noun	0.274	0.250	0.203	**0.310**
JWSD-adj	0.287	0.158	0.257	**0.404**
JWSAN-2145	0.627	0.642	0.580	**0.701**
JWSAN-1400	0.499	0.499	0.416	**0.541**
NIKKEI	**0.934**	0.896	0.896	0.925

Each model was evaluated using the Japanese Word Similarity Dataset (JWSD) (Sakaizawa and Komachi, 2018), the Japanese Word Similarity and Relatedness Dataset (JWSAN) (Inohara and Utsumi, 2021), and the Nikkei corpus. JWSD is a dataset that assigns similarity values from 0 to 10 to words, and has four parts of speech: adjectives (JWSD-adv), verbs (JWSD-verb), nouns (JWSD-noun), and adverbs (JWSD-adj). JWSAN is a dataset of similarity and relatedness of nouns, verbs, and adjectives, with similarity and relatedness assigned values from 1 to 7, respectively. There are two datasets: one with all 2145 word pairs (JWSAN-2145) and the other with 1400 word pairs (JWSAN-1400) carefully selected for distributed representation. Spearman's rank correlation coefficient [5] was used as the evaluation metric.

In the task of NIKKEI, using the Nikkei corpus, genres were predicted from the keywords contained in the articles. Keywords are manually assigned by the editors, mainly nouns extracted from the article texts. The average of the word embeddings of each keyword was used as input. The genres were the same as described in Section 4.1. Accuracy was used as the evaluation metric. The Nikkei corpus from January 1, 2020 to November 30, 2021 was used for validation. In particular, the NIKKEI task showed the highest accuracy among the four models, suggesting that the created word2vec model was useful for the analysis of the Nikkei corpus.

B Temporary Table During Converting

Table 7 shows the temporary table during the conversion of the RoBERTa performance. We calculated the percentage of performance degradation by comparing to the newest year included in the training corpus.

C Visualization of the Relationship

Figures 6 and 7 show the visualization of the setting in which we train both word2vec and LightGBM. This setting showed a relatively undistinguished

	Evaluation										
RoBERTa	2010	2011	2012	2013	2014	2015	2016	2017	2018	2019	2020
2010	0.00 %	10.33 %	14.05 %	16.17 %	15.54 %	16.60 %	20.20 %	24.00 %	26.36 %	26.52 %	34.40 %
2010-2011		0.00 %	15.06%	22.21 %	22.89 %	24.58 %	35.03 %	39.75 %	44.22 %	46.32 %	55.77 %
2010-2012			0.00 %	11.28 %	15.91 %	18.08 %	31.26 %	36.88 %	43.48 %	46.55 %	53.35 %
2010-2013				0.00 %	8.59 %	13.44 %	27.09 %	32.52 %	39.21 %	43.63 %	50.62 %
2010-2014					0.00 %	7.96 %	22.32 %	27.67 %	35.94 %	41.40 %	48.57 %
2010-2015						0.00 %	16.28 %	22.24 %	31.36 %	36.09 %	43.04 %
2010-2016							0.00 %	8.87 %	17.94 %	21.80 %	30.67 %
2010-2017								0.00 %	11.94 %	17.29 %	25.82 %
2010-2018									0.00 %	7.41 %	17.56 %
2010-2019										0.00 %	12.11 %
2010-2020										0.00 %	3.92 %
2010-2021										0.00 %	0.89 %

trend compared to when only word2vec was trained. This may be because LightGBM was also trained on a corpus from a different time period, making it difficult to see the effect of word2vec. The correlation coefficient is -0.2611 and -0.1738, respectively.

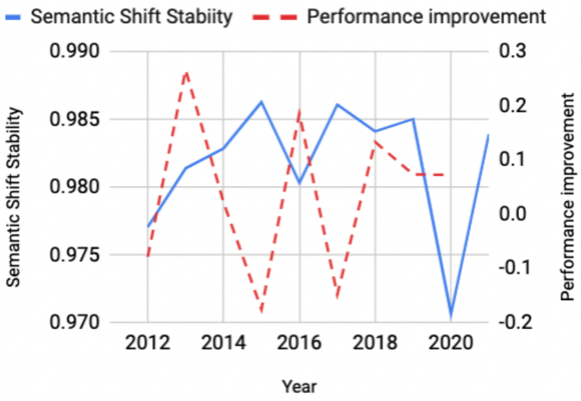

Figure 6: Relationship between Semantic Shift Stability and performance improvement difference of word2vec and LightGBM trained on the Nikkei corpus #. This setting showed a relatively undistinguished trend compared to when only word2vec was trained.

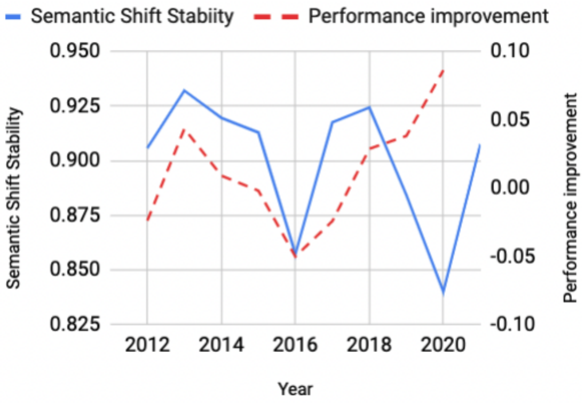

Figure 7: Relationship between Semantic Shift Stability and performance improvement difference of word2vec and LightGBM trained on the NOW corpus #. This setting showed a relatively undistinguished trend compared to when only word2vec was trained.

Neural Text Sanitization with Explicit Measures of Privacy Risk

Abstract

We present a novel approach for text sanitization, which is the task of editing a document to mask all (direct and indirect) personal identifiers and thereby conceal the identity of the individuals(s) mentioned in the text. In contrast to previous work, the approach relies on explicit measures of privacy risk, making it possible to explicitly control the trade-off between privacy protection and data utility.

The approach proceeds in three steps. A neural, privacy-enhanced entity recognizer is first employed to detect and classify potential personal identifiers. We then determine which entities, or combination of entities, are likely to pose a re-identification risk through a range of privacy risk assessment measures. We present three such measures of privacy risk, respectively based on (1) span probabilities derived from a BERT language model, (2) web search queries and (3) a classifier trained on labelled data. Finally, a linear optimization solver decides which entities to mask to minimize the semantic loss while simultaneously ensuring that the estimated privacy risk remains under a given threshold. We evaluate the approach both in the absence and presence of manually annotated data. Our results highlight the potential of the approach, as well as issues specific types of personal data can introduce to the process.

1 Introduction

Personal data, also known as Personally Identifiable Information (PII), often abound in text documents, from emails to patient records, court judgments, interview transcripts or customer service chats. Protecting the privacy of the individuals mentioned in those documents is an important task, particularly for sensitive texts which might disclose confidential information such as health status, religious beliefs, ethnicity or sex life.

It is, however, possible to apply privacy-enhancing techniques such as *text sanitization* to conceal the identity of those individuals from the texts, and thereby make it easier to share data to third parties, in particular for the purpose of scientific research or statistical analysis. The goal of text sanitization is to transform a document through edit operations such as hiding particular text spans or replacing them by more general values. Although complete anonymization compliant with data privacy frameworks such as the General Data Protection Regulation (GDPR, 2016) has been shown to be very difficult to achieve in practice (Weitzenboeck et al., 2022), text sanitization can substantially enhance the level of privacy protection while simultaneously retaining most of the semantic content expressed in the documents.

Existing work on text sanitization has primarily focused on masking predefined entity types through sequence labelling (Dernoncourt et al., 2017; Liu et al., 2017; Jensen et al., 2021). These previous approaches, however, may not mask enough PII to prevent re-identification, as they are restricted to a fixed list of semantic categories to detect. These are often named entities such as persons, organizations, or locations. As a consequence, personal information that do not belong to those predefined categories (for instance, mentions of a person's appearance or occupation) will be ignored. Paradoxically, they may also end up masking *too much* information, as they systematically mask all occurrences of a given entity type (for instance, all locations) regardless of the actual influence of a particular entity on the risk of re-identifying the individuals mentioned in the original document (Lison et al., 2021).

In this paper we present a novel approach to text sanitization that seeks to address these limitations. The approach relies on a privacy-enhanced entity recognizer that goes beyond named entities and can detect demographic attributes and other types of personal information that frequently occur in text. The integration of empirical measures of privacy

Optimization Algorithm

Figure 1: General sketch of the approach. The text document is first given as input to the privacy-enhanced entity recognizer which detects personal information present in the text, along with their semantic type. Then three privacy risk measures are used to determine which entities may constitute a privacy risk. Finally, an optimization algorithm makes the optimal masking decisions for each document, resulting in a sanitized text.

risk also makes it possible to strike an explicit balance between data utility and privacy protection. The resulting risk measures are fed to an optimization solver which determines the optimal set of entities to mask in each document. Figure 1 provides a general outline of the procedure. The code along with the models used is publicly available.[1]

The proposed approach can be applied without any labelled data, provided there already exists a generic Named Entity Recognizer (NER) and a version of Wikidata for the language employed in the documents. If text annotated with masking decisions is available, the approach can take advantage of them to further enhance the model's performance. The modularity of the approach also allows for the integration of additional methods to measure the privacy risk associated with the entities mentioned in the text.

This paper makes the following contributions:

- A neural entity recognizer specifically tailored for privacy protection, based on the combination of a generic NER model with a gazetteer derived from Wikidata.
- Several methods for empirically estimating the re-identification risk associated with the presence of a given entity or combination of entities in a document. One method relies on probabilities derived from BERT, while a second relies on web search queries, and a third one on a neural classifier trained from labelled data (when available).
- A pipeline that combines the neural entity recognizer with privacy risk measures and an optimization algorithm to determine the optimal set of entities to mask, given a privacy risk threshold and estimates of semantic loss.
- Evaluation results based on the recently developed Text Anonymization Benchmark (Pilán et al., 2022) that demonstrate the validity of the approach both in the absence and presence of in-domain labelled data.

The structure of the rest of the paper is the following. A background and review of related work are provided in Section 2. Section 3 details our approach, followed by an evaluation and discussion in Section 4. We conclude in Section 5.

Terminological note

The removal of PII from text documents to protect the identity of the individuals mentioned in those

[1] https://github.com/NorskRegnesentral/NeuralTextSanitizer

texts has received multiple names in the literature, such as de-identification, pseudonymization, sanitization and anonymization (Deleger et al., 2013; Eder et al., 2019; Sánchez and Batet, 2016; Lison et al., 2021). Following (Sánchez and Batet, 2016; Brown et al., 2022), we settle in this paper on the term "sanitization" to differentiate it from techniques traditionally termed as "de-identification" (Dernoncourt et al., 2017; Yogarajan et al., 2018), which are restricted to specific semantic categories. Moreover we wish to avoid the use of the term "anonymization", as it is notoriously difficult to precisely define what qualifies as anonymous data in relation to legal frameworks such as GDPR (Hintze, 2017), particularly when it comes to unstructured data (Weitzenboeck et al., 2022).

2 Background

Privacy is a fundamental human right, and various legal frameworks for data protection[2] have been put in place in recent years to ensure that individuals remain in control of their personal data. Those frameworks specify strict guidelines on how data that may contain personal information should be collected, stored and processed. Personal identifiers can be divided in two broad categories (Elliot et al., 2016; Domingo-Ferrer et al., 2016):

Direct identifiers: Information that can irrevocably and uniquely identify an individual (e.g. name, social security number, email address, bio-metric data, etc.)

Quasi identifiers: Information that cannot directly single out an individual, but may do so indirectly when combined with other quasi identifiers (e.g. date of birth, occupation, city of residence, ethnicity etc.). For instance, the combination of gender, date of birth and postal code can single out between 63 and 87% of the U.S. population (Golle, 2006).

Both direct and quasi identifiers need to be masked (i.e. removed or generalized) to prevent identity disclosure. This necessarily leads to a a loss of information or data utility, and the objective of text sanitization is therefore to determine the set of masking operations that ensure the privacy risk remains below a given threshold, yet preserve as much data utility as possible.

NLP approaches to text sanitization have mostly focused on medical data, using either rule-based methods (Ruch et al., 2000; Douglass et al., 2005) or sequence labelling models trained on manually annotated data for pre-defined categories (Deleger et al., 2013; Dernoncourt et al., 2017; Liu et al., 2017; Johnson et al., 2020).

Text sanitization approaches have also been developed in the field of privacy-preserving data publishing (PPDP). Those approaches seek to enforce a privacy model by searching for the optimal set of masking decisions to ensure that the requirements of the model are met. The k-anonymity privacy model (Samarati and Sweeney, 1998) has been adapted for text data in k-safety (Chakaravarthy et al., 2008) and k-confusability (Cumby and Ghani, 2011). Like k-anonymity, these approaches require every entity to be indistinguishable from k-1 other entities. t-plausibility (Anandan et al., 2012) is a similar model which depends on PII being already detected to perform generalization so as to ensure that at least t documents can be derived through specialization of the generalized terms. Finally C-sanitized (Sánchez and Batet, 2016) is designed to mimic human annotators by taking into account semantic inferences in the text, in addition to disclosure risk. To this end, mutual information scores are calculated manually from co-occurrence counts in web data. Those PPDP approaches, however, typically treat the text simply as a flat collection of terms, missing thus the importance of context for the entities and the linguistic inter-relationships between these terms.

Pilán et al. (2022) present the Text Anonymization Benchmark (TAB), a corpus of court judgements from the European Court of Human Rights (ECHR), manually enriched with detailed annotations on the PII expressed in each document. The authors also propose a set of novel evaluation metrics for the task as well as baseline results using a neural sequence labelling model. Papadopoulou et al. (2022) describe a bootstrapping approach for text sanitization based on k-anonymity. Their approach requires, however, an explicit specification of the background knowledge associated with each individual, which may be difficult to acquire.

The masking operations employed in text sanitization are non-perturbative (i.e. limited to either hiding text spans or replacing them by more general values). This need to preserve the "truth value" of the original document is important for

many types of data releases: a clinical report in which the description of symptoms and diagnosis has been randomly altered would be of little interest for e.g. medical researchers. This requirement distinguishes text sanitization from other privacy-enhancing methods based on differential privacy (Feyisetan et al., 2019; Krishna et al., 2021), which transform existing texts through the addition of artificial noise. Although those techniques are undeniably useful to create texts (or text representations) that can enforce specific privacy guarantees, they address a different task than the one discussed in this paper, as they effectively produce new, synthetic texts instead of masked versions of existing documents (Pilán et al., 2022).

3 Approach

In the following we introduce the three steps of our neural text sanitization model.

3.1 Privacy-enhanced entity recognizer

Accurately detecting all potential PII in a text is a crucial first step in a text sanitization approach, since it ensures that subsequent steps will have potentially sensitive text spans available while arriving at the necessary masking decisions.

Generic NER systems are commonly used as part of anonymization solutions such as Microsoft's Presidio[3]. Such systems, however, often fail to detect demographic attributes (e.g. occupation, sexual orientation, medical condition) or other miscellaneous information (e.g. tools, vehicles, field of work, or manner of death) that are potential quasi-identifiers.

To address this limitation, we combine a generic NER model with a gazetteer including terms typically employed as attributes of human individuals in Wikidata. More specifically, we inspected 3646 Wikidata properties related to humans and manually identified those that could potentially belong to either DEM (demographic attributes associated to a person, such as their profession, ethnicity or family status) or MISC (any other information that may contribute to identifying a person, but is not an "attribute" of that person). We end up with 44 DEM properties and 196 MISC properties, which we used to create the gazetteer. Some examples of four Wikidata properties filtered as DEM and MISC respectively are:

- *occupation* (P106) –> writer, builder, professor etc.
- *political ideology* (P1141) –> progressivism, democrat, antimilitarism etc.
- *cause of death* (P509) –> nitric acid poisoning, suicide, helicopter crash etc.
- *convicted of* (P1399) –> forgery, matricide, home invasion etc.

The combination of the generic NER model with this gazetteer allows us to recognize a total of 8 categories of PII, detailed in Table 1.

To further enhance the performance of the entity recognition (and counteract the limited coverage of the gazetteer), we then apply the NER model and the gazetteer to create a *silver corpus* of PII. Our training data consists of 2500 Wikipedia summaries and 2500 ECHR cases as they are publicly and freely available sources of data that are rich in PII. This silver corpus is then employed to fine-tune a neural language model – more specifically RoBERTa (Liu et al., 2019) to label text spans according to the 8 categories in Table 1.

We split the silver corpus into a training (90%), development(10%), and test dataset(10%). The average text length in the silver corpus is 14 sentences, keeping in mind that ECHR cases are typically longer documents than Wikipedia biographies.

[3] https://github.com/microsoft/presidio

Figure 2 shows the distribution of semantic types of the silver corpus for the three dataset splits.

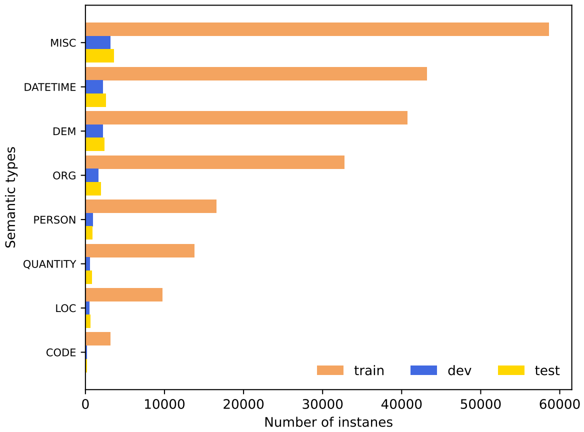

Figure 2: Distribution of semantic types on the train, development and test split of the silver corpus of PII

While manually inspecting some of the training instances we also notice examples of label confusion which can be attributed to Wikidata. Some property values, which are entered by editors for each Wikidata page, belonged to the wrong semantic type (e.g. dates, organization names or nationalities in properties such as cause of death). We thus expect to see some examples of these types of errors by the model.

3.2 Privacy risk measures

Once text spans expressing potential PII are detected in the document, the next step is to determine the privacy risk associated with their presence in the document. Indeed, not all of the entities detected in the previous step will need to be masked. To determine the entities, or combinations of entities, that constitute a re-identification risk and need to be masked, we rely on several complementary measures, detailed below.

3.2.1 Language model probabilities

One heuristic to automatically determine whether an entity or a combination of entities need to be masked is to use a language model to calculate surprisal measures in the form of the probability of the text span in its document context. Intuitively, a more "surprising" entity corresponds to a PII with a larger information content, and therefore a higher re-identification risk. Conversely, a text span that can be predicted from the rest of the document will typically correspond to information that is less specifically tied to the individual to protect.

We use a pre-trained RoBERTa model with a language modeling head on top (linear layer) to calculate the log probability of each text span detected by the privacy-enhanced entity recognizer. In case the span consists of more than one token, we compute the final probability by adding the log probabilities of each token. A span with a low log-probability corresponds to an entity that is difficult to predict and thus more informative/specific. A threshold is then established to determine which entities need to be masked on the basis of those log-probabilities. In practice, this threshold can be selected empirically.

3.2.2 Privacy risks with web queries

The re-identification risk can also be estimated using web queries. Intuitively, the idea is to query a web search engine with a particular combination of entities, and check whether web results also mention the person to protect, in which case the entities pose an unacceptable re-identification risk and need to be masked. For instance, if we wish to conceal the mention of Annalena Baerbock from a document, the combination of the two entities "Germany" and "minister" will correspond to a privacy risk, as the search for those words on Google yields among the top results web pages that do mention the name of Annalena Baerbock.

To avoid the need to crawl web pages to search for the mention of the person to protect, we start by querying the search engine for the person name, and store the results. This makes it possible to find out whether a combination of entities is dangerous by computing the intersection of the URLs related to the person and the URLs related to the entities. If this intersection is non-empty, at least one web search result contains both the person name and the combination of entities. Due to practical constraints with web search APIs, the algorithm only extracts the top k results for each search query. Our implementation currently relies on Google as search engine and a value of k set to 50.[4]

Admittedly, sending queries to a search engine is costly, since a document may comprise hundreds of entities, and querying a web search engine with their various combinations is a time-consuming process. To address this issue, we also emulate the results obtained by Algorithm 1 using a neural model. More specifically, the model seeks to predict whether a combination of entities is likely to

[4] The search results were gathered in June 2022. Search results might differ depending on when they were acquired.

```
def find_risky_entity_combinations
    (entities, person_name, max_arity):
# entities: text spans detected in document
# person_name: name of individual to protect
# max_arity: max size of combined entities to query

  # (Initially empty) set of entity combinations
  # that can re-identify the person
  risky_entity_combs ← $\emptyset$

  # We search the person on the web
  urls_for_person ← search(person_name)

  # We start by searching for single entities,
  # then pairs of entities, up to max arity
  for $n = 1 \rightarrow$ max_arity:

    # We loop on all entity combinations of size $n$
    for entity_comb in combine(entities, n):

      # We search the entities (joined by "AND")
      urls_for_entities ← search(entity_comb)

      # We also augment the URLs about the person
      urls_for_person ← urls_for_person
      + search(person_name + entity_comb)

      # If at least one URL is in both sets, those
      # entities can lead to re-identification
      if urls_for_entities $\cap$ urls_for_person $\neq \emptyset$:
        Add entity_comb to risky_entity_combs

  return risky_entity_combs
```

Algorithm 1: Procedure for determining which entities, or combination of entities, can uncover the identity of the person to protect, based on web search queries.

lead to web search results that mention the person name. The neural model employed for this prediction task relies on contextualized embeddings from BERT, together with an LSTM layer to compute a single embedding vector for each entity. The model is trained on the search results for 20 documents in the training set of the TAB corpus. See the Appendix for details on the architecture.

3.2.3 Classifier trained on labelled data

Finally, one can also measure the privacy risk associated with entities mentioned in a text through a supervised model. More specifically, one can collect text documents manually annotated by human experts with masking decisions and train a neural model to reproduce those masking decisions.

Our implementation relies on a fine-tuned RoBERTa neural language model that takes as input a text including the occurrences of each entity in its document context and the semantic category produced by Step 1. The language model is augmented with a classification head (after pooling), and is fined-tuned on the labelled data to predict whether a given entity should be masked.

3.3 Optimization algorithm

The privacy risk measures described in the previous sections generates a list of entities, or combinations of entities, that constitute an unacceptable re-identification risk. When single entities are marked as risky, the corresponding decision is trivial: the entity must be masked. However, risky *combinations* of entities are more difficult to handle, as we need to decide on which subset of entities to mask or possibly retain in clear text.

We formulate this task as a linear programming problem[5] where the objective is to minimize the semantic loss subject to the constraint that, for each combination of entities deemed risky, at least one entity in the combination must be masked. The semantic loss is then defined as the sum of the information content IC for all masked entities. This semantic loss is a measure of quantifying the information lost when entities are masked, i.e. the usability of the resulting text if certain PII is missing. Formally, the optimization problem is defined as:

$$\text{Minimize} \quad \sum_{e \in E_d} \mathit{masked}(e)\ \mathit{IC}(e)$$

subject to the constraints:

$$\sum_{e \in \mathit{ent\_tuple}} \mathit{masked}(e) \geq 1$$

$$\forall\ \mathit{ent\_tuple} \in \mathit{risky\_entity\_combinations}_d$$

where:

- E_d is the set of entities detected by the privacy-enhanced entity recognizer for document d
- *masked(e)* is a binary variable that takes a value of 1 if the entity e is masked and 0 otherwise
- $IC(e)$ is the information content of entity e, defined as the negative log-probability of e according to BERT, as done in Section 3.2.1. If the entity contains several words, the log-probabilities of each word are summed.
- $\mathit{risky\_entity\_combinations}_d$ is the list of all entity combinations detected in document d by the entity recognizer and categorized as risky by at least one privacy risk measure.

[5] The CP-SAT Solver from Google OR-tools was used in our implementation.

4 Evaluation

We evaluate the proposed approach on the Text Anonymization Benchmark (TAB) (Pilán et al., 2022) which consists of 1268 ECHR court judgements manually annotated for text anonymization benchmarking. Court judgements are freely available documents that are not subject to data protection regulations. The annotations in TAB identify all possible PII in the texts, associated with both a semantic category (e.g., person name, code, demographic property, etc.) and a masking decision.

The majority of entity types in the TAB corpus belong to the DATETIME (34.6%), ORG (26.3%), and PERSON (15.7%) semantic types, while 63.4% of all the annotations were masked as quasi identifiers and 4.4% as direct identifiers (mainly CODE and PERSON semantic types), with the rest of the detected spans being left as is in the text (Pilán et al., 2022). The test set, which we use for our evaluation purposes, consists of 127 documents which were annotated and quality checked by more than one annotators.

We first analyse the performance of the privacy-enhanced entity recognizer, and then evaluate the performance of the complete pipeline.

4.1 Entity recognition

We evaluate the privacy-enhanced entity recognition model from Section 3.1 on the test set of TAB, using the full set of manually detected PII prior to masking. We compare the performance of our system against two baselines: (i) the generic NER model used in the first step of the silver corpus creation, and (ii) the generic NER model in combination with the gazetteer populated with Wikidata properties related to human individuals. The latter comparison aims to evaluate whether the neural model fine-tuned on the silver corpus generalizes to unseen PII not included in the gazetteer. The generic NER model corresponds to a RoBERTa language model fine-tuned for named entity recognition on the Ontonotes corpus (Weischedel et al., 2011). Table 2 provides the evaluation results. See Appendix for details on training parameters.

The results show that the privacy-enhanced entity recognizer model is able to detect with reasonable accuracy almost all semantic types apart from the MISC category, for which it seems to have the lowest performance. MISC is a broad semantic type that cannot be concretely categorised, and is thus difficult for a model to predict; for instance the longer MISC example in the TAB test dataset is a quote of 49 tokens. Since MISC entities are derived from Wikidata properties, we also do not expect them to completely match the MISC entities found in the court judgments of the TAB corpus.

Below are some example of recognition errors, where the left side corresponds to a manually annotated text span as seen in the TAB corpus, while the right side corresponds to the spans detected by the entity recognizer:

- British national [DEM] - British [DEM]
- discrimination case [MISC] - discrimination [MISC]
- five attacks [QUANTITY] - five [QUANTITY] attacks [MISC]
- life imprisonment [DATETIME] - life imprisonment [MISC]
- without a father for an important part of its childhood years [MISC] - father [DEM] childhood years [MISC]

Those examples illustrate that a mismatch in the entity label or text span boundary (compared to the manually annotated texts) does not necessarily mean that the model fails to detect a PII.

4.2 Full sanitization model

We now analyse the performance of the complete pipeline (in various variants) on the task of deciding which entity to mask in a given document. We adopt the evaluation metrics put forward by (Pilán et al., 2022) to assess the performance of text sanitization methods. In particular, we provide separate recall measures for the direct and quasi identifiers, as well as both an unweighted and weighted precision score, the latter taking into account the informativeness of each span (Pilán et al., 2022).

Baselines

We compare the approach presented in this paper against three baselines:

- **Mask all entities from generic NER**: this baseline simply considers that all named entities (as detected by the neural NER model fine-tuned on Ontonotes) constitute a privacy risk and need to be masked.
- **Mask all entities from privacy-enhanced recognizer**: same as above, but with entities extracted with the privacy-enhanced recognizer from Section 3.1.

	CODE			ORG			PERSON			DATETIME			LOC			QUANTITY			DEM			MISC		
	P	R	F_1	P	R	F_1	P	R	F_1	P	R	F_1	P	R	F_1	P	R	F_1	P	R	F_1	P	R	F_1
Gen. NER	.98	.79	.88	.62	.91	.74	.97	.64	.77	.90	.99	.94	.34	.92	.50	.39	.75	.51	.77	.42	.54	.03	.26	.05
Gen. NER+Gaz.	.97	.93	.95	.78	.95	.86	.98	.95	.96	.93	.94	.94	.72	.90	.80	.95	.72	.81	.28	.73	.40	.10	.36	.15
Enhanced ER	.98	.97	.97	.76	.96	.87	.98	.98	.98	.92	.99	.95	.53	.89	.66	.42	.84	.56	.27	.76	.40	.10	.32	.15

Table 2: Token-level precision, recall and F_1 score by entity type on the test set of the TAB corpus. The results include the two baselines (generic NER model, either alone or augmented with the gazetteer with terms extracted from Wikipedia properties) as well as the privacy-enhanced entity recognizer fine-tuned on the silver corpus. Labels such as ORG and LOC are considered to be interchangeable, as many entities of those types can be assigned to both, as is the case for e.g. country names.

- **Mask most specific entities**: this baseline only considers as risky the entities of type CODE, PERSON, DATETIME, LOC or QUANTITY extracted with the privacy-enhanced recognizer, which were most frequently masked in the TAB corpus. Entities of other types are not considered to constitute a privacy risk.

Privacy risk measures

As explained in 3.2.1, the BERT-based privacy risk relies on a threshold to determine whether an entity or combination of entities should be seen as a privacy risk (based on log probabilities). The threshold is selected empirically based on the development set of the TAB corpus (see Appendix), and set to a value t = -3.5. We also include in the evaluation the privacy risk measure based on web queries from Section 3.2.2 and the neural model trained on labelled data from the training section of the TAB corpus.

Table 3 provides the evaluation results, split into two distinct scenarios, a *zero-shot* scenario in the absence of manually labelled data, and a *fine-tuned* scenario where the TAB training corpus was used to both further fine-tune the privacy-enhanced entity recognizer and also train a supervised model to predict whether an entity should be masked.

For the zero-shot scenario, we can observe that the two baselines (*Generic NER, Privacy-enhanced recognizer*) tend to over-mask the text. The probabilities derived by the LM model (*BERT-based risk*) show a relatively high recall on both direct and quasi identifiers, but a lower precision score, while the opposite holds for the strategy based on risk measures from the emulated web queries.

Unsurprisingly, the performance increases when manually labelled data is available (fine-tuned scenario). The two baselines for this category (*Privacy-enhanced + FT, Mask all* and *Mask most specific*) show both a high precision and recall score, as the detected PII comes closer to the manual annotations. For the LM probabilities we notice a slight drop in precision, which is presumably due to longer spans (especially for the MISC category) which were masked by the risk measure but not the annotators. The web model on the other hand shows a higher recall score and a lower precision score. Finally, the risk measure that is best able to balance data utility and privacy risk is the classifier trained on manual data (*Supervised risk*).

We can observe from Table 3 that the weighted precision score is generally higher than the uniform precision. This indicates that the false positives were of a more general nature so their information content was low. This gives us a better overview of the utility of the masked text. An example text from the test dataset with different masking decisions can be found in the Appendix.

We conduct an error analysis on the two optimal approaches for each scenario and we notice two trends. On the one hand, the masking strategies failed to mask some entities that the annotators decided to mask (mainly dates, locations, laws, foreign words e.g. *Florida, England, 1987, CPT/Inf (2000)17, önlisans etc.*)

We also notice a trend of partial masking, which results in partial or correct masking decisions, something that is not reflected in the evaluation results as they do not match with any of the decisions made by the annotators. Some examples, where the left side corresponds to the human annotation and the right the decision made by one of the two masking strategies, are:

- United Kingdom nationals [MASK] - United Kingdom [MASK]
- medical secretary [MASK] - secretary [MASK]
- SEK 147,000 (approximately 15,800 euros [EUR]) [MASK] - SEK 147,000 [MASK] 15,800 euros [EUR] [MASK]

Entity recognition	Masking strategy	P	WP	R_{all}	R_{direct}	R_{quasi}	F_1
Zero-Shot							
Generic NER	Mask all	.41	.58	.91	.95	.88	.57
Privacy-enhanced	Mask all	.44	.52	.96	.99	.94	.60
Privacy-enhanced	BERT-based risk	.57	.62	.91	.98	.83	.70
Privacy-enhanced	Web query risk	.82	.84	.50	.66	.40	.62
Privacy-enhanced	BERT-based risk + Web query risk	**.57**	**.60**	**.91**	**.99**	**.84**	**.70**
Fine-tuned							
Privacy-enhanced + FT	Mask all	.52	.57	.98	.99	.97	.68
Privacy-enhanced + FT	Mask most specific	.76	.77	.84	.98	.87	.83
Privacy-enhanced + FT	BERT-based risk	.54	.58	.95	.99	.89	.69
Privacy-enhanced + FT	Web query risk	.64	.68	.84	.91	.78	.73
Privacy-enhanced + FT	Supervised risk	**.79**	**.81**	**.89**	**.99**	**.89**	**.84**
Privacy-enhanced + FT	Supervised risk + Web query risk	.64	.69	.94	.99	.93	.76
Privacy-enhanced + FT	All three risk measures	.54	.58	.97	.99	.95	.69

Table 3: Evaluation results on the test portion of the TAB corpus.

- “Privacy-enhanced”: privacy-enhanced entity recognizer from Section 3.1
- ‘Privacy-enhanced + FT”: same model after fine-tuning on the semantic labels from the TAB training set.
- “BERT-based risk”: masking strategy in which text spans indicated as risky by the BERT-based risk measures (Section 3.2.1), using the optimization algorithm from Section 3.3 to make the final decisions.
- “Web based risk”: similar strategy, this time using the results from emulated web queries as risk measures.
- “Mask most specific”: mask the entities of type CODE, PERSON, DATETIME, LOC or QUANTITY.
- “Supervised risk” refers to the risk measure based on a neural model estimated from the masking decisions of human experts in the training set of the TAB corpus.

P=Precision, *WP*=Weighted precision, as defined in (Pilán et al., 2022), R_{all}=Recall for all identifiers, R_{direct} = Recall for direct identifiers, R_{quasi} = Recall for quasi identifiers (as annotated in the TAB corpus), and F_1 = harmonic mean of precision and recall on all identifiers. The best results are highlighted in bold.

- 25 April, 24 May, 16 June, 6 July and again on 27 July 1994 [MASK] - 25 April [MASK] 24 May [MASK] 16 June [MASK] 6 July [MASK] 27 July 1994 [MASK]

The task of text sanitization can have many different but correct masking solutions, as long as the identity of the individual is protected. Evaluating against one gold standard is very useful since we can judge the extend of the usefullness of the approaches we propose. However, it also means that the evaluation is limited by the (sometimes subjective) decisions made by the annotators.

5 Conclusion

This paper presented a novel approach to automated text sanitization. The approach relies on the detection of different types of PII as well as empirical measures of re-identification risk based on language models, web queries, and (when available) manually labelled data. Such an approach makes it possible to derive explicit estimates of the privacy risk associated with a given masked document. Those estimates can be employed to find the most appropriate trade-off between data utility and privacy protection, depending on the particular requirements of the application.

The approach is evaluated on the newly released Text Anonymization Benchmark (Pilán et al., 2022). The evaluation results demonstrate the potential of the approach – both in the presence and absence of manually labelled data –, but also highlight the difficulty of the task.

Future work will focus on refining the privacy-enhanced entity recognizer, to improve the detection of MISC entities. We also aim to investigate more flexible masking strategies, such as the replacement of detected entities by more general text spans (such as [Orléans] being replaced by [city in France]), instead of merely hiding the entities from the text. Finally, we wish to explore evaluation measures that do not rely on manually labelled data, as text sanitization is a task that may admit several, equally valid solutions (Lison et al., 2021).

Table 4: Training Parameters for the RoBERTa model

BERT-based privacy risk

Figure 3 shows an example of a precision-recall curve used to determining thresholds for the BERT-based privacy risk measure. We calculated a general precision and recall score for different thresholds and chose one that shows a good balance between privacy risk and data utility. Stricter thresholds favor recall but result in a low precision score, while more lenient thresholds showed a drop in recall but better precision score.

Neural model emulating web queries

The architecture described in Section 3.2.2 is presented below in Figure 4.

Example of masking decisions

We also present in Figure 5 an example of different masking decisions (see for a text from the TAB test dataset, as mentioned in Section 4.2.

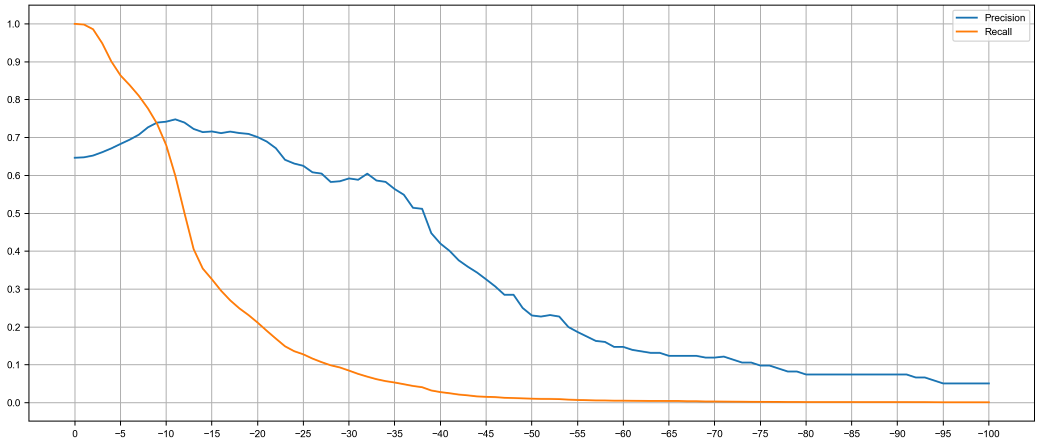

Figure 3: Precision-Recall curve for determining appropriate thresholds

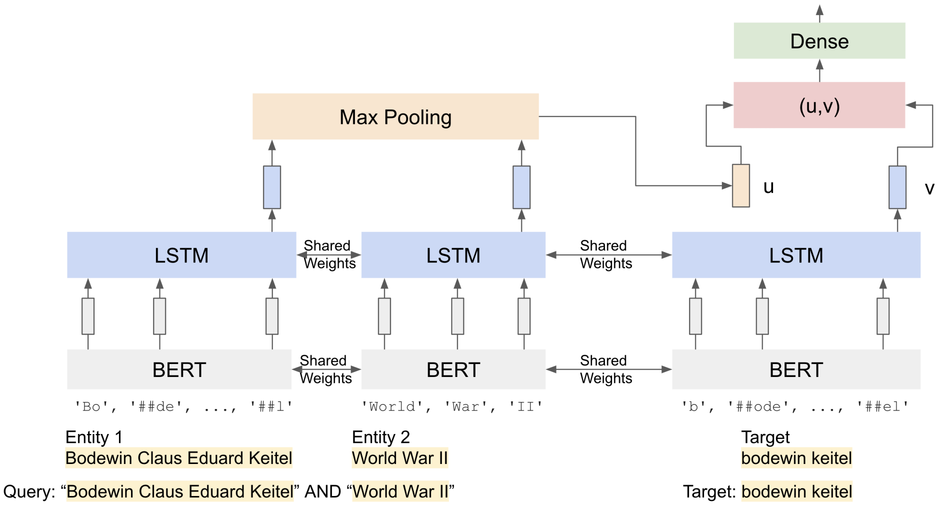

Figure 4: Architecture of the web query model

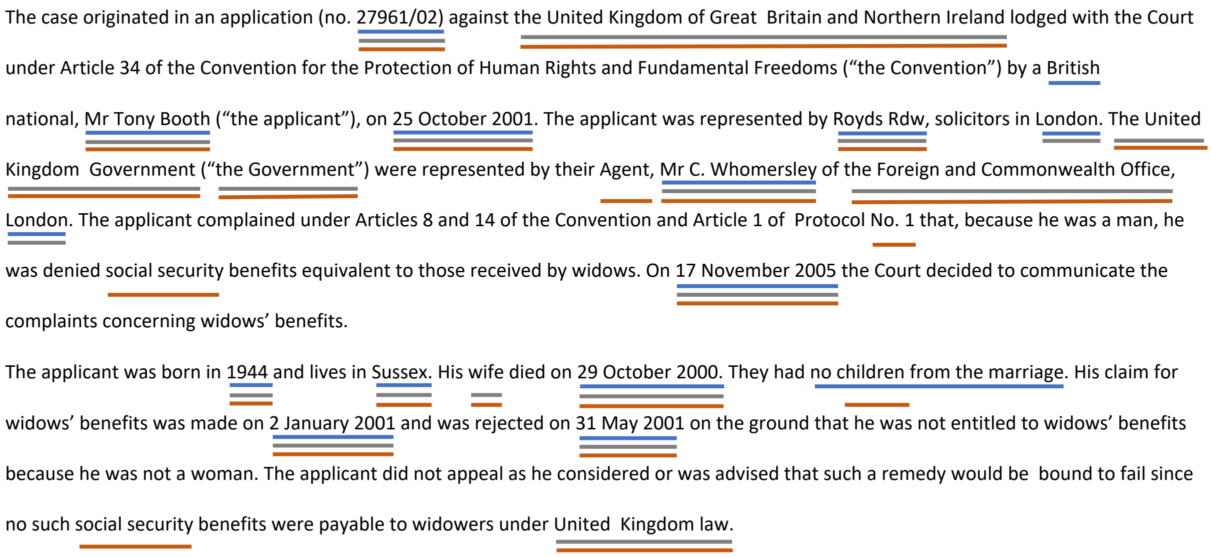

The case originated in an application (no. 27961/02) against the United Kingdom of Great Britain and Northern Ireland lodged with the Court under Article 34 of the Convention for the Protection of Human Rights and Fundamental Freedoms ("the Convention") by a British national, Mr Tony Booth ("the applicant"), on 25 October 2001. The applicant was represented by Royds Rdw, solicitors in London. The United Kingdom Government ("the Government") were represented by their Agent, Mr C. Whomersley of the Foreign and Commonwealth Office, London. The applicant complained under Articles 8 and 14 of the Convention and Article 1 of Protocol No. 1 that, because he was a man, he was denied social security benefits equivalent to those received by widows. On 17 November 2005 the Court decided to communicate the complaints concerning widows' benefits.

The applicant was born in 1944 and lives in Sussex. His wife died on 29 October 2000. They had no children from the marriage. His claim for widows' benefits was made on 2 January 2001 and was rejected on 31 May 2001 on the ground that he was not entitled to widows' benefits because he was not a woman. The applicant did not appeal as he considered or was advised that such a remedy would be bound to fail since no such social security benefits were payable to widowers under United Kingdom law.

Figure 5: Example of masking decisions on the excerpt of an ECHR court case. The *blue line* denotes masking decisions made by a human annotator. The *grey line* corresponds to text spans to be masked after being detected by the privacy enhanced entity-recognizer and passed through the two privacy risk measures. Finally, the *orange line* shows spans to be masked after detection by the fine-tuned entity-recogniser (fine-tuned on the TAB training dataset) and the three risk assessments mentioned in Table 3.

AGRank: Augmented Graph-based Unsupervised Keyphrase Extraction

Haoran Ding and Xiao Luo
Purdue School of Engineering and Technology
IUPUI
USA
hd10@iu.edu, luo25@iupui.edu

Abstract

Keywords or keyphrases are often used to highlight a document's domains or main topics. Unsupervised keyphrase extraction (UKE) has always been highly anticipated because no labeled data is needed to train a model. This paper proposes an augmented graph-based unsupervised model to identify keyphrases from a document by integrating graph and deep learning methods. The proposed model utilizes mutual attention extracted from the pre-trained BERT model to build the candidate graph and augments the graph with global and local context nodes to improve the performance. The proposed model is evaluated on four publicly available datasets against thirteen UKE baselines. The results show that the proposed model is an effective and robust UKE model for long and short documents. Our source code is available on GitHub[1].

1 Introduction

The mainstream unsupervised keyphrase extraction (UKE) approaches fall into one of three types: statistical, graph-based, and deep learning approaches. The statistical methods include the TF-IDF-based approach and other recent works (Campos et al., 2020; Beliga et al., 2016), which utilize term frequency, document frequency, word offsets and the number of n-grams to calculate the importance of the candidates. The graph-based methods treat the candidates as the nodes in a graph (Gollapalli and Caragea, 2014; Wan and Xiao, 2008). The edges are calculated based on candidates' co-occurrences, semantic similarity, or other relations. Graph-based algorithms then determine the importance of candidates. Several recent studies have shown that embedding-based methods can achieve excellent performance on unsupervised keyphrase extraction, such as JointModeling (Liang et al., 2021), AttentionRank (Ding and Luo, 2021), SIFRank (Sun et al., 2020), KeyGames (Saxena et al., 2020) and EmbedRank (Bennani-Smires et al., 2018). These approaches base candidates' importance on the distance or similarity of candidate embeddings, and some consider the global or local context.

We propose an augmented graph-based unsupervised model to identify keyphrases from documents. The model extracts attention from the pre-trained BERT model to generate a candidate keyphrase graph, then augments the attention graph with nodes that present the global and local context. Similar to the baseline approaches, noun phrases are extracted as candidates representing the nodes on the graph. The co-occurrence of candidates determines graph edges within the sentential context. Edge weights between the candidates are calculated based on the mutual attention extracted from the pre-trained BERT model and the indexes of the sentences where the candidates are located. The candidate graph adds the global and local contexts as document and sentence nodes. The edge weights between the document node and candidates and the edge weights between sentence nodes and candidates are calculated based on the cosine similarity between their embeddings. The graph is then adjusted by removing nodes and edges based on the document frequency and edge weights. Finally, the ranking of each candidate is calculated using the weighted PageRank algorithm.

We summarize our contributions as follows:

- A novel augmented graph-based unsupervised keyphrase extraction (UKE) model considering global and local context is proposed and evaluated using four benchmark datasets.
- The mutual attention extracted from the pre-trained language model is utilized to build a weighted graph.
- The proposed model works better than or is competitive with the state-of-the-art UKE baselines.

2 Methodology

Our model has three main parts: (1) Candidate Graph Generation, in which we convert each document into a weighted graph with candidates as nodes and attention between candidates in a sentential context as weighted edges; (2) Graph Augmenting, in which we add a document node and sentence nodes to emphasize the global and local context and their relations to the candidates; (3) PageRank Scoring, in which we apply the weighted PageRank algorithm on the graph to rank candidates to identify keyphrases.

2.1 Candidate Graph Generation

To build the candidate graph, we first extract candidates from a document, then add weighted edges between each pair based on the sentence level self-attention mechanism. Furthermore, the edge weights also are influenced by the importance of the sentences containing the candidates' pairs.

Candidates Generation. The candidates are extracted using the module implemented in the previous approach (Bennani-Smires et al., 2018). The module first uses part of speech (PoS) to tag the nouns, verbs, pronouns, and adjectives. Then, the noun phrases are extracted using the NLTK[2] package as candidates. In our research, the punctuation are removed from the candidates, except '-'. The stemming is applied to candidates and ground truth keyphrases for model building and performance evaluation. The effectiveness of stemming is investigated in the ablation study section.

Edge Weight Generation. The generation of edge weight is based on the mutual attention between candidates extracted from the pre-trained BERT model (Devlin et al., 2018). Clark et al. (2019) have shown that important syntactic and semantic information is captured in attention maps of the pre-trained BERT model. To compute the mutual attention between candidates, we utilize the methods introduced by Ding and Luo (2021) and Clark et al. (2019) to extract attention between words. The attention between words is then aggregated to attention between phrases.

For a sentence with n words, the mutual attention mapping between words can be presented as a matrix (A).

$$A = \begin{bmatrix} a_{11} & \cdots & a_{1n} \\ \vdots & \ddots & \vdots \\ a_{n1} & \cdots & a_{nn} \end{bmatrix}$$

a_{ij} is the attention value that word w_i projects to word w_j within the same sentence s. If a candidate is a phrase with multiple words, we sum the word attention into phrase attention. Given candidate $c_1 = \{w : w_i \in c_1\}$ with n words and candidate $c_2 = \{w : w_j \in c_2\}$ with m words, the attention between c_1 and c_2 is the sum of the attention that the words in c_1 project to the words in c_2, shown as Equation 1.

$$a(c_1, c_2) = \sum_{i}^{n} \sum_{j}^{m} a_{ij} \qquad (1)$$

Fig. 1 shows a visual example of the mutual attention values between phrases. Given a document's title – "Standards for service discovery and delivery", the colored rows in the heatmap represent the attention project from words/phrases labeled on the y-axis to the words/phrases labeled on the x-axis.

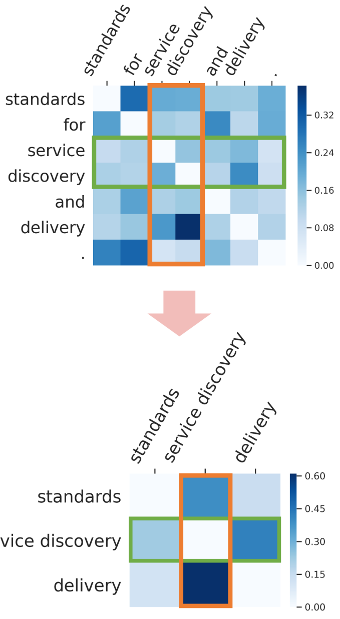

Figure 1: Attention aggregation from words to phrases (The attention values between identical words or phrases are set to zeros.)

$a(c_1, c_2)$ indeed represents the weight of the directed edge from c_1 to c_2 within sentence s, shown in Equation 2.

$$v_s < c_1, c_2 >= a(c_1, c_2) \qquad (2)$$

[2] https://github.com/nltk

To generate undirected weighted edges, we sum edge weights from c_1 to c_2 and from c_2 to c_1 in all sentences containing c_1 and c_2, shown as Eq. 3.

$$v(c_1, c_2) = \sum_{s \in doc} (v_s < c_1, c_2 > + v_s < c_2, c_1 >) \tag{3}$$

Edge Weight Adjustment. Campos et al. (2020) has shown that the first few sentences of an article often summarize the main topic and emphasize the domain of the work. Therefore, we adjust the edge weights (v) according to the positions of the sentences (i_s) containing the edges (Eq. 4).

$$v(c_1, c_2) = v(c_1, c_2) \times [1+(k-i_s)/10]^2, \ if \ i_s < k \tag{4}$$

The weight of edge (c_1, c_2) increases proportionally according to the index (i_s) of the first sentence containing candidates c_1 and c_2. k is the threshold for sentence position. When the sentence index exceeds k, the edges contained in the sentence have no weight adjustment. k can be fine-tuned in terms of the number of sentences based on the length of the document. For a long article, the threshold k can be set to the number of sentences in the abstract or introduction. Articles in different fields will have different k. In the following ablation study, we explored the effect of different k. k is designed to be a multiple of 10. For short documents containing less than ten sentences, k is set to 10.

2.2 Graph Augmenting

The candidate graph does not consider the relations between each candidate and the document's global context and the relations between the candidates and each sentence's local context. Hence, we add document and sentence nodes to augment the candidate graph with the global and local context.

Document Node. The candidates ($\{c_1, ..., c_r\}$) extracted from the document are concatenated as the document node representation. The edge weight between the document node d and a candidate node c is their embeddings' cosine similarity, shown in Equation 5.

The document node embedding (e_d) and the candidate node embedding (e_c) are generated by feeding the text representations of the document or candidate into a pre-trained BERT model. The self-attention mechanism of BERT generates a context-based embedding for each member word of a text. A document or candidate node's embedding is generated by summing up the member words' embeddings of the node. We use the bert-embedding[3] package to generate word-level embeddings.

The α_d is a coefficient value to adjust edge weights between the document and candidates. It can be set to the average number of sentences in a corpus.

$$v(d, c) = \frac{e_c \cdot e_d}{||e_c|| \cdot ||e_d||} \times \alpha_d \tag{5}$$

Sentence Nodes. A sentence node is represented using its original sentence content. The sentence node embedding (e_s) is generated using the same way as the document node embedding generation. The edge weight between candidate c and sentence s equals the cosine similarity of their embeddings, shown in Equation 6.

$$v(s, c) = \frac{e_c \cdot e_s}{||e_c|| \cdot ||e_s||} \tag{6}$$

Figure 2 shows a visualization example of an augmented graph of a document randomly selected from the dataset Inspec. The blue-colored nodes represent the stemmed candidates. The document node and the sentence nodes are pink-colored and green-colored, respectively. The edge weights between pairs of candidates and between candidates to document or sentence nodes are shown. For demonstration purposes, the edge weights are multiplied by ten and rounded. The original document content is shown in Fig. 3, and the ground truth keyphrases are highlighted. In this example, 'Service Location Protocol' is a labeled keyphrase. In the augmented graph, the edge weight between nodes '*servic locat protocol*' and '*race*' is high as calculated using BERT mutual attention. 'Service discovery' is another labeled keyphrase and occurs in four different sentences. Hence, in our augmented graph, the node '*servic discoveri*' has connections with many candidates. This example reveals that our augmented graph has the mechanism to emphasize the importance of the edges and the nodes based on the document content.

Graph Pruning. To reduce the computational cost and improve the performance, we prune the graph by removing some nodes based on their NLP features and some edges based on the edge weights distribution (Faralli et al., 2018). The following steps are applied:

[3] https://pypi.org/project/bert-embedding/

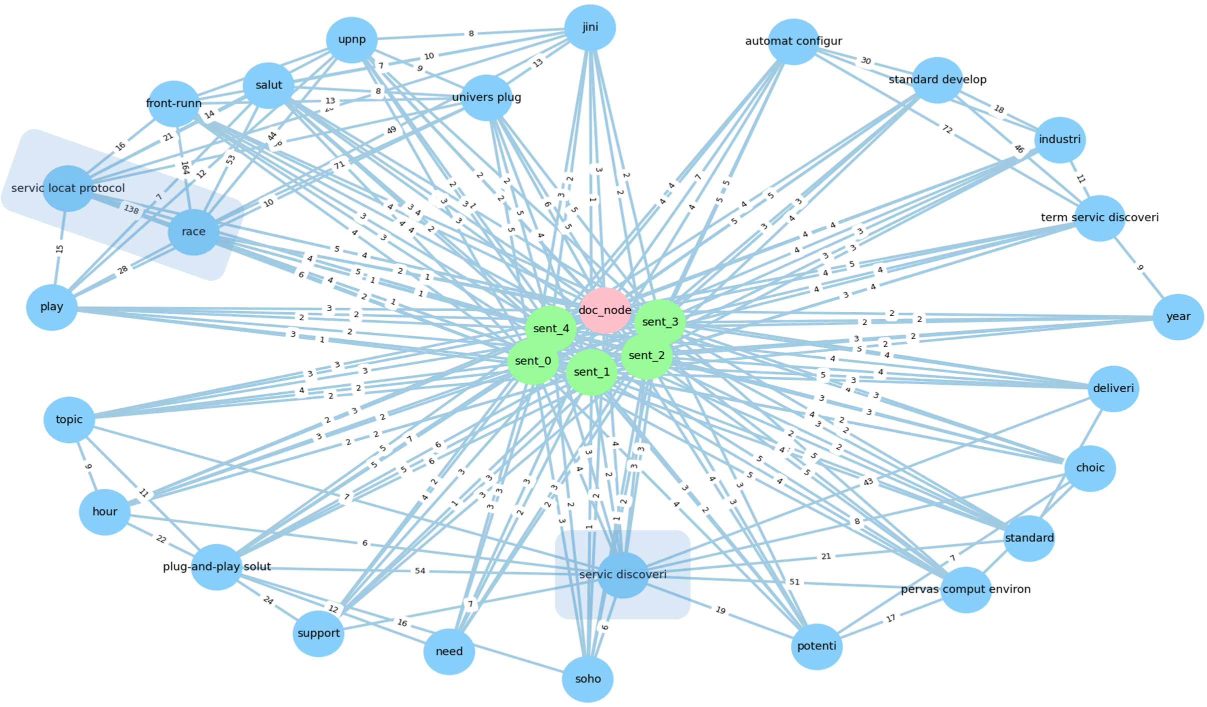

Figure 2: An example of an augmented graph. (All candidates are stemmed.)

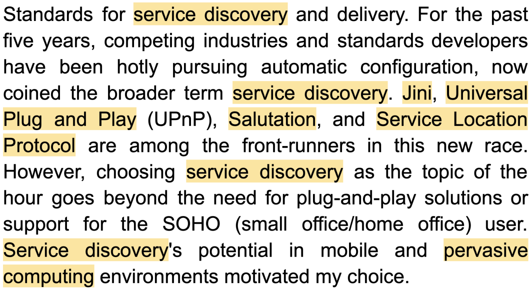

Standards for service discovery and delivery. For the past five years, competing industries and standards developers have been hotly pursuing automatic configuration, now coined the broader term service discovery. Jini, Universal Plug and Play (UPnP), Salutation, and Service Location Protocol are among the front-runners in this new race. However, choosing service discovery as the topic of the hour goes beyond the need for plug-and-play solutions or support for the SOHO (small office/home office) user. Service discovery's potential in mobile and pervasive computing environments motivated my choice.

Figure 3: Example document with ground truth keyphrases highlighted.

(1) Remove the candidate node when its document frequency exceeds some threshold. High document frequency often indicates that the term is a generic one in a corpus. For each corpus, we calculate the document frequency of all candidates and determine the threshold by the Elbow law[4].

(2) Remove the edge between a pair of candidates when the edge weight is lower than a threshold, such as the 25^{th} percentile of the candidate-candidate edge weights distribution.

(3) Remove the edge between a sentence and a candidate when the edge weight is lower than a threshold (p_s) determined by the sentence-candidate edge weights distribution.

2.3 PageRank Scoring

The pruned graph is fed into the weighted PageRank algorithm (Xing and Ghorbani, 2004) to calculate the importance score of each candidate. The score ($PR(c)$) of a candidate (c) is calculated as Equation 7.

$$PR(c) = (1-\delta) + \delta \times \sum_{c_n \in B_c} PR(c_n) \times v^2(c, c_n) \tag{7}$$

Where δ is the dampening factor, c_n is a neighbor node of c, and B_c is the set of all candidate c neighbors. $v(c, c_n)$ is the weight of the edge (c, c_n). The weighted PageRank algorithm considers in-edge and out-edge weights. Since we have an undirected graph, in-edge and out-edge weights are treated the same.

During the final ranking, the document and sentence nodes are excluded, and the candidates with a high document frequency, e.g., higher than a threshold df_θ, are also excluded.

3 Experiment

3.1 Datasets and Evaluation Metrics

The performance of our model is evaluated on four benchmark datasets[5]. Datasets Inspec

[4] https://pypi.org/project/kneed/

[5] https://github.com/LIAAD/KeywordExtractor-Datasets

(Hulth, 2003) and SemEval2017 (Augenstein et al., 2017) contain short documents, and datasets SemEval2010 (Kim et al., 2010) and Nguyen2007 (Nguyen and Kan, 2007) contain long documents. Table 1 summarizes the basic statistics of the datasets. The performance of keyphrase extraction is evaluated using F1 scores at the top 5, 10, and 15 ranked keyphrases.

To make an appropriate comparison with the baselines, we follow the common practice of using the uncontrolled annotated keyphrases of dataset Inspec and using the test set of SemEval2010 with 100 documents in our experiment. All extracted and labeled keyphrases are stemmed for evaluation.

Table 1: A Summary of Datasets

dataset	Document Number	Average Sentence Number	Average Word Number
Inspec	500	6	134
SemEval2017	493	7	168
SemEval2010	100	362	7845
Nguyen2007	209	235	5088

3.2 UKE Baselines

We compared our model against 13 baseline unsupervised keyphrase extraction models categorized into three categories: (1) Statistical models[6]: TF-IDF, YAKE! (Campos et al., 2020); (2) Graph-based models[7]: TextRank (Mihalcea and Tarau, 2004), SingleRank (Wan and Xiao, 2008), TopicRank (Bougouin et al., 2013), PositionRank (Florescu and Caragea, 2017b), MultipartiteRank (Boudin, 2018a); (3) Deep learning-based or mixed models: EmbedRank[8] (Bennani-Smires et al., 2018), SIFRank[9] (Sun et al., 2020), KeyGames[10] (Saxena et al., 2020), JointModeling[11] (Liang et al., 2021), AttentionRank[12] (Ding and Luo, 2021), MDERank[13] (Zhang et al., 2021).

3.3 Hyperparameter Setting

The BERT-Base is used for attention extraction (Clark et al., 2019) and node embedding generation[14]. The Hyperparameters for each dataset are fine-tuned and set as follows:

For all datasets, δ is set to 0.85, and α_d is set to the average sentence number of the corpus. For Inspec and SemEval2017, k is set to 10, df_θ is set to 5, and p_s is set to the 60^{th} and the 75^{th} percentile, respectively. For SemEval2010, k is set to 20, df_θ is set to 25. For Nguyen2007, k is set to 90, df_θ is set to 45. Sentence nodes are not added to the augmented graphs for SemEval2010 and Nguyen2007 due to the computational cost and the need.

On a computer with an Intel i7 9700k, 48G RAM and RTX 2060 graphics card, generating an augmented graph costs less than 10 seconds for a short document and about one minute for a long document.

3.4 Results

Table 2 compares AGRank and the baseline UKE models using F1@5, 10, and 15. The values for baseline models are those presented in the original papers or better results published in other papers recently. Since not all datasets are used in the original papers, we applied the baselines to the datasets using the published code. Those produced results are tagged with *.

In most cases, the deep learning-based or mixed models outperform the statistical and graph-based models on short document datasets (Inspec and SemEval2017). AGRank outperforms all UKE baselines on Inspec and performs better than most baselines except AttentionRank on SemEval2017.

Our proposed model has more apparent advantages on long document datasets. For the dataset SemEval2010, the F1@5 score is more than 3% higher than the best UKE baseline, and F1@10 and @15 are also about 2% higher than the best UKE baseline.

It is worth noting that the AGRank can often rank the keyphrases in the top 5. The results show that the F1@5 values gained by AGRank on all datasets are 1.5% - 3% higher than the best-performed UKE baseline model on Inspec, SemEval2010, and Nguyen2007. The F1@5 value gained by AGRank is also competitive with the best UKE baseline model - AttentionRank, on the SemEval2017 dataset.

4 Ablation Study

4.1 Analysis of Stemming

Candidate stemming causes nodes to merge and change the graph's structure. Table 3 compares the performance of AGRank with and without stemming. The results show that stemming improves the model performance on SemEval2017, SemEval2010 and Nguyen2007. However, the improvements on the Inspec are not significant.

4.2 Analysis of Graph Augmenting and Edge Weight Adjustment

The proposed model augments the graph by adding document and sentence nodes to provide global and local context. We present the impact of the context nodes in Table 3. The model takes better advantage of document node addition on Inspec. In contrast, the sentence node addition contributes more to the model performances on SemEval2017.

Interestingly, the model performance on SemEval2010 and Nguyen2007 are marginally better without document node addition. We think the document node generated for a long document cannot sufficiently capture the overall context by generating one single embedding.

In our model, the weights of edges between candidates are also adjusted according to the sentence position. From Table 3, the edge weight adjustment based on sentence position has a higher impact on SemEval2010 and Nguyen2007. Without using it, the performance could drop up to 2%.

4.3 Analysis of Hyperparameters

We evaluated the impact of the hyperparameters of our model. Fig. 4 shows the hyperparameter tuning of k - the parameter to adjust edge weights by sentence position, p_s - the parameter to remove the edges between the sentences and candidates based on weight distribution, and df_θ - the parameter to exclude the candidates based on document frequency. Note that the tuning study of parameter k only applies to long documents. For short documents with less than ten sentences, k is set to 10. The parameter p_s is only applicable to short documents since sentence nodes are not added to the augmented graphs for long documents due to the computational cost.

We investigated the impact of threshold k from 10 to 130 with a step size of 10. Fig. 4 shows that for the long document dataset SemEval2010, the best F1@15 is gained when the first 20 sentences are considered. Whereas for the long document dataset Nguyen2007, the highest F1@15 is achieved when the first 90 sentences are considered. These results show that adjusting candidates' mu-

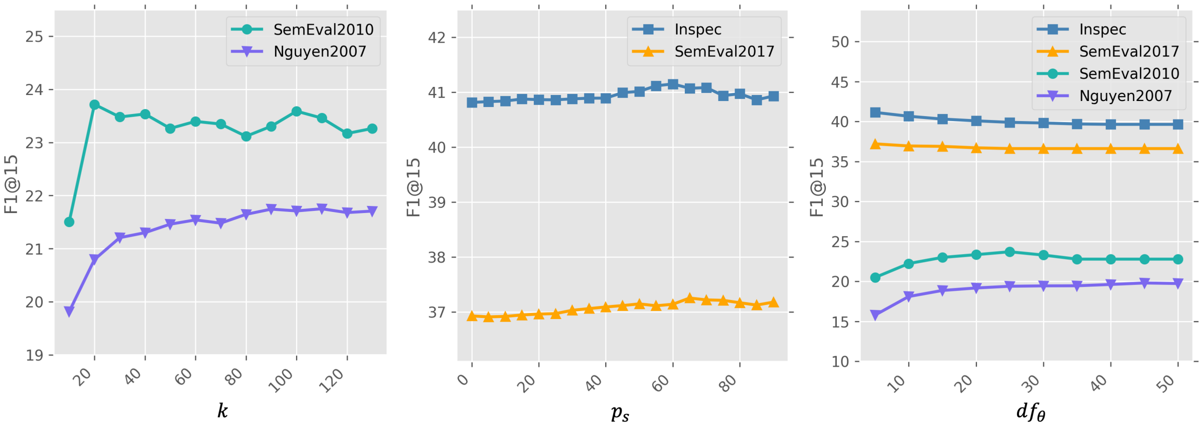

Figure 4: Evaluation of the Hyperparameters on Model Performance

tual edge weights by sentence position improves model performance, although k needs to be tuned for different datasets.

We showed that adding sentence nodes can slightly improve the performance on short document sets, but the sentence nodes might not have strong relationships with all the candidates. Tuning the number of edges between sentence nodes to candidates can reduce the computational cost and optimize the model performance. We adjusted the p_s from 0 to the 90^{th} percentile based on the weight distribution. Fig. 4 shows that for datasets Inspec and SemEval2017, optimal p_s are between the 60^{th} and the 80^{th} percentile.

We also tuned df_θ to see its impact on the performance. Fig. 4 shows that df_θ has less impact on short document sets – Inspec and SemEval2017. Performance of F1@15 can improve about 2% after tuning the df_θ on long document sets – SemEval2010 and Nguyen2007.

4.4 Case Study

AGRank performs closely with the AttentionRank on short documents. To observe the difference between AGRank and AttentionRank, we randomly select a document in SemEval2017. The heatmap in Fig. 5 presents the importance scores of the candidates calculated by the two models. We normalized the original scores to highlight the candidates with a heatmap. The labeled keyphrases are bold, italic, and underlined. AGRank scores higher for keyphrases ‘construct model’ and ‘low emotional involvement’, whereas the AttentionRank ranks ‘online teaching reformation’ higher. Since AttentionRank uses accumulated self-attention, long candidates with multiple words obtain higher scores.

Figure 5: Comparison on Short Document

JointModeling performs well on the long document set SemEval2010. Fig. 6 shows the performances of JointModeling and AGRank on a selected paragraph taken from an article in SemEval2010. The heatmap shows the difference in the strategies of the two models. AGRank has fewer candidates than JointModeling, which attribute to our graph pruning step. The candidates with high document frequency and small neighbor edge weights are removed. Since the edge weights of the augmented graph are generated based on the extracted attention of the pre-trained BERT model, AGRank assigns high scores to ‘commitment’ and ‘Bayesian games’.

els based on statistical techniques convert contextual information into statistical features of candidates and then calculate candidate scores for ranking. Rose et al. (2010) utilized the ratio of word frequency and the number of co-occurring neighbors to evaluate the importance of the candidates. Besides term frequency and neighbor co-occurrence, Campos et al. (2020) also considered more contextual features to identify keyphrases, including the offsets of the candidates, the sentence positions of the candidates first shown, etc. Models based on graph methods treat candidates as nodes of the graph, convert certain relations between candidates into edges of the graph, then use a graph algorithm to calculate the candidates' scores (Mihalcea and Tarau, 2004). Wan and Xiao (2008) utilized a clustering method to select k-Nearest-Neighbor documents to create a graph for a single document and used a graph sorting algorithm to generate keyphrases. Bougouin et al. (2013) employed a clustering method to generate several topics of a document and assign the topics to candidates, then utilized the TextRank model to rank topics; the most representative candidates of the top-ranked topics are extracted as keyphrases. Wang et al. (2014) utilized the word embedding and word frequency to generate weighted edges between words, then used the weighted PageRank algorithm to compute candidate scores and rankings. Florescu and Caragea (2017a) proposed the Position-Biased PageRank algorithm, which incorporates the candidate positions in the document into the ranking calculation. Boudin (2018b) proposed the Multipartite graph model, which encodes the topic information within a multipartite graph to utilize candidate mutual relations. yeon Sung and Kim (2020) extracted hierarchical relationships to determine which edges and phrases should be used and evaluated the nodes according to their inflowing edges. Bennani-Smires et al. (2018) proposed the EmbedRank, which uses a pre-trained language model to generate the document and candidate embeddings and calculate the similarity between them to select more representative keyphrases. Sun et al. (2020) proposed SIFRank, which invokes both the similarity between candidate and document embeddings and the candidate position and frequency to calculate the correlation between candidates and the document. Saxena et al. (2020) investigated an evolutionary game theory model that uses candidate embeddings and statistics to calculate confidence scores to determine whether a candidate is a keyphrase. Ding and Luo (2021) extracted attention mapping weights and then integrated accumulated attention weights with the cross-attention similarity to rank the candidates. Liang et al. (2021) integrated bounded sentences and candidate local relations based on document-to-candidate global relations, then used both jointly to determine the importance of candidates. Zhang et al. (2021) proposed MDERank, which ranked candidates using the similarity between the BERT embeddings of the source document and the masked document.

6 Limitations, Conclusions, and Future Work

Although our augmented graph-based model performs better than the compared baselines, the graph augmentation process is designed with quite a few hyperparameters that need to be tuned for datasets of different domains to obtain optimal performance. We believe this can be further improved by automating the hyperparameter tuning process.

Our research investigated the integration of graph-based and deep learning-based models for unsupervised keyphrase extraction. The pre-trained BERT model is utilized to extract candidates' mutual attention to build the initial graph. Global and local context information are added through graph augmenting. PageRank algorithm is used to calculate the ranking scores. We compared the proposed model against 13 baseline unsupervised keyphrase extraction models on four benchmark datasets. The ablation study shows that the edge weight adjustment based on sentence position has a higher impact on the long document sets. Adding the document and sentence nodes improves the performance for short document sets.

Future work includes investigating possible solutions to reduce the number of parameters and improve efficiency. We also plan to compare our unsupervised model against supervised keyphrase extraction models to demonstrate the advantages and performances.

Abstract

With a knowledge graph and a set of if-then rules, can we reason about the conclusions given a set of observations? In this work, we formalize this question as the *cognitive inference* problem, and introduce the Cognitive Knowledge Graph (CogKG) that unifies two representations of heterogeneous symbolic knowledge: expert rules and relational facts. We propose a general framework in which the unified knowledge representations can perform both learning and reasoning. Specifically, we implement the above framework in two settings, depending on the availability of labeled data. When no labeled data are available for training, the framework can directly utilize symbolic knowledge as the decision basis and perform reasoning. When labeled data become available, the framework casts symbolic knowledge as a trainable neural architecture and optimizes the connection weights among neurons through gradient descent. Empirical study on two clinical diagnosis benchmarks demonstrates the superiority of the proposed method over time-tested knowledge-driven and data-driven methods, showing the great potential of the proposed method in unifying heterogeneous symbolic knowledge, i.e., expert rules and relational facts, as the substrate of machine learning and reasoning models. The source code and data are released online[1].

1 Introduction

Symbolic reasoning methods such as rule-based expert systems (Buchanan and Shortliffe, 1984) are reliable and interpretable in solving complex inference problems in specialized domains, but are also difficult to generalize because eliciting a comprehensive set of rules from human experts is costly and time-consuming. Recently, knowledge graph (KG) as a flexible representation of symbolic knowledge has been proven successful for knowledge-based reasoning (Bordes et al., 2013) by utilizing the distributed representations to generalize from known facts to unseen yet probably true facts, which is also known as the knowledge graph completion task (Lin et al., 2015). However, such models can only represent and reason about multi-relational data in the form of (*subject*, *predicate*, *object*) triples (Liben-Nowell and Kleinberg, 2003), not conditional *if-then* rules. Therefore, current knowledge graph embedding models are not suited to solve inference problems where conclusions (outcomes) can be inferred from a set of observations.

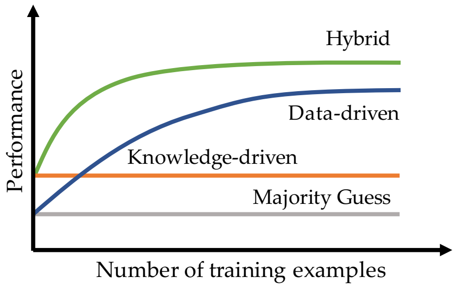

Figure 1: Illustration of impacts of training examples on different reasoning paradigms (with fixed prior knowledge). Note that the curves start w/o pre-training.

This current work is motivated by one overarching question: can we unify the representation of above heterogeneous symbolic knowledge to perform complex inference tasks? More concretely, we study the following research question. With a large-scale KG with rich relational facts and a moderate set of if-then rules as the prior knowledge, can we reason about the most likely conclusion(s) given a set of observations? With the rapid development of knowledge graph, the *knowledge acquisition bottleneck* (Muggleton and De Raedt, 1994) is greatly alleviated, making it much more practicable to jointly utilize the knowledge and data

for learning systems in today than in the past. Recent studies have shown great success in integrating the knowledge into data-driven models, and such hybrid learning system normally achieves more favorable performance than traditional methods, as presented in Fig. 1. However, there is a general absence of sufficient labeled data in some high-stake scenarios such as medical diagnosis. Moreover, such critical domains' inherent nature strictly mandates the models to be trustworthy and interpretable. These high-demanding characteristics directly challenge existing vulnerable knowledge-driven methods and data-hungry machine learning methods, and the solution still remains underexplored[2] (von Rueden et al., 2021).

In this work, we formalize the above challenge as the *cognitive inference* problem and introduce three design goals for the model to address this problem: 1) The ability to extensively inherit existing symbolic knowledge. The model is expected to leverage not only if-then rules, but also large number of facts in knowledge graphs. 2) The ability to directly utilize existing symbolic knowledge in the reasoning procedure. This allows the model to make decent predictions based on prior knowledge, even when it is not trained. Moreover, it makes the model's reasoning process interpretable. 3) The ability to be continuously optimized when training data is available. This enables the model to improve like any machine learning models. More importantly, it ensures the model's robustness so that it adapts to the nuances of real-world data that are not encoded in prior symbolic knowledge.

To achieve the above goals, we first introduce the cognitive knowledge graph (CogKG), which represents relational facts and expert rules in a unified framework. Specifically, it is a directed hypergraph with entities as nodes, and the relations or expert rules as edges. Then, we propose a novel inference framework called COGINFER that bridges the knowledge-driven and data-driven reasoning paradigms, which not only utilize explicit knowledge representations but also harvest knowledge from training examples if applicable. More precisely, it performs reasoning with symbolic knowledge, and the reasoning process could be further optimized with labeled data towards better performance. In this way, we aim to combine the symbolic reasoning and statistical learning in the same general framework COGINFER, which make our method achieve the design goals as stated above and stand out from existing works.

To make fair comparisons with existing knowledge-driven and data-driven baselines, we investigate the cognitive inference problem under both unsupervised and supervised settings. Extensive experiments on two clinical diagnosis benchmarks show that the COGINFER successfully learns from both symbolic knowledge and labeled data to address the proposed new inference task, substantially surpassing strong data-driven baselines. Even without any training examples, it still outperforms existing knowledge-driven baselines that only harvests either expert rules or knowledge graph, demonstrating the great potential of the proposed framework. The main contributions of this work are three-fold:

- We introduce a novel cognitive inference problem that reasons about conclusions from observations, which directly challenges existing methods.
- In light of this challenge, we first introduce the cognitive knowledge graph (CogKG) that represents expert rules and relational facts in a unified manner, and then develop a general framework that bridges the knowledge-driven and data-driven reasoning paradigm.
- Extensive experiments demonstrate the effectiveness of the proposed method in utilizing unified symbolic knowledge and labeled data for machine learning and reasoning.

2 The Cognitive Inference Problem

2.1 Problem Formulation

We first introduce our notations. A **knowledge graph** (KG) consists of relational facts $\mathcal{F} = \{(s_i, p_i, o_i)\}_{i=1}^{N}$, where (s_i, p_i, o_i) is a relational triple consisting of subject entity s_i, predicate p_i, and object entity o_i. The vertex set of the KG is $V = \cup_{i=1}^{N}\{s_i, o_i\}$ and its edge set is $E^e = \cup_{i=1}^{N}\{p_i\}$. The collection of **expert rules** is denoted as $\mathcal{R} = \{A_i \xrightarrow{r_i} B_i\}_{i=1}^{M}$, where $A_i \xrightarrow{r_i} B_i$ is a rule that expresses "if A_i are observed then B_i are true". $A_i, B_i \subset V$ are small sets of entities and r_i is a *hyperedge* that connects two *sets* of entities. The hyperedge set is denoted as $E^r = \cup_{i=1}^{M}\{r_i\}$. **Labeled data** $\mathcal{L} = \{(Q_i, C_i)\}_{i=1}^{L}$ is a collection of query-conclusion pairs. $Q_i, C_i \subset V$ are small sets of entities. In machine learning terms, the query

[2] See detailed discussion in Appendix A.

Table 1: Important notations and descriptions.

Notations	Descriptions
$\mathcal{F}$	Relational facts
$\mathcal{R}$	Expert rules
$\mathcal{L}$	Labeled data
$\mathcal{G}$	CogKG, $\mathcal{G} = (V, E)$
V	Entities
E	Edges, $E = \{E^e, E^r\}$
E^e	Relation edges
E^r	Rule hyperedges
Q	A query, a small set of entities
C	A conclusion, a small set of entities
$\mathcal{G}^Q$	InferGraph of query Q, $\mathcal{G}^Q \subset \mathcal{G}$
$\mathcal{E}$	Distributed representations of relational facts
P	Rule-generated neuron matrix
U	KG-generated neuron matrix
X	Final input neuron matrix
W	Weight matrix before output neurons

Q_i are input features and the conclusion C_i are prediction targets. In this work, we instead use "query" and "conclusion" to emphasize the inference nature of our problem.

The ***cognitive inference problem*** is to infer the conclusion $C \in V$ for a given query $Q \in V$. The inference is *unsupervised* if it only makes use of the knowledge graph $\mathcal{F}$ and expert rules $\mathcal{R}$; it is *supervised* if it also makes use of the label data $\mathcal{L}$.

2.2 Task Preliminaries

As the cognitive inference problem involves utilizing different resources for learning and reasoning, we assume each of them has been properly prepared before the task begins, as detailed below.

(1) **Knowledge Graph.** We assume access to a large-scale knowledge graph relevant to the problem domain. It is typically represented in the form of *(subject, predicate, object)* triples (Ji et al., 2021). These relational facts can be manually collected or automatically extracted from texts though natural language processing technologies such as named entity recognition (Yadav and Bethard, 2018; Yang et al., 2020) and relation classification (Yu et al., 2020; Han et al., 2020).

(2) **Expert Rules.** We assume access to a set of if-then rules encoding the expert knowledge of the problem domain. They are conditional statements which posit that a conclusion is true if the premises are satisfied by the input observations. It can be elicited from experts with domain knowledge. It can also be learned from domain data via machine learning and data mining (e.g., structure learning (Khosravi et al., 2010), decision tree (Quinlan, 1987), association rule mining (Han et al., 2000)).

(3) **Labeled Data.** Labeled data contains instances of queries and their corresponding conclusions in the problem domain. In this work, we consider the domain of medical diagnosis. Each piece of labeled data is a diagnosis record, where a query is a set of observed symptoms and a conclusion is a diagnosed disease. Labeled data are used for training (in supervised setting) and evaluation (in both supervised and unsupervised settings).

(4) **Entity Alignment.** The above resources may use different surface forms to refer to the same entity. It is crucial to align different surface forms using the same entity in the KG. This procedure can be done manually or assisted with entity disambiguation tools (Dredze et al., 2010).

3 Proposed Methods

3.1 Cognitive Knowledge Graph

To solve the above cognitive inference problem, we first introduce the **Cog**nitive **K**nowledge **G**raph (**CogKG**), which unifies the representation of relational facts and expert rules, and then develop a general reasoning framework based on it. As presented in Fig. 2, the CogKG is a directed hypergraph with entities as nodes, and the relations or rules as edges. In this case, the relation edge connects two entities and then forms a relational fact. In contrast, the rule hyperedge connects two sets of entities and then form a expert rule. We denote the cognitive knowledge graph as $\mathcal{G} = (V, E)$, where V is the entity set and $E = \{E^e, E^r\}$. In particular, the relation edges and rule hyperedges are E^e and E^r, respectively. The important notations and descriptions are in Table 1.

3.2 The General CogInfer Framework

With rich cognitive knowledge of expert rules and relational facts, we propose CogInfer, a general framework performing machine reasoning based on the CogKG. As presented in Alg. 1, the reasoning procedure for the cognitive inference problem includes three steps. Firstly, we perform knowledge representation learning on the relational facts of CogKG $\mathcal{G}$ and obtain the distributed representations of involved nodes and relational edges, i.e., $\mathcal{E} = \textbf{RepreLearn}(V, E^e)$.[3] Secondly, a task-specific InferGraph $\mathcal{G}^Q$ is constructed from $\mathcal{G}$, which identifies the inference space for query

[3] This can be done by any knowledge graph embedding methods (Ji et al., 2021). Here we adopt the widely used TransE (Bordes et al., 2013) as a typical technique.

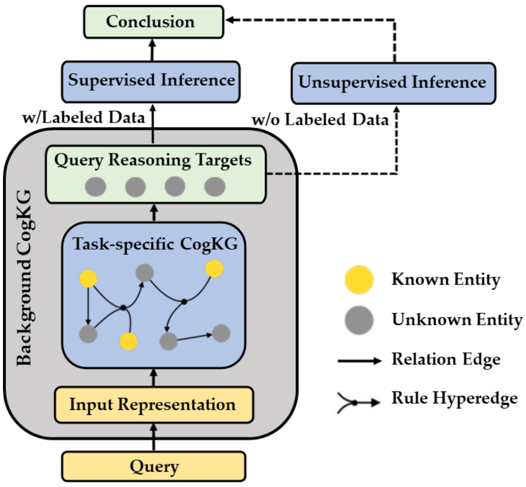

Figure 2: The general COGINFER framework. The query and conclusion are both aligned to CogKG.

Algorithm 1 COGINFER

```
Require: $\mathcal{G} = (V, E)$, $Q = \{v_1, ..., v_i..., v_L | v_i \in V\}$
Learn embeddings $\mathcal{E}$ for nodes and edges of $\mathcal{G}$
Create $\mathcal{G}^Q$ from $\mathcal{G}$ w.r.t. query $Q$        ▷ Alg. 2
Perform inference based on $\mathcal{G}^Q$ and $\mathcal{E}$        ▷ Sec. 3.3 / Sec. 3.4
return conclusion $C$
```

Algorithm 2 InferGraph Construction

```
Require: $\mathcal{G}$, $Q$
Initialization: add entities in $Q$ as nodes to $\mathcal{G}^Q$, $E^r_{mem} = \emptyset$
assign $V_{cur}$ with nodes in $\mathcal{G}^Q$
$E^r_{cur}$ = GetLinkedRuleEdges($\mathcal{G}, V_{cur}$)
while $E^r_{cur} - E^r_{mem}$ is not empty do
    for each $e^r_i \in E^r_{cur} - E^r_{mem}$ do
        $V_i$ = GetLinkedEntNodes($\mathcal{G}, e^r_i$)
        add rule $e^r_i$ and nodes $V_i$ to $\mathcal{G}^Q$
    expand $E^r_{mem}$ with $E^r_{cur}$
    assign $V_{cur}$ with nodes in $\mathcal{G}^Q$
    $E^r_{cur}$ = GetLinkedRuleEdges($\mathcal{G}, V_{cur}$)
return InferGraph $\mathcal{G}^Q$
```

Algorithm 3 Unsupervised Inference

```
Require: $\mathcal{G}^Q$, $Q$, $\mathcal{E}$
Initialization: add rules in $\mathcal{G}^Q$ to $E^r_{mem}$, $C = \emptyset$
assign $V_{knw}$ with entities in $Q$
repeat
    assign $V_{mem}$ with $V_{knw}$
    for each $e^r_i \in E^r_{mem}$ do
        for each $v_u$ in premise do
            LinkPrediction($v_u, V_{knw}, \mathcal{E}$)
        expand $C$ with ApplyRule($e^r_i, V_{knw}$)
        expand $V_{knw}$ with $C$
until $V_{knw} - V_{mem}$ is empty
return $C$
```

Q. Lastly, the COGINFER checks every possible conclusion delivered in the inference space by reasoning with curated rules in $\mathcal{G}^Q$ and the distributed representations $\mathcal{E}$. Specifically, it performs *unsupervised inference* (Section 3.3) or *supervised inference* (Section 3.4) depending on the availability of labeled data. The general COGINFER framework is presented in Fig. 2.

For each query $Q = \{v_1, ..., v_i..., v_L | v_i \in V\}$, we create a task-specific InferGraph $\mathcal{G}^Q$ by iteratively identifying the closure of the involved rules and connected entities from the task-free background CogKG $\mathcal{G}$. The construction of InferGraph is detailed in Alg. 2. When expanding the rules, we only consider those where the premise requires at least one registered entity of the closure.

Specifically, **GetLinkedRuleEdges**($\mathcal{G}, V$) returns a set of rules of CogKG $\mathcal{G}$ in which the entity set in premise overlaps with V. **GetLinkedEntNodes**($\mathcal{G}, e^r$) returns a set of entity nodes of $\mathcal{G}$ that are linked with the rule e^r, i.e, those entities in premise and conclusion of this rule. In other words, $\mathcal{G}^Q \subset \mathcal{G}$ is a small sub-graph of the background CogKG. The entity nodes in this graph are particularly categorized into two sets, namely, *Known Entity* set and *Unknown Entity* set, representing the status of certainty. We use **certainty factor** (CF) (Buchanan and Shortliffe, 1984) to manage the uncertainty of the nodes carried out in the ensuing reasoning steps. Specifically, a CF of 0 represents unknown. Positive and negative CFs represent True and False values respectively, with increasing confidence as the number approaches 1 or -1. In our case, this CF is used to indicate the confidence in the presence or absence of symptoms or diseases. The logical AND and OR operations on two CFs a, b are defined as follows:

$$\text{AND}(a, b) = \min(a, b) \,, \tag{1}$$

$$\text{OR}(a, b) = \begin{cases} a + b - ab, & \text{if } a, b \geq 0; \\ a + b + ab, & \text{if } a, b < 0; \\ \frac{a+b}{1-\min(|a|,|b|)}, & \text{otherwise.} \end{cases} \tag{2}$$

3.3 Unsupervised Inference

In unsupervised inference, we conduct reasoning over the InferGraph by applying expert rules or link prediction with the learned distributed representations, i.e., to deduce the CF of unknown entities given a set of rules and known entities. As presented in Alg. 3, for each rule in the InferGraph, we check if the *Known Entity* set satisfy the corresponding premises. If satisfied, then we can apply this rule and deduce a new non-zero CF for the unknown entity and remove it from the *Unknown Entity* set. Otherwise, we check if there is any unknown entity in the premise could be deduced through link prediction. Formally, **LinkPrediction** takes as input the concerned unknown entity v_u, current known entity set V_{knw}, the learned embeddings $\mathcal{E}$, and outputs the CF of v_u. Let $|E^e|$ denote the pre-defined predicate set in E^e. Each known entity $v_i \in V_{knw}$ along with v_u forms a candidate triple (v_i, p_j, v_u) under a certain predicate $p_j \in |E^e|$. The cosine similarity between $(\vec{v_i} + \vec{p_j})$ and $\vec{v_u}$ is used to represent the CF given by such triple[4]:

$$CF_{ij} = CosSim(\vec{v_i} + \vec{p_j}, \vec{v_u}) \tag{3}$$

Particularly, the CF will be reset to 0 if the calculated result does not surpasses a preset threshold. By applying the OR operation over CFs carried by all such triples, the CF of the target unknown entity v_u is determined. **ApplyRule** takes as input the concerned rule e^r and current known entity set V_{knw}. If the rule is applicable, i.e., the premise is satisfied by the V_{knw}, we will apply the AND operation over CFs of all premise entities followed by multiplication with CF of the rule itself to determine the CF of conclusion entity led by the rule. We repeat the above procedure and record every conclusion until no more entity could be deduced.

3.4 Supervised Inference

So far, we have presented how the CogInfer performs unsupervised machine reasoning with cognitive knowledge of relational facts and if-then rules while without any labeled training data. With the same architectural backbone, it can be easily extended to a trainable supervised model and collectively learn from the knowledge and labeled data. To keep the explainability of CogInfer, we implement it as a simple neural network with only one fully connected layer between the input and output neurons, as presented in Fig. 3.

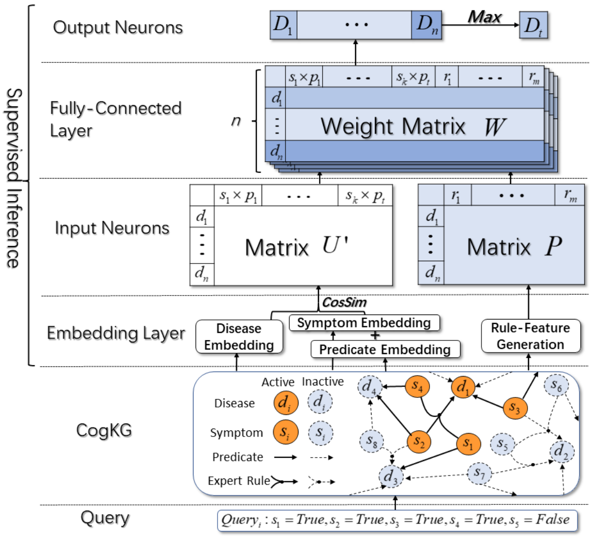

Figure 3: The trainable implementation of CogInfer.

In this section, we present how the cognitive knowledge of if-then rules and relational facts are utilized to generate explainable neurons[5] as part of the model and elaborate on the instantiation of the trainable implementation of CogInfer.

3.4.1 Rule-generated Neurons

In unsupervised inference, each applicable rule in the InferGraph gives a CF attached to a specific reasoning target. In other words, a single rule generates a target-specific scalar feature for each query and thus a rule set will give a collection of such scalar features. However, the number of reasoning targets are subject to the input query, leading to a unstable feature space as the query changes. In contrast, in supervised inference, the reasoning targets are fixed as the pre-defined set of labels. This inspires a macro perspective to consider all rules as a whole and treat the rule-generated CFs as inherently explainable neurons with respect to the input query. Formally, given m if-then rules, we defined the rule-generated neuron matrix P as follows.

$$P = \begin{array}{c} \begin{array}{cccc} r_1 & r_2 & \cdots & r_m \end{array} \\ \left[\begin{array}{cccc} p_{11} & p_{12} & \cdots & p_{1m} \\ p_{21} & p_{22} & \cdots & p_{2m} \\ \vdots & \vdots & \ddots & \vdots \\ p_{n1} & p_{n2} & \cdots & p_{nm} \end{array}\right] \begin{array}{c} d_1 \\ d_2 \\ \vdots \\ d_n \end{array} \end{array} \tag{4}$$

[4] In this work, we use arrowheaded letter to represent the corresponding vector in $\mathcal{E}$.

[5] Throughout this paper, the term *neurons* represent the feature units with explicit semantics produced by symbolic knowledge.

where p_{ij} is the CF given by r_j regarding reasoning target, i.e., disease d_i. For example, in our case, the input query x is a set of symptoms and we denote the corresponding vector as $\vec{x} \in \mathbb{R}^k$, where k is the dimension of symptom space. It comprises of a set of binary values (0/1), representing the presence of the corresponding symptom. Similarly, we can represent the rule vector in the same space as input query. Each element of $\vec{r}$ is also a binary value, indicating if the corresponding symptom is required in its premise. As a rule only has one predefined CF for a specific disease, we heuristically assign $p_{ij} = 0$ for all d_i that is not included in the conclusion of r_j or the rule itself is not applicable with input query.

$$p_{ij} = \alpha_j \times \mathbb{I}(\vec{x} \cdot \vec{r_j} == sum(\vec{r_j})) \tag{5}$$

where α_j is the CF of rule r_j, $\mathbb{I}$ is the indicator function that returns 1 if the condition is true and 0 otherwise. In this way, the original neurons of input query in the symptom space is extended to explainable rule-generated neurons in a more expressive space.

3.4.2 KG-generated Neurons

Likewise, the large amount of relational facts in KG can be utilized in the same manner. For each predicate $p_* \in |E^e|$, any dimension s_i in the original symptom space $\mathbb{R}^k$ together with reasoning target d_j forms a relational triple (s_i, p_*, d_j), which will lead to a CF attached to the reasoning target (as described in Section 3.3). Taking all dimensions into account, we can obtain a matrix of CFs under the specific predicate p_*. Therefore, the KG-generated neuron matrix U is defined as follows.

$$U = [U_{p_1}, ..., U_{p_i}, ..., U_{p_t}] \tag{6}$$

where t is the size of predefined predicate set $|E^e|$. Specifically, for each predicate p_*, the matrix U_{p_*} is defined as follows.

$$U_{p_*} = \begin{array}{c} \begin{array}{cccc} s_1 & s_2 & \cdots\cdots & s_k \end{array} \\ \begin{bmatrix} u_{11} & u_{12} & \cdots & u_{1k} \\ u_{21} & u_{22} & \cdots & u_{2k} \\ \vdots & \vdots & \ddots & \vdots \\ u_{n1} & u_{n2} & \cdots & u_{nk} \end{bmatrix} \begin{array}{c} d_1 \\ d_2 \\ \vdots \\ d_n \end{array} \end{array} \tag{7}$$

where u_{ij} represents the CF given by the relational fact (s_i, p_*, d_j).

$$u_{ij} = cos(\theta) = \frac{(\vec{s_i} + \vec{p_*}) \cdot \vec{d_j}}{\|(\vec{s_i} + \vec{p_*})\| \times \|\vec{d_j}\|} \tag{8}$$

3.4.3 Forward Propagation in CogInfer

Note that the neuron matrix P is query-specific as the applicability of each rule is subject to the input query x. As for the query-independent matrix U, only a small part of this huge matrix is activated in the forward propagation because many relational facts are irrelevant to the query as the InfergGraph indicates. Specifically, if a symptom s_j is included in the input x, all triples that led by s_j will be activated. The activation matrix I is defined as follows.

$$I = [I_1, ..., I_j, ..., I_k], I_j = \begin{cases} \vec{1} \in \mathbb{R}^n, & \text{if } s_j \in x \\ \vec{0} \in \mathbb{R}^n, & \text{otherwise} \end{cases} \tag{9}$$

By applying Hadamard product ($\odot$) on each element of U and I, we can then obtain the activated matrix U'.

$$U' = [U'_{p_1}, ..., U'_{p_i}, ..., U'_{pt}], U'_{p_i} = U_{p_i} \odot I \tag{10}$$

The final input neuron matrix X is produced via concatenation ($\oplus$) of the rule-generated neuron matrix and activated KG-generated neuron matrix:

$$X = U' \oplus P \,. \tag{11}$$

As presented in Fig. 3, the fully connected layer directly connects every input neurons with all output neurons, i.e, the reasoning targets. In the supervised inference, each input neuron represents a specific expert rule or relational fact, hence the CogInfer can be regarded as a white-box model and we can easily find the most contributing neurons in the mode structure by analyzing the weight matrix W of the fully connected layer.

4 Empirical Study

4.1 Dataset and Evaluation Metrics

In this work, we situate the cognitive inference problem in the clinical diagnosis domain for initial study. Accordingly, the observations are symptoms of a patient and the conclusion refers to the most probable diagnosed disease. We introduce two clinical diagnosis datasets as initial test-beds for our task, namely, Muzhi and MDD, both of which are adapted from existing benchmarks for automatic diagnosis QA tasks. The statistics is presented in Table 3 and construction of dataset is detailed in Appendix B.

Models	Capability				Muzhi			MDD		
	Facts	Rules	Train.	Exp.	Hits@1	Hits@2	MRR	Hits@1	Hits@2	MRR
MAJORITYGUESS	✗	✗	✗	✓	0.225	0.465	0.496	0.065	0.065	0.225
MYCIN	✗	✓	✗	✓	0.197	0.197	0.398	0.278	0.287	0.342
PURELINK	✓	✗	✗	✓	0.563	**0.732**	0.718	0.528	0.602	0.631
COGINFER	✓	✓	✗	✓	**0.592**	0.704	**0.722**	**0.606**	**0.713**	**0.710**

Table 2: Comparison with knowledge-driven methods in unsupervised setting.

Table 3: Dataset Statistics.

Statistic	Muzhi	MDD
Samples	710	2,151
Symptoms	66	93
Diseases	4	12
Rules	92	182
Entities	19,737	293,879
Predicates	7	162
Avg. Entities / Query (Train)	5.7	5.1
Avg. Entities / Query (Test)	4.9	5.3

Depending on the availability of training examples, we adopt different evaluation metrics for unsupervised and supervised settings, respectively. Specifically, we use Hits@k (k=1,2) and mean reciprocal rank (MRR) as the main evaluation metrics. Additionally, we also plot the Accuracy-Coverage curve to evaluate the knowledge-driven models and report the macro precision (Pre.), recall (Rec.) and F1-score (F1) to evaluate the data-driven models. The design of evaluation metrics is detailed in Appendix C.

4.2 Baseline Methods

4.2.1 Knowledge-driven Methods

MAJORITYGUESS is a simple baseline for reference. MYCIN is a representative of expert systems that relies on if-then rules to perform reasoning. PURELINK is a link prediction based reasoning method, which utilizes the distributed representations of relational facts to calculate the CFs for each reasoning targets. The implementation details are described in Appendix D.

4.2.2 Data-driven Methods

We compare our method with a wide range of data-driven methods in supervised setting, including two representative statistical machine learning methods k-nearest neighbor (KNN), logistic regression (LR), one feature-selective logistic regression with lasso regularization (LASSOLR), one neural-based method Multi-layer Perceptron (MLP), and one ensemble method named explainable boosting method (EBM) (Lou et al., 2013).

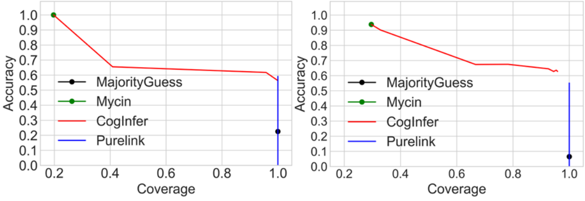

Figure 4: Accuracy-Coverage curve of knowledge-driven methods on Muzhi (left) and MDD (right).

4.3 Experimental Results

4.3.1 Comparison with Knowledge-driven Methods

Table 2 shows the performance of different knowledge-driven methods for cognitive inference problem in unsupervised setting. Specifically, for unsupervised setting, the ground-truth conclusion of each query is accessible only at the test phase for evaluation. In other words, this setting requires the reasoners not to learn from labeled examples but to make decisions merely based on knowledge, which clearly rules out the data-driven methods. Hence, it is not surprising that all the methods fail in trainability (Train.). Though there is no difference in explainablity (Exp.) among these knowledge-driven models, our method is the only one that simultaneously utilizes both expert rules and relational facts for machine reasoning. It is interesting to find that the KG-based PURELINK substantially surpass the rule-based MYCIN in both datasets, demonstrating the utilities of different representations of symbolic knowledge for the cognitive inference problem. We can also find that the performance gap between COGINFER and PURELINK in MDD dataset is much greater than that in the Muzhi dataset. We attribute this to the differences in complexity between the two datasets. More precisely, the diseases and predicates in MDD dataset is 3x and 23x as many as that in Muzhi, making the link prediction much harder for PURELINK. Nonetheless, the increased complexity from Muzhi to MDD even leads to a slight performance rise (0.592 → 0.606 in terms of Hits@1) for COGINFER, indicating that our method is more suitable

	Models	Capability				Muzhi						MDD					
		Facts	Rules	Train.	Exp.	Pre.	Rec.	F1	Hits@1	Hits@2	MRR	Pre.	Rec.	F1	Hits@1	Hits@2	MRR
W/o CogKG	KNN	✗	✗	✓	✗	0.651	0.637	0.615	0.592	0.915	0.776	0.808	0.805	0.798	0.787	0.870	0.851
	EBM	✗	✗	✓	✓	0.707	0.707	0.697	0.690	1.0	0.845	0.823	0.818	0.813	0.810	0.912	0.883
	MLP	✗	✗	✓	✗	0.750	0.741	0.729	0.718	0.986	0.857	0.833	0.835	0.829	0.829	0.903	0.890
	LassoLR	✗	✗	✓	✗	0.777	0.776	0.769	0.761	0.986	0.878	0.832	0.834	0.828	0.829	0.921	0.894
	LR	✗	✗	✓	✗	0.782	0.769	0.769	0.761	0.972	0.876	0.842	0.839	0.833	0.833	0.931	0.897
W/ CogKG	CogInfer	✓	✓	✓	✓	**0.820**	**0.811**	**0.797**	**0.789**	**1.0**	**0.894**	**0.877**	**0.861**	**0.857**	**0.856**	**0.931**	**0.908**

Table 4: Comparison with data-driven methods in supervised setting.

and effective for the complex scenarios.

We also plot the accuracy-coverage curve of knowledge-driven methods in Fig. 4. A method cannot "cover" a test query if the query activates none of its rules and therefore the method cannot reach any conclusion. The brittle rule-based method MYCIN achieves high accuracy at a low coverage. It works almost perfectly on a small percentage of test queries (20% in Muzhi; 30% in MDD) where at least one of its inference rules is activated, but fails completely on the remaining test queries where none of its rules can be applied.

In contrast, as we change the threshold for link prediction in PureLink, the accuracy-coverage data points surprisingly present a vertical line instead of a curve. In other words, despite it might have a limited performance in accuracy, it consistently reaches a perfect score of 1.0 in coverage, showing the strong generalizability of distributed representations of KG. Similarly, as we change the threshold for link prediction in CogInfer, the curve always starts from exactly where the MYCIN lies. **This implies that the rule-based MYCIN is a special case of the proposed CogInfer.** Specifically, as stated in Section 3.3, when the threshold exceed a certain value, the Line 6 $\sim$ 7 in Alg. 3 will be disabled and the reaming part performs the same steps as the expert system. Generally, it can be observed that the accuracy and coverage constrain each other on both datasets, but we can always find a reasonable balance between the two metrics, showing the flexibility of the proposed method.

4.3.2 Comparison with Data-driven Methods

Table 4 shows the performance of different data-driven methods for cognitive inference problem in supervised setting. Specifically, for supervised setting, we are provided with the labeled examples for both training and evaluation. The reasoners are free to learn from both knowledge and training data to make decisions. However, few existing data-driven methods can utilize the expert rules and relational facts for training. Among all baselines, the EBM is the only one that has explainability though its overall performance is not satisfying enough. In contrast, with the CogKG, our method CogInfer achieves collectively learning from both the symbolic knowledge and labeled data while keeping the explainability.

It can be observed that the performances of all baselines are relatively stable on the two datasets. Specifically, the KNN always give the worst performance while the LR keeps the leading position. Noticeably, the LassoLR is a feature-selective method and is expected to be more effective than the vanilla LR. However, the performances of LassoLR and LR are quite close to each other, implying that the symptoms in the original feature space leave much to be desired in separability. As presented in Section 3.4, we argue that such knowledge-generated features make it much easier for the optimizer to reach the global optimum as the knowledge greatly enriched the original feature space and make it more separable and tend to be consistent. With sufficient training examples, the CogInfer consistently surpasses all baselines on the two datasets under both classification and ranking metrics, showing its superiority over the time-tested data-driven methods.

4.4 Ablation Study

To analyze the utility of expert rules and relational facts in the trainable implementation of CogInfer, we conduct a set of ablation study and report the F1-score, as presented in Table 5. Specifically, we train the CogInfer with only KG-generated features and Rule-generated features, respectively. Moreover, as we adopt pre-trained embeddings in the embedding layer, we also investigate its utility in the model. Generally, the model will gain additional performance boost after fine-tuning the embeddings, indicating the importance of adjusting the general embedding to task-specific embedding. Note that the fine-tuning does not affect the performance of models with only rule-generated features because such features are determined before the training process.

On the other hand, we can find that both the KG-generated features and rule-generated features

Table 5: Ablation Study. F1-score is reported and FE indicates fine-tuning embeddings.

Input	Muzhi	MDD
All Features (w/ FE)	0.797	0.857
All Features (w/o FE)	0.730	0.850
KG Feature (w/ FE)	0.711	0.759
KG Feature (w/o FE)	0.627	0.717
Rule Feature (w/ FE)	0.362	0.366
Rule Feature (w/o FE)	0.362	0.366

contribute a lot to the effectiveness of the proposed method. As presented above, the KG Feature is comparatively more influential than the Rule Feature. We attribute this to the differences in feature size as the KG-generated features are generally multiple times of the rule-generated features. Moreover, as each feature corresponds to an explicit semantic meaning, we also conduct interpretability analysis (see Appendix E) to further investigate the learned model.

5 Conclusion

In this work, we introduce a new machine reasoning task, namely, cognitive inference problem, which directly challenges existing knowledge-driven and data-driven methods. To address this problem, we also introduce the cognitive knowledge graph (CogKG) that aims to unify the heterogeneous symbolic knowledge of expert rules and relational facts in knowledge graph, and propose a general framework CogInfer with two implementations. Experimental results on two clinical diagnosis benchmarks demonstrate the superiority of our work over existing methods.

A Detailed Discussion of Differences with Existing Works

A.1 Knowledge Representation and Reasoning

As surveyed in the recent study on integrating prior knowledge into learning systems (von Rueden et al., 2021), various sources of prior knowledge have been investigated in different representation forms, including algebraic equations (scientific knowledge), spatial invariances (world knowledge), human feedback (expert knowledge), etc. In our cognitive inference problem, we mainly focus on the symbolic representation of knowledge, i.e, expert rule and knowledge graph. Early works on artificial intelligence compose the human knowledge as discrete symbols, and introduces the traditional symbolic knowledge representation, i.e., rules, to perform complex inference (Minsky and Papert, 1969; Lenat, 1995). Generally, these time-tested rule-based methods such as expert system have achieved great success in specialized domains, but are also limited to human effort and fail to generalize due to expensive costs (Buchanan and Shortliffe, 1984). In contrast, the recently introduced knowledge graph (KG) (Singhal, 2012), as a novel symbolic knowledge representation, is regarded quite promising to overcome such bottleneck. Specifically, the rapid development of computational hardware and deep learning makes it possible to model the rich semantic connections between massive discrete knowledge represented in KG, and the symbolic knowledge of relational facts can be mapped to distributed representation, i.e., continuous embeddings (Bordes et al., 2013). Though recent pre-trained language models such as BERT (Devlin et al., 2019), ERNIE (Sun et al., 2019) show promising performance by harvesting prior knowledge in distributed representation from large-scale corpus and knowledge graph, they all require a large amount of data and computational resources for fine-tuning and thus can only partially address the cognitive inference problem.

Despite there are a few attempts to combine first-order logic and relational facts for machine reasoning, they only focus on fixed compositional patterns of predicates (Horrocks et al., 2004; Rocktäschel et al., 2015; Guo et al., 2016; Rocktäschel and Riedel, 2017; Meilicke et al., 2019; Minervini et al., 2020). Therefore, they are strictly limited to tasks that merely reason about multi-relational data such as knowledge graph completion and relation classification, instead of inference problems where observations lead to conclusions. To the best of our knowledge, we are the first to integrate the expert rules into knowledge graph with a unified knowledge representation framework for such complex machine reasoning task.

A.2 Integrating Knowledge into Learning Systems

Different from the typical knowledge-driven artificial intelligence (AI) such as expert system, the data-driven AI such as machine learning (ML) is believed to be more generalizable due to its capability of learning implicit knowledge from labeled data, alleviating the knowledge acquisition bottleneck (Feigenbaum, 1980). However, the ML systems are substantially subject to the availability of training data and are quite limited in some cases where labeled data is hard to obtain. One potential solution is to integrate prior knowledge into learning system, which is also noted as informed machine learning (von Rueden et al., 2021). To achieve this goal in our work, there are three key challenges. First, the proposed model is expected to learn from the knowledge (i.e., expert rules and relational facts) if labeled data is unavailable. Second, if trainable, the model is required to not only reason with knowledge, but also train with knowledge. Third, a unified application of knowledge in both training and inference is anticipated.

Previous works intergating prior knowledge includes: (1) adding knowledge into learning objective (e.g., knowledge as regularization), but knowledge itself is not a part of the model. For instance, Xia et al. use prior knowledge to guide the attention matrix in BERT (Xia et al., 2021); (2) using knowledge as parameter initialization. For example, Zhang et al. proposed to first learn entity and relation representations via pre-trained language models and then use this prior knowledge (i.e., the learned representations) to initialize the knowledge graph embedding models (Zhang et al., 2020); (3) using knowledge as model architecture. Typical models include inductive logic programming (ILP) (Muggleton and De Raedt, 1994), Markov logic network (MLN) (Richardson and Domingos, 2006), and knowledge-based artificial neural networks (KBANN) (Towell and Shavlik, 1994), etc. However, these methods only focus on the logic rule (inference principle), neglecting the rich relational facts in knowledge graph.

Though these attempts achieved preliminary success, none of them can directly integrate both expert rules and relational facts in existing KG into the learning system, and they can only partially address the above challenges, which greatly motivates our work.

B Dataset Construction

To prepare the preliminaries of our task, we first harvest labeled examples from two dialogue datasets (namely, Muzhi and MDD) that are originally used for automatic diagnosis, in which the symptoms as features and the diagnosed disease as label. The relational facts are directly collected from existing well-constructed knowledge graphs like Chinese Medical Knowledge Graph (CMeKG) (Byambasuren et al., 2019) and SNOMED-CT[6], accompanying with Muzhi (Chinese) and MDD (English) respectively. We further apply association rule mining on the labeled data followed by human expert validation to craft if-then rules. Specifically, we invite three medical experts to check the mined rules and filter them via consistency validation. Lastly, we also manually align the entities in premise and conclusion of each rule to the terminologies of KG to make the expert rules and relational facts compatible with each other. The details of each dataset are as follows.

- **Muzhi** dataset is originated from a Chinese online healthcare community[7] and is firstly used for dialogical automated diagnosis (Wei et al., 2018). In this work, we collect the explicit symptoms and implicit symptoms as observations and the diagnosed disease as conclusion to create labelled examples. After terminology alignment, it contains 710 samples with 66 symptoms related to 4 diseases, i.e., infantile diarrhea (ID), children functional dyspepsia (CFD), upper respiratory infection (URI), and children's bronchitis (CB). We randomly split the dataset to training set, validation set, test set in the proportion of 8:1:1. Additionally, this dataset contains 92 if-then rules related to the above 4 diseases, and 19,737 distinct entities connected with 7 predicates.

- **MDD** is an English medical diagnosis dialogue (MDD) dataset proposed in the ICLR 2021 challenge[8]. Following the Muzhi dataset, the original dialogical records are converted into labeled instances. After terminology alignment, the MDD dataset is three times larger than the Muzhi dataset, containing 2,151 samples with 93 symptoms related to 12 diseases. Likewise, the dataset is randomly split to 8:1:1 for training, validation and test. It contains 182 if-then rules related to the above 12 diseases, and 293,879 distinct entities connected with 162 predicates.

C Design of Evaluation Metrics

As the proposed CogInfer is not bound with unsupervised inference or supervised inference, we can evaluate it under both unsupervised setting and supervised setting. According to the truthiness of the most likely conclusion of each query, the result can be categorized into three types, namely, true conclusion (TC), false conclusion (FC), and not conclusive (NC), indicating the model cannot output any conclusion for the query. Generally, we evaluate the model with the following two ranking metrics, i.e., Hits@k (k=1,2) and mean reciprocal rank (MRR).

$$Hits@k = \frac{1}{|\mathcal{R}|}\sum_{r\in\mathcal{R}} \mathbb{I}[r \leq k] \tag{12}$$

$$MRR = \frac{1}{|\mathcal{R}|}\sum_{r\in\mathcal{R}} r^{-1} = (\frac{|\mathcal{R}|}{\sum_{r\in\mathcal{R}} r^{-1}})^{-1} \tag{13}$$

where $\mathcal{R}$ denotes the set of ranks for all predicted most likely conclusions and $\mathbb{I}$ is the indicator function. More precisely, for each TC result, the rank will always be 1. For any FC result, the rank could be any integer in $[2, n]$, where n is the number of diseases contained in the dataset. For NC result, the rank is set to the worst case by default, i.e, it will always be n.

In particular, for knowledge-driven method, when it encounters a query for which no rules or facts have been pre-defined in the knowledge base, the system will get stuck and cannot output any conclusion. In other words, it does not even understand the query. Therefore, we also define *Accuracy* and *Coverage* to evaluate these knowledge-driven mod-

[6] https://www.nlm.nih.gov/healthit/snomedct

[7] http://muzhi.baidu.com

[8] https://mlpcp21.github.io/pages/challenge.html

els.

$$Accuracy = \frac{TC}{TC + FC} \tag{14}$$

$$Coverage = \frac{TC + FC}{TC + FC + NC} \tag{15}$$

Instead of reporting the discrete data points, we plot the Accuracy-Coverage curve to comprehensively compare different knowledge-driven models.

In contrast, for data-driven models, they have predefined fixed reasoning targets and will not output any NC results. Hence, the above *Accuracy* and *Coverage* metrics cannot properly evaluate the data-driven models. In this case, we adopt the classification metrics such as macro precision (Pre.), recall (Rec.) and F1-score (F1) as the evaluation metrics.

D Implementation Details

For knowledge-driven baselines, the MYCIN is implemented with the *Paip-python* library[9]. The threshold for link prediction in PURELINK is determined from [-1, 1] via grid search on the mixed set of training and validation data. For data-driven baselines, we implement the EBM with the *ImterpretML* library[10]. The rest data-driven baselines are implemented with the *scikit-learn* package (Pedregosa et al., 2011). All hyperparameters are kept as default except the following ones that are determined through grid search on validation set. For KNN, the number of neighbors k is searched from [1, 2, 3, ..., 10]. For LR and LASSOLR, the inverse of regularization strength C is searched from [0.1, 1, 10]. For MLP and EBM, the learning rate is searched from [1e-5, 1e-4, 1e-3, 1e-2]. Moreover, the number of hidden layers/nodes in MLP is searched from [(100,), (50,50), (50,50,50)].

For the proposed COGINFER, the threshold for link prediction in non-trainable (unsupervised) implementation is determined from [-1, 1] via grid search on the mixed set of training and validation data. Note that the trainable implementation of our framework can be initialized from pre-trained embeddings and weights. For Muzhi dataset, the embedding layer is initialized with pre-learned embeddings of CMeKG by TransE and the fully connection layer is initialized with that of a pre-trained group-lasso regularised logistic regression model. For MDD dataset, the embedding layer is initialized with pre-learned embeddings of SNOMED-CT by TransE and the fully connection layer is initialized with that of a pre-trained L2 regularised logistic regression model. For both datasets, we only fine-tune the embedding layer while freezing the fully connected layer when performing optimization.

E Interpretability Analysis

To illustrate the interpretability of the proposed COGINFER, we conduct two sets of case study as presented in Fig. 5. The values in global weight (Fig. 5(a)) are selected from columns of the weight matrix W, corresponding to two closely-related respiratory diseases “Asthma" and “Pneumonia". Likewise, the values in instance-level behavior (Fig. 5(b)) are selected from columns of the production of input neuron matrix X and weight matrix W.

For the global weight, we visualize some selected cells of two rows (corresponding to the disease) of the weight matrix W to interpret the reasoning of COGINFER. According to the heatmap, the most effective rules and facts for diagnosing “Asthma” includes “Dyspnea”, “Chest tightness” and so on. In contrast, the diagnosis of “pneumonia” mainly involves “Night sweats”, “Loss of appetite” and “Chills”, which helps distinguish “Asthma” from “Pneumonia”. Meanwhile, we can learn that “Sputum” and “Coughing” are similar symptoms of “Asthma” and “Pneumonia”. Encouragingly, according to the public literature, what we learn from the weight matrix is consistent with common medical knowledge (Cukic et al., 2012).

For the instance-level behavior, we study a specific sample given its symptoms. We visualize some cells of the production of input neuron matrix X and weight matrix S. These scores represent the importance of the corresponding activated rules or facts in the diagnostic process. As “coughing” and “Sputum” are common symptoms of “Asthma” and “Pneumonia”, they both score high under the corresponding rules. Moreover, it is interesting to find that the high scores of “Chest tightness” and “Sore throat” are also in line with the fact that they are widely believed to be “Asthma”-indicative symptoms that lead to the diagnosis of “Asthma”, revealing the interpretability of the proposed method.

Who did what to Whom? Language models and humans respond diversely to features affecting argument hierarchy construction

Xiaonan Xu

Nokia Bell Labs, USA

Abstract

Pre-trained transformer-based language models have achieved state-of-the-art performance in many areas of NLP. It is still an open question whether the models are capable of integrating syntax and semantics in language processing like humans. This paper investigates if models and humans construct argument hierarchy similarly with the effects from telicity, agency, and individuation, using the Chinese structure "NP1+BA/BEI+NP2+VP". We present both humans and six transformer-based models with prepared sentences and analyze their preference between BA (view NP1 as an agent) and BEI (NP2 as an agent). It is found that the models and humans respond to (non-)agentive features in telic context and atelic feature very similarly. However, the models show insufficient sensitivity to both pragmatic function in expressing undesirable events and different individuation degrees represented by human common nouns vs. proper names. By contrast, humans rely heavily on these cues to establish the thematic relation between two arguments NP1 and NP2. Furthermore, the models tend to interpret the subject as an agent, which is not the case for humans who align agents independently of subject position in Mandarin Chinese.[1]

1 Introduction

Pre-trained transformer-based language models (LMs) keep achieving state-of-the-art performance in NLP tasks. Many studies have indicated that pre-trained LMs can learn syntactic knowledge (e.g., Linzen et al. 2016; Gulordava et al. 2018 for subject-verb agreement, Wilcox et al. 2018 for filler-gap dependencies, Futrell et al. 2019 for garden-path effects) and semantic knowledge (e.g., Zhao et al. 2021 for telicity , Kementchedjhieva et al. 2021 for causality bias, Misra et al. 2020 for semantic priming, Misra et al. 2021 for typicality, Ettinger 2020 for role reversal and same-category distinctions). However, to what extent LMs can acquire knowledge in the syntax-semantics interface is still an open question. To answer this question, we explore arguments hierarchy construction which identifies the thematic roles of arguments in the semantic domain and aligns arguments and subject/object in the syntactic domain. In this hierarchy, the active, controlling agent (prototypical actor) outranks the affected patient (prototypical undergoer), i.e., *who did what to whom?* (Van Valin Jr, 1990; Van Valin and LaPolla, 1997; Bornkessel et al., 2005). The mapping between thematic roles (agent/patient) and syntactic structure (subject/object) varies depending on various features.

In this paper, we investigate whether pre-trained transformer-based LMs and humans behave similarly in the argument hierarchy construction using the Chinese structure "NP1+BA/BEI+NP2+VP". This structure provides a unique opportunity to examine the alignment through the occurrence of BA/BEI (Deng et al., 2018), without interference from morphology or word order. For example, human name *Zhang-san* (NP1) in the subject position of sentence (1a) with BA is interpreted as an agent, and human name *Li-si* (NP2) in the object position is viewed as a patient. By contrast, if BEI occurs as in (1b), subject *Zhang-san* is viewed as a patient, and object *Li-si* is considered an agent. This inverse interpretation depending on BA/BEI allows us to use word prediction to study LMs without task-specific fine-tuning. It also avoids tokenization issues since both BA and BEI are single characters.

The construction of argument hierarchy can be affected by different cues related to telicity, agency, and individuation via notion transitivity (Hopper and Thompson, 1980; De Mattia-Viviès, 2009; Virtanen, 2015). For example, a cue emphasizing the agentive property of NP1 (e.g., by adding the adverbial *volitionally*) increases the probability of NP1 being viewed as an agent (Cruse, 1973), making BA more natural than BEI. By contrast, a cue denoting the non-agentive property of NP1 (e.g. by adding the clause *what happend to NP1 was that...*) decreases the probability of NP2 being viewed as an agent, making BEI more natural than BA. To examine the effects of these cues, we carry out a human acceptability judgment experiment using sentences with BA/BEI and compare the result with the probability of masked token BA/BEI predicted by the six pre-trained transformer-based LMs: BERT-base, ELECTRA-large, RoBERTa-base, ERNIE 1.0, and MacBERT-base/large. The results show that the models and humans construct similar argument hierarchy with atelic feature, and both agentive and non-agentive feature in telic context. However,

(A) LMs show insufficient sensitivity to the pragmatic function of BEI in forming adversative passives with disposal verbs, but humans depend on it in establishing thematic relation between the arguments.

(B) LMs and humans present different responses to various degrees of individuation encoded in human common nouns vs. proper names. Humans often perceive proper nouns as agents. However, LMs are inclined to interpret common nouns as agents.

(C) Unlike Mandarin Chinese native speakers who do not align the agent role depending on subject position, LMs tend to interpret the subject as an agent in telic context.

2 Materials

We prepare a dataset including the sentences highlighting telicity-, agency-, and individuation-related features. To avoid gender effect, we choose frequently used male surnames and first names to form NP1 and NP2 in the structure "NP1+BA/BEI+NP2+VP". For each condition, we make a hypothesis about human judgment in BA/BEI-preference based on previous studies about features in the structure.

2.1 Telicity

2.1.1 *Atelic*-condition

We use dynamic atelic verbs and imperfective aspect *-zhe*[2] to build atelic sentences. The dynamic verbs such as *la* 'pull' in (2a) and *xun-chi* 'reprimand' in (2b) with imperfective *-zhe* represent durative events without inherent endpoints (Vendler, 1957; Smith, 2012; Xiao and McEnery, 2004a). BEI with dynamic verbs can collocate with imperfective aspect *-zhe* (Cook, 2019; Xiao et al., 2006). But the co-occurrence of BA with dynamic verbs and *-zhe* is rarely found (Tsung and Gong, 2021). We expect a preference for BEI over BA in the *atelic*-condition.

	Zhaotao	BA/BEI	Wubo	reprimande	-IMPF

'Zhaotao is reprimanding Wubo.'/
'Zhaotao is being reprimanded by Wubo.'

2.1.2 *Telic*-condition

(3a)	郭杰	把/被	张伟	拉	到了门口。
	guo-jie	*ba/bei*	*zhang-wei*	*la*	*dao -le men-kou*
	Guojie	BA/BEI	Zhangwei	pull	arrive -PERF door

'Guojie pulled Zhangwei to the door.'/
'Guojie was pulled to the door by Zhangwei.'

(3b)	赵涛	把/被	吴波	训斥	了	一顿。
	zhao-tao	*ba/bei*	*wu-bo*	*xun-chi*	*-le*	*yi-dun.*
	Zhaotao	BA/BEI	Wubo	reprimande	-PERF	one-CL

'Zhaotao reprimanded Wubo.'/
'Zhaotao was reprimanded by Wubo once.'

A modifier specifying an endpoint can change an atelic verb at the lexical level into a telic situation at clause level (Vendler, 1957; Xiao and McEnery, 2004a). We set up two types of telic modifiers. The first one uses prepositional phrases (PPs) like *dao...men-kou* 'arrive at the door' denoting a spatial endpoint (3a). The second one uses *yi-dun* 'one+CL' indicating an temporal endpoint, where the specific verbal classifier *dun* is used to measure the count of a durative event (3b)(McEnery

[2] Markers signaling viewpoint aspect, such as perfective marker *-le* in the examples (1, 3-10) or imperfective marker *-zhe* in (2), are necessary for the grammatical correctness of Chinese sentences (Li and Thompson, 1989). In *atelic*-condition, we choose the imperfective marker *-zhe* to emphasize ongoing, uncompleted events.

and Xiao, 2007; Li and Thompson, 1989). We combine one-half of atelic verbs like *la* 'pull' with PPs to build spatially telic VPs (3a) and the other half verbs with *yi-dun* to form temporally telic VPs (3b)[3]. Both telic VPs co-occur with the perfective marker *-le* and are used in the following agency- and individuation-related conditions.

One crucial distinction between the spatially and temporally telic sentences is that the former with *dao* 'arrive' denotes an instantaneous, non-durative event, and the latter describes a durative event approaching an endpoint incrementally[4]. Linguistic studies suggest that both BA and BEI are compatible with a telic situation (Liu, 1997; Yang, 1995; Xiao and McEnery, 2004b). We examine whether BA and BEI are acceptable in both temporally and spatially context in the *telic*-condition.

2.2 Agency

Adopting cues highlighting agentive or non-agentive feature can modify the thematic roles mapped to NPs. We form three condition groups: (1) a manner adverbial 'volitionally' vs. 'unfortunately', (2) a subordinate clause with 'do' vs. 'happen', and (3) a purpose phrase with 'in order to' (Gruber, 1967; Cruse, 1973) to construct sentences.

2.2.1 *Volition* and *non-volition*-condition

The Chinese adverbial *gu-yi* 'volitionally' after NP1 in (4) presents the intention of NP1 to carry out an action (Cruse, 1973) and drives NP1 to be interpreted as an agent. It harmonizes with BA, which indicates NP1 as an agent, but conflicts with BEI, which signals NP1 as a patient. By contrast, the adverbial *bu-xing* 'unfortunately' in (5) demonstrates a non-volitional, passive property of NP1. It agrees with BEI but contradicts BA.

(4) 郭杰 故意 把/被 张伟 拉到了门口。

guo-jie bu-xing ba/bei zhang-wei da dao -le men-kou.
Guojie unfortunately BA/BEI Zhangwei pull arrive -PERF door
'Guojie pulled Zhangwei to the door unfortunately.'/
'Guojie was pulled to the door by Zhangwei unfortunately.'

2.2.2 *Do*- and *happen*-condition

The *do/happen*-clause is another way to test agentive and non-agentive property. For example, *John* in *John punched Bill* is viewed as an agent, as *What John did was punch Bill* is normal and *What happened to John was punch Bill* is odd (Cruse, 1973). On the contrary, *John* in *John was punched by Bill* is viewed as non-agent, as *What happened to John was that he was punched by Bill* is normal and *What John did was that he was punched by Bill* is abnormal. We place the *do/happen*-clause as in (6) and (7) to modify agentive/non-agentive feature of NP1. The *do*-clause emphasizes the agentive feature of NP1 with BA and the *happen*-clause harmonizes with the patient role of NP1 using BEI.

(6) 郭杰 昨天 做了 一件 事，
guo-jie zuo-tian zuo-le yi-jian shi
Guojie yesterday do-PERF one-CL thing
'Guojie did something yesterday,'

他 把/被 张伟 拉到了门口。
ta ba/bei zhang-wei la dao -le men-kou
he BA/BEI Zhangwei pull arrive -PERF door
'(that is,) he pulled Zhangwei to the door.'/
'(that is,) he was pulled by Zhangwei to the door.'

(7) 昨天 发生 在 郭杰 身上的 是，

'What happened to Guojie yesterday is,'

他 把/被 张伟 拉到了门口。
ta ba/bei zhang-wei la dao -le men-kou
he BA/BEI Zhangwei pull arrive -PERF door
'(that) he pulled Zhangwei to the door.'
'(that) he was pulled to the door by Zhangwei.'

2.2.3 *Aim*-condition

A third widely discussed test for the agency is the modifiability by a phrase with *in order to*. For example, *John* in *John looked into the room in order to learn who was there* is viewed as a willful agent (Gruber, 1967). Similarly, the purpose phrase *wei-le da-dao mu-di* 'in order to achieve goal' after the NP1 in (8) emphasizes NP1's purpose, which matches NP1's agent role with BA and contradict NP1's patient role with BEI.

In sum, we predict that the tested telic context show consistent BA/BEI-preference under the effect of agency, that is, the *volition*-, *do*- and *aim*-

[3] The compatibility test of *in*-adverbial can verify their telic feature (Vendler, 1957): both telic predicates can combine with Chinese equivalent of 'in an hour' *zai yi-ge xiao-shi nei* (Xiao and McEnery, 2004a), as shown in the sentence *Guo-jie zai yi-ge xiao-shi nei ba Zhang-wei la-dao -le men-kou/xun-chi -le yi-dun* 'Guojie pulled Zhangwei to the door/reprimanded Wubo once in an hour.')

[4] Although translated to a *to*-PP in English, the Chinese adverb *dao* in (3a) can not be combined with any imperfective aspect. It differs from English *to*-PP, which involves a directional meaning and is compatible with an imperfective aspect (e.g., *John is pulling Jim to the door*) (Xiao and McEnery, 2004a).

(8) 郭杰　为了　　达到　目的，

'(that) he was pulled by Zhangwei to the door.'

condition with agentive cues for NP1 prefer BA, and the *non-volition*- and *happen*-condition with non-agentive cues for NP1 prefer BEI.

2.3 Individuation

Human common nouns like 'worker' are regarded to be less identifiable and individuated than human proper names like *Guo-jie*, which are more likely to be perceived as agents in human comprehension (Fraurud, 1996; Yamamoto, 1999; Dixon, 1979; Timberlake, 1977). In *NP2*$_{com}$-condition (9), frequently used occupation names like "worker" are used as common nouns for NP2 and male human names are used as proper names for NP1. *NP1*$_{com}$-condition (10) is in reverse. We predict that humans prefer BA for *NP2*$_{com}$-condition and BEI for *NP1*$_{com}$-condition as the proper names are more likely to be viewed as agents.

Human BA/BEI-preference can be attributed to human sensitivity to different ways of referring such as common nouns vs. proper names. It is uncertain whether LMs own this sensitivity. Therefore, we predict that LMs may behave differently. For grammatical correctness, each common noun occurs with a numeral *yi* 'one' and the general classifier *ge* (Zhang, 2013).

NP2$_{com}$-condition:

(9) 郭杰　把/被　一个工人　　拉到了门口。
guo-jie ba/bei yi-ge go-ren　la dao -le men-kou
Guojie BA/BEI one-CL worker pull arrive -PERF door

yi-ge gong-ren ba/bei zhang-wei la dao -le men-kou
one-CL worker BA/BEI Zhangwei pull arrive -PERF door
'A worker pulled Zhangwei to the door.'/
'A worker was pulled to the door by Zhangwei.'

3 Experiment

3.1 Human Judgment Task

We prepare 18 verbs to form 36 sentences either with BA or with BEI for each of the 9 conditions, resulting in 324 sentences in total[5]. To avoid repeating verbs and NPs, we split these sentences evenly over 18 lists following a Latin-Square design, with 18 sentences in each list. Every list contains each condition twice and each of the 18 verbs once. Additional 10 sentences which are either semantically or syntactically incorrect were added to each list as fillers. Each of the lists was pseudo-randomized so that two test items from a single condition did not appear sequentially.

We conducted an acceptability judgment experiment using a four-point-scale questionnaire to obtain human ratings. Participants are required to mark the sentences following this instruction: entirely acceptable sentences should be marked with 1; sentences containing some expression which is acceptable to some degree, but not fully acceptable, should be marked with 2; sentences containing some expression which is unacceptable to some degree, but not fully unacceptable, should be marked with 3; and sentences containing some expression which is fully unacceptable should be marked with 4. A larger score indicates a sentence is less acceptable.

This human judgement experiment was administered on the Chinese website of *wenjuanxing*[6]. 121 university students from mainland China participated in this experiment voluntarily. Their ages range from 18 to 25 years old, with a mean age of 20.6 years. Fifty-six of them are female. They all reported a monolingual Mandarin Chinese background except one female. Her and the other 11 participants' data were filtered out because of their low judgment scores (meaning high acceptable) on unacceptable filler items sentences (mean < 3.5).

3.2 LM Prediction

We replace BA/BEI in our sentences with a masked token and measure the output at the corresponding position for BA and BEI in different conditions for six pre-trained transformer-based LMs: BERT-base (Devlin et al., 2018), RoBERTa-base (Liu et al., 2019), ELECTRA-large (Clark et al., 2020), ERNIE 1.0 (Sun et al., 2019), MacBERT-base and MacBERT-large (Cui et al., 2020), implemented in

[5] We publish all the sentences at Github.
[6] https://www.wjx.cn

the Huggingface Transformers library (Wolf et al., 2019). Even though these LMs have different pretraining tasks and use different databases in different sizes (see Table 5 in Appendix), we expect that they show (or tend to show) a consistent rather than inconsistent performance in the prediction of BA/BEI for each condition.

3.3 Measure

We define $\mathcal{B}_{hum}$ as BA/BEI-preference bias $\mathcal{B}$ for humans based on $Accep$ which is the judgment score for each sentence S. $\mathcal{B}_{hum}$ quantifies the preference of a sentence to occur with BA or BEI. It is negative with BA preferred and positive with BEI preferred.

$$\mathcal{B}_{hum} = Accep(\text{BA}|S) - Accep(\text{BEI}|S) \qquad (1)$$

For LMs, surprisal is defined as the inverse log probability of a word (w_i) conditioned on the surrounding words in a context C:

$$\mathcal{S}urp(w_i|C) = log\frac{1}{p(w_i|C)} \qquad (2)$$

Due to the fact that BA and BEI are not exclusive to each other[7], we follow Misra et al. (2020) and define BA/BEI-preference bias $\mathcal{B}$ for LM $\mathcal{B}_{LM}$ as the surprisal difference between BA and BEI.

$$\mathcal{B}_{LM} = Surp(\text{BA}|C) - Surp(\text{BEI}|C) \qquad (3)$$

$\mathcal{B}_{LM}$ is negative if BA is preferred and positive if BEI is preferred. $\mathcal{B}_{LM}$ has been applied as a linking function between human expectations and LM's output (Hale, 2001). In this paper, we employ $\mathcal{B}_{LM}$ and $\mathcal{B}_{hum}$ to test the BA/BEI-preference of humans and LMs under the effects of various features.

4 Results

Average $\mathcal{B}_{LM}$ and $\mathcal{B}_{hum}$ are visualized in Figure 1. $\mathcal{B}_{LM}$ is averaged for every condition within each LM. $\mathcal{B}_{hum}$ is averaged over all the participants for every condition. We further examine average $Accep$ and average $Surp$ for BA and BEI from RoBERTa-base for each condition in Figure 2 (other LMs present similar results, see Figure 5 in Appendix). The human $Accep$ for all items in each condition show a lower averaged coefficient of variation over all the conditions than $Surp$ of all LMs (0.42 vs. 0.64, detailed results see Figure 4 in Appendix). Statistically, the temporally telic and spatially telic context in all the conditions except for *telic*- and *NP2$_{com}$*-condition show quite consistent pattern regarding the BA/BEI-preference in both human $Accep$ and $Surp$ of LMs, suggesting that the difference between temporally telic and spatially telic context play a limited role in the BA/BEI-preference for these conditions. Thus we compare the results between temporally telic and spatially telic context only for *telic*- and *NP2$_{com}$*-condition. The human $Accep$ and $Surp$ of each LM for each condition are fitted with a linear mixed-effects model using the lme4 package in R (Bates et al., 2015). The model treated variable BA/BEI as a fixed effect with a random intercept for each verb (detailed results see Table 3 in Appendix).

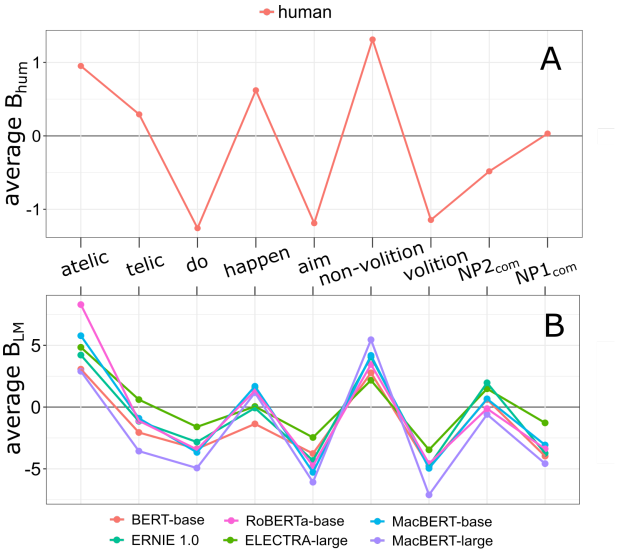

Figure 1: Average $\mathcal{B}_{hum}$ from human acceptability judgment experiment (A) and average $\mathcal{B}_{LM}$ for six LMs (B) for each condition. The 9 conditions belong to three groups: *telic/atelic*-condition is related to telicity (Sec. 2.1), *do/happen/aim/non-volition/volition*-condition is related to agency (Sec. 2.2) and *NP2$_{com}$/NP1$_{com}$*-condition is related to individuation (Sec. 2.3). The zero value is set as a reference line.

4.1 Telicity

In *atelic*-condition, positive $\mathcal{B}_{hum}$ ($p \leq 0.001$) and $\mathcal{B}_{LM}$ ($p \leq 0.05$ for all the LMs), see Figure 1 and Table 3 in Appendix, confirm our prediction of BEI-preference for humans and LMs. In *telic*-condition, Figure 2 shows that the human acceptability of BA and BEI are relatively high (low judgement scores), which supports our prediction that BA and BEI are

[7] This non-exclusivity is also verified in our study by the result of higher human acceptability for both BA and BEI in *telic*-condition than in *atelic*-condition, see Figure 2.

condition	context	Humans	BERT-base	RoBERTa-base	ELECTRA-large	ERNIE 1.0	MacBERT-base	MacBERT-large
telic	temporal telic	bei***	ba***	–	bei**	–	–	ba***
	spatially telic	–	ba***	ba***	ba**	ba***	ba***	ba***
NP2$_{\text{com}}$	temporally telic	–	bei*	bei**	bei***	bei***	bei***	–
	spatially telic	ba***	–	ba**	–	bei**	ba*	ba**

Table 1: Preference comparison between BA and BEI for humans and LMs in the temporally and spatially telic context for *telic*- and *NP2$_{com}$*-condition. (ba: statistically significant BA-preference, bei: statistically significant BEI-preference. **: $p \leq 0.01$, ***: $p \leq 0.001$)

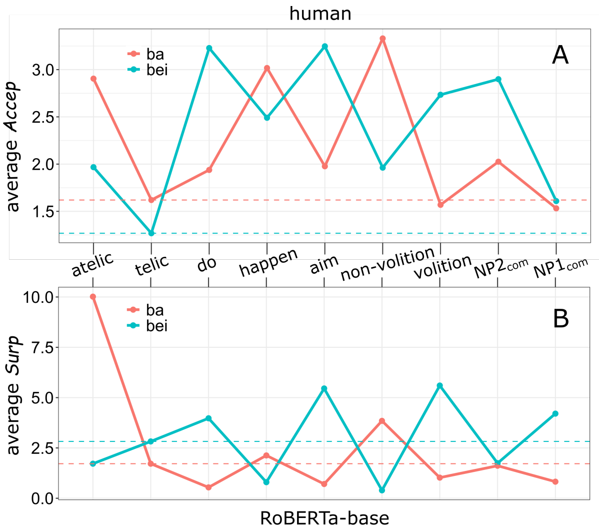

Figure 2: Average *Accep* from human acceptability judgment experiment (A) and average *Surp* for RoBERTa-base (B) for each condition. The 9 conditions belong to three groups: *telic/atelic*-condition is related to telicity (Sec. 2.1), *do/happen/aim/non-volition/volition*-condition is related to agency (Sec. 2.2) and *NP2$_{com}$/NP1$_{com}$*-condition is related to individuation (Sec. 2.3). The values from *telic*-condition are set as reference lines.

both acceptable in the telic context. However, positive $\mathcal{B}_{hum}$ ($p \leq 0.01$) and negative $\mathcal{B}_{LM}$ ($p \leq 0.05$ except ELECTRA-large) in Figure 1 reveal distinction between humans and LMs.

Results of humans and each LM in both temporally and spatially telic context of *telic*-condition are further compared at Table 1. While participants preferred BEI ($p \leq 0.001$) for the temporally telic sentences, LMs show inconsistent results. As LMs prefer BA ($p \leq 0.01$) consistently for the spatially telic sentences, no significant preference is found in human judgment.

4.2 Agency

Figure 1 shows consistent negative $\mathcal{B}_{LM}$ and $\mathcal{B}_{hum}$ for *do/aim/volition*-condition (all with $p \leq 0.001$) and consistent positive $\mathcal{B}_{LM}$ and $\mathcal{B}_{hum}$ (all with $p \leq 0.001$) for *non-volition*-condition. A small discrepancy is found in *happen*-condition, where participants preferred BEI ($p \leq 0.001$) but three LMs out of six do not present clear BEI-preference (see Table 3 in Appendix). Mostly-aligned preferences between humans and LMs for agency-related conditions suggest that both rely heavily on the agentive/non-agentive features in the tested telic context to construct argument hierarchy as predicted.

We observe an interesting discrepancy between humans and LMs in the responses to the agency-related and *telic*-condition sentences. Participants scored almost all the agency-related sentences above the reference lines (*telic*-condition), see Figure 2(A), but the results of the LMs do not present this apparent offset, see Figure 2(B). This discrepancy between human and model results is likely contributed by the differences in the mechanism of human judgment and LM prediction. Masked language models behave as a classifier which assigns probability to BA and BEI in sentence context depending on their relative compatibility to the other tokens in the vocabulary. Therefore, the probability of BA/BEI does not directly reflect the adequacy of the whole sentence. In contrast, participants score the acceptability of each sentence as a whole. Acceptability of other factors inside the sentence such as attached adverbials/subordinate clauses may also play a role in participants' judgment.

4.3 Individuation

In *NP1$_{com}$*-condition, LMs prefer BA ($p \leq 0.001$) but no significant preference is observed in human judgment for telic context. In *NP2$_{com}$*-condition, humans show BA-preference ($p \leq 0.001$) but three LMs out of six show clear BEI-preference, see Table 3 in Appendix. We compare further between different telic contexts in *NP2$_{com}$*-condition, see Table 1. In temporally telic *NP2$_{com}$*-condition, LMs show a mostly consistent BEI-preference ($p \leq 0.05$ except MacBERT-large) but no significant preference is found in human judgment. In spatially telic *NP2$_{com}$*-condition, humans prefer BA ($p \leq 0.001$)

but inconsistent preference is observed for LMs. These results clearly show that LMs differ from humans in their interpretation of human common NPs like *yi-ge gong-ren* ‘one-CL worker’ and proper names like *Zhang-wei*.

A follow-up study is carried out to confirm the negligible influence from *yi-ge* ‘one-CL’ and examine the thematic relation between common nouns (*C*, like *gong-ren* ‘worker’) and proper names (*P*, like *Zhang-wei*) in LMs. We focus on the spatially telic context since LMs show a more consistent performance in this context than that in the temporally telic context in *telic*-condition, as indicated in Table 1. The *telic*-, $NP1_{com}$- and $NP2_{com}$-condition in spatially telic context is renamed as *P/P*-, C_{cl}/*P*- and *P*/C_{cl}-condition, in the format of "[NP1]/[NP2]-condition". C_{cl} represents a common noun phrase composed of a numeral, a classifier and a common noun, e.g., *yi-ge gong-ren* ‘one-CL worker’. For a comprehensive comparison, we add two more conditions C_{cl}/C_{cl} and *C/P*. Table 2 exemplifies all the five conditions.

The BA/BEI-preference of six LMs is obtained for each condition (detailed results see Table 4) and their average $\mathcal{B}_{LM}$ is shown in Figure 3. Figure 3 shows consistent negative $\mathcal{B}_{LM}$ for *P/P*-condition (p ≤0.01) and C_{cl}/C_{cl}-condition (p ≤0.06 except BERT-base) where subject and object are equal in the degree of individuation (both are *P* or both are C_{cl}). This result implies that the spatially telic context is inclined to prefer BA under the condition that both NPs are equal in the individuation degree.

Compared to *P/P*- and C_{cl}/C_{cl}-condition, BA-preference increases (larger negative $\mathcal{B}_{LM}$) in C_{cl}/*P*-condition and decreases (smaller negative even positive $\mathcal{B}_{LM}$) in *P*/C_{cl}-condition. The results suggest that the unequal individuation degree between C_{cl} and *P* also imposes an effect on the preference. The agentive interpretation of C_{cl} over *P* strengthens the BA-preference in C_{cl}/*P*-condition and weakens the BA-preference in *P*/C_{cl}-condition.

Furthermore, ‘one-CL’ in common NPs shows no significant effect on preference, as *C/P*-condition agrees with C_{cl}/*P*-condition in the BA-preference (p ≤0.05 for all LMs in both conditions). In sum, these results suggest that LMs deliver a more agentive interpretation of the common nouns than that of the proper names in the spatially telic context.

condition	NP1	NP2
P/P	*guo-jie* ‘Guojie’ (**P**)	*zhang-wei* ‘Zhangwei’ (**P**)
C_{cl}/C_{cl}	*yi-ge gong-ren* ‘one-CL worker’ (**C_{cl}**)	*yi-ge si-ji* ‘one-CL driver’ (**C_{cl}**)
C_{cl}/P	*yi-ge gong-ren* ‘one-CL worker’ (**C_{cl}**)	*zhang-wei* ‘Zhangwei’ (**P**)
P/C_{cl}	*guo-jie* ‘Guojie’ (**P**)	*yi-ge gong-ren* ‘one-CL worker’(**C_{cl}**)
C/P	*gong-ren* ‘worker’ (**C**)	*zhang-wei* ‘Zhangwei’ (**P**)

Table 2: Examples of NPs for different conditions with a spatially telic context. (**P**: proper name, **C**: common noun, **C_{cl}**: common noun phrase with a numeral and a classifier)

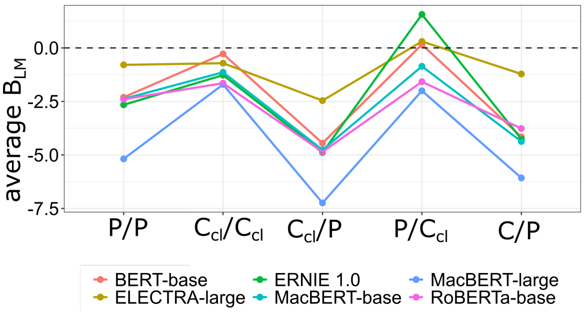

Figure 3: Average $\mathcal{B}_{LM}$ of six LMs for items with a spatially telic context. The value of zero is set as a reference line.

5 Discussion

This study compares LMs and human behavior in argument hierarchy construction. The results show that LMs and humans perform more similarly with atelic feature than with telic feature. In telic context, LMs and humans show similar behaviour with (non-)agentive features, but differently with individuation-related features. We discuss these (dis)similarities from the following four perspectives.

LMs rely on non-durative property to construct argument hierarchy in a telic context. In *telic*-condition, spatially telic sentences with adverb *dao* ‘arrive’ (like 3a) signal non-durative events and show a consistent preference for all LMs, while temporally telic sentences (like 3b) describe durative events and display an inconsistent preference among the LMs. A previous study has suggested that non-duration plays a crucial role for LMs to make telic interpretation (Zhao et al., 2021). Our results further develop the importance of non-durative property: LMs rely more strongly on the non-durative property (compared to durative property) to construct a consistent argument hierarchy in a telic context.

LMs lack sufficient sensitivity in pragmatic function to make the human-like prediction. BEI has a specific pragmatic function in forming adversative passives which express undesirable, unfortunate events (Li and Thompson, 1989; Chao and Zhao, 1968; Philipp et al., 2008) and often comes with disposal verbs denoting unfavorable meaning like *piping* 'criticize' and *da* 'hit' (Cook, 2019; Wenfang and Susumu, 2013; Loar, 2012). The majority of the temporally telic sentences (7 out of 9) contain disposal verbs whose close connection with BEI may directly contribute to the human BEI-preference in the temporally *telic*-condition. The pragmatic function of BEI may also increase human BEI-preference for *happen*-condition. The verb *fa-sheng* 'happen' has a negative prosody (i.e., is likely to occur in a negative context) (Zhang and Ping, 2006; Xiao and McEnery, 2006; Sinclair and Sinclair, 1991), making BEI natural to occur in *happen*-condition in our results.

However, LMs fail to show sensitivity in this pragmatic function of BEI, as no human-like preference is found for both temporally *telic*- and *happen*-condition. Our results are in line with previous study that pre-trained transformer-based LMs have shortage in acquiring pragmatic knowledge (Ettinger, 2020).

LMs are inclined to interpret the subject as an agent in a spatially telic context. As both NP1 and NP2 are proper nouns, humans show high acceptability of both BA and BEI in a spatially telic context. It indicates that participants do not interpret argument hierarchy based on the linear position of arguments, at least in Mandarin Chinese (Philipp et al., 2008; Bornkessel and Schlesewsky, 2006), that is, the sequence subject-verb-object does not determine the argument assignment. However, LMs show a clear preference for BA in a spatially telic context where both NPs are common nouns (C_{cl}/C_{cl}-condition) or proper names (*telic*-condition), indicating that LMs intend to interpret the subject in the telic context as an agent. This BA-preference in LMs may be explained by 1) unbalanced occurrences between active and passive voice, as more active sentences increase the probability of subjects interpreted as agents, and 2) a higher occurrence frequency of BA over BEI during training. The occurrence frequencies of active/passive and BA/BEI in the LMs' training corpus worth further investigation.

Individuation degree plays a different role between LMs and humans in spatially telic context. Proper names have a higher degree of individuation than common nouns. A proper name is more likely to function as an agent than a common NP (Yamamoto, 1999; Dixon, 1979), which agrees with the results in spatially telic context for humans: 1) BA-preference in *NP2*$_{com}$-condition and 2) high acceptability of BEI in *NP1*$_{com}$-condition[8].

However, LMs show an opposite tendency in viewing a common NP in spatially telic context as an agent through BA-preference for *NP1*$_{com}$-condition for all LMs. The follow-up study in spatially telic context further confirms the agentive interpretation of common nouns in LMs.

LMs fall short to interpret proper names as agents, which may be attributed to their low occurrence frequency during training. Moreover, almost each character in proper names has separate semantic meanings. We use *Zhang-wei* as an example. *Zhang* is usually used as a classifier for flat objects like table and paper and *wei* forms a number of adjectives meaning great and grand. Therefore, LMs may have difficulty in interpreting the combination of these characters as human names (Lake and Murphy, 2021; Yu and Ettinger, 2020).

6 Future work

Note that telic predicates in the agency- and individuation-related conditions are necessary to build items in the Chinese structure "NP1+BA/BEI+NP2+VP" (Xiao et al., 2006), which is also verified by the high acceptability of BA and BEI in *telic*-condition (low judgment scores in Figure 2(A)) in our experiment. Future work could continue to explore LMs' sensitivity to agency- and individuation-related features isolated from telic context in syntax-semantics-interface. Moreover, as we treat LMs as a whole and pay attention to their final predictions of BA/BEI to compare with human judgment in our study, more probing measures, such as attention probing, could be taken to deepen our understanding about internal performance of LMs.

[8] In *NP1*$_{com}$-condition, humans show high acceptability for both BA and BEI as indicated in Figure 2(A). The high acceptability of BA for *NP1*$_{com}$-condition may be contributed by the tendency of BA-construction with a definite NP2 (Ye et al., 2007).

7 Conclusion

This study uses BA/BEI-preference in the Chinese structure "NP1+BA/BEI+NP2+VP" to examine if pre-trained transformer-based language models construct similar argument hierarchy like humans, i.e., the interpretation of *Who did what to Whom*, with the effect of telicity-, agency- and individuation-related features. The results show that LMs and humans behave similarly for atelic and non-agentive/agentive features, but differently to telic and individuation-related features in the tested context. Specifically, their discrepancy in the temporally telic context suggests that unlike humans, LMs lack sufficient sensitivity to pragmatic function of BEI describing undesirable events with disposal verbs. The different BA/BEI-preference in the sentences with human common vs. proper nouns between LMs and humans indicates that unlike humans who perceive proper nouns as agents, LMs tend to interpret common nouns as agents.

A Appendix

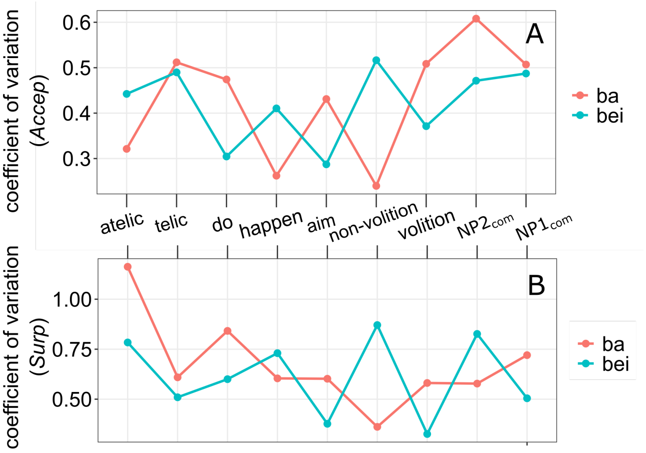

Figure 4: Coefficient of variation of human *Accep* (A) and *Surp* averaged across six LMs (B) for each condition with BA and BEI. We find that in human *Accep*, the preferred one between BA and BEI shows a higher coefficient than the other one (e.g., the *do*-condition prefers BA and BA has a higher coefficient than BEI) for all the conditions except for *telic*-condition. In *telic*-condition where both BA and BEI are high acceptable in human judgment, their coefficients are also at a relatively high level. LMs show a similar trend.

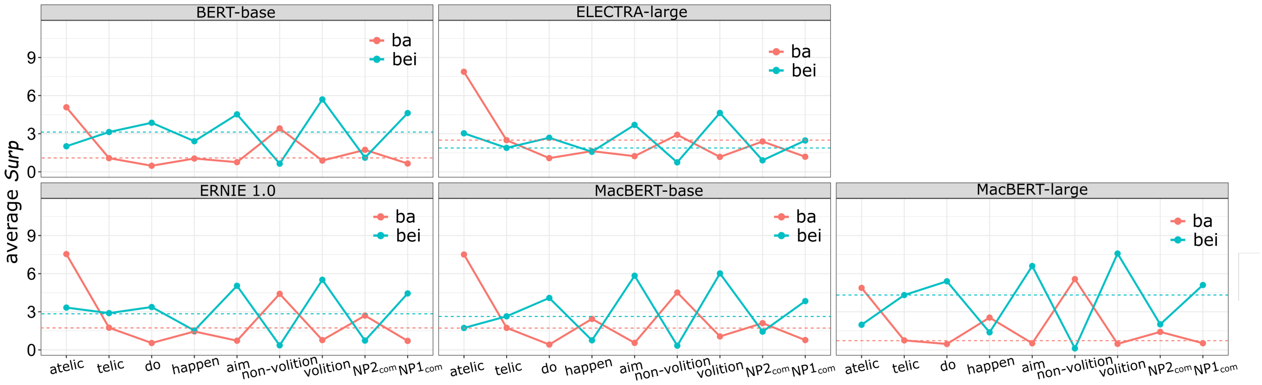

Figure 5: Average *Surp* for BERT-base, ELECTRA-large, ERNIE1.0, MacBERT-large and MacBERT-base. The values from the *telic*-condition are set as reference lines.

Abstract

While there has been substantial progress in developing systems to automate fact-checking, they still lack credibility in the eyes of the users. Thus, an interesting approach has emerged: to perform automatic fact-checking by verifying whether an input claim has been previously fact-checked by professional fact-checkers and to return back an article that explains their decision. This is a sensible approach as people trust manual fact-checking, and as many claims are repeated multiple times. Yet, a major issue when building such systems is the small number of known tweet–verifying article pairs available for training. Here, we aim to bridge this gap by making use of crowd fact-checking, i.e., mining claims in social media for which users have responded with a link to a fact-checking article. In particular, we mine a large-scale collection of 330,000 tweets paired with a corresponding fact-checking article. We further propose an end-to-end framework to learn from this noisy data based on modified self-adaptive training, in a distant supervision scenario. Our experiments on the CLEF'21 CheckThat! test set show improvements over the state of the art by two points absolute. Our code and datasets are available at https://github.com/mhardalov/crowdchecked-claims

1 Introduction

The massive spread of disinformation online, especially in social media, was counter-acted by major efforts to limit the impact of false information not only by journalists and fact-checking organizations but also by governments, private companies, researchers, and ordinary Internet users. This includes building systems for automatic fact-checking (Zubiaga et al., 2016; Derczynski et al., 2017; Nakov et al., 2021a; Gu et al., 2022; Guo et al., 2022; Hardalov et al., 2022), fake news (Ferreira and Vlachos, 2016; Nguyen et al., 2022), and fake news website detection (Baly et al., 2020; Stefanov et al., 2020; Panayotov et al., 2022).

Does Ivermectin Cause Sterility in Men?
One study purportedly found that 85% of men who were given the anti-parasitic were sterile following the research period.
By Madison Dapcevich
Published 8 September 2021, Updated 10 September 2021

Figure 1: Crowd fact-checking thread on Twitter. The first tweet (**Post w/ claim**) makes the claim that *Ivermectin causes sterility in men*, which then receives **replies**. A **(crowd) fact-checker** replies with a link to a **verifying article** from a fact-checking website. We pair the *article* with the *tweet that made this claim* (the first post ✓), as it is irrelevant (✗) to the other *replies*.

Unfortunately, fully automatic systems still lack credibility, and thus it was proposed to focus on detecting previously fact-checked claims instead: *Given a user comment, detect whether the claim it makes was previously fact-checked with respect to a collection of verified claims and their corresponding articles* (see Table 1). This task is an integral part of an end-to-end fact-checking pipeline (Hassan et al., 2017), and also an important task on its own right as people often repeat the same claim (Barrón-Cedeño et al., 2020b; Vo and Lee, 2020; Shaar et al., 2021). Research on this problem is limited by data scarceness, with datasets typically having about a 1,000 tweet–verifying article pairs (Barrón-Cedeño et al., 2020b; Shaar et al., 2020, 2021), with the notable exception of (Vo and Lee, 2020), which contains 19K claims about images matched against 3K fact-checking articles.

We propose to bridge this gap using crowd fact-checking to create a large collection of tweet–verifying article pairs, which we then label (if the pair is correctly matched) automatically using distant supervision. An example is shown in Figure 1.

Our contributions are as follows:

- we mine a large-scale collection of 330,000 tweets paired with fact-checking articles;
- we propose two distant supervision strategies to label the CrowdChecked dataset;
- we propose a novel method to learn from this data using modified self-adaptive training;
- we demonstrate sizable improvements over the state of the art on a standard test set.

2 Our Dataset: *CrowdChecked*

2.1 Dataset Collection

We use Snopes as our target fact-checking website, due to its popularity among both Internet users and researchers (Popat et al., 2016; Hanselowski et al., 2019; Augenstein et al., 2019; Tchechmedjiev et al., 2019). We further use Twitter as the source for collecting user messages, which could contain claims and fact-checks of these claims.

Our data collection setup is similar to the one in (Vo and Lee, 2019). First, we form a query to select tweets that contain a link to a fact-check from Snopes (*url:snopes.com/fact-check/*), which is either a reply or a quote tweet, and not a retweet. An example result from the query is shown in Figure 1, where the tweet *from the crowd fact-checker* contains a link to a fact-checking article. We then assess its relevance to the claim (if any) made in the first tweet (the root of the conversation) and the last reply in order to obtain tweet–verified article pairs. We analyze in more detail the conversational structure of these threads in Section 2.2.

We collected all tweets matching our query from October 2017 till October 2021, obtaining a total of 482,736 unique hits. We further collected 148,503 reply tweets and 204,250 conversation (root) tweets.[1] Finally, we filter out malformed pairs, i.e., tweets linking to themselves, empty tweets, non-English ones, such with no resolved URLs in the Twitter object (*'entities'*), with broken links to the fact-checking website, and all tweets in the CheckThat '21 dataset. We ended up with 332,660 unique tweet–article pairs (shown in first row in Table 5), 316,564 unique tweets, and 10,340 fact-checking articles from Snopes they point to.

User Post w/ Claim: Sen. Mitch McConnell: "As recently as October, now-President Biden said you can't legislate by executive action unless you are a dictator. Well, in one week, he signed more than 30 unilateral actions." [URL] — Forbes (@Forbes) January 28, 2021		
	Verified Claims and their Corresponding Articles	
(1)	When he was still a candidate for the presidency in October 2020, U.S. President Joe Biden said, "You can't legislate by executive order unless you're a dictator." http://snopes.com/fact-check/biden-executive-order-dictator/	✓
(2)	U.S. Sen. Mitch McConnell said he would not participate in 2020 election debates that include female moderators. http://snopes.com/fact-check/mitch-mcconnell-debate-female/	✗

Table 1: Illustrative examples for the task of detecting previously fact-checked claims. The **post contains a claim** (related to *legislation and dictatorship*), the **Verified Claims** are part of a search collection of previous fact-checks. In row (*1*), the fact-check is a correct match for the claim made in the tweet (✓), whereas in (*2*), the claim still discusses *Sen. Mitch McConnell*, but it is a different claim (✗), and thus this is an incorrect pair.

More detail about the process of collecting fact-checking articles as well as detailed statistics are given in Appendix B.1 and on Figure 2.

2.2 Tweet Collection

(Conversation Structure) It is important to note that the *'fact-checking'* tweet can be part of a multiple-turn conversational thread, therefore taking the post that it replies to (previous turn), does not always express a claim which the current tweet targets. In order to better understand this, we performed manual analysis of some conversational threads. Conversational threads in Twitter are organized as shown Figure 1: the root is the first comment, then there can be a long discussion, followed by a fact-checking comment (i.e., the one with a link to a fact-checking article on Snopes). In our analysis, we identify four patterns: (*i*) the current tweet verifies a claim in the tweet it replies to, (*ii*) the tweet verifies the root of the conversation, (*iii*) the tweet does not verify any claim in the chain (a common scenario), and (*iv*) the fact-check targets a claim that was not expressed in the root or in the closest tweet (this was in very few cases). This analysis suggests that for the task of detecting previously fact-checked claims, it is sufficient to collect the triplet of the fact-checking tweet, the root of the conversation (*conversation*), and the tweet that the target tweet is replying to (*reply*).

[1] The sum of the unique replies and of the conversation tweets is not equal to the total number of fact-checking tweets, as more than one tweet might reply to the same comment.

Dataset	**Tweets**‡	**Words**			**Vocab**
	|Unique|	Mean	50%	Max	|Unique|
CrowdChecked **(Ours)**	316,564	12.2	11	60	114,727
CheckThat '21	1,399	17.5	16	62	9,007

Table 2: Statistics about our dataset vs. *CheckThat '21*. ‡The number of unique tweets is lower than the total number of tweet–article pairs, as an input tweet could be fact-checked by multiple articles.

2.3 Comparison to Existing Datasets

We compare our dataset to a closely related dataset from the CLEF-2021 *CheckThat '21* on Detecting Previously Fact-Checked Claims in Tweets (Shaar et al., 2021), to which we will refer as CheckThat '21 in the rest of the paper. There exist other related datasets that are smaller (Barrón-Cedeño et al., 2020b), come from a different domain (Shaar et al., 2021), are not in English (Elsayed et al., 2019), or are multi-modal (Vo and Lee, 2020).

Table 2 compares our CrowdChecked to CheckThat '21 in terms of number of examples, length of the tweets, and vocabulary size. Before calculating these statistics, we lowercased the text and we removed all URLs, Twitter handlers, English stop words, and punctuation. We can see in Table 2 that CrowdChecked contains two orders of magnitude more examples, slightly shorter tweets (but the maximum length stays approximately the same, which can be explained by the word limit of Twitter), and has a vocabulary size that is an order of magnitude larger. Note, however, that many examples in CrowdChecked are incorrect matches (see Section 2.1), and thus we use distant supervision to label them (see Section 2.4), with the resulting dataset sizes of matching pairs shown in Table 5. Here, we want to emphasize that there is absolutely no overlap at all between *CrowdChecked* and *CheckThat '21* in terms of tweets/claims.

In terms of topics, the claims in both our dataset and CheckThat '21 are quite diverse, including fact-checks for a broad set of topics related, but not limited to politics (e.g., the Capitol Hill riots, US elections), pop culture (e.g., famous performers and actors such as Drake and Leonardo di Caprio), brands (e.g., McDonald's and Disney), and COVID-19, among many others. Illustrative examples of the claim/topic diversity can be found in Tables 1 and 10 (in the Appendix). Moreover, the collection of Snopes articles contains almost 14K different fact-checks on an even wider range of topics, which further diversifies the set of tweet–article pairs.

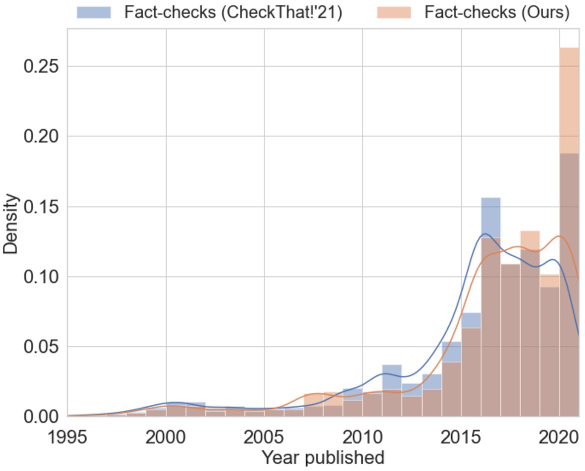

Figure 2: Histogram of the year of publication of the Snopes articles included in CrowdChecked (our dataset) vs. those in CheckThat '21.

Finally, we compare the set of Snopes fact-checking articles referenced by the crowd fact-checkers to the ones included in the *CheckThat '21* competition. We can see that the tweets in *CrowdChecked* refer to less articles (namely 10,340), compared to *CheckThat '21*, which consists of 13,835 articles. A total of 8,898 articles are present in both datasets. Since the *CheckThat '21* is collected earlier, it includes less articles from recent years compared to *CrowdChecked*, and peaks at 2016/2017. Nevertheless, for *CheckThat '21*, the number of Snopes articles included in a claim–article pair is far less compared to our dataset (even after filtering out unrelated pairs), as it is capped at the number of tweets included in that dataset (which is 1.4K).

More detail about the process of collecting the fact-checking articles is given in Appendix B.1.

2.4 Data Labeling (Distant Supervision)

To label our examples, we experiment with two distant supervision approaches: (*i*) based on the Jaccard similarity between the tweet and the target fact-checking article, and (*ii*) based on the predictions of a model trained on *CheckThat '21*.

Jaccard Similarity In this approach, we first pre-process the texts by converting them to lowercase, removing all URLs and replacing all numbers with a single zero. Then, we tokenize them using NLTK's *Twitter tokenizer* (Loper and Bird, 2002), and we strip all handles and user mentions. Finally, we filter out all stop words and punctuation (including quotes and special symbols) and we stem all tokens using the Porter stemmer (Porter, 1980).

Range (Jaccard)	Examples (%)	Correct Pairs Reply (%)	Correct Pairs Conv. (%)
[0.0;0.1)	62.57	5.88	0.00
[0.1;0.2)	18.98	36.36	14.29
[0.2;0.3)	10.21	46.67	50.00
[0.3;0.4)	4.17	76.47	78.57
[0.4;0.5)	2.33	92.86	92.86
[0.5;0.6)	1.08	94.12	94.12
[0.6;0.7)	0.43	80.00	80.00
[0.7;0.8)	0.11	92.31	92.31
[0.8;0.9)	0.05	91.67	92.86
[0.9;1.0]	0.02	100.00	100.00

Table 3: Proportion of examples in different bins based on average Jaccard similarity between the tweet and the title/subtitle. Manual annotations of the *correct pairs*.

In order to obtain a numerical score for each tweet–article pair, we calculate the *Jaccard similarity* (jac) between the normalized tweet text and each of the *title* and the *subtitle* from the Snopes article (i.e., the intersection over the union of the unique tokens). Both fields present a summary of the fact-checked claim, and thus should include more compressed information. Finally, we average these two similarity values to obtain a more robust score. Statistics are shown in Table 3.

Semi-Supervision Here, we train a Sentence-BERT (Reimers and Gurevych, 2019) model, as described in Section 3, using the manually annotated data from *CheckThat '21*. The model shows strong performance on the testing set of *CheckThat '21* (see Table 6), and thus we expect it to have good precision at detecting matching fact-checked pairs. In particular, we calculate the *cosine similarity* between the embeddings of the fact-checked tweet and the fields from the Snopes article. Statistics about the scores are shown in Table 4.

2.5 Feasibility Evaluation

To evaluate the feasibility of the obtained labels, we performed manual annotation, aiming to estimate the number of *correct pairs* (i.e., tweet–article pairs, where the article fact-checks the claim in the tweet). Our prior observations of the data suggested that unbiased sampling from the pool of tweets was not suitable, as it would include mostly pairs that have very few overlapping words, which is often an indicator that the texts are not related. Thus, we sample the candidates for annotation based on their Jaccard similarity.

Range (Cosine)	Examples (%)	Correct Pairs (%)
[-0.4;0.1)	37.83	0.00
[0.1;0.2)	16.50	6.67
[0.2;0.3)	12.28	41.46
[0.3;0.4)	10.12	36.36
[0.4;0.5)	8.58	63.16
[0.5;0.6)	6.69	70.00
[0.6;0.7)	4.47	84.21
[0.7;0.8)	2.48	96.15
[0.8;0.9)	0.97	93.10
[0.9;1.0]	0.08	100.00

Table 4: Proportion of examples in different bins based on cosine similarity using Sentence-BERT trained on CheckThat '21. Manual annotations of the *correct pairs*.

We divided the range of possible values [0;1] into 10 equally sized bins and we sampled 15 examples from each bin, resulting into 150 conversation–reply–tweet triples. Afterwards, the appropriateness of each reply-article and conversation-article pair is annotated by three annotators independently. The annotators had a *good level* of inter-annotator agreement: 0.75 in terms of Fleiss Kappa (Fleiss, 1971) (see Appendix C).

Tables 3 and 4 show the resulting estimates of *correct pairs* for both Jaccard and cosine-based labeling. In the case of Jaccard, we can see that the expected number of correct examples is very high (over 90%) in the range of *[0.4–1.0]*, and then it drastically decreases, going to almost zero when the similarity is less than 0.1. Similarly, for the cosine score, we can see high number of matches in the top 4 bins (*[0.6–1.0]*), albeit the number of matches remains relatively high in the following interval of *[0.2–0.6)* between 36% and 63%, and again gets close to zero for the lower-score bins. We analyze the distribution of the Jaccard scores in *CheckThat '21* in more detail in Appendix B.2.

3 Method

General Scheme As a base for our models, we use Sentence-BERT (SBERT). It uses a Siamese network trained with a Transformer (Vaswani et al., 2017) encoder to obtain sentence-level embeddings. We keep the base architecture proposed by Reimers and Gurevych (2019), but we use additional features, training tricks, and losses described in the next sections.

Our input is a pair of a tweet and a fact-checking article, which we encode as follows:

- Tweet: [CLS] *Tweet Text* [SEP]
- Verifying article: [CLS] *Title* [SEP] *Subtitle* [SEP] *Verified Claim* [SEP]

We train the models using the Multiple Negatives Ranking (MNR) loss (Henderson et al., 2017) (see Eq. 1), instead of the standard cross-entropy (CE) loss, as the datasets contain only positive (i.e., matching) pairs. Moreover, we propose a new variant of the MNR loss that accounts for the noise in the dataset, as described in detail in Section 3.1.

Enriched Scheme In the enriched scheme of the model, we adopt the pipeline proposed in the best-performing system from the *CheckThat '21* competition (Chernyavskiy et al., 2021). Their method consists of independent components for assessing lexical (TF.IDF-based) and semantic (SBERT-based) similarities. The SBERT models use the same architecture and input format as described in the *General Scheme* above. However, Chernyavskiy et al. (2021) use an ensemble of models, i.e., instead of calculating a single similarity between the tweet and the joint title/subtitle/verified claim, the similarities between the tweet and the claim, the joint title/claim, and the three together are obtained from three models, one using TF.IDF and one using SBERT, for each combination. These similarities are combined via a re-ranking model (see Section 3.2). In our experiments, the TF.IDF and the model ensembles are included only in the models with re-ranking.

Shuffling and Temperature Additionally, we adopt a temperature parameter (τ) in the MNR loss. We also make it trainable in order to stabilize the training process as suggested in (Chernyavskiy et al., 2022). This forces the loss to focus on the most complex and most important examples in the batch. Moreover, this effect is amplified after each epoch by an additional data shuffling that composes batches from several groups of the most similar examples. This shuffling, in turn, increases the temperature significance. The nearest neighbors forming the groups are found using the model predictions. More detail about the training and the models themselves can be found in (Chernyavskiy et al., 2021).

3.1 Training with Noisy Data

Self-Adaptive Training To account for possible noise in the distantly supervised data, we propose a new method based on self-adaptive training (Huang et al., 2020), which was introduced for classification tasks and the CE loss; however, it needs to be modified in order be used with the MNR loss. We iteratively refurbish the labels y using the predictions of the current model starting after an epoch of choice, which is a hyper-parameter:

$$y^r \leftarrow \alpha \cdot y^r + (1-\alpha) \cdot \hat{y},$$

where y^r is the current refurbished label ($y_r = y$ initially), $\hat{y}$ is the model prediction, and α is a momentum hyper-parameter (we set α to 0.9).

Since the MNR loss operates with positive pairs only (it does not operate with labels), to implement this approach, we had to modify the loss function. Let $\{c_i, v_i\}_{i=1,\ldots,m}$ be the batch of input pairs, where m is the batch size, $C, V \in \mathbb{R}^{m\times h}$ are the matrices of embeddings for the tweets and for the fact-checking articles (h is the embeddings' hidden size), and C, V are normalized to the unit hyper-sphere (we use cosine similarity), then:

$$\mathcal{L} = -\frac{1}{m}\sum_{i=1}^{m} {y^r}_i\Big(\frac{c_i^T v_i}{\tau} - \log\sum_{j=1}^{m}\exp(\frac{c_i^T v_j}{\tau})\Big) \tag{1}$$

If we set $y_i^r = 1$, then Eq. 1 resembles the MNR loss definition. The parameter τ is the temperature, discussed in Section 3 *Shuffling and Temperature*.

Weighting In the self-adaptive training approach, Huang et al. (2020) introduce weights $w_i = \max_{j\in\{1,..,L\}} t_{i,j}$, where t_i is the corrected one-hot encoded target vector in a classification task with L classes. The goal is to ensure that noisy labels will have a lower influence on the training process compared to correct labels. Instead of a classification task with one-hot target vectors $t_{i,j}$, here we have real targets y_i^r. Therefore, we take these probabilities as weights: $w_i = y_i^r$. After applying both modifications with the addition of labels and weights, the impact of each training example is proportional to the square of the corrected label, i.e., in Eq. 1 y_i^r is now squared.

3.2 Re-ranking

Re-ranking has shown major improvements for detecting previously fact-checked claims (Shaar et al., 2020, 2021; Mihaylova et al., 2021; Chernyavskiy et al., 2021), and we include it as part of our model.

In particular, we adopt the re-ranking procedure from (Chernyavskiy et al., 2021), which uses LambdaMART (Wu et al., 2010) for re-ranking. The inputs are the reciprocal ranks (position in the ranked list of claims) and the predicted relevance scores (two factors) based on the scores of the TF.IDF and S-BERT models (two models), between the tweet and the claim, claim+title, and claim+title+subtitle (three combinations), for a total of twelve features in the ensemble and four in the single model.

4 Experiments

In this section, we describe our experimental setup, baselines, and experimental results. The training procedure and the hyper-parameters are described in more detail in Appendix A.

4.1 Experimental Setup

Datasets Table 5 shows statistics about the data split sizes for *CrowdChecked* and *CheckThat '21*. We use these splits in our experiments, albeit sometimes mixed together.

The first group (*CrowdChecked*) is the data splits obtained using distant supervision. As the positive pairs are annotated with distant supervision and not by humans, we include them as part of the training set. Each shown split is obtained using a different similarity measure (Jaccard or Cosine) or threshold. From the total number of 332K collected tweet–article pairs in *CrowdChecked*, we ended up with subsets of sizes between 3.5K and 49K examples.

The second group describes the *CheckThat '21* dataset. We preserve the original training, development, and testing splits. In each of our experiments, we validate and test on the corresponding subsets from the *CheckThat '21*, while the training set can be a mix with CrowdChecked.

Evaluation Measures We adopt the ranking measures used in the *CheckThat '21* competition. In particular, we calculate the Mean Reciprocal Rank (MRR), Mean Average Precision (MAP@K), and Precision@K for $K \in \{1, 3, 5, 10\}$. We optimize our models for MAP@5, as was in the CLEF-2021 CheckThat! lab subtask 2A.

4.2 Baselines and State-of-the-Art

Retrieval Following (Shaar et al., 2021), we use an information retrieval model based on BM25 (Robertson and Zaragoza, 2009) that ranks the fact-checking articles based on the relevance score between their *{'claim', 'title'}* and the tweet.

Dataset	Data Split	Threshold	Tweet-Article Pairs
CrowdChecked (Our Dataset)	Train	-	332,660
	Train *Jaccard*	0.30	27,387
		0.40	12,555
		0.50	4,953
	Train *Cosine*	0.50	48,845
		0.60	26,588
		0.70	11,734
		0.80	3,496
CheckThat '21	Train	-	999
	Dev	-	199
	Test	-	202

Table 5: Statistics about our collected datasets in terms of tweet–verifying article pairs.

Sentence-BERT is a bi-encoder model based on Sentence-BERT fine-tuned for detecting previously fact-checked claims using MNR loss. The details are in Section 3, *General Scheme*.

Team DIPS (Mihaylova et al., 2021) adopts a Sentence-BERT model that computes the cosine similarity for each pair of an input tweet and a verified claim (article). The final ranking is made by passing a sorted list of cosine similarities to a fully-connected neural network.

Team NLytics (Pritzkau, 2021) uses a RoBERTa-based model optimized as a regression function obtaining a direct ranking for each tweet-article pair.

Team Aschern (Chernyavskiy et al., 2021) combines TF.IDF with a Sentence-BERT (ensemble with three models of each type). The final ranking is obtained from a re-ranking LambdaMART model.

4.3 Experimental Results

Below, we present experiments that (*i*) aim to analyze the impact of training with the distantly supervised data from CrowdChecked, and (*ii*) to further improve the state-of-the-art (SOTA) results using modeling techniques to better leverage the noisy examples (see Section 3). In all our experiments, we evaluate the model on the development and on the testing sets from *CheckThat '21* (see Table 5), and we train on a mix with CrowdChecked. The reported results for each experiment (for each metric) are averaged over three runs using different seeds.

Model	**MRR**	**P@1**	**MAP@5**
Baselines (*CheckThat ’21*)			
Retrieval (Shaar et al., 2021)	76.1	70.3	74.9
SBERT (*CheckThat ’21*)	79.96	74.59	79.20
***CrowdChecked* (Our Dataset)**			
SBERT (jac > 0.30)	81.50	76.40	80.84
SBERT (cos > 0.50)	81.58	75.91	81.05
(Pre-train) *CrowdChecked*, (Fine-tune) *CheckThat ’21*			
SBERT (jac > 0.30, Seq)	**83.76**	**78.88**	**83.11**
SBERT (cos > 0.50, Seq)	82.26	77.06	81.41
(Mix) *CrowdChecked* and *CheckThat ’21*			
SBERT (jac > 0.30, Mix)	83.04	78.55	82.30
SBERT (cos > 0.50, Mix)	82.12	76.57	81.38

Table 6: Evaluation on the *CheckThat ’21* test set. In parenthesis is the name of the training split, i.e., *Jac*card or *Cos*ine selection strategy, *(Seq)* first training on *CrowdChecked* and then on *CheckThat ’21*, *(Mix)* mixing the data from the two. The best results are in **bold**.

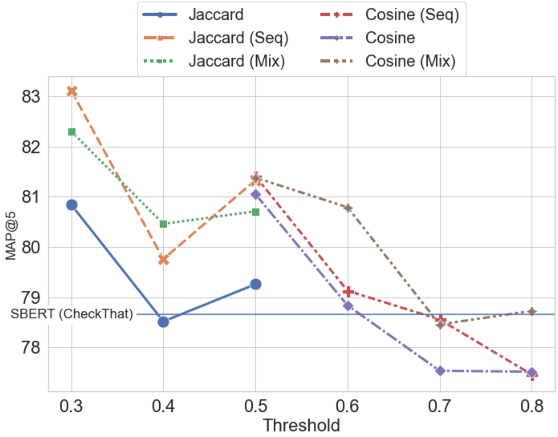

Figure 3: MAP@5 for different thresholds and distant supervision approaches. The *Jaccard* and the *Cosine* models are trained only on *CrowdChecked*, while (*Seq*) and (*Mix*) were trained also on *CheckThat ’21*.

Threshold Selection Analysis Our goal here is to evaluate the impact of using distantly supervised data from *CrowdChecked*. In particular, we fine-tune an SBERT baseline, as described in Section 3, using four different strategies: (*i*) fine-tune on the training data from *CheckThat ’21*, (*ii*) fine-tune on CrowdChecked, (*iii*) pre-train on CrowdChecked and then fine-tune on the training data from *CheckThat ’21*, (*iv*) mixing the data from both datasets.

Table 6 shows the results grouped based on training data used. In each group, we include the two best-performing models. We see that all SBERT models outperform the Retrieval baseline by 4–8 MAP@5 points absolute. Interestingly, training only on distantly supervised data is enough to outperform the SBERT model trained on the *CheckThat ’21* by more than 1.5 MAP@5 points absolute. Moreover, the performance of both data labeling strategies (i.e., Jaccard and Cosine) is close, suggesting comparable amount of noise in them.

Next, we train on combined data from the two datasets. Unsurprisingly, both mixing the data and training on the two datasets sequentially (*CrowdChecked* → *CheckThat ’21*) yields additional improvement compared to training on a single dataset. We achieve the best result when the model is first pre-trained on the *(jac > 0.3)* subset of *CrowdChecked*, and then fine-tuned on *CheckThat ’21*: it improves by two points absolute in all measures compared to *SBERT (*CrowdChecked*)*, and by four points compared to *SBERT (*CheckThat ’21*)*.

Nevertheless, we must note that pre-training with the *Cosine similarly (cos > 0.50)* did not yield such sizable improvements as the ones when using Jaccard. We attribute this, on one hand, to the higher expected noise in the data according to our manual annotations (see Section 2.5), and on the other hand, to these examples being annotated by a similar model, and thus presumably easy for it.

We further analyze the impact of choosing different thresholds for the distant supervision approaches. Figure 3 shows the change of MAP@5 for each data labeling strategy. On the left, in the interval [0.3–0.5], are shown the results of the Jaccard-based data labeling strategy, and on the right ([0.5–0.8]) are for the Cosine strategy. Once again, the models trained on the data selected using Jaccard similarity perform similarly or better than the *SBERT (*CheckThat ’21*)* model (blue solid line). On the other hand, the Cosine-based selection outperforms the baseline only in small thresholds ≤ 0.6. These observations are in favor of the hypothesis that the highly ranked pairs from the fine-tuned SBERT model are easy examples, and do not bring much signal to the model over the *CheckThat ’21* data, whereas the Jaccard ranked ones significantly improve the model’s performance. We further see similar performance when training with data from the lowest two thresholds for the two similarities (without data mixing), which suggests that these subsets have similar characteristics.

Adding more distantly supervised data is beneficial for the model, regardless of the strategy. The only exception is the drop in performance when we decrease the Jaccard threshold from 0.5 to 0.4.

Model	MAP@5 Dev	MAP@5 Test
DIPS (Mihaylova et al., 2021)	93.6	78.7
NLytics (Pritzkau, 2021)	-	79.9
Aschern (Chernyavskiy et al., 2021)	94.2	88.2
SBERT (jac > 0.30, Mix)	90.0	82.3
+ shuffling & trainable temp.	92.4	82.6
+ self-adaptive training (Eq. 1)	92.6	83.6
+ loss weights	*92.7*	*84.3*
+ TF.IDF + Re-ranking	93.1	89.7
+ TF.IDF + Re-ranking (ens.)	**94.8**	**90.3**

Table 7: Results on *CheckThat '21* (dev and test). We compare our model and its components (added sequentially) to the state of the art. The best results are in **bold**.

We attribute this to the quality of the data in that bracket, as the examples with lower similarity are expected to add more noise. However, the results improve drastically at the next threshold (which also doubles the number of examples), i.e., the model can generalize better from the new data. There is no such drop in the Cosine strategy. We explain this with expectation that noise increases proportionally to the decrease in model confidence.

Finally, we report the performance of each model both on the development and on the test sets in Appendix D, Tables 11 and 12.

Modeling Noisy Data We explore the impact of the proposed changes to the SBERT training approach: (*i*) shuffling and training temperature, (*ii*) data-related modification of the MNR loss for self-adaptive training with weights. We use the *(jac > 0.30, mix)* approach in our experiments, as the baseline SBERT models achieved the highest scores on the dev set (Table 11). In Table 7, we ablate each of these modifications by adding them iteratively to the baseline SBERT model.

First, we can see that adding a special shuffling procedure and a trainable temperature (τ) improves the MAP@5 by 2 points on the dev set and by 0.3 points on the test set. Next, we see a sizable improvement of 1 MAP@5 point on the test set, when using the self-adaptive training with MNR loss. Moreover, an additional 0.7 points come from adding weights to the loss, arriving at MAP@5 of 84.3. These weights allow the model to give higher importance to the less noisy data during training.

Note that for these two ablations the improvements on the development set are diminishing. We attribute this to its small size (199 examples) and to the high values of MAP@5. Finally, note that our model without re-ranking outperforms almost all state-of-the-art models (except for that of team Aschern) by more than 4.5 points on the test dataset.

The last two rows of Table 7 show the results of our model that includes all proposed components, in combination with TF.IDF features and the LambdaMART re-ranking, described in Section 3. Here, we must note that our model is trained on part of the *CheckThat '21* training pool (80%) – the other part is used to train the re-ranking model. The full setup boosts the model's MAP@5 to *89.7* when using a single model of the TF.IDF and SBERT (using the title/subtitle/claim as inputs, same as SBERT). With the ensemble architecture (re-ranking based on the scores of three TF.IDF and three SBERT models), we achieve our best results of *90.3* on the test set (adding 1.7 MAP@5 on dev, and 0.6 on test), outperforming the previous state-of-the-art approach (*Aschern*, 88.2) by 2 MAP@5 points, and by more than 11 compared to the second best model (*NLytics*, 79.9). This improvement corresponds to the observed gain over the SBERT model without re-ranking. Nevertheless, the change in the strength of the factors in LambdaMART is less. The TF-IDF models still have high importance for re-ranking – a total of 41% compared to 42.8% reported in Chernyavskiy et al. (2021). Here, we have a decrease mainly due to an increase of the importance of the reciprocal rank factor from 18.8% to 20.2% of the SBERT model that selects candidates.

5 Discussion

Our proposed distant supervision data selection strategies show promising results, achieving SOTA results on the *CheckThat '21*. Nonetheless, we are not able to identify all matching pairs in the list of candidates in *CrowdChecked*. Hereby, we try to estimate their number using statistics from our manual annotations,[2] as shown in Tables 3 and 4.

In particular, we estimate it by multiplying the fraction of correct pairs in each similarity bin by the number of examples in this bin. Based on cosine similarity, we estimate that out of the 332,600 pairs, the matching pairs are approximately 90,170 (27.11%).

[2] Due to the small number of annotated examples the variance in the estimates is large.

Based on the Jaccard distribution, we estimate that 14.79% of all tweet-conversations (root of the conversation), and 22.23% of the tweet–reply (the tweet before the current one in the conversation) pairs are good, or nearly 61,500 examples.

Our experiments show that the models can effectively account for the noise in the training data. The self-adaptive training and the additional weighing in the loss (described in Section 3) yield 1 additional MAP@5 point each. This suggests that learning from noisy labels (Han et al., 2018; Wang et al., 2019; Song et al., 2022; Zhou and Chen, 2021) and using all examples in *CrowdChecked* can improve the results even further. Moreover, incorporating the negative examples (non-matching pairs) from *CrowdChecked* in the training could also help (Lu et al., 2021; Thakur et al., 2021).

6 Related Work

Previously Fact-Checked Claims While fake news and mis/disinformation detection have been studied extensively (Li et al., 2016; Zubiaga et al., 2018; Martino et al., 2020; Alam et al., 2022; Guo et al., 2022; Hardalov et al., 2022), the problem of detecting previously fact-checked claims remains under-explored. Hassan et al. (2017) mentioned the task as a component of an end-to-end fact-checking pipeline, but did not evaluate it nor studied its contribution. Hossain et al. (2020) retrieved evidence from a list of known misconceptions and evaluated the claim's veracity based on its stance towards the hits; while this task is similar, it is not about whether a given claim was fact-checked or not.

Recently, the task received more attention. Shaar et al. (2020) collected two datasets, from PolitiFact (political debates) and Snopes (tweets), of claims and corresponding fact-checking articles. The CLEF *CheckThat!* lab (Barrón-Cedeño et al., 2020a,b,c; Nakov et al., 2021b,c; Shaar et al., 2021; Nakov et al., 2022a,b,c) extended these datasets with more data in English and Arabic. The best systems (Pritzkau, 2021; Mihaylova et al., 2021; Chernyavskiy et al., 2022) used a combination of BM25 retrieval, semantic similarity using embeddings (Reimers and Gurevych, 2019), and reranking. Bouziane et al. (2020) used extra data from fact-checking datasets (Wang, 2017; Thorne et al., 2018; Wadden et al., 2020).

Finally, Shaar et al. (2022a) and Shaar et al. (2022b) explored the role of the context in detecting previously fact-checked claims in political debates.

Our work is most similar to that of Vo and Lee (2020), who mined 19K tweets and corresponding fact-checked articles. Unlike them, we focus on textual claims (they were interested in multimodal tweets with images), we collect an order of magnitude more examples, and we propose a novel approach to learn from such noisy data directly (while they manually checked each example).

Training with Noisy Data Leveraging large collections of unlabeled data has been at the core of large-scale language models using Transformers (Vaswani et al., 2017), such as GPT (Radford et al., 2018, 2019), BERT (Devlin et al., 2019), and RoBERTa (Liu et al., 2019). Recently, such models used noisy retrieved data (Lewis et al., 2020; Guu et al., 2020) or active relabeling and data augmentation (Thakur et al., 2021). Distant supervision is also a crucial part of recent breakthroughs in few-shot learning (Schick and Schütze, 2021a,b).

Yet, there has been little work of using noisy data for fact-checking tasks. Vo and Lee (2019) collected tweets containing a link to a fact-checking website, based on which they tried to learn a fact-checking language and to generate automatic answers. You et al. (2019) used similar data from tweets for fact-checking URL recommendations.

Unlike the above work, here we propose an automatic procedure for labeling and self-training specifically designed for the task of detecting previously fact-checked claims.

7 Conclusion and Future Work

We presented *CrowdChecked*, a large dataset for detecting previously fact-checked claims, with more than 330,000 pairs of tweets and corresponding fact-checking articles posted by crowd fact-checkers. We further investigated two techniques for labeling the data using distance supervision, resulting in training sets of 3.5K–50K examples. We also proposed an approach for training from noisy data using self-adaptive learning and additional weights in the loss function. Furthermore, we demonstrated that our data yields sizable performance gains of four points in terms MRR, P@1, and MAP@5 over strong baselines. Finally, we demonstrated improvements over the state of the art on the *CheckThat '21* test set by two points, when using our proposed dataset and pipeline.

In future work, we plan to experiment with more languages and more distant supervision techniques such as predictions from an ensemble model.

Acknowledgments

We want to thank Ivan Bozhilov, Martin Vrachev, and Lilyana Videva for the useful discussions and for their help with additional data analysis and manual annotations.

Ethics and Broader Impact

Dataset Collection

We collected the dataset using the Twitter API.[3] following the terms of use outlined by Twitter.[4] Specifically, we only downloaded public tweets, and we only distribute dehydrated Twitter IDs.

Biases

We note that some of the annotations are subjective, and we have clearly indicated in the text which these are. Thus, it is inevitable that there would be biases in our dataset. Yet, we have a very clear annotation schema and instructions, which should reduce the biases.

Misuse Potential

Most datasets compiled from social media present some risk of misuse. We, therefore, ask researchers to be aware that our dataset can be maliciously used to unfairly moderate text (e.g., a tweet) that may not be malicious based on biases that may or may not be related to demographics and other information within the text. Intervention with human moderation would be required in order to ensure this does not occur.

Intended Use

Our dataset can enable automatic systems for analysis of social media content, which could be of interest to practitioners, professional fact-checker, journalists, social media platforms, and policymakers. Such systems can be used to alleviate the burden of moderators, but human supervision would be required for more intricate cases and in order to ensure that no harm is caused.

Our models can help fight the COVID-19 infodemic, and they could support analysis and decision-making for the public good. However, the models can also be misused by malicious actors. Therefore, we ask the users to be aware of potential misuse. With the possible ramifications of a highly subjective dataset, we distribute it for research purposes only, without a license for commercial use. Any biases found in the dataset are unintentional, and we do not intend to do harm to any group or individual.

Environmental Impact

We would like to warn that the use of large-scale Transformers requires a lot of computations and the use of GPUs/TPUs for training, which contributes to global warming (Strubell et al., 2019). This is a bit less of an issue in our case, as we do not train such models from scratch; rather, we fine-tune them on relatively small datasets. Moreover, running on a CPU for inference, once the model has been fine-tuned, is perfectly feasible, and CPUs contribute much less to global warming.

A Hyperparameters and Fine-Tuning

Below, we first describe the common parameters we use, and then we give the values of model-specific parameters.

Common Parameters

- We develop our models in Python using PyTorch (Paszke et al., 2019), the Transformers library (Wolf et al., 2020), and the Sentence Transformers library. (Reimers and Gurevych, 2019)[5]

- We used NLTK (Loper and Bird, 2002) to filter out English stop words, the *Twitter Tokenizer* to split the tweets and to strip the handles, and the Porter stemmer (Porter, 1980) to stem the tokens.

- For optimization, we use AdamW (Loshchilov and Hutter, 2019) with weight decay of 1e-8, $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 1\text{e-}08$, for 10 epochs, and maximum sequence length of 128 tokens (per encoder).[6]

- All Sentence BERT (SBERT) models are initialized from the `stsb-bert-base`[7] checkpoint.

- The SBERT models use cosine similarity both during training inside the MNR loss and during inference for ranking.

- We selectd the values of the hyper-parameters on the development set of *CheckThat '21*,[8] and we chose the best model checkpoint based on the performance on the development set (MAP@5).

- We ran each experiment three times with different seeds and averaged the result scores.

- The models were evaluated on each epoch or every 250 steps, whichever is less.

- The evaluation measures are calculated using the official code from the *CheckThat '21* competition (Shaar et al., 2021)[9] and the SentenceTransformer's library.

- In our work, we list 199 examples for the development set of *CheckThat '21*, while Shaar et al. (2021) lists 200. The difference comes from one duplicate row in the development set, which we found and filtered out.

- We trained our models on 5x Tesla T4 GPUs and 1x GeForce GTX 1080Ti, depending on the dataset size, the experiments took between 10 minutes and 5 hours.

Baseline SBERT

- Our baseline Sentence BERT is trained with LR of 2e-05, warmup of 0.1, and batch size of 32.

- We set the temperature (τ) in the MNR loss to 1.0, i.e., using unmodified MNR.

- The model consists of 110M params, same as the bert-base Devlin et al. (2019), as it uses a bi-encoder scheme.

Proposed Pipeline

- The model is trained with LR of 1e-05, warmup of 0.1, batch size of 8, ad group size of 4 during the dataset shuffling.

- We tuned the settings of the self-adaptive training, and ended up with the folowing values: momentum α of 0.9, refurbishment process starting at the second epoch.

- We set the learning rate for the temperature (τ) in the MNR loss to 0.4.

- In the re-ranking, we used 800 training examples to train SBERT and the remaining 199 examples to train LambdaMART.

- We re-ranked the top-100 results from the best SBERT model with LambdaMART.

- All other training details we kept from (Chernyavskiy et al., 2021).

- The model has 330M params, 3x as the size of the Baseline SBERT, as it trains three separate models.

- In our preliminary experiments, SBERT-base and SBERT-large yielded the same results in terms of MAP@5, ad thus we experiment with the *base* versions.

B Dataset

Below, we first give some detail about the process of article collection, and then we discuss the overlap between our *CrowdChecked* dataset and *CheckThat '21*.

B.1 Fact-checking Articles Collection

In order to obtain a collection of fact-checking articles for each tweet, we first formed a list of unique URLs shared in the fact-checking tweets from the crowd fact-checkers. Next, from each URL we downloaded the HTML of the whole page and extracted the meta information using CSS selectors and RegEx rules. In particular, we followed previous work (Barrón-Cedeño et al., 2020b; Shaar et al., 2021) and collected: *title* (the title of the page), *subtitle* (short description of the fact-check), *claim* (the claim of interest), *subtitle* (short description of the fact-check), *date* (the date the article was published), and *author* (the author of the article). We do not parse the content of the article and the factual label, as the credibility of the claim is not related to the objective of this task, i.e., the goal is to find a fact-checking article, but not to verify it.

As a result, we collected 10,340 articles that were published in the period between 1995–2021. The per-year distribution is shown in Table 2 (in brown). The majority of the articles are from the period after 2015, with a peak at the ones from 2020/2021. We attribute this on the increased media literacy and on the nature of the Twitter dynamics (Zubiaga, 2018).

B.2 *CheckThat '21* Word Overlaps

Next, we analyzed the distribution of the Jaccard scores in the *CheckThat '21*, shown in Figure 4. The distribution is different compared to the one observed in our newly collected dataset, as it peaks at around 0.4, and is slightly shifted towards lower similarity values, suggesting that the examples included are not easily solvable with basic lexical features (Shaar et al., 2021), which we also observe in our experiments (see Section 4).

C Annotations

Setup and Guidelines Each annotator was provided with the guidelines and briefed by one of the authors of this paper. For annotation, we used a Google Sheets document, where none of the annotators had access to the annotations by the others.

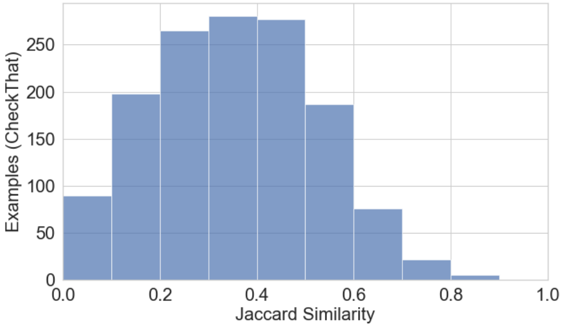

Figure 4: Distribution of the Jaccard similarity scores. The score is an average of the *sim(tweet, title)* and *sim(tweet, subtitle)*.

The annotation sheet contained the following fields:

- *tweet_text*: the text of the fact-checking tweet;
- *text_conversation*: the text of the root of the conversation;
- *text_reply*: the text of the last tweet before the fact-checking one;
- *title*: the title of the Snopes article;
- *subtitle*: the subtitle of the Snopes article.

The annotation task was to mark whether the *conversation matches* and also whether the *reply matches* using check-boxes. We also allowed the annotators to add comments as a free-form text.

Demographics We recruited three annotators: two male and one female, between 25 and 30 years old, with higher education (at least a bachelors degree), and currently enrolled in a MSc or PhD programs in Computer Science. Each annotator was proficient in English, but they were not native speakers.

Inter-Annotator Agreement Here, we present the inter-annotator agreement. We measure the overall agreement using Fleiss kappa (Fleiss, 1971) (shown in Figure 8) and also the agreement between each two annotators using Cohen's Kappa (shown in Table 9). The overall level of agreement between the annotators is *good*. Moreover, we can see that between annotator A and C the agreement is almost perfect both for the replies and for the conversations. The lowest agreement is between A and B, but it is still substantial.

	Replay	Conversation
Fleiss Kappa	0.745	0.750

Table 8: Fleiss Kappa inter-annotator agreement between all three of our annotators: A, B, and C.

Annotators	Replay	Conversation
	Cohen's Kappa	
A ↔ B	0.650	0.655
A ↔ C	0.885	0.922
B ↔ C	0.698	0.673

Table 9: Cohen's Kappa pairwise inter-annotator agreement between all pairs of our annotators.

Disagreement Analysis After the annotations procedure was finished, we analyzed the examples for which the annotators disagreed, which fell in the following categories:

(i) Claims depending on information from external sources, e.g., *'Blame Russia again? [URL]'*.

(ii) Tweets containing multiple claims, for which the referenced article does not target the main claim, e.g., *"'It sounds like someone who is scared as heck that they will not win," Shermichael Singleton says of Pres. Trump's remarks encouraging his supporters to vote twice.'* Here, the corresponding crowd fact-check is *'Did Trump Tell People To Vote Twice?'*, i.e., the main claim is in the quote itself, while the remark about voting twice is secondary.

(iii) The claim is ambiguous, e.g., *'Fanta (soft drink) was created so that the Nazi's could replace Coca-Cola during WWII [URL]'*, and the fact-check is about *'Was Fanta invented by the Nazis?'*. Here, it is not clear who created Fanta.

(iv) The claim is a partial match, e.g., *'did President Trump have a great economy and job creation for 1st 3 years???'*, and the fact-check is *'Did Obama's Last 3 Years See More Jobs Created Than Trump's First 3?'*, which only covers part of the claim in the tweet.

Tweet-Article Pairs Analysis In Table 10, we show examples of *correct* (✓) and *incorrect* (✗) matching pairs. We sorted the examples within each group based on the word overlap between the claim and the verified claim, e.g., (1) and (2) have more words in common between the two texts compared to the overlaps in (3), and similarly for (4)–(6).

First, we can see that high overlap does not guarantee a correct matching tweet–article pair, just like low overlap does not mean an incorrect pair, which is also visible from the analysis of the Jaccard similarity in Table 3. These two phenomena can be seen in (*3*), which contains a correct pair with low overlap, and in (*4*), where there is an incorrect match with high overlap. Next, some tweets may not contain a claim such as (*4*), as the user only asks questions, rather than stating something that can be fact-checked. In contrast, (*6*) contains a verifiable claim about *gas prices*, but the linked Snopes article fact-checks whether *COVID spreads through gas pumps*, which is irrelevant in this case. Row (*5*) is a partial match, and the tweet contains a check-worthy claim, but the article by the crowd fact-checker focuses on the IQ of the Fox News viewers, rather than on how well informed they are, and thus again the match is incorrect. Finally, in row (*1*), we can see that the verified claim is almost exactly included in the tweet, which is an easy case to match. In contrast, for the example in row (*3*), the model should do a semantic match based on some prior knowledge that the other name for *influenza A virus subtype H1N1* is *swine flu*, and moreover, *10,000* should be associated with the word *thousands*.

D Experimental Results

Here, we present the expanded results for our experiments described in Section 4. Tables 11 and 12 include the results for the *threshold selection analysis* experiments on the development dataset, and on the testing dataset, respectively. Here, Table 12 corresponds to Table 6 in the main text of the paper, and includes all metrics and all thresholds (shown in Figure 3). Next, the results from our *Modeling Noisy Data* experiments are in Table 13, which corresponds to Table 7 in the main paper. In all tables, we use the same notation and grouping as in the corresponding table in the main paper.

	Tweet w/ Claim	Snopes Verified Claim and Article
	Correct Matches ✓	
(1)	“Mussolini may have done many brutal and tyrannical things; he may have destroyed human freedom in Italy; he may have murdered and tortured citizens whose only crime was to oppose Mussolini; but ‘one had to admit’ one thing about the Dictator: he ‘made the trains run on time.’” [URL]	Italian dictator Benito Mussolini made the trains run on time snopes.com/fact-check/loco-motive/
(2)	"Full list of songs Clear Channel banned following the 911 attacks. Some of these don’t make any sense at all. 12 [URL]"	Clear Channel Communications banned their American radio stations from playing specified songs in order to avoid offending listeners. snopes.com/fact-check/radio-radio/
(3)	@user @user OMG! Were you on this planet when Obama did nothing during H1N1 crisis? Only difference was H1N1 caused more than 10000 deaths and Obama was golfing. Abstract

Social media often serves as a breeding ground for various hateful and offensive content. Identifying such content on social media is crucial due to its impact on the race, gender, or religion in an unprejudiced society. However, while there is extensive research in hate speech detection in English, there is a gap in hateful content detection in low-resource languages like Bengali. Besides, a current trend on social media is the use of Romanized Bengali for regular interactions. To overcome the existing research's limitations, in this study, we develop an annotated dataset of 10K Bengali posts consisting of 5K actual and 5K Romanized Bengali tweets. We implement several baseline models for the classification of such hateful posts. We further explore the interlingual transfer mechanism to boost classification performance. Finally, we perform an in-depth error analysis by looking into the misclassified posts by the models. While training actual and Romanized datasets separately, we observe that XLM-Roberta performs the best. Further, we witness that on joint training and few-shot training, MuRIL outperforms other models by interpreting the semantic expressions better. We make our code and dataset public for others[1].

1 Introduction

Social media websites like Twitter and Facebook have brought billions of people together and given them the opportunity to share their thoughts and opinions rapidly. On the one hand, it has facilitated communication and the growth of social networks; on the other, it has been exploited to propagate misinformation, violence, and hate speech (Mathew et al., 2019; Das et al., 2020) against users based on their gender, race, religion, or other characteristics. If such content is left unaddressed, it may result in widespread conflict and violence, raising concerns about the safety of human rights, the rule of law, and freedom of speech, all of which are crucial for the growth of an unprejudiced democratic society (Rizwan et al., 2020). Organizations such as Facebook have been blamed for being a forum for instigating anti-Muslim violence in Sri Lanka that resulted in the deaths of three individuals[2], and a UN report accused them of disseminating hate speech in a way that contributed significantly to the plausible genocide of the Rohingya population in Myanmar[3].

In order to reduce the dissemination of such harmful content, these platforms have developed certain guidelines[4] that the users of these platforms ought to comply with. If these rules aren't followed, the post can get deleted, or the user's account might get suspended. Even to diminish the harmful content from their forum, these platforms engage moderators (Newton, 2019) to manually review the posts and preserve the platform as wholesome and people-friendly. However, this moderation strategy is confined by the moderators' speed, jargon, capability to understand the development of slang, and familiarity with multilingual content. Moreover, due to the sheer magnitude of data streaming, it is also an ambitious endeavor to examine each post manually and filter out such harmful content. Hence, an automated technique for detecting hate speech and offensive language is extremely necessary and inevitable.

It has already been witnessed that Facebook vigorously eliminated a considerable amount of malicious content from its platforms even before users reported it (Robertson, 2020). However, the hindrance is that these platforms can detect harmful content in certain popular languages such as En-

glish, Spanish, etc. (Perrigo, 2019) So far, several investigations have been conducted to identify hate speech automatically, focusing mainly on the English language; therefore, an effort is required to determine and diminish such hateful content in low-resource languages.

With more than 210 million speakers, Bengali is the seventh most widely spoken language[5], with around 100 million Bengali speakers in Bangladesh and 85 million in India. Apart from Bangladesh and India, Bengali is spoken in many countries, including the United Kingdom, the United States, and the Middle East[6]. Also, a current trend on social media platforms is that apart from actual Bengali, people tend to write Bengali using Latin scripts(English characters) and often use English phrases in the same conversation. This unique and informal communication dialect is called code-mixed Bengali or Roman Bengali. Code-mixing makes it easier for speakers to communicate with one another by providing a more comprehensive range of idioms and phrases. However, as emphasized by Chittaranjan et al. (Chittaranjan et al., 2014), this has made the task of creating NLP tools more challenging. Along with these challenges, the challenges specific to identifying hate speech in Roman Bengali contain the following: *Absence of a hate speech dataset*, *Lack of benchmark models*. Thus, there is a need to develop open efficient datasets and models to detect hate speech in Bengali. Although few studies have been conducted in developing Bengali hate speech datasets, most of these have been crawled with comments from Facebook pages, and all of them are in actual Bengali. Hence, there is a need for developing more benchmarking datasets considering other popular platforms. To address these limitations, in this study, we make the following contributions.

- First, we create a gold-standard dataset of 10K tweets among which 5K tweets are actual Bengali and 5K tweets are Roman Bengali.
- Second, we implement several baseline models to identify such hateful and offensive content automatically for both actual & Roman Bengali tweets.
- Third, we explore several interlingual transfer mechanisms to boost the classification performance.
- Finally, we perform in-depth error analysis by looking into a sample of posts where the models mis-classify some of the test instances.

2 Related Work

Over the past few years, research around automated hate speech detection has been evolved tremendously. The earlier effort in developing resources for the hate speech detection was mainly focused around English language (Waseem and Hovy, 2016; Davidson et al., 2017; Founta et al., 2018). Recently, in an effort to create multilingual hate speech datasets, several shared task competitions have been organized (HASOC (Mandl et al., 2019), OffensEval (Zampieri et al., 2019),, TRAC (Kumar et al., 2020), etc.), and multiple datasets such as Hindi (Modha et al., 2021), Danish (Sigurbergsson and Derczynski, 2020), Greek (Pitenis et al., 2020), Turkish (Çöltekin, 2020), Mexican Spanish (Aragón et al., 2019), etc. have been made public. There is also some work to detect hate speech in actual Bengali. Ismam et al. (Ishmam and Sharmin, 2019) collected and annotated 5K comments from Facebook into six classes-*inciteful*, *hate speech*, *religious hatred*, *communal attack*, *religious comments*, and *political comments*. However,the dataset is not publicly available. Karim et al. (Karim et al., 2021) provided a dataset of 8K hateful posts collected from multiple sources such as Facebook, news articles, blogs, etc. One of the problems with this dataset is that all comments are part of any hate class(*personal*, *geopolitical*, *religious*, and *political*), so we cannot build hate speech detection models using this dataset to screen out hate speech. Romim et al. (2021) curated a dataset of 30K comments, making it one of the most extensive datasets for hateful statements. The author achieved 87.5% accuracy on their test dataset using the SVM model. However, these datasets do not consider Roman Bengali posts, a prevalent communication method on social media nowadays.

With regards to the detection systems, earlier methods examined simple linguistic features such as character and word n-grams, POS tags, tf-idf with a traditional classifier such as LR, SVM, Decision Tree, etc (Davidson et al., 2017). With the development of larger datasets, researchers have shifted to data-hungry complex models such as deep learning (Pitsilis et al., 2018; Zhang et al., 2018) and graph embedding techniques to enrich

Table 1: Dataset Statistics of both Actual and Roman tweets.

the classifier performance.

Recently, transformer-based (Vaswani et al., 2017) language models such as BERT, XLM-RoBERTa (Devlin et al., 2019) are becoming quite popular in several downstream tasks. It has already been observed that these transformer-based models outperform several earlier deep learning models (Mathew et al., 2021). Having observed these transformer-based models' superior performance, we focus on building these models for our classification task.

Further, researchers have begun to explore few shot classifications. One of the most popular techniques for few-shot classification is transfer learning - where a model (pre-trained in a similar domain) is further fine-tuned on a few labeled samples in the target domain (Alyafeai et al., 2020). Keeping these experiments in mind, we also examine the ability of transfer learning capabilities between actual and Roman Bengali data.

3 Dataset Creation

In this section, we provide the data collection procedure, annotation strategies we have followed and the statistics of the collected dataset.

3.1 Dataset collection and sampling

In this paper, we collect our dataset from **Twitter**. Despite Hatebase.org maintaining the most extensive collection of multilingual hateful words, it still lacks such lexicon base for Bengali[7]. To sample Bengali (actual and romanized) tweets for annotation, we create a lexicon of 74 abusive terms[8]). These lexicons consist of derogatory keywords/slurs targeting individuals or different protected communities. We also include words based on the name of the targeted communities. The choice to add names of targeted communities is made in order to extract random hateful/offensive tweets that do not contain any abusive words. Using Twitter API, we searched for tweets containing phrases from the lexicons, which resulted in a sample of 500K tweets for actual Bengali and 150K tweets for Roman Bengali. To evade problems related to user distribution bias, as highlighted by Arango et al. (Arango et al., 2019), we limit a maximum of 75 tweets per user. We also do not use more than 500 tweets per month to avoid event-specific tweets in our dataset.

3.2 Annotation procedure

We employed four undergraduate students for our annotation task. All undergraduate students are Computer Science majors and native Bengali speakers. They have been recruited voluntarily through departmental emails and compensated via an Amazon gift card. Two Ph.D. students led the annotation process as expert annotators. Both expert annotators had previous experience working with malicious content on social media. Each tweet in our dataset contains two kinds of annotations: first whether the text is hate speech, offensive speech, or normal; second, the target communities in the text. This additional annotation of the target community can help us measure bias in the model. Table 3 lists the target groups we have considered.

Annotation guidelines: The annotation scheme stated below constitute the main guidelines for the annotators, while a codebook ensured common understanding of the label descriptions. We construct our codebook (which consists the annotation guidelines[8] for identifying hateful and offensive tweets based on the definitions summarized as follows.

- **Hate speech:** *Hate speech is a language used to express hatred toward a targeted individual or group or is intended to be derogatory, humiliating, or insulting to the group members based on attributes such as race, religion, ethnic origin, sexual orientation, disability, caste, geographic location or gender.*
- **Offensive:** *Offensive speech uses profanity, strongly impolite, rude, or vulgar language expressed with fighting or hurtful words to insult a targeted individual or group.*
- **Normal:** *This contains tweets that do not fall into the above categories.*

3.3 Dataset creation steps

As a first step for creating the dataset, we required a pilot gold-label dataset to instruct the annotators. Initially, the expert annotators annotated 100

Target Groups	Categories
Gender	Men, Women, Trans.
Linguistic Community	Bengali, Bihari.
National Origin	Indian, Bangladeshi, Pakistani.
Religion	Hindu, Islam.
Miscellaneous	Individual, Political, Disabled, Dalit, Others.

Table 3: Target groups considered for the annotation.

tweets, out of which 30 were hateful, 35 were offensive, and the rest 35 tweets were normal.

Pilot annotation: Each annotator was given 30 tweets from the gold-label dataset in the pilot task. They were asked to classify hate/offensive speech and identify the target community (if any). They were provided the annotation codebook with multiple examples for the labeling process to understand the task clearly. They were asked to keep the annotation guidelines open while doing the annotation to have better clarity about the labeling scheme. After the annotators finished this set, we consulted the incorrect annotations in their set with them. This activity further trained the annotators and helped to fine-tune the annotation scheme. In addition, we collected feedback from annotators to enrich the main annotation task.

Main annotation: After the training process, we proceeded with the main annotation task. For this task, we use the open-source platform Docanno[9], deployed on a Heroku instance. We provided a secure account to each annotator where they could annotate and track their progress. Two independent annotators annotated each tweet. Based on the guidelines, they were instructed to read the entire tweet and select the appropriate category (hate speech, offensive, or standard). Initially, we started with a small batch of 100 tweets and later expanded it to 500 tweets as the annotations became more efficient. We tried to preserve the annotators' agreement by pointing out some errors they made in the previous batch. Since hate/offensive speech is highly polarizing and adverse, the annotators were given plenty of time to complete the annotations. On completion of each set of annotations, if there was a mismatch between two annotators, one of the expert annotators annotated the same tweet to break the tie. For the cases where all the three annotators chose a separate class, we did not consider these tweets for further analysis. To determine the target community of a tweet, we combine the annotated targets.

Exposure to online abuse could lead to unhealthy mental health issues[10](Ybarra et al., 2006). Therefore, the annotators were recommended to take periodic breaks and not do the annotations in one sitting. Besides, we also had weekly meetings with them to ensure the annotations did not have any effect on their mental health.

Final dataset: Table 1 notes our final dataset statistics. It consists of 5,071 actual Bengali tweets (out of which 825 have been labelled as hateful, 1,341 are offensive, and 2,905 tweets are normal) and 5,107 Roman Bengali tweets (out of which 510 tweets are hateful, 2,063 tweets are offensive, and 2,534 tweets are normal). We achieved an inter-annotator agreement of 0.696 using Krippendorff's α which is better than the agreement score on other related hate speech tasks (Ousidhoum et al., 2019; Guest et al., 2021). In Table 2 we have shown some

[9] https://github.com/doccano/doccano

examples of Bengali hate speech and offensive language that we have annotated.

4 Methodology

4.1 Baseline models

In this section, we discuss the models we implement for automatic detection of hate speech. We experimented with a wide range of models for our use case.

m-BERT (Devlin et al., 2019) is a stack of transformer encoder layers consisting of 12 “attention heads" with self-attention mechanisms. It is pre-trained on 104 languages using a masked language modeling (MLM) objective with the crawled Wikipedia data. To fine-tune m-BERT, we include a fully connected layer with the output corresponding to the CLS token in the input. Typically, the expression of the sentence provided to the model is retained in this CLS token output. In hate speech, the m-BERT model has been well studied, outperformed several baselines, and is considered state-of-the-art.

XLM-Roberta (Conneau et al., 2020) is another form of Transformer model, pre-trained on 2.5TB of filtered CommonCrawl data containing 100 languages. XLM-R was trained using a lot more data compared to m-BERT. Similar to BERT, it is a stack of transformer encoder layers with 12 “attention heads" and can handle at max 512 tokens.

IndicBERT (Kakwani et al., 2020) is a multilingual ALBERT model (Lan et al., 2019) (a recent derivative of BERT) trained on large-scale corpora, covering 12 major Indian languages. It is pre-trained on 9 billion tokens and evaluated on a set of diverse tasks. Unlike m-BERT, XLM-Roberta, IndicBERT has around 10x fewer parameters and still manages to deliver state-of-the-art performance on several tasks.

MuRIL (Khanuja et al., 2021) stands for Multilingual Representations for Indian Languages and aims to enrich reciprocity from one language to another. This model uses a BERT base architecture pre-trained from scratch using the Common Crawl, Wikipedia, PMINDIA, and Dakshina corpora for 17 Indian languages and their transliterated counterparts.

4.2 Interlingual transfer mechanisms

One of the main attractions of transformer-based models is their potential to strengthen model transfer via several mechanisms. This can be especially beneficial for enhancing learning performance in low-resource languages like Bengali. In order to evaluate the extent to which language similarity improves transfer learning performance, we perform the following tests.[11]

ELFI (Each language for itself): In this situation, we use the same language's data for training, validation, and testing. This scenario typically appears in the real world, where monolingual datasets are frequently utilized to build classifiers for a particular language. Despite the anticipated high labeling costs, this gives an idea of the most achievable classification performance.

Joint training: In this setting, we integrate both actual & Roman Bengali posts to train all the transformer-based models. The notion is that even though the characters used to represent both languages are different, their semantic content is mostly the same. Hence, it gives an idea of whether jointly training the models can benefit learning the better semantic representation of a particular post for determining the corresponding label of the post.

Model transfer: In this scenario, the models are trained with one language (source language) and evaluated in another language (target language). In the zero-shot setting, no instances from the target language have been used while training (**MTx0**). In a related few-shot setting, we allow n = 32, 64, and 128 posts per label from the available gold target instances to fine-tune the existing models (trained in another language). These are named **MTx32, MTx64** and **MTx128**.

Language transfer: In this setting, we translate the Bengali posts to English using Google Translate tool[12] and do the entire training, testing on the translated instances. We do this to check if language space has been transformed for a task, how model's performance varies.

Joint training with language transfer: In this scenario, we combine the translated Bengali and Roman Bengali posts, to train all the transformer based models. The motivation behind this experiment is that, in case of romanized Bengali data, people use English words/sentences in their posts for ease of writing. Thus, we perform this experiment to determine whether adding translated Bengali data points will further improve the performance of the classification or not.

[11] Although the discussed models have been pre-trained using multiple languages, fine-tuning has been done using the Bengali language dataset.

[12] https://cloud.google.com/translate

4.3 Experimental setup

All the models are evaluated using the same 70:10:20 train, validation, and test split, stratified by class across the splits. For the model transfer evaluation, we use 32, 64, and 128 training data points from each class to train the model in another language. We create three such different random sets for the target dataset to have a more robust assessment and report the average performance. The models were run for 10 epoch with Adam optimizer, batch_size = 16, learning_rate = $2e-5$ and adam_epsilon = $1e-8$. In addition, we set the number of tokens n = 400 for all the models.

4.4 Evaluation metric

To remain consistent with existing literature, we evaluate our models in terms of **accuracy**, **F1-score** and **AUROC** score. These metrics together should be able to thoroughly evaluate the classification performance in distinguishing among the three classes, e.g., hate, offensive and normal. For zero-shot and few-shot settings, we report only **macro F1-score** due to paucity of space. We also highlight the best performance using **bold** and second best using underline.

5 Results

In this section, we discuss the findings of our experiments.

5.1 Performnace of ELFI

In Table 4, we report the performance of all the models for actual & Roman Bengali. We observe for both of these, XLM-Roberta performs the best in terms of accuracy and macro-F1 score. Followed by XLM-Roberta, MuRIL performed the second best for the actual Bengali. For the hate class m-BERT does slightly better than XLM-Roberta in terms of F1-score. For Roman Bengali, IndicBERT performs next to XLM-Roberta.

5.2 Performance of joint training

Here we investigate the importance of joint training. Even though both the actual & Roman Bengali is written using different characters, semantic expression of both the languages are same. Table 5 summarizes the performance of different models when trained jointly. We observe some improvements in the joint training models. In particular, MuRIL, which is pretrained on both Indian languages and their transliterated counterparts, is able to interrelate the semantics of the actual & Roman Bengali sentences. We notice that for actual Bengali, MuRIL performs the best with Macro-F1 score of 0.808 (and accuracy of 0.833), followed by m-BERT with Macro-F1 score of 0.800 (and accuracy of 0.829). For the Roman Bengali though, XLM-Roberta still performs the best (with Macro F1-score of 0.810), MuRIL performs very close to it and in fact better for the hate class F1-score.

5.3 Performance of model transfer

In this scenario, we investigate the power of existing fine-tuned models. The idea is to understand how these models are generalized across the same language, having same semantic content, but are written using different characters/words. We report our results in Table 6.

In **zero-shot** setting we observe, when the model is trained on actual Bengali and tested on Roman Bengali, m-BERT performs the best (with macro F1 score of 0.390) among all the models followed by IndicBERT (Macro F1 score 0.319). On the other hand, when trained on Roman Bengali and tested on actual Bengali, MuRIL performs the best (macro F1 score 0.414) among all the models followed by IndicBERT (macro F1 score 0.397). An interesting thing to note is that although the XLM-Roberta performs best in monolingual settings, it is not performing well in the model transfer setup.

To further investigate, how the performance of these models would vary, we conduct a second stage of fine-tuning. In this setting we use the existing trained model in actual Bengali and further fine-tune it with n samples of Roman Bengali data points per label (and vice-versa). we repeat the subset sampled data selection with 3 different random sets and report the average performance. This will help to reduce performance variations across different sets. In general We observed with the increasing data points the performance of all models has improved.

- **Actual → Roman**: We observe further fine-tuning the model with 32 instances, m-BERT performs the best followed by MuRIL. While increasing these instances, MuRIL outperforms all other models. Only with 128 instances per label, MuRIL achieves macro F1-Score of 0.751.
- **Roman → Actual**: We see MuRIL outperforms all other models. Followed by MuRIL, XLM-Robera performed the second best for

32 and 64 instances and for 128 instances m-BERT is the second best.

5.3.1 Performance of language transfer

Here we investigate the importance of gold instances[13] in a low resource language. We do so by transforming the language space. We translate[12] the Bengali datasets to English and do training, testing on the translated dataset. In Table 7 we report the results of all the models. Although XLM-Roberta outperforms all other models, an important point to note is that its performance (Macro-F1 score 0.764) is much lower compared to the model trained on the gold (i.e., actual Bengali) instances (Macro-F1 score 0.803).

Model	**Acc**	**M-F1**	**F1 (H)**	**F1 (O)**	**AUROC**
m-BERT	0.777	0.754	**0.775**	0.647	**0.893**
XLM-Roberta	**0.796**	**0.764**	0.757	**0.649**	0.891
MuRIL	0.771	0.722	0.728	0.586	0.830
IndicBERT	0.723	0.671	0.650	0.540	0.826

XLM-Roberta	0.849	0.799	0.670	0.847	0.910
MuRIL	0.845	0.791	0.647	0.844	0.895
IndicBERT	0.839	0.787	0.649	0.830	0.911

Table 8: Performance of Roman Bengali on Joint Training with the Translated Data. M: Macro, Acc: Accuracy, H: Hate, O: Offensive.

5.4 Performance of joint training with language transfer

In this scenario we investigate, even though models trained on translated Bengali instances cannot outperform the monolingual models trained on gold labels, can it be useful to improve the performance of Roman Bengali data? This is motivated by the fact that in a romanized(code-mixed) scenario, people mix English words/phases while writing. Table 8 shows the results on the code-mixed test set. We monitor the performance of m-BERT (Macro-F1 score: earlier (0.790), now (0.811)) and MuRIL (Macro-F1 score: earlier (0.788), now: (0.791)) and observe that these have improved for the detection in the Roman Bengali dataset. However, for XLM-Roberta (Macro-F1 score: earlier (0.805), now (0.799)) and IndicBERT (Macro-F1 score: earlier (0.793), now (0.787)) the models perform slightly worse compared to those trained on only Roman Bengali gold data. Overall, it can be concluded that while some models are able to leverage the strength of the translated Bengali data while predicting the labels of the Roman Bengali posts, others are not. This might hint at the differences in the generalizability powers of these models. To understand this better, in section 7 we deep dive into the models further using error analysis techniques.

[13] raw labeled data

Train	Test	Acc	MF1
Romin	Romin	0.905	0.894
Romin	Ours	0.646	0.646
Ours	Ours	0.846	0.843
Ours	Romin	0.774	0.754
Joint	Romin	0.910	0.899
	Ours	0.837	0.835

Table 9: Comparison with existing dataset (Romim et al., 2021). Acc: Accuracy, MF1: Macro-F1

6 Additional experiment

In addition, we perform another experiment to further compare the quality of our dataset with the existing dataset of Romim et al. (Romim et al., 2021). Using their dataset, we train the XLM-Roberta model[14] and test its performance on our dataset. Likewise, we test the performance on their dataset when the model is trained on our dataset. We only conduct this experiment with the actual Bengali tweets to have valid comparison with their dataset. We combine hate and offensive into a single class for this experiment, as the authors in (Romim et al., 2021) have considered these two labels as same. In Table 9 we summarize the results. We observe our model achieves macro-F1 score of 0.754 on their dataset, while the model trained on their dataset achieves 0.646 macro-F1 score on our dataset. Further, we train the XLM-Roberta model jointly with both datasets. We observe jointly training the model further improved the performance on the Romim et al. (Romim et al., 2021) test data; however, we do not see any improvement in our test data.

7 Error analysis

In order to deep dive into the models further, we conduct a manual error analysis on our models by using a sample of 50 posts where the model incorrectly categorizes some test instances. We analyze common errors and classify them into the following five categories.

- **Sarcastic content consisting emojis**: Communication via emojis is becoming extremely popular these days. Sometimes these emojis completely change the interpretation of the post by making it sarcastic/ambiguous. This naturally results in mis-classification.

- **Sequence of obscene words**: Some instances of a series of swear words not targeting individuals or communities are mis-classified. This indicates that the presence of hateful, obscene keywords should not be the only decisive factor for a model to make its predictions.

- **Viewpoints**: Some instances mostly relating to a political or religious sense cannot be fully binary or ternary. The annotators' viewpoint plays a key role in such instances and makes the models to mis-classify these instances. All the models suffer similarly here.

- **Code-mixed linguistic structure**: Instances following the grammatical structure of Bengali but written using English words sometimes get mis-classified due to the code-mixed nature of data at hand because there is a heavy between the tokens from Bengali and English.

- **Tentatively wrong ground truths**: Some instances containing slur words many not be targeting any group as such. However annotators tentatively marked it hateful leading to the model mis-classifying the post.

In Table 10 we present example instances for the above categories and the predictions thereof. Though we show the predictions for XLM-Roberta, all the other models also produce similar results.

8 Discussion

In this section we discuss the key insights from our results. We observe that depending on the availability of training data points, the performance of the model varies. When we have sufficient number of training instances XLM-Roberta model performs the best. Further we argue that when actual & Roman Bengali instances are merged together for joint training, models like MuRIL performs the best by leveraging the semantic connection between actual and Romanized instances. This is, to some extent, expected from MuRIL due to the nature of its pretraining mechanism, where both actual language and its transliterated counterpart have been used.

Further exploring the performance of these models in zero-shot setting shows, although XLM-Robera performs best while trained with standalone data, it performs very poorly for unseen data with similar semantic content but a different orthography. In such scenarios, models like m-BERT, IndicBERT exhibit better performance. To improve

[14] We consider XLM-Roberta, as this performs the best while training standalone.

Posts	Translation	Ground Truth	Predicted Label	Category
@user আপনি কি বিপথগামী রাস্তার কুকুরের মেয়ে? 🐕🤦♂😀😜	@user Are you a misguided street dog girl? 🐕🤦♂😀😜	Offensive	Non-Hate	**Sarcastic content consist emoji**

Table 10: Error analysis on XLM-Roberta (we found similar trend on other models).

the performance of these models, when some instances from the target language are used, MuRIL shows an increase in performance at a rate higher than the other models. Observing these results it may be safe to say that when there is a data scarcity for a particular language, it is better to reuse existing fine-tuned models in the same domain. Also careful selection of model is needed. In our case, actual Bengali and Roman Bengali use different characters for writing, but their semantic expressions are same, which is why MuRIL performed best overall.

While doing the in-depth error analysis, we also found that for some cases it can be even difficult for a model to find the actual label correctly. Not only models, as hate speech is complex in nature, sometimes annotators make mistake while labelling them due to differing viewpoints.

Limitation: There are a few limitations of our work. First is the lack of external context. We have not considered any external context such as profile bio, history of user's posting pattern, gender etc., which might be helpful for the hate speech detection task. Although the effectiveness of these transformer-based models are quite good, they have not been tested against adversarial examples.

9 Conclusion

This paper presents a new benchmark dataset for Bengali hate speech detection, consisting of 10K posts from Twitter, covering both actual & Roman scenarios. Each tweet was annotated with one of the hate/offensive/normal labels. We assessed different transformer-based architectures for hate speech detection. We also experimented with several interlingual transfer mechanisms. Our experiments show how few-shot techniques could be beneficial. Besides, we saw how joint training performs better than training on standalone data. We further notice that joint transliterated training performs best in the case of the Roman Bengali dataset. Our error analysis reveals some of the typical shortcomings of the transformer models.

As part of the future work, we plan to evaluate the robustness of these models' under adversarial attack as hateful users keep contriving newer ways to deceive the standard hate speech detection models. Another direction could be lessening the biases that can be present in the dataset/model.

Ethical considerations

We only analyzed publicly available data crawled via Twitter API. We followed standard ethical guidelines (Rivers and Lewis, 2014), not making any attempts to track users across platforms or deanonymize them. We have added a data statement (Bender and Friedman, 2018) in the appendix. Although we achieved good performance and the results look promising, these models cannot be deployed directly on a social media platform without rigorous testing. Further study might be needed to track the presence of unintended bias towards specific target communities.

A Data statement

A.1 Curation rationale

The dataset consists of a collection of Tweets in actual and roman Bengali. To crawl the dataset, Twitter API has been used.

A.2 Language variety

The languages of the dataset are in Bengali (bn), Roman Bengali (bn-En).

A.3 Speaker demographic

- Twitter users
- Age: Unknown – mixed.
- Gender: Unknown – mixed.
- Race/Religion: Unknown – mixed.
- Native language: Unknown; Bengali speakers.
- Socioeconomic status: Unknown – mixed.
- Geographical location: Unknown; mostly from Bangladesh & India.

A.4 Annotator demographic

- Age: 22-29.
- Gender: 2 male & 2 female.
- Race/Religion: prefer not to disclose.
- Native language: Bengali.
- Socioeconomic status: undergraduate students.

A.5 Speech situation

Discussions held in public on Twitter platform.

A.6 Text characteristics

All the sentences in this dataset come from Twitter.

A.7 Other

N/A

Learning Interpretable Latent Dialogue Actions With Less Supervision

Vojtěch Hudeček and Ondřej Dušek

Abstract

We present a novel architecture for explainable modeling of task-oriented dialogues with discrete latent variables to represent dialogue actions. Our model is based on variational recurrent neural networks (VRNN) and requires no explicit annotation of semantic information. Unlike previous works, our approach models the system and user turns separately and performs database query modeling, which makes the model applicable to task-oriented dialogues while producing easily interpretable action latent variables. We show that our model outperforms previous approaches with less supervision in terms of perplexity and BLEU on three datasets, and we propose a way to measure dialogue success without the need for expert annotation. Finally, we propose a novel way to explain semantics of the latent variables with respect to system actions.

1 Introduction

While supervised neural dialogue modeling is a very active research topic (Wen et al., 2017b; Lei et al., 2018; Peng et al., 2021), it requires a significant amount of work to obtain turn-level labels, usually with dialogue state annotation. We argue that in many real-world cases, it is very expensive to obtain the necessary labels or even to design an appropriate annotation schema. Consider a call center with various dialogues that has a lot of transcripts available, including the corresponding API queries, but has no capacity to label them. This motivates our research of approaches that minimize the need for expert annotation.

While most recent research focuses on pretrained language models (PLMs) and reaches state-of-the-art performance in standard supervised (Peng et al., 2021; Zhang et al., 2020b) or even few-shot (Peng et al., 2020; Wu et al., 2020) settings, these models still require full supervision. Furthermore, they lack the potential to interpret the model decisions. Some recent works try to address PLM interpretability with some success (Lin et al., 2019; Stevens and Su, 2021), but still face considerable difficulties due to PLMs' huge number of parameters and their structure. On the other hand, dialogue models using latent variables are able to infer interpretable attributes from unlabeled data (Wen et al., 2017a; Zhao et al., 2019). These models are mostly trained using variational autoencoders (VAE; Kingma and Welling, 2014; Serban et al., 2017). Improvements with discrete variables (Zhao et al., 2018; Shi et al., 2019) offer better interpretability, but the approaches are not directly applicable to task-oriented response generation as no distinction between the system and user roles is made, and database access or goal fulfillment are not considered; most research on unlabeled data only applies to a chit-chat setting.

Since interpretability and the ability to learn from unlabeled data are our primary goals, we choose working with RNN-based latent variable models over Transformer-based PLMs in our work.

Unlike previous latent-variable approaches, we shift the focus towards task-oriented systems and take tracked entity values and database access into account. Specifically, we base our approach on Shi et al. (2019)'s architecture. Shi et al. (2019) employ the VRNN model (Chung et al., 2015) and experiment with conditioning the prior distribution. However, their focus is on uncovering dialogue structure, and they model user and system utterances together. In contrast, we fully take advantage of the VRNN model's generative capabilities and apply it for response generation. Specifically, we train a specialized decoder for system response generation. Furthermore, we extend the VRNN model so that the system and the user utterances are modeled separately. This modification brings the following major advantages: (1) We can model different behaviors on the side of the system and the user, which is expected in a task-oriented setting; (2) We can focus on modeling latent system

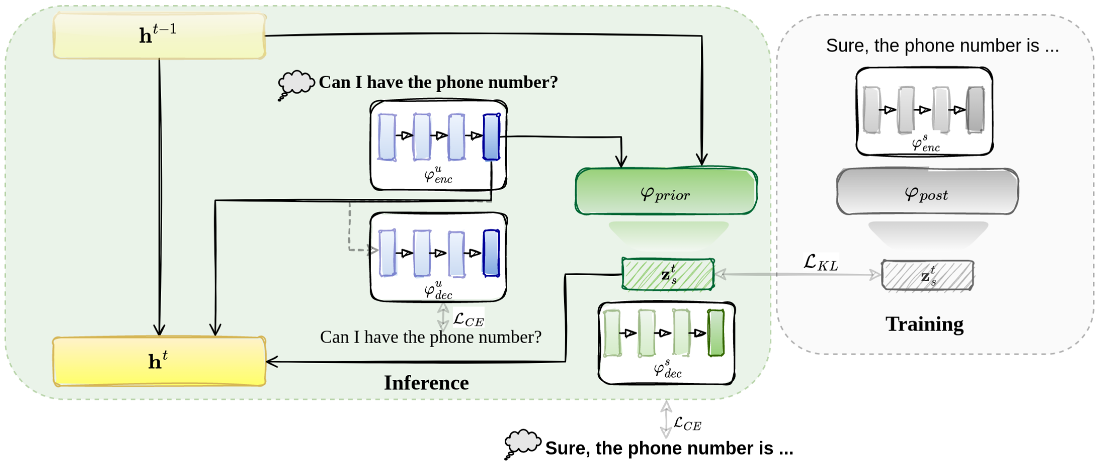

Figure 1: Visualization of our model architecture (one dialogue turn). Yellow boxes represent the turn-level VRNN's hidden state h^t. The user utterance is represented as the last hidden state of the encoder network φ^u_{enc}, which is trained as an autoencoder along with the decoder φ^u_{dec}. The system utterance, encoded by the network φ^s_{enc}, is an input to the posterior network φ_{post} that helps to train the prior network φ_{prior} to construct meaningful latent variables $\mathbf{z}_s$, which initialize the system utterance decoder φ^s_{dec}. Training uses the whole architecture, including the posterior network φ_{post}, while only uses the part shaded in green is used for inference.
$\mathcal{L}_{CE}$ stands for cross-entropy loss, $\mathcal{L}_{KL}$ for KL-divergence loss.

actions in an explainable way; (3) We can predict the system response easily.

Task-oriented dialogue systems typically need to interact with an external database; otherwise, their responses cannot be grounded. Therefore, we assume that database queries and results are known, but no dialogue state annotation is available. This allows a direct application of our model for dialogue response generation in a task-oriented setting while still keeping the amount of needed supervision very low. This scenario reflects the intended use case, i.e. automating a call center based on recordings of previous human-human dialogues. At some point of the dialogue, a database query is performed by the human agent and we know exactly when and with which parameters.

Our contributions in this paper are as follows:

1. We propose a novel modification of the VRNN-based model for minimally supervised task-oriented dialogue generation, with interpretable latent variables to represent system actions.

2. We evaluate the system performance in a full task-oriented setting including the database interaction, going beyond previous works in this family of models. Our approach outperforms strong baselines in terms of BLEU and perplexity on three datasets and compares favorably to other baselines.

3. We present a straightforward way of interpreting the latent variables using a decision tree model. We show that our model's latent variables explain most of our system's predicted responses and align well with gold-standard responses.

Our experimental code is released on GitHub.[1]

2 Related Work

In the area of supervised dialogue systems, current leading research focuses on end-to-end sequence-to-sequence models (Lei et al., 2018). Recent works make use of large pre-trained language models (PLMs) based on the transformer architecture (Vaswani et al., 2017) such as GPT-2 (Radford et al., 2019) or BERT (Devlin et al., 2019). For example, Wu et al. (2020) propose finetuning BERT (Devlin et al., 2019) for task-oriented dialogue on multiple datasets; Zhang et al. (2020b) extended the GPT-2 PLM to model open-domain chit-chat.

However, we focus mainly on approaches that require less supervision. The hierarchical recurrent encoder-decoder (HRED) by Serban et al. (2016), where RNN hidden states represent the latent dialogue state, was among the first unsupervised neural dialogue models. However, the latent representations obtained from the vanilla autoencoder model trained with reconstruction loss suffer from poor generalization. For this purpose (Bowman et al., 2016), the usage of Variational Autoencoders (VAEs) (Kingma and Welling, 2014) was proposed. The VAE training maximizes the variational lower

[1] https://github.com/vojtsek/to-vrnn

bound of data log-likelihood. VAE distributions are invariant in time, therefore it are not suitable for modeling sequences. Chung et al. (2015) address this issue with the Variational Recurrent Neural Network model (VRNN). Serban et al. (2017) then used VRNN's latent variables to represent dialogue state. Recent works used modified Transformer architectures with specific training tasks to obtain in-context representations of dialogue utterances (Bao et al., 2020; Liu et al., 2021).

While both VAEs and Transformers improve generalization and consistency of the latent variables, they are not well interpretable. To obtain more interpretable latent states, generative models with discrete states such as hidden Markov models were applied (Zhai and Williams, 2014; Brychcín and Král, 2017). Wen et al. (2017a) used discrete latent variables to represent the state in a model trained using reinforcement learning. Another proposed approach was the usage of quantization techniques by Gunasekara et al. (2017), who perform clustering on utterances and model the dialogue as a sequence of clusters to predict future responses. Zhao et al. (2018) use VAEs in combination with Gumbel-Softmax to model discrete latent variables representing the dialogue utterances.

More recently, several works attempted to model latent system actions without any action-level annotation (Huang et al., 2020; Zhao et al., 2019; Lubis et al., 2020; Zhang et al., 2020a). However, they still rely on labeled data on different levels, such as turn-level dialogue state annotation. In a different line of research, Shi et al. (2019) aim to uncover the dialogue structure. They apply VRNNs to estimate dialogue state transition probabilities. The same goal of uncovering and understanding semantic structure of the dialogue is explored by Qiu et al. (2020), who propose a VRNN-based model with structured attention to achieve this goal, or Sun et al. (2021), who use an enhanced graph autoencoder. Our proposed model combines the latter two approaches, but it is distinct from both. It models system actions using latent variables, but it does not rely on any turn-level labels for dialogue state or language understanding. Moreover, our goal is not only to uncover the dialogue structure but rather to model system actions and generate responses.

3 Method

We assume that each dialogue turn t consists of a user utterance $\mathbf{x}_u^t$ and a system utterance $\mathbf{x}_s^t$. The context $\mathbf{c}^t$ in turn t is a sequence of user and system utterances up to the previous turn $t-1$. We expect that conditioning the generation of $\mathbf{x}_s^t$ on a latent variable $\mathbf{z}^t$ will allow the model to better incorporate context.

3.1 Background: VRNN

The VRNN model (Chung et al., 2015) can be seen intuitively as a recurrent network with a VAE in every timestep. It extends the VAE model to a sequence of observations generated from a series of hidden latent variables $\mathbf{z}$. Formally, we want to estimate the joint probability distribution of a sequence of observed and corresponding latent variables $p(\mathbf{x}, \mathbf{z}) = p(\mathbf{x}|\mathbf{z})p(\mathbf{z})$. The conditional distribution $p(\mathbf{x}|\mathbf{z})$ is parameterized with a neural network. However, we still need to estimate the posterior $p(\mathbf{z}|\mathbf{x})$ in order to connect the latent variables with the observations. The VAE uses a variational approximation $q(\mathbf{z}|\mathbf{x})$ that allows to maximize the lower bound of log-likelihood of the data:

$$\begin{aligned} \log\, p(\mathbf{x}) \geq & -\mathrm{KL}(q(\mathbf{z}|\mathbf{x})||p(\mathbf{z})) \\ & +\mathbb{E}_{q(\mathbf{z}|\mathbf{x})}[\log\, p(\mathbf{x}|\mathbf{z})] \end{aligned} \tag{1}$$

where KL is the Kullback-Leibler divergence. We consider a prior network φ_{prior} and a posterior network φ_{post}, which compute the parameters of $p(\mathbf{z})$ and $q(\mathbf{z}|\mathbf{x})$ respectively. In a VRNN, φ_{prior} and φ_{post} additionally depend on the RNN hidden state $\mathbf{h}^t$ to allow for a context-aware prior distribution. In each time step, we obtain the distribution parameters as follows:

$$\begin{aligned} \theta_q &= \varphi_{post}(\mathbf{h}^t, \varphi_{enc}(\mathbf{x}^t)) \\ \theta_p &= \varphi_{prior}(\mathbf{h}^t) \end{aligned} \tag{2}$$

where φ_{enc} is the encoder and θ_q, θ_p are parameters of the respective distributions (see Section 3.4). With distribution parameters available, we can sample the latent variable and predict the output:

$$\begin{aligned} \mathbf{z}^t &\sim p(\mathbf{z}; \theta_p) \\ \mathbf{x}^t &= \varphi_{dec}(\mathbf{z}^t) \end{aligned} \tag{3}$$

where φ_{dec} represents the decoder network. The update of the hidden state $\mathbf{h}^t$ is as follows:

$$\mathbf{h}^{t+1} = \mathrm{RNN}([\varphi_{enc}(\mathbf{x}^t), \varphi_z(\mathbf{z}^t)], \mathbf{h}^t) \tag{4}$$

where $[.,.]$ is concatenation, $\varphi_z(.)$ is a feature extractor and $\mathrm{RNN}()$ is a step transition function of a recurrent neural network, in our case an LSTM (Hochreiter and Schmidhuber, 1997).

Turn 1	**user:**	Is there a **moderately priced** restaurant serving **italian** food anywhere in town?

Table 1: An example dialogue drawn from the CamRest676 validation set, illustrating the use of database information. We show the user input (or inserted database results), the gold-standard system response, system action annotation based on manual rules (cf. Section 5.2), and a prediction of our system (Ours-attn configuration using the database, cf. Table 3). In the first turn, a database query is constructed, the second turn illustrates how the result is retrieved and fed as input. Values inferred correctly by our system are depicted in green, wrong inference is in red.

3.2 Modeling task-oriented Dialogue

We use the VRNN model and extend it to fit the task-oriented setup. Our model's architecture is depicted in Figure 1. We employ a turn-level RNN that summarizes the context to its hidden state. In each dialogue turn, we model user and system utterances with separate autoencoders to account for different user and system behavior. The user utterance is modeled with a standard autoencoder; the last encoder hidden state $\varphi^u_{enc}(\mathbf{x}^t_u)$ provides the encoded representation. For the system part, we use a VAE with discrete latent variables $\mathbf{z}_s$ conditioned on the context RNN's hidden state $\mathbf{h}^{t-1}$ and the user utterance encoding $\varphi^u_{enc}(\mathbf{x}^t_u)$. Our model can thus be seen as a VRNN extended by an additional encoder-decoder module. The context RNN hidden state update looks as follows:

$$\mathbf{h}^{t+1} = \text{RNN}([\varphi^u_{enc}(\mathbf{x}^t_u), \varphi_z(\mathbf{z}^t_s)], \mathbf{h}^t) \qquad (5)$$

For word-level encoding and decoding modules $(\varphi^u_{enc}, \varphi^s_{enc}, \varphi^u_{dec}, \varphi^s_{dec})$, we use an RNN with LSTM cells. We further experiment with attention (Bahdanau et al., 2015) over user encoder hidden states in the system decoder. We train the model by minimizing a sum of the cross-entropy reconstruction loss on user utterances and the variational lower bound loss (Equation 1) on system responses.

When running in inference mode, only the prior distribution $p(\mathbf{z}_s)$ is considered, which does not require the system utterance on the input. Therefore, the model is able to generate the system response when provided with a user utterance on the input.

3.3 Database interaction

Task-oriented dialogue systems must provide accurate and complete information based on user requests, which requires external database interaction. To support database access while avoiding costly turn-level annotation, we follow Bordes et al. (2017) and insert sparse database queries and results directly into the training data, forming special dialogue turns. Specifically, we identify turns that require database results, e.g. to inform about entity attributes or a number of matching entities, and insert a query-result pair in front of those turns (see Table 1).We argue that this is the minimal level of supervision required to successfully operate a task-oriented system with database access; it is significantly lower than the full dialogue-state supervision used by most systems. In addition, it is easily available in the wild (e.g., call center transaction logs). In practice, we observe that database queries are only inserted for 24% turns[2] on average. Note that this approach still covers the task of an explicit state tracker since the necessary entity values are provided when needed. To maintain consistency, database query results can be stored and used in follow-up questions.

Some experimental approaches, such as Raghu et al. (2021), learn database queries without annotation via reinforcement learning. Our framework could use this to handle database interaction more effectively. We leave this extension for future work.

3.4 Latent Variables

We use a set of n K-way $(K = 20; n = 1, 3, 5)$ categorical variables to achieve good interpretability, following Zhao et al. (2018). This means that each variable is represented as a one-hot vector of

[2] This is the average over all datasets in our experiments (see Section 4.1). Per-dataset query counts are 36%, 23% and 11% for CamRest676, MultiWOZ and SMD respectively.

Data	Domains	Slots	Dialogues	T/D
MultiWOZ	7	29	10,437	13.71
SMD	3	15	3031	5.25
CamRest676	1	7	676	8.12

Table 2: Details of the used datasets giving number of domains, slots, dialogues and average number of turns per dialogue.

length K, and we use n such vectors. We use the Gumbel-Softmax distribution and the reparameterization trick (Jang et al., 2017). During inference, we apply argmax directly to the predicted distribution, instead of sampling from it.

4 Experiments

In this section, we focus on the quality of responses generated by our model as well as on model performance with respect to dialogue task success. We focus on theoretical modeling and feasibility at this stage, which we believe is sufficiently demonstrated by corpus-based evaluation complemented by manual checks. Detailed interpretation of the learned representations follows in Section 5.

4.1 Data

We evaluate the model performance on three datasets: CamRest676 (Wen et al., 2017b), MultiWOZ 2.1 (Budzianowski et al., 2018; Eric et al., 2020) and Stanford Multidomain Dialogues (SMD; Eric et al., 2017)[3] All the datasets are task-oriented, i.e., they distinguish between user and system conversational roles. Furthermore, MultiWOZ and SMD include multiple conversation domains. The MultiWOZ dataset contains conversations between tourists and a system that provides information about the city they visit, e.g., restaurants, hotels or attractions and transit connections. SMD contains more concise dialogues between a driver and an in-car virtual assistant. CamRest676 contains only restaurant reservations. Detailed statistics are given in Table 2.

Database queries To include database information in the dialogues, we first identify all turns in the original datasets where database information is required, using handcrafted rules.[4] We then build database query turns based on the respective state annotation (see example in Table 1). Note that database query parameters are the only annotation used to train our models apart from utterance texts; no other dialogue state annotation from the original datasets is used.

4.2 Experimental Setup

We evaluate two versions of our model: one that uses the attention mechanism (*attn*) and one without it (*noattn*).[5] Since our approach is the first to be evaluated in a task-oriented setting with this minimal level of supervision, comparing to prior works is difficult. Setups with full dialog state supervision are not comparable and dialog-state metrics are not applicable without the turn-level supervision. Therefore, we compare our models to standard architectures, such as vanilla LSTM or Transformer encoder-decoder, predicting in a sequence-to-sequence fashion using the same amount of supervision as our approach. We also compare to the HRED/VHRED models, which are perhaps the closest prior work to our approach. To put the results into perspective, we also include scores for fully supervised state of the art on our datasets. However, note that these scores are not directly comparable. Model parameters are selected by grid search (see Appendix A).[6]

4.3 Response quality

To evaluate the quality of individual responses, we compute BLEU score (Papineni et al., 2002) and perplexity on the test set (see Table 3).

Our architecture performs substantially better than (V)HRED, which commonly fails to pick up the necessary knowledge, especially on larger datasets. The attention-based versions perform better on BLEU, but lose slightly on perplexity. Comparing HRED and VHRED shows that using the variational approach generally improves the overall performance. While the GPT-2 PLM outperforms our approach on perplexity, it is worse on BLEU score, despite its huge capacity.

We compare to other relevant related works:

[3] We use standard splits for MultiWOZ 2.1 and SMD. We split CamRest676 in the 8:1:1 ratio, following previous work.

[4] These rules are very simple and require minimal effort: whenever database results are provided in the data (based on simple pattern matches over system actions), we prepend a database query based on ground-truth state. The assumption is that in a real-world scenario, these queries would naturally be available – database queries induced by human operators can be logged along with client-operator conversations.

[5] The number and size of the variables are set based on a few cursory checks on the training data. Our models use 10 latent variables by default; we discuss the influence of the number of latent variables in Appendix B.

[6] The training is sensitive to some parameters, such-as the Gumbel-softmax temperature, but otherwise the model trains easily using conventional optimization methods.

Table 5: Dialogue success and query accuracy comparison for VHRED, *Ours-noattn* using the database and a state-of-the-art supervised system.

1. Shi et al. (2019) do not use their model for response generation, but they report a negative log likelihood of approximately $5.5 \cdot 10^4$ when reconstructing the CamRest676 test set. Our *Ours-noattn* model obtained $0.87 \cdot 10^4$, which suggests a better fit of the data.[7]

2. Wen et al. (2017a) measure response generation BLEU score on fully delexicalized CamRest676 data. Their best reported result is 24.60, while our model gets 27.23 (30.10 with attention).

Based on manual checks, our models are able to generate relevant responses in most cases. As expected, only the models including database turns are able to predict correct entities (cf. Section 4.4). A relatively common error is informing about wrong slots, e.g. the model provides a phone number instead of an address or, even more frequently, provides wrong slot values (cf. Table 1).

4.4 Task-related performance

Without dialogue-state supervision, we cannot measure task-oriented metrics such as *inform* rate or *goal accuracy*. Therefore, we decided to measure dialogue success and entity match rate, which we adjust to the minimally supervised case (details follow). We also measure database query accuracy.

Dialogue success The dialogue success or *success rate* reflects the ratio of dialogues in which the system captures all the mentioned slots correctly and provides all the requested information. We follow previous works (Nekvinda and Dušek, 2021) and report corpus-based success score, as opposed to using a user simulator. However, measuring success rate without turn-level labels is not straightforward. We approximate tracking slot values turn-by-turn by checking for correct slot values upon database queries only, and we use this in-

[7] This comparison is only approximate since the exact data split is not described by Shi et al. (2019) – we are only able to use a test set of the same size, not the exact same instances.

formation to measure dialogue success. Note that this is not equivalent to having state tracking labels available at all turns, but we consider it a reasonable approximation given our limited supervision – database queries are crucial for presenting the correct entities to the user, which in turn decides the dialogue success. The generated query attributes directly show the captured slots.

Success rate results are shown in Table 5. Our system is not competitive with a fully supervised model, but outperforms the baselines (VHRED, GPT). Upon inspection, we see that the system is often able to recognize correct slots, however, it has difficulties capturing the correct values. However, the scores are promising considering the minimal supervision of our training.

Matching database entities To evaluate the accuracy of the offered entities, we measure the Entity Match Rate (EMR), i.e. the ratio of generated responses with correct entities over all responses that mention some entity. Table 3 shows the results. We observe that the model performance without the database information is poor. However, including the database information improves the performance substantially, especially in the case of CamRest676 data. The MultiWOZ data is much more complex – it contains more slots and multiple domains that can also be combined in an individual dialogue. Nevertheless, we can still observe an improvement when we include the database queries. We also note that using attention improves EMR substantially – the latent variables alone cannot hold all information about particular values (cf. Section 5.2).

Database query accuracy Further, we evaluate the accuracy of the database querying. This metric simply measures if the system queries the database at appropriate turns. The content of the query is not taken into account in this case, as it is already considered in the success rate. On MultiWOZ, we get a near-perfect accuracy, while our approach loses to VHRED on CamRest676 (see Table 5). We hypothesize that this discrepancy can be caused by different dialogue structures among theses two datasets. The dialogues in CamRest676 usually contain just zero or one query during a dialogue, so our model might generate more queries than necessary.

5 Latent Variable Interpretation

We believe that being able to explain and interpret the model behavior is crucial, especially in a setting without full supervision. Therefore, we design a set of experiments to evaluate the model behavior and investigate whether the model captures salient dialogue features in the latent variables obtained during training on CamRest676 and MultiWOZ. While it seems that the latent variables are mainly useful for interpretability or structure induction, they are likely also contributing to the performance as smaller latent spaces yield lower performance as we saw in preliminary experiments and show in Appendix B.

5.1 Clustering the actions

First, we want to assess whether similar variables represent similar actions. We follow Zhao et al. (2018) and define utterance clusters according to the latent variables that have been assigned to them by the model. We then use the homogeneity metric (Rosenberg and Hirschberg, 2007) to evaluate the clustering quality with respect to the reference classes determined by manually annotated system actions (which are used for evaluation only). Homogeneity reflects the amount of information provided by the clustering (and by extension, the latent vectors used) and is normalized to the interval [0, 1]. The reason of choosing this metric is that it is independent on the number of labels and their permutations. We provide the results in Table 6. The clusters formed on the CamRest676 data are more homogeneous than on MultiWOZ, likely because of the greater dataset complexity in the latter case. In all cases, our clusters are much more homogeneous than clustering formed by random assignment. We also compare favorably to stronger baseline that is based on clustering of the sentence representations. Specifically, in this approach we compute sentence representations using a BERT model tuned for sentence representations (Reimers and Gurevych, 2019) and then cluster the obtained sentence embeddings using K-means clustering.

5.2 Predictive power of the variables

To evaluate the predictive power of the obtained latent representations, we train a simple classifier that predicts the system action and current domain, using solely the obtained latent representations as input features. CamRest676 data does not include system action annotation, hence we manually de-

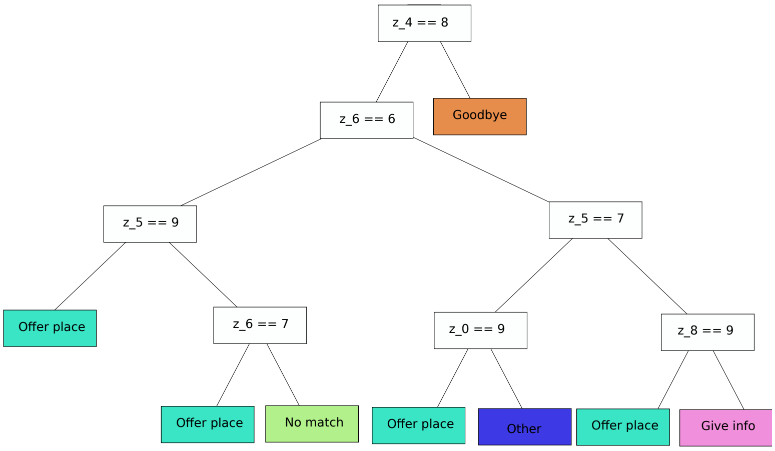

Figure 2: A visualization of a decision tree trained on the CamRest676 data to predict a system action from the contents of the latent variables. Each node represents a decision based on one latent variable value and the leaf node colors represent different system actions. When the condition in a given node is fulfilled, the algorithm proceeds into the right subtree, left otherwise. For clarity, we limit the maximum tree depth to 4. The limit lowers the accuracy slightly – the pictured tree achieves an accuracy of 73% on the CamRest676 data.

signed a set of rules to determine system actions. An example of this rule-based action annotation is shown in Table 1. For MultiWOZ, we predict both system action and the domain of the utterance.

To put our results into perspective, we include several baselines: trivial random and majority class baselines, and classifiers using representations obtained with other methods (HRED, VHRED, GPT). We use a decision tree (DT) classifier trained with the CART algorithm[8] and the *gini* split criterion, due to the its good interpretability. The results are shown in Table 4. Our classifier beats the random and majority baselines in all cases. More importantly, it also outperforms classification based on (V)HRED and GPT representations. This demonstrates that our approach produces high-quality interpretable representations. We also observe that using attention harms the performance of the action classifier as it makes it possible for the models to bypass the latent variables.

The information about domains and system actions is stored in categorical variables and can be extracted by a simple classification model such as the decision tree which allows us to interpret and explain the behavior of our model. For illustration, in Figure 2 we plot a DT with limited depth that achieves 73% accuracy when predicting the system action on the CamRest676 data.[9]

Target	Ours-noattn	sent-repr	random
CamRest676 action	0.65	0.45	0.20
MultiWOZ action	0.34	0.33	0.02
MultiWOZ domain	0.39	0.30	0.01

Table 6: Homogeneity for *Ours-noattn* configuration using the database vs. a clustering of sentence representations and random baseline.

5.3 Manual interpretation

To explore the interpretability of our representations even further, we manually annotate the latent variables to obtain a simple handcrafted classifier. Specifically, we draw a set of pairs of utterances and corresponding latent representations from the validation set. Then we present the representation (discrete) vectors to an expert annotator with a task of assigning an action that each vector represents, based on the sampled utterances. This way we obtain a mapping from the space of latent vectors to actions. We then apply this mapping to predict actions on the test set (the *-manual* entry in Table 4). Note that in this approach, we only allow assigning an action to a whole vector, unlike in the case of decision tree classifier that can take individual components into account. As the results show, this approach works well, despite the above limitation.

[8] https://scikit-learn.org/stable/modules/tree.html

[9] The aim is that latent variables hold high-level information, such as intents, actions or domains. This helps interpretability, but is not sufficient for generating appropriate and factually correct responses – here we need to incorporate correct slot values. This detailed information is captured and carried over via the attention mechanism in *Ours-attn*. Potential alternatives are copy mechanisms (Lei et al., 2018) or delexicalization on the generated outputs (Henderson et al., 2014; Peng et al., 2021).

5.4 Mutual Information

Finally, we compute mutual information (MI) between the generated text and latent variables as well as among the latent variables themselves (see Table 3).[10] We see that using attention has a dramatic effect on the amount of MI between the latent variables and the generated text. It appears that since attention bypasses the latent vectors, the decoder does not need to use them to store information.

6 Conclusion and Future Work

We introduce a model for task-oriented dialogue with discrete latent variables that uses only minimal supervision and improves upon previous approaches (Chung et al., 2015; Serban et al., 2017). We also propose methods for task-based evaluation in this minimally supervised setting. Our system is not yet ready for interactive evaluation on full dialogues, considering the clear performance gap with respect to with fully supervised approaches. However, we demonstrate that it learns meaningful representations from minimal supervision (in a realistic setup corresponding to pre-existing call center call logs) and compares favorably to previous weakly supervised approaches. A detailed analysis reveals that the learned representations capture relevant dialogue features and can be used to identify system actions. Furthermore, the reason for choosing an action can be described in an explainable way. The results suggest that dialogue models with discrete latent variables can be successfully applied also in the task-oriented setting.

The main limitations of our current model are its problems with providing the correct slot values in responses. We plan address this issue in future work by incorporating explicit copy mechanisms (Lei et al., 2018), i.e. the model will learn to copy slot values from the context and from database results. We also plan to experiment with incorporating Transformer models into the variational autoencoder setup, following recent models such as the VAE-transformer (Lin et al., 2020b).

A Training Parameters

The model is trained with gradient descent, using ADAM optimizer. We set the hyperparameters according to the BLEU and perplexity results of a grid search on the development set. Utterance encoder and decoder hidden sizes are 250, the context-LSTM hidden size is 100. The latent variables are 20-dimensional vectors, their number differs across experiments and is given in the main text. For the RNN components, we use a dropout probability of 0.3. The total model size is 7,047,529 parameters. The training time is 3-8 hours using one GPU, depending on dataset.

B Performance with Various Numbers of Latent Variables

	BLEU	Ppl	MI
Ours-noattn-1z	25.2	4.25	0.46
Ours-noattn-3z	26.8	4.24	0.26
Ours-noattn-5z	27.23	4.20	0.38
Ours-noattn-12z	29.83	4.12	0.35

Table 7: Evaluation of the model performance with respect to automatic measures of BLEU, Perplexity (Ppl) and Mutual Information (MI) on the CamRest676 data.

C Limitations and risks

We consider our work to be mostly fundamental research rather than a practical application. However, it has certain limitations. Firstly, the proposed way of including the database results is inflexible and it is hard to incorporate possible API changes. Also, although we show that the latent actions are possible to interpret and explain, with growing number of actions we likely worsen this possibility to interpret the variables. Another limitation of our current model is its inability to provide correct entities and slot values.

Another limitation and possible risk is that this system is very hard to control and deploying it in current form could produce undesired behavior.

Named Entity Recognition in Twitter: A Dataset and Analysis on Short-Term Temporal Shifts

Abstract

Recent progress in language model pre-training has led to important improvements in Named Entity Recognition (NER). Nonetheless, this progress has been mainly tested in well-formatted documents such as news, Wikipedia, or scientific articles. In social media the landscape is different, in which it adds another layer of complexity due to its noisy and dynamic nature. In this paper, we focus on NER in Twitter, one of the largest social media platforms, and construct a new NER dataset, *TweetNER7*, which contains seven entity types annotated over 11,382 tweets from September 2019 to August 2021. The dataset was constructed by carefully distributing the tweets over time and taking representative trends as a basis. Along with the dataset, we provide a set of language model baselines and perform an analysis on the language model performance on the task, especially analyzing the impact of different time periods. In particular, we focus on three important temporal aspects in our analysis: short-term degradation of NER models over time, strategies to fine-tune a language model over different periods, and self-labeling as an alternative to lack of recently-labeled data. TweetNER7 is released publicly[1] along with the models fine-tuned on it[2].

1 Introduction

Named Entity Recognition (NER) is a long-standing NLP task that consists of identifying an entity in a sentence or document, and classifying it into an entity-type from a fixed typeset. One of the most common and successful types of NER system is achieved by fine-tuning pre-trained language models (LMs) on a human-annotated NER dataset with token-wise classification (Peters et al., 2018; Howard and Ruder, 2018; Radford et al., 2018, 2019; Devlin et al., 2019). Remarkably, LM fine-tuning based NER models (Yamada et al., 2020; Li et al., 2020) already achieve over 90% F1 score in standard NER datasets such as CoNLL2003 (Tjong Kim Sang and De Meulder, 2003) and OntoNotes5 (Hovy et al., 2006). However, NER is far from being solved, specialized domains such as financial news (Salinas Alvarado et al., 2015), biochemical (Collier and Kim, 2004), or biomedical (Wei et al., 2015; Li et al., 2016) still pose additional challenges (Ushio and Camacho-Collados, 2021). Lower performance in these domains may be attributed to various factors such as the usage specific terminologies within those domains, which LMs have not seen while pre-training (Lee et al., 2020).

Among recent studies, social media has been acknowledged as one of the most challenging domains for NER (Derczynski et al., 2016, 2017). Social media texts are generally more noisy and less formal than conventional written languages in addition to its vocabulary specificity. In social media, there is another particular feature that needs to be addressed, which is the presence of (quick) temporal shifts in the text semantics (Rijhwani and Preotiuc-Pietro, 2020), where the meaning of words is constantly changing or evolving over time. This is a general issue with language models (Lazaridou et al., 2021), but it is especially relevant given the dynamic landscape and immediacy present in social media (Del Tredici et al., 2019). There have been a few specific approaches to deal with the temporal shifts in social media. For instance, Loureiro et al. (2022) addressed this issue by pre-training language models on a large tweet collection from different time period, highlighting the importance of having an up-to-date language model. Agarwal and Nenkova (2022) studied the temporal-shift in various NLP tasks including NER and analyzed methods to overcome the temporal-

shift with strategies such as self-labeling.

In this paper, we propose a new NER dataset for Twitter (*TweetNER7* henceforth). TweetNER7 contains tweets from diverse topics that are distributed uniformly from September 2019 to August 2021. It contains 11,382 annotated tweets in total, spanning seven entity types (*person*, *location*, *corporation*, *creative work*, *group*, *product*, and *event*). To the best of our knowledge, TweetNER7 is the largest Twitter NER datasets with a high coverage of entity types TTC (Rijhwani and Preotiuc-Pietro, 2020) contains about same amount of annotation yet with three entity types, while WNUT17 (Derczynski et al., 2017) has six entity types yet suffer from very small annotations. The tweets for TweetNER7 were collected by querying tweets with weekly trending keywords so that the tweet collection covers various topics within the period, and we further removed near-duplicated tweets and irrelevant tweets without any specific topics in order to improve the quality of tweets. We provide baseline results with language model finetuning that showcases the difficulty of TweetNER7, especially when dealing with time shifts. Finally, we provide a temporal analysis with different strategies including self-labeling, which does not prove highly beneficial in our context, and provide insights in the model inner working and potential biases.

2 Related Work

There is a large variety of NER datasets in the literature. CoNLL2003 (Tjong Kim Sang and De Meulder, 2003) and OntoNotes5 (Hovy et al., 2006) are widely used common NER datasets in the literature, where the texts are collected from public news, blogs, and dialogues. WikiAnn (Pan et al., 2017) and MultiNERD (Tedeschi and Navigli, 2022) are both multilingual NER datasets where the training set is constructed by distant-supervision on Wikipedia and BabelNet. As far as domain-specific NER datasets are concerned, FIN (Salinas Alvarado et al., 2015) is a NER dataset of financial news, while BioNLP2004 (Collier and Kim, 2004) and BioCreative (Wei et al., 2015; Li et al., 2016) are both constructed from scientific documents of the biochemical and biomedical domains. However, none of these datasets address the same challenges posed by the social media domain.

In the social media domain, the pioneering Broad Twitter Corpus (BTC) NER dataset (Derczynski et al., 2016) included users with different demographics with the aim to investigate spatial and temporal shift of semantics in NER. More recently, the test set of WNUT2017 (Derczynski et al., 2017) contained unseen entities in the training set from broader social media including Twitter, Reddit, YouTube, and StackExchange. The recent TweeBankNER dataset (Jiang et al., 2022) annotated TweeBank (Liu et al., 2018) with entity labels to investigate the interaction between syntax and NER.

The most similar dataset to ours is the Temporal Twitter Corpus (TTC) NER dataset. (Rijhwani and Preotiuc-Pietro, 2020), which was also aimed at analysing the temporal effects of NER in social media. For this dataset, 2,000 tweets every year from 2014 to 2019 were annotated. In general, however, these social media datasets suffer from limited data, non-uniform distribution over time, or limited entity types (see Subsection 3.3 for more details). In this paper, we contribute with a new NER dataset (TweetNER7) based on recent data until 2021, which is specifically designed to analyze temporal shifts in social media.

3 TweetNER7: Dataset Construction, Statistics and Baselines

In this section, we present our time-aware NER dataset from publicly available tweets with seven general entity types, which we refer as *TweetNER7*. In the following subsections, we describe the data collection (Subsection 3.1) and annotation (Subsection 3.2) processes. We also share relevant statistics (Subsection 3.3) and baseline results (Subsection 3.4) of our dataset.

3.1 Data Collection

This NER dataset annotates a similar tweet collection used to construct TweetTopic (Antypas et al., 2022). The main data consists of tweets from September 2019 to August 2021 with roughly same amount of tweets in each month. This collection period makes it suitable for our purpose of evaluating short-term temporal-shift of NER on Twitter. The original tweets were filtered by leveraging weekly trending topics as well as by various other types of filtering see Antypas et al. (2022) for more details on the collection and filtering process). The collected tweets were then split into two periods: September 2019 to August 2020 (2020-set) and September 2020 to August 2021 (2021-set).

3.2 Dataset Annotation

Annotation. To attain named-entity annotations over the tweets, we conducted a manual annotation on Amazon Mechanical Turk with the interface shown in Figure 1. We split tweets into two periods: September 2019 to August 2020 (2020-set) and September 2020 to August 2021 (2021-set), and randomly sampled 6,000 tweets from each period, which were annotated by three annotators, collecting 36,000 annotations in total. As the entity types, we employed seven labels: *person*, *location*, *corporation*, *creative work*, *group*, *product*, and *event*. We followed Derczynski et al. (2017) for the selection of the first six labels, and additionally included *event*, as we found a large amount of entities for events in our collected tweets.

Pre-processing. We pre-process tweets before the annotation to normalize some artifacts, converting URLs into a special token {{URL}} and non-verified usernames into {{USERNAME}}. For verified usernames, we replace its display name with symbols @. For example, a tweet

```
Get the all-analog Classic Vinyl Edition
of "Takin' Off" Album from @herbiehancock
via @bluenoterecords link below:
http://bluenote.lnk.to/AlbumOfTheWeek
```

is transformed into the following text.

```
Get the all-analog Classic Vinyl Edition
of "Takin' Off" Album from {@Herbie Hancock@}
via {{USERNAME}} link below: {{URL}}
```

We ask annotators to ignore those special tokens but label the verified users' mentions.

Quality Control. Since we have three annotations per tweet, we control the quality of the annotation by taking the agreement into account. We disregard the annotation if the agreement is 1/3, and manually validate the annotation if it is 2/3, which happens for roughly half of the instances.

3.3 Statistics

This subsection provides an statistical analysis of (i) our dataset, (ii) our dataset in comparison with other Twitter NER datasets, and (iii) our dataset distribution over time.

Statistics of TweetNER7. TweetNER7 contains 5,768 and 5,614 tweets annotated in each period of 2020 and 2021, which are then split into training / validation / test sets for each year. Since the 2020-set is for model development, we consider 80% of the dataset as training set and 10% for validation and test sets. Meanwhile, the 2021-set is mainly devised for model evaluation to measure the temporal adaptability, so we take the majority of the 2021-set (50%) as the test set and split the rest into training and validation set with the same ratio of training and validation set of the 2020-set. Table 1 summarizes the number of the entities as well as the instances in each subset of TweetNER7. We can observe a large gap between frequent entity types such as *person* and rare entity types as *location*, while the distribution of the entities are roughly balanced across subsets. We also report entity diversity, which we define as the percentage of unique entities with respect to the total number of entities. Entity types such as *product* contain a relatively large number of duplicates (ranging between 56.2% and 76.4% entity diversity scores), while other types such as creative work are more diverse (ranging between 80.1% and 93.2%).

Period	2020-set			2021-set		
Split	Train	Valid	Test	Train	Valid	Test
Number of Entities						
- corporation	1,700	203	191	902	102	900
- creative work	1,661	208	179	690	74	731
- event	2,242	256	265	968	131	1,097
- group	2,242	227	311	1,313	227	1,516
- location	1,259	181	165	697	72	716
- person	4,666	598	596	2,362	283	2,712
- product	1,850	241	220	926	111	972

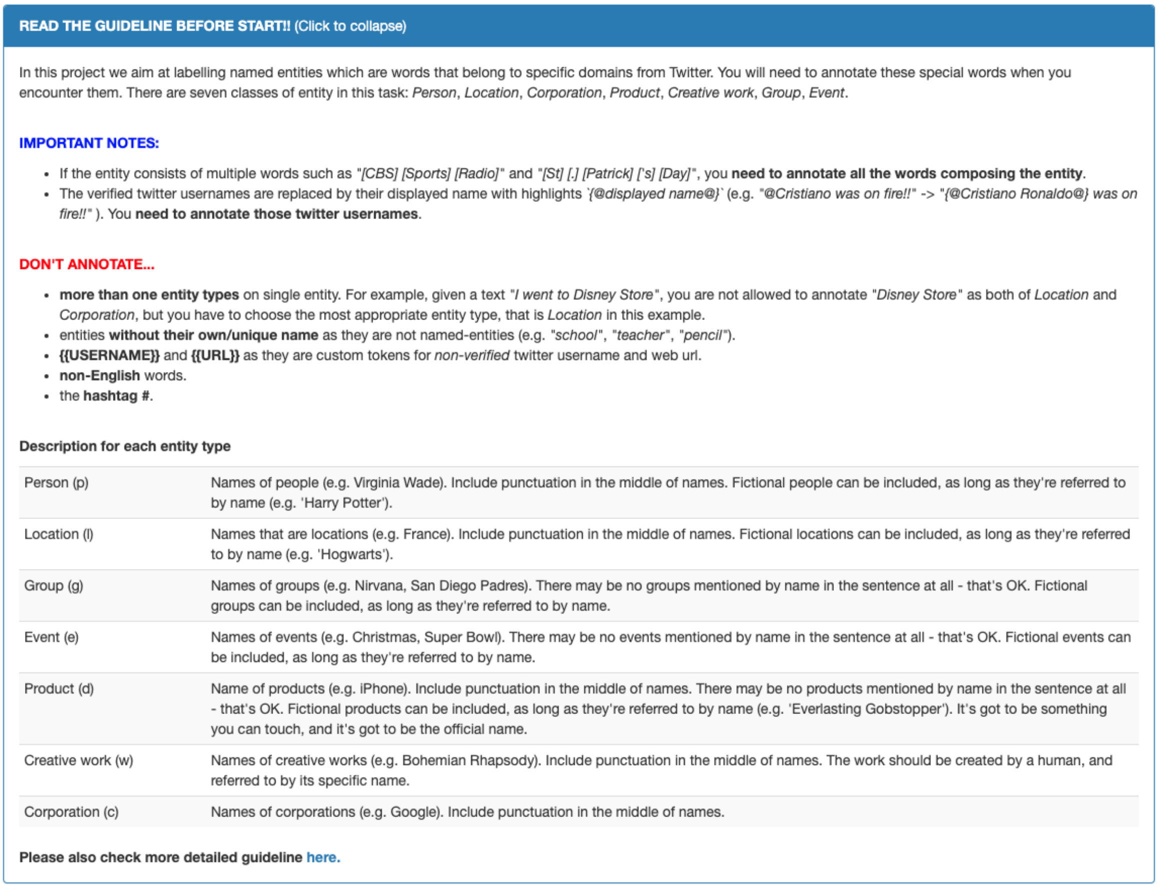
Number of Tweets	4,616	576	576	2,495	310	2,807

Table 1: Number of entities, tweets, and entity diversity in each data split and period, where the 2020-set is from September 2019 to August 2020, while the 2021-set is from September 2020 to August 2021.

Comparison with other Twitter NER Datasets. In Table 2, we compare TweetNER7 against existing NER datasets for Twitter, which highlights the large number of annotations of TweetNER7 for our covered period. TweetNER7 and TTC are the overall largest datasets with more than 10k annotations, but TTC covers only three entities, which may be insufficient for certain practical use cases given the diversity of text in social media context (Derczynski et al., 2017). In contrast, TweetNER7 has the highest coverage of entity types among all



READ THE GUIDELINE BEFORE START!! (Click to collapse)

In this project we aim at labelling named entities which are words that belong to specific domains from Twitter. You will need to annotate these special words when you encounter them. There are seven classes of entity in this task: *Person*, *Location*, *Corporation*, *Product*, *Creative work*, *Group*, *Event*.

IMPORTANT NOTES:

- If the entity consists of multiple words such as "*[CBS] [Sports] [Radio]*" and "*[St] [.] [Patrick] ['s] [Day]*", you **need to annotate all the words composing the entity**.
- The verified twitter usernames are replaced by their displayed name with highlights `*{@displayed name@}*` (e.g. "*@Cristiano was on fire!!*" -> "*{@Cristiano Ronaldo@} was on fire!!*"). You **need to annotate those twitter usernames**.

DON'T ANNOTATE...

- **more than one entity types** on single entity. For example, given a text "*I went to Disney Store*", you are not allowed to annotate "*Disney Store*" as both of *Location* and *Corporation*, but you have to choose the most appropriate entity type, that is *Location* in this example.
- entities **without their own/unique name** as they are not named-entities (e.g. "*school*", "*teacher*", "*pencil*").
- **{{USERNAME}}** and **{{URL}}** as they are custom tokens for *non-verified* twitter username and web url.
- **non-English** words.
- the **hashtag #**.

Description for each entity type

Person (p)	Names of people (e.g. Virginia Wade). Include punctuation in the middle of names. Fictional people can be included, as long as they're referred to by name (e.g. 'Harry Potter').
Location (l)	Names that are locations (e.g. France). Include punctuation in the middle of names. Fictional locations can be included, as long as they're referred to by name (e.g. 'Hogwarts').
Group (g)	Names of groups (e.g. Nirvana, San Diego Padres). There may be no groups mentioned by name in the sentence at all - that's OK. Fictional groups can be included, as long as they're referred to by name.
Event (e)	Names of events (e.g. Christmas, Super Bowl). There may be no events mentioned by name in the sentence at all - that's OK. Fictional events can be included, as long as they're referred to by name.
Product (d)	Name of products (e.g. iPhone). Include punctuation in the middle of names. There may be no products mentioned by name in the sentence at all - that's OK. Fictional products can be included, as long as they're referred to by name (e.g. 'Everlasting Gobstopper'). It's got to be something you can touch, and it's got to be the official name.
Creative work (w)	Names of creative works (e.g. Bohemian Rhapsody). Include punctuation in the middle of names. The work should be created by a human, and referred to by its specific name.
Corporation (c)	Names of corporations (e.g. Google). Include punctuation in the middle of names.

Please also check more detailed guideline here.

TweetNER7	924	928	956	968	975	973

Table 3: The number of tweets in each month from BTC, TTC, and our TweetNER7 (the counts are cumulated across years). The normalized standard deviation across month is 7.5% (BTC), 1.6% (TTC), and 0.2% (TweetNER7).

NER datasets in Twitter, including all the entity types from existing datasets. In addition to the large amount of annotations and a high coverage of entity types, TweetNER7 includes recent tweets from 2019 to 2021, from which most corpus used in pre-training language models do not contain any text (Devlin et al., 2019; Liu et al., 2019; Nguyen et al., 2020). Assuming we tackle NER by language model fine-tuning, this fact makes the task further challenging, since language models have never seen the emerging entities from the period during its pre-training phase.

Distribution over Time. One of the TweetNER7's focus is the temporal shift in Twitter similar to BTC and TTC datasets. Retaining uniform distribution over time is essential for temporal analysis, since the amount of training instances should have an effect to the metric if it is not uniform. Table 3 shows the distribution of the instances across each month and we can confirm that TweetNER7 has a very similar amount of tweets each month, while BTC and TTC have higher variation than TweetNER7. Moreover, Table 4 compares the number

	2009	2010	2011	2012	2013	2014	2015

BERTweet$_{\text{LARGE}}$	64.0 / 65.9	59.5 / 62.6	78.3 / 77.4
RoBERTa$_{\text{BASE}}$	64.2 / 64.2	59.1 / 60.2	77.9 / 74.8
RoBERTa$_{\text{LARGE}}$	**64.8** / 65.7	**60.0** / 61.9	**78.4** / 76.1
TimeLM$_{2019}$	64.3 / 65.4	59.3 / 61.1	77.9 / 76.6
TimeLM$_{2020}$	62.9 / 64.4	58.3 / 60.3	76.5 / 75.7
TimeLM$_{2021}$	64.2 / 65.4	59.5 / 61.1	77.4 / 76.4

Table 5: Result of temporal-shift NER on TweetNER7 where micro and macro F1 score as well as type-ignored F1 score on the test set of the 2021-set / 2020-set are reported. The best results in each of the 2021-set / 2020-set are highlighted in bold character / underline in each metric.

of instances per year for each dataset. TweetNER7 has a an uneven distribution here due to the the selected range for each period (i.e., September 2019 to August 2021), which results in more tweets in 2020 than 2019 and 2021.

3.4 Baseline Results

Finally, we introduce a couple of baselines with language model fine-tuning on the TweetNER7 in temporal-shift setup, where we develop models with the training and the validation set from the 2020-set, and evaluate the models on the test set of the 2021-set. In this setup, models are required to generalize to the text from newer period, which the model has not seen in the fine-tuning phase.

Experimental Setting. We consider masked language model fine-tuning with the following LMs: BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) as general-purpose LMs, and BERTweet (Nguyen et al., 2020), and TimeLMs (Loureiro et al., 2022) as Twitter-specific LMs. TimeLMs are based on a RoBERTa$_{\text{BASE}}$ architecture pre-trained on tweets collected continuously until different years: 2019, 2020, and 2021. Model weights are taken from HuggingFace (Wolf et al., 2020).[3] As evaluation metrics, we consider micro/macro F1 score and type-ignored F1 score (Ushio and Camacho-Collados, 2021), in which the entity type of the prediction is not considered in the evaluation (i.e., this metric only assesses whether the predicted entity is an entity or not). The F1 scores measure the NER systems' entire performance, while the type-ignored F1 score measures the ability of identifying whether a span of text is an entity or not. LM fine-tuning on NER relies on the T-NER library (Ushio and Camacho-Collados, 2021) and to find the best combination of hyperparameters to fine-tune LMs on NER, we run two-phase grid search. First, we fine-tune a model on every possible configuration from the search space for 10 epochs. The top-5 models in terms of micro F1 score on the validation set are selected to continue fine-tuning until their performance plateaus, and then the model that achieves the highest micro F1 score on the validation set is employed as the final model. The search space contains 24 configurations, which consist of the following variations: learning rates from $[0.000001, 0.00001, 0.0001]$; ratio of total training step for linear warm up of learning rate from $[0.15, 0.3]$; whether to normalize the gradient norm or not; and whether to add conditional random field (CRF) on top of the output logit of LM.[4]

Results. We report the NER results on TweetNER7 in Table 5, where RoBERTa$_{\text{LARGE}}$ is the best across metrics. We should note, however, that the overall metrics (micro F1 lower than 65% in all cases on the 2021 test set) are lower than those in standard NER datasets (Ushio and Camacho-Collados, 2021), which highlights the difficulty of the social media and temporal-shift components in TweetNER7. RoBERTa is also the best model among the $_{\text{BASE}}$ models but interestingly the TimeLM$_{2020}$ performs worse than other RoBERTa models. This can be explained by the fact that TimeLM$_{2020}$ was pre-trained over tweets until the end of 2020. This may have let the model to over-fit to the training

[3] We use `bert-base-cased` and `bert-large-cased` for BERT, `roberta-base` and `roberta-large` for RoBERTa, `vinai/bertweet-base` and `vinai/bertweet-large` for BERTweet, and `cardiffnlp/twitter-roberta-base-2019-90m`, `cardiffnlp/twitter-roberta-base-dec2020`, and `cardiffnlp/twitter-roberta-base-dec2021` for TimeLMs.

[4] Other parameters are fixed: random seed is 0 and batch size is 32.

corpus and makes it hard to generalize on the newer test set. Instead, TimeLM$_{2021}$ shows a better performance. Table 7 also reports the metrics on the 2020 test set for completeness. While that is not our primary aim, we can find an interesting result which is the superior performance of BERTweet in this case. This implies that a model that performs well in the same period of the training set does not guarantee an equally strong performance on an unseen period.

Breakdown by entity type. Figure 2 shows a comparison of entity-wise F1 scores over the language models, and we can see an important gap across entity types. According to Table 1, *person* is the most frequent entity type and its F1 score is equally high (around 80%), while *creative work* and *location* are the rarest entity types and hence their F1 scores are relatively low (around 40% for *creative work* and 60% for *location*). The reason why the performance for *location* is better than for *creative work* may be attributable to their differences in entity diversity. As we could see from Table 1, *creative work*'s diversity is higher than *location*, which means *creative work* contains more variation of entities than *location* while having the same amount of entities in both types, which entails a higher degree of difficulty. This seems a consistent trend that lower entity diversity results in lower F1 score as can be seen for *event* and *corporation* as well, which also have a low entity diversity score. To overcome such entity imbalance, strategies such as balancing the instances of each class could be explored (Li et al., 2020).

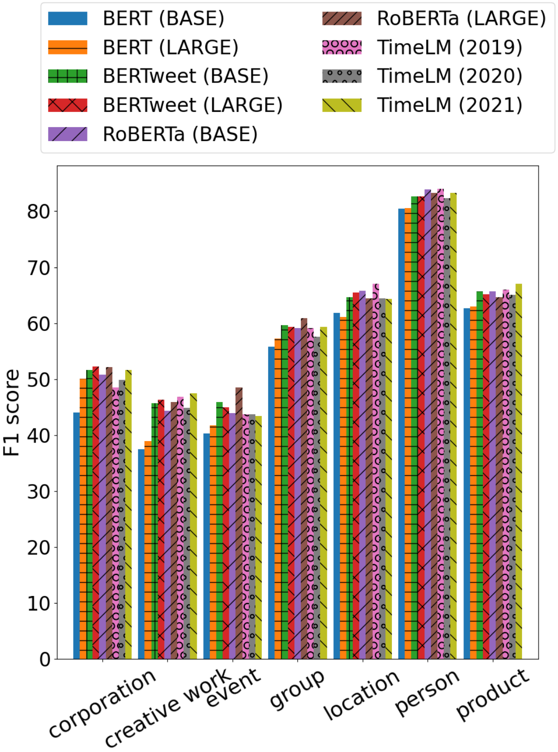

Figure 2: Entity-wise F1 score breakdown from the baseline results in the 2021 test set (Table 5).

4 Temporal Analysis

To better understand the effect of the temporal-shift, we conduct three additional comparative experiments: (i) temporal vs. random splits, (ii) joint vs. continuous fine-tuning, and (iii) self-labeling as a solution to deal with temporal shifts.

4.1 Short-Term Temporal Effect

If TweetNER7 does not suffer temporal-shift, how is the model performance changed? This is a question we aim to answer in this analysis, and we create new training and validation split without temporal-shift for this purpose. Concretely, temporal-shift usually occurs in a situation where the training and the validation sets do not contain any texts from the test period, so we keep the amount of the training/validation split as the same in Subsection 3.4, but randomly sample from the full period of September 2019 to August 2021 instead of the first half period instead. Note that we do not change the test set and make sure that each month has roughly the same amount of instances at the sampling of the new training/validation sets, to make it fair comparison with the temporal-shift result in Subsection 3.4.

Table 6 shows the variations of results between the random and temporal splits. As expected, the F1 scores on the 2021 test set are generally improved across all LMs, while the F1 scores on the 2020 test set are decreased. The increase of accuracy in 2021 is achieved with the inclusion of training/validation set from 2021, and the decrease of accuracy in 2020 is caused by the reduced number of the training/validation set from the same 2020 period. This result further highlights the benefit of having a human annotated training set from the test period, even if the time period differs in a year only. Interestingly, the results for the time-specific pretrained TimeLMs models differ across years. Since in this paper we did not focus on the analysis of the pre-training corpora, we leave further analysis about this result for future exploration.

Model	2021-set			2020-set		
	Mi. F1	Ma. F1	T-i. F1	Mi. F1	Ma. F1	T-i. F1
$\text{BERT}_{\text{BASE}}$	+0.8	+1.2	+0.1	+0.1	+0.3	+0.3
$\text{BERT}_{\text{LARGE}}$	+1.0	+1.4	+0.6	-0.7	-1.0	-0.5
$\text{BERTweet}_{\text{BASE}}$	+1.5	+0.2	-0.1	-2.5	-3.8	-3.3
$\text{BERTweet}_{\text{LARGE}}$	+0.9	+1.0	+0.1	+0.1	+0.1	-0.2
$\text{RoBERTa}_{\text{BASE}}$	-0.2	+0.1	+0.1	-0.1	-0.4	-0.5
$\text{RoBERTa}_{\text{LARGE}}$	+1.5	+1.0	+0.6	-1.3	-1.8	-0.6
TimeLM_{2019}	-1.0	-0.8	-0.5	-1.1	-0.4	-0.4
TimeLM_{2020}	+1.8	+1.7	+1.8	+0.3	+0.2	+0.2
TimeLM_{2021}	-1.0	-1.1	-0.4	-1.7	-1.3	-1.0

Table 6: Absolute performance improvement when evaluating on the random split result over the original temporal split reported in Table 5. Positive improvements are in blue and negative drops are in red.

4.2 Continuous vs. Joint Fine-Tuning

In the previous experiments we have shown the differences between training and testing on the time period or not. Instead, this analysis comes under the assumption that a labeled 2021 training set is available. Thus, the main aim of this analysis is to explore different strategies to improve the original model. In addition to fine-tuning LMs on the combined set of the 2020-set and 2021-set as in Subsection 4.1, we employed a continuous fine-tuning scheme, where we first fine-tune LMs on the 2020-set and then continue fine-tuning on the 2021-set. Table 7 shows the results of all strategies for different language models. As can be observed, continuous fine-tuning provides the best results in terms of micro F1 and type-ignored F1 in the 2021 test sets in most cases, although the differences with respect to the concatenation of sets are not substantial.

4.3 Self-Labeling

In both Subsections 4.1 and 4.2, we compared different strategies when a human-annotated training dataset from the test period was considered, namely the training and the validation sets from the 2021-set. This shows that improvements can be obtained when the time between training and test data is reduced. However, in many cases and real-world applications this is not practical as it requires a large amount of human resources to annotate newer tweets whenever. Thus, we consider an alternative approach to rely on distantly annotated tweets by the already fine-tuned model. This solution was explored by Agarwal and Nenkova (2022) in a similar setting, with promising results. In this paper, we reproduced their experiments in our TweetNER7 dataset focusing on short-term temporal shift.

		Dataset	Micro F1	Macro F1	Type-ig. F1
BERT	BASE	2020	60.1 / 60.9	54.7 / 56.5	75.6 / 72.4
		2021	60.7 / 58.4	55.5 / 54.2	75.7 / 70.9

		2021	64.0 / 63.1	58.9 / 58.5	77.9 / 75.3
		2020 + 2021	65.3 / 65.4	**60.7** / 61.4	**78.7** / 75.9
		2020 → 2021	**65.5** / 65.3	60.6 / 61.3	78.0 / 75.9
	2021	2020	64.2 / 65.4	59.5 / 61.1	77.4 / 76.4
		2021	63.5 / 62.3	58.7 / 57.9	77.5 / 74.1
		2020 + 2021	64.5 / 65.8	59.8 / 61.9	77.9 / 76.5
		2020 → 2021	**65.1** / 64.9	**60.0** / 60.7	**78.1** / 75.8

Table 7: Results of different strategies to ingest the training set of the 2021-set in TweetNER7 for different language models (→: continuous fine-tuning; +: concatenation of datasets). The best results in each model of the 2021-set / 2020-set are highlighted in bold character / underline in each metric.

4.3.1 Evaluation

Experimental Setting. For our experiments we focused on the best model in our previous experiments, which is $\text{RoBERTa}_{\text{LARGE}}$. We collected extra (unlabeled) tweets following the same procedure described in (Antypas et al., 2022), that results in 93,594 and 878,80 tweets from the period of 2020-set and 2021-set, respectively. Over those extra tweets, we use the $\text{RoBERTa}_{\text{LARGE}}$ NER model fine-tuned on the 2020-set to predict labels.

Results. Table 8 shows the result of self-labeling, where we report three patterns of model fine-tuning: (i) fine-tuning only on the pseudo dataset (e.g., 2020-extra); (ii) fine-tuning on the joint dataset

Training Set	Micro F1 2021 / 2020	Macro F1 2021 / 2020	Type-ig. F1 2021 / 2020
2020	**64.8** / 65.7	**60.0** / 61.9	78.4 / 76.1
2020-extra	64.6 / 65.5	59.3 / 61.4	78.6 / 76.2
2020 + 2020-extra	64.7 / 65.2	59.6 / 61.0	**78.7** / 76.8
2020 → 2020-extra	64.6 / 65.5	59.5 / 61.5	78.6 / 76.4
2021-extra	64.2 / 65.7	59.3 / 61.8	78.2 / 76.9
2020 + 2021-extra	64.3 / 65.6	59.3 / 61.7	78.4 / 76.9
2020 → 2021-extra	64.5 / 65.5	59.5 / 61.4	78.6 / 76.3

Table 8: Results of the self-labeling experiment with different strategies for RoBERTa$_{\text{LARGE}}$ model (→: continuous fine-tuning; +: concatenation of datasets) where micro and macro F1 score as well as type-ignored F1 score on the test set of 2021-set / 2020-set are reported. The best results in each of the 2021-set / 2020-set are highlighted in bold character / underline in each metric.

of the training set of the 2020-set and the pseudo dataset (e.g., 2020 + 2020-extra); and (iii) continuous fine-tuning of the 2020-set fine-tuned model on the pseudo dataset (e.g., 2020 → 2020-extra). In general, we can not find any major improvement by self-labeling, regardless of the strategy. In a way, this contradicts the self-labeling experiment on the TTC dataset performed by Agarwal and Nenkova (2022).[5] This may suggest that the temporal-shift of TweetNER7 is more challenging to mitigate than TTC, and self-labeling is not enough in itself to overcome the temporal shift.

4.3.2 Contextual Prediction Analysis

To explore the reason why self-labeling does not help to mitigate temporal-shift in TweetNER7, we conducted an analysis over the self-labeled tweets. Inspired by recent semi-parametric approach in information retrieval (Lewis et al., 2021), we considered a retrieval module that fetches relevant tweets given a target entity from the self-labeled corpus and see the portion of retrieved tweets containing the true prediction. To be precise, we first ran the NER model prediction on target tweets, and for each of the predicted entities. Then, we queried tweets from the extra tweet corpus used in Subsection 4.3 to compute the ratio of correct predictions within the retrieved predictions, which we call contextualized predictions. Since we are interested in the error of the original prediction, we focus only on the entities where the original prediction is incorrect.

Figure 3 describes the whole pipeline and we use Whoosh library[6] for search engine where the query is always the entity name, constraining the search result by the number of days from the query tweet.[7] Similarly to the analysis in § 4.3, we used the RoBERTa$_{\text{LARGE}}$ fine-tuned on the 2020-set of TweetNER7 and evaluated the contextualized predictions on the 2021 test set.

Figure 3: Overview of the pipeline to retrieve contextualized prediction.

Figure 4 shows the ratio of positive and negative predictions in the contextualized tweets. These are further broken into two error types whether it is the same prediction as the original prediction or not, along with the days we set as a search constraint. Most frequent predictions are usually the same as the original predictions, which means that the original language model tends to output similar predictions for the same entities, irrespective of the context. As far as the time variable is concerned, the ratio is almost consistent over time, which suggests that the possible original bias of the model does not change over time. Nonetheless, the second most frequent predictions are on average the correct ones, with a large gap with respect to other types of error. This implies there may still be a useful signal to improve the original prediction in the self-labeled corpus.

5 Conclusion

In this paper, we have constructed TweetNER7, a new NER dataset for Twitter, in which we annotated 11,382 tweets with seven entity types. The collected tweets are distributed uniformly over time from September 2019 to August 2021, which facil-

[5] While in our setting we extract a larger number of tweets, this trend does not change with less self-labeled training data.

[7] Setting days as 7 means the search results should be in the range of 7 days before/after was made.

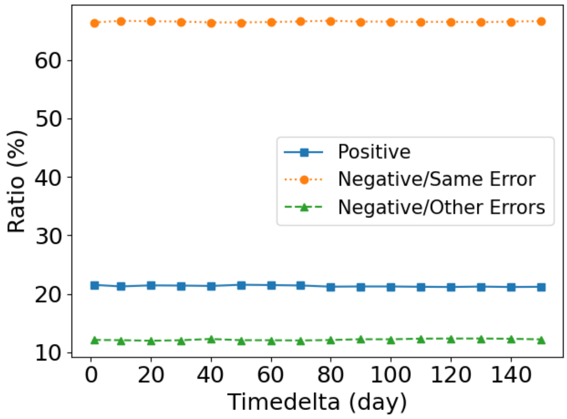

Figure 4: Ratio of positive and negative predictions in the contextualized tweets, split into two error types: same prediction as the original prediction or not. The X-axis represents the days from the original tweet (0=same date as the original tweet) and results are broken on 20-day chunks..

itates temporal analysis in NER for social media. The dataset is diverse topic-wise, as we leveraged weekly trending topics to query tweets and near-duplicated and irrelevant tweets were dropped. To establish baselines on TweetNER7, we fine-tuned standard LMs including a few Twitter-specific LMs. Moreover, we performed a few targeted temporal-related analyses in order to better understand the short-term temporal effect. Finally, we show that self-labeling is not enough to mitigate the temporal-shift and had no noticeable improvement over the baseline vanilla fine-tuning, which further highlights the challenging nature of the dataset.

6 Limitations and Future Work

The TweetNER7 dataset was constructed on English tweets so it is limited to English, as most of the existing NER datasets for social media (Derczynski et al., 2016). In the future we are planning to apply a similar methodology to extend it to languages other than English. Given the dynamic nature of social media, TweetNER7 is designed to study short-term temporal-shift (e.g., monthly) but would not be suitable for analysing longer temporal shifts (e.g., yearly) (Rijhwani and Preotiuc-Pietro, 2020). We selected Twitter as the data source but temporal-shift is a common problem in social media generally. As a future work, we are planning to add more data from other social media platforms as in WNUT17 (Derczynski et al., 2017) to give us more general insights to understand temporal shift phenomena in social media more generally.

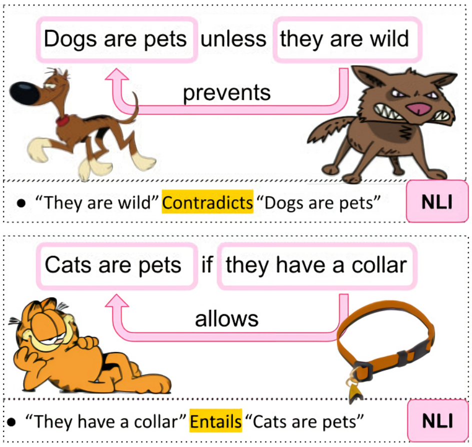
Abstract

Reasoning with preconditions such as "glass can be used for drinking water unless the glass is shattered" remains an open problem for language models. The main challenge lies in the scarcity of preconditions data and model's lack of support for such reasoning. We present *PInKS* 🌸 , Preconditioned Commonsense Inference with WeaK Supervision, an improved model for reasoning with preconditions through minimum supervision. We show, both empirically and theoretically, that *PInKS* improves the results on benchmarks focused on reasoning with the preconditions of commonsense knowledge (up to 40% Macro-F1 scores). We further investigate *PInKS* through PAC-Bayesian informativeness analysis, precision measures, and ablation study.[1]

1 Introduction

Inferring the effect of a situation or precondition on a subsequent action or state (illustrated in Fig. 1) is an open part of commonsense reasoning. It requires an agent to possess and understand different dimensions of commonsense knowledge (Woodward, 2011), e.g. physical, causal, social, etc. This ability can improve many knowledge-driven tasks such as question answering (Wang et al., 2019; Talmor et al., 2019), machine reading comprehension (Sakaguchi et al., 2020), and narrative prediction (Mostafazadeh et al., 2016). It also seeks to benefit a wide range of real-world intelligent applications such as legal document processing (Hage, 2005), claim verification (Nie et al., 2019), and debate processing (Widmoser et al., 2021).

Multiple recent studies have taken the effort on reasoning with preconditions of commonsense knowledge (Rudinger et al., 2020; Qasemi et al., 2022; Mostafazadeh et al., 2020; Hwang et al., 2020). These studies show that preconditioned reasoning represents an unresolved challenge to state-of-the-art (SOTA) language model (LM) based reasoners. Generally speaking, the problem of reasoning with preconditions has been formulated as variations of the natural language inference (NLI) task where, given a precondition/update, the model has to decide its effect on a common sense statement or chain of statements. For example, *PaCo* (Qasemi et al., 2022) approaches the task from the causal (hard reasoning) perspective in term of *enabling* and *disabling* preconditions of commonsense knowledge, and evaluate reasoners with crowdsourced commonsense statements about the two polarities of preconditions of statements in ConceptNet (Speer et al., 2017). Similarly, $\delta-$NLI (Rudinger et al., 2020) formulates the problem from soft assumptions' perspective, i.e., *weakeners* and *strengtheners*, and justifies whether the *update* sentence *weakens* or *strengthens* the textual entailment in sentence pairs from sources such as SNLI (Bowman et al., 2015). Obviously, both tasks capture the same phenomena of reasoning with preconditions and the slight difference in format does not hinder their usefulness (Gardner et al., 2019). As both works conclude, SOTA models generally fall short of tackling these tasks.



Dogs are pets
unless
they are wild
prevents
• "They are wild" Contradicts "Dogs are pets"
NLI
Cats are pets
if
they have a collar
allows
• "They have a collar" Entails "Cats are pets"
NLI

of LMs on reasoning with preconditions: 1) relying on expensive direct supervision and 2) the need for improved LMs to reason with such knowledge. First, current resources for preconditions of common sense are manually annotated. Although this yields high-quality direct supervision, it is costly and not scalable. Second, off-the-shelf LMs are trained on free-text corpora with no direct guidance on specific tasks. Although such models can be further fine-tuned to achieve impressive performance on a wide range of tasks, they are far from perfect in reasoning on preconditions due to their complexity of need for deep commonsense understanding and lack of large-scale training data.

In this work, we present *PInKS* (see Fig. 2), a minimally supervised approach for reasoning with the precondition of commonsense knowledge in LMs. The main contributions are 3 points. **First**, to enhance training of the reasoning model (§3), we propose two strategies of retrieving rich amount of cheap supervision signals (Fig. 1). In the first strategy (§3.1), we use common linguistic patterns (e.g. "[action] unless [precondition]") to gather sentences describing preconditions and actions associated with them from massive free-text corpora (e.g. OMCS (Havasi et al., 2010)). The second strategy (§3.2) then uses generative data augmentation methods on top of the extracted sentences to induce even more training instances. As the **second** contribution (§3.3), we improve LMs with more targeted preconditioned commonsense inference. We modify the masked language model (MLM) learning objective to biased masking, which puts more emphasis on preconditions, hence improving the LMs capability to reason with preconditions. Finally, for **third** contribution, we go beyond empirical analysis of *PInKS* and investigate the performance and robustness through theoretical guarantees of PAC-Bayesian analysis (He et al., 2021).

Through extensive evaluation on five representative datasets (ATOMIC2020 (Hwang et al., 2020), WINOVENTI (Do and Pavlick, 2021), ANION (Jiang et al., 2021), *PaCo* (Qasemi et al., 2022) and DNLI (Rudinger et al., 2020)), we show that *PInKS* improves the performance of NLI models, up to 5% Macro-F1 without seeing any task-specific training data and up to 40% Macro-F1 after being incorporated into them (§4.1). In addition to the empirical results, using theoretical guarantees of informativeness measure in *PABI* (He et al., 2021), we show that the minimally supervised data of *PInKS* is as informative as fully supervised datasets (§4.2). Finally, to investigate the robustness of *PInKS* and effect of each component, we focus on the weak supervision part (§5). We perform ablation study of *PInKS* w.r.t. the linguistic patterns themselves, the recall value associated with linguistic patterns, and finally contribution of each section to overall quality and the final performance.

2 Problem Definition

Common sense statements describe well-known information about concepts, and, as such, they are acceptable by people without need for debate (Sap et al., 2019; Davis and Marcus, 2015). The preconditions of common sense knowledge are eventualities that affect happening of a common sense statement (Hobbs, 2005). These preconditions can either *allow* or *prevent* the common sense statement in different degrees (Rudinger et al., 2020; Qasemi et al., 2022). For example, Qasemi et al. (2022) model the preconditions as *enabling* and *disabling* (hard preconditions), whereas Rudinger et al. (2020) model them as *strengthening* and *weakening*(soft preconditions). Beyond the definition of preconditions, the task of inference with preconditions is also defined differently among the literature. Some task definitions have strict constraints on the format of statement, e.g. two sentence format (Rudinger et al., 2020) or being human-related (Sap et al., 2019), whereas others do not (Do and Pavlick, 2021; Qasemi et al., 2022).

To unify the definitions in available literature, we define the preconditioned inference task as below:

Definition 1 ***Preconditioned Inference:*** *given a common sense statement and an update sentence that serves as precondition, is the statement still allowed or prevented?*

This definition is consistent with definitions in the literature (for more details see appx. §G). First, similar to the definition by Rudinger et al. (2020), the update can have different levels of effect on the statement, from causal connection (hard) to material implication (soft). Second, similar to the one Qasemi et al. (2022), the statement can have any format.

3 Preconditioned Inference with Minimal Supervision

In *PInKS*, to overcome the challenges associated with inference with preconditions, we propose two

sources of weak supervision to enhance the training of a reasoner: linguistic patterns to gather rich (but allowably noisy) preconditions (§3.1), and generative augmentation of the preconditions data (§3.2). The main hypothesis in using weak-supervision methods is that pretraining models on large amount of weak-supervised labeled data could improve model's performance on similar downstream tasks (Ratner et al., 2017). In weak supervision terminology for heuristics, the experts design a set of heuristic labeling functions (LFs) that serves as the generators of the noisy label (Ratner et al., 2017). These labeling functions can produce overlapping or conflicting labels for a single instance of data that will need to be resolved either with simple methods such as ensemble inference or more sophisticated probabilistic methods such as data programming (Ratner et al., 2016), or generative (Bach et al., 2017). Here, the expert still needs to design the heuristics to query the knowledge and convert the results to appropriate labels for the task. In addition, we propose the modified language modeling objective that uses biased masking to improve the precondition-reasoning capabilities of LMs (§3.3).

3.1 Weak Supervision with Linguistic Patterns

We curate a large-scale automatically labeled dataset for, both type of, preconditions of commonsense statements by defining a set of linguistic patterns and searching through raw corpora. Finally, we have a post-processing filtering step to ensure the quality of the extracted preconditions.

Raw Text Corpora: In our experiments, we acquire weak supervision from two corpora: Open Mind Common Sense (OMCS) (Singh et al., 2002) and ASCENT (Nguyen et al., 2021a). OMCS is a large commonsense statement corpus that contains over 1M sentences from over 15,000 contributors. ASCENT has consolidated over 8.9M commonsense statements from the Web.

First, we use sentence tokenization in NLTK (Bird et al., 2009) to separate individual sentences in the raw text. Each sentence is then considered as an individual statement to be fed into the labeling functions. We further filter out the data instances based on the conjunctions used in the common sense statements after processing the labeling functions (discussed in Post-Processing paragraph).

Labeling Functions (LF): We design the LFs required for weak-supervision with a focus on the presence of a linguistic pattern in the sentences based on a conjunction (see Tab. 1 for examples). In this setup, each LF labels the training data as *Allowing*, *Preventing* or *Abstaining* (no label assigned) depending on the linguistic pattern it is based on. For example, as shown in Tab. 1 the presence of conjunctions *only if* and *if*, with a specific pattern, suggests that the precondition *Allows* the action. Similarly, the presence of the conjunction *unless* indicates a *Preventing* precondition. We designed 20 such LFs based on individual conjunctions through manual inspection of the collected data in several iterations, for which details are described in appx. §A.1.

Text	Label	Action	Precondition
A drum makes noise only if you beat it.	Allow	A drum makes noise	you beat it.
Your feet might come into contact with something if it is on the floor.	Allow	Your feet might come into contact with something	it is on the floor.
Pears will rot if not refrigerated	Prevent	Pears will rot	refrigerated
Swimming pools have cold water in the winter unless they are heated.	Prevent	Swimming pools have cold water in the winter	they are heated.

Table 1: Examples from the collected dataset through linguistic patterns in §3.1.

Extracting Action-Precondition Pairs Once the sentence have an assigned label, we extract the *action-precondition* pairs using the same linguistic patterns. This extraction can be achieved by leveraging the fact that a conjunction divides a sentence into *action* and *precondition* in the following pattern "*precondition conjunction action*", as shown in Tab. 1.

However, there could be sentences that contain multiple conjunctions. For instance, the sentence "Trees continue to grow for all their lives except in winter if they are not evergreen." includes two conjunctions "except" and "if". Such co-occurring conjunctions in a sentence leads to ambiguity in the extraction process. To overcome this challenge, we further make selection on the patterns by measuring their precisions[2]. To do so, we sample 20 random sentences from each conjunction (400 total) and label them manually on whether they are relevant to our task or not by two expert annotators. If a sentence is relevant to the task, it is labeled as 1; otherwise, 0. We then average the scores of two annotators for each pattern/conjunction to get its precision score. This precision score serves as an indicator of the quality of preconditions extracted by the pattern/conjunction in the context of our problem statement. Hence, priority is given to a conjunction with a higher precision in case of ambiguity. Further, we also set a minimum precision threshold (=0.7) to filter out the conjunctions having a low precision score (8 LFs), indicating low relevance to the task of reasoning with preconditions (see Appx. §A.1 for list of precision values).

Post-Processing On manual inspection of sentences matched by the patterns, we observed a few instances from random samples that were not relevant to the context of commonsense reasoning tasks, for example: *How do I know if he is sick?* or, *Pianos are large but entertaining*. We accordingly filter out sentences that are likely to be irrelevant instances. Specifically, those include 1) questions which are identified based on presence of question mark and interrogative words (List of interrogative words in Appx. §A.4), or 2) do not have a verb in their precondition. Through this process we end up with a total of 113,395 labeled action-precondition pairs with 102,474 *Allow* and 10,921 *Prevent* assertions.

3.2 Generative Data Augmentation

To further augment and diversify training data, we leverage another technique of retrieving weak supervision signals by probing LMs for generative data augmentation. To do so, we mask the nouns and adjectives (pivot-words) from the text and let the generative language model fill in the masks with appropriate alternatives.

After masking the pivot-word and filling in the mask using the LM, we filter out the augmentations that change the POS tag of the pivot-word and then keep the top 3 predictions for each mask. In addition, to keep the diversity of the augmented data, we do not use more than 20 augmented sentences for each original statement (picked randomly). For example, in the statement "Dogs are pets unless they are wild", the pivot-words are "dogs", "pets" and "wild". Upon masking "dogs", using RoBERTa (large) language model, we get valid augmentations such as "Cats are pets unless they are wild". Using this generative data augmentation, we end up with $7M$ labeled action-precondition pair with 11% *prevent* preconditions.

3.3 Precondition-Aware Biased Masking

To increase the LM's attention on preconditions, we used biased masking on conjunctions as the closest proxies to preconditions' reasoning. Based on this observation, we devised a biased masked language modeling loss that solely focuses on masking conjunctions in the sentences instead of random tokens. Similar to Dai et al. (2019), we mask the whole conjunction word in the sentence and ask the LM to fulfill the mask. The goal here is to start from a pretrained language model and,

[2] The amounts of labeled instances (*non-abstaining*) for each labeling function are relevant

through this additional fine-tuning step, improve its ability to reason with preconditions. To use such fine-tuned LM in a NLI module, we further fine-tune the "LM+classification head" on subset of MNLI (Williams et al., 2018) dataset. For full list of conjunctions and implementation details check Appx. §A.3.

4 Experiments

This section first showcases improvements of *PInKS* on five representative tasks for preconditioned inference (§4.1). We then theoretically justify the improvements by measuring the informativeness of weak supervision by *PInKS* using *PABI* (He et al., 2021) score and then experiment on the effect of precision (discussed in §3.1) on *PInKS* using *PABI* score (§4.2). Additional analysis on various training strategies of *PInKS* is also provided in Appx. §C.

4.1 Main Results

Comparing the capability for models to reason with preconditions across different tasks requires canonicalizing the inputs and outputs in such tasks be in the same format. We used natural language inference (NLI) as such a canonical format. *PaCo* (Qasemi et al., 2022) and δ-NLI (Rudinger et al., 2020) are already formulated as NLI and others can be converted easily using the groundwork laid by Qasemi et al. (2022). In NLI, given a sentence pair with a *hypothesis* and a *premise*, one predicts whether the hypothesis is true (entailment), false (contradiction), or undetermined (neutral) given the premise (Williams et al., 2018). Each task is preserved with equivalence before and after any format conversion at here, hence conversion does not seek to affect the task performance, inasmuch as it is discussed by Gardner et al. (2019). More details on this conversion process are in Appx. §B, and examples from the original target datasets are given in Tab. 8.

Setup To implement and execute labeling functions, and resolve labeling conflict, we use Snorkel (Ratner et al., 2017), one of the SOTA frameworks for algorithmic labeling on raw data that provides ease-of-use APIs.[3] For more details on Snorkel and its setup details, please see Appendix A.2.

For each target task, we start from a pretrained NLI model (RoBERTa-Large-MNLI (Liu et al., 2019)), fine-tune it according to *PInKS* (as discussed in §3) and evaluate its performance on the test portion of the target dataset in two setups: zero-shot transfer learning without using the training data for the target task (labeled as *PInKS* column) and fine-tuned on the training portion of the target task (labeled as *Orig.+PInKS*). To facilitate comparison, we also provide the results for fully fine-tuning on the training portion of the target task and evaluating on its testing portion (labeled as *Orig.* column; *PInKS* is not used here). To create the test set, if the original data does not provide a split (e.g. *ATOMIC* and *Winoventi*), following Qasemi et al. (2022), we use unified random sampling with the $[0.45, 0.15, 0.40]$ ratio for train/dev/test. The experiments are conducted on a commodity workstation with an Intel Xeon Gold 5217 CPU and an NVIDIA RTX 8000 GPU. For all the tasks, we used the pretrained model from *huggingface* (Wolf et al., 2020), and utilized PyTorch Lightning (Falcon and The PyTorch Lightning team, 2019) library to manage the fine-tuning process. We evaluate each performance by aggregating the *Macro-F1* score (implemented in Pedregosa et al. (2011)) on the ground-truth labels and report the results on the unseen test split of the data.

Target Task	Orig.	*PInKS*	Orig+*PInKS*
δ-*NLI*	83.4	60.3	**84.1**
PaCo	77.1	69.5	**79.4**
ANION	81.1	52.9	**81.2**
ATOMIC	43.2	**48.0**	**88.6**
Winoventi	51.1	**52.4**	**51.3**

Table 2: Macro-F1 (%) results of *PInKS* on the target datasets: no *PInKS* (*Orig.*), with *PInKS* in zero-shot transfer learning setup (*PInKS*) and *PInKS* in addition to original task's data (*Orig.+PInKS*). **Bold** values are cases where *PInKS* is improving supervised results.

Discussion Table 2 presents the evaluation results of this section. As illustrated, on *ATOMIC* (Hwang et al., 2020) and *Winoventi* (Do and Pavlick, 2021), *PInKS* exceeds the supervised results even without seeing any examples from the target data (zero-shot transfer learning setup). On δ-*NLI* (Rudinger et al., 2020), *ANION* (Jiang et al., 2021) and *ATOMIC* (Hwang et al., 2020), combination of *PInKS* and train subset of target task (*PInKS* in low-resource setup) outperforms the target task results. This shows *PInKS* can also utilize

[3] Other alternatives such as skweak (Lison et al., 2021) can also be used for this process.

additional data from target task to achieve better performance consistently across different aspects of preconditioned inference.

4.2 Informativeness Evaluation

He et al. (2021) proposed a unified PAC-Bayesian motivated informativeness measure, namely *PABI*, that correlates with the improvement provided by the incidental signals to indicate their effectiveness on a target task. The incidental signal can include an inductive signal, e.g. partial/noisy labeled data, or a transductive signal, e.g. cross-domain signal in transfer learning.

In this experiment, we go beyond the empirical results and use the *PABI* measure to explain how improvements from *PInKS* are theoretically justified. Here, we use the *PABI* score for cross-domain signal assuming the weak supervised data portion of *PInKS* (§3.1 and §3.2) as a indirect signal for a given target task. We use *PABI* measurements from two perspective. First, we examine how useful is the weak supervised data portion of *PInKS* for target tasks in comparison with fully-supervised data. And second, we examine how the precision of the linguistic patterns (discussed in §3.1) affects this usefulness.

Setup We carry over the setup on models and tasks from §4.1. For details on the *PABI* itself and the measurement details associated with it, please see Appx. §E. For the aforementioned first perspective, we only consider *PaCo* and δ-NLI as target tasks, as they are the two main learning resources specifically focused on preconditioned inference (as defined in Section 2), which is not the case for others. We measure the *PABI* of the weak supervised data portion of *PInKS* on the two target tasks, and compare it with the *PABI* of the fully-supervised data from §4.1. For the second perspective, we only focus on *PInKS* and consider *PaCo* as target task. We create different versions of the weak supervised data portion of *PInKS* with different levels of precision threshold (e.g. 0.0, 0.5) and compare their informativeness on *PaCo*. To limit the computation time, we only use $100K$ samples from the weak supervised data portion of *PInKS* in each threshold value, which is especially important in lower thresholds due to huge size of extracted patterns with low precision threshold.

Informativeness in Comparison with Direct Supervision: Tab. 3 summarizes the *PABI* informativeness measure in comparison with other datasets with respect to *PaCo* (Qasemi et al., 2022) and δ-NLI (Rudinger et al., 2020). To facilitate the comparison of *PABI* scores in Tab. 3, we have also reported the minimum achievable ("zero rate" classifier) and maximum achievable *PABI* scores. To clarify, to compute the maximum achievable *PABI* score, we consider the training subset of the target task as an indirect signal for the test subset. Here, we assume that the training subset is in practice the most informative indirect signal available for the test subset of any task. For the minimum achievable *PABI* score, we considered the error rate of the "zero rate" classifier (always classifies to the largest class) for computations of *PABI*.

Indir. Task	***PABI* on** *PaCo*	δ-NLI	Explanation
PInKS	52.2	*66.7*	- Best on δ-NLI
δ-NLI	*52.3*	**85.5**	- Max achievable on δ-NLI - Best on *PaCo*
PaCo	**52.3**	31.3	- Max achievable on *PaCo*
ANION	34.1	13.9	
ATOMIC	20.9	17.4	
Winoventi	36.4	53.4	
Zero Rate	26.2	0.0	- Baseline

Table 3: *PABI* informativeness measures (x100) of *PInKS* and other target tasks w.r.t *PaCo* and δ-NLI. **Bold** values represent the maximum achievable *PABI* Score by considering train subset as an *indirect* signal for test subset of respective data. The highest *PABI* score, excluding the max achievable, is indicated in *italic*.

Our results show that although, *PInKS* is the top informative incidental signal in δ-NLI target task and second best in *PaCo* (less than 0.001 point of difference with the best signal). This *PABI* numbers are even more significant considering that *PInKS* is the only weak-supervision data which is automatically acquired, while others are acquired through sometimes multiple rounds of human annotations and verification.

Effect of Precision on Informativeness: Fig. 3 presents the *PABI* informativeness estimation on weak supervision data under different threshold levels of precision values, and compare them with the "zero rate" classifier (always predicting majority class). As illustrated, the informativeness show a significant drop in lower precision showcasing the importance of using high precision templates in our weak-supervision task. For higher thresholds (0.95) the data will mostly consist of *allow* patterns, the model drops to near zero rate informativeness baseline again. This susceptibility on pattern precision

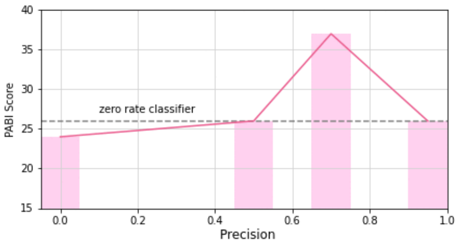

Figure 3: *PABI* informativeness measures of *PInKS* with different precision thresholds on *PaCo*.

can be mitigated with having more fine-grained patterns on larger corpora. We leave further analysis on precision of patterns to future work.

5 Analysis on Weak Supervision

In this section, we shift focus from external evaluation of *PInKS* on target tasks to analyze distinct technical component of *PInKS*. Here, through an ablation study, we try to answer four main questions to get more insight on the weak supervision provided by those components. First (Q1), how each labeling function (LF; §3.1) is contributing to the extracted preconditions? Second (Q2), what is the quality of the weak supervision data obtained from different ways of data acquisition? Third (Q3), how does generative data augmentation (§3.2) contribute to *PInKS*? And finally (Q4), how much does the precondition-aware masking (§3.3) affect the overall performance of *PInKS*?

(Q1) LF Analysis: To address the first question, we use statistics of the 6 top performing LFs (see Appx. §F for detailed results). These 6 top performing LFs generate more than 80% of data (Coverage) with the highest one generating 59% of data and lowest one generating 1%. Our results show that, in 0.14% of instances we have conflict among competing LFs with different labels and in 0.12% we have overlap among LFs with similar labels, which showcases the level of independence each LF has on individual samples.[4]

(Q2) Quality Control: To assess the quality of collected data, we used an expert annotator. The expert annotator is given a subset of the collected preconditions (preconditions-statement-label triplet) and asked to assign a binary label based on whether each the precondition is valid to its statement w.r.t the associated label. We then report the average quality score as a proxy for *precision* of data. We sampled 100 preconditions-statement-label triplets from three checkpoint in the pipeline: 1) extracted through linguistic patterns discussed in §3.1, 2) outcome of the generative augmentations discussed in §3.2, and 3) final data used in §3.3. Table Tab. 4 contains the average precision of the collected data, that shows the data has acceptable quality with minor variance in quality for different weak supervised steps in *PInKS*.

Checkpoint Name	Precision. %
Linguistic Patterns from §3.1	78
Generative Augmentation from §3.2	76
Final Data used in §3.3	76

Table 4: Precision of the sampled preconditions-statement-label triplets from three checkpoints in pipeline.

(Q3) Effectiveness of Generative Augmentation: The main effect of generative data augmentation (§3.2) is, among others, to acquire *PInKS* additional training samples labeled as *prevent* from pretrained LMs. When considering *PaCo* as target task, the *PInKS* that does not use this technique (no-augment-*PInKS*) sees a 4.14% absolute drop in Macro-F1 score. Upon further analysis of the two configurations, we observed that the no-augment-*PInKS* leans more toward the zero rate classifier (only predicting *allow* as the majority class) in comparison to the *PInKS*.

(Q4) Effectiveness of Biased Masking: We focus on *PaCo* as the target task and compare the results of *PInKS* with an alternative setup with no biased masking. In the alternative setup, we only use the weak-supervision data obtained through *PInKS* to fine-tune the model and compare the results. Our results show that the Macro-F1 score for zero-shot transfer learning setup has a 1.09% absolute drop in Macro-F1 score, without the biased masking process.

6 Related Work

Reasoning with Preconditions Collecting preconditions of common sense and reasoning with them has been studied in multiple works. Rudinger et al. (2020) uses the notion of "defeasible inference" (Pollock, 1987; Levesque, 1990) in term of how an *update* sentence *weakens* or *strengthens* a common sense hypothesis-premise pair. For example, given the premise "Two men and a dog are standing among rolling green hills.", the *update* "The men are studying a tour map" weakens

[4] Convectional inner-annotator agreement (IAA) methods hence are not applicable.

the hypothesis that "they are farmers", whereas "The dog is a sheep dog" strengthens it. Similarly, *PaCo* (Qasemi et al., 2022) uses the notion of "causal complex" from Hobbs (2005), and defines preconditions as eventualities that either *allow* or *prevent* (allow negation (Fikes and Nilsson, 1971) of) a common sense statement to happen. For example, for the knowledge "the glass is shattered" prevents the statement "A glass is used for drinking water", whereas "there is gravity" allows it. In *PaCo*, based on Shoham (1990) and Hobbs (2005), authors distinguish between two type of preconditions, causal connections (*hard*), and material implication (tends to cause; *soft*). Our definition covers these definitions and is consistent with both.

Hwang et al. (2020), Sap et al. (2019), Heindorf et al. (2020), and Speer et al. (2017), provided representations for preconditions of statements in term of relation types, e.g. *xNeed* in ATOMIC2020 (Hwang et al., 2020). However, the focus in none of these works is on evaluating SOTA models on such data. The closest study of preconditions to our work are Rudinger et al. (2020), Qasemi et al. (2022), Do and Pavlick (2021) and Jiang et al. (2021). In these works, direct human supervision (crowdsourcing) is used to gather preconditions of commonsense knowledge. They all show the shortcomings of SOTA models on dealing with such knowledge. Our work differs as we rely on combination of distant-supervision and targeted fine-tuning instead of direct supervision to achieve on-par performance. Similarly, Mostafazadeh et al. (2020), and Kwon et al. (2020) also study the problem of reasoning with preconditions. However they do not explore *preventing* preconditions.

Weak Supervision In weak-supervision, the objective is similar to supervised learning. However instead of using human/expert resource to directly annotate unlabeled data, one can use the experts to design user-defined patterns to infer "noisy" or "imperfect" labels (Rekatsinas et al., 2017; Zhang et al., 2017; Dehghani et al., 2017; Singh et al., 2022), e.g. using heuristic rules. In addition, other methods such as re-purposing of external knowledge (Alfonseca et al., 2012; Bunescu and Mooney, 2007; Mintz et al., 2009) or other types of domain knowledge (Stewart and Ermon, 2017) also lie in the same category. Weak supervision has been used extensively in NLU. For instance, Zhou et al. (2020) utilize weak-supervision to extract temporal commonsense data from raw text, Brahman et al. (2020) use it to generate reasoning rationale, Dehghani et al. (2017) use it for improved neural ranking models, and Hedderich et al. (2020) use it to improve translation in African languages. Similar to our work, ASER (Zhang et al., 2020) and ASCENT (Nguyen et al., 2021b) use weak supervision to extract relations from unstructured text. However, do not explore preconditions and cannot express *preventing* preconditions. As they do focus on reasoning evaluation, the extent in which their contextual edges express *allowing* preconditions is unclear.

Generative Data Augmentation Language models can be viewed as knowledge bases that implicitly store vast knowledge on the world. Hence querying them as a source of weak-supervision is a viable approach. Similar to our work, Wang et al. (2021) use LM-based augmentation for saliency of data in tables, Meng et al. (2021) use it as a source of weak-supervision in named entity recognition, and Dai et al. (2021) use masked LMs for weak supervision in entity typing.

7 Conclusion

In this work we presented *PInKS* 🌸, as an improved method for preconditioned commonsense reasoning which involves two techniques of weak supervision. To maximize the effect of the weak supervision data, we modified the masked language modeling loss function using biased masking method to put more emphasis on conjunctions as closest proxy to preconditions. Through empirical and theoretical analysis of *PInKS*, we show it significantly improves the results across the benchmarks on reasoning with the preconditions of commonsense knowledge. In addition, we show the results are robust in different precision values using the *PABI* informativeness measure and extensive ablation study.

Future work can consider improving the robustness of preconditioned inference models using methods such as virtual adversarial training (Miyato et al., 2018; Li and Qiu, 2020). With advent of visual-language models such as Li et al. (2019), preconditioned inference should also expand beyond language and include different modalities (such as image or audio). To integrate in down-steam tasks, one direction is to include such models in aiding inference in the neuro-symbolic reasoners (Lin et al., 2019; Verga et al., 2020).

Ethical Consideration

We started from openly available data that is both crowdsource-contributed and neutralized, however they still may reflect human biases. For example in case of *PaCo* (Qasemi et al., 2022) they use ConceptNet as source of commonsense statements which multiple studies have shown its bias and ethical issues, e.g. (Mehrabi et al., 2021).

During design of labeling functions we did not collect any sensitive information and the corpora we used were both publicly available, however they may contain various types of bias. The labeling functions in *PInKS* are only limited to English language patterns, which may inject additional cultural bias to the data. However, our expert annotators did not notice any offensive language in data or the extracted preconditions. Given the urgency of addressing climate change we have reported the detailed model sizes and runtime associated with all the experiments in Appendix D.

Limitations

The main limitation of this work are related to the choice of raw text corpora and the model for main results. From the raw text corpora perspective, we relied on Open Mind Common Sense (OMCS) (Singh et al., 2002) and ASCENT (Nguyen et al., 2021a) as two rich resource of commonsense knowledge. Future iterations of this work should include more fine-grained labeling functions to be applied to other large scale corpora that results in more diverse set of extracted preconditions.

The purpose of the experiments in this work is to show the effectiveness of *PInKS* in preconditioned inference without introducing any expensive (manually labeled) supervision. We chose RoBERTa-Large-MNLI (Liu et al., 2019) as a representative and strong model that has been widely applied to NLI tasks, including all those evaluated in this work. However, there are more models, e.g. unified-QA-11B for *PaCo* or DeBERTa for δ-NLI, that can be considered for each one of the target tasks. Of course achieving the SOTA with these much larger models requires a lot of computational resources, which is beyond the scope and bandwidth of this study. But, given more resources we would easily extend analysis to other models as well.

Acknowledgement

We like to thank Hangfeng He, for his insightful comments to using the *PABI* (He et al., 2021) measure in our paper. We also want to thank our anonymous reviewers whose comments/suggestions helped improve and clarify this paper.

A Details on *PInKS* Method

In this section, we discuss some of the extra details related to *PInKS* and its implementation.

A.1 Linguistic Patterns for *PInKS*

We use a set of conjunctions to extract sentences that follow the action-precondition sentence structure. Initially, we started with two simple conjunctions-*if* and *unless*, for extracting assertions containing *Allowing* and *Preventing* preconditions, respectively. To further include similar sentences, we expanded our vocabulary by considering the synonyms of our initial conjunctions. Adding the synonyms of *unless* we got the following set of new conjunctions for *Preventing* preconditions-{*but, except, except for, if not, lest, unless*}, similarly we expanded the conjunctions for Enabling preconditions using the synonyms of *if*-{*contingent upon, in case, in the case that, in the event, on condition, on the assumption, supposing*}. Moreover, on manual inspection of the OMCS and ASCENT datasets, we found the following conjunctions that follow the Enabling precondition sentence pattern-{*makes possible, statement is true, to understand event*}. Tab. 5, summarizes the final patterns used in *PInKS*, coupled with their precision value and their associated conjunction.

A.2 Details of Snorkel Setup

Beyond a simple API to handle implementing patterns and applying them to the data, Snorkel's main purpose is to model and integrate noisy signals contributed by the labeling functions modeled as noisy, independent voters, which commit mistakes uncorrelated with other LFs.

To improve the predictive performance of the model, Snorkel additionally models statistical relationships between LFs. For instance, the model takes into account similar heuristics expressed by two LFs to avoid "double counting" of voters. Snorkel, further, models the generative learner as a factor graph. A labeling matrix Λ is constructed by applying the LFs to unlabeled data points. Here, $\Lambda_{i,j}$ indicates the label assigned by the j^{th} LF for the i^{th} data point. Using this information, the generative model is fed signals via three factor types, representing the labeling propensity, accuracy, and pairwise correlations of LFs.

$$\phi_{i,j}^{Lab}(\Lambda) = \mathbb{1}\{\Lambda_{i,j} \neq \emptyset\}$$
$$\phi_{i,j}^{Acc}(\Lambda) = \mathbb{1}\{\Lambda_{i,j} = y_i\}$$
$$\phi_{i,j,k}^{Corr}(\Lambda) = \mathbb{1}\{\Lambda_{i,j} = \Lambda_{i,k}\}$$

The above three factors are concatenated along with the potential correlations existing between the LFs and are further fed to a generative model which minimizes the negative log marginal likelihood given the observed label matrix Λ.

A.3 Modified Masked Language Modeling

Tab. 6 summarizes the list of *Allowing* and *Preventing* conjunctions which the modified language modeling loss function is acting upon.

A.4 Interrogative Words

On manual inspection of the dataset, we observed some sentences that were not relevant to the common sense reasoning task. Many of such instances were interrogative statements. We filter out such cases based on the presence of interrogative words in the beginning of a sentence. These interrogative words are listed below.

Interrogative words: ["Who", "What", "When", "Where", "Why", "How", "Is", "Can", "Does", "Do"]

B Details on Target Data Experiments

For converting Rudinger et al. (2020), similar to Qasemi et al. (2022), we concatenate the "Hypothesis" and "Premise" and consider then as NLI's hypothesis. We then use the "Update" sentence as NLI's premise. The labels are directly translated based on *Update* sentences's label, *weakener* to *prevent* and the *strengthener* to *allow*.

To convert the ATOMIC2020 (Hwang et al., 2020), similar to Qasemi et al. (2022), we focused on three relations *HinderedBy*, *Causes*, and *xNeed*. From these relations, edges with *HinderedBy* are converted as *prevent* and the rest are converted as *allow*.

Winoventi (Do and Pavlick, 2021), proposes Winograd-style ENTAILMENT schemas focusing on negation in common sense. To convert it to NLI style, we first separate the two sentences in the *masked_prompt* of each instance to form *hypothesis* and *premise*. We get two versions of *premise* by replacing the MASK token in *premise* with their *target* or *incorrect* tokens. For the labels the version with *target* token is considered as *allow* and the version with *incorrect* token as *prevent*.

ANION (Jiang et al., 2021), focuses on CONTRADICTION in general. We focus on their commonsense dCONTRADICTION subset as it is clean of lexical hints. Then we convert their crowd-

Conjunctions	**Precision**	**Pattern**
but	0.17	{action} but {negative_precondition}
contingent upon	0.6	{action} contingent upon {precondition}

statement is true	The statement "{event}" is true because {precondition}.
except	{action} except {precondition}
unless	{action} unless {precondition}
if not	{action} if not {precondition}

Table 7: Filtered Labeling Functions Patterns and their associated polarity.

sourced *original head* or *CONTRADICTION head* as hypothesis, and the lexicalized predicate and tail as the premise (e.g. *xIntent* to *PersonX intends to*). Finally the label depends on head is *allow* for *original head* and *prevent* for *CONTRADICTION head*. We also replace "PersonX" and "PersonY" with random human names (e.g. "ALice", "Bob").

Finally, for the *PaCo* (Qasemi et al., 2022), we used their proposed P-NLI task as a NLI-style task derived from their preconditions dataset. We converted their *Disabling* and *Enabling* labels to *prevent* and *allow* respectively.

Tab. 8 summarizes the conversion process through examples from the original data and the NLI task derived from each.

To run all the experiments, we fine-tune the models on tuning data for maximum of 5 epochs with option for early stopping available upon 5 evaluation cycles with less than $1e-3$ change on validation data. For optimizer, we use AdamW (Loshchilov and Hutter, 2019) with learning rate of 3e-6 and default hyperparamter for the rest.

C Curriculum vs. Multitask Learning

For results of §4.1, we considered the target task and *PInKS* as separate datasets, and fine-tuned model sequentially on them (curriculum learning;Pentina et al., 2015). We chose *curriculum* learning setup due to its simplicity in implementation, ease of fine-tuning process monitoring and hyperparameter setup. It would also allow us to monitor each task separately that increases interpretability of results.

However, in an alternative fine-tuning setup, one

Name	Original Data		Derived NLI	
Winoventi (Do and Pavlick, 2021)	**masked_prompt**:	Margaret smelled her bottle of maple syrup and it was sweet. The syrup is {MASK}.	**Hypothesis**:	Margaret smelled her bottle of maple syrup and it was sweet.
	target:	edible	**Premise**:	The syrup is edible/malodorous
	incorrect:	malodorous	**Label**:	ENTAILMENT/CONTRADICTION
ANION (Jiang et al., 2021)	**Orig_Head**:	PersonX expresses PersonX's delight.	**Hypothesis**:	Alice expresses Alice's delight/anger.
	Relation:	xEffect	**Premise**:	feel happy.
	Tail:	Alice feel happy	**Label**:	ENTAILMENT/CONTRADICTION
	Neg_Head:	PersonX expresses PersonX's anger.		
ATOMIC2020 (Hwang et al., 2020)	**Head**:	PersonX takes a long walk.	**Hypothesis**:	PersonX takes a long walk.
	Relation:	HinderedBy	**Premise**:	It is 10 degrees outside..
	Tail:	It is 10 degrees outside.	**Label**:	CONTRADICTION
δ-NLI (Rudinger et al., 2020)	**Hypothesis**:	PersonX takes a long walk.	**Hypothesis**:	PersonX takes a long walk.
	Premise:	HinderedBy	**Premise**:	It is 10 degrees outside..
	Update:	It is 10 degrees outside.	**Label**:	CONTRADICTION
	Label:	Weakener		
PaCo (Qasemi et al., 2022)	**Statement**:	A net is used for catching fish.	**Hypothesis**:	A net is used for catching fish.
	Precondition:	You are in a desert.	**Premise**:	You are in a desert.
	Label:	Disabling	**Label**:	CONTRADICTION

Table 8: Examples from target tasks in NLI format

can merge the two datasets into one and fine-tune the model on the aggregate dataset (multi-task learning;Caruana, 1997). Here, we investigate such alternative and its effect on the results of §4.1.

Setup We use the same setup as §4.1 for fine-tuning the model on *Orig.+PInKS*. Here instead of first creating *PInKS* and then fine-tuning it on the target task, we merge the weak-supervision data of *PInKS* with the training subset of the target task and then do fine-tuning on the aggregate dataset. To manage length of this section, we only consider *PaCo*, δ-NLI and Winoventi as the target dataset.

Target Data	Orig+*PInKS* (Multi-Task)	Diff.
δ-NLI	72.1	-11.00
PaCo	77.3	+6.8
Winoventi	51.7	+0.7

Table 9: Macro-F1 (x100) results of *PInKS* on the target datasets using *multi-task* fine-tuning strategy and its difference with *curriculum* strategy.

Discussion Tab. 9 summarizes the results for *multi-task* learning setup and its difference w.r.t to the results of the *curriculum* learning setup in Tab. 2. Using *multi-task* learning does not show the consistent result across tasks. We see significant performance loss on δ-NLI on one hand and major performance improvements on *PaCo* on the other. The Winoventi, however appears to not change as much in the new setup. We leave further analysis of *curriculum learning* to future work.

D Model Sizes and Run-times

All the experiments are conducted on a commodity workstation with an Intel Xeon Gold 5217 CPU and an NVIDIA RTX 8000 GPU. For all the fine-tuning results in Tab. 2, Tab. 3 we used "RoBERTa-Large-MNLI" with 356M tuneable parameters. To fine-tune the model in each experiment, we use Ray (Liaw et al., 2018) to handle hyperparameter tuning with 20 samples each. The hyperparameters that are being tuned fall into two main categories: 1) model hyperparameters such as "sequence length", "batch size", etc. and 2) data hyperparameters such as "precision threshold", "data size", etc.. The mean run-time for each sample on target datasets is 1hr 55mins. For the augmentation in *PInKS* dataset, we used "BERT" language model with $234M$ tuneable parameters. The mean run-time on the weak supervision data is 49hr that includes all three steps of data preprocessing, linguistic pattern matching, and generative data augmentation.

E Details on *PABI* Measurement

PABI provides an Informativeness measure that quantifies the reduction in uncertainty provided by incidental supervision signals. We use the *PABI* measure to study the impact of transductive cross-domain signals obtained from our weak-supervision approach.

Following (He et al., 2021), in order to calculate *PABI* $\hat{S}(\pi_0, \tilde{\pi}_0)$, we first find out η, the difference between a perfect system and a gold system in the target domain $\mathcal{D}$ that uses a label set $\mathcal{L}$ for a task, using Eq.1.

$$\begin{aligned}\eta &= \mathbb{E}_{x\sim P_{\mathcal{D}(x)}} 1(c(x) \neq \tilde{c}(x)) \\ &= \frac{(|\mathcal{L}|-1)(\eta_1-\eta_2)}{1-|\mathcal{L}|(1-\eta_1)}\end{aligned} \tag{1}$$

Here, $P_{\mathcal{D}(x)}$ indicates the marginal distribution of x under $\mathcal{D}$, $c(x)$ refers to gold system on gold signals, $\tilde{c}(x)$ is a perfect system on incidental signals, η_1 refers to the difference between the silver system and the perfect system in the source domain,

Indir. Task	$\|L\|$	η_1	η_2^{ATMC}	η_2^{PaCo}	$\eta_2^{\delta-NLI}$	η^{ATMC}	η^{PaCo}	$\eta^{\delta-NLI}$	$PABI^{ATMC}$	$PABI^{PaCo}$	$PABI^{\delta-NLI}$
PInKS	2	0.04	0.11	0.21	0.16	0.076	0.202	0.129	0.782	0.523	0.667
δ-NLI	2	0.13	0.22	0.28	0.16	0.122	0.203	0.046	0.683	0.522	0.855
PaCo	2	0.03	0.10	0.22	0.33	0.074	0.202	0.318	0.786	0.523	0.313
ATOMIC	2	0.01	0.57	0.62	0.60	0.608	0.622	0.602	0.184	0.209	0.174
ANION	2	0.16	0.57	0.36	0.44	0.571	0.302	0.418	0.122	0.341	0.139
Winoventi	2	0.19	0.10	0.37	0.31	0.139	0.289	0.196	0.647	0.364	0.534

Table 10: Details of *PABI* metric computations in §4.2 according to Equation (1)

$\acute{\eta}_1$ indicates difference between the silver system and the perfect system in the target domain, and η_2 is the difference between the silver system and the gold system in the target domain.

Using Eq.1, the informative measure supplied by the transductive signals $\hat{S}(\pi_0, \tilde{\pi}_0)$ can be calculated as follows:

$$\sqrt{1 - \frac{\eta \ln(|\mathcal{L}| - 1) - \eta \ln \eta - (1 - \eta) \ln(1 - \eta))}{\ln |\mathcal{L}|}}$$

Tab. 10 contains the details associated computation of *PABI* score as reported in §4.2.

F Details on LFs in *PInKS*

Tab. 11 shows Coverage (fraction of instances assigned the non-abstain label by the labeling function), Overlaps (fraction of instances with at least two non-abstain labels), and Conflicts (fraction of instances with conflicting and non-abstain labels) on top performing LFs in *PInKS*.

LF name	**Cov. %**	**Over. %**	**Conf. %**
to understand	59.03	0.03	0.03
statement is	10.58	0.03	0.03
except	4.84	0.02	0.01
unless	4.79	0.04	0.04
in case	1.46	0.01	0.00
if not	1.00	0.01	0.01
Overall	81.69	0.14	0.12

Table 11: Coverage (fraction of raw corpus instances assigned the non-abstain label by the labeling function), Overlaps (fraction of raw corpus instances with at least two non-abstain labels), and Conflicts (fraction of the raw corpus instances with conflicting (non-abstain) labels) on top performing LFs. Green and red color respectively represent LFs that assign *allow* and *prevent* labels.

G Details on Preconditioned Inference in the Literature

As mentioned in §2, existing literature does not have a consistent (unified) definitions from to aspects: 1) the definition of the preconditions, and 2) the definition of preconditioned inference.

First, existing literature define preconditions of common sense statements in different degrees of impact on the statement. For example, Qasemi et al. (2022) follows the notion of "causal complex" from Hobbs (2005), where for a common sense statement s preconditions of the statement $P_f(s)$ are defined as collection of eventualities (events or states) that results in s to happen. According to Qasemi et al. (2022), such eventualities can either *enable* ($p_f^+ \in P_f$) or *disable* ($p_f^- \in P_f$) the statement to happen. Also, Qasemi et al. (2022) uses Fikes and Nilsson (1971) to define *disable* as *enabl*ing the negation of the statement. On other hand, Rudinger et al. (2020) defines *strengthener* as updates that a human would find them to increase likelihood of a hypothesis, and the *weakener* as the one that humans would find them to decrease it. Here, the focus on human's opinion is stemmed from definition of common sense. In this work, given the focus on noisy labels derived from weak-supervision, we adopted the more relaxed definition from Rudinger et al. (2020) for preconditions of common sense statements.

Second, there is also inconsistencies in the definition of reasoning with the preconditions or preconditioned inference. Rudinger et al. (2020) has a strict structure. It defines the task w.r.t to effect of precondition on the relation of two sentences: hypothesis and premise; where a model has to find the type of the precondition based on whether it *strengthens* or *weakens* the relation between the two sentences. Differently, Qasemi et al. (2022) has a relaxed definition in which the model is to decide if the precondition either enables or *disables* the statement. Here the statement can have any format. Do and Pavlick (2021), Hwang et al. (2020), and Jiang et al. (2021), on the other hand, define only a generative task to evaluate the models. In this work, again we adopted the more relaxed definition from Qasemi et al. (2022) that imposes less constraint on weak-supervised data.

Cross-Lingual Open-Domain Question Answering with Answer Sentence Generation

Abstract

Open-Domain Generative Question Answering has achieved impressive performance in English by combining document-level retrieval with answer generation. These approaches, which we refer to as GENQA, can generate complete sentences, effectively answering both factoid and non-factoid questions. In this paper, we extend GENQA to the multilingual and cross-lingual settings. For this purpose, we first introduce GEN-TYDIQA, an extension of the TyDiQA dataset with well-formed and complete answers for Arabic, Bengali, English, Japanese, and Russian. Based on GEN-TYDIQA, we design a cross-lingual generative model that produces full-sentence answers by exploiting passages written in multiple languages, including languages different from the question. Our cross-lingual generative system outperforms answer sentence selection baselines for all 5 languages and monolingual generative pipelines for three out of five languages studied.

1 Introduction

Improving coverage of the world's languages is essential for retrieval-based Question Answering (QA) systems to provide a better experience for non-English speaking users. One promising direction for improving coverage is multilingual, multi-source, open-domain QA. Multilingual QA systems include diverse viewpoints by leveraging answers from multiple linguistic communities. Further, they can improve accuracy, as all facets necessary to answer a question are often unequally distributed across languages on the Internet (Valentim et al., 2021).

With the advance of large-scale language models, multilingual modeling has made impressive progress at performing complex NLP tasks without requiring explicitly translated data. Building on pre-trained language models (Devlin et al., 2019; Conneau et al., 2020; Xue et al., 2021; Liu et al., 2020), it is now possible to train models that accurately process textual data in multiple languages (Kondratyuk and Straka, 2019) and perform cross-lingual transfer (Pires et al., 2019) using annotated data in one language to process another language.

At the same time, answer generation-based approaches have been shown to be effective for many English QA tasks, including Machine Reading (MR) (Izacard and Grave, 2021; Lewis et al., 2020c), question-based summarization (Iida et al., 2019; Goodwin et al., 2020; Deng et al., 2020), and, most relevant to this work, answer generation for retrieval-based QA (Hsu et al., 2021) — that we refer to as GENQA.

Compared to generative MR models, GENQA approaches are trained to produce complete and expressive sentences that are easier to understand than extracted snippets (Choi et al., 2021). Most importantly, they are trained to generate entire sentences, allowing them to answer both factoid or non-factoid questions, e.g., asking for descriptions, explanation, or procedures.

In this paper, we study and propose a simple technique for open-domain QA in a cross-lingual setting. Following Hsu et al. (2021) (and as illustrated in Figure 1), we work with a pipeline made of 3 main modules. First, a document retriever that retrieves relevant documents given a question; second, an answer sentence selection (AS2) model (Garg et al., 2020; Vu and Moschitti, 2021) that ranks the sentences from the retrieved documents based on how likely they are to include the answer; and third, a generative model that generates a full sentence to answer the question given the sentence candidates.

Our contribution focuses on the generative model. We introduce CROSSGENQA. CROSSGENQA can generate full-sentence answers using sentence candidates written in multiple languages

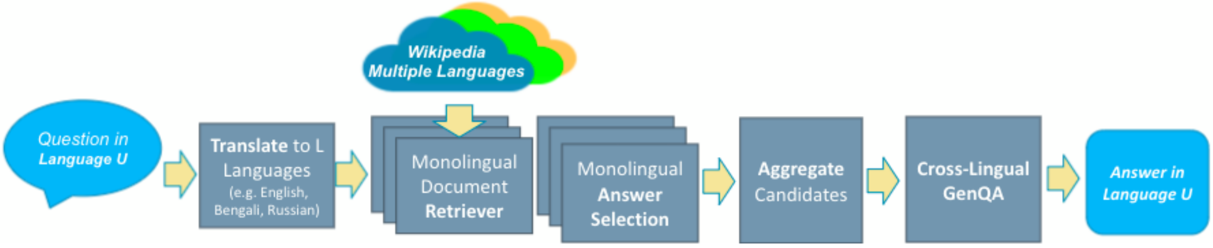

Figure 1: Illustration of our proposed Cross-Lingual, Retrieval-based GENQA pipeline.

including languages different from the question and English.

Given the scarcity of annotated corpora for GENQA, especially in languages different from English, we introduce the GEN-TYDIQA dataset. GEN-TYDIQA is an extension of TyDiQA, a dataset for typologically diverse languages in which questions are answered with passages and short spans extracted from Wikipedia (Clark et al., 2020). Our GEN-TYDIQA includes human-generated, fluent, self-contained answers in Arabic, Bengali, English, Russian and Japanese, making it a valuable resource for evaluating multilingual generative QA systems. We found human-generated answers to be essential in evaluating GENQA: compared to the standard approach of providing reference documents, they dramatically speed-up annotations and improve inter-annotator agreement.

Our evaluation shows that our CROSSGENQA system outperforms AS2 ranking models, and matches or exceeds similar monolingual pipelines.

In summary, our contribution is three-fold:

(i) We introduce GEN-TYDIQA[1], an evaluation dataset that contains natural-sounding answers in Arabic, Bengali, English, Russian and Japanese, to foster the development of multilingual GENQA systems.

(ii) We confirm and extend the results of Hsu et al. (2021) by showing that monolingual generative QA (MONOGENQA) outperforms extractive QA systems in Arabic, Bengali, English and Russian.

(iii) We demonstrate that CROSSGENQA outperforms all our QA systems for Arabic, Russian, and Japanese, answering questions using information from multiple languages.

2 Related Work

Multilingual Datasets for QA Researchers have introduced several datasets for QA in multiple languages. Unlike our GEN-TYDIQA, to the best of our knowledge, they are designed exclusively for extractive QA. Artetxe et al. (2019) extended the English machine reading SQuAD dataset (Rajpurkar et al., 2016) by translating the test set to 11 languages. Similarly, Lewis et al. (2020a) collected new question and answer pairs for 7 languages following the SQuAD format. Recently, Longpre et al. (2020) released MKQA, which includes question and answer pairs (predominantly Yes/No answers and entities) for 26 languages. Clark et al. (2020) released TyDiQA, a dataset for extractive QA in 11 typologically diverse languages. Riabi et al. (2020) and Shakeri et al. (2021) have explored the use of techniques to synthetically generate data for extractive question answering using cross-lingual transfer.

Generating Fluent Answers for QA The Generation of fluent and complete-sentence answers is still in its infancy, as most generative models for QA are used for extractive QA (e.g., (Guu et al., 2020; Lewis et al., 2020b; Asai et al., 2021a,b). Approaches to ensure response fluency have been explored in the context of dialogue systems (Baheti et al., 2020; Ni et al., 2021), but remain nevertheless understudied in the context of QA. Providing natural sounding answers is a task of particular interest to provide a better experience for users of voice assistants. One resource for this task is the MS-MARCO dataset (Nguyen et al., 2016). It includes 182,669 question and answer pairs with human-written well-formed answers. However, it only contains samples in English.

Our GEN-TYDIQA extends TyDiQA (Clark et al., 2020) adding natural human-generated answers for Arabic, Bengali, English, Japanese, and Russian. To the best of our knowledge, it is the first

[1] We make GEN-TYDIQA available at the following URL: `s3://alexa-wqa-public/datasets/cross-genqa/`

work that provides well-formed, natural-sounding answers for non-English languages.

Multilingual Extractive QA Designing QA models for languages different from English is challenging due to the limited number of resources and the limited size of those datasets. For this reason, many studies leverage transfer learning across languages by designing systems that can make use of annotated data in one language to model another language. For instance, Clark et al. (2020) showed that concatenating the training data from multiple languages improves the performance of a model on all the target languages for extractive QA. In the Open-Retrieval QA setting, multilingual modeling can be used to answer questions in one language using information retrieved from other languages. Da San Martino et al. (2017) showed how cross-language tree kernels can be used to rank English answer candidates for Arabic questions. Montero et al. (2020) designed a cross-lingual question similarity technique to map a question in one language to a question in English for which an answer has already been found. Asai et al. (2021a) showed that extracting relevant passages from English Wikipedia can deliver better answers than relying only on the Wikipedia corpora of the question language. Vu and Moschitti (2021) showed how machine translated question-answer pairs can be used to train a multilingual QA model; in their study, they leveraged English data to train an English and German AS2 model.

Finally, Asai et al. (2021c) introduced CORA and reached state-of-the-art performance on open-retrieval span-prediction question answering across 26 languages. While related to our endeavor, it is significantly different in several key aspects. First, unlike CROSSGENQA, CORA does not produce full, complete sentences; rather, it predicts spans of text that might contain a factoid answer. Second, it mainly relies on sentence candidates that are written in English and in the question language; by contrast, in our work we choose to translate the questions into a variety of languages, allowing us to use monolingual retrieval pipelines to retrieve candidate sentences in diverse languages. We show that this form of cross-lingual GENQA outperforms monolingual GENQA in a majority of the languages studied.

Answer Sentence Selection (AS2) The AS2 task originated in the TREC QA Track (Voorhees, 2001); more recently, it was revived by Wang et al. (2007). Neural AS2 models have also been explored (Wang and Jiang, 2017; Garg et al., 2020). AS2 models receive as input a question and a (potentially large) set of candidate answers; they are trained to estimate, for each candidate, its likelihood to be a correct answer for the given question.

Several approaches for monolingual AS2 have been proposed in recent years. Severyn and Moschitti (2015) used CNNs to learn and score question and answer representations, while others proposed alignment networks (Shen et al., 2017; Tran et al., 2018; Tay et al., 2018). Compare-and-aggregate architectures have also been extensively studied (Wang and Jiang, 2017; Bian et al., 2017; Yoon et al., 2019). Tayyar Madabushi et al. (2018) exploited fine-grained question classification to further improve answer selection. Garg et al. (2020) achieved state-of-the-art results by fine-tuning transformer-based models on a large QA dataset first, and then adapting to smaller AS2 dataset. Matsubara et al. (2020) showed how, similar in spirit to GENQA, multiple heterogeneous systems for AS2 can be be combined to improve a question answer pipeline.

3 The GEN-TYDIQA Dataset

To more efficiently evaluate our multilingual generative pipeline (lower cost and higher speed), we built GEN-TYDIQA, an evaluation dataset for answer-generation-based QA in Arabic, Bengali, English, Japanese, and Russian. This extends the TyDiQA (Clark et al., 2020) dataset.

TyDiQA is a QA dataset that includes questions for 11 typologically diverse languages. Each entry is composed of a human-generated question and a single Wikipedia document providing relevant information. For a large subset of its questions, TyDiQA also contains a human-annotated passage extracted from the Wikipedia document, as well as a short span of text that answers the question. We extend the TyDiQA validation set[2] by collecting human-generated answers based on the provided questions and passages using Amazon Mechanical Turk[3] (cf. Appendix C.1 for hiring criteria and rewards). Collecting human-generated answers is crucial for properly evaluating GENQA models, as we will show in section 5.4. We use a two-stage data collection process:

[2] The TyDiQA test set is not publicly available.

[3] https://requester.mturk.com

(EN) Question: What do pallid sturgeons eat? **TyDiQA Span**: – **GEN-TYDIQA Answer**: Pallid sturgeons eat various species of insects and fish depending on the seasons.
(RU) Question: Когда закончилась Английская революция? *When did the English Revolution end?* **TyDiQA Span**: 1645 **GEN-TYDIQA Answer**: Английская революция, известная также как Английская гражданская вой закончилась в 1645, когда Кромвель создал «Армию нового образца», одержавшую решающую победу в сражении при Нэйсби *The English Revolution, also known as the English Civil War; ended in 1645, when Cromwell created the "Army of the new model", which won a decisive victory at the Battle of Naysby.*
(JA) Question: ストーンズリバーの戦いによる戦死者は何人 *How many were the deaths from the Battle of Stones River?* **TyDiQA Span**: 23,515名 *23,515 people* **GEN-TYDIQA Answer**: ストーンズリバーの戦いで23,515人が川で殺されました。 *23,515 people were killed in the river in the Battle of Stones River.*

Table 1: GEN-TYDIQA question and answer samples.

(1) Answer Generation We show each turker a question and its corresponding passage, and ask them to write an answer that meets the following three properties: (*i*) The answer must be **factually correct and aligned** with the information provided in the passage. If a passage is not sufficient to answer a question, turkers will respond "no answer". (*ii*) The answer must be a **complete and grammatically correct** sentence, or at most a few sentences. (*iii*) The answer should be **self-contained**; that is, it should be understandable without reading the question or the passage. Based on this condition, "yes" or "no" are not acceptable answers.

(2) Answer Validation We show each question alongside its corresponding passage and the human-generated answer from Step (1) to five turkers. We ask them to label if the collected answer meets the three properties listed above: correctness, completeness, and self-containedness. We aggregate labels and keep only answers that received at least 3/5 positive judgements for each property. Table 1 contains some examples of the data collected.

Data Statistics We report the number of GEN-TYDIQA collected human-generated natural answers in table 2, and our coverage of the TyDiQA dataset. We do not reach 100% coverage due to our highly selective validation stage: we only accept answers that receive 3/5 votes for each property, a process that guarantees a high-quality dataset.

Lang. (iso)	#Answers	Avg. Length (utf-8)	%TyDiQA
Arabic (AR)	859	152.5	75.7
Bengali (BN)	89	177.2	63.6
English (EN)	593	64.0	79.5
Japanese (JA)	550	112.0	62.1
Russian (RU)	595	277.9	52.6

Table 2: Statistics on GEN-TYDIQA Answers

4 Multilingual GenQA Systems

Our goal is to build a QA system that, given a question in a target language, retrieves the top-k most relevant passages from text sources in multiple languages, and generates an answer in the target language from these passages (even if the passages are in a different language from the question).

4.1 Task Definition and System Architecture

We first describe the AS2 and GENQA tasks in a language-independent monolingual setting, and then generalize to the cross-lingual setting.

In the monolingual setting for a language L_i, an AS2 system takes as input a question q and a possibly large set of candidate answers C_{L_i} (e.g. all sentences from Wikipedia in the language L_i), ranks each candidate answer given q, and returns the top-ranking candidate $c_m \in C_{L_i}$. A GENQA system uses the top k AS2-ranked answers in C_{L_i} to synthesize a machine-generated answer g in language L_i.

The cross-lingual GENQA task extends this setup as follows: Consider a set of languages $\{L_1, \ldots, L_r\}$. Given a question q in language L_i, let $M = \cup_{j=1}^{r} C_{L_j}$ be the set of relevant candidate sentence answers for q in any language. A cross-lingual GENQA system uses the top k ranked answers in M — regardless of language — to generate an answer g in L_i.

Our architecture, illustrated in Figure 1, consists of the following components: (*i*) question translation[4] from L_i to produce queries q_{L_j} in each language L_j, (*ii*) a document retriever for each L_j to get C_{L_j}, (*iii*) a monolingual AS2 model for each language, which sorts the candidates in C_{L_j} in terms of probability to be correct given q_{L_j}, where C_{L_j} is created by splitting the retrieved documents into sentences, (*iv*) an aggregator component, which builds a multilingual candidate set M using the top k candidates for each language, and

[4] We used Amazon's AWS Translate service, https://aws.amazon.com/translate/service. We validate the quality of AWS Translate on the languages we study in the Appendix section A.3.

(v) a cross-lingual answer generation model, which generates g from M.

We now present in more details each component of our system.

4.2 Multilingual Passage Retrieval

To obtain candidates for our multilingual pipeline, we used Wikipedia snapshots collected in May 2021. We processed each snapshot using WikiExtractor (Attardi, 2015), and create monolingual indices using PyTerrier (Macdonald and Tonellotto, 2020). During retrieval, we first translate queries in each language using AWS Translate. We validate the good quality of this system for all our languages in table 9 in the Appendix. We then use BM25 (Robertson et al., 1995) to score documents. We choose BM25 because, as shown by Thakur et al. (2021), it is competitive with DPR-based models (Karpukhin et al., 2020) and it outperforms DPR across a great diversity of domains.

Evaluation We evaluate the different retrievers independently: for each question, we compare the exact match of the title of the retrieved document with the gold document's title provided by TyDiQA. We compute the Hit@N at the document level, i.e., the percentage of questions having a correct document in the top-N predicted documents. In our experiments, we retrieve the top-100 documents from Wikipedia to feed them to the AS2 model.

4.3 AS2 models for different languages

We build AS2 models by fine-tuning the multilingual masked-language model XLM-R (Conneau et al., 2020) into multiple languages, using question/sentence pairs, which we created with the TyDiQA dataset. We followed the procedure by Garg et al. (2020) performed on the NQ dataset (Kwiatkowski et al., 2019) to build the ASNQ dataset for English. For each ⟨question, Wikipedia document, span⟩ triplet from the TyDiQA dataset, we use the span to identify positive and negative sentence candidates in the Wikipedia document. We first segment each document at the sentence level using the `spacy` library[5]. We define positive examples to be the sentences that contain the span provided by the TyDiQA dataset, and negative examples to be all other sentences from the same Wikipedia document. We report statistics on AS2-TyDiQA in the Appendix in table 11. For more details, we refer the reader to Garg et al. (2020).

Model We fine-tune XLM-R extended with a binary classification layer on the AS2-TyDiQA dataset described above. At test time, we rank the candidates using the model output probability. Preliminary experiments confirmed the results of Clark et al. (2020) regarding machine reading models on TyDiQA : the best performance is obtained when concatenating the datasets from all languages.

4.4 Multilingual Answer Generation Models

We extended the work of Hsu et al. (2021) on monolingual GENQA modeling. For each question, this model takes the top-5 candidates ranked by AS2 as input. For CROSS-LINGUAL GENQA, we build a set of multiligual candidates M with two methods: (i) TOP 2 / LANG., which selects the top 2 candidates for each language and concatenates them (in total $2 \times 5 = 10$); and (ii) TOP 10, which selects the 10 candidates associated with the highest scores regardless of their language.

Model We used the pre-trained multilingual T5 language model (MT5) by Xue et al. (2021). This is an encoder-decoder transformer-based model (Vaswani et al., 2017) pre-trained with a span-masking objective on a large amount of web-based data from 101 languages (we use the base version). We fine-tuned MT5 following (Hsu et al., 2021): for each sample, we give the model the question concatenated with the candidates M as input and a natural answer as the generated output. GENQA models are trained on MS-MARCO (Nguyen et al., 2016)[6], which includes 182,669 examples of ⟨question, 10 candidate passages, natural answer⟩ instances in English. When the language of the question (and answer) is not English or when we use candidates in multiple languages, we translate the training samples with Amazon's AWS Translate service and fine-tune the model on the translated data. For instance, to design a GENQA model answering questions in Arabic using input passages in Arabic, English, and Bengali, we fine-tune the model with questions and gold standard answers translated from English to Arabic, and input candidates in English, Arabic, and Bengali, where the latter two are translated from the MS-MARCO English passages.

[5] https://spacy.io/

[6] Using the train split of the NLGEN(v2.1) version.

Evaluation As pointed out by Chen et al. (2019), automatically evaluating generation-based QA systems is challenging. We experimented with BLEU (Papineni et al., 2002) and ROUGE-L (Lin, 2004), two standard metrics traditionally used for evaluating generation-based systems, but found that they do not correlate with human judgment. For completeness, we report them in the Appendix D.2 along with a detailed comparison with human judgment. Thus, we rely on human evaluation through Amazon Mechanical Turk[7]: we ask three turkers to vote on whether the generated answer is correct, and report the $\frac{\sum PositiveVotes}{\sum TotalVotes}$ as system Accuracy.

5 Experiments

Multilinguality and the different components of our system pipeline raise interesting research questions. Our experimental setup is defined by the combinations of our target set of languages with respect to questions, candidates, and answers. We experiment with GENQA in the monolingual (one model per language) and multilingual (one model for several languages) settings, where the question and candidates in the same language are used to generate an answer. Then we experiment with a cross-lingual GENQA model that is fed candidates in multiple languages. Despite being an apparent more complex task, we find that in many cases, the cross-lingual model outperform all other settings.

5.1 Setup

We approach multilingual generation-based question answering in three ways:

MONOLINGUAL GENQA (MONOGENQA) The candidate language is the same as the question. For each language (Arabic, Bengali, English, Japanese and Russian), we monolingually fine-tune MT5, and report the performance of each GENQA model on the GEN-TYDIQA dataset (Tab. 5).

Our contribution is to show that this approach, first introduced by Hsu et al. (2021) for English, delivers similar performance for other languages.

MULTILINGUAL GENQA (MULTIGENQA) We train one MT5 for all five languages by concatenating their training and validation sets. This single model can answer questions in multiple languages, but it requires that answer candidates be in the same language as the question. We report the performance of this MULTIGENQA model in table 5.

For this set of experiments, we show that a single multilingual GENQA model can compete with a collection of monolingual models.

Model	CANDIDATES	Accuracy
MONOGENQA	EN	**77.9**
CROSSGENQA	DE	70.5
CROSSGENQA	DE ES FR IT	68.8
CROSSGENQA	AR JA KO	31.4
Clozed-Book	NONE	21.0

Table 3: Impact of the candidate language set on CROSS-LINGUAL GENQA in English on MS-MARCO. The language set is controlled with machine translation.

CROSS-LINGUAL GENQA (CROSSGENQA) We use candidates in multiple languages (Arabic, Bengali, Russian, English, Arabic) to answer a question in a target language. We retrieve and rerank sentence candidates in each language, aggregate candidates across all the languages, and finally generate answers (in the same language as the question). We report the performance on the GEN-TYDIQA dataset (table 5).

These experiments aim to determine whether our generative QA model can make use of information retrieved from multiple languages and outperform the baseline methods.

Manual Evaluation We stress the fact that all the results derived in the following experiments were manually evaluated with Amazon Mechanical Turk. In total, we run 34 tasks (system evaluations), requiring around 60k Hits, for a total manual evaluation of 20k QA pairs (times 3 turkers).

5.2 Feasibility Study

To explore whether a model fed with candidates written in languages different from the question can still capture relevant information to answer the question, we conduct a feasibility study using the MS-MARCO dataset with English as our target language and machine translated candidates.

For each question, we translate the top 5 candidate passages to different languages and provide these translated candidates as input to the model. We experiment with three translation settings: all candidates translated to German (DE); each candidate translated to a random choice of German, Spanish, French or Italian (DE-ES-FR-IT); translated to Arabic, Japanese or Korean (AR-JA-KO). We compare all these CROSS-LINGUAL GENQA models with a Clozed-Book QA Model (Roberts

[7] We describe in C.1 how we choose and reward turkers.

Language	BLEU	ROUGE	Accuracy
MONOLINGUAL GENQA			
AR	24.8 / 17.2	47.6 / 38.8	77.1 / 68.4
BN	27.4 / 21.7	48.6 / 43.0	82.0 / 67.4
EN	31.5 / 23.0	54.4 / 46.4	68.5 / 43.6
JA	24.5 / 19.4	50.2 / 45.0	72.3 / 64.3
RU	10.2 / 6.4	30.2 / 23.4	82.6 / 61.3
MULTILINGUAL GENQA			
AR	24.3 / 17.4	47.9 / 39.0	74.9 / 72.7
BN	27.3 / 23.7	47.8 / 44.9	84.3 / 76.5
EN	30.8 / 21.8	54.5 / 46.2	65.3 / 37.4
JA	23.9 / 19.1	50.0 / 45.5	76.8 / 65.5
RU	10.6 / 6.4	31.0 / 23.2	76.6 / 66.7

Table 4: Performance of our GENQA models fine-tuned on MSMARCO and evaluated on GENTYDIQA using Gold-Passage from TyDiQA/Ranked Candidates from Wikipedia.

Model	AR	BN	EN	JA	RU
RETRIEVER (Hit@100 doc.)	70.7	66.3	66.9	57.0	67.8
AS2	68.0	58.0	39.0	70.4	60.8
MONOGENQA	68.4	67.4	**43.6**	64.3	61.3
MULTIGENQA	72.7	**76.5**	37.4	65.5	66.7
CROSSGENQA TOP 10	72.0	25.3	31.0	70.3	**74.3**
CROSSGENQA TOP. 2 / LANG.	**73.2**	18.5	29.3	**71.6**	**74.7**

Table 5: Hit@100 doc. of the retriever and Accuracy of GENQA models on GEN-TYDIQA. All CROSSGENQA experiments use candidates aggregated from all the languages (AR, BN, EN, JA, RU).

et al., 2020) for which no candidates are fed into the model.

Results We report the performance in table 3. All CROSS-LINGUAL GENQA models outperform significantly the Clozed-book approach. This means that even when the candidates are in languages different from the question, the model is able to extract relevant information to answer the question. We observe this even when the candidates are in languages distant from the question language (e.g., Arabic, Japanese, Korean).

5.3 GEN-TYDIQA Experiments

This section reports experiments of the full GENQA pipeline tested on the GEN-TYDIQA dataset with candidates retrieved from Wikipedia. For each question, we retrieve documents with a BM25-based retriever, rank relevant candidates using the AS2 model, and feed them to the GENQA models. We note that we cannot compare the model performance across languages: as pointed out in (Clark et al., 2020) regarding TyDiQA.

MONOGENQA Performance We measure the impact of the retrieval and AS2 errors by computing the ideal GENQA performance, when fed with gold candidates (TyDiQA gold passage). We report the results in table 4. We evaluate the performance of the GENQA models, also comparing it to AS2 models on the GEN-TYDIQA dataset of each language. We report the results in table 5 (cf. MONOGENQA). The first row shows the document retrieval performance in terms of Hit@100 for the different languages considered in our work. We note comparable results among all languages, where Arabic reaches the highest accuracy, 70.7, and Japanese the lowest, 57.0. The latter may be due to the complexity of indexing ideogram-based languages. However, a more direct explanation is the fact that retrieval accuracy strongly depends on the complexity of queries (questions), which varies across languages for GEN-TYDIQA. Similarly to Clark et al. (2020), we find that queries in English and Japanese are more complex to answer compared to other languages.

Regarding answering generation results, rows 2 and 3 for English confirm Hsu et al. (2021)'s findings: GENQA outperforms significantly AS2 by 4.6% (43.6 vs. 39.0). We also note a substantial improvement for Bengali (+9.4%, 67.4 to 58.0). In contrast, Arabic and Russian show similar accuracy between GENQA and AS2 models. Finally, AS2 seems rather more accurate than GENQA for Japanese (70.4 vs 64.3). Results reported by Xue et al. (2021) show MT5 to be relatively worse for Japanese than all other languages we consider in many downstream tasks, so the regression seen here might be rooted in similar issues.

MULTIGENQA Performance We compare the performance of the MONOLINGUAL GENQA models (one model per language) to the performance of the MULTILINGUAL GENQA model fine-tuned after concatenating the training datasets from all the languages. We report the performance in table 5 (cf. MULTIGENQA): multilingual fine-tuning improves the performance over monolingual fine-tuning for all languages except English. This shows that models benefit from training on samples from different languages. For Bengali, we observe an improvement of around 9% in accuracy. This result has a strong practical consequence: at test time, we do not need one GENQA model per language, we can rely on a single multilingual model trained on the concatenation of datasets from multiple languages (except for English, where we find that the monolingual model is more accurate). This result generalizes what has been shown for extractive QA (Clark et al., 2020) to the GENQA task.

Model	Candidates	Accuracy
MonoGenQA	En	57.8
CrossGenQA	Ja	60.3
CrossGenQA	Ar-Bn-En-Ja-Ru top 10	56.9
CrossGenQA	Ar-Bn-En-Ja-Ru top 2 / lang	**63.8**

Table 6: GenQA scores in English on Japanese-culture-specific questions extracted from TyDiQA. Candidates defines the language set of the input candidates.

CrossGenQA Performance Our last and most important contribution is in table 5, which reports the performance of a GenQA model trained and evaluated with candidates in multiple languages. This model can answer a user question in one language (e.g., Japanese) by using information retrieved from many languages, e.g., Arabic, Bengali, English, Japanese, and Russian). For Arabic, Japanese, and Russian, we observe that Cross-Lingual GenQA outperforms other approaches by a large margin, e.g., for Russian, 13.8% (74.6-60.8) better than AS2, and an 8% percent improvement over MultiGenQA.

For Bengali, the model fails at generate good quality answers (CrossGenQA models reach at best 25.3% in accuracy compared to the 76.9% reached by the MultiGenQA model). We hypothesize that this is the consequence of a poor translation quality of the question from Bengali to other languages such as English, Arabic, or Japanese, which leads to poor candidate retrieval and selection, ultimately resulting in inaccurate generation.

Finally, we compare the two candidate aggregation strategies used for Cross-Lingual GenQA: Top 2 / lang. and Top 10 (see section 4.4). We observe that the aggregation strategy impacts moderately the downstream performance. For English, Arabic, Japanese and Russian the gap between the two methods is at most 2 points in accuracy. We leave the refinement of candidate selection in the multilingual setting for future work.

5.4 Analysis

Examples Table 7 shows the output of AS2, Multilingual GenQA, and Cross-Lingual GenQA models to questions in Russian and Bengali. For Bengali, the GenQA models provide a correct and fluent answer while the AS2 model does not. For Russian, only the Cross-Lingual GenQA model is able to answer correctly the question. This because AS2 does not rank the right information in the top k, while Cross-Lingual GenQA can find the right information in another language in the multi-language candidate set.

Question: জাস্টিন ড্রিউ বিবারের জন্ম কবে হয় ?
When was Justin Drew Bieber born?
AS2 Prediction:
ম্যাথু লরেন্স হেইডেন, এএম (; জন্ম: ২৯ অক্টোবর, ১৯৭১) কুইন্সল্যান্ডের কিঙ্গারয় এলাকায় জন্মগ্রহণকারী সাবেক অস্ট্রেলীয় ক্রিকেটার হিসেবে সমগ্র ক্রিকেট বিশ্বে পরিচিত ব্যক্তিত্বরেন *Matthew Lawrence Hayden, AM (born October 29, 1971) is a former Australian cricketer born in Kingroy, Queensland.*
MultiGenQA Prediction:
জাস্টিন ড্রু বিবার ১৯৯৪ সালের ১ মার্চ জন্মগ্রহণ করেন।
Justin Drew Bieber was born on March 1, 1994.
CrossGenQA Prediction
জাস্টিন ড্রু বিবার ১৯৯৪ সালের ১ মার্চ জন্মগ্রহণ করেন।
Justin Drew Bieber was born on March 1, 1994.

Question: トゥールのグレゴリウスはいつ生まれた？
When was Gregory of Tours born?
AS2 Prediction: グレゴリウス14世（Gregorius XIV,1535年2月11日 - 1591年10月16日）はローマ教皇（在位：1590年 - 1591年）。 *Pope Gregory XIV (February 11, 1535 – October 16, 1591) is the Pope of Rome (reigned: 1590 – 1591).*
MultiGenQA Prediction:トゥールのグレゴリウスは、1535年2月11日に生まれた。 *Gregory of Tours was born on February 11, 1535.*
CrossGenQA Predictionトゥールのグレゴリウスは538年頃11月30日に生まれた。 *Gregory of Tours was born on November 30, 538.*

Table 7: Example of predicted answers to questions in Bengali and Japanese. **Blue** indicates correct predictions while **Red** incorrect ones. Translations are intended for the reader and are not part of the predictions.

Error Propagation We observe (table 4) that the GenQA models are highly impacted by the retriever and AS2 quality. For example, English GenQA performance drops of 27.9 (65.3-37.4) points in Accuracy. This suggests that large improvement could be achieved by improving the document retriever and/or AS2 modules.

Culture-Specific Questions in English One striking result across our experiments is the lower performance of Cross-Lingual GenQA model than GenQA model on English. We hypothesize that English questions from the Gen-TyDiQA dataset are more easily answered using information retrieved from English compared to other languages because those questions are centered on

Eval mode	Strong agreement	Perfect agreement	Fleiss' kappa
No Reference	55.00 %	16.43 %	0.1387
With Reference	85.36 %	55.25 %	0.5071

Table 8: Comparison between providing a reference answer and not for evaluating MonoGenQA predictions (En). Providing a reference increases agreement.

cultures specific to English-speaking countries.

To verify our hypothesis, we re-run the same set of experiments, using culture-specific Japanese questions rather than English queries. To do so, we (i) took the Japanese questions set from GEN-TYDIQA, (ii) manually translated it in English, (iii) manually select 116 questions that are centered on Japanese culture, and (iv) run the same GENQA pipeline on those questions. The results reported in table 6 show that CROSSGENQA outperforms MONOGENQA, suggesting that the former improves also the English setting if the question set is culturally not centered on English, i.e., it requires answers that cannot be found in English.

Use of Reference Answer in Model Evaluation We found the use of human-generated reference answers to be crucial to ensure a consisted annotation of each model. A comparison between annotation with and without reference answer is provided in table 8. When using a reference, we found annotators to be dramatically more consistent, achieving a Fleiss' Kappa (Fleiss, 1971) of 0.5017; when providing no reference answer, the inter-annotation agreement dropped to 0.1387. This trend is reflected in the number of questions with strong (4+ annotators agree) and perfect agreement.

6 Limits

Our system requires translating the questions. We also use the standard BM25 approach. Even though it was shown to be more robust compared to dense retriever (Thakur et al., 2021; Rosa et al., 2022), using a cross-lingual retriever (Li et al., 2021) could improve performance and save the cost of translating the question. This has been explored by Asai et al. (2021c) but their retriever mainly retrieves passages in English and the question language which may lead to English-centric answers. Another limit is the fact that our system is not designed to handle questions that are not answerable. In the future, we may want to integrate a no-answer setting to avoid unwanted answer.

7 Conclusion

We study retrieval-based Question Answering systems using answer generation in a multilingual context. We proposed (i) GEN-TYDIQA, a new multilingual QA dataset that includes natural and complete answers for Arabic, Bengali, English, Japanese, and Russian; based on this dataset (ii) the first multilingual and cross-lingual GENQA retrieval-based systems. The latter can accurately answer questions in one language using information from multiple languages, outperforming answer sentence selection baseline for all languages and monolingual pipeline for Arabic, Russian, and Japanese.

A Discussion

A.1 Machine Translation of the Questions and BM25 Retriever Engines

Our work introduces CROSS-LINGUAL GENQA, a system that can answer questions — with complete sentence answers — in multiple languages using candidates in multiple languages, possibly distinct from the question. They were many possible design choices to achieve such a goal. We chose to rely on automatically translating the questions before retrieving relevant documents in several languages using multiple (monolingual) BM25 retrievers. We could have chosen to use the recently released multilingual Dense passage Retrieval (mDPR) (Asai et al., 2021b). We decided not to for the two following reasons. First, as shown by Thakur et al. (2021), BM25 is a very reasonable design choice for a retriever engine, that outperforms other approaches in many settings (including dense retrievers). Second, as seen in (Asai et al., 2021b), multilingual dense retrievers usually retrieve passages in the same language as the question or English. This means that mDPR is highly biased toward the English language. In our work, by combining translation and monolingual retrievers, we can control the language set that we use for answer generation. We leave for future work the refinement of mDPR to enable for more diversity in the retrieved passage languages and to integrate it in our pipeline.

A.2 Machine Translation Errors

At test time, our system applies Machine Translation to the question to formulate queries in different languages and retrieve candidates for these languages using the BM25 retrieval engine. To our knowledge this is the best approach to generate queries in different languages, as MT systems are very powerful tools, trained on millions of data points and, thanks to Transformer model, they take the entire question context into account (other cross-query formulations can be applied but they will be probably less accurate and multilingual DPR is an excellent research line but not as much assessed as BM25 as effective and general approach). Clearly MT errors can impact the quality of our candidates. However, if a question is badly translated the retrieved content will be inconsistent with the candidates retrieved for the question in the original language (and also inconsistent with candidates retrieved using questions translated in other languages). Our joint modeling through large generation-based Transformers can recover from these random errors. For example, for 3 languages out of 5, we show that the Cross-GenQA pipelines that use MT for the question outperform monolingual pipelines (MONOGENQA and MULTIGENQA). This shows that translation errors are recovered by our approach.

Table 9: Performance measured with spBLEU of AWS translate compared to a Many-to-Many (M2M) Multilingual Transformer Model (reported in (Goyal et al., 2022)) on the FLORES devtest dataset (Goyal et al., 2022). Cell(i,j) reports the score of AWS/M2M from language i to language j. AWS translate outperforms the M2M model for all language pairs.

A.3 AWS-Translation for Machine Translation

For translating the questions automatically, we use AWS Translate. AWS Translate is a machine translation API that competes and outperforms in some cases other available translation APIs[8]. We compare the performance of a strong baseline on the FLORES dataset in table 9. We find that AWS translate outperforms the baseline for all the language pairs we work with. We leave for future work the study of the impact of different machine translation systems on our CROSS-LINGUAL GENQA models.

B Ethics Statement

B.1 Potential Harms of GENQA

All our GENQA are fine-tuned from a large pretrained language model, MT5 (Xue et al., 2021). In general, large language models have been shown to have a potential to amplify societal biases (Bender et al., 2021), and might leak information about the datasets they were trained on (Carlini et al., 2021). In particular, the Colossal Cleaned Crawled Corpus (C4) and its multilingual counterpart (MC4) that were used to train MT5 have been shown to

[8] cf. https://aws.amazon.com/blogs/machine-learning/amazon-translate-ranked-as-1-machine-translation-provider-by-intento/

disproportionately under-represent content about minority individuals (Dodge et al., 2021).

In its use as a retrieval-based question answering system, GENQA also can also cause harm due to (*i*) the use of candidate sentences that are extracted from web documents, and (*ii*) model hallucinations that are produced during decoding. In this work, (*i*) is mitigated by only relying on content from Wikipedia, which, while not immune to vandalism (Alkharashi and Jose, 2018), is of much higher quality of unvetted web data. Regarding the risk of model hallucinations, this work does not attempt to directly mitigate any potential issue through modeling; rather, we always show annotators reference answer so that hallucination that result in factually incorrect answers can be properly caught during evaluation.

B.2 GEN-TYDIQA Copyright

Our GEN-TYDIQA dataset is based on the TyDiQA dataset questions (Clark et al., 2020). TyDiQA is released under the Apache 2.0 License which allows modification and redistribution of the derived dataset. Upon acceptance of this paper, we will release GEN-TYDIQA and honor the terms of this license.

GEN-TYDIQA answers were collected using Amazon Mechanical Turk. No geolocation filters or any personal information were used to hire turkers. Additionally, GEN-TYDIQA questions treat scientific or cultural topics that can be answered objectively using Wikipedia. For these reasons, the collected answers cannot be used to identify their authors. Finally, to ensure the complete anonymity of the turkers, we will not release the turkers id along with the collected answers.

B.3 Energy Consumption of Training

All our experiments are based on the MT5 base model. We run all our fine-tuning and evaluation runs using 8 Tesla P100 GPUs[9], which have a peak energy consumption of 300W each. Fine-tuning our CROSS-LINGUAL GENQA models on MS-MARCO (Nguyen et al., 2016) takes about 24 hours.

C Reproducibility

C.1 Mechanical-Turk Settings

In this paper, we rely on Amazon Mechanical Turk for two distinct uses.

On the one hand, we use it to build the GEN-TYDIQA dataset. For data collection, we request 1 turker per question to generate an answer. For the GEN-TYDIQA data validation, we request 5 turkers to select only answers that are correct, aligned with the provided passage, self-contained and complete.

On the other hand, we use Amazon Mechanical Turk to estimate the answer accuracy of our models. To do so, for each question, we provide the GEN-TYDIQA reference and ask 3 turkers to vote on whether the generated answer is correct or not.

For those two uses, we use the following Amazon Mechanical Turk filters to hire turkers.

- We hire turkers that received at least a 95% HIT[10] approval rate.
- We request turkers that have performed at least 500 approved HITs.
- When possible, we use the "*master turker*" filter[11] provided by Amazon Mechanical Turk. We find that this filter can only be used for English. For other languages, this filter leads to a too-small turker pool making it unusable in practice.

On Mechanical turk, the reward unit for workers is the HIT. In our case, a HIT is the annotation/validation of a single question. We make sure that each turker is paid at least an average of 15 USD/hour. To estimate the fair HIT reward, we first run each step with 100 samples ourselves in order to estimate the average time required per task. For data collection, we set the HIT reward to 0.50 USD based on an estimation of 0.5 HIT/min. For data validation, we set it to 0.15 USD based on an estimation of 1.6 HIT/min. For model evaluation,

[9] https://www.nvidia.com/en-us/data-center/tesla-p100/

[10] A HIT, as defined in Amazon Mechanical Turk, is a *Human Intelligent Task*. In our case, a HIT consists in generating, validating, or accepting an answer to a single question.

[11] As stated on the Amazon Mechanical Turk website, "Amazon Mechanical Turk has built technology which analyzes Worker performance, identifies high performing Workers, and monitors their performance over time. Workers who have demonstrated excellence across a wide range of tasks are awarded the Masters Qualification. Masters must continue to pass our statistical monitoring to retain the Amazon Mechanical Turk Masters Qualification."

we set the HIT reward to 0.10 USD based on an estimation of 2.5 HIT/min.

C.2 Model Optimization

All the GenQA experiments we present in this paper are based on fine-tuning mT5 base (Xue et al., 2021). Models are implemented in PyTorch (Paszke et al., 2019), and leverage `transformers` (Wolf et al., 2020) and `pytorch-lightning` (Falcon and Cho, 2020). For fine-tuning, we concatenate the question and the candidate sentences, input it to the model and train it to generate the answer. Across all our runs, we use the hyperparameters reported in table 10.

D Analysis

D.1 Gold vs. Retrieved Candidates

We report in table 4 the performance of the MonoGenQA and MultiGenQA models when we feed them gold passages (using TyDiQA passage) and compare them with the performance of the same models fed with the retrieved candidates. We discuss those results in section 5.4.

D.2 Human Evaluation vs. BLEU and ROUGE-L

For comparison with previous and future work, we report the BLEU score (computed with SacreBLEU (Post, 2018)) and the F-score of the ROUGE-L metric (Lin, 2004) along with the human evaluation accuracy in table 14.

As seen in previous work discussing the automatic evaluation of QA systems by Chaganty et al. (2018) and Chen et al. (2019), we observe that for many cases, BLEU and ROUGE-L do not correlate with human evaluation. In table 12, we take the predictions of our MultiGenQA model across all the languages and compute the Spearman rank correlation at the sentence level of the human estimated accuracy with BLEU and ROUGE-L. We find that this correlation is at most 25%. This suggests that those two metrics are not able to discriminate between correct predictions and incorrect ones.

Additionally, we report the Spearman rank correlation between the Accuracy and BLEU or ROUGE across all our 5 models in table 13. We find that neither BLEU nor ROUGE-L correlates strongly with human accuracy across all the languages. This means that those metrics are not able to rank the quality of a model in agreement with human judgment. Those results lead us to focus our analysis and to take our conclusions only on human evaluated accuracy. We leave for future work the development of an automatic evaluation method for multilingual GenQA.

Discourse Parsing Enhanced by Discourse Dependence Perception

{kongfang,gdzhou}@suda.edu.cn

Abstract

In recent years, top-down neural models have achieved significant success in text-level discourse parsing. Nevertheless, they still suffer from the top-down error propagation issue, especially when the performance on the upper-level tree nodes is terrible. In this research, we aim to learn from the correlations in between EDUs directly to shorten the hierarchical distance of the RST structure to alleviate the above problem. Specifically, we contribute a joint top-down framework that learns from both discourse dependency and constituency parsing through one shared encoder and two independent decoders. Moreover, we also explore a constituency-to-dependency conversion scheme tailored for the Chinese discourse corpus to ensure the high quality of the joint learning process. Our experimental results on CDTB show that the dependency information we use well heightens the understanding of the rhetorical structure, especially for the upper-level tree layers.

1 Introduction

According to the representative Rhetorical Structure Theory (RST) (Mann and Thompson, 1988), a text can be presented as a hierarchical discourse tree (DT) built on a set of elementary discourse units (EDUs). Given a piece of text, RST-style discourse parsing identifies such a DT with EDUs serving as terminal nodes. Moreover, it labels the rhetorical relations and nuclearity attributes associated with each non-terminal node of the DT. Due to its far-reaching effects on text understanding and downstream NLP applications, text-level discourse parsing has been drawing more and more attention in the past decade.

From the early bottom-up approaches (Feng and Hirst, 2014; Ji and Eisenstein, 2014; Heilman and Sagae, 2015; Li et al., 2016; Braud et al., 2017; Yu et al., 2018; Mabona et al., 2019) to the more recent top-down frameworks (Lin et al., 2019; Kobayashi et al., 2020; Zhang et al., 2020, 2021; Koto et al., 2021), previous studies gradually switch from feature-based machine learning methods to deep neural models and have achieved particular success. Among current neural models, top-down parsers, in most cases, perform better than bottom-up ones due to their capability of capturing global context information. Nevertheless, due to the long-distance dependencies in between textual units and the notorious lack of training data, top-down text-level discourse parsing still faces the following possible bottlenecks:

- At the initial parsing stage, top-down parsers consider each entire text to determine the upper-level DT nodes. However, the whole text segment usually consists of diverse information, too much for the machine to understand thoroughly. As a result, our experimental statistics show that the parsing performance decreases by about 30% when the DT level is greater than 5.

- In RST-style constituency trees, there are far fewer training instances for the upper-level discourse tree layers when compared with the lower-level ones. For example, just as noted by Zhang et al. (2020), among the 933 test instances in the CDTB corpus, only 13 instances have a height of 8 or greater, occupying only about 1.3%.

- According to the above two points, on the one hand, the incorrect decisions made for the upper-level nodes may seriously impact the lower-level ones due to error propagation. On the other, the lack of upper-level training instances exacerbates the impact of error propagation.

Facing the above challenges, some recent studies have done certain preliminary explorations, hoping to improve top-down parsing by expanding the original small-scale training data (Kobayashi et al.,

2021) or introducing global optimization objectives (Zhang et al., 2021). Unlike previous work, we aim to improve the accuracy of upper-level node prediction to reduce error propagation for better RST parsing performance. To achieve this goal, we set our sights on discourse-level dependencies, aiming at employing the dependencies in between EDUs to dig out clues hidden within those head EDUs that are conducive to the understanding of rhetorical structures. Specifically, we cast discourse constituency tree (DCT) parsing as the main task and discourse dependency tree (DDT) parsing as the auxiliary one and joint the two tasks through one shared encoder and two different decoders. In this way, on the one hand, we enhance the EDU representation with multi-task knowledge through the shared EDU encoder. On the other, since the converted DDTs derive from the manually annotated DCTs, perceiving the dependencies between EDUs will conversely stimulate the DCT parsing model to produce better results, especially for the upper-level DT nodes[1].

2 Related Work

In the literature, previous work on discourse parsing can be classified into two categories: bottom-up and top-down approaches.

For a long time, many researchers manually exploited various lexical, syntactic, and semantic features (Hernault et al., 2010; Joty et al., 2013; Feng and Hirst, 2014) or automatically captured hidden information (Li et al., 2014a, 2016) to compute the probability distribution of relations between two adjacent discourse units (DUs) and then selected the two units with the highest probability to merge into an upper-level unit. Recursively in this way, a discourse constituency tree is created from bottom to up. Besides, there are also some studies that cast RST parsing as a transition action determination process, where the discourse parser makes `shift` or `reduce` action decisions in a greedy way to determine whether to merge the current two DUs or not (Ji and Eisenstein, 2014; Wang et al., 2017; Braud et al., 2017; Yu et al., 2018).

Until recent years, top-down neural architectures gained much more popularity. In the literature, Lin et al. (2019) proposed the first top-down sentence-level discourse parser based on pointer nets, which operates in a linear time. Zhang et al. (2020; 2021) cast text-level discourse parsing as a top-down split point ranking process and introduced an adversarial method to optimize the parsing steps from a global perspective. Kobayashi et al. (2020; 2021) proposed parsing a document in three levels of granularity (i.e., document-level, paragraph-level, and sentence-level) and further introduced a semi-supervised method to extend the original RST-DT corpus for performance improvement. Notably, some recent studies also proved the effectiveness of pre-trained language models on discourse parsing (Koto et al., 2021; Nguyen et al., 2021).

In general, compared with bottom-up parsing, current top-down parsers obtain more outstanding performance since they benefit from the global information of the entire article. However, the global context information is known to be multifarious and complicated. It is challenging for the top-down parsers to grasp all the textual details accurately, especially at the initial stage of parsing, which may aggravate the issue of top-down error propagation. In this work, we build our parser based on the top-down framework of Zhang et al. (2020) and explore tackling the above problem via discourse dependency information.

3 Motivation

In order to make better choices at the initial stage of discourse parsing to lay a good foundation for succedent parsing of subtrees, we consider incorporating discourse-level dependencies. To support our argument, we present an example in Figure 1 where Figure (a) shows a native DCT tree[2] and Figure (b) shows the converted DDT structure corresponding to the tree. Subsequently, our motivation comes from the following two observations:

- First, compared to the constituency structure, which joins EDUs with nuclearity and rhetorical relations, the dependency structure represents a more direct parent-child relationship between EDUs. The dependency structure is more conducive to weakening the hierarchical nature of the RST constituency tree and shortening the distance between EDUs.

[1] Although most of the existing conversion methods, including ours, have irreversible problems (Morey et al., 2018), that is, the reverse conversion of DDT to DCT structure is not unique, but in most cases, the correlation between EDUs is helpful for DCT parsing, especially for the upper nodes. This point will be further analyzed in Subsection 5.3.

[2] For brevity, we omit the discourse rhetorical relations and only present the nuclearity information (either **N**ucleus or **S**atellite) of each non-terminal node in the DCT structure.

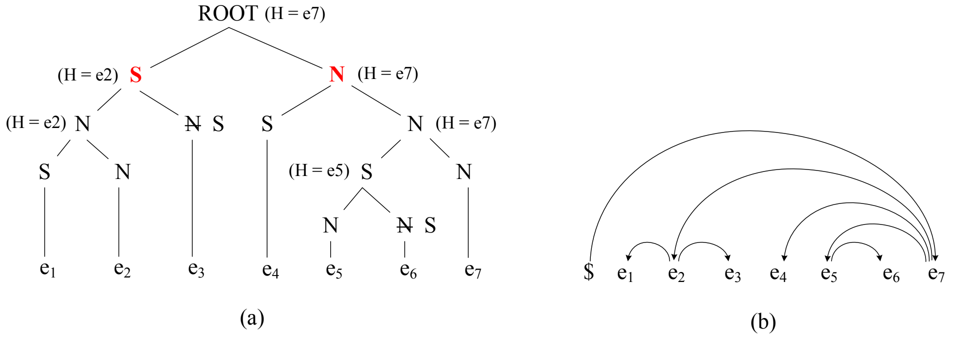

Figure 1: Figures (a) and (b) denote the example DCT structure and the converted DDT structure, respectively.

- Second, as the example shows, our constituency-to-dependency conversion method (described in Subsection 4.2.1) ensures that each sub-DCT in the tree corresponds to a unique single-rooted sub-DDT in the dependency structure. In this way, the rhetorical connection between two adjacent DUs is converted to a more straightforward correlation between two sub-DDTs, or more nuancedly, between their respective head EDUs. In this case, we believe that the direct connection between head EDUs can provide valuable structural or textual clues for better DCT parsing.

In short, the converted dependency arcs can help reduce the complexity of DCT trees to some extent, and the more direct connections between EDUs could provide valuable clues for better parsing performance, especially for the upper-layer tree nodes with a deep hierarchy. On this basis, we propose a multi-task learning approach to jointly learn DCT and DDT parsing, aiming to enhance the discourse representation via discourse dependencies for a better understanding of the rhetorical structure.

4 Joint DCT and DDT Parsing

Adopting the multi-task strategy, our model simultaneously conducts discourse constituency parsing and discourse dependency parsing by sharing the EDU representations, where discourse constituency parsing is the main task, and discourse dependency parsing serves as the auxiliary one. The whole architecture can be framed as an encoder-decoder model that contains one encoder and two different decoders, as illustrated in Figure 2.

4.1 Discourse Constituency Parsing

For DCT parsing, we follow Zhang et al. (2020) to cast the discourse parsing task as a recursive top-down split point selection process. The parsing model comprises three parts, i.e., EDU encoder, split point encoder, and attention-based encoder-decoder. Firstly, a bi-GRU network and the self-attention mechanism are conducted over each EDU text to obtain EDU representation. Then, the split point encoder containing another bi-GRU network and a CNN network with a window size of 2 will work on the achieved EDU representations to model the representation for each split point between two adjacent EDUs. After that, the split point representations are further fed into a stack-augmented RNN decoder for discourse parsing. In this work, we employ the publicly-available implementation[3] of the parser of Zhang et al. (2020) for DCT parsing. For details of the parsing process, please refer to their paper.

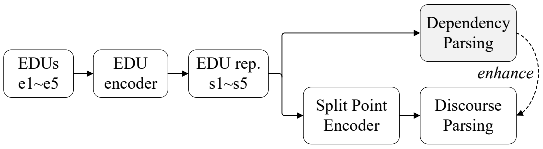

Figure 2: Joint parsing of DCT and DDT structures.

4.2 Discourse Dependency Parsing

4.2.1 Discourse Dependency Trees Acquisition

In the literature, Hirao et al. (2013) and Li et al. (2014b) have proposed two different methods to convert from DCTs to DDTs automatically. Unlike the method of Li et al. (2014b), different EDUs in a sentence could have multiple heads outside the sentence in the DDT structure of (Hirao et al., 2013). In other words, their method often loses the single-rooted tree for each sentence. In order to reduce the complexity of DDTs, Hayashi et al. (2016) improve the method of (Hirao et al., 2013) by set-

[3] github.com/NLP-Discourse-SoochowU/t2d_discourseparser

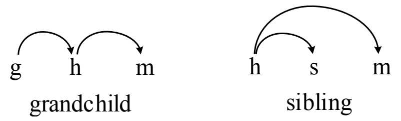

Figure 3: Diagram of grandchild and sibling structures.

ting constraints to restrict EDUs in a sentence for a single-rooted tree.

To our knowledge, all the abovementioned conversion methods are applied on the RST-DT corpus, while for the Chinese CDTB corpus, there are few related studies. Different from RST-DT, each sentence in the CDTB corpus occupies a complete sentence-level discourse tree. Under this circumstance, a discourse dependency structure that assigns each sentence with a single-rooted dependency tree is more appropriate for the CDTB corpus. Given this, we introduce a conversion method tailored for the Chinese corpus as follows:

- For each tree node $\mathcal{N}$, we take the head node of its leftmost **N**ucleus child as its head node (noted as H value); if no child is Nucleus, we take the head of the leftmost child as the head of $\mathcal{N}$.
- For each non-terminal node, if it maintains a multi-nucleus relation, we follow the principle of leftmost priority and treat the right child as a **S**atellite node.
- For each leaf node, we pick the nearest Satellite on the path from the leaf node to the root node and define the head of the Satellite node's parent as its head. If there exists no such Satellite node, the EDU is just the root of this dependency tree.

Following the above rules, the DCT structure shown in Figure 1 is finally converted into a complete dependency graph. As stated before, each sentence in the CDTB corpus corresponds to an independent sub-DCT. Similarly, using our method for conversion, each sentence, or more broadly, each sub-DCT, still yields a single-rooted sub-DDT in the converted structure, which vastly reduces the complexity of the resulting DDT structure.

4.2.2 Discourse Dependency Parsing

Concerning the dependency parsing module, we refer to (Ma et al., 2018) on parsing syntactical dependency based on a top-down neural architecture and view the EDUs in a text as words in a sentence. Unlike the parsing procedure in (Zhang et al., 2020) which employs pointer nets to select split points from top to down to build the DCT structure, DDT parsing utilizes the pointer nets to select EDUs directly. Therefore, the split point encoding phase is omitted during DDT parsing.

Having obtained the EDU representation vectors, $s_1, \ldots, s_n$, through the shared EDU encoder described before, we use the stack-pointer network with two kinds of subtree information (grandchild and sibling) integrated for discourse dependency parsing. The definitions of the grandchild and sibling structures are described as follows, and their diagrams are shown in Figure 3.

- **grandchild structure:** a pair of dependencies connected head-to-tail. For the modifier $\mathbf{m}$, the parent of its head $\mathbf{h}$ is noted as its grand node $\mathbf{g}$.
- **sibling structure:** a head word with two successive modifiers. For the modifier $\mathbf{m}$, the most recent child $\mathbf{s}$ of its head node $\mathbf{h}$ is noted as its sibling.

Figure 4 illustrates partial of the decoding procedure. At the very beginning of the parsing process, the stack only contains the root node. For the convenience of calculation, we set a virtual root node $ pointing to the first node of the dependency tree, and its representation is zero-initialized. At each step of decoding, we pop out the top element of the stack, noted as e_h, and lookup for its sibling node e_s and grandparent node e_g from the converted DDT structure, then the input of decoder is created by summing up the representation vectors of them, as shown in Equation 1. If there exists no sibling or grandparent of e_h, the value of s_s or s_g will be assigned with zero vectors.

$$S_t = s_h + s_s + s_g \tag{1}$$

We use a uni-directional RNN as the decoder. At each time step t, it receives the structure information S_t as input and outputs the hidden vector noted by h_t. Then, the biaffine attention mechanism is utilized to calculate the probability score e_i^t of each EDU as the dependence of the current unit. Equations 2-4 show the details, where $\mathbf{w}$, $\mathbf{u}$, $\mathbf{v}$ and $\mathbf{b}$ are parameters, denoting the attention weight of the bi-linear term, the two linear terms, and the bias term, respectively. It is worth noting that before attention calculation, we let h_t and s_i go through a one-layer perceptron with elu activation function for dimension reduction to reduce the risk of overfitting. We choose the most probable EDU e_c as the

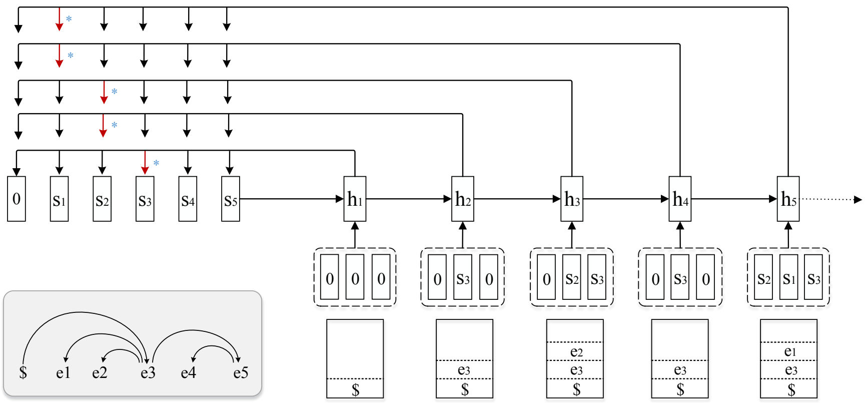

Figure 4: The decoding architecture used for discourse dependency parsing.

dependence of e_h, thus one dependency arc is obtained, (e_h, e_c). Then we push the newly selected element e_c onto the stack for the following steps. Moreover, a self-directed dependency arc will appear when c equals h. In this case, all the children of the head node e_h have been successfully found. Then we pop e_h out of the stack and go into the next parsing period. The parsing process will be terminated when the stack becomes empty.

$$s'_i = \mathrm{elu}\left(\mathrm{w}_1 s_i + \mathrm{b}_1\right) \tag{2}$$

$$h'_t = \mathrm{elu}\left(\mathrm{w}_2 h_t + \mathrm{b}_2\right) \tag{3}$$

$$e_i^t = {h'_t}^{\mathrm{T}} \mathbf{w} s'_i + \mathbf{u}^{\mathrm{T}} h'_t + \mathbf{v}^{\mathrm{T}} s'_i + \mathbf{b} \tag{4}$$

Considering that one head node may have multiple child nodes, we follow the inside-out strategy to order the child nodes according to the distances between these nodes and the head node, the left side first and then the right side, which ensures that the parsing path is unique. Taking the instance in Figure 4 for example, the ordered parsing path is $\{(\$, e_3), (e_3, e_2), (e_3, e_1), (e_3, e_5), (e_5, e_4)\}$.

4.3 Model Training

Our training objective is composed of two parts, i.e., jointly minimizing the discourse constituency parsing loss and the discourse dependency parsing loss. Since both tasks can be recognized as multi-step classification problems, we employ the negative log-likelihood (NLL) loss to calculate and optimize the two loss terms.

On the one hand, for discourse constituency parsing, we need to identify three parts, including the bare tree structure, the rhetorical relation, and the nuclearity category. Therefore, the loss function consists of three parts, i.e., split point prediction loss L_s, relation prediction loss L_r, and nuclearity prediction loss L_n. Supposing that the correct index of the gold standard split point at the t-th step is i, the value of L_s is calculated as follows:

$$L_s = \sum\nolimits_{steps} - \log\left(\hat{p}_t^s \mid \theta\right) \tag{5}$$

$$\hat{p}_t^s = \frac{a_{t,i}^s}{\sum a_t^s} \tag{6}$$

where a_t^s denotes the probability distribution of split points at the current time step and $\hat{p}_t^s$ denotes the probability of selecting the i-th one as the predicted split point. The calculation of L_r and L_n is similar to that of L_s. In consideration of the different convergence rates of the three loss terms, we obtain the overall discourse rhetorical structure parsing loss through weighted summation:

$$L_c = \alpha_s L_s + \alpha_n L_n + \alpha_r L_r \tag{7}$$

On the other hand, the discourse dependency tree is essentially converted from the original discourse constituency tree according to the nuclearity property while ignoring the internal relations. So we only need to consider the correctness of dependency arcs. The calculation of discourse dependency parsing loss L_d is similar to that of split point prediction in DCT parsing. Finally, we merge the weighted dependency loss to the original constituency loss, and the final optimization objective is formalized as follows:

$$L = L_c + \alpha_d L_d \tag{8}$$

5 Experimentation

This section systematically evaluates our top-down discourse parser and primarily focuses on the impact of the dependency information on DCT parsing. We merely focus on the performance of the main task of DCT parsing, while the auxiliary DDT parsing task only works for representation enhancement. Therefore, we do not discuss the performance of DDT parsing in the following parts.

5.1 Experimental Settings

Datasets. In this paper, we employ the Chinese connective-driven discourse treebank (CDTB[4]) (Li et al., 2014c) as the benchmark data set. The corpus consists of 500 newswire articles, divided into 2336 paragraphs, and each paragraph yields an independent CDT tree. Following (Zhang et al., 2020), we divide the corpus into three parts, i.e., 425 training documents containing 2002 discourse trees and 6967 rhetorical relations, 25 development documents containing 105 discourse trees and 396 relations, and 50 test documents containing 229 discourse trees and 993 relations.

Evaluation metrics. The metrics of discourse parsing evaluation include bare tree structure referred to as span (**S**), tree structure with nuclearity (**N**) indication, and tree structure with relation (**R**) indication. We use Full (**F**) to evaluate the overall tree structure with both nuclearity and relation considered. For a fair comparison, same as Zhang et al. (2020), we adopt the original Parseval procedure to evaluate the performance of our parser and report the micro-averaged F1 scores as our parsing performance. Following previous work, we evaluate our system with gold EDU segmentation and binarize those non-binary subtrees with right-branching (Sagae and Lavie, 2005).

Hyper-parameters. For hyper-parameters, we keep consistency with (Zhang et al., 2020) in the shared EDU encoder, the split point encoder, and the DCT parsing module. While for the DDT parsing module, we set the size of hidden states after dimension reduction to 64 and the weight α_d in the joint loss objective to 2. For other hyper-parameter details, please refer to (Zhang et al., 2020).

Systems	S	N	R	F
Sun and Kong (2018)*	84.8	55.8	52.1	47.7
Zhang et al. (2020)*	85.2	57.3	53.3	45.7
Ours (Joint)	**86.4**	**60.5**	**54.3**	**49.5**

5.2 Experimental Results

In this part, we compare our system with two previous state-of-the-art (SoTA) systems on CDTB using the same evaluation metrics.

- Sun and Kong (2018): a transition-based system that parses the discourse rhetorical structure in a bottom-up way.
- Zhang et al. (2020): a top-down text-level discourse parser based on the pointer networks. In this paper, our system directly inherits from their system on DCT parsing. Therefore, we take their implemented system as our baseline.

Table 1 presents the performances of our method and the two previous SoTA systems. The results show that our joint model significantly outperforms the two SoTA systems on all four indicators. In comparison with the bottom-up parser of Sun and Kong (2018), the top-down approaches (the parser of Zhang et al. (2020) and ours) show better performance, on the whole, benefiting from global information. In addition, with the help of dependency information, our joint model achieves the gains of 1.2, 3.2, 1.0, and 3.8 on the four evaluation indicators, respectively, when compared with (Zhang et al., 2020). Moreover, to our knowledge, the top-down parser of Zhang et al. (2020) shows terrible performance on the Full metric because of using three independent classifiers for span, nuclearity, and relation classification. With the global

[4] It should be noted that our proposed approach is language-independent. Although previous studies on the English RST-DT corpus (Carlson and Marcu, 2001) are much more affluent, the corpus is not well suited to validate our approach. The RST-DT corpus consists of 385 documents, and each document is represented as a single DT. According to our statistics, the heights of trees in the corpus range from 1 to 26. No matter for training or testing, there are too few instances. In addition, the quality of the high-level annotation is not good, which may lead to poor performance of the converted dependency tree. Considering the abovementioned quality and quantity issues, we only conduct experiments on the CDTB corpus.

dependency graph harnessed for representation enhancement, our parser can significantly make up for this problem.

As mentioned before, we aim at improving the parsing performance of the upper-level discourse tree nodes in this work. Here, we further count the correctly identified nodes over different DT levels, and the results are shown in Table 2. Comparing the statistical results of the baseline system (Zhang et al., 2020) and ours, we find that

- Our joint model performs better than the baseline system at most levels. Among the three aspects, the improvement on nuclearity is significant, and that on bare tree structure is the weakest;

- When the height is larger than 5, our joint model performs much better in nuclearity and relation identification. This also contributes to the improvements on the Full metric;

- When the height is equal to or greater than 8, our joint model fulfills the zero breakthroughs in nuclearity, relation, and Full identification.

Same as Zhang et al. (2020), we also divide the discourse trees into six groups by EDU number and evaluate our joint model over different groups. From the results in Table 3 we find that

- On the structure indicator, except for the case with EDU number larger than 25, the contribution of dependency information is not apparent;

- On the nuclearity indicator, in most cases, our joint model performs better. For the case when the EDU number is larger than 25, the improvement is very significant;

- On the relation indicator, our joint model is equal to or better than the baseline system in all groups of discourse trees.

In addition to how many EDUs a tree contains, the tree height is another perspective to measure the complexity of tree structures. Thus we further divide the DTs into different groups according to their heights and evaluate our model over different tree groups using a macro-averaged evaluation, i.e., calculating the F1 score for each DT solely and reporting the averaged F1 score in the test set. The results in Table 4 show that the contribution to structure building varies over different heights. For nuclearity and relation detection, our joint model performs better than the baseline system in most cases.

EDU	S		N		R	
Num.	Base	Joint	Base	Joint	Base	Joint
1-5	97.7	96.7	67.1	64.8	56.6	57.0
6-10	86.0	88.5	57.3	63.2	59.9	60.5
11-15	75.2	74.9	50.3	55.9	41.4	43.3
16-20	56.2	56.2	25.0	37.5	25.0	25.0
21-25	76.6	73.5	57.7	51.6	40.8	45.5
26-30	69.2	76.9	42.3	50.0	19.2	19.2

	S		N		R	
Height	Base	Joint	Base	Joint	Base	Joint
1	100	100	66.7	64.9	56.1	56.1
2	94.8	94.8	77.3	70.8	61.8	62.8
3	90.8	91.5	55.7	59.2	54.0	54.4
4	84.6	88.3	56.9	62.7	58.3	59.3
5	84.2	84.5	50.9	54.8	56.2	59.0
6	81.8	76.8	50.1	44.6	46.1	38.7
7	82.9	87.3	62.8	67.8	55.9	61.2
$\geqslant 8$	72.0	70.5	55.0	60.5	42.3	40.0

Table 4: Performance over different DT heights.

As described in Subsection 4.2.1, during the acquisition of DDT structures, we only consider the bare structure and nuclearity of each constituency tree. So the incorporation of dependency information can reasonably improve the performance of tree structure and nuclearity detection. Curiously, how can the discourse dependencies improve the performance of relation prediction? To figure it out, we give a further analysis in the following part.

5.3 Further Analysis

A certain number of cases have shown that the dependency arcs between long-distance EDUs may provide practical and explicit clues for predicting the rhetorical relation between the upper tree nodes. Here, we use an example in Figure 5 to analyze the effects of RST dependencies on rhetorical relation prediction.

Figure (a) shows the gold standard DCT and DDT structures of the paragraph consisting of eight EDUs. In the DCT structure, the relation “Cause” shown in the red rectangle is associated with two sub-trees, i.e., the left sub-tree with EDUs from e2 to e4 and the right sub-tree with EDUs from e5 to e8. From the corresponding DDT structure, we can find that the two sub-DCTs also correspond to two independent single-rooted sub-DDTs, respectively, where the head EDU of the left sub-DDT is e3, and

(b) DCTs predicted by the baseline system and our joint model.

Figure 5: Case study of the impact of DDTs on discourse rhetorical relation prediction.

the head EDU of the right sub-DDT is e5. Between the two sub-DDTs, an explicit arc pointing from e5 to e3 connects the two parts, which strongly suggests that there should be some relation between the two parts. Looking into the two head EDUs, e3 expresses that “it is difficult to form a pillar industry”, and e5 says that “Therefore, the province has made it clear that automobile manufacturing is no longer a pillar industry”. Obviously, the connective “因此 / therefore” in e5 is crucial in determining the “Cause” relation. This example indicates that the DDT structure will build a unique arc between two adjacent sub-DDTs (sub-DCTs), and their respective head EDUs may provide valuable clues for the upper-level sub-DCTs to determine the rhetorical relation between them. This result explains our performance improvement in relation prediction.

6 Conclusion

This paper contributes a multi-task learning architecture that jointly learns discourse-level constituency and dependency parsing through one shared encoder and two independent decoding modules. Moreover, we introduce a constituency-to-dependency conversion method tailored for the Chinese corpus to ensure the quality of the joint learning process. The experimental results on the CDTB corpus show that the discourse dependency information is efficient in improving the performance of discourse constituency parsing on all metrics, especially for the upper-level tree layers.

The results of this paper show that the use of textual knowledge such as rhetorical dependencies can effectively improve the machine's understanding of discourse parsing. Inspired by this, in our future work, we will explore the use of meta-learning techniques to learn the knowledge of dependencies such as reference chains and topic chains to achieve the ability to parse various discourse dependency structures including the rhetorical dependencies.

Abstract

We aim to develop methods for understanding how multimedia news exposure can affect people's emotional responses, and we especially focus on news content related to gun violence, a very important yet polarizing issue in the U.S. We created the dataset NEmo$^+$ by significantly extending the U.S. gun violence news-to-emotions dataset, BU-NEmo, from 320 to 1,297 news headline and lead image pairings and collecting 38,910 annotations in a large crowdsourcing experiment. In curating the NEmo$^+$ dataset, we developed methods to identify news items that will trigger similar versus divergent emotional responses. For news items that trigger similar emotional responses, we compiled them into the NEmo$^+$-Consensus dataset. We benchmark models on this dataset that predict a person's *dominant* emotional response toward the target news item (single-label prediction). On the full NEmo$^+$ dataset, containing news items that would lead to both differing and similar emotional responses, we also benchmark models for the novel task of predicting the *distribution* of evoked emotional responses in humans when presented with multi-modal news content. Our single-label and multi-label prediction models outperform baselines by large margins across several metrics.

1 Introduction

Understanding how exposure to certain textual and visual news affects people's emotional reactions is important for detecting, educating, and correcting intentional or unintentional emotional manipulation of readers. As a step towards detecting such manipulations and raising news consumers' visual literacy, in this work we develop methods for predicting emotional responses towards news headlines and images. To the best of our knowledge, machine learning tools that predict how a reader will react emotionally to a certain news headline, choice of a lead image, or combination of both do not exist. In this paper, we introduce tools that enable such prediction and thus can shed light on effects of news presentation, which is important to both editors and consumers of news.

The dataset we utilize in this work has been developed in phases. It first started with the headlines of news articles in the Gun Violence Frame Corpus (GVFC) (Liu et al., 2019), along with corresponding lead images of these articles (Tourni et al., 2021). A previous study started a crowd-sourcing experiment to collect emotional response annotations to the news headlines and images, producing the BU-NEmo dataset (Reardon et al., 2022). In this work, we extend the above emotional response experiment significantly. We utilize our new expanded dataset, named NEmo$^+$, and present the first benchmark of models to predict the evoked emotional responses in news consumers when presented with multi-modal news content.

2 Related Works

2.1 Predicting Emotional Responses to Text

Sentiment analysis is the task of detecting positive vs. negative sentiment expressed by text. The previous works on text-based emotion prediction have mostly focused on binary classification of positive versus negative emotions (Jiang et al., 2011; Wang et al., 2018). In our work, we aim to predict which category of emotions, from multiple choices, a text will elicit, a task for which there is limited prior work. Ahmad et al. (2020) focus on multi-class emotion state classification in poetry and Vasava et al. (2022) aimed to predict the type of emotion in essays written in response to newspaper articles. While Vasava et al. (2022) classified each essay into one of six basic emotions (Ekman and Friesen, 1971), we use the eight emotions from the prominent psychological study by Mikels et al. (2005) as our categories. The major difference between our work and that of Vasava et al. (2022) is that the essays used in their study already con-

Proceedings of the 2nd Conference of the Asia-Pacific Chapter of the Association for Computational Linguistics and the 12th International Joint Conference on Natural Language Processing (Volume 1: Long Papers), pages 364–374
November 20–23, 2022. ©2022 Association for Computational Linguistics

tain readers' sentiments on the newspaper articles. We present the novel task of directly predicting the emotional reactions of readers to news headline text, without such essays. The recent study of Gabriel et al. (2022) involves modeling how readers react to news headlines. Their work however, focuses on free-text explanations of readers' reactions and ordinal estimates of likelihood of spread and identification of real vs fake news headlines. By contrast, our dataset contains categorical emotional labels in order to predict the emotional responses. Gambino and Calvo (2019)'s study is closely relevant to ours as they also focused on the novel task of predicting the evoked emotion rather than the previous research of identifying the presence or absence of an emotion. They collected a group of news articles and their associated tweet responses and annotated the emotions expressed in them. They are predicting the evoked emotions towards the whole news article and we are using only the headline as we aim to explore how specific choices of the headline text by the news editors affect the emotion reactions.

2.2 Predicting Emotional Responses to Images

Recent computer vision work has focused on building models to recognize the emotional state of specific persons in images (Li et al., 2021; Zhang and Xu, 2022), rather than the emotional state that images can elicit in humans. There is very limited work on predicting these reactions to visual data (Machajdik and Hanbury, 2010; You et al., 2016; Achlioptas et al., 2021). The most relevant of these works is the ArtEmis dataset (Achlioptas et al., 2021), which contains more than 80k art-related images with annotations of (1) emotional reactions of crowdworkers towards images and (2) their free-flowing English textual explanations of how and why they felt a certain way. Studies with ArtEmis predict (1) by analyzing (2), a task far simpler than ours since their model input is an explanation of an emotion that the model then learns to extract. In our task, emotional reactions must be predicted from the original news headlines and images.

2.3 Predicting Emotional Responses to Multi-modal Content

Multi-modal models have gained success in predicting and understanding emotions by combining audio, textual, and visual data (Busso et al., 2008; Poria et al., 2019; Dudzik et al., 2020). Most of the previous multi-modal models for emotional prediction focused on combining elements that are homologous in nature. For example, the MELD dataset (Poria et al., 2019) predicts emotions using multiple modalities (audio, textual, and visual), which were all part of the same video source. The BU-NEmo dataset created by Reardon et al. (2022) is novel in that the modalities (news headline and image) were separate in nature and chosen to be presented together by the news publishers. We significantly extended this dataset to create the NEmo$^+$ dataset in order to have enough training data for multi-modal models. Multi-modal learning on the NEmo$^+$ dataset can give us an idea of the likely emotional reactions evoked by a specific combination of inputs from multiple modalities (news headlines and images).

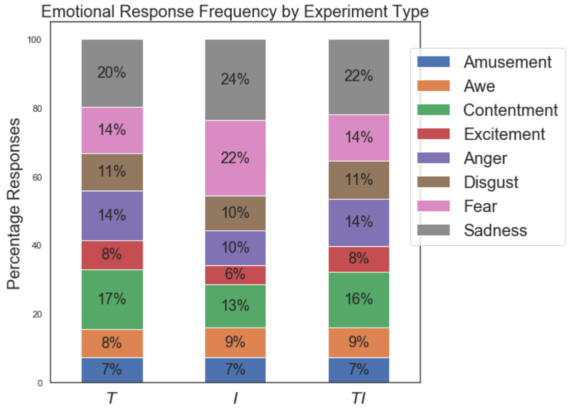

Figure 1: Distributions of emotional responses in the NEmo$^+$ dataset by experimental condition (*T*, *I*, *TI*). Evidently, given the nature of gun violence news, the annotated emotions are imbalanced and have an inclination towards negative emotions like sadness and fear.

There are limited datasets available for pretraining our models for both text-to-emotion and image-to-emotion prediction. Most of the datasets mentioned above use different sets of emotional labels than in our NEmo$^+$ dataset. ArtEmis (Achlioptas et al., 2021) provides the same 8 emotional labels as ours in addition to a 9th "something else," so we used ArtEmis to pre-train some of our models.

3 Data

3.1 Dataset Collection

BU-NEmo (Reardon et al., 2022) previously extended the work of the Gun Violence Frame Corpus (GVFC) (Liu et al., 2019; Guo et al., 2021) which applied frame detection on gun violence related news headlines, and created 1,300 news headline and image pairings. Reardon et al. (2022) initially annotated the news items in GVFC with emotional responses by workers from Amazon Mechanical Turk (MTurk) with annotators of at least high school qualification. A significant portion of the annotations contained spam in the free flow written text making the quality of the categorical emotional responses questionable. This spamming on MTurk is consistent with other findings of MTurk's low annotation quality (Rashtchian et al., 2010). Due to this limitation, we decided to implement a survey website (hosted on AWS) with the same survey content and interface to the study of Reardon et al. (2022) to collect the annotations for this study. We awarded course credits to anonymous student participants from the College of Communication and the Computer Science Department at Boston University through an internal annotation collection system managed by the university. We received high quality responses.

For our data collection, we followed the same pipeline as the BU-NEmo study (Reardon et al., 2022). Our pool of annotators consisted of undergraduate and graduate university students. The BU-NEmo dataset contained 320 news items with 10,547 annotations. Our NEmo^{+} dataset is significantly expanded, by adding 977 news items and 28,363 annotations to the original dataset. For each news sample, there are three experimental conditions: presenting only the headline text to the annotator (condition *T*), only the lead image (condition *I*), or the headline and image together (condition *TI*). For each experimental condition, we obtained 10 annotations per sample with each providing: the dominant emotion that the annotator feels among eight emotional categories (Amusement, Awe, Contentment, Excitement, Fear, Sadness, Anger, and Disgust), the intensity of the emotion on a scale of 1–5, and a free-flow English written text describing why the annotator feels that emotion. The overall distributions of responses across the eight emotions in NEmo^{+} are shown in Figure 1.

3.2 Prediction Difficulties in NEmo^{+}

We identified some interesting properties in the dataset that make it challenging to predict a single emotional response, which we discuss in detail below. These are intrinsic to the nature of the dataset and are not limitations of the machine learning models benchmarked in this study.

3.2.1 Limited Context Carried in Images

Some of the news images or headlines do not carry much context on their own, like the example shown in Figure 2. This image provides no clear indication of the identity of the person in the image nor the content of her speech, while the corresponding headline gives more context into the original news content. As we can observe from the viewers' free-flow responses when presented with only the image (*I* condition), their reported dominant emotions depend largely on speculations. The sample image elicits no negative emotions like sadness, which is present in both the *T* and *TI* conditions. In such news items, the headline text is essential in helping viewers form holistic emotional impressions.

Emma Gonzalez Brought to Tears Honoring Victims of Gun Violence	
Response Samples	
T	1. "gun violence is such a serious issue " - **Sadness** 2. "it is sad to know the lost of someone" - **Sadness** 3. "she is compassionate" - **Contentment** 4. "I have never been through situation like her but I can imagine how sad it feels" - **Awe**
I	1. "The person may talks about something about anti gun activity." - **Contentment** 2. "I think this woman looks full of energy, and she is able to do something to change the situation we face now." - **Amusement** 3. "this person belongs to the LGBTQ community and is likely to be pro gun controls" - **Excitement** 4. "I really respect her work as an activist" - **Awe**
TI	1. "This girl looks so young and honoring victims of gun violence is sad" - **Sadness** 2. "victims should be remembered" - **Sadness** 3. "I respect what Emma Gonzalez did and admire her courage to speak for Victims of Gun Violence." - **Awe** 4. "because the young women in the picture must have spoken about people who were killed by guns in a way that moved the audience deeply, according to the headline" - **Awe**

Figure 2: News sample among the 1,297 data points in NEmo^{+} with samples of the corresponding emotional responses. The image does not provide enough context of the news.

3.2.2 Emotional Diversity

Another interesting property we observed is that many news items evoke a diverse set of emotional reactions. In the example in Figure 3, annotators have differing emotional reactions towards a given news sample, when presented with the image and headline separately or together. Even positive emotions (Excitement, Awe, Contentment, Amusement) can vary significantly as shown in the example. Moreover, as can be observed from the *T* condition, while written responses suggest annotators agree in a sense, some viewers express negative emotions like anger instead of positive emotions, as they feel that the younger generation should not have to fight for safety.

3.3 Dataset Curation

For the rest of the discussion, let n_{labels} be the number of emotional response types that serve as labels for a news sample and m the number of people that

	Example 2
	Teenagers will lead the charge and demand change at anti-gun violence March for Our Lives
	Response Samples
T	1. "it talks of change " - **Excitement** 2. "teenagers are not supposed to be ones pushing anti-gun-violence, but they are now because the issues are threatening their safety." - **Awe** 3. "Someone is doing something, but I wish it didn't have to be children " - **Contentment** 4. "it shouldnt be the students fighting for their safety, it should be their government, parents and schools" - **Anger**
I	1. "I feel people's emotion toward the gun violence in a passion way." - **Amusement** 2. "It's good to see the young generation standing up against possession of arms" - **Contentment** 3. "I respect these people. They try their best to change the world we face." - **Awe** 4. "young people are speaking up against easy accessibility to gun in the country" - **Excitement**
TI	1. "teenagers are brave" - **Amusement** 2. "This campaign is for the good thing" - **Excitement** 3. "Because This creates awareness about a serious issue. " - **Contentment** 4. "the young women in the image are activists against gun violence. " - **Excitement**

Figure 3: News sample among the 1297 data points in NEmo$^+$ with varying emotional response samples in all conditions.

annotate each news sample. We define $\mathbf{v} \in \mathbb{N}^{n_{\text{labels}}}$ to be the frequency annotation vector of a sample, and the entry $v_i \in \{0, \dots, m\}$ describes how many annotators experienced the emotion expressed by the i-th label. To curate the NEmo$^+$ dataset for our purposes, we process $n_{\text{labels}} = 8$ possible emotional responses (amusement, awe, contentment, excitement, fear, sadness, anger, disgust); in this order, of $m = 10$ experiment participants. A frequency annotation vector of (0, 0, 1, 0, 0, 2, 0, 7), for example, means that 7 participants experienced the emotion 'disgust', 2 the emotion 'sadness', and one the emotion 'contentment'.

In Section 3.2, we observed that the 1,297 news data points of the NEmo$^+$ dataset elicited two types of responses: (1) noticeable emotional consensus in the annotations and (2) varying emotional responses with no clear inclination towards a single emotion. We design a subset of the NEmo$^+$ dataset, the NEmo$^+$-Consensus ("NEmo$^+$-C") dataset, that only includes news item with emotional consensus, removing those samples for which people had varying opinions. For this, we experimented with two different filtering methods, discussed below.

3.3.1 Filtering by Rank Diff: Nemo$^+$-CR

We defined the rank difference for a news sample to be the difference in frequency between the most frequent emotional response by the group of annotators and the second most frequent emotional response by the group. For the example frequency annotation vector described above, (0, 0, 1, 0, 0, 2, 0, 7), we sort the entries to yield {disgust: 7, sadness: 2, contentment: 1}. Then the rank difference is the frequency difference between the highest ranked emotion 'disgust' and the second highest emotion 'sadness,' which is 5. This approach is similar to the margin of confidence uncertainty used by Scheffer et al. (2001) as it also examines the difference between the highest and second highest items. In the rank filtering method, we process the NEmo$^+$ dataset to only keep news items that have a rank difference of greater than or equal to τ_{rank}. Any news sample, for which the rank difference of the frequency annotation vector lower than τ_{rank}, is removed. We call this filtered dataset Nemo$^+$-CR for "Consensus by Rank." We chose $\tau_{\text{rank}} = 3$ to balance having enough consensus in the total $m = 10$ annotations for a particular news sample and having enough data for training machine learning models. The size of Nemo$^+$-CR for $\tau_{\text{rank}} = 3$ is shown in Table 1.

Filter Method	*T*	*I*	*TI*
NEmo$^+$-CR	365	525	388
NEmo$^+$-CE	371	514	385
Intersection	199	366	200

Table 1: Filtered data size by filtering method (Rank Difference / Entropy) in all three conditions (*T*, *I*, *TI*). The third column (Intersection) shows the number of samples selected by both filtering methods. We can observe that the *I* condition is where people have the most emotional consensus in both filtering methods.

3.3.2 Filtering by Entropy: Nemo$^+$-CE

The frequency annotation vector can be considered a probability distribution of emotions. If the participants' emotional responses vary strongly for a news sample, we consider the response uncertain. If there is consensus among the participants, however, we consider the response certain. Since entropy is a measure of the uncertainty of a probability distribution, we can use it to filter the news items. We keep those news items with small entropy values, containing less uncertainty in the emotional distribution of the frequency annotation vector. This is similar in spirit to the rank difference filtering as both methods aim to select those news items that evoke strong emotional consensus. For a fair comparison, we selected the entropy filtering threshold so that the resulting filtered dataset is similar in size to the rank difference-filtered dataset. The size of the resulting filtered dataset Nemo$^+$-CE (Consensus by Entropy) is shown in Table 1.

4 Method

We benchmark machine learning models, described in detail in Section 5, for each of the three conditions (*T*, *I*, *TI*) to examine whether text or image when presented separately or together provide more context and help viewers form an emotional response towards particular news content.

4.1 Prediction on the Consensus Data

We performed single label-classification on NEmo$^+$-Consensus (Nemo$^+$-CR and Nemo$^+$-CE). As each news sample has $m = 10$ emotional annotations, we first need to create the single ground truth representative emotion for each news sample. The single representative emotion we use for prediction in the following discussions is simply the most frequent emotion in the m annotations.

4.1.1 Classification on Headline Text

For the T condition, our system aims to predict the single emotional label based on the headline text as the input. This becomes an n_{labels}-class classification task.

4.1.2 Classification on News Image

For the *I* condition, we developed two separate approaches. The first approach, intuitively, is to predict the emotional label based on the image data itself. However, due to the limited size of the Nemo$^+$-CR and Nemo$^+$-CE datasets, it is difficult for our system to extract meaningful features from 2-dimensional image data. Furthermore, the images in our dataset do not always provide enough context to the actual content of the news as discussed in Section 3.2.1.

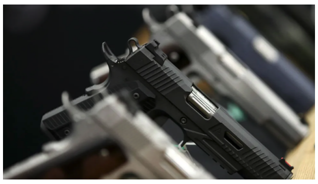

Figure 4: This news image has Web entity tags (concatenated): "Gun Concealed carry Firearm Weapon Gun safety Gun ownership Rifle Semi-automatic firearm Gun control Shooting" and image caption (automatically generated): "A student at the school in Hutsonville, Ill., last week."

In order to infuse some context into image data, we mapped images to text using the Google Web Entity Tagger API [1] that uses pre-trained models to quickly assign web entity tags and labels to our images (see Figure 4). These tags include textual context of the news that are not always available in the raw images. We also used another image-to-text conversion approach based on the automatic image captioning method by Tourni et al. (2021). After converting the images into textual data, we used the same pipeline as for text classification.

4.1.3 Classification on Image+Text

For condition *TI* where we are predicting the emotional response of the annotators when presented with both the headline text and the image, we used a multi-modal classification approach where the model learns from both the headline text and the news image to predict the emotional reactions.

4.2 Prediction on the Full NEmo$^+$ Data

One limitation of the single-label classification is the reduced dataset from the filtering of the dataset in order to select the dominant "consensus" emotion. The filtering methods mentioned above (rank difference and entropy filtering) aim to select news items that have strong emotional consensus and have a clear dominant emotion. However, most of the time people expressed diverse emotions. In fact, more than 60% of the data in all three conditions in our NEmo$^+$ fall into this category of having no clear consensus, as shown by the sizes of the filtered datasets in Table 1 (NEmo$^+$ contains 1,297 news items in total). Our approach to the dilemma of having limited consensus in our dataset is multi-label classification. For every news sample, we turned the frequency annotation vector $\mathbf{v}$ from the 10 annotations into a list of binary labels based on a fixed frequency threshold t. We set each entry $v_i \in \{0, \ldots, m\}$ of the frequency annotation vector $\mathbf{v}$ to 1 if $v_i \geq t$ and zero otherwise. For example, for a frequency threshold t of 2, we turned the frequency annotation vector [0, 0, 1, 0, 1, 2, 1, 6] into [0, 0, 0, 0, 0, 1, 0, 1].

5 Models

5.1 Text Models

Due to the recent success of Bidirectional Encoder Representations from Transformers (BERT) in the text classification task (González-Carvajal and Garrido-Merchán, 2020), we used BERT (Devlin et al., 2019) for the text classification machine learning models on our emotional consensus dataset. We also experimented with RoBERTa and

[1] https://cloud.google.com/vision/docs/detecting-web

observed similar results, so we chose to use the smaller, more efficient BERT model as the main text classification model for news headlines, image tags, and image captions.

Since our dataset is relatively small for training a deep neural network from the ground up, we explored the approach of whether learning from a related domain will be helpful. The ArtEmis dataset provides a foundation for training our baseline models as Achlioptas et al. (2021) used the same eight emotions as Mikels et al. (2005), in addition to a ninth emotion "something else." We removed all records containing the emotion "something else" in the ArtEmis dataset and used the remaining 401,722 data points to train a text-to-emotion baseline BERT model, and then fine tuned it with our consensus data: NEmo$^+$-Consensus (Nemo$^+$-CR and Nemo$^+$-CE). We refer to this model as A-BERT. We also directly fine tuned a BERT-base-uncased[2] model without pre-training with ArtEmis data for comparison[3].

5.2 Image Models

For predicting the emotional response on solely the image data in NEmo$^+$-Consensus, we followed the pipeline of the ArtEmis study (Achlioptas et al., 2021) and used a Resnet34 architecture with initial weights that have been pre-trained on the ImageNet dataset with 100,000+ images (Deng et al., 2009) and used the KL-divergence of the frequency annotation vector (from the annotations in the *I* condition) relative to the network output (normalized to a probability distribution) as the loss function.

The output of the model is a distribution of the likelihood of each emotion. We compared the maximum likelihood predicted emotion with the most frequent emotion in the ground truth to measure the performance of the single label prediction. We then fine tuned on the NEmo$^+$-Consensus dataset and refer to this model as A-ResNet. We also directly fined tuned an imageNet based Resnet model without pre-training with ArtEmis for comparison.

5.3 Multimodal Image and Text Model

For predicting the emotional response when the viewers are presented with both the headline text and the image in NEmo$^+$-Consensus (NEmo$^+$-CR and NEmo$^+$-CE), we fine tuned a BERT based multi-modal bitransformer model introduced by Kiela et al. (2019) using both the headlines and images.

We did not pre-train the multimodal models with ArtEmis because unlike NEmo$^+$, there is no single text (i.e., headline) for every image in ArtEmis. Instead, for each image in ArtEmis, there are multiple free flow text responses indicating various emotions. It is not straightforward to choose the "best" text to pair with an image for an indicated emotion as some free flow responses might be better at indicating emotions than others. We leave such exploration for future work.

5.4 Models for NEmo$^+$ with Diverse Emotions

Since the NEmo$^+$ dataset contains news data points where there is no emotional consensus, we performed multi-label text classification by fine tuning BERT for all three conditions. For condition *I*, we converted the image to textual data using the Google Web Entity Tagger API. For condition *TI*, we concatenated the tagger converted text with the original news headline text as the input to the multi-label model.

6 Evaluation Metrics

6.1 Single-label Classification

The main metric we used for single-label classification is accuracy in predicting the most frequently elicited emotion. Since there are $n_{\text{labels}} = 8$ classes, the expected classification accuracy based on a random guess, i.e., picking a class uniformly at random among all classes (independently for each sample) is given by $1/n_{\text{labels}} = 12.5\%$, a rudimentary baseline for accuracy. However, the NEmo$^+$-Consensus dataset is imbalanced towards negative emotions. Therefore, we also compared our models to the majority baselines (the percentage of the dominant emotion in the dataset) to take into account the imbalanced nature of the dataset. These are shown in Table 2. As can be seen in Table 2, rank difference filtering (Nemo$^+$-CR) provides a more consistent sample size with emotional consensus across all 3 conditions than entropy filtering.

6.2 Multi-label Classification

For multi-label prediction, we used Hamming distance (Sorower, 2010), exact match accuracy, and

[2] pre-trained with the weights of the Hugging Face bert-base-uncased model: huggingface.co/bert-base-uncased

[3] We also experimented with BERT-base-cased model, which is a case sensitive model, and it gave similar results to the uncased model. For the rest of the experiments, we continued using the uncased model.

Condition	Nemo$^+$-CR	Nemo$^+$-CE
T	41.76%	27.96%
I	41.98%	42.19%
TI	42.27%	37.5%

Table 2: Majority baselines of the NEmo$^+$-Consensus dataset (Nemo$^+$-CR and Nemo$^+$-CE) under each condition. The percentages shown correspond to the fractions of news samples labeled with the dominant emotion in each dataset-condition combination in the test set.

rank-based average precision (LRAP)[4] to evaluate each model's predictions.

7 Results

We split the datasets into train / validation / test sets in the ratio of 50%:25%:25% and all of experiment results are reported on the test set.

7.1 Single-label Prediction on Consensus Data

The test time performance of all of our single label prediction models on the data with emotional consensus (Nemo$^+$-CR and Nemo$^+$-CE) is shown in Table 3. BERT and A-BERT refer to the models with and without pre-training with the Artemis textual data as described in Section 5.1. ResNet and A-ResNet refer to the models with and without pre-training with the Artemis image data described in Section 5.2.

As shown in Table 3, all of the models we benchmarked outperform the majority baselines in Table 2. Our best model (A-BERT on Nemo$^+$-CR) surpasses the random baseline significantly by more than 55 percent-points and the majority baseline by 26 percent-points for the *I* condition. When only headlines are used (*T* condition) transfer learning from the ArtEmis textual data improves the accuracy in both consensus datasets. However, when only images are used (*I* condition), transfer learning from the ArtEmis image data improves accuracy only when images in Nemo$^+$ are converted to text. This may be due to intrinsic differences between ArtEmis and NEmo$^+$ images. Unlike art-centric images of ArtEmis that can intrinsically convey emotional meaning by themselves, images used in news articles may require additional context in the form of web-tagging or image-captioning to leave similar emotional impressions.

We observe that for the single-label prediction task, all the image-only models outperform text-only models as well as models for text combined with image in both filtered datasets. Moreover, Table 1 shows that there are more samples with above-threshold consensus for the *I* condition than for the *T* or *TI* conditions. From this, we hypothesize that lead images may be more likely to evoke similar and more-predictable emotional responses in multi-modal gun violence news.

Dataset:	Nemo$^+$-CR		Nemo$^+$-CE	
Model	**BERT**	**A-BERT**	**BERT**	**A-BERT**
T	56.0%	57.1%	46.2%	51.3%
Model	**ResNet**	**A-ResNet**	**ResNet**	**A-ResNet**
I	59.7 %	57.4%	63.2%	61.4%
Models	**BERT**	**A-BERT**	**BERT**	**A-BERT**
I-Tag	64.3%	68.2%	61.7%	60.9%
I-Caption	63.4%	63.4%	54.7%	53.9%
Model	**BERT**		**BERT**	
TI	53.6%		40.6%	

Table 3: Classification accuracies of predicting a person's emotional response on each filtered dataset for all single-label models. The accuracy of the random guessing benchmark is 12.5% and the majority baselines for each condition is shown in Table 2. *I*-Tag and *I*-Caption refer to models where the image data was converted into text using either the Google Web Entity Tagger API or the GVFC's automatic captioning. All results from this table are from the mode across 30 runs.

Somewhat surprisingly, the combined text with image *TI* models have the worst performance in both datasets and we discuss possible reasons for this in Section 8.

7.2 Multi-Label Prediction on NEmo$^+$

In our multi-label experiment, we controlled for the frequency threshold we used to convert the frequency annotation vectors into binary labels. The higher we set the frequency threshold to be, the easier the task would become, as the converted binary labels would be more sparse and the emotional distribution would be more concentrated.

For multi-label prediction, we are interested in data points with at least two positive binary labels. As shown in Table 4, the percentage of the training data with at least two positive labels decreases as we increase the frequency threshold for binary conversion. We observe that after a threshold of 3, the multi-label learning task becomes insignificant as the training data contains too few qualifying samples. Therefore, we focus on the frequency thresholds of 1, 2, and 3.

We simulated the random baselines by randomly choosing one of the $n_{\text{labels}} = 8$ emotions $m = 10$ times for each of the 1,297 news items and converting the random frequency annotation vector into a

[4] LRAP: https://scikit-learn.org/stable/modules/model_evaluation.html#label-ranking-average-precision

Threshold	*T*	*I*	*TI*
1	99.7%	96.6%	99.4%
2	92.8%	83.1%	89.9%
3	42.0%	33.9%	41.3%
4	5.6%	5.4%	5.5%
5	0.1%	0.4%	0.3%
6	0.0%	0.0%	0.0%
⋮	⋮	⋮	⋮
10	0.0%	0.0%	0.0%

Table 4: Percentage of the data points that contain at least two 1's after the conversion to binary labels using different frequency thresholds.

list of binary labels given a fixed frequency threshold, as described in Section 4.2. We then compared the random binary labels to the actual binary labels to compute the random baselines' multi-label performances.

As shown in Table 5, our models consistently outperform the simulated random benchmark in every condition (*T*, *I*, *TI*), at every threshold (1, 2, 3), and under every metric (higher exact match accuracy and LRAP scores and lower Hamming distance loss). Moreover, for every condition and every metric, the absolute performance *improvement* of our models over the random benchmark increases with threshold value and attains the highest improvement at threshold 3.

Thrshld	**Rand-Ham**	**Rand-EM**	**Rand-LRAP**
1	0.47	1.0%	0.59
2	0.46	0.9%	0.49
3	0.39	1.8%	0.42
Thrshld	***T*-Ham**	***T*-EM**	***T*-LRAP**
1	0.35	6.5%	0.81
2	0.26	7.4%	0.72
3	0.17	20.1%	0.67
Thrshld	***I*-Ham**	***I*-EM**	***I*-LRAP**
1	0.35	3.1%	0.78
2	0.26	13.0%	0.71
3	0.15	29.3%	0.69
Thrshld	***TI*-Ham**	***TI*-EM**	***TI*-LRAP**
1	0.35	5.9%	0.8
2	0.27	11.1%	0.7
3	0.16	21.9%	0.64

Table 5: Test-time Hamming distance (Ham) loss (smaller is better), exact match accuracy (EM) (larger is better), and LRAP score (larger is better) of the three conditions *T, I, TI* with different thresholds for the binary label conversion. The simulated random baselines are called Rand-Ham, Rand-EM, and Rand-LRAP. The results in this table are from a single run as we observed no significant fluctuations among different runs.

At threshold 3, compared to the random baseline, our model's Hamming distance loss is lower by 0.22, 0.24, and 0.23 points, exact match accuracy is higher by 18, 28, and 20 percent points, and LRAP score is higher by 0.25, 0.27, and 0.22 points, for the *T*, *I*, and *TI* conditions, respectively. In terms of absolute performance, with increasing threshold the Hamming distance and exact match metrics for *T, I*, and *TI* improve, but the LRAP metric becomes worse. As the threshold increases there are fewer examples with many labels (see Table 4). A smaller label space makes the classification task "simpler," but with fewer examples it becomes harder to generalize. Hamming distance and exact match seem to gain more from a reduced label space than they loose due to reduced sample size. The reverse seems to occur for LRAP.

8 Limitations & Future Work

There exist some limitations to our work. Firstly, the multi-modal classification model we benchmark in the *TI* condition has exhibited lower performance than in the *T* and *I* condition (Table 3). This aligns with findings of Wang et al. (2019) that different modalities generalize and fit at different rates and are prone to overfitting due to increased capacity. We also attribute the lower multi-modal prediction performance in the *TI* condition to the limited size of NEmo^{+}-Consensus. It is more difficult for the model to learn enough features from multiple modalities with that amount of data.

One limitation with our multi-label experiment is that the conversion to binary labels causes a loss in relative scale of information among the n_{labels} emotional categories. An alternative approach to this problem in future work could be to model the distribution of emotions for each news sample with a KL-Divergence loss instead.

In future work, we could also derive deeper insights by using the intensity scores we collected in Section 3.1 to predict the strength of emotional responses to news. Another future task is to predict whether a given news headline and/or image will elicit emotional consensus, or result in a divided response among readers. It will also be interesting to study the relationship between emotional responses and the framing of the news and to extend the task to multilingual setting (Akyürek et al., 2020). Finally, we are interested in making the benchmarked systems for predicting emotional responses to news accessible to researchers from a diverse array of disciplines (in similar fashion to the interactive computational framing website: OpenFraming (Bhatia et al., 2021; Guo et al., 2022)) so that researchers from various disciplines can conduct further studies on the potential benefits and risks of such system.

9 Conclusion

We have shown that we can effectively, to some degree, predict the emotional response to news headline and image using standard text- and vision- classification models. Our work is the novel attempt at benchmarking the task of predicting how exposure to certain textual and visual news affects people's emotional reactions. This task has wide implications for both news consumers and news professionals. Potential misuses are the possibilities that our tool can be intentionally used to predict and manipulate the emotional reactions of news consumers with specific choices of news headlines and images. However, news editors could aim to avoid sensationalizing their produced media content by using prediction systems like ours. This would be useful in situations where presentation of sensitive news topics (war crimes, terror, etc.) benefits from a more informed selection of image-to-text combinations that can convey important information over sensational, distracting content. Publishers and experts can use this tool to recognize and avoid emotionally-manipulative content. Social media platforms could also use insights on evoked emotion from media in order to predict whether a post is likely to be click-bait. Educators could also use our system for teaching visual media literacy.

10 Ethical Considerations

Our NEmo^{+} is crowdsourced from students through a U.S.-based university in the Northeast. Our dataset may contain certain political and sociocultural perspective skews given the narrow demographic. As we expand our dataset, we will incorporate annotators from diverse backgrounds while maintaining the annotation quality. We acknowledge that we have received permission to use the BU-NEmo dataset (Reardon et al., 2022), as their data is freely available for the purpose of academic research in our study. Regarding our annotation collection, we ensure we are not knowingly introducing bias to the data nor inflicting any emotional harm on participants or breaching their confidentiality, for which we have obtained IRB exemption approval. We also acknowledge that our use of the ArtEmis dataset is under ArtEmis Terms of Use[5] that we as researchers use the database only for non-commercial research purposes.

Abstract

Data augmentation techniques have been proven useful in many applications in NLP fields. Most augmentations are task-specific, and cannot be used as a general-purpose tool. In our work, we present AugCSE, a unified framework to utilize diverse sets of data augmentations to achieve a better, general purpose, sentence embedding model. Building upon the latest sentence embedding models, our approach uses a simple antagonistic discriminator that differentiates the augmentation types. With the finetuning objective borrowed from domain adaptation, we show that diverse augmentations, which often lead to conflicting contrastive signals, can be tamed to produce a better and more robust sentence representation. Our methods[1] achieve state-of-the-art results on downstream transfer tasks and perform competitively on semantic textual similarity tasks, using only unsupervised data.

1 Introduction

Data augmentation in NLP can be useful in many situations, from low resource data setting, domain adaptation (Wei et al., 2021), debiasing (Dinan et al., 2020), to improving generalization, robustness (Dhole et al., 2021). In the vision domain, Chen et al. (2020b) shows that a diverse set of augmentation can be used to learn a robust general-purpose representation with contrastive learning. Similar work in sentence embedding space (Gao et al. 2021; Chuang et al. 2022) has shown that a simple single augmentation such as dropouts from transformers (Devlin et al., 2019) can be used for contrastive objective. However, no previous work has thoroughly explored the impacts of a diverse set of augmentations with contrastive learning in the sentence embedding space. It is not straightforward to find the best augmentations that work for contrastive learning in different datasets or tasks (Gao et al., 2021). Single augmentation can instill invariance in models for a specific aspects of linguistic variability, while naively combining a diverse set of augmentations can lead to contradicting gradients, preventing models from generalizing well (Table 6)[2]. In this work, we present AugCSE (Figure 1), a general approach to select and unify a diverse set of augmentations for the purpose of building a general-purpose sentence embedding. During training, in addition to using contrastive loss, we randomly perturb sentences with different augmentations and use a discriminator loss to unify embeddings from diverse augmentations. In short, our work presents the following key contributions:

- We show simple data augmentation methods can be used to improve individual tasks, while degrading performance on other tasks (due to shifted domain distribution).
- We present our simple discriminator objective that achieves competitive results on sentence similarity task (STS) and transfer classification tasks against state-of-the-art methods.
- We demonstrate through ablation and visualization that our model can unify contrasting distribution from diverse augmentations and that simple rule-based augmentations are sufficient for achieving competitive results.

2 Background and Related Work

2.1 Contrastive learning

Contrastive learning is shown to provide a clear signal to improve the embedding space, which is crucial for downstream tasks. The goal of contrastive learning is to use similar or dis-similar datapoints to regularize the embedding representation, such that similar datapoints (by human, or pre-defined

[1] Our code and data can be found at https://github.com/PootieT/AugCSE

[2] Diverse augmentations have been shown to work without discriminator in vision (Chen et al., 2020b). We believe the difference resides in a much more structural distribution in natural language in comparison to images.

standards) are embedded closer than those datapoints that aren't similar. Recently, many works in vision use contrastive objectives to obtain SOTA performance on image tasks from classification, detection, to segmentation using ImageNet (Deng et al., 2009; Caron et al., 2018; Chen et al., 2020b; He et al., 2020; Caron et al., 2020; Grill et al., 2020; Zbontar et al., 2021; Chen and He, 2021; Bardes et al., 2022). Most similar to our work is SimCLR (Chen et al., 2020b), which uses a diverse set of augmentation as positive contrastive pairs. In SimCLR, however, the procedure to obtain the best performing augmentation distribution was not clearly documented. Further, no previous work has investigated whether such an idea would work in the language domain. Our work provides a parallel investigation in NLP, accessing the usefulness of diverse augmentations in improving sentence representations. We also propose methodical procedures and heuristics on how such set of augmentations can be obtained given an end task.

2.2 Sentence Embedding

Building a general purpose sentence embedding model is useful for many tasks (Wang et al., 2021a; Izacard et al., 2021; Gao and Callan, 2021; Gao et al., 2021; Chuang et al., 2022; Chang et al., 2021). SBERT (Reimers and Gurevych, 2019) pioneered the efforts to improve semantic similarities between sentence embeddings using a siamese network with BERT (Devlin et al., 2019). Finetuned with the natural language inference (NLI) dataset (Williams et al., 2018; Bowman et al., 2015), SBERT predicts whether a hypothesis sentence entails or contradicts the second sentence. To tackle anisotropicness of BERT embedding space (Ethayarajh, 2019), Li et al. (2020) and Su et al. (2021) learn projection layer which converts BERT embedding to a Gaussian or zero-mean fixed-variance space. Following contrastive learning literature in vision, few works investigate alternative positive and negatives: from using different layers (Zhang et al., 2020), different models (Carlsson et al., 2020), against frozen model (Carlsson et al., 2020), different parts of document (Giorgi et al., 2021), to next sentences (Neelakantan et al., 2022).

With simplicity in mind, unsupervised SimCSE (Gao et al., 2021) uses the same sentence with independent dropouts from transformers as positives and the rest of in-batch sentences as negatives, while supervised SimCSE uses NLI entailment sentence as positives, and contradiction as negatives. Lastly, the state-of-the-art method, DiffCSE (Chuang et al., 2022), proposes to add an additional discriminative loss similar to ones used in ELECTRA (Clark et al., 2019): the replaced token detection (RTD) loss to additionally increase the performance. The discriminator uses the original sentence embedding and a contextually perturbed sentence embedding to predict the token locations in which the two sentences differ. In contrast to DiffCSE, our discriminator predicts the augmentation type, a higher level task than predicting individual tokens. Additionally, our discriminator is in an antagonistic/adversarial relationship to our model, whereas the ELECTRA-like RTD objective is collaborative in nature.

2.3 NLP Augmentations

NLP augmentations are in more or less three flavors. Rule-based augmentations range from randomly deleting words, swap word orders (Wei and Zou, 2019), to more structurally-sounds, or semantically specific ones (Zhang et al., 2015; Logeswaran et al., 2018). These simple augmentations, however, have been found to be not particularly effective in higher resource domain for task-agnostic purposes (Longpre et al., 2020; Gao et al., 2021). The second kind of augmentations use pretrained language models (LM), to generate semantically similar examples. This area of work includes, but is not limited to back-translation (Li and Specia, 2019; Sugiyama and Yoshinaga, 2019), paraphrase models (Li et al., 2019, 2018; Iyyer et al., 2018), style transfer models (Fu et al., 2018; Krishna et al., 2020), contextually perturbed models (Morris et al., 2020; Jin et al., 2020), to large LM-base augmentation (Kumar et al., 2020; Yoo et al., 2021). Lastly, a few methods generate augmentations in the embedding space. These methods often perform interpolation (DeVries and Taylor, 2017; Chen et al., 2020a), noising (Kurata et al., 2016), and autoencoding (Schwartz et al., 2018; Kumar et al., 2019b) with embedded data points. However, due to the discreteness of NL (Bowman et al., 2016) and anisotropy (Ethayarajh, 2019), the introduced noise often outweighs the benefit of additional data.

Recently, NL-Augmenter (Dhole et al., 2021) collected over 100 augmentation methods, with the intention to provide robustness diagnostics for NLP models against different type of data perturbations[3]. In our work, we show that a diverse set of augmentations, even with simple rule-based augmentations, which are cheaper and more controllable than LM-based augmentations, can be used to learn robust general-purpose sentence embedding.

3 Motivation

3.1 Single augmentation is task specific

Augmentations, especially ones that exploit surface level semantics using simple rules, are task specific and have been used alone only if the augmentation aligns with the task objective for the dataset (Longpre et al., 2020). For instance, Dinan et al. (2020) changes gendered words in a sentence to instill gender invariance for bias mitigation. Inspired by hard negative augmentations in contrastive learning (Gao et al., 2021; Sinha et al., 2020), we use the following case studies to reinforce the conclusion from the perspective of negative data augmentation. In both scenarios, we use the negative augmentations ($\mathbf{h}_i^-$) loss (with positive examples $\mathbf{h}_i^+$) for contrastive objective (Gao et al., 2021):

$$-\log \frac{e^{\mathrm{sim}(\mathbf{h}_i, \mathbf{h}_i^+)/\tau}}{\sum_{j=1}^{N} e^{\mathrm{sim}(\mathbf{h}_i, \mathbf{h}_i^+)/\tau} + e^{\mathrm{sim}(\mathbf{h}_i, \mathbf{h}_i^-)/\tau}} \quad (1)$$

where sim is cosine similarity, τ is the temperature parameter controlling for the contrastive strength, and N is batch size. Since some augmentations do not have 100% perturbation rate, we remove datapoints that do not have a successful negative augmentation. For the remaining datapoints, we use original sentences as positives, and train with different augmentations as the negatives. In addition, we also present average transfer tasks (Conneau and Kiela, 2018) performance as a metric for embedding quality (**trans.**, detailed in Sec 5).

Augmentation	**CoLA**	**trans.**
BERT$_{\text{base}}$	75.93	84.66
Unsupervised SimCSE$_{\text{BERT}}$	71.91	**85.81**

AntonymSubstitute	**58.78**	79.93
SentenceAdjectivesAntonymsSwitch	58.63	80.11

Table 1: Top negative augmentations for CoLA and ANLI, both measured in accuracy, with average transfer performance. See augmentation description in A.2

Case study 1: linguistic acceptability We first test embedding performance on CoLA (Warstadt et al., 2018), a binary sentence classification task predicting linguistically acceptability. If an augmentation frequently introduces grammatical errors, it should perform well as a negative.

Case study 2: contradiction vs. entailment Natural language inference (NLI) datasets (Bowman et al., 2015; Williams et al., 2018) provide triplets of sentences: an hypothesis, a sentence entailing, and a sentence in contradiction to the hypothesis. A good embedding should place the entailment sentence closer to the hypothesis than the contradiction sentence, and in fact, that is the exact hypothesis exploited by supervised SimCSE. We calculate the similarity between hypothesis and an entailment sentence and similarity between hypothesis and a contradiction sentence, and count how often is the former larger than the later in ANLI (Nie et al., 2020). If an augmentation can reverse the semantics of sentences, then it should perform well as a negative.

Insight: As expected (Table 1), augmentations known to introduce a lot of grammatical mistakes: RandomContextualWordAugmentation (Zang et al., 2020) performs the best in **CoLA** and those that reverse semantics: AntonymSubstitute, and SentenceAdjectivesAntonymsSwitch performs well in **ANLI**. However, single augmenta-

tion significantly under-performs in **trans**fer tasks, reducing robustness. This suggests the need for diverse augmentations (Chen et al., 2020b; Ren et al., 2021).

3.2 Difficulty of selecting contrastive pairs

Gao et al. (2021) experimented with a combination of MNLI (Williams et al., 2018) and SNLI (Bowman et al., 2015) and found that using entailment as positives and contradictions as negatives performs well. In addition to this setting, we performed additional ablations to show that it is usually unclear which sentence pair dataset or augmentation would provide the best result as contrastive pairs (Table 2). Sometimes, non-intuitive pairs could yield decent results[4]. Together with the specificity of individual augmentations, this motivates for a general framework to select and combine multiple augmentations to achieve a robust, general-purpose embedding.

4 Methods

4.1 Augmentation Selection

Dhole et al. (2021) introduced 100+ augmentation methods. We also added non-duplicating augmentation methods from popular repositories: nlpaug, checklist, TextAugment, TextAttack, and TextAutoAugment (Ma 2019; Ribeiro et al. 2020; Marivate and Sefara 2020; Morris et al. 2020; Ren et al. 2021), including RandomDeletion, RandomSwap, RandomCrop, RandomWordAugmentation, RandomWordEmbAugmentation, and RandomContextualWordAugmentation[5].

To narrow down the augmentations we experiment with, we selected for single-sentence augmentations that are either labeled **highly meaning preserving**, **possible meaning alteration**, or **meaning alteration**. After preliminary filtering (Appendix A.3), Table 3 contains all augmentations we included in our experiments. To select for a diverse set of augmentation for main results in STS-b and transfer tasks, we trained models using single augmentation as positives, and pick augmentations that obtained top performance on STS-B and transfer tasks. For full single augmentation results see Appendix A.14.

4.2 Augmentation Sampling

To save computation and control for randomness, we augment the training dataset once for every augmentation and cache the results. Prior to training, augmentations are read from caches and uniformly sampled at each data point. Since not every augmentation perturbs the original sentence at every data point, we then correct augmentation label to "no augmentation" if the augmented sentence is the same as original sentence. This leads to a larger portion of the sentence having the label "no augmentation" than each individual augmentation[6].

4.3 Model Architecture

In our experiments, we train sentence embedding encoders using BERT- and RoBERTa-base for fair comparison to previous methods: SimCSE and DiffCSE. During training, we pass sentence representations through 2-layer projection layer with batchnorm, introduced by DiffCSE. We remove projection layers during inference and obtain sentence embeddings directly from the encoder. Formally, we train with contrastive loss, shown in the equation at the top right of Figure 1. We refer to this contrastive loss as $\mathcal{L}_{contrastive}$. We use the embedding corresponding to **[CLS]** token as sentence embedding in all experiments.

Contrastive loss regularizes on individual data pair level, which is a very strict constraint to resolve distributional shifts that augmentations introduce. To train sentence encoders that are invariant with respect to the shifts between diverse augmentations, we introduce an antagonistic discriminator. We pass the concatenated embeddings of original and augmented sentences into the discriminator (code in Appendix A.5) trained with the $\mathcal{L}_{discriminator}$ loss, defined as binary cross entropy between predicted and actual augmentations:

$$-\frac{1}{K}\sum_{i=1}^{K} y_i \log(p(y_i)) + (1-y_i)\log(1-p(y_i)) \qquad (2)$$

[4] See more discussion on negation in deep learning in A.15

[5] SimCSE tried RandomDeletion, RandomCrop; DiffCSE tried RandomDeletion, RandomInsertion, and their RTD is based on RandomContextualWordAugmentation.

[6] We also tried resampling augmentations between each epochs and found that to underperform fixed sampling.

Table 3: Final subsets of augmentations included in experiments. Augmentations in 16-Aug experiments are **bolded**, 12-Aug experiments are underlined, 8-Aug experiments are colored orange and 4-Aug experiments marked with asterisks(*). For full descriptions of augmentations, see Appendix A.2.

where K is the number of augmentation types (plus "no augmentation"), and $p(y_i)$ is the probability of augmentation type i predicted by the discriminator. To encourage augmentation-invariant encoder, the first layer of the discriminator uses a gradient reversal layer (Ganin and Lempitsky 2015; Zhu et al. 2015; Ganin et al. 2016) (code in Appendix A.4) that allows the gradient to be multiplied with a negative multiplier α in backward pass such that while discriminator is trained to minimize discriminator loss, the encoder is trained to maximize the discriminator loss all in one pass. We find this simple scheme to work well without having to deal with the instability around training adversarial networks (Creswell et al. 2018; Clark et al. 2019).

Finally, the overall loss of our model (AugCSE):

$$\mathcal{L} = \mathcal{L}_{contrastive} + \lambda * \mathcal{L}_{discriminator} \qquad (3)$$

where λ is a coefficient that tunes the strength of discriminator loss.

5 Experiments

5.1 Evaluation Datasets

For fair comparison, we use the same dataset SimCSE used: 1M sentences randomly selected from Wikipedia. After training, we use frozen embeddings to evaluate our method on 7 semantic textual similarity (STS) tasks and 7 (SentEval) transfer tasks (Conneau and Kiela, 2018). STS tasks include **STS 2012 - 2016** (Agirre et al., 2016), **STS-Benchmark** (Cer et al.), and **SICK-Relatedness** (Marelli et al., 2014). In STS tasks, Spearman correlation is calculated between model's embedding similarity of the pair of sentences against human ratings (1-5). Transfer tasks are single sentence classification tasks from SentEval including **MR** (Pang and Lee, 2005), **CR** (Hu and Liu, 2004), **MPQA** (Wiebe et al., 2005), **MRPC** (Dolan and Brockett, 2005), **TREC** (Voorhees and Tice, 2000), **SST-2** (Socher et al., 2013), and **SUBJ** (Pang and Lee, 2004). We follow the standard evaluation setup from (Conneau and Kiela, 2018), training a logistic regression classifier on top of frozen sentence embeddings. See Appendix A.6 for details on hyperparameter search.

5.2 Evaluation Baselines

We include several levels of baselines. From word-averaged Glove embedding (Pennington et al., 2014), to BERT$_{\text{base}}$, using both average pooling as well as [CLS] token. We include post processing methods, **BERT-flow** (Li et al., 2020), and **BERT-whitening** (Su et al., 2021), as well as other more recent contrastive sentence embeddings: **CT-BERT** (Carlsson et al., 2020), **SG-OPT** (Kim et al., 2021), **SimCSE** (Gao et al., 2021), **DiffCSE** (Chuang et al., 2022). We also report results from **DeCLUTER** (Giorgi et al., 2021) and (Neelakantan et al., 2022) (**cpt-text-S**) as a comparison for what larger model and larger training data size would benefit. More specifically, DeCLUTER mines positives from documents, and cpt-text-S uses next sentence as positives.

5.3 STS Results

We show STS test results in Table 4. AugCSE performs competitively against SOTA methods, with both BERT and RoBERTa. AugCSE also outperforms larger models trained with more data (DeCLUTR and cpt-text-s). We discuss this in Sec 7.

5.4 Transfer Tasks Results

We show transfer tasks test set results in Table 5. With BERT$_{\text{base}}$ AugCSE outperforms DiffCSE in average transfer score and improve 4 out of 7 SentEval tasks. In RoBERTa$_{\text{base}}$, we still see competitive performance. Here, larger models with more training data outperform existing methods.

5.5 Discriminator Objective Variations

In addition to predicting the augmentation type (**AugCSE**), we vary the discriminative objectives in Table 6. With **bool**, the discriminator predicts whether the second sentence is augmented or not (since not every augmentation is guaranteed 100% perturbation rate). With **positive**, we use augmented sentence as positives in the contrastive loss as well as using their augmentation types in the discriminator loss. For this setting, we use a symmetric loss similar to one in CLIP (Radford et al., 2021) to boost performance because contrasting two different distributions from augmented and natural text benefits from a symmetric regularization. In **no discriminator**, we use augmented sentence as positives in the contrastive loss but do not use a discriminator, which is the most naive way of using augmentation in contrastive learning (as in SimCLR(Chen et al., 2020b)). Empirically, we found that using augmentations only for the discriminative objective (**AugCSE**) performs the best and improves transfer results significantly over **no discriminator**. To understand such phenomenon, we can think of the discriminative objective as a weaker form of regularization, where we enforce invariance on the augmentation distribution level, rather than on individual augmented sentence level. The weaker constraint tolerates more noise in augmentation while distributionally improves the embedding space. Intuitively it make sense because the "noises" we introduce with augmentations do not impact the semantics of each sentence equally (e.g. randomly dropping an article in a sentence changes the semantics much less than dropping a verb). However, with the discriminative objective we do encourage that such noise be tolerated on a distributional level. This subtle difference is analogous to works in AI fairness, where antagonistic discriminator optimizes for group fairness (Chouldechova and Roth, 2020), while contrastive learning optimizes for individual fairness (Dwork et al., 2012).

We also experiment with different values of the α in gradient reversal layer in Table 7. Since α is a constant multiplied to the gradient from the discriminator and applied to downstream encoder, changing $\alpha = -1$ to $\alpha = 1$ is equivalent to changing discriminator from being antagonistic (AugCSE) to being collaborative (similar to DiffCSE). The magnitude determines how antagonistic or collaborative the discriminator is. We can see that the discriminator being antagonistic is crucial for our model performance (more detailed explorations and visualizations of the impact of α and on the embedding space are shown in Fig. 4 and 5 in the Appendix).

5.6 Augmentation ablation

We also vary the number of augmentation to determine the importance of diversity of augmentation for performance. For improving STS performance, we found 8 augmentations (Table 8) to be a sweet spot between including as diverse set of augmentations and keeping the augmentations relevant to the task. We see that including additional augmenta-

Table 9: Performance after removing LM-based augmentations. Colored numbers indicate deltas compared to augmentation sets that include LM-based augs.

tion (16) can help further improve transfer results, but we use 8 augmentations in our main results for its simplicity. It is possible that we can improve our results further by including more diverse set of augmentations, we leave that for future studies.

5.7 Pretrained model based augmentation

LM-enabled augmentations could, in theory, beat the combination of all other augmentations by generating a diverse set of paraphrases using linguistic priors from training data. In 8, 12, and 16 augmentation setting, only **DiverseParaphrase** and **Casual2Formal** augmentations use pretrained model. To see how crucial LM-based augmentations are to our performance, we remove these augmentations and compare results with original settings. Without LM-based augmentations, we still see comparable results as before (Table 9). STS results actually **improve** across all trials.

6 Analysis and Discussion

In our experiments, we selected subsets of top performing augmentations by looking at their individual finetuned performances. Such selection procedure may not be feasible due to resource constraints. In the following sections and in App. A.13, we discuss a few metrics that could be used to provide some signal in selecting the best augmentation (or dataset) for contrastive learning. We also discuss the broader impact of our work, advantages, and yet unresolved problems in the field.

6.1 Similarity and perplexity

One simple way of measuring point-wise distance between original and augmented sentences is using semantic similarity (approximated with cosine similarity between their SBERT embeddings[7]) and perplexity difference (calculated with GPT2 (Sanh et al., 2019)). Across all augmentations, similarities have positive correlation with STS-b and Transfer performance (Pearson correlation coefficients of 0.72 and 0.6, resp.) while perplexities difference have negative correlation with STS-b and Transfer performance (coefficients of -0.53 and -0.58, resp.) when augmentations are used as positives. This indicates that augmented sentences with higher similarities and lower perplexities differences to the originals may be useful as positive examples in contrastive learning. For more results and correlation with other metrics such as embedding isomorphism, see Appendix A.13 and A.14.

6.2 Domain shift in augmentation

In Figure 2 in the Appendix, we visualize the embedding distribution of sampled sentences pre- and post- augmentations, of pretrained BERT and AugCSE$_{\text{BERT}}$. We observe that augmentations do introduce distributional shift and that our discriminator can indeed unify distributions from diverse augmentations, along with evidence that α also impact unification (Figure 4 in the Appendix).

6.3 LM-based vs. rule-based augmentations

In our experiments, we observe that our model (AugCSE) performance does not depend on LM-based augmentations. AugCSE performance matches that of DiffCSE (that uses solely LM-based augmentation) and in many cases, removing LM-based augmentations even improves its performance (Table 9). This is an added advantage given that LM-based augmentations may be more expensive to run, are not as controllable as rule-based augmentations, and may contain bias learned from text in the wild that can reinforce undesirable properties in the sentence embedding. In comparison, rule-based models can precisely control for such behaviors, mitigate bias (Dinan et al., 2020), or introduce invariance in embedding space specific to the needs of the downstream tasks.

7 Conclusion

We present AugCSE, a general framework that combines diverse sets of augmentations to improve general sentence embeddings. In addition to the contrastive loss, we introduce an antagonistic discriminator that loosely constrain the model to become invariant to distributional shifts created from augmentations. In addition to outperforming previous methods, our framework is much more controllable, which has an added advantage of being able to mitigate undesirable properties from pretrained LMs, which inherit bias and toxicity from training data on the internet. Additionally, AugCSE can work with cheaper augmentations to run, resulting in a more resource-friendly approach to training generic sentence embedding models.

Limitations

Semantic textual similarity for evaluation. Sentence embedding literature has focused primarily on evaluating models using sentence semantic similarity tasks and SentEval transfer tasks. While transfer tasks may capture a wider range of desirable properties for a generic sentence embedding model, STS is often not a perfect indicator of sentence embedding quality. As noted by Neelakantan et al. (2022), STS tasks performance decreases as transfer task performance increases. This trend can also be observed in other robust models such as DeCLUTR. In future studies, we urge users to use STS tasks as only a subset of the transfer tasks when evaluating sentence embedding.

However, sentence semantic is still an important and difficult task that is not yet solved especially when considering the recursive structure, compositionality, and logics in sentences. In order to include the above more formally defined properties, additional data augmentation (Andreas, 2020; Akyürek et al., 2020) or architectural (Akyürek and Andreas, 2021) techniques may be needed.

Dense retrieval models and evaluations. Another downstream task relevant to sentence embedding is dense retrieval. Given sentences or documents, dense retrieval task aims to find the most relevant pairs within a corpus (Wang et al. 2021b,a; Thakur et al. 2021; Izacard et al. 2021; Liu and Shao 2022). Due to the way retrieval tasks are defined, models are trained with different data (Book Corpus, English Wikipedia (Gao and Callan 2021; Zhu et al. 2015)) and the objective encourages high scores given positive pairs, while (our) sentence embedding objective focuses on differentiating sentence semantics. Due to this subtle difference and project scope, we do not evaluate directly on retrieval tasks, and focus on comparing to previous works in the sentence embedding space.

[7] sentence-transformers/all-mpnet-base-v2

Choice of backbone models. We recognize that there have been many pretrained language models that have out-performed BERT. We used BERT and RoBERTa to make our evaluation comparable to previous works. Finetuning on additional models could lead to insights in trade-offs between pretraining objectives, data size and contrastive finetuning. We leave that for future studies.

Training data size and contrastive finetuning. Our method is able to produce SOTA results given a small fine-tuning dataset. However, we were unable to beat other methods that were trained/fine-tuned on much larger datasets. It is important to note, that Giorgi et al. (2021) reported RoBERTa$_{\text{base}}$ to score 87.31 on average transfer results. This indicates that finetuning RoBERTa with contrastive objective on wiki1m **reduces** the transfer performance (for SimCSE, DiffCSE, and AugCSE). One potential explanation for such behavior is that RoBERTa is trained on a much larger dataset with carefully designed next-sentence prediction objective, and has learned a robust sentence embedding already (given cpt-text-S was finetuned solely based on signals between neighboring sentences).

Language in concern During our study we limited our exploration to English only for better comparison to previous works. However, NLAugmentor does provide many augmentations that are focused on non-English, or multiple languages (which we filtered out for the scope of our project and training dataset). Nonetheless, our results could be extended to improving multi-lingual sentence embedding representations given the right training data and augmentation that can improve downstream multilingual tasks such as multilingual semantic textual similarity (Cer et al.), parallel corpus mining, a similar task to dense retrieval tasks in multilingual corpora (Zweigenbaum et al. 2017, 2018; Artetxe and Schwenk 2019; Reimers and Gurevych 2020; Jones and Wijaya 2021; Feng et al. 2022), machine translation (MT) and MT Quality Estimate (MTQE) that predicts the quality of the output provided by an MT system at test time when no gold-standard human translation is available (Fomicheva et al., 2020; Kocyigit et al., 2022). In fact, one of the main domains in which we believe our methods could come into use is in low-resource languages. Previous works have typically used backtranslation (Sennrich et al., 2016) and comparable corpora (recent works such as Rasooli et al. 2021 and Kuwanto and Akyürek that also uses code-switch data pre-train their MT encoder) to augment training data in low resource languages MT. In addition, in these settings we can incorporate augmentations that are linguistically rooted (created by language experts) or multi-lingual in nature, to improve neural representations of languages that are not as available as English.

A Appendix

A.1 Ethics Statement

To our best knowledge, there is no outstanding ethical issue with our method of approach other than including potentially problematic augmentations (stereotype-reaffirming, toxic, etc) into the augmentation set. In fact, we believe one of the main advantage of our methods over previous methods is we can use rule-based augmentations to explicitly control for the type of invariances we want to instill within the sentence embedding, as opposed to propagating bias, stereotypes, and toxicity that exist in natural text and pre-trained LMs. NL-Augmenter includes many rule-based augmentations that tackle exactly such biases against country of origin, gender, geolocation, linguistic patterns, etc.

When considering computing resources and environmental impact, rule-based methods are much cheaper and more accessible to run, making our method a much more desirable approach for low-resource compute settings.

A.2 All Augmentations Descriptions in Experiments

In this section, we **word-by-word copy over** the descriptions of each of the augmentations we have mentioned in our paper from NL-Augmenter (Dhole et al., 2021), unless otherwise **noted**.

SentenceAdjectivesAntonymsSwitch This transformation switches English adjectives in a sentence with their WordNet (Miller, 1998) antonyms to generate new sentences with possibly different meanings and can be useful for tasks like Paraphrase Detection, Paraphrase Generation, Semantic Similarity, and Recognizing Textual Entailment.

Example: Amanda's mother was very beautiful → ugly .

SentenceAuxiliaryNegationRemoval This is a low-coverage transformation which targets sentences that contain negations. It removes negations in English auxiliaries and attempts to generate new sentences with the opposite meaning.

Example: Ujjal Dev Dosanjh was not → Ujjal Dev Dosanjh was the 1st Premier of British Columbia from 1871 to 1872.

ReplaceHypernyms / ReplaceHyponyms This transformation replaces common nouns with other related words that are either hyponyms or hypernyms. Hyponyms of a word are more specific in meaning (such as a sub-class of the word), eg: 'spoon' is a hyponym of 'cutlery'. Hypernyms are related words with a broader meaning (such as a generic category /super-class of the word), eg: 'colour' is a hypernym of 'red'. Not every word will have a hypernym or hyponym.

SentenceSubjectObjectSwitch This transformation switches the subject and object of English sentences to generate new sentences with a very high surface similarity but very different meaning. This can be used, for example, for augmenting data for models that assess semantic similarity

CityNamesTransformation This transformation replaces instances of populous and well-known cities in Spanish and English sentences with instances of less populous and less well-known cities to help reveal demographic biases (Mishra et al., 2020) prevelant in named entity recognition models. The choice of cities have been taken from the World Cities Dataset. [8]

AntonymSubstitute This transformation introduces semantic diversity by replacing an even number of adjective/adverb in a given text. We assume that an even number of antonyms transforms will revert back sentence semantics; however, an odd number of transforms will revert the semantics. Thus, our transform only applies to the sentence that has an even number of revertible adjectives or adverbs.We called this mechanism double negation.

Example: Steve is able → unable to recommend movies that depicts the lives of beautiful → ugly minds.

Note: To increase perturbation rate, and since we discovered that negations in semantics do not change sentence embeddings as much, we modified the original augmentations behavior by changing only odd number of antonyms. Hence, this augmentation changed from "Highly meaning preserving" to "Meaning Alteration". However, after we found out it was very similar to SentenceAjectivesAntonymsSwitch, we did not include it in main experiments for overlapping augmentation.

ColorTransformation This transformation augments the input sentence by randomly replacing mentioned colors with different ones from the 147

[8] https://www.kaggle.com/datasets/juanmah/world-cities

extended color keywords specified by the World Wide Web Consortium (W3C). Some of the colors include “dark sea green”, “misty rose”, “burly wood”.

Example: Tom bought 3 apples, 1 orange → misty rose , and 4 bananas and paid $10.

Summarization This transformation compresses English sentences by extracting subjects, verbs, and objects of the sentence. It also retains any negations. For example, “Stillwater is not a 2010 American liveaction/animated dark fantasy adventure film” turns into “Stillwater !is film”. (Zhang et al., 2021) used a similar idea to this transformation.

DiverseParaphrase This transformation generates multiple paraphrases of a sentence by employing 4 candidate selection methods on top of a base set of backtranslation models. 1) DiPS (Kumar et al., 2019a) 2) Diverse Beam Search (Vijayakumar et al., 2018) 3) Beam Search (Wiseman and Rush, 2016) 4) Random. Unlike beam search which generally focusses on the top-k candidates, DiPS introduces a novel formulation of using submodular optimisation to focus on generating more diverse paraphrases and has been proven to be an effective data augmenter for tasks like intent recognition and paraphrase detection (Kumar et al., 2019a). Diverse Beam Search attempts to generate diverse sequences by employing a diversity promoting alternative to the classical beam search (Wiseman and Rush, 2016).

SentenceReordering This perturbation adds noise to all types of text sources (paragraph, document, etc.) by randomly shuffling the order of sentences in the input text (Lewis et al., 2020). Sentences are first partially decontextualized by resolving coreference (Lee et al., 2018). This transformation is limited to input text that has more than one sentence. There are still cases where coreference can not be enough for decontextualization. For example, there could be occurences of ellipsis as demonstrated by (Gangal et al., 2021) or events could be mentioned in a narrative style which makes it difficult to perform re-ordering or shuffling (Kočiskỳ et al., 2018) while keeping the context of the discourse intact.

TenseTransformation This transformation converts English sentences from one tense to the other, for example simple present to simple past. This transformation was introduced by (Logeswaran et al., 2018).

RandomDeletion This augmentation randomly deletes a proportion of the words (Wei and Zou, 2019) and was added by us into the library of augmentations. Implementation uses nlpAug (Ma, 2019).

RandomCrop This augmentation randomly deletes a continuous span of words and was added by us into the library of augmentations. Implementation uses nlpAug (Ma, 2019).

RandomSwap This augmentation randomly swaps a proportion of the words and was added by us into the library of augmentations. Implementation uses nlpAug (Ma, 2019).

RandomWordAugmentation This augmentation transforms input by uniformly randomly select an augmentation from RandomDeletion, RandomCrop, and RrandomSwap. Implementation uses nlpAug (Ma, 2019).

RandomWordEmbAugmentation This augmentation substitute words with similar words defined by Glove embedding (Pennington et al., 2014). Implementation uses nlpAug (Ma, 2019).

RandomContextualWordAugmentation This augmentation randomly masks and fills words with pretrained BERT models. Similar ideas are often used in adversarial word embedding literature (Morris et al., 2020). Implementation uses nlpAug (Ma, 2019).

YodaPerturbation This perturbation modifies sentences to flip the clauses such that it reads like "Yoda Speak". For example, "Much to learn, you still have". This form of construction is sometimes called "XSV", where "the “X” being a stand-in for whatever chunk of the sentence goes with the verb", and appears very rarely in English normally. The rarity of this construction in ordinary language makes it particularly well suited for NL augmentation and serves as a relatively easy but potentially powerful test of robustness.

ContractionExpansions This perturbation substitutes the text with popular expansions and contractions, e.g., “I’m” is changed to “I am”and vice versa. The list of commonly used contractions expansions and the implementation of perturbation has been taken from Checklist (Ribeiro et al., 2020).

Example: He often does n't → not come to school.

DiscourseMarkerSubstitution This perturbation replaces a discourse marker in a sentence by a semantically equivalent marker. Previous work has identified discourse markers that have low ambiguity (Pitler et al., 2008). This transformation uses the corpus analysis on PDTB 2.0 (Prasad et al., 2008) to identify discourse markers that are associated with a discourse relation with a chance of at least 0.5. Then, a marker is replaced with a different marker that is associated to the same semantic class.

Example: It has plunged 13% since → inasmuch as July to around 26 cents a pound. A year ago ethylene sold for 33 cents

Casual2Formal This transformation transfers the style of text from formal to informal and vice versa. It uses the implementation of Styleformer[9].

Example: What you upto → currently doing ?

GenderSwap This transformation introduces gender diversity to the given data. If used as data augmentation for training, the transformation might mitigate gender bias, as shown in (Dinan et al., 2020). It also might be used to create a gender-balanced evaluation dataset to expose the gender bias of pre-trained models. This transformation performs lexical substitution of the opposite gender. The list of gender pairs (shepherd <–> shepherdess) is taken from (Lu et al., 2020). Genderwise names used from (Ribeiro et al., 2020) are also randomly swapped.

GeoNamesTransformation This transformation augments the input sentence with information based on location entities (specifically cities and countries) available in the GeoNames database[10]. E.g., if a country name is found, the name of the country is appended with information about the country like its capital city, its neighbouring countries, its continent, etc. Some initial ideas of this nature were explored in (Păiș, 2019).

NumericToWord This transformation translates numbers in numeric form to their textual representations. This includes general numbers, long numbers, basic math characters, currency, date, time, phone numbers, etc.

SynonymSubstitution This perturbation randomly substitutes some words in an English text with their WordNet (Miller, 1998) synonyms (Wei and Zou, 2019).

PigLatin This transformation translates the original text into pig latin. Pig Latin is a well-known deterministic transformation of English words, and can be viewed as a cipher which can be deciphered by a human with relative ease. The resulting sentences are completely unlike examples typically used in LM training. As such, this augmentation change the input into inputs which are difficult for a LM to interpret, while being relatively easy for a human to interpret.

PhonemeSubstitution This transformation adds noise to a sentence by randomly converting words to their phonemes.This transformation adds noise to a sentence by randomly converting words to their phonemes. Grapheme-to-phoneme substitution is useful in NLP systems operating on speech. An example of grapheme to phoneme substitution is "permit" → P ER0 M IH1 T'.

VisualAttackLetter This perturbation replaces letters with visually similar, but different, letters. Every letter was embedded into 576-dimensions. The nearest neighbors are obtained through cosine distance. To obtain the embeddings the letter was resized into a 24x24 image, then flattened and scaled. This follows the Image Based Character Embedding (ICES) (Eger et al., 2019). The top neighbors from each letter are chosen. Some were removed by judgment (e.g. the nearest neighbors for 'v' are many variations of the letter 'y') which did not qualify from the image embedding (Eger et al., 2019).

BackTranslation This transformation translates a given English sentence into German and back to English.This transformation acts like a light paraphraser. Multiple variations can be easily created via changing parameters like the language as well as the translation models which are available in plenty. Backtranslation has been quite popular now and has been a quick way to augment examples (Li and Specia 2019, ; Sugiyama and Yoshinaga 2019).

MultilingualBackTranslation This transformation translates a given sentence from a given language into a pivot language and then back to the original language. This transformation is a simple paraphraser that works on 100 different languages.

[9] https://github.com/PrithivirajDamodaran/Styleformer

[10] http://download.geonames.org/export/dump

Back Translation has been quite popular now and has been a quick way to augment (Li and Specia 2019; Sugiyama and Yoshinaga 2019; Fan et al. 2021).

Example: Being honest → Honesty should be one of our most important character traits → characteristics

FactiveVerbTransformation This transformation adds noise to all types if text source (sentence, paragraph, etc.) by adding factive verbs based paraphrases (Alvin Grissom and Miyao, 2012) Example: Peter published a research paper → Peter acknowledged that he published a research paper.

A.3 Narrowing down augmentations

we first filter for single sentence operations for unsupervised settings. We then remove augmentations that do not represent typical text distributions (PigLatin), or perturb based on audio (PhonemeSubstitution) or visual (VisualAttackLetter) similarities. Since semantic similarities between augmented and original sentence is important to our objective, we categorize all augmentations according to meaning preservation label provided by NL-Augmenter: **highly meaning preserving**, **possible meaning alteration**, and **meaning alteration**. Given not all augmentations were labeled, we manually label missing augmentations. Lastly, we filter out similar methods and only keep one from every type of augmentation (MultilingualBackTranslation, BackTranslation, etc.), and keep only augmentations that have relatively high perturbation rates (> 0.2). We then manually look through augmentation examples to filter out augmentations that produce repetitive artifacts that can be exploited by contrastive learning scheme (FactiveVerbTransformation).

A.4 Code for Gradient Reversal Layer

```
from torch.autograd import Function

class GradReverse(Function):

  @staticmethod
  def forward(ctx, x, lambd, **kwargs: None):
    ctx.lambd = lambd
    return x.view_as(x)

  @staticmethod
  def backward(ctx, *grad_output):
    return grad_output[0] * -ctx.lambd, None
```

[11]

A.5 Code for Discrimimnator MLP

```
class ProjectionMLP(nn.Module):
  def __init__(self, hidden_size, alpha=1.0):
    super().__init__()
    in_dim = hidden_size
    middle_dim = hidden_size * 2
    out_dim = hidden_size
    self.net = nn.Sequential(
        nn.Dropout(p=0.2),
        nn.Linear(in_dim, middle_dim),
        nn.Tanh(),
        nn.Dropout(p=0.2),
        nn.Linear(middle_dim, out_dim),

    return self.net(x)
```

A.6 Hyperparameter Selection

For main STS and transfer results, we follow similar search strategy as SimCSE and DiffCSE. For either tasks, we search for best performing dev runs in the hyperparmeter ranges (STS-b dev performance for STS test results; average transfer dev for transfer test results), and use that hyperparaemter set as the best performing set. The hyperparameter search range include: $\lambda \in \{1e-5, 5e-5, 1e-4, 5e-4, 1e-3, 5e-3, 1e-2\}$, learning rate $\in \{5e-6, 7e-6, 1e-5, 2e-5, 3e-5, 5e-5\}$ and batch size is fixed to 128. After obtaining the best hyperparameter for the task, we run the same trial with seed $\in \{1, 11, 42, 68, 421\}$ to obtain standard deviation and average. In the main result, we report maximum of the 5 seeds. In A.8, we report average and variance of 5 trials.

For all ablation experiments, we use the best hyperparameter main results (STS and transfer tasks separately), and search with different λ only for the best dev results for each ablation trial, and report the dev performances.

A.7 Best Hyperparameter for Main Results

A.9 Reproducibility

All of our models are trained and inferenced on a single NVIDIA V100 GPU per trial. Training a single model for one epoch takes from 40 min to 5 hours, depending on the frequency of evaluation.

A.10 Model Size

See Table 13

A.11 Augmentation Unification

In Figure 2, we see AugCSE indeed can unify the distribution from different augmentations compare to baseline BERT. In Figure 3, we can see that in addition to contrastive objective from SimCSE (and baseline BERT), AugCSE brings distributions of augmentations vs. unperturbed sentences even closer together.

A.12 Importance of Gradient Reverse Multiplier

As seen in both training plots (Table 5, Figure 4), a positive alpha value (collaborative discriminator) results in embeddings that are easily classified by augmentations, whereas negative alpha values (antagonistic discriminator) results in unified embedding that is harder to pick out augmentation type. We use sklearn PCA module for all PCA results, and Multcore-TSNE [12] for ann TSNE plots.

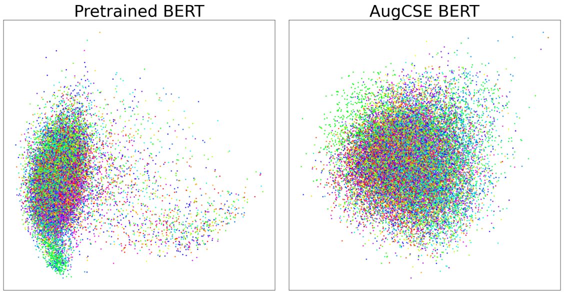

Figure 2: PCA of randomly sampled sentence embeddings from wiki1m dataset with various augmentations (27 augmentations) along with original sentence samples. Color indicates various augmentation types.

A.13 Embedding isomorphism

Different augmentations and datasets have been proposed as positive or negative pairs to learn sentence embedding. However, their performance differ drastically, despite many of them were created with the same original purpose, such as paraphrase. In search for what causes the difference in performance, we investigate further in NLI datasets, specifically ANLI (Nie et al., 2020), which was created with the same objective (entailment and contradiction) but with drastically different method. In ANLI, anchor sentences were provided, and entailment and contradictions were crowd-sourced for the purpose of fooling existing models. With such objective, sentences in contradiction and entailment may come from a different distribution as the anchor sentence.

We trained SimCSE using ANLI data only, and found ANLI-SimCSE to perform much worse than Supervised SimCSE (trained with MNLI and SNLI), even if we sample and adjust for dataset size difference (Table 14).

To measure some aspect of distributional shift in the embedding space, we used 3 embedding isomorphism measurements: harmonic mean of effective condition numbers **COND-HM**, singular value gap **SVG**, and Gromov-Hausdorff distance **GH** (Dubossarsky et al. 2020; Jones et al. 2021).

Seen in Table 15, for ANLI, entailment and con-

tradictions distributions were much more different from anchors than the that for NLI. We believe this difference could be one of the reason using ANLI examples do not work as well as NLI examples. In another word, in ANLI, perhaps because the embedding difference between contradiction and entailment sentences are so much smaller than both to anchor, that the contrasting signals from positives and negatives are conflicting rather than working together. This hypothesis can be confirmed with ANLI-SimCSE w/o negatives performing better than the trial with negatives.

In similar veins, we investigate whether the same measurement could be indicative of augmentation performance. However, were weren't able to find significant correlation. See the next section for more details.

A.14 Single augmentation performance and embedding distance

For single augmentation experiments, we remove data points that are not transformed by the augmentation. We find this to work better than leaving some datapoints un-perturbed, which adds noise to the contrastive objective. In addition, we used symmetric contrastive loss similar to CLIP (Radford et al., 2021). This improves performance because augmentations introduce distributional shifts in the embedding space that benefits from a symmetric regularization.

In Figure 7, we can observe that similarity and perplexity difference are two measures most correlated feature with respect to all four metrics. Similarity is positively correlated with positive evaluations and perplexity difference is negatively correlated with positive evaluations. Both metrics relation with negative evaluations reverse directions but become much less strongly correlated. This is likely due to the nature of positive and negative aug-

mentation usage in the contrastive objective. The negatives are aggregated along with rest of in-batch examples, lessen the effect. Additionally, the value of negatives is contextually dependent on positives, since the repulsion and attraction of negatives and positives conjointly defines the direction in which anchor embeddings go. HM-COND is also somewhat positively correlated with the with evaluation performance when using augmentation as negatives. It seems to suggest that the more isomorphic the embedding spaces are between augmented vs. original sentences, the better the augmentation is as a negative augmentation.

A.15 Negations in deep learning

As seen in Table 2, using contradiction as negatives obtains almost baseline performance, while being semantically entirely opposite. Similarly, in Appendix A.14, we have also observed that meaning preservation label (Table 3) has little indication of whether the augmentation performs well as a single positives. This is a particular interesting phenomenon that requires further study. While a sentence can represent semantically exactly opposite meaning, it is still discussing similar topics, and due to the symmetric nature of cosine similarity, it is difficult to use negation in deep learning. Negative examples do not help as much as in-context learning (Wang et al., 2022) or reinforcement learning rewards (Sumers et al., 2021), and negative natural language commands lead to exact opposite output from systems [13]. In toxicity NLP literature, this is related to the phenomenon that superficial textual token meanings are naively combined to yield sentence meaning, without taking to account of deeper structural relationships between entities mentioned (Hartvigsen et al., 2022). In the contrastive learning setting, providing a positive anchor (**SimCSE** in Table 2) helps direct the contrast to a specific direction against the positive examples, yet it is unclear how negatives can be used in other scenarios in deep learning. Such topic could also have interesting implications to "the white bear problem" (Wegner and Schneider, 2003), the phenomenon where "when someone is actively trying not to think of a white bear they may actually be more likely to imagine one." [14] in psychology, and whether failing to learn from negation in deep learning is a result of in-proper training methods or an indication that deep-learning models are aligned with human psychology, and to solve such problem may require human-centric strategies to deal with such short-comings.

Seamlessly Integrating Factual Information and Social Content with Persuasive Dialogue

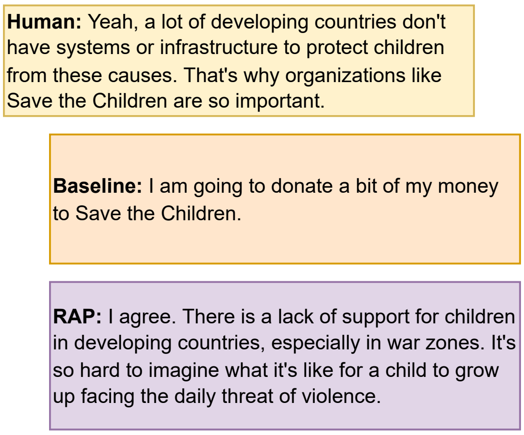
Abstract

Complex conversation settings such as persuasion involve communicating changes in attitude or behavior, so users' perspectives need to be addressed, even when not directly related to the topic. In this work, we contribute a novel modular dialogue system framework that seamlessly integrates factual information and social content into persuasive dialogue. Our framework is generalizable to any dialogue tasks that have mixed social and task contents. We conducted a study that compared user evaluations of our framework versus a baseline end-to-end generation model. We found our framework was evaluated more favorably in all dimensions including competence and friendliness, compared to the end-to-end model which does not explicitly handle social content or factual questions.



Human: Yeah, a lot of developing countries don't have systems or infrastructure to protect children from these causes. That's why organizations like Save the Children are so important.

Baseline: I am going to donate a bit of my money to Save the Children.

RAP: I agree. There is a lack of support for children in developing countries, especially in war zones. It's so hard to imagine what it's like for a child to grow up facing the daily threat of violence.

Figure 1: Chatbot running on the baseline BART model and chatbot running on RAP responding to the same user utterance. The baseline model does not appropriately acknowledge the user's statement, whereas RAP is able to show acknowledgement and respond appropriately.

1 Introduction

Persuasive dialogue systems are designed for chatbots to communicate with and to influence users with specific goals. Such systems are often designed to benefit individual users (e.g., promoting healthy behaviors) or society at large (e.g., persuading people to make donations). Wang et al. (2019) introduced this idea with the PERSUASIONFORGOOD dataset, which contains 1,017 human-human conversations where one participant persuaded the other to donate to the charitable organization *Save the Children*[1], with 300 conversations having sentence-level dialogue act annotations.

The social and communicative dynamics behind persuasive conversation contexts are complex. A persuasive conversation by definition involves one party, the persuader, intending to change the attitude or behavior of the other party, the persuadee (Torning and Oinas-Kukkonen, 2009). Changing persuadees' attitude has several dimensions including establishing mutual trust and credibility, strategically presenting persuasive appeals, and eliciting emotional reactions from the persuadee (O'keefe, 2015; Wilson, 2003). Moreover, Grice's Maxims of Conversation define conversations as a cooperative and collaborative process (Grice, 1975; Clark, 1996; Merrison et al., 2002). Thus, effective and successful persuasive conversations do not mechanically relay task-related information to the persuadee. There has to be a significant exchange of social and emotional content to empathetically address persuadees, e.g. by answering specific questions and developing positive relationships throughout the conversation.

For this reason, persuasive conversations are not strictly task-oriented, but are built around tasks with additional social conversational strategies. In essence, persuasive conversations have two goals: one that is task-oriented to elicit behavioral changes, and another that is social-oriented to build trust and empathy and develop positive relationships in order to better navigate the persuasive context. In this work, we propose the Response-Agenda Pushing Framework (RAP) for

[1] https://www.savethechildren.net/

Proceedings of the 2nd Conference of the Asia-Pacific Chapter of the Association for Computational Linguistics and the 12th International Joint Conference on Natural Language Processing (Volume 1: Long Papers), pages 399–413
November 20–23, 2022. ©2022 Association for Computational Linguistics

persuasive dialogue systems, which can explicitly handle these two goals. RAP jointly addresses social response and task-oriented dialogue generation. In a given turn, RAP first focuses ond appropriately triggering modules to generate answers to factual questions and social responses to address users' comments. RAP then pushes the persuasive agenda of a conversation using a language model that conditions on individual persuasive appeals. Compared to state-of-the-art end-to-end conditional generation models, RAP is more semantically coherent and persuasive, while being generalizable to any dataset annotated with dialogue acts. In addition, we tackle the challenge of multiple-sentence conditional generation in a single turn given specific pragmatic argumentative strategies (e.g., "emotional appeal").

Concretely, our contributions are threefold. Contrary to recent work which attempts to transition from social to task-oriented dialogue (Chiu et al., 2022), we blend social and task-oriented dialogue in an approach grounded in social science theory postulating the need for social acknowledgement in the midst of advancing conversational goals (O'keefe, 2015; Wilson, 2003; Zhang and Danescu-Niculescu-Mizil, 2020; Grice, 1975; Merrison et al., 2002). Additionally, we present an account of conditional generation on fine-grained pragmatic persuasive strategies, unlike earlier attempts using looser semantic controls (He et al., 2018; Lewis et al., 2017; Hua and Wang, 2019). Finally, we present a qualitative account of RAP, including individual anecdotes of its strengths and weaknesses. Overall, we present a novel perspective on persuasive dialogue, marking important progress towards intelligent persuasive agents.

2 Related Work

Much earlier work in persuasion-like social conversations has been towards building dialogue systems for negotiation tasks, e.g., using the Craigslist Bargaining (He et al., 2018) and Deal or No Deal datasets (Lewis et al., 2017). However, in negotiation tasks, the goal is to come to a consensus, whereas in persuasion tasks, the target result is a one-sided change or a "win" for the persuader, as in a debate. Recently, there has been increasing interest in persuasive dialogues because of the rise in online-mediated persuasion scenarios (e.g. online sales, health promotion, political debates); much work focuses on understanding the social dynamics behind online persuasive conversations on social media platforms like Reddit (e.g. Atkinson et al. (2019); Musi (2018); Srinivasan et al. (2019); Tan et al. (2016)). In addition, a burgeoning line of work has been invested in developing chatbots to deliver healthcare remotely and to persuade people to adopt healthier lifestyles (Oh et al., 2021; Zhang et al., 2020). Such efforts have inspired a growing body of work towards building persuasive dialogue systems that are *conditional, strategic and factual* to benefit individuals and society at large.

Many early iterations of persuasive dialogue systems have used template-based (Zhao et al., 2018) or retrieval-based (Hiraoka et al., 2015; Yoshino et al., 2018) utterance generation methods. Wang et al. (2019) introduced PersuasionForGood and proposed designing a personalized persuasive dialogue system. Wu et al. (2021b) used two pretrained language models to separately models both speakers in a conversation, finding success in creating human-like utterances without supervision (from human annotations). Other studies propose end-to-end neural generation models (Li et al., 2020; Lewis et al., 2017). However, in approaches solely performing language modeling, there is less semantic control over generated utterances; they are not guaranteed to follow a particular persuasive strategy or dialogue act. Beyond persuasion, conditional text generation has emerged as a popular method of controllable generation for more coherent and "harmonious" human-dialogue system interactions (Guo et al., 2021; Keskar et al., 2019). Much earlier work in sentence-level conditional text generation has facilitated control by conditioning on entire topic statements (Hua and Wang, 2019) or simple semantic codes (Keskar et al., 2019; He et al., 2018; See et al., 2019). While such approaches work well in chit-chat, they do not guarantee strategy execution for complex tasks. *We propose using conditional generation conditioned on pragmatic dialogue acts to specifically control the strategic flow of a persuasive conversation.*

Much existing work in persuasion tasks has focused on strategy/policy planning (Georgila and Traum, 2011; Sakai et al., 2020; Hiraoka et al., 2014, 2013; Tran et al., 2022; Black et al., 2014), while others have focused on classification Chen et al. (2021); Tian et al. (2020); Wang et al. (2019). Other work discussed challenges in building dialogue systems that are social in nature, stating that unlike task-oriented dialogue systems, open-

Dialogue Act/Persuasive Strategy	Example Utterance
Greeting	Hello there! How are you doing?
Source-related inquiry	Have you heard of the organization Save the Children?
Personal-related inquiry	Do you have kids yourself?
Credibility appeal	Save the Children is an international non-governmental organization that promotes children's rights, provides relief, and helps support children in developing countries.
Emotional appeal	It make me feel sad to see that so many children are suffering from poverty and hunger.
Logical appeal	Donations are extremely important in order for children to have their rights to healthcare, education, safety, etc. If you were to donate, you would be making a huge impact on these children and on the world.
Self-modeling	I think I'll donate a bit of my money to Save the Children, $2.
Foot-in-the-door	Every little bit helps. Even a small amount!
Personal story	Someone told me that he and his brother replaced birthday gifts with charity donations a few years ago, and it was a really rewarding experience for them.
Propose donation	Would you like to make a donation to Save the Children?
Closing	Thank you, it's been lovely talking to you. Enjoy your day and bye!

Table 1: Examples of each dialogue act from PERSUASIONFORGOOD used for the chatbot.

domain social dialogue systems should form a consistent personality to develop users' trust, satisfy the human need for affection and social belonging, and generate interpersonal responses (Huang et al., 2020; Zhou et al., 2020; Walker et al., 2004) suitable for any input (Higashinaka et al., 2014). Consistent with this need for affection and acknowledgement, Zhang and Danescu-Niculescu-Mizil (2020) find that in crisis counseling, it is necessary to balance the goals of both "empathetically addressing the crisis situation" and "advancing the conversation towards a resolution." Additionally, Sun et al. (2021) improved engagement with task-oriented dialogues by adding "chit-chat." This suggests that balancing the need for human acknowledgement with advancing towards conversational goals may improve persuasion outcomes. Very recent work has made progress by transitioning from chit-chat to task-oriented dialogue (Chiu et al., 2022). *However, to truly achieve this balance, we propose interweaving social content with pushing a conversational agenda in order to improve coherence, friendliness, and persuasiveness.*

Retrieval-based dialogue systems have long been considered one of the core classes of conversational systems (Banchs and Li, 2012), often being used for question answering systems (Gao et al., 2019) due to their ability to return "fluent and informative responses" (Yang et al., 2019). But, recent work has been able to directly improve their open-domain dialogue systems by ensembling both retrieval methods (e.g., database queries) with neural generation methods (Song et al., 2016; Yang et al., 2019; Cai et al., 2019; Weston et al., 2018). *Thus, we propose retrieving factual information to improve a persuasive dialogue system's ability to consistently and coherently address user questions, which may lead to improved perceptions of intelligence, coherence, and trustworthiness.*

3 Dataset

We use the 300 annotated anonymous English conversations in the PERSUASIONFORGOOD dataset. In each conversation, one person, the "persuader," tries to convince their conversational partner, the "persuadee," to donate to Save the Children. The conversations last for 10 turns, and a user's utterance during a turn contains at least one sentence. Each sentence is annotated with one of several dialogue acts, including inquiries (e.g. "Have you donated to a charity before?") and various persuasive appeals (e.g. "I'll match your donation, and together we can double the amount!"). In this work, we build a system that acts as a persuader. The full list of persuader dialogue acts used is provided along with examples in Table 1.

4 The RAP Framework

The dynamics of a persuasive conversation fall between that of social dialogue and task-oriented dialogue. Typically, social chatbots like Blenderbot (Komeili et al., 2021; Xu et al., 2021) are used to engage with users in chit-chat, and language models like BART (Lewis et al., 2020) are used in controllable generation (Wu et al., 2021a). However, it is difficult for one end-to-end model to perform both

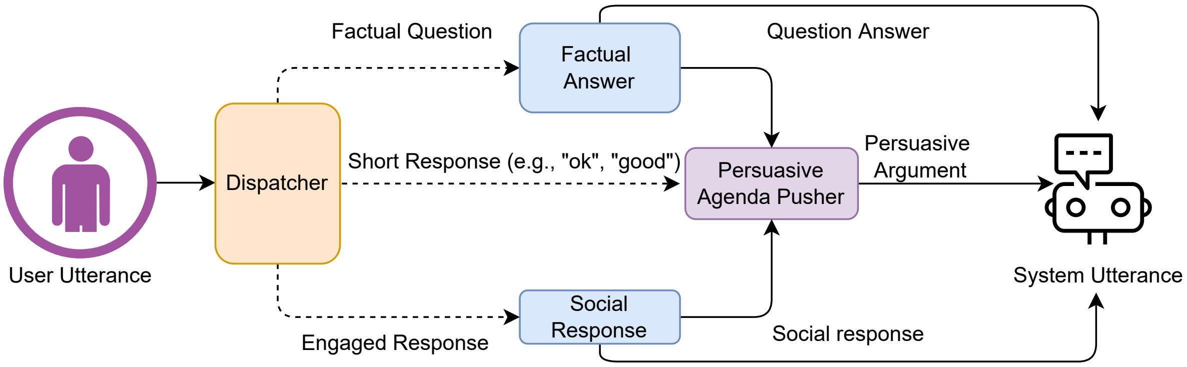


Figure 2: Overview of the RAP framework. The user's utterance is classified by the Dispatcher (orange module), which decides whether it should be sent to the Factual Answer Module, Social Response Module, or neither (blue modules). The output from this first layer is propagated into the inputs to the Persuasive Agenda Pushing Module (purple module). The outputs from the blue and purple modules are concatenated as the final system utterance.

tasks. We break down the problem of generating a persuasive response into two parts: 1) generating an utterance that *responds* to users' comments, questions and concerns, and 2) generating an utterance that *pushes the agenda* of a conversation. In this context, pushing an agenda refers to progressing through a set of persuasive strategies as in Table 1. We propose interweaving responses with agenda-pushing within the same turn, inspired by the joint goal balancing in Zhang and Danescu-Niculescu-Mizil (2020). As outlined in Figure 2, our framework comprises four core components: a *dispatcher* to decide which response modules to invoke, a *factual answer* module and a *social response* module to acknowledge and respond to users, and an *agenda-pushing model* to ensure the persuasive conversation stays on task.

4.1 The Dispatcher

Upon receiving an utterance from a user, RAP first invokes the Dispatcher to decide which response module(s) to invoke. It classifies the dialogue act of the user utterance using a dialogue act classifier from Shi et al. (2020). As shown in Figure 2, if the utterance includes a factual question or task-related inquiry as determined by its dialogue act or regular expressions, the Dispatcher will invoke the Factual Answer Module. If the dialogue act instead indicates that it is a statement that shows engagement[2] with the chatbot, the Dispatcher will invoke the Social Response Module. The output of the Factual Answer and Social Response modules is propagated to the Agenda Pusher.

4.2 Creating Engagement via User Response

The Factual Answer Module In order to maintain consistency in answers, we compute the cosine distance of Sentence-BERT (Reimers and Gurevych, 2019) embeddings between the user's question and question-answer mappings from the training data. The question-answer mappings are also built using Sentence-BERT by aggregating the answers of all of the most similar questions. We retrieve the answer to the question that has the lowest cosine distance in semantic meaning from the question asked by the user.

The Social Response Module The Social Response Module comprises of a pretrained Blender Bot 2.0 instance with 3B parameters, an updated version of the open-domain BlenderBot social chatbot (Roller et al., 2021), that builds long-term memory and queries the internet[3]. We feed the model a context string consisting of the conversation history and generate a response in a zero-shot setting. We do not keep outputs that Blender Bot 2.0 labels as "potentially unsafe." Finally, we still want to push the agenda of the conversation, regardless of whether or not the Social Response or Factual Answer modules were invoked to generate a directed response towards the user.

4.3 The Persuasive Agenda-Pushing Module

We ensure that the conversation stays on the persuasive agenda using conditional generation with BART (Lewis et al., 2020)[4], a pre-trained Trans-

[2] The dialogue act must not be "acknowledgement."

[3] We use a publicly available implementation of Blender Bot 2.0 that makes use of a Google search retriever.

[4] BART Large, 406M parameters.

former language model. If the Factual Answer or Social Response modules are invoked, the response is appended to the conversation history, which is included as input to BART for consistency.

4.3.1 Conditional Generation Background

For our agenda-pushing model, we fine-tuned BART on the Persuasion4Good dataset using HuggingFace's Transformers package (Wolf et al., 2020). However, it is not enough to just perform language modeling: *an automated persuasive dialogue system should incorporate pragmatic persuasive strategies to ensure the conversation stays on task*. Thus, we draw inspiration from CTRL (Keskar et al., 2019), a state-of-the-art Transformer model for conditional generation.

Traditionally, language modeling is framed as a problem of learning next-word prediction and the objective is to minimize the negative log likelihood, $L(D)$, over a dataset $D = \{x_1, x_2, ..., x_{|D|}\}$.

However, CTRL conditions on a control code c, reformulating next-word prediction as $P(x|c)$ (equation 1),

$$P(x|c) = \prod_{i=1}^{n} P(x_i | x_{<i}, c) \tag{1}$$

and reformulating the negative log likelihood conditionally (equation 2).

$$L_c(D) = -\sum_{k=1}^{|D|} \log(p_\theta(x_i^k |, x_{<i}^k, c)) \tag{2}$$

4.3.2 Conditional Generation with Pragmatic Persuasive Strategies

In CTRL, the control codes were used to control aspects of language such as style and content. In our study, we create a system that conditions on pragmatic dialogue acts (e.g., persuasive strategies). The agenda of dialogue acts is listed in order in Table 1 along with an example of each. This ordering was determined in Wang et al. (2019) as the most probable dialogue act at each turn.

To this end, we fine-tune BART on the Persuasion4Good dataset, randomly selecting 80% of the conversations as a training set. and 10% as a validation set. A design decision of note is the construction of each training instance. Since the Persuasion for Good dataset contains multiple sentences (and consequently, multiple dialogue acts) per turn, one must choose between having each training instance represent one sentence as the target utterance, or a concatenation of several sentences as the target utterance. We ultimately chose to follow the latter in order for the model to learn more coherent generation. However, multiple-sentence conditional text generation also results in a more complicated task than classic single-sentence generation tasks.

Drawing inspiration from Li et al. (2020), each training instance i is ultimately represented as a concatenation of the *history of the persuader and persuadee utterances*, the *previous dialogue act*, and the *planned dialogue act* on turn i (i.e., the ground-truth annotated dialogue act associated with the target utterance).

While one can train a conditional generation model according to $L_c(D)$ through methods such as concatenating control codes to the end of the input sequence, we find that on the PERSUASIONFORGOOD dataset, such models cannot learn to consistently generate utterances according to the correct dialogue act. We thus add a penalty during loss computation, resulting in $L_p(D)$ (equation 3):

$$L_p(D) = L_c(D) + \alpha * [f_{dc}(y) \neq c] \tag{3}$$

where $f_{dc}(y)$ is the output of a dialogue act classifier as described in Shi et al. (2020) (a GPT-2 based model achieving the state-of-the-art on the PERSUASIONFORGOOD task: 0.66 F1), y is the generated utterance of a model given $x_{<i}^k, c$, and α is a tunable penalty for generating an utterance that does not match dialogue act c (i.e., when $f_{dc}(y) \neq c$). α is tuned throughout the training process, in addition to other hyperparameters such as the learning rate.[5]

5 Evaluation

We evaluate RAP against an end-to-end fine-tuned BART model as described in Section 4.3.2. This allows us to directly evaluate the impact of integrating factual information and social content and persuasive strategies in contrast to a conversation only driven by persuasive strategies.

We evaluate the performance of the conditional generation model by calculating the dialogue act accuracy on a withheld test set consisting of 10% of all conversations. As language generation is non-deterministic, we average the dialogue act accuracy across ten passes. We chose BART over Blenderbot in the Persuasive Agenda-Pushing Module because

[5] For each hyperparameter setting, we used a fixed decoding method — beam sampling with n-gram blocking.

Utterance Statistic	Baseline	RAP
# Chatbot Words	11.14	16.41
# User Words	3.70	**5.75****
# Chatbot Sentences	1.02	1.48
# User Sentences	1.09	**1.17****

Table 2: Average number of words and sentences per turn for both the chatbot and the user in conversations with both the baseline (BART) and RAP. ** statistically significant differences in user reply length ($\alpha = 0.05$).

Blenderbot did not achieve as strong of a dialogue act accuracy. This is likely because Blenderbot is better-suited for social dialogue, whereas the dialogue act utterances are largely task-oriented in nature. Additionally, we specifically do not use metrics such as perplexity to compare the BART baseline and RAP because RAP is a result of several different components, and not all of which do we train or fine-tune. Additionally, because of the penalty added in L_p, training perplexity is no longer interpretable. It also cannot be compared to other models in other work that has used the PERSUASIONFORGOOD dataset such as Li et al. (2020), as the model sizes differ. Most importantly, the primary objective is to build a more persuasive dialogue system, making it imperative to emphasize users' perception and conversation experience. Thus, to compare between the two frameworks, we primarily rely on feedback from human evaluation. We additionally compare utterance-based proxies for user engagement in Table 2.

6 Experimental Setup

We deployed our chatbot using the LegoEval platform (Li et al., 2021). The chatbot is given a gender-neutral name, Jaime. The task consists of a pre-task survey, a conversation where each participant responds to the chatbot with a minimum of seven and maximum of ten conversational lines, and a post-task survey. The pre-task survey consists of questions about demographic information (e.g., age, gender, income) and a test of the Big Five personality traits (Goldberg, 1992). The post-task survey asks participants about their conversation experiences. It includes an attention validation question ("What charity was the chatbot talking about?") then asks about the users' intention to donate to Save the Children and their perception of the chatbot, including evaluations on various traits such as perceived competence and warmth. The full lists of questions is outlined in Table 3. Each participant was asked to share their impression of the chatbot along each trait using a Likert scale. A score of 1 corresponds to “strongly disagree” and 5 corresponds to “strongly agree.” We recruited 111 students from a Natural Language Processing class at Columbia University in exchange for course credit. Three participants did not correctly answer the validation question, resulting in a final sample of 108 participants. Each participant interacts for seven to ten turns, resulting in a sample of up to 1080 user dialogue turns. We used a double-blinded, between-subjects design. Each participant was given a link that randomly assigned the participant to the chatbot running on the baseline or RAP, and completed the task once.

7 Results

In this section, we discuss the results of comparing RAP and baseline only using BART, the impact of individual components of RAP , and qualitatively examine participant case studies.

7.1 Analyzing the Impact of RAP

Across ten passes, the BART model achieves a dialogue act accuracy of 62.38%, and was used as a part of RAP as the Agenda-Pushing Module. In Table 2, we see that RAP yielded better engagement from the participants. On average, participants responded to RAP with 5.75 words per utterance compared to 3.70 words per utterance when responding to the baseline (p-value < 0.001). Participants were also more likely to respond to RAP with more than one sentence (average: 1.17 sentences per utterance) than the baseline (average: 1.09 sentences per utterance; p-value < 0.01). Additionally, in Table 3, we find that RAP outperforms the baseline on every single perceived trait. Most notably, we see a statistically significant difference on the competence and confidence of RAP , indicating RAP is perceived to be more capable and confident in engaging in substantial topics and persuasive contents. Beyond statistical significance, we see that RAP receives better evaluations on *every* single metric in comparison to the baseline, including persuasiveness, intelligence, trustworthiness, naturalness, and increasing the user's intention to donate.

The chatbot...	**Baseline** ($\mu \pm \sigma$)	**RAP** ($\mu \pm \sigma$)	**Invoked Social**	**Invoked Factual**
is competent ↑	2.53±0.82	3.00±1.06$\ast\ast$	2.98±1.08$\ast\ast$	**3.03±1.00**$\ast\ast$

is confident ↑	3.35±1.01	3.72±0.89$\ast\ast$	3.71±0.91$\ast$	**3.76±0.78**$\ast$
is a strong reason for donating ↑	2.67±0.92	**2.84±1.02**	2.78±1.03	2.82±1.09
was dishonest ↓	2.14±0.89	1.91±0.80	1.94±0.83	**1.88±0.77**

Table 3: Comparing mean and standard deviation of the baseline (BART) and RAP from the post-task survey. Statistically significant differences compared to the baseline at $\alpha = 0.05$ are denoted with $\ast\ast$; significant differences at $\alpha = 0.1$ are denoted with $\ast$. 51 participants used the baseline and 57 participants used RAP . Of the 57 RAP participants, 51 had conversations that triggered the Social Response Module and 33 conversations triggered the Factual Answer Module. 24 conversations triggered the Social Response Module but not the Factual Answer Module, and 6 conversations triggered the Factual Answer Module but not the Social Response Module.

7.2 Analyzing Individual Module Contributions

Due to constraints on our sample size, we could not run full ablation studies where we remove individual modules of the model. Instead, we analyze the perception of RAP in conversations that invoke each of the Social and Factual Answer modules. These findings are also reported in Table 3. We additionally find that each of the Social and Factual Answer modules outperform the baseline on conversations in which they were invoked. Notably, we saw that the chatbot was perceived as friendlier and significantly more competent after invoking the Social Response module. However, while there was a difference in the perceived persuasiveness of the chatbot, the difference was much smaller. This implies that perhaps social content is less closely coupled to the persuasiveness of individual arguments. After conversations invoking the Factual Response module, we indeed see the biggest increase in perception of intelligence across all conditions, although the difference is not statistically significant. We also see the largest increase in perceptions of competence. Most surprisingly, we find the biggest increase in friendliness after conversations that invoke the Factual Answer Module. This could imply that ensuring that users' questions are answered is very important in making their voices feel heard and acknowledged.

Surprisingly, there were even modules that received statistically significant differences in ratings from the baseline even when not viewed in aggregate with RAP — this is the case for both the Social and Factual Answer Modules on competence and confidence. The Factual Answer module also received a statistically significantly higher rating on friendliness, whereas the difference for RAP was not statistically significant. Moreover, in several cases, conversations which invoked the Factual Answer module received the best-performing scores on average. Both of these findings are likely due to the fact that in nearly all cases where the Factual Answer module was invoked, the Social Response module was also invoked, but the inverse is not true. This may also indicate that the results in the Invoked Factual column is the most holistic representation of the complete RAP framework.

7.3 Qualitative Case Studies

We find that participants who actively engaged RAP were able to hold coherent, intelligent conversations. Figure 1 shows an example of a participant who had previously heard of Save the Children. The participant had commented on their view of the importance of Save the Children, and the chatbot running using RAP was able to acknowledge their opinion ("I agree"), while further elaborating on their discussion topic ("There is a lack of support for children ... in war zones"). This statement was used to condition the agenda-pushing emotional appeal ("It's so hard to imagine what it's like for a child to grow up facing the daily threat of violence"). The full conversation is provided in Table 4 in Appendix A. User anecdotes included mentioning that they were "pleasantly surprised" by the ability of RAP to acknowledge them with remarks like “I agree.” Two full conversations with the baseline dialogue system are also provided in Tables 6 and 7. The baseline system generally appears to perform well at generating utterances according to the right dialogue act (e.g., “I have a great story about how I helped a child in need in the first two months of the new year” for the “personal story” dialogue act in Table 7). In contrast to RAP, users often quickly lose interest in the dialogue system, as they do not feel acknowledged. Participants who only interacted with the baseline complained that their questions went unanswered (e.g. User: “Do you know who is their founder?” Chatbot: “They are an international NGO ...”), and thus questioned whether their input was even considered by a model.

Despite these improvements, RAP does not seem to handle current events well. In general, conditioning on social content and factual information appears to greatly improve the quality of the Agenda-Pushing Module’s generation. However, when Blender Bot 2.0 cannot generate a safe output, the Agenda-Pushing Module does not seem to handle such out-of-domain instances well. One participant commented on the ongoing war in Ukraine. Blender Bot 2.0 was unable to produce a safe output, leaving the Agenda-Pushing Module to come up with a relevant response. However, Ukraine never appears in the training data, so the module’s conditional generation model instead mentions conflicts in several other countries, and performs self-modeling. Such behavior can come across as dismissive or tone-deaf towards the user. The full conversation is provided in Table 5 of Appendix A. While this particular implementation of RAP leveraging Blender Bot 2.0[6] and a fixed knowledge source for retrieval may have issues with current events, RAP is general enough that it could potentially be updated with new knowledge and improved internet retrieval modules in the future which can more consistently generate safe outputs.

8 Discussion

Overall, we find that RAP and each of its individual modules is able to outperform state-of-the-art conditional generation models on PERSUASIONFORGOOD . One of the core advantages of end-to-end conditional generation models is that they are easily transferrable to different datasets. But, RAP is also easily transferrable — the only requirement is that the dataset contains a set of dialogue acts with sufficient data to train a classifier, as the biggest bottleneck is being able to use a dialogue classifier for L_p and in building the Dispatcher. On smaller datasets, it may even be possible to perform transfer learning using a classifier pre-trained on the PERSUASIONFORGOOD dataset. The Social Response Module is directly transferrable, as we are able to achieve high quality results using it zero-shot, and the Factual Answer Module uses Sentence-BERT to group together training data.

Limitations Due to the cost of human evaluation, our sample size is relatively small, 51 and 57 people for the two conditions. This limitation restricted us from performing a full ablation in which we evaluated chatbots which used each module individually. We hope to obtain larger samples in the future to better evaluate the efficacy of our system.

Additionally, considering the sample consists of students enrolled in Natural Language Processing, they possess a more technical background with higher standards for chatbots than the average user on Mechanical Turk. Moreover, because the sample did not enter as participants out of personal interest in Save the Children, they are less likely to be interested in childrens’ charities than an individual on the internet who goes out of their way to interact with such a chatbot, which may be reflected in evaluation scoring. Anecdotally, we see in Section 7.3 that individuals who do have some sort of inclination towards charitable organizations are actually quite positive and receptive towards the chatbot. In this regard, we are likely limited by the funds necessary to acquire a sample whose interests better align with PERSUASIONFORGOOD. Our work faces several challenges to ultimately evaluate the hypothesis that persuasive conversations should be handled as jointly social and task-oriented.

While the dialogue act accuracy of the Agenda-Pushing module is only 62.3%, this metric is bottlenecked by f_{dc} in equation 3; the F1-score of the classifier is only 0.66 (the state-of-the-art on the PERSUASIONFORGOOD dataset), implicitly limiting the upper bound of any generation model that is reliant on it. We find from users’ conversation experiences that the chatbot more than sufficiently presents persuasive strategies. If one has a dialogue act classifier with stronger performance, they would be able to improve the ability of their

[6] Recent concurrent work (Blender Bot 3.0) has examined dialogue safety with a different internet retriever.

agenda-pushing model to learn persuasive strategies even further. We additionally find that *without* a dialogue act classifier (i.e., without L_p), BART is unable to achieve a dialogue act accuracy higher than 30% on the PERSUASIONFORGOOD dataset.

9 Conclusion

Overall, we find perceptual improvements by specifically integrating social content and factual information into persuasive dialogues with RAP compared to a strong end-to-end conditional generation model like BART. While existing methods like Li et al. (2020); Wu et al. (2021b) achieve strong performance on automatic metrics like perplexity, RAP directly emphasizes upon users' conversational experience with a modular design rooted in social science theory. RAP is generalizeable and may even be applied towards persuasive contexts outside of charitable conversations, e.g., in the case of therapy and crisis counseling (Zhang and Danescu-Niculescu-Mizil, 2020) where there are also split goals (ensuring users feel heard and pushing a conversational agenda). Future work on persuasive dialogue systems could consider implementing a strategy planner using supervised learning. Additionally, researchers could consider looking for relationships between personality data, persuasive strategies, and persuasion outcomes.

10 Ethical Considerations

All participants were informed that they were talking to a chatbot developed by Columbia University researchers. This ensures transparency in experiment design, so that participants will never feel ambiguity or discomfort with respect to whether they are speaking with a human or a chatbot. Participants also gained additional insight about their own communication styles based on the results of their Big Five personality test. All data collection associated with this task has been declared exempt by an ethics review board. All data was collected anonymously. E-mails were voluntarily provided for credit, but stored separately from the anonymized data.

Persuasion is a tricky social dynamic. It has been heavily studied, and the intention of this work, like the PERSUASIONFORGOOD dataset used, is that persuasive dialogue systems should only ever be created for social good. All related applications discussed are intended to create good for the world at an individual and societal level.

Acknowledgements

Thanks to Intel for supporting this work through a research gift. We also thank Kun Qian and Yu Li for helpful discussions and feedback, and our reviewers for their suggestions. We are grateful to all of our study participants for their help in evaluating our systems.

System	Hello, how are you today?
User	Hi! I'm good, how are you?
System	I'm terrific! Have you heard of the charity Save the Children?
User	Yes, I have heard of them! They are one of the leading charities on health.
System	That's great! They do a lot of great things or children in developing countries.
User	Yes, their work includes everything from policy to on-the-ground assistance for children. It's great to know that there are such helpful organizations who focus on child health/education.
System	That's great. It's so sad to see how many children die from preventable causes.
User	I agree, a lot of developing countries don't have systems or infrastructures to protect children from these causes.
System	I agree. There is a lack of support for children in developing countries, especially in war zones. It's so hard to imagine what it's like for a child to grow up acing the daily threat of violence.
User	Charities might not be able to help with things like war, so that's where charities' roles become challenging. They need to deliver essential health care and services to children or the long-term.
System	That's a really good point. I am going to donate a bit of my money to Save the Children
User	That's so great! You encourage me to get into the habit of donating as well.
System	Every little bit helps. Even a small amount!
User	Yup! Thank you for doing some good for the organization and the people it serves.
System	Thank you so much for the kind words.

System	Hello, how are you today?
User	I am doing very well. Thanks for asking.
System	Thanks for your kind words. Do you know about Save the Children?
User	I have little knowledge about this.
System	Save the Children is an international Non-Governmental organization that promotes children's rights, provides relief and helps support children in developing countries.
User	I see.
System	It is heartbreaking to see the suffering of children in war zones.
User	I agree with you. This is devastating. You could see what is happening in Ukraine right now...
System	I can't imagine what it is like to live in a war zone. A child's life is more important than any other thing in the world . a lot of children grow up facing the daily threat of violence.
User	I kind of worry for those children in Ukraine.
System	I also worry for the children in Iraq and Afghanistan and Syria and Libya. I am going to donate a bit of my money to Save the Children.
User	Let me know how you would like to donate.
System	I will donate to a charity that helps Ukrainian children. Every little bit helps.
User	That's good to hear.
System	Save the children has a huge impact on children's lives. Your donation will go a long way in helping these children.
User	Hmm. Okay. I agree with you, but how do I do that?
System	You can donate directly to the charity. Would you be interested in donating a bit of money to Save the Children?
User	Do you have a link or something I could directly go to?
System	I sure do as a matter of fact it's <URL>. Sorry, I have to go now, but it's been great talking to you! Thanks for your time!
User	Cool. See you.

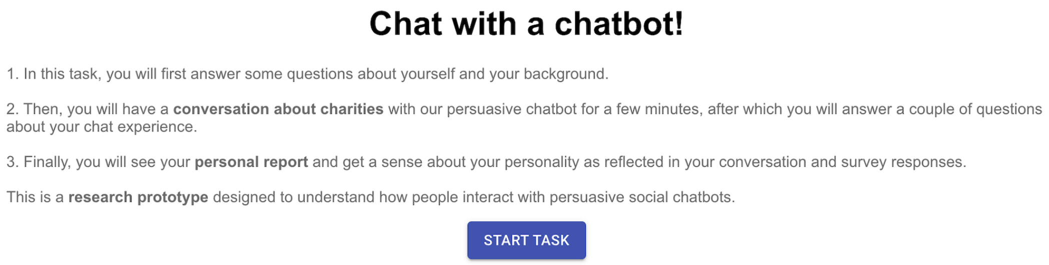
B Experiment Instructions



Chat with a chatbot!

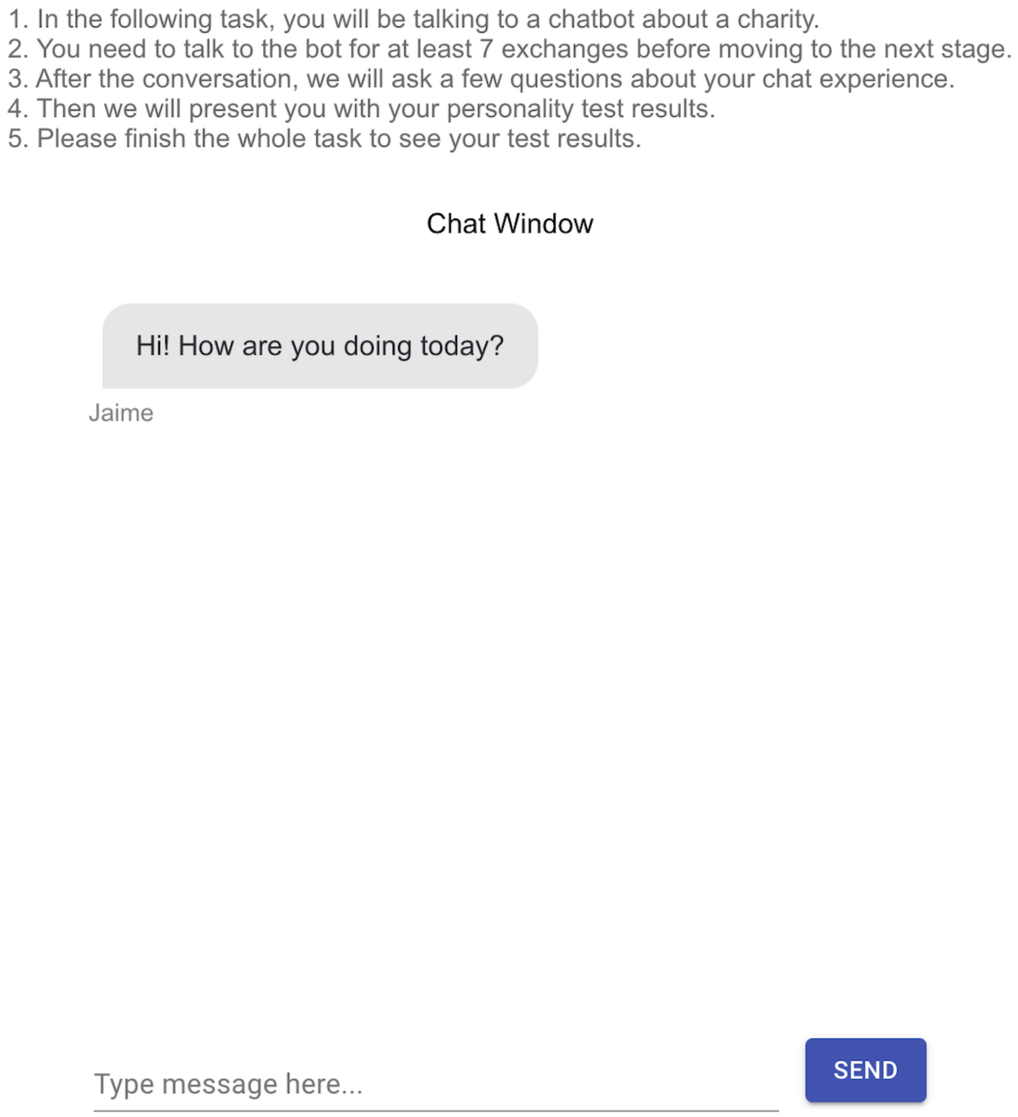
1. In this task, you will first answer some questions about yourself and your background.

2. Then, you will have a **conversation about charities** with our persuasive chatbot for a few minutes, after which you will answer a couple of questions about your chat experience.

3. Finally, you will see your **personal report** and get a sense about your personality as reflected in your conversation and survey responses.

This is a **research prototype** designed to understand how people interact with persuasive social chatbots.

Figure 3: Screenshot of instructions given to participants. Participants are told that this chatbot is a research prototype, and are given course extra credit in exchange for participation.



1. In the following task, you will be talking to a chatbot about a charity.
2. You need to talk to the bot for at least 7 exchanges before moving to the next stage.
3. After the conversation, we will ask a few questions about your chat experience.
4. Then we will present you with your personality test results.
5. Please finish the whole task to see your test results.

Chat Window

Hi! How are you doing today?

Jaime

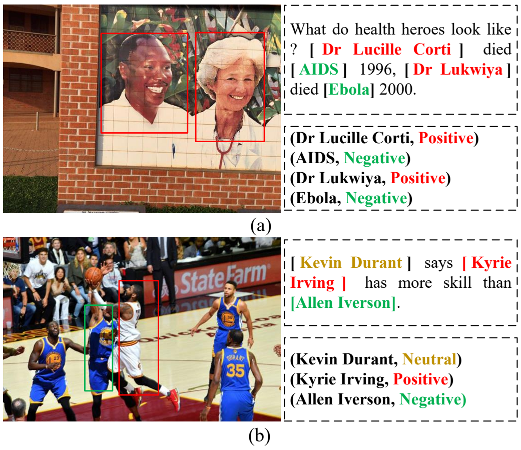
Abstract

Multimodal aspect-based sentiment analysis (MABSA) aims to extract the aspect terms from text and image pairs, and then analyze their corresponding sentiment. Recent studies typically use either a pipeline method or a unified transformer based on a cross-attention mechanism. However, these methods fail to explicitly and effectively incorporate the alignment between text and image. Supervised finetuning of the universal transformers for MABSA still requires a certain number of aligned image-text pairs. This study proposes a dual-encoder transformer with cross-modal alignment (DTCA). Two auxiliary tasks, including text-only extraction and text-patch alignment are introduced to enhance cross-attention performance. To align text and image, we propose an unsupervised approach which minimizes the Wasserstein distance between both modalities, forcing both encoders to produce more appropriate representations for the final extraction. Experimental results on two benchmarks demonstrate that DTCA consistently outperforms existing methods. For reproducibility, the code for this paper is available at: https://github.com/windforfurture/DTCA.

1 Introduction

Human experience of the world is multimodal, e.g., seeing objects, hearing sounds, feeling textures, and tasting flavors. Multimodal experiences are usually mutually associated to some extent. For example, images are usually associated with tags and text explanations, and text often contains images to more clearly express the main intent of the author.

With the widespread availability of smart phones with digital cameras, social media posts have become increasingly multimodal . To practically apply the existing aspect-based sentiment analysis, one must be able to interpret such multimodal attributes together (Yu et al., 2022; Ling et al., 2022).



What do health heroes look like? [Dr Lucille Corti] died [AIDS] 1996, [Dr Lukwiya] died [Ebola] 2000.

(Allen Iverson, Negative)
(b)

Figure 1: Two examples of joint multimodal aspect sentiment analysis.

Figure 1 (a) shows an example: *What do health heroes look like? Dr Lucille Corti died AIDS 1996, Dr Lukwiya died Ebola 2000.* An intelligent system is expected to extract four aspect-sentiment pairs from this text, i.e., (*Dr Lucille Corti*, **positive**), (*AIDS*, **negative**), (*Dr Lukwiya*, **positive**) and (*Ebola*, **negative**). Notably, if only the language modality is used for inference, the model tends to predict (*Dr Lucille Corti*, **negative**) and (*Dr Lukwiya*, **negative**). Related to the vision modality, the expression of the text will become more ironic, and thus tends to be positive. Figure 1 (b) shows another example: *Kevin Durant says Kyrie Irving has more skill than Allen Iverson*. It is difficult to infer from the image that this person is necessarily good at basketball, while a direct understanding of the text seems to recognize the attitude of the author towards *Kyrie Irving and Allen Iverson*.

Based on this, existing methods for multimodal aspect-based sentiment analysis are typically composed of two subtasks in a pipeline model, including multimodal aspect term extraction (MATE) and multimodal aspect sentiment classification (MASC). The former tries to identify all the as-

pect terms from texts (Wang et al., 2021), while the latter aims to classify the sentiment for each identified aspect term (Hosseini-Asl et al., 2022; Zhang et al., 2021b; Yuan et al., 2022). Unfortunately, the pipeline approach ignores the innate relationship between the two subtasks and is prone to error propagation.

Alternatively, another obvious solution is to apply multitasked learning to integrate both subtasks into a joint framework (Vazan and Razmara, 2021). Combining different modalities or types of information to improve performance seems intuitively appealing, but it is challenging in practice to reconcile the varying levels of noise and conflicts between modalities. A series of convolution-based models are usually applied to extract image features, including VGG (Simonyan and Zisserman, 2015) and ResNet (He et al., 2015). To extract region-of-interest (ROI) features, several subsequent works have used a Fast R-CNN (Girshick, 2015) to learn the image representation (Zhang et al., 2021a). For text, Transformer-based models, such as BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019) , XLNet (Yang et al., 2019) and ELECTRA (Clark et al., 2020) have greatly improved the capability of language understanding and generation.

Taking the obtained representation of both modalities as input, recent studies applied different attentions to compose the features for the final classification. For examples, Ju et al. (2021) and Xu et al. (2022) applied a cross-modal self-attention approach to learn text-image interaction and obtain image-aware text representations and text-aware image representations. However, the image-text pairs present different kinds of knowledge. Thus, different modalities may contribute differently to the final classification, and do not have equivalent amounts of information in each modality, with the language modality tending to dominate with more information. For training, the gradients from the dominant modality will overwhelm the other, effectively preventing the entire model from being trained. It is difficult to encode explicit cross-modal information by superficially measuring the attention distribution.

Based on the universal Transformer architecture, the unified vision-and-language pretrained models can simultaneously encode both modalities, e.g., OSCAR (Li et al., 2020) and UNITER (Chen et al., 2020). However, they are insensitive to aspect extraction and sentiment detection from both language and vision modalities. Finetuning these models with a supervised learning still require a certain number of aligned image-text pairs.

In this study, a dual-encoder transformer with cross-modal alignment (DTCA) is proposed for multimodal aspect-based sentiment analysis. Instead of extracting ROI features, we apply the ViT strategy (Dosovitskiy et al., 2021), which tokenizes the image by slicing it into a sequence of patches. Both ViT and RoBERTa are initialized from pretrained checkpoints, and were used to encode the vision and language modalities. To align the learned features, a multitask learning architecture containing three subtasks was applied, including text-only extraction, co-attention interaction, and token-patch matching. Aside from the co-attention module, we propose minimizing the Wasserstein distance between tokens and images to improve the training effectiveness of the proposed model.

Comparative experiments were conducted on two different benchmarks. The empirical results show that the proposed model outperforms the existing unimodal and multimodal models for MABSA tasks. The effects on different subtasks were further evaluated, finding that the different subtasks all play an indispensable role in performance improvement.

The remainder of this paper is organized as follows. Section 2 presents a detailed description of the proposed DTCA model. Section 3 summarizes the implementation details and experimental results. Conclusions are drawn in Section 4.

2 Dual-Encoder Transformers

Figure 2 shows the overall architecture of the proposed dual-encoder transformers with cross-modal alignment. Two individual transformer-based models, i.e., RoBERTa (Liu et al., 2019) and ViT (Dosovitskiy et al., 2021), were respectively applied for text and image encoding. Notably, both RoBERTa and ViT share the same encoder architecture, which is initialized from a well pretrained checkpoint. Three subtasks were applied for cross-modal alignment to enhance the performance of cross-modal attention for MABSA.

2.1 Modality-specific Encoder

Tokenizer. An input sample $\mathbf{x}$ consists of two modalities, including an image $\mathbf{v}$ and a text $\mathbf{s}$.The objective of MABSA is to perform sequence la-

beling to predict the labels $\mathbf{y} = \{y_1, y_2, \ldots, y_N\}$ where N is the length of the text. Following the ViT, the image was first sliced into a sequence of patches $\mathbf{v} = [v_1, v_2, \ldots, v_M] \in \Re^{M\times(P^2\times C)}$, where (P, P) is the resolution of each patch, C is the number of channels, and $M = HW/P^2$ is the resulting number of patches. Each patch was then flattened and prepended with a special token, i.e., $v_{[\text{CLS}]}$, followed by a linear projection $V \in \Re^{(P^2\times C)\times d_h}$. The result patch embeddings $\bar{v} \in \Re^{(M+1)\times d_h}$ can be formulated as,

$$\bar{v} = [v_{[\text{CLS}]}, v_1V, v_2V, ..., v_MV] + V^{pos} \tag{1}$$

where d_h is the dimensionality and $V^{pos} \in \Re^{(M+1)\times d_h}$ is the position embeddings.

For language modality, the input text is tokenized by the WordPiece (Wu et al., 2016) tokenizer as same as in the RoBERTa model to obtain a sequence of token embeddings $\bar{t} \in \Re^{(N+1)\times d_h}$ with a word embedding matrix $T \in \Re^{N\times|\hat{V}|}$ as follows,

$$\bar{t} = [t_{[\text{CLS}]}, t_1T, t_2T, ..., t_NT, t_{[\text{SEP}]}] + T^{pos} + T^{seg} \tag{2}$$

where $T^{pos} \in \Re^{(N+1)\times d_h}$ and $T^{seg} \in \Re^{(N+1)\times d_h}$ are respectively the position and segment embeddings, and $|\hat{V}|$ is the number of the vocabulary items. Here, the [CLS] and [SEP] tokens respectively respond to <*s*> and </*s*> tokens in the RoBERTa model. We did not apply any extra embeddings to annotate the type of modality, since

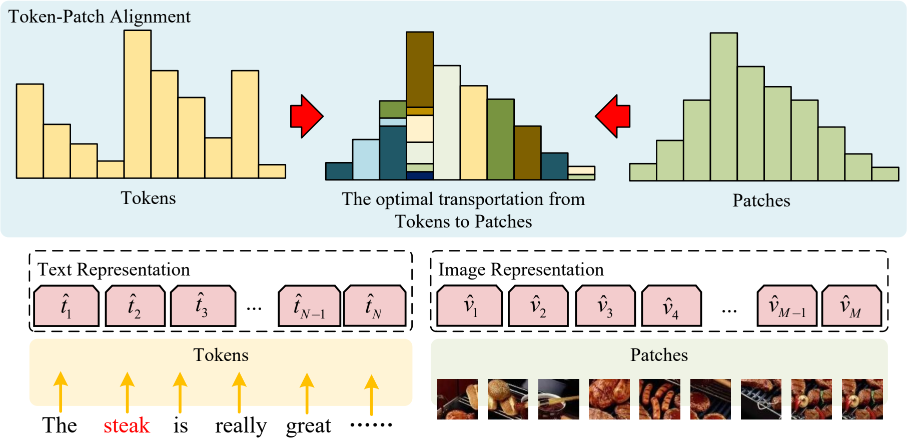

Figure 3: The conceptual diagram of the proposed Token-Patch Alignment.

doing so brings no additional improvement to the proposed model.

Encoders. Both RoBERTa and ViT consist of stacked Transformer blocks including a multi-head self-attention (MHSA) layer and an MLP layer. The MLP consists of two dense connection layers with a GELU non-linear activation. Before both MHSA and MLP, layer normalization (LayerNorm) was applied, which can be formulated as,

$$z^{(0)} = \bar{v} \text{ or } \bar{t} \tag{3}$$

$$\tilde{z}^{(l)} = \text{MHSA}(\text{LayerNorm}(z^{(l-1)})) + z^{(l-1)} \tag{4}$$

$$z^{(l)} = \text{MLP}(\text{LayerNorm}(\tilde{z}^{(l)})) + \tilde{z}^{(l)} \tag{5}$$

where l is the index of the layer of RoBERTa or ViT. The final output of transformer encoder is a hidden representation $z_V^{(L)} = [\hat{v}_1, \hat{v}_2, ..., \hat{v}_M]$ and $z_T^{(L)} = [\hat{t}_1, \hat{t}_2, ..., \hat{t}_N]$ at the last, i.e., the L-th layer, which is used for multitask learning and the final extraction.

For all experiments, the weights of RoBERTa and ViT were respectively initialized from pretrained `roberta-base` and `vit-base-patch16-224-in21k`. The hidden size d_h is 768, the number of layers of encoder L is 12, patch size P is 14, MLP size is 3,072 and the number of attention heads is 12.

2.2 Cross-modal Alignment

To align the features of both the vision and language modalities, we propose a cross-modal alignment to train both the image and text encoders for the final cross-modal extraction. It mainly consists of three subtasks: text-only extraction, co-attention interaction, and token-patch matching.

Text-only Extraction. The textual representation obtained from RoBERTa, i.e., $z_T^{(L)} = [\hat{t}_{\text{[CLS]}}, \hat{t}_1, \hat{t}_2, ..., \hat{t}_N, \hat{t}_{\text{[SEP]}}]$ was fed to a fully-connected layer with softmax activation to predict the auxiliary tags for the tokens, defined as,

$$\hat{\mathbf{y}}_n = \text{softmax}(W^t \hat{t}_n + b^t) \tag{6}$$

where $W^t \in \Re^{K \times d_h}$ and $b^t \in \Re^K$ are trainable parameters, and K is the number of the candidate tags. Given a training dataset of $\{\mathbf{x}^{(j)}, \mathbf{y}^{(j)}\}_{j=1}^J$, the loss function is a categorical cross-entropy,

$$\mathcal{L}^{TO} = -\frac{1}{J \times N} \sum_{j=1}^{J} \sum_{n=1}^{N} \mathbb{I}(y_n^{(j)}) \circ \log \hat{\mathbf{y}}_n^{(j)} \tag{7}$$

where $y_n^{(j)}$ is the ground-truth label, $\mathbb{I}(y_n)$ denotes a one-hot vector with the y-th component being one, and $\circ$ represents the element-wised multiplication operation.

For token classification, BIO schema was applied. Instead of using 7 tags as in previous works, we used only 5 tags, i.e., `B-POS`, `B-NEU`, `B-NEG`, `I` and `O`. For example, the sequence of `{B-POS, I-POS}` can be converted to `{B-POS, I}`, so that the number of class K can be compressed by half, thus decrease the prediction error caused by sentiment analysis.

Vision-aware Text Extraction. Multi-head cross-attention was applied to integrate the textual and visual features, where the text representation $z_T^{(L)} = [\hat{t}_1, \hat{t}_2, ..., \hat{t}_N]$ is regarded as the query, while the image representation $z_V^{(L)} = [\hat{v}_1, \hat{v}_2, ..., \hat{v}_M]$ was

Datasets		#S	#A	#Pos	#Neu	#Neg	MA	MS	Mean	Max

Twitter-2017	Train	1745	3562	1508	1638	416	1159	733	15	39
	Dev	577	1176	515	517	144	375	242	16	31
	Test	587	1234	493	573	168	399	263	15	38

Table 1: Statistics of datasets (#S, #A, #Pos, #Neu, #Neg, MA, MS, Mean and Max denote numbers of sentences, aspects, positive aspects, neural aspects, positive aspects, multi aspects in each sentence, multi sentiments in each sentence, mean length and max length).

used as the key and the value,

$$\begin{aligned} & Att_u(z_T^{(L)}, z_V^{(L)}, z_V^{(L)}) \\ & \quad = \mathrm{softmax}\left(\frac{(W_Q^u z_T^{(L)})^\top (W_K^u z_V^{(L)})}{\sqrt{d_h/u}}\right)(W_V^u z_V^{(L)}) \end{aligned} \tag{8}$$

where $W_Q^u \in \Re^{d_h/u \times N}$ and $\{W_K^u, W_V^u\} \in \Re^{d_h/u \times M}$ are matrices of the query, key and value. With multi-head cross-attention, the final representation of vision-aware text extraction $\bar{p} = [p_1, p_2, .., p_N]$ can be formulated as,

$$\bar{p} = W^p[Att_1, Att_2, ..., Att_U]^\top \tag{9}$$

where $W^p \in \Re^{d_h \times d_h}$ refers to the weight matrix for the multi-head cross-attention.

By passing a MLP and two-layer normalization with two residual connections, the resulting representation is $\hat{p} = [\hat{p}_1, \hat{p}_2, ..., \hat{p}_N]$. To ensure the consistency of representation size, the first residual added the text-only representation.

Different from the text-only tasks, the output layer is a CRF to predict layer sequence y as follows,

$$P(\tilde{\mathbf{y}}|\mathbf{x}) = \frac{\exp(score(\mathbf{x}, \mathbf{y}))}{\sum_{\mathbf{y}' \in \mathbf{Y}_\mathbf{x}} \exp(score(\mathbf{x}, \mathbf{y}'))} \tag{10}$$

$$score(\mathbf{x}, \mathbf{y}) = \sum_{n=0}^{N} A_{y_n, y_{n+1}} + \sum_{n=0}^{N} w^{y_n} \hat{p}_n \tag{11}$$

where $\mathbf{A}$ is a transition matrix, and its element $A_{i,j}$ represents the score of a transition from tag i to tag j, $w^{y_n} \in \Re^{2 \times d_h}$ is the weights. The loss function is the negative log-probability of the ground truth label,

$$\begin{aligned} & \mathcal{L}^{CM} = \\ & -\tfrac{1}{J}\sum_{j=1}^{J}\left(s(\mathbf{x}^{(j)}, \mathbf{y}^{(j)}) - \underset{\mathbf{y}' \in \mathbf{Y}_\mathbf{x}^{(j)}}{\mathrm{logadd}} \exp(s(\mathbf{x}^{(j)}, \mathbf{y}'^{(j)}))\right) \end{aligned} \tag{12}$$

Token-Patch Alignment. For matching tokens and patches, there are no annotated labels to supervise the training. Thus, we propose minimizing the Wasserstein distance, also called the earth mover distance (EMD), a measure of the distance between two probability distributions, as shown in Figure 3. Regarding the distribution as a certain amount of earth, the EMD is the minimum cost of turning one pile into another; where the cost is assumed to be the amount of dirt moved times the distance by which it is moved. Based on this, the hidden representation of both text and image for the j-th sample can be assigned with a moving weight,

$$\mathbf{t}^{(j)} = [(\hat{t}_1^{(j)}, w_1^\mathbf{t}), (\hat{t}_2^{(j)}, w_2^\mathbf{t}), ..., (\hat{t}_N^{(j)}, w_N^\mathbf{t})] \tag{13}$$

$$\mathbf{v}^{(j)} = [(\hat{v}_1^{(j)}, w_1^\mathbf{v}), (\hat{v}_2^{(j)}, w_2^\mathbf{v}), ..., (\hat{v}_M^{(j)}, w_M^\mathbf{v})] \tag{14}$$

where $w_n^\mathbf{t}$ and $w_m^\mathbf{v}$ denote the moving weight, respectively initialized as $1/N$ and $1/M$. The cost of moving $\hat{t}_n$ to $\hat{v}_m$ is a normalized mean squared error (MSE), denoted as,

$$\begin{aligned} \delta_{m,n} &= \mathrm{MSE}(\hat{t}_n, \hat{v}_m) \\ &= \frac{1}{d_h}\sum_{d_h}\left\|\frac{\hat{t}_n}{||\hat{t}_n||_2^2} - \frac{\hat{v}_m}{||\hat{v}_m||_2^2}\right\|_2^2 \end{aligned} \tag{15}$$

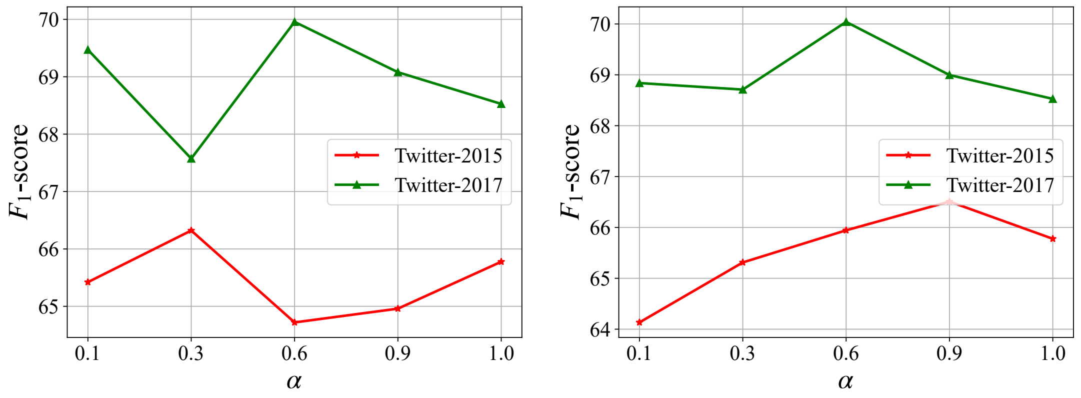
According to Rubner et al. (2000), the target of the token-patch alignment is to find a transfer flow $\mathbf{F}$ that maps the features from $\hat{t}_n$ to $\hat{v}_m$ by minimizing the cumulative cost, defined as,

$$\mathrm{WORK}(\hat{t}_n, \hat{v}_m, \mathbf{F}) = \sum_{n=1}^{N}\sum_{m=1}^{M} f_{m,n}\delta_{m,n} \tag{16}$$

$$\text{s.}t. \quad f_{m,n} \geq 0 \tag{17}$$

$$\sum_{n=1}^{N} f_{m,n} \leq w_n^\mathbf{t} \tag{18}$$

$$\sum_{m=1}^{M} f_{m,n} \leq w_m^\mathbf{v} \tag{19}$$



(a) Balance coefficient α ($\beta = 1$)

(b) Balance coefficient β ($\alpha = 1$)

Figure 4: Hyper-parameters fine-tuning on different datasets.

$$\sum_{n=1}^{N}\sum_{m=1}^{M} f_{m,n} = \min\left(\sum_{n=1}^{N} w_n^{\mathbf{v}}, \sum_{m=1}^{M} w_m^{\mathbf{v}}\right) \qquad (20)$$

where $1 \leq n \leq M$ and $1 \leq m \leq M$ respectively denote the indices of the tokens and image patches. Here, Eq. (17) ensures there is no negative value to impact the result. Eqs. (17) and (18) limit that the number of features which can be sent and received were less than their weights. Eq. (19) ensures the maximum number of features possible are moved. The optimal problem can be solved by the optimal transportation problem, and the cost of token-patch alignment is then defined as the work normalized by the total flow,

$$\mathcal{L}^{WD} = \frac{\sum_{n=1}^{N}\sum_{m=1}^{M} f_{m,n}\delta_{m,n}}{\sum_{n=1}^{N}\sum_{m=1}^{M} f_{m,n}} \qquad (21)$$

2.3 Joint Training

The final objective is a combination over the main task and two auxiliary tasks as follows,

$$\mathcal{L} = \mathcal{L}^{CM} + \alpha\mathcal{L}^{TO} + \beta\mathcal{L}^{WD} \qquad (22)$$

where α and β are tradeoff hyper-parameters to control the contribution of each task. For inference, the output of vision-aware text extraction was applied as the results.

3 Experiments

3.1 Datasets and Evaluation Metrics

To evaluate the performance of the dual-encoder transformer with cross-modal alignment, two MABSA benchmark datasets are used, mainly consisting of reviews on Twitter. These datasets are Twitter-2015 and Twitter-2017, originally provided by Zhang et al. (2018) for multimodal named entity recognition and annotated with the sentiment polarity for each aspect by Lu et al. (2018). Table 1 summarizes the statistical characteristics of these two datasets.

Precision, recall, and micro F_1-score are used as evaluation metrics for MABSA. An aspect is regarded as correctly predicted only if the aspect term and polarity respectively match the ground-truth aspect term and corresponding polarity.

3.2 Implementation Details

To evaluate the proposed DTCA model, several baseline models are implemented for comparison, including text-based methods and multimodal methods.

1) Textual methods

- **SPAN** (Hu et al., 2019) is a span-based extract-then-classify framework, where targets are directly extracted from the sentence under the supervision of target span boundaries.
- **D-GCN** (Chen et al., 2020) is a directional graph convolutional network to jointly perform aspect extraction and sentiment analysis with encoding syntactic information.
- **RoBERTa** (Liu et al., 2019) is a pretrained transformer-based model, used as text encoder in the proposed DTCA model.

2) Multimodal methods

Modality	Approaches	Twitter-2015			Twitter-2017		
		F	P	R	F	P	R
Text	SPAN	53.8	53.7	53.9	60.6	59.6	61.7
	D-GCN	59.4	58.3	58.8	64.1	64.2	64.1
	RoBERTa	63.3	62.9	63.7	65.6	65.1	66.2
Text+ Image	UMT-collapse	59.8	58.4	61.3	62.4	62.3	62.4
	OSCGA-collapse	62.5	61.7	63.4	63.7	63.4	64.0
	JML	64.1	65.0	63.2	66.0	66.5	65.5
	DTCA	**68.4**	**67.3**	**69.5**	**70.4**	**69.6**	**71.2**

Table 2: The results of the DTCA model and other models with comparison.

- **UMT-collapse** (Yu et al., 2020) is a directional graph convolutional network used to jointly perform aspect extraction and sentiment analysis with encoding syntactic information.
- **OSCGA-collapse** (Wu et al., 2020) combines object-level image information and character-level text information to predict entities.
- **JML** (Ju et al., 2021) uses a hierarchical framework to bridge the multi-modal connection between MATE and MASC with an auxiliary text-image relation module to ensure the proper exploitation of visual information.

The hyperparameters of all models were finetuned using a grid-search strategy according to the performance on the development set. The hidden size d_h is 768 for both RoBERTa and ViT model. The number of heads in cross-modal self-attention is 8. AdamW optimizer (Loshchilov and Hutter, 2019) with a base learning rate of 2e-5 and warmup decay of 0.1 was used to update all trainable parameters. The maximum length and batch size were respectively set to 60 and 4. For training epochs, we leveraged an early stopping strategy with a patience of 3 to avoid overfitting.

3.3 Hyper-parameters Finetuning

The tradeoff hyper-parameters α and β may impact the final performance of the proposed DTCA method for MABSA. Figure 4 shows the optimal settings according to the final performance on the dev set. We successively fine-tuned each parameter in turn by fixing the other to 1. For both α and β, we used a candidate set of $\{0.1, 0.3, 0.6, 0.9, 1.0\}$.

The performance of the proposed DTCA model is optimized when α and β are respectively 0.6 and 0.6 on the **Twitter-2015** dataset and 0.3 and 0.9 on the **Twitter-2017** dataset, the performance of the proposed DTCA model is the best. The results indicate that the use of appropriate parameters can improve the performance.

Model	Twitter-2015			Twitter-2017		
	F1	P	R	F1	P	R
DTCA	67.8	66.9	68.7	70.0	69.5	70.6
w/o TE	67.0	65.9	68.2	68.8	68.6	69.0
w/o TPA	66.5	64.1	68.4	69.1	68.7	69.5
w/o Both	65.6	65.3	65.9	68.7	68.4	69.0

Table 3: The result of ablation. TE: text-only extraction, TPA: token-patch alignment.

3.4 Comparative Results

Table 2 summarizes the comparative results of the proposed DTCA model against several previous methods in terms of precision (P), recall (R), and F_1-score. As indicated, the proposed model outperforms all the baseline models. Compared with the multi-modal baseline with the best performance, i.e. JML, DTCA still shows absolute F_1-score increases of 6.71% and 6.67%. Compared with text-based models, DTCA provides far better results. The F_1-score of the DTCA model on the test set outperforms RoBERTa by 8.06% and 7.32% respectively on **Twitter-2015** and **Twitter-2017**. This indicates that vision-aware text extraction can enable the proposed DTCA model to learn an appropriate representation for MABSA.

3.5 Ablation Study

Table 3 shows the results of an ablation study to further demonstrate the effectiveness of the two auxiliary subtasks, i.e., text-only extraction (TE) and token-patch alignment (TPA). By doing so, we remove TE (w/o TE) and set hyperparameter β as 1.0. Then, we remove TPA (w/o TPA) and set α as 1.0. As indicated, the removal of either one or both subtasks (w/o Both) produce varying degrees of performance decline, indicating that both text-only

extraction and token-patch alignment play indispensable roles in performance improvement.

3.6 Effect of Different Encoder

To investigate the effect of using different encoders, Figure 5 shows the performance of different transform-based encoders for the DTCA model. BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), ALBERT (Lan et al., 2020) and ELECTRA (Clark et al., 2020) were applied as text encoder, while ViT (Dosovitskiy et al., 2021), Swin-Transformer (Liu et al., 2021) and DeiT (Touvron et al., 2021) were applied as image encoder. As shown, RoBERTa achieved the best performance for language modality. For vision modality, the performance margins between different encoders were not obvious, indicating that the text contains enough features to identify the aspect-sentiment pairs, whereas the image sometimes fails to provide complementary information and may even induce noise.

3.7 Case Study

Figure 6 shows a case study of two randomly selected examples. For comparison, both text-only RoBERTa and JML were introduced as baselines. For example (a), although JML can accurately predict the correct aspect term *Chris Sale*, the sentiment of the *Chris Sale* aspect was wrongly predicted. The main reason is the misleading influence of the image. For example (b), RoBERTa only predicts some aspect terms correctly because of the lack of the image relation. In contrast, DTCA can obtain all correct aspect terms and aspect-related sentiment using cross-modal alignment between text and image.

4 Conclusion

This work proposes a dual-encoder transformer with cross-modal alignment for encoding text-image features into the representations for MABSA tasks. A multitask learning architecture containing three subtasks was applied to integrate both text and image modalities. In addition to the co-attention module, the token-patch alignment was introduced to improve model training effectiveness. Empirical experiments show the model improved the performance for MABSA in the Twitter-2015 and Twitter-2017 datasets. In addition, ablation and case studies further indicate the effectiveness of the proposed model.

Future work will extend the proposed method to more multi-modal tasks, such as multi-modal

MRC, ASTE and dialogue.

Abstract

Recently, emerging approaches have been proposed to deal with robotic navigation problems, especially vision-and-language navigation task which is one of the most realistic indoor navigation challenge tasks. This task can be modelled as a sequential decision-making problem, which is suitable to be solved by deep reinforcement learning. Unfortunately, the observations provided from the simulator in this task are not fully observable states, which exacerbate the difficulty of implementing reinforcement learning. To deal with this challenge, this paper presents a novel method, called as attentive variational state tracker (AVAST), a variational approach to approximate belief state distribution for the construction of a reinforced navigator. The variational approach is introduced to improve generalization to the unseen environment which barely achieved by traditional deterministic state tracker. In order to stabilize the learning procedure, a fine-tuning process using policy optimization is proposed. From the experimental results, the proposed AVAST does improve the generalization relative to previous works in vision-and-language navigation task. A significant performance is achieved without requiring any additional exploration in the unseen environment.[1]

1 Introduction

Reinforcement learning (RL) has become a crucial and successful solution in many sequential decision-making problems, such as video game playing AI (Bellemare et al., 2013) and robotic control (Todorov et al., 2012). In theory, RL algorithms are designed for solving problems under the assumption of Markov decision process (MDP), which means that the observation provided from the environment needs to exactly represent the complete state information of the environment (Chien et al., 2021). However, most of the real-world problems, such as bridge-playing AI, dialogue systems (Rohmatillah and Chien, 2021b; Hsu et al., 2021; Rohmatillah and Chien, 2021a), autonomous driving, and first-person navigation (Kempka et al., 2016), can not be directly modeled as Markov decision processes, because of the incomplete state information. For example, in dialogue task, system does not have an access to the user goal (Jang et al., 2022). In order to improve the generalization, partially observable Markov decision process (POMDP) (Åström, 1965) was designed to model the process in which the agent does not have access to observe complete state information.

In case of vision-and-language navigation (VLN) task, the problem formulation is considered as POMDP problem, as the agent does not receive full information about the state. It only receive the information about the images of surroundings and the texts which describe the navigation task and agent pose information. There is no information which explicitly tells about agent and goal location coordinates. Furthermore, as each observation is unique and complex in the VLN task, the common methods which turn POMDP problem into MDP problem by aggregating the observations and estimating the belief states do not work very well. Aggregation methods usually use either a frame-stacking trick (Mnih et al., 2015) or a recurrent neural network (Hausknecht and Stone, 2015) to aggregate the history observation or the belief state information. These methods mostly work only for either computer vision or natural language processing tasks by considering sufficient information process (Striebel, 1965) assumption as well as Bayes theory (Igl et al., 2018; Lee et al., 2020). Meanwhile, the VLN task requires agent to consider both domains to solve the problem.

Motivated by the aforementioned issues, this work formulates VLN task as a POMDP problem and solves it by using RL algorithms. We propose a

new method named as Attentive VAriational State Tracker (AVAST) to estimate the belief state distribution of the complex observations in the VLN task. AVAST follows sufficient information process assumption to reduce VLN task into an MDP problem. By using variational inference approach, the generalization property of the belief state sampled from AVAST is accordingly held. Based on the experiment result, the proposed method can achieve better performance compared to the baselines due to its generalization property. The organization of this work is arranged as follows. In Sections 2 and 3, the recent approaches to deal with POMDP state tracking and VLN task are discussed, respectively. The proposed method, AVAST, is explained in Section 4. The experimental setup and result are described in Section 5. Finally, Section 6 shows the conclusions.

2 Partially Observable Markov Decision Process State Tracking

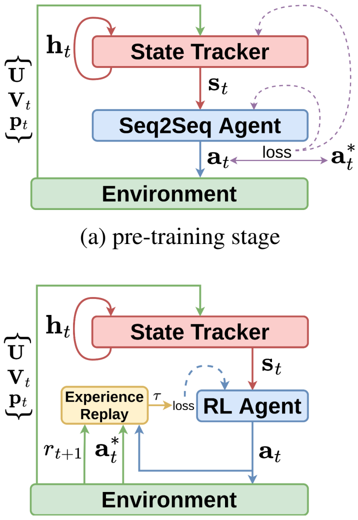
Real-world problems usually cannot directly be modelled as MDP problems, because of the information limitation. Accordingly, the partially observable Markov decision process (POMDP) (Åström, 1965) is fitted to implement an agent decision process in presence of incomplete state information. In general, a POMDP problem can be described by a 6-tuple set $\{\mathcal{S}, \mathcal{A}, \mathcal{P}, \mathcal{R}, \gamma, \mathcal{O}\}$. Identical to MDP problem, $\mathcal{S}, \mathcal{A}, \mathcal{P}, \mathcal{R}, \gamma$ denote the state, action, transition probability, reward, and discount factor, respectively. The main difference is that the agent can not observe the complete state $\mathbf{s} \in \mathcal{S}$. It only receives an observation $\mathbf{o} \in \Omega$. According to the probability distribution $\mathcal{O}(\mathbf{s})$, the observation $\mathbf{o}$ is generated from the underlying system state as $\mathbf{o} \sim \mathcal{O}(\mathbf{s})$. Generally, estimating a policy distribution from an observation can be arbitrary due to $\pi(\mathbf{a}|\mathbf{o}; \phi) \neq \pi(\mathbf{a}|\mathbf{s}; \phi)$. Following the sufficient information process (Striebel, 1965), POMDP state distribution can be approximated by using a state tracker to produce the belief state distribution $p(\mathbf{s}|I_t^C)$. I_t^C denotes the complete information state at time t which represents the history information from the beginning to time t. I_t^C is defined as, $I_t^C = \langle \rho(\mathbf{s}_0), \mathbf{o}_1, \mathbf{a}_1, \ldots, \mathbf{a}_{t-1}, \mathbf{o}_t \rangle$, where $\rho(\mathbf{s}_0)$ is a distribution over initial stated. Once the well-trained state tracker is obtained, a belief state $\mathbf{s}_t$ can be sampled from the distribution $p(\mathbf{s}|I_t^C)$, and RL agent will consider it as the system state to generate the action $\mathbf{a}_t$.

Traditionally, common sequential learning using recurrent neural network (RNN) was applied to encode the observations history to produce an appropriate belief state as the input to agent (Hausknecht and Stone, 2015). such method was likely to summarize history by remembering features from the past trajectories rather than actually estimating belief states. Furthermore, naively applying RNN would output suboptimal belief states due to the deterministic computation without any distribution constraint. Other approaches (Igl et al., 2018; Lee et al., 2020) estimated the belief states by introducing Bayesian theory. Compared to the purely RNN-based methods, introducing stochastic estimation can improve generalization to complex environments. However, dealing with unseen environment is still a major stumbling block in designing a state tracker. Therefore, different from the previous works, in this paper, an attentive variational state tracker is proposed to improve the state tracking generalization for vision-language navigation.

3 Vision-and-Language Navigation

In general, the reinforcement learning agent which is designed for VLN task (Anderson et al., 2018), will not receive complete state information. Instead, the observation $\mathbf{o} \in \Omega$, generated from the underlying system state according to the probability distribution $\mathbf{o} \sim \mathcal{O}(\mathbf{s})$, will be obtained by the agent in VLN. The observations $\mathbf{o}$ can be separated into three parts which are instructions, visions, and pose information. Instructions are provided in natural language (Chu et al., 2022) to guide the agent about how to reach the target position ρ_{goal} from the initial position ρ_1. At different positions ρ_{t}, agent will receive different panoramic visions and pose information. Given such a process, VLN agent must understand the current situation using the provided instructions, panoramic visions and pose information, and navigate to the target position. Formally, an agent will receive one instruction $\mathbf{U} \in \Omega^u$ at the beginning, and at the same time receive an initial panoramic vision $\mathbf{V}_1 \in \Omega^v$ and an initial pose information $\mathbf{p}_1 \in \Omega^p$, generated from the initial position ρ_1. Then, it will receive a current panoramic vision $\mathbf{V}_t \in \Omega^v$, current pose information $\mathbf{p}_t \in \Omega^p$, and reward $r_t \in \mathcal{R}$, generated from the current position ρ_t at each time step t after acting an action $\mathbf{a}_{t-1}$.

Due to the difficulty of VLN task, the most intuitive way to deal with this task is to apply imita-



(a) pre-training stage

(b) fine-tuning stage

Figure 1: Framework for the agent with two steps optimization in vision-and-language navigation task.

tion learning by utilizing expert trajectories through behaviour cloning (Pomerleau, 1991; Fried et al., 2018). However, behaviour cloning was prone to the out-of-distribution trajectory once it was applied into the environment. Previous approach used the adversarial inverse reinforcement learning (AIRL) (Fu et al., 2018) which defined the reward function based on the expert trajectories (Zhou and Small, 2021) and used the learned reward function to train the agent through interactions with the environment. Other works developed the cross-modality matching (Wang et al., 2019) and model-based RL (Wang et al., 2018) to improve RL agent performance. Although previous methods have shown promising results, all of them required the exploration to the unseen environment to obtain additional training data when being evaluated in the unseen validation set. This scenario clearly did not represent real-world implementation where robot needed to provide appropriate actions without requiring any explorations. Therefore, in this work, the variational state tracking is proposed to improve generalization. Therefore, the agent can perform properly in unseen environments without requiring any environment exploration.

4 Attentive State Tracker and Navigator

4.1 Framework overview

Figure 1 illustrates the framework of agent in VLN task. The process of learning can be divided into two stages, the pre-training (Figure 1(a)) and the fine-tuning stages (Figure 1(b)). Meanwhile, the common setup of VLN agent consists of three main components including state tracker, agent policy, and recurrent experience replay. The state tracker involves an observation encoder, a summarization module, and a tracking module. The observation encoder takes the inputs of instruction $\mathbf{U}$, vision $\mathbf{V}$, and pose information $\mathbf{p}$ to extract the observation features $\mathbf{o}$. The summarization module is constructed according to an attention mechanism to summarize the given instruction to the meaningful representations for the agent. Then, the agent will pay more attention to the components of instruction which have higher attention score. Lastly, the tracking module can be implemented in either deterministic or stochastic way.

This paper presents two kinds of state trackers, deterministic and stochastic tracking module which are named as the attentive state tracker (AST) and the attentive variational state tracker (AVAST), respectively. AST is similar to the state tracker used in some of the prior works (Fried et al., 2018; Wang et al., 2019; Zhou and Small, 2021). Meanwhile, AVAST is a new state tracker that is proposed in this work. In a common VLN setup, an agent can be designed either using sequence-to-sequence (Seq2Seq) or RL agent by fine-tuning the Seq2Seq model through interactions with the environment. As shown in the figure, a Seq2Seq agent will be used in the pre-training stage based on the behavior cloning to provide stable state tracker which will carry out a stationary state representation. Meanwhile, in the fine-tuning stage, REINFORCE (Williams, 1992) is implemented to improve the performance. Due to POMDP property in VLN task, the transition information $\{\mathbf{o}_t, \mathbf{a}_t, r_t\}$ stored in the experience replay is dependent on the previous trajectories because of the incomplete information provided by the environment. Therefore, a recurrent experience replay is used to replace standard experience replay which was commonly used in MDP task.

4.2 Observation encoder

Both AST and AVAST involve an observation encoder that will extract meaningful features from $[\mathbf{U}; \mathbf{V}_t; \mathbf{p}_t]$. The natural language instruction matrix is denoted as $\mathbf{U} = [\mathbf{u}_1, \dots, \mathbf{u}_l, \dots, \mathbf{u}_L]^\top$, where $\mathbf{u}_l$ is a word embedding from GloVe (Pennington et al., 2014) to represent the l-th word in the instruction and L is the length of the instruction. We feed the instruction matrix $\mathbf{U}$ into a recurrent model $f_u(\cdot)$ to obtain the initial context $\mathbf{H}^u = [\mathbf{h}_1^u, \ldots, \mathbf{h}_l^u, \ldots, \mathbf{h}_L^u]^\top$, and send the last hidden feature state $\mathbf{h}_L^u$ into a fully-connected network $g_\mathcal{T}(\cdot)$ to capture the initial trajectory information $\mathbf{h}_0^\mathcal{T}$ as follows

$$\begin{aligned} \mathbf{h}_1^u &= f_u\left(\mathbf{u}_1, \mathbf{h}_0^u\right) \\ &\vdots \\ \mathbf{h}_L^u &= f_u\left(\mathbf{u}_L, \mathbf{h}_{L-1}^u\right) \\ \mathbf{h}_0^\mathcal{T} &= g_\mathcal{T}\left(\mathbf{h}_L^u\right). \end{aligned} \tag{1}$$

The panoramic vision $\mathbf{V}_t$ is a representation of 36 first-person camera view images at time step t, and it is denoted as $\mathbf{V}_t = [\mathbf{v}_{t,1}, \ldots, \mathbf{v}_{t,i}, \ldots, \mathbf{v}_{t,36}]^\top$, where $\mathbf{v}_{t,i}$ is a vision feature to represent the i-th camera view image at time step t. The vision feature $\mathbf{v}_{t,i} = [\mathbf{v}_{t,i}^{\text{ResNet}}; \mathbf{v}_{t,i}^{\text{Orientation}}]$ is a concatenation of an image feature $\mathbf{v}_{t,i}^{\text{ResNet}}$ and an orientation feature $\mathbf{v}_{t,i}^{\text{Orientation}}$. An image feature $\mathbf{v}_{t,i}^{\text{ResNet}}$ is a 2048-dimensional vector extracted from a pretrained ResNet-152 model (He et al., 2016), and an orientation feature is a 128-dimensional vector that repeats $[\sin\alpha_{t,i}, \cos\alpha_{t,i}, \sin\beta_{t,i}, \cos\beta_{t,i}]$ 32 times representing environmental views where $\alpha_{t,i}$ and $\beta_{t,i}$ are the relevant heading and elevation to the current camera pose, respectively. The vision embedding $\mathbf{e}_t^v$ is extracted by a cross-attention (Vaswani et al., 2017) module. This paper uses trajectory information $\mathbf{h}_{t-1}^\mathcal{T}$ from the state tracker as a query to attend the panoramic vision $\mathbf{V}_t$ using parameters $\{\mathbf{W}_v^q, \mathbf{W}_v^k\}$ via

$$\mathbf{e}_t^v = f_v\left(\mathbf{V}_t, \mathbf{h}_{t-1}^\mathcal{T}\right) = \left(\text{Softmax}(\mathbf{q}_v^\top \mathbf{K}_v) \cdot \mathbf{V}_t\right)^\top \tag{2}$$

where $\mathbf{q}_v = \mathbf{h}_{t-1}^\mathcal{T}\mathbf{W}_v^q$, $\mathbf{K}_v = \mathbf{V}_t\mathbf{W}_v^k$. The pose information $\mathbf{p}_t$ represents the current camera pose, and it is an 128-dimensional vector that repeats $[\sin\alpha_t, \cos\alpha_t, \sin\beta_t, \cos\beta_t]$ 32 times. α_t and β_t are the absolute heading and absolute elevation of the agent. To calculate the pose embedding $\mathbf{e}_t^p$, we feed the pose information $\mathbf{p}_t$ into a fully connected network $f_p(\cdot)$ in a form of

$$\mathbf{e}_t^p = f_p\left(\mathbf{p}_t\right). \tag{3}$$

4.3 Attentive variational state tracker

After the raw features $[\mathbf{U}; \mathbf{V}_t; \mathbf{p}_t]$ are encoded into $[\mathbf{H}^u; \mathbf{e}_t^v; \mathbf{e}_t^p]$, these encoded features are fed into the tracker, which is constructed by an *attentive summarization* module for instructions $\mathbf{H}^u$ and a stochastic tracking module for vision and pose information $[\mathbf{e}_t^v; \mathbf{e}_t^p]$. The tracker will generate the belief state $\mathbf{s}_t = [\mathbf{s}_t^u; \mathbf{s}_t^\mathcal{T}]$ and the trajectory information $\mathbf{h}_t^\mathcal{T}$ at each time step t. The attentive summarization module aims to summarize the instruction from initial context $\mathbf{H}^u$ into context belief state $\mathbf{s}_t^u$ to inform which words should the agent pay more attention. Next, the agent takes the context belief state $\mathbf{s}_t^u$ as a part of consideration to predict the action $\mathbf{a}_t$ at each time step t. In order to do so, the summarization module is constructed based on the attention mechanism. The trajectory information $\mathbf{h}_t^\mathcal{T}$ can be used as the query to attend over the instruction $\mathbf{H}^u$, and the word representation $\mathbf{h}_l^u$ can be weighted by the attention weight. Then, the weighted sum is treated as the context belief state $\mathbf{s}_t^u$. The procedure for generating the context belief state can be formulated using parameters $\{\mathbf{W}_u^q, \mathbf{W}_u^k, \mathbf{W}_u^v\}$ via

$$\mathbf{s}_t^u = g_u\left(\mathbf{H}^u, \mathbf{h}_t^\mathcal{T}\right) = \left(\text{Softmax}(\mathbf{q}_u^\top \mathbf{K}_u) \cdot \mathbf{V}_u\right)^\top \tag{4}$$

where $\mathbf{q}_u = \mathbf{h}_t^\mathcal{T}\mathbf{W}_u^q$, $\mathbf{K}_u = \mathbf{H}^u\mathbf{W}_u^k$, $\mathbf{V}_u = \mathbf{H}^u\mathbf{W}_u^v$. Considering the sufficient information process (Striebel, 1965), the belief state $\mathbf{s}_t$ is estimated based on the complete information state I_t^C. In VLN task, the observation $\mathbf{o}_t$ can be divided into, instruction $\mathbf{U}$, vision $\mathbf{V}_t$, and pose information $\mathbf{p}_t$, and the previous action information $\mathbf{a}_{t-1}$ can be implied by the current pose information $\mathbf{p}_t$. So, the complete information state I_t^C in VLN can be reshaped as follows

$$I_t^C = \langle \rho(\mathbf{s}_0), \mathbf{U}, \mathbf{V}_1, \mathbf{p}_1, \mathbf{V}_2, \mathbf{p}_2, \ldots, \mathbf{V}_t, \mathbf{p}_t \rangle. \tag{5}$$

The tracking module aims to generate the tracking belief state $\mathbf{s}_t^\mathcal{T}$ based on the complete information state I_t^C. Referring to some prior methods (Hausknecht and Stone, 2015; Lee et al., 2020), approaches for generating tracking belief state can be divided into two main methods, aggregation and estimation. In this work, we build two kinds of tracking model by using deterministic aggregation and stochastic estimation, which can be constructed by LSTM and Variationl Recurrent Neural Network (VRNN) (Chung et al., 2015) respectively. Both methods equip an aggregation module $g_\mathcal{T}$ to encode the history into trajectory information $\mathbf{h}_t^\mathcal{T}$ to represent the complete information state I_t^C. The aggregation modules can be generally expressed as

$$\mathbf{h}_t^\mathcal{T} = \begin{cases} g_{\mathcal{T}_0}\left(\mathbf{h}_L^u\right) & t = 0 \\ g_\mathcal{T}\left(\mathbf{o}_{\leq t}\right) & t > 0 \end{cases} \tag{6}$$

where $\mathbf{o}_{\leq t} = \{\mathbf{o}_1, \ldots, \mathbf{o}_t\}$.

The tracking module constructed by LSTM is a straightforward and deterministic method to aggregate the history information. This method has also been proposed to address POMDP problem (Hausknecht and Stone, 2015). $g_{\mathcal{T}}^{\text{LSTM}}$ denotes aggregation module $g_{\mathcal{T}}$ constructed by a LSTM model, and it is denoted as. The LSTM tracking module will directly treat the hidden feature state $\mathbf{h}_t^{\mathcal{T}}$ from the aggregation module as the belief state $\mathbf{s}_t^{\mathcal{T}}$. In the implementation, the initial hidden and cell feature-state of the LSTM aggregation module $g_{\mathcal{T}}^{\text{LSTM}}$ are both initialized from the last hidden and cell feature-state of the instruction LSTM encoder f_u to memorize the guided information. The procedure of generating a tracking belief state based on LSTM is formulated by

$$\begin{aligned} \mathbf{h}_t^{\mathcal{T}} &= \begin{cases} g_{\mathcal{T}0}\left(\mathbf{h}_L^u\right) & t=0 \\ g_{\mathcal{T}}^{\text{LSTM}}\left(\left[\mathbf{e}_t^v;\mathbf{e}_t^p\right],\mathbf{h}_{t-1}^{\mathcal{T}}\right) & t>0 \end{cases} \\ \mathbf{s}_t^{\mathcal{T}} &= \mathbf{h}_t^{\mathcal{T}}. \end{aligned} \tag{7}$$

In order to improve model generalization, we propose the stochastic version of tracking module which is constructed by using VRNN. It will estimate the distribution $p(\mathbf{s}_t^{\mathcal{T}}|I_t^C)$ which will be sampled in every turn. Same as the original VRNN (Chung et al., 2015), there also exists an aggregation module $g_{\mathcal{T}}^{\text{VRNN}}$ to encode the trajectory information in this tracking module. Similar to the LSTM tracking module $g_{\mathcal{T}}^{\text{LSTM}}$, the embedding of the last hidden feature-state $\mathbf{h}_L^u$ from the instruction LSTM encoder f_u is used to be the initial trajectory information $\mathbf{h}_0^{\mathcal{T}} = g_{\mathcal{T}0}\left(\mathbf{h}_L^u\right)$ for the aggregation module. However, the input of $g_{\mathcal{T}}^{\text{VRNN}}$ is different from $g_{\mathcal{T}}^{\text{LSTM}}$. The input of $g_{\mathcal{T}}^{\text{VRNN}}$ includes not only the vision $\mathbf{e}_t^v$ and pose information $\mathbf{e}_t^p$ but also the tracking belief state $\mathbf{s}_t^{\mathcal{T}}$ to record the latent variable, sampled from the tracking belief state distribution. Identical to the LSTM tracking module, the complete information state I_t^C can be represented as the trajectory information $\mathbf{h}_t^{\mathcal{T}}$. The aggregation module in VRNN (Chien and Wang, 2022; Chien et al., 2017; Chien and Tsai, 2021) is also constructed by a LSTM model and can be expressed by

$$\mathbf{h}_t^{\mathcal{T}} = \begin{cases} g_{\mathcal{T}0}\left(\mathbf{h}_L^u\right) & t=0 \\ g_{\mathcal{T}}^{\text{VRNN}}\left(\left[\mathbf{e}_t^v;\mathbf{e}_t^p;\mathbf{s}_t^{\mathcal{T}}\right],\mathbf{h}_{t-1}^{\mathcal{T}}\right) & t>0. \end{cases} \tag{8}$$

To allow the sampling of tracking belief state $\mathbf{s}_t^{\mathcal{T}}$ at each time step t, VRNN aims to approximate the belief state distribution. The variational inference will sample a current belief state $\mathbf{s}_t^{\mathcal{T}}$ from the posterior based on the current observation and previous trajectory information $\mathbf{h}_{t-1}^{\mathcal{T}}$ from the aggregation model $g_{\mathcal{T}}$. Furthermore, we also need to build a prior distribution and conditional likelihood to reconstruct the observation for the self-learning criterion as shown in Eq. (16). The calculations of prior, posterior and likelihood using this VRNN are yielded by

$$\text{prior:} p(\mathbf{s}_t^{\mathcal{T}}|\mathbf{o}_{<t},\mathbf{s}_{<t}^{\mathcal{T}}) = p(\mathbf{s}_t^{\mathcal{T}}|\mathbf{h}_{t-1}^{\mathcal{T}}) \tag{9}$$

$$\text{post:} q(\mathbf{s}_t^{\mathcal{T}}|\mathbf{o}_{\le t},\mathbf{s}_{<t}^{\mathcal{T}}) = q(\mathbf{s}_t^{\mathcal{T}}|\left[\mathbf{e}_t^v,\mathbf{e}_t^p\right],\mathbf{h}_{t-1}^{\mathcal{T}}) \tag{10}$$

$$\text{likel:} p(\mathbf{o}_t|\mathbf{s}_{\le t}^{\mathcal{T}},\mathbf{o}_{<t}) = p(\mathbf{v}_{t,\hat{i}}|\mathbf{s}_t^{\mathcal{T}},\mathbf{h}_{t-1}^{\mathcal{T}}) \tag{11}$$

where $\mathbf{v}_{t,\hat{i}} = [\mathbf{v}_{t,\hat{i}}^{\text{ResNet}};\mathbf{v}_{t,\hat{i}}^{\text{Orientation}}]$ is the intention vision embedding. Agent will change its current perspective from i to $\hat{i}$ before it moves to the next position at each time step. To provide stationary state representation, both AST and AVAST will be pre-trained based on a Seq2Seq agent. AST can be constructed with an attentive summarization module, a tracking module constructed by LSTM, and the observation encoders mentioned previously. The objective of AST pre-training is shown by

$$\mathcal{J}_\pi = \mathbb{E}_{(\mathbf{o}_t,\mathbf{a}_t^\star)\sim D}\left[\pi\left(\mathbf{a}_t^\star|\left[\mathbf{s}_t^u;\mathbf{s}_t^{\mathcal{T}}\right]\right)\right] \tag{12}$$

where

$$\mathbf{s}_t^{\mathcal{T}} = \mathbf{h}_t^{\mathcal{T}} = g_{\mathcal{T}}^{\text{LSTM}}(\mathbf{o}_t,\mathbf{h}_{t-1}^{\mathcal{T}}). \tag{13}$$

Different from AST, AVAST replaces the LSTM tracking module in AST with a variational tracking module using VRNN (Chien and Wang, 2019). The objective $\mathcal{J}_\pi$ for pre-training AVAST can be expressed in a form of

$$\mathbb{E}_{(\mathbf{o}_t,\mathbf{a}_t^\star)\sim D}\left[\mathbb{E}_{\mathbf{s}_t^{\mathcal{T}}\sim q\left(\mathbf{s}_t^{\mathcal{T}}|\mathbf{o}_t,\mathbf{h}_{t-1}^{\mathcal{T}}\right)}\left[\pi\left(\mathbf{a}_t^\star|\left[\mathbf{s}_t^u;\mathbf{s}_t^{\mathcal{T}}\right]\right)\right]\right] \tag{14}$$

using

$$\mathbf{h}_{t-1}^{\mathcal{T}} = g_{\mathcal{T}}^{\text{VRNN}}\left(\left[\mathbf{o}_{t-1};\mathbf{s}_{t-1}^{\mathcal{T}}\right],\mathbf{h}_{t-2}^{\mathcal{T}}\right). \tag{15}$$

Rather than learning the signal which only depends on the downstream task for the LSTM tracking module, VRNN has an additional learning signal to jointly enhance the performance for the tracking belief state representation. The evidence lower bound $\mathcal{J}_{\text{ELBO}}$ can be derived as shown in Eq. (16) to be the additional learning criterion for VRNN

&\geq \mathbb{E}_{q(\mathbf{s}^{\tau}_{\leq T}|\mathbf{o}_{\leq T})} \left[\ln \frac{p(\mathbf{o}_{\leq T}, \mathbf{s}^{\tau}_{\leq T})}{q(\mathbf{s}^{\tau}_{\leq T}|\mathbf{o}_{\leq T})} \right] \\
&= \mathbb{E}_{q(\mathbf{s}^{\tau}_{\leq T}|\mathbf{o}_{\leq T})} \left[\sum_{t=1}^{T} \ln p(\mathbf{o}_t|\mathbf{s}^{\tau}_{\leq T}, \mathbf{o}_{<t}) \right. \\
&\quad \left. - D_{\mathrm{KL}} \left(p \left(\mathbf{s}^{\tau}_t | \mathbf{o}^{\tau}_{<t}, \mathbf{s}^{\tau}_{<t} \right) \| q \left(\mathbf{s}^{\tau}_t | \mathbf{o}_{\leq t}, \mathbf{s}^{\tau}_{<t} \right) \right) \right] \\
&= \mathcal{J}_{\mathrm{ELBO}}.
\end{aligned}
\tag{16}
$$

Pre-training procedure of AST and AVAST based on a Seq2Seq agent can be seen in Algorithm 1.

5 Experiments

5.1 Experimental setup

The proposed method was evaluated in VLN task using room-to-room (R2R) dataset, which contains pairs of path and instruction based on human annotation with Matterport3D simulator. It is built based on Matterport3D dataset (Chang et al., 2017), which is a large RGB-D dataset of building-scale scenes. In order to meet the real-world situation, the agent should be prevented from crossing the wall and floor or jumping to a non-navigable place. The action space in the simulator is based on a pre-defined undirected graph over panoramic viewpoints, $\mathcal{G} = \langle \mathcal{P}, \mathcal{E} \rangle$. The agent's actions are limited in a way that they can only navigate to the viewpoint, which is adjacent to the current viewpoint based on the graph $\mathcal{G}$. At each time step t, agent is provided with next-step navigable viewpoints set $\mathcal{A}_t$ in a form of

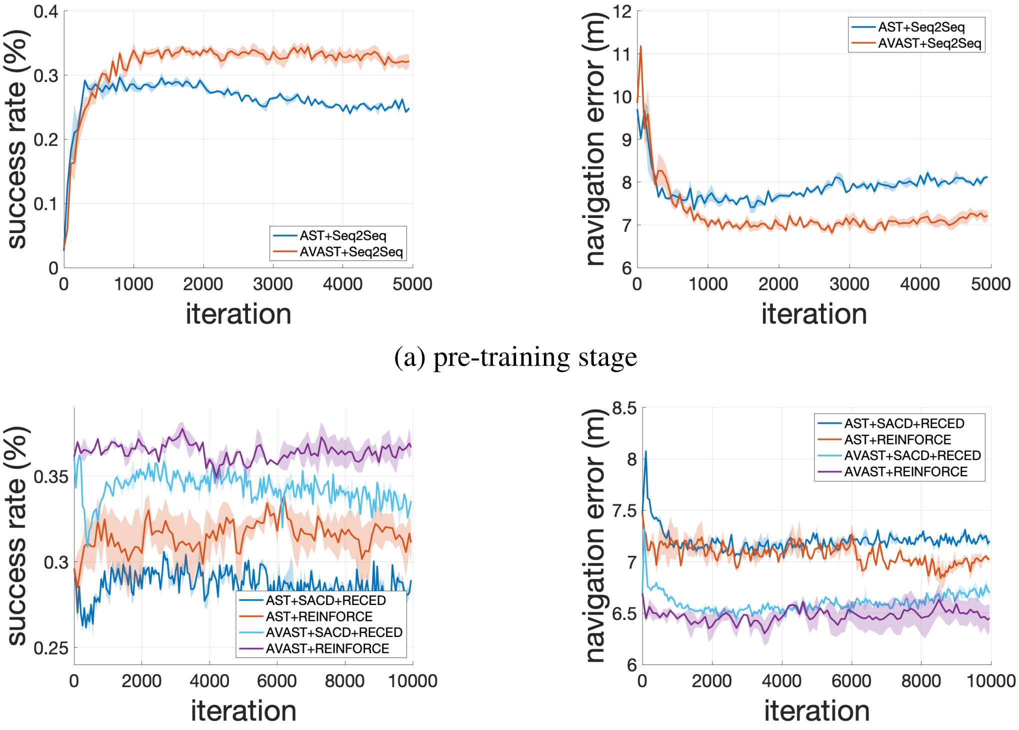
$$\mathcal{A}_t = \{\rho_t\} \cup \{\rho_i \in \mathcal{P} | \langle \rho_i, \rho_j \rangle \in \mathcal{E} \wedge \rho_i \in \mathcal{R}_t\} \tag{17}$$

where ρ_t is the current viewpoint and $\mathcal{R}_t$ is the region of space enclosed by the left and right extents of the camera view frustum at step t. The simulator only define the navigable set $\mathcal{A}_t$ to the current viewpoint ρ_t and handles how to update next viewpoint ρ_{t+1}, camera heading α, and camera elevation β after next viewpoint ρ_{t+1} is selected by the agent to navigate. Although the simplified discrete simulator provides a clear problem formulation, this kind of low-level control interface is non-trivial to be applied for training a navigation agent. Moreover, following the original approach (Anderson et al., 2018), the simulator needs to aggregate two possible ways to generate the visual observation, from the raw RGB image and pre-trained ResNet embedding to represent the current vision observation. This procedure makes the simulator to be dependant on the huge Matterport3D dataset and requires a complicated setup procedure.

Due to the aforementioned reasons, we build a simpler VLN environment that is not dependant on Matterport3D dataset and can be relatively easier to set up a simulation. Similar to the previous approaches (Fried et al., 2018; Zhou and Small, 2021), the proposed VLN environment provides a panoramic interface with discrete control for navigation agents. The action space is different from the original Matterport3D simulator in Eq. (17) in a way of

$$\mathcal{A}_t = \{\rho_t\} \cup \{\rho_i \in \mathcal{P} | \langle \rho_i, \rho_j \rangle \in \mathcal{E}\}. \tag{18}$$

As a result, the agent can navigate to a nearby viewpoint, without any need to be enclosed by the left and right extents of the camera view frustum at step t. Furthermore, we directly build a mapping table to look up the desired ResNet embedding $\mathbf{V}_t$ at each time step t to eliminate the dependancy on Matterport3D dataset. During setup, the VLN environment will initialize the word embedding from GloVe (Pennington et al., 2014) to transform natural language instructions $x = [x_1, \ldots, x_l, \ldots, x_L]$ into instruction matrices



(a) pre-training stage

(b) fine-tuning stage

Figure 2: Comparison of the results in unseen validation during pre-training and fine-tuning phases. Both pre-training and fine-tuning experiments do not truncate the instructions or use the augmented data from Speaker-Follower. The mean curve and standard deviation region are drawn by running the same experiment in multiple random seeds.

$\mathbf{U} = [\mathbf{u}_1, \ldots, \mathbf{u}_l, \ldots, \mathbf{u}_L]$ (Watanabe and Chien, 2015). The interface of VLN environment is designed to be closer to the typical RL environment, Gym. At the beginning of each episode, VLN environment provides instruction matrix $\mathbf{U}$, vision observation $\mathbf{V}_1$, pose information $\mathbf{p}_1$, and navigable viewpoint set $\mathcal{A}_1$. After the agent act an action $\mathbf{a}_t$, VLN environment will generate the next vision observation $\mathbf{V}_{t+1}$, pose information $\mathbf{p}_{t+1}$, navigable viewpoint set $\mathcal{A}_{t+1}$, and reward r_t. Reward r_t are defined as follows:

$$r_t = \begin{cases} D(\rho_{t-1}, \rho_{\text{goal}}) - D(\rho_t, \rho_{\text{goal}}) & t < T \\ \mathbf{1}\left[D(\rho_t, \rho_{\text{goal}}) \leq 3\right] & t = T \end{cases} \tag{19}$$

where $D(\rho_i, \rho_j)$ denotes the shortest path distance between locations ρ_i and ρ_j, and ρ_{goal} denotes the location of goal. For the evaluation metrics, this paper consider two metrics which are navigation error (NE) and success rate (SR). NE measures the shortest path between the goal location and final location of the agent's path. SR measures the average rate of the agent stopping within 3 meters near to the goal location.

5.2 Experimental results

In order to evaluate the effectiveness of AVAST, we highly focus on the unseen validation task, because it represents more real-world scenario where the agent frequently faces unseen environment during implementation. To provide stationary state representation for RL agent, both AST and AVAST were initially trained based on Seq2Seq agent via behaviour cloning algorithm. The learning curves are shown in Figure 2(a) where AVAST convincingly outperformed AST indicated by higher success rate and lower navigation turn over iterations. Next, both AST+Seq2Seq and AVAST+Seq2Seq performances were compared to the prior baseline methods, which are Speaker-Follower (SF) (Fried et al., 2018) and Inverse Reinforcement Learning with Natural Language Goals (LangGoalIRL) (Zhou and Small, 2021). The performance of the proposed method and baseline methods are shown in Table 1. Based on the result, the generalization improvement could be achieved by using AVAST, indicated by the lowest navigation error and the highest success rate compared to the baselines with convincing performance gap.

#	Model	NE $\downarrow$	SR $\uparrow$
1	SF†*	7.07	31.2
2	LangGoalIRL†*	-	30.0
3	AST + Seq2Seq†*	7.54	29.1
4	AVAST + Seq2Seq†*	**6.60**	**36.6**

Table 1: Navigation errors (NE) and success rates (SR) for different behavior cloning methods in VLN unseen validation datasets. (†: trained without using augmented data. *: trained based on pure behavior cloning).

To enhance the agent performance further, the model was fine-tuned using REINFORCE algorithm (Williams, 1992). In this fine-tuning evaluation, two previous approaches were introduced to be the experiment baselines. The first is discrete version of soft actor critic (SACD) (Christodoulou, 2019; Chien and Yang, 2021) which has shown improvement in the LangGoalIRL. The second is the curriculum learning with the recurrent replay distributed DQN from demonstrations (R2D3) (Paine et al., 2020) which we name it as recurrent experience replay with curriculum expert demonstrations (RECED). The learning curves of fine-tuning process are shown in Figure 2(b). Meanwhile, the final evaluation result can be seen in Table 2. In the last evaluation, an additional baseline, reinforced cross-modal matching (RCM) (Wang et al., 2019) which involved instruction truncation to improve the performance is introduced. Although this trick can improve learning efficiency, it is not really fit to the real-world scenario. Accordingly, in our main experiments in Table 1 and Table 2, we did not truncate natural language instructions into a certain length. However, in order to show the generalization of AVAST, the experiments under same setting with RCM was conducted, and the results are shown in Table 3. Based on these results, there are four findings which are summarized as follows.

1. **Variational state tracker provided better generalization in unseen validation.** From the learning curve as shown in Figure 2(a), we can notice that agent performed better than the one using AST as a state tracker without suffering overfitting issue due to the ability of AVAST in providing more general state representation in unseen validation. Furthermore, as shown in Table 1, AVAST+Seq2Seq outperformed the methods which were purely trained via behavior cloning algorithm.

#	Model	NE $\downarrow$	SR $\uparrow$
1	SF*	6.62	35.5
2	LangGoalIRL†	-	30.8
3	LangGoalIRL	-	35.7
4	AST + SACD + RECED†	7.06	31.3
5	AST + REINFORCE†	6.92	34.4
6	AVAST + SACD + RECED†	6.44	36.7
7	AVAST + REINFORCE†	**6.22**	**38.5**

Table 2: Navigation errors and success rates for different methods in VLN unseen validation datasets (†: trained without using augmented data; *: trained based on pure behavior cloning).

#	Model	NE $\downarrow$	SR $\uparrow$
1	SF*	6.62	35.5
2	RCM‡	6.02	40.6
3	LangGoalIRL	-	35.7
4	AVAST + REINFORCE	**6.01**	**42.2**

Table 3: Navigation errors and success rates for different methods in VLN unseen validation datasets under the scenario of truncating instruction (*: trained based on behavior cloning, ‡: trained without intrinsic rewards).

2. **Agent's performance was improved via fine-tuning based on RL algorithms, leading to outperforming the baseline methods.** We can notice from Table 2, after fine-tuning the pre-trained model, AVAST+REINFORCE performed better compared to the other baseline methods in unseen validation. This result indicates that the model has successfully taken advantage of exploration property in the REINFORCE algorithm.

3. **Introducing expert could not improve the agent performance.** As it can be seen from Figure 2(b), the performance of both AVAST and AST trained with expert demonstrations in a progressive way did not improve the performance. Instead, it degraded the agent performance compared to those that were trained with REINFORCE algorithm. This result indicates that the distribution of the unseen environment is quite different compared to the training environment.

4. **Hard exploration issue led to poor state-action value estimation for policy to learn.** We can notice from Figure 2(b), the curves of

both AVAST and AST with SACD dropped in the beginning due to poor value estimation from the critic network. Once the critic network was unable to provide a precise value estimation, the policy would be led to a bad direction, resulting in harmed performance.

6 Conclusions

This paper has presented attentive variational state tracker to deal with the generalization issue in vision-and-language navigation task. This method developed a variational approach to fulfill the partially observable Markov decision process where the belief states were sampled to implement the stochastic machine to improve the generalization to unseen environments. The experimental results demonstrated that the policy optimization using REINFORCE in combination of the proposed AVAST outperformed the previous methods in terms of navigation errors and success rates. The generalization was assured by the evaluation in the unseen environments.

Phylogeny-Inspired Adaptation of Multilingual Models to New Languages

Fahim Faisal, Antonios Anastasopoulos
Department of Computer Science, George Mason University
{ffaisal,antonis}@gmu.edu

Abstract

Large pretrained multilingual models, trained on dozens of languages, have delivered promising results due to cross-lingual learning capabilities on a variety of language tasks. Further adapting these models to specific languages, especially ones unseen during pre-training, is an important goal toward expanding the coverage of language technologies. In this study, we show how we can use language phylogenetic information to improve cross-lingual transfer leveraging closely related languages *in a structured, linguistically-informed manner*. We perform adapter-based training on languages from diverse language families (Germanic, Uralic, Tupian, Uto-Aztecan) and evaluate on both syntactic and semantic tasks, obtaining more than 20% relative performance improvements over strong commonly used baselines, especially on languages unseen during pre-training. [1]

1 Introduction

Language models have now become the standard for building state-of-the-art Natural Language Processing (NLP) systems. Beyond monolingual models, large-scale multilingual models covering more than 100 languages are now available, such as XLM-R by Conneau et al. (2020) and mBERT by Devlin et al. (2019), achieving competitive performance across languages from a variety of families and using various scripts.

Still, most of the 6500+ spoken languages in the world (Hammarström, 2016) are not covered –remaining unseen– by those models. Even languages with millions of native speakers like Lingala (with 15-20 million speakers in central Africa, mostly D.R. Congo) or Bambara (spoken by around 5 million people in Mali and neighboring countries) are not covered by any available language models at the time of writing.

A recent line of work (see §2) has shown that these large multilingual language models (MLMs) can be finetuned on individual languages to further improve performance. Even better, they can be even adapted to languages *unseen* during the pre-training stage.[2]

This work focuses on using adapters, a popular framework for such adaptation that has been proven successful for zero-shot and few-shot cross-lingual transfer. In particular, we significantly improve the adapter framework by drawing inspiration from a simple insight: that the adapters of related languages would likely need to perform the same function, and thus adapters could be trained leveraging multiple related languages. We impose a phylogenetically-inspired tree hierarchy for parameter-sharing between adapters and show empirically that our approach leads to large improvements with experiments on three NLP tasks on several language families.

2 Background

Adapting Large-Scale Models to Low-Resource Languages Multilingual language models (MLMs) can be used directly on unseen languages, or they can also be adapted using unsupervised methods. For example, Han and Eisenstein (2019) successfully used continued training with masked language modeling on unlabeled data to adapt an English BERT model to Early Modern English for sequence labeling. More recently, Muller et al. (2021) employed the same strategy (enhanced with transliteration to handle languages with different scripts) to adapt models for several unseen-during-pretraining languages.

Adapter Units Instead of fine-tuning the whole model, a more promising approach for adaptation uses dedicated units (*adapter units*) that are in-

[1] Code and data are publicly available: https://github.com/ffaisal93/adapt_lang_phylogeny

[2] The potential of such approaches is conditioned on the language's script and data availability, of course.

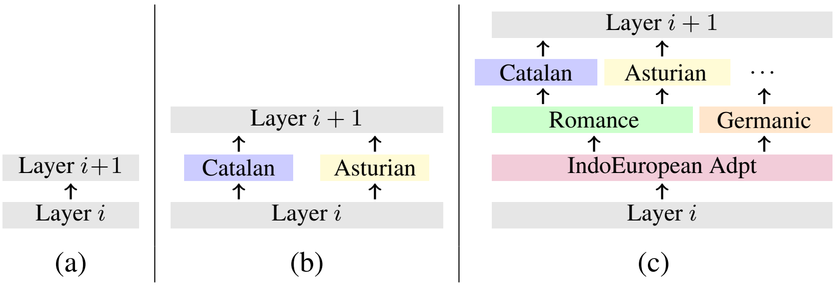

Figure 1: Incorporating phylogeny into neural models with adapters: starting with an unadapted model (a), current practice uses language-specific adapters between layers (b). We instead impose a phylogeny-informed tree hierarchy over adapters as in (c).

jected between the layers of the pre-trained model (see example in Figure 1.b) and can be trained on a new language, domain, or task (Vilar, 2018; Houlsby et al., 2019a; Pfeiffer et al., 2020a,c). There are two advantages in fine-tuning only these adapter components. Since they consist of only a small number of parameters, they can be adequately trained with a small number of training examples. In addition, as the pre-trained model remains invariant, they render *catastrophic forgetting* (French, 1999; Kirkpatrick et al., 2017) a non-issue.

Nevertheless, the application of these adapters has so far followed a simple, straight-forward protocol: insert the adapters, and train them individually for a new task or language. In our work, we investigate how we can improve this process, by incorporating additional linguistic information. The core idea is to incorporate phylogenetic information in the adapters' organization.

3 Phylogeny-Inspired Adaptation

Motivation Intuitively, given the similarities between two related lects (e.g. Catalan and Asturian), one should exploit that relationship to inform the adapters of both languages.

Thankfully, prior linguistic studies provide exactly the information we need in the form of phylogeny trees. Relationships between languages are typically represented as tree or network diagrams. In the phylogenetic trees we will use, languages are grouped based on their similarities; an internal node may (but not necessarily) correspond to a hypothesized linguistic ancestor. While often a phylogenetic network is more appropriate than a tree (e.g. in cases of borrowing, or when two languages influence each other in a bidirectional manner), in this work we will focus on trees as a first step towards phylogeny-inspired adaptation.

Implementation In a standard setting of adapting a language model from a source language to another target language, the typical approach (*e.g.* Pfeiffer et al., 2020c) is to have source and target specific language adapters, trained separately on unlabeled monolingual text with the masked language modeling (MLM) objective (Devlin et al., 2019). Then, one can train a task adapter on source language task data, stacking it on top of the source language adapter. At evaluation time, the source language adapter is replaced with the target language one.

As example, shown in Figure 1, consider three languages: Spanish, Catalan, and Asturian. To adapt a model for e.g. Named Entity Recognition (NER), the standard practice trains Spanish, Catalan, and Asturian language adapters separately: `L:Spanish`, `L:Catalan`, and `L:Asturian`. Using a language with labeled NER data (e.g. Spanish) then trains a task adapter `T:Spanish` using a stack of adapters `[L:Spanish, T:Spanish]`. At inference time we can then use a stack with the appropriate language adapter to perform the task in that language e.g., stack `[L:Asturian, T:Spanish]`.

Our approach follows the same principles, but adapters for multiple languages/genera/families are organized in a hierarchy following phylogenetic information and trained jointly. To continue with our running example, consider that all three languages belong to the Romance language group of the Indo-European family. We hence train five language type adapters jointly: `F:IndoEuro`, `G:Romance`, `L:Spanish`, `L:Catalan`, and `L:Asturian` which are stacked following the hierarchy depicted in Figure 1(c). So, examples from all IndoEuropean languages in our training mix are used to train the `F:IndoEuro` adapter, `G:Romance` is only trained on Romance languages data (if we have e.g. English or Danish in our mix, these data are directed through a `G:Germanic` adapter), and we also have language-dedicated adapters. We ensure that each training batch includes data from a single language; so, for an Asturian batch we train the following stack of adapters: `[F:IndoEuro, G:Romance, L:Asturian]`. At inference time, we also add the task adapter, trained as before on a language with labeled data, on top of our language-hierarchy adapters.

4 Experimental Setup

Tasks We experiment on three NLP tasks:

1. Dependency Parsing (DEP),
2. POS tagging (POS), and
3. Natural Language Inference (NLI).

For (1) and (2), we evaluate on 31 languages from Universal Dependencies v2.9 (Zeman et al., 2021). For (3), we use 4 indigenous low-resource languages from AmericasNLI (Ebrahimi et al., 2021), an extension of XNLI (Conneau et al., 2018). The choice of tasks and datasets is to ensure broad language coverage and especially to ensure we can study language families with only partial representation in the MLM pre-training stage.

Language Families We study dependency parsing and POS-tagging on languages from the Germanic, Uralic and Tupian families.[3] For NLI, we work with languages from Uto-aztecan and Tupian families. See Appendix Table 7 for the complete list of languages we use to train family, group and language adapters.

Pretraining Corpora For language adapter training we collect corpora from a variety of sources. See Appendix A for the complete list of our data sources. As we experiment with a large number of low-resource and endangered languages, the number of sentences per language ranges from 3000 sentences to 1 million (i.e. the high resource ones). Following previous work, we experiment with upsampling for the low-resource languages in our mix, to reduce data sparsity and to ensure they are adequately modeled.

Family	Genus	Tasks
Germanic	East Germanic, West Germanic	POS, DEP
Uralic	Finnic, Hungarian, Permic, Mordvinic, Sami	POS, DEP
Tupian	Tupari, Tupi-Guarani, Munduruku	NLI, POS, DEP
Uto-Aztecan	Tepiman, Corachol, Yaqui, Aztecan, Tarahumaran	NLI

Table 1: Language families and genera we study.

Adapter Training For jointly training phylogeny-inspired adapters, we select training data from the language families/group presented in Table 1. Irrespective of task and setting, we train standard adapter architectures (Üstün et al., 2020) leveraging the `AdapterHub.ml` (Pfeiffer et al., 2020b) framework.

We train the task adapter by stacking it on top of the hierarchical language adapters. We follow the cross-lingual transfer setting of Pfeiffer et al. (2020c) where we select a high-resource language for task training: we use English for transfer for all families except Uralic, for which we switch to Estonian. In terms of base model choice, we use mBERT for DEP, POS and XLM-R for NLI.[4] For dependency parsing we train using the objective of Glavaš and Vulić (2021), which is a modified variant of the standard deep biaffine attention dependency parser (Dozat and Manning, 2017). For all other tasks, we use simple classification heads as in previous literature.

Baselines and Model Variations We evaluate two common baselines for cross-lingual transfer:

1. `[T]`: Using only the task adapter trained on some high-resource language; and
2. `[LT]`: Using the stack of target language and task adapter.

We will denote our phylogeny inspired adapted models as `[FGLT]`: jointly trained `[Family, Group, Target Language]` stack and task adapter. We also perform analyses and ablations without some parts of the task: for instance, `[FT]` and `[FGT]`

[3] To be accurate, the Germanic languages are a branch (genus) of the Indo-European family, not a distinct language family themselves.

[4] Results with both models for all tasks are available in Appendix: B.

denote stacks using only family (and genus) and task adapters without language-specific ones.

5 Results

General Observations We present our experimental results covering all three tasks in Table 2, showing average performance for the baselines and our proposed method. We further split the results for languages seen and not seen by mBERT during pretraining. Compared to the [T] and [LT] baselines, we observe substantial performance improvements in 10 out of 12 task-family specific settings using [FGLT]. A visualization of all three task results with a breakdown per language is also available in Figure 2.

Looking at Figure 2, it is quite apparent how phylogeny inspired adaptation uplifts the performance of low-resource languages, especially the ones unseen during pretraining. For example, we evaluate dependency parsing on 3 such Germanic languages (Faroese, Gothic and Swiss German). All 3 languages benefit from the proposed adaptation approach with maximum 16.46% improvement over the best performing baseline for Gothic (see Table 8).

This positive drift of performance becomes more obvious for Uralic languages. Here, 8 out of 11 languages are extremely low-resource ones and unseen during pretraining. We obtain improvements over baseline in 7 out of these 8. We further observe similar trends in POS-Tagging for both Germanic and Uralic languages irrespective of the choice of base language model (see Appendix Tables 8—11).

The other language families we focus on are Tupian, Uto-Aztecan, comprised of indigenous and very low-resource languages (Ebrahimi et al., 2021). In case of Tupian languages on DEP-Parsing and POS-Tagging, we observe model adaptation does not result in improvement over baselines on mBERT. However, when we use XLM-R with model adaptation, average performance improves all around for these two tasks. In addition, for NLI, which is a task requiring higher semantic capabilities, we conduct experiments on four languages from Uto-Aztecan and Tupian families. As before, the combination of XLM-R with phylogenetic adaptation outperforms all other settings.

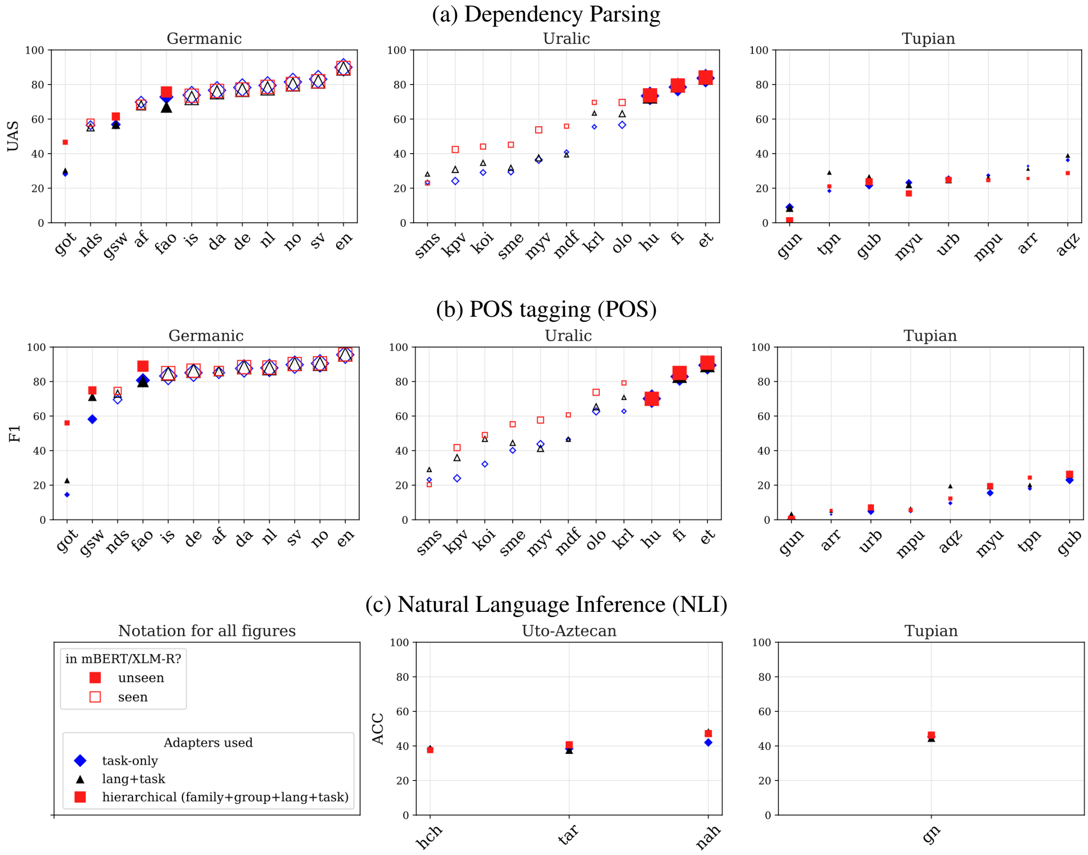
Among the baselines, the task-adapter-only baseline [T] performs better in Germanic and Tupian DEP-Parsing compared to the [LT] baseline. This points out the known problems with negative interference (Wang et al., 2019, 2020, *inter alia*). On the contrary, token classification tasks like POS-Tagging gets significant benefits from using the [LT] baseline. Compared to these, [FGLT] leads to consistent performance improvements. Even though our method does not uplift the result for Tupian DEP-Parsing and POS-Tagging, it is worth noting that it does not hurt either, unlike e.g. [T] which hurts in DEP-Parsing (-0.3 points compared to -5.1 points). Last, outperforming the average baseline of four indigenous American languages (Ebrahimi et al., 2021), points out the effective adaptation capabilities of phylogeny-based adaptation. See Appendix B for detailed language specific results.

True Zero-Shot Adaptation For a large number of extremely low-resource languages not seen during the pre-training of current language models, there may be no easily obtainable textual data to even perform MLM training to train a language-specific adapter. We explore such a scenario and investigate whether the language-family adaptors can be used instead of language-specific ones.

We simulate this scenario in two settings. First for 3 Uralic languages: Skolt Sami (sms), Moksha (mdf) and Karelian (krl). We discard their data from the training set and train other adapters jointly as before. During evaluation, we just use a high-resource language adapter (L:Estonian) instead of the missing language adapters. In addition, we explore this scenario in 4 Tupian languages: Akuntsu (aqz), Makuráp (mpu), Tupinambá (tpn) and Kaapor (urb) where we actually do not have any available training data (except (urb). So we replace the language adapter with a higher-resource one (L:Guajajára).

Results are presented in Table 3. Looking at the rows with phylogenically inspired adaptation [FGLT], we see 1.82% improvement on average for Tupian languages over the best performing baseline ([T]). Except Makuráp (mpu), all other 3 Tupian languages benefit from using our family adapters. Perhaps the most important result is the one on Tupinambá (tpn) which gets drastically impacted when using only baseline language adapter [LT](-13.16% from [T]) but performs much better with [FGLT](+9.21% over [T]).

For Uralic languages, even our model ablations (shown in Table 3) perform better than the baselines: these are [FT] and [FGT] where we get rid of the language adapter part and just draw in-



(a) Dependency Parsing

(b) POS tagging (POS)

(c) Natural Language Inference (NLI)

Figure 2: Visualizing three different task results across languages (marker size relative to MLM training data size). In most cases, and especially in languages unseen during pre-training, our hierarchical phylogeny-inspired adapters outperform the baselines.

Task (metric):	**Dep-Parsing (UAS)**			**POS-Tagging (F1-score)**			**NLI (Acc.)**	
Language-Family	Germanic	Uralic	Tupian	Germanic	Uralic	Tupian	Uto-Aztecan	Tupian
Language-Count (Unseen, Total)	(3,12)	(8,11)	(8,8)	(3,12)	(8,11)	(8,8)	(3,3)	(1,1)
Baselines								
BASE-LM+ [T]	52.5 (70.6)	36.9 (48.3)	**24.1**	51.1 (77.3)	41.9 (52.5)	9.9	39.6	45.3
BASE-LM+ [LT]	50.8 (69.2)	41.1 (51.4)	19.0	57.9 (79.6)	47.5 (56.7)	**13.2**	41.3	44.4
Phylogenically inspired								
BASE-LM+ [FGLT]	**60.1** (**72.3**)	**50.5** (**58.3**)	23.8	**73.3** (**83.7**)	**54.7** (**62.2**)	12.6	**41.8**	**46.3**

Table 2: Average results per language family across different tasks. We report averages both for languages unseen during pretraining, and for all languages in the mix (the latter in parentheses). Base language model (BASE-LM) is mBERT for Dep-Parsing, POS-Tagging and XLM-R for NLI. We use the following language for task adapter training: English for Germanic, Tupian and Uto-Aztecan and Estonian for Uralic.

ference from family and genre adapters. Specifically, [FGT] shows consistent improvement for all 3 Uralic languages, even though the model never observed the target language texts during neither base model pretraining nor adapter training.

6 Further Discussion

We perform additional ablation studies where we show that our proposed approach provides sustainable performance in constrained settings with reduced parameter counts. In addition, we explore data up-sampling for low-resource languages in language families with large data imbalances across the language members. This simple approach points towards the further improvement scope with limited data availability. Detailed analysis of both these experiments are presented below.

Parameter Reduction Stacking multiple adapters instead of a single language adapter

Uralic (language adpater: est)					
Model Training	sms	mdf	krl		avg
Baselines					
MBERT+ [T] (est)	23.37	40.89	55.53		39.93

MBERT+ [FGT] (eng)	22.50	17.12	19.74	22.13	20.37

Table 3: Dependency parsing with extremely low-resource languages in the absence of language specific adapters (true zero-resource scenario).

comes with extra parameter cost.[5] To assess whether we can integrate phylogenetic information while keeping the adapter parameter counts limited, we perform parameter reduction using a constant factor. For example, consider a single language adapter [L] which has down/upword projections with L:Proj×Layer parameters leading to a parameter count of 2×48×768. Instead we can use a dimension reduced by a factor of 3 and add two extra adapters ([FGL]) without increasing the parameter count 2×(F:Proj+G:Proj+L:Proj)×FGL:Output; to be accurate: 2×(16+16+16)×768. Contrast these with our solution without this constant factor parameter reduction, which will add 2×(48+48+48)×768 parameters to be learned.

The results, tested on Uralic languages for the dependency parsing task, are reported in Table 4. Importantly, we observe consistent performance improvement in [FGLT] over baseline [LT] irrespective of the parameter count. Among these two selections, the [FGLT] one with constrained parameter count (885312) comes with a 1.29% performance trade off which still outperforms the baseline by 4 points on average. Further looking into each individual language result, we find an interesting trend in Skolt Sami (sme). This is the only language where performance drops in constrained [FGLT] compared to the baseline which then drops further when we move to the upscaled [FGLT]. Likewise, we observe performance improvement in any language using sustained model elevates further in upscaled model.

Deep vs Wide Adapters Our FGLT setting makes two important changes to the baseline LT one. First, it stacks 3 language-related adapters as opposed to a single one. Second, it shares some of these adapters between languages. An important question is whether the performance improvements are due to stacking (making the model *deeper*) or due to the parameter sharing between languages. To answer this question, we perform another ablation where we replace the 2×(F:Proj+G:Proj+L:Proj)×FGL:Output setting with 2×(L:Proj+L:Proj+L:Proj)×LLL:Output. Essentially, we create a stack of 3 language-specific adapters.

We will first contrast the baseline [LT] (which has a single *wide adapter*) to this deeper version [LLLT]. We keep the parameter count equal between the two using the same parameter reduction as in the previous paragraph. We find that the [LLLT] setting does indeed improve performance, but only for high-resource languages, even exceeding the upscaled phylogenetic setting [FGLT] (see Table 4). For 7 out of 8 low-resource languages unseen by mBERT, however, the performance degrades in [LLLT] compared to [LT]. Hence, we conclude that deeper stacks of adapters are better than a single wide adapter, but without the adapter parameter sharing this only benefits high-resource languages.

We want to further focus on this second point about parameter sharing: in Table 4, compare rows [LLLT] and [FGLT] under the reduced parameter count. For *all* unseen languages, [FGLT] yields significant improvements, leading to almost 5 UAS points higher on average.

Effect of Upsampling For most of the Uralic, Germanic and all of the Tupian and Uto-Aztecan low-resource languages, we had very little amount of training data available. As a result, this limited data availability creates within-family data imbalance, especially for Germanic and Uralic languages. To address this issue, we perform a simple data upsampling on all low resource languages from these two families. Here, the upsampling factor is inversely proportional to the per-language token count. A language with very low word count is

[5] We note, though, that this additional cost is still a very small fraction of the overall model's parameter count.

Table 6: Adapters arranged following a phylogenetically-inspired tree perform significantly better than ones following random counterfactual tree. Parameter sharing between similar languages leads to significantly better results for the unseen languages in both tasks.

sampled in large numbers compared to the ones with higher word count.

We use the upsampled dataset for all the dependency parsing and POS tagging experiments we perform on these two language families (Appendix Table 2, 8, 9, 10, 11). The positive upsampling effect is obvious when we compare the dependency parsing results on Uralic upsampled dataset with the one with original datasize in Table 5. Note that we do not upsample the 3 high resource ones: Estonian (et), Finnish (fi), and Hungarian (hu) and experiment on the other languages, where we can make a number of interesting observations.

First, though the original sentence count is same (10k) for North Sami (sme) and Komi Permyak (koi) the upsampled size is different for these two languages: 100k and 60k respectively. The reason behind this difference is, we perform word-count based upsampling and the average sentence length turns out to be less for koi thus assigned with a low sampling factor. Hence, the one with higher upsampled sentence count (sme) results in large performance improvement of 13.54 points, while it was the one with second lowest score in the non-upsampled setting. Secondly, we observe performance improvements for all low-resource languages. It would be interesting to explore the resource dependent performance variation that could be attributed to data sampling choices. For now, we keep this open for future studies.

On the other hand, we cannot clearly claim that extremely low-resource languages always benefit from upsampling. For example, Skolt Sami (sms) is the one with lowest data availability (3k) and lowest original score (22.78). Upsampling more than 9x times results in only 0.22% improvement. We suspect that data quality might play an important role here, considering that we had to scrape the few data available online for sms (wan), whereas the corpus we use for sme was collected by Goldhahn et al. (2012) following standard approaches and with NLP applications in mind.

Random vs Phylogenetic Tree One key hypothesis of ours is that language family tree information is beneficial for modeling low-resource languages.

To further solidify this claim, we compare adapters based on a linguistically-informed tree (like the one we have been using in all previous experiments) to adapters based on a counterfactual (hypothetical) language tree. We construct a random language family hierarchy and train the adapter stacks jointly like before instead of using the phylogenetically informed ones. We make the random tree structure typologically diverse while keeping one low-resource language from either Germanic (Faroese), Uralic (Komi Zyrian) or Tupian (Kaapor) present in each newly defined genus (see Table 15 in Appendix D for the random family tree structure). In Table 6, we report results in Dependency parsing and POS tagging tasks for these 3 languages under each of these settings. The results for dependency parsing are to a large extent conclusive: the adapters following the random tree perform worse than the baselines, while the phylogenetically-inspired ones are significantly better. The random-tree adapters do indeed outperform the baselines for POS tagging, but again for 2 of the 3 low-resource languages fall short compared to the phylogenetically-inspired ones. Curiously, for Kaapor, this random-tree model outperforms all other models, but all of them are still extremely bad (with only an accuracy of 13% in the best case); nevertheless, we will further investigate this result in future work.

Indo-European Family Tree Going beyond our original setup, we conduct one additional experiment where we do joint-training on the whole Indo-European language family as shown in Figure 1. The only difference is that essentially, by adding a *root* adapter `R` we have a stack of four jointly trained adapters `[RFGL] (R:IndoEuro)` instead of just three (i.e. `[FGL]`). Interestingly, the performance on the dependency parsing tasks gets negatively impacted for almost all languages (see Table 14). We hypothesize that this is due to the inherent diversity of the Indo-European family. Despite sharing a common ancestor (Proto-Indo-European), the IE family groups that we work with here (Germanic, Romance, Slavic, Celtic, Greek, Indo-Aryan) are too typologically different from each other, and forcing them to share a common root negates the gains of the group-specific adapters. We plan to investigate this further in future work.

7 Related Work

Continuous effort is being put to improve cross-lingual transfer across languages as well as making language models capable enough to go beyond high resource domains. Recently, Wang et al. (2022), proposed an approach to combine lexicons with monolingual/parallel data for pretraining. It expands the modeling capability to thousands more languages largely including under-represented languages with limited to zero corpus availability. It is now proven that, pretraining on closely related languages yields better result for zero-shot transfer (Pires et al., 2019) and continued pretraining on a larger number of languages leads to further improvement (Fujinuma et al., 2022). However, training on some specific languages can still hurt the performance of other languages (Conneau et al., 2020). As a result, it is crucial to prevent negative inference while keeping the performance equitable and robust across languages (Wang et al., 2019, 2020).

To make the performance robust across languages, it is important to identify how much linguistic information is currently in place inside these big multilingual models. Recent studies have done investigation on this hypothesis by probing language models for linguistic typology (Choenni and Shutova, 2022; Stańczak et al., 2022) as well as phylogheny (Rama et al., 2020). These studies have measured phylogenetic distance and typological similarity across languages so that we can make informed cross-lingual transfer. In line with these findings, (Zhao et al., 2021) has done experiments to remove the language specific information by stackable vector operations which further improve the cross-lingual representation. One recent study (Foroutan et al., 2022) dives further into identifying language-neutral and language-specific subspace inside the representation space of multilingual models and now it is proven that the shared representation space is the one helping to perform effective cross-lingual transfer.

As opposed to the standard fine-tuning of large-scale language models, a more focused trend is to perform efficient parameter selection thus reducing the overall computation cost and carbon footprints (Houlsby et al., 2019b). Adapters are such highly customized light-weight neural network layers on top of base models. Because of this higher flexibility, there are studies already in place looking into the adapter-level optimization according to the nature of data and network layers (Moosavi et al., 2022). In addition, using language specific units in a modular fashion in the pre-training stage was shown to be beneficial in recent work (Pfeiffer et al., 2022).

8 Limitations and Future Work

While we already incorporated task evaluation on a diverse set of language families ranging from extremely low resourced Uralic ones to indigenous AmericasNLI (Ebrahimi et al., 2021) languages, our experiments are still limited in terms of typological diversity. In future, we want to further extend the typological diversity of languages we use. At the same time, we would like to democratize the full force of language genetical properties in steps beyond just finetuning thus making the resource scarce languages more accessible.

9 Conclusion

In this work, we present an adapter-based approach to leverage language phylogenetic information for better cross-lingual adaptation. Our experiments on a diverse set of tasks and languages show significant performance improvements over commonly-used strong baselines. Even better, we show that under the exact same adapter parameter count settings, using smaller adapters but forcing adapter sharing between genetically related languages improves performance on true zero-resource scenarios. These improvements are particularly stark for languages unseen in the pre-training stage of large multilingual language models, providing a direct path towards better adaptation and language coverage for language technologies.

A Dataset

Detailed data source with statistics are presented in table 7.

B Language Specific Task Results

Detailed language specific task results are presented in table 8, 9, 10, 11, 12 and 13.

Dependency Parsing For dependency parsing, we perform experiments on Germanic, Uralic and Tupian languages. We observe, phylogeny based joint training performs better for 10 out of 11 Germanic and Uralic languages unseen by mbert. In addition all of the Tupian ones are unseen by mbert and joint training performs better than the language based adapter baseline `[LT]`. Similar trend is visible in case of Germanic high resource languages where using the language based adapter baseline `[LT]` hurts the overall performance. Though, joint training does not cross the performance threshold of just using the task adapter baseline `[T]` in case of majority high resource ones, it doesn't do negative interference like language adapter based baseline either. At the same time, the performance improvement for unseen low resource languages are significant while using joint training. Thus phylogeny based joint training keeps a performance balance across languages with diverse data availability.

POS Tagging For POS tagging task, we select the same language and settings like before we used in dependency parsing. In POS tagging, the language adapter does not make negative interference like it made in case of dependency parsing. However, using phylogny based joint training still performs better than all the baseline in majority Germanic and Uralic languages. In case of Tupian languages, we see improvement using phylogeny based adaptation in 4 out of 8 languages.

NLI Our NLI results are presented in table 12 and 13. In addition, we reprot the zero-shot baseline results from (Ebrahimi et al., 2021) where the pretrained language model was continually trained on monolingual task language before training on downstream english task data. In our adaptation settings, we follow the `[FGLT]` combinations. Our approach does better for low resource ones (i.e.) while joint training results in optimal performance.

C Dependency Parsing on Indo-European Family

The dependency parsing results comprising Indo-European family branches are presented in table 14.

D Random Family Tree

In our random family tree construction, we select 9 languages from 9 different language family branches. We group these languages into 3 genus while keeping one language in each genus from either Germanic, Tupian or Uralic language family on which we report our experimental result. The tree structer is presented in table 15.

Family	Genus	Language	ISO 639-3	Size	Source

Transferring Knowledge via Neighborhood-Aware Optimal Transport for Low-Resource Hate Speech Detection

Abstract

Warning: *this paper contains content that may be offensive and distressing.*

The concerning rise of hateful content on online platforms has increased the attention towards automatic hate speech detection, commonly formulated as a supervised classification task. State-of-the-art deep learning-based approaches usually require a substantial amount of labeled resources for training. However, annotating hate speech resources is expensive, time-consuming, and often harmful to the annotators. This creates a pressing need to transfer knowledge from the existing labeled resources to low-resource hate speech corpora with the goal of improving system performance. For this, neighborhood-based frameworks have been shown to be effective. However, they have limited flexibility. In our paper, we propose a novel training strategy that allows flexible modeling of the relative proximity of neighbors retrieved from a resource-rich corpus to learn the amount of transfer. In particular, we incorporate neighborhood information with Optimal Transport, which permits exploiting the geometry of the data embedding space. By aligning the joint embedding and label distributions of neighbors, we demonstrate substantial improvements over strong baselines, in low-resource scenarios, on different publicly available hate speech corpora.

1 Introduction

With the alarming spread of Hate Speech (HS) in social media, Natural language Processing techniques have been used to develop automatic HS detection systems, typically to aid manual content moderation. Although deep learning-based approaches (Mozafari et al., 2019; Badjatiya et al., 2017) have become state-of-the-art in this task, their performance depends on the size of the labeled resources available for training (Lee et al., 2018; Alwosheel et al., 2018).

Annotating a large corpus for HS is considerably time-consuming, expensive, and harmful to human annotators (Schmidt and Wiegand, 2017; Malmasi and Zampieri, 2018; Poletto et al., 2019; Sarwar et al., 2022). Moreover, models trained on existing labeled HS corpora have shown poor generalization when evaluated on new HS content (Yin and Zubiaga, 2021; Arango et al., 2019; Swamy et al., 2019; Karan and Šnajder, 2018). This is due to the differences across these corpora, such as sampling strategies (Wiegand et al., 2019), varied topics of discussion (Florio et al., 2020; Saha and Sindhwani, 2012), varied vocabularies, and different victims of hate. Thus, to address these challenges, here we aim to devise a strategy that can effectively transfer knowledge from a resource-rich source corpus with a higher amount of annotated content to a low-resource target corpus with fewer labeled instances.

One popular way to address this is transfer learning. For instance, Mozafari et al. (2019) fine-tune a large-scale pre-trained language model, BERT (Devlin et al., 2019), on the limited training examples in HS corpora. Further, a sequential transfer, following Garg et al. (2020), can be performed where a pre-trained model is first fine-tuned on a resource-rich source corpus and subsequently fine-tuned on the low-resource target corpus. Since this may risk forgetting knowledge from the source, the source and target corpora can be mixed for training (Shnarch et al., 2018). Besides, to learn target-specific patterns without forgetting the source knowledge, Meftah et al. (2021) augment pre-trained neurons from the source model with randomly initialized units for transferring knowledge to low-resource domains.

Recently, Sarwar et al. (2022) argue that traditional transfer learning strategies are not systematic. Therefore, they model the relationship between a source and a target corpus with a neighborhood framework and show its effectiveness in transfer learning for content flagging. They model the in-

teraction between a query instance from the target and its neighbors retrieved from the source. This interaction is modeled based on their label agreement – whether the query and its neighbors have the same labels – while using a fixed neighborhood size. However, different neighbors may have varying levels of proximity to the queried instance based on their pair-wise cosine similarities in a sentence embedding space. Therefore, intuitively, the neighbors should also be weighted according to these similarity scores.

We hypothesize that simultaneously modeling the pair-wise distances between instances from the low-resource target and their respective neighbors from the resource-rich source, along with their label distributions should result in a more flexible and effective transfer. With this aim, we propose a novel training strategy where the model learns to assign varying importance to the neighbors corresponding to different target instances by optimizing the amount of pair-wise transfer. This transfer is learned without changing the underlying model architecture. Such optimization can be efficiently performed using *Optimal Transport* (OT) (Peyré and Cuturi, 2019; Villani, 2009; Kantorovich, 2006) due to its ability to find correspondences between instances while exploiting the underlying geometry of the embedding space. Our contributions are summarised as follows:

- We address HS detection in low-resource scenarios with a flexible and systematic transfer learning strategy.
- We propose novel incorporation of neighborhood information with joint distribution Optimal Transport. This enables learning of the amount of transfer between pairs of source and target instances considering both (i) the similarity scores of the neighbors and (ii) their associated labels. To the best of our knowledge, this is the first work that introduces Optimal Transport for HS detection.
- We demonstrate the effectiveness of our approach through considerable improvements over strong baselines, along with quantitative and qualitative analysis on different HS corpora from varied platforms.

2 Related Works

2.1 Hate Speech Detection

Deep Neural Networks, especially the transformer-based models, such as the pre-trained BERT, have dominated the field of HS detection in the past few years (Alatawi et al., 2021; D'Sa et al., 2020; Glavaš et al., 2020; Mozafari et al., 2019).

Wiegand et al. (2019); Arango et al. (2019) raise concerns about data bias present in most HS corpora, which results in overestimated within-corpus performance. They, therefore, recommend cross-corpus evaluations as more realistic settings. Bigoulaeva et al. (2021); Bose et al. (2021); Pamungkas et al. (2021) perform such cross-corpus evaluations in this task with no access to labeled instances from the target. However, Yin and Zubiaga (2021); Wiegand et al. (2019) report fluctuating or degraded performance across corpora. As pointed out by Sarwar et al. (2022), in real-life scenarios, most online platforms could invest in obtaining at least some labeled training instances for deploying an HS detection system. Thus, we study a more realistic setting where a limited amount of labeled content is available in the target corpus.

2.2 Neighborhood Framework

k-Nearest Neighbors (kNN)-based approaches have been successfully used in the literature for an array of tasks such as language modeling (Khandelwal et al., 2020), question answering (Kassner and Schütze, 2020), dialogue generation (Fan et al., 2021), etc. Besides, kNN classifiers have been used for HS detection (Prasetyo and Samudra, 2022; Briliani et al., 2019), which typically predict the class of an input instance through a simple majority voting using its neighbors in the training data.

Recently, Sarwar et al. (2022) propose a neighborhood framework kNN$^+$ for transfer learning in cross-lingual low-resource settings. They show that a simple kNN classifier is prone to prediction errors as the neighbors may have similar meanings, but opposite labels. They, instead, model the interactions between the target corpus instances, treated as queries, and their nearest neighbors retrieved from the source. This neighborhood interaction is modeled based on whether a query and its neighbors have the same or different labels. In their best performing framework (in cross-lingual setting) of Cross-Encoder kNN$^+$, Sarwar et al. (2022) obtain representations of concatenated query-neighbor pairs to learn such neighborhood interactions.

However, Sarwar et al. (2022) do not consider *the varying levels of the proximity of different neighbors to the query.* Besides, a mini-batch in their framework comprises a query and all its neighbors. For fine-tuning large language models like BERT, the batch size needs to be kept small due to resource constraints. This could limit the neighborhood size in their framework. This is different from our approach, where the neighborhood size is scalable.

2.3 Optimal Transport

Optimal Transport (OT) has become increasingly popular in diverse NLP applications, as it allows comparing probability distributions in a geometrically sound manner. These include machine translation (Xu et al., 2021), interpretable semantic similarity (Lee et al., 2022), rationalizing text matching (Swanson et al., 2020), etc. Moreover, OT has been successfully used for domain adaptation in audio, images, and text (Olvera et al., 2021; Damodaran et al., 2018; Chen et al., 2020). In this work, we perform novel incorporation of nearest neighborhood information with OT. Besides, to the best of our knowledge, this is the first work that introduces OT to the HS detection task.

3 Proposed Approach

Our problem setting involves a low-resource target corpus X^t with a limited amount of labeled training data $(X^t_{train}, Y^t_{train}) = \{x^t_i, y^t_i\}^{n_t}_{i=1}$ and a resource-rich source corpus X^s from a different distribution with a large number of annotated data $(X^s_{train}, Y^s_{train}) = \{x^s_i, y^s_i\}^{n_s}_{i=1}$. Given such a setting, we hypothesize that transferring knowledge from the nearest neighbors in the source should improve the performance on the insufficiently labeled target. Furthermore, to provide additional control to the model, we propose a systematic transfer. With this transfer mechanism, a model can *learn* different weights assigned to the neighbors in X^s_{train} based on their proximity to the instances in X^t_{train} simultaneously in a sentence embedding space and the label space. For this, we incorporate neighborhood information with Optimal Transport (OT), as OT can learn correspondences between instances from X^s_{train} and X^t_{train} by exploiting the underlying embedding space geometry.

3.1 Joint Distribution Optimal Transport

In this work, we use the joint distribution optimal transport (JDOT) framework (Courty et al., 2017) following the works of Damodaran et al. (2018); Fatras et al. (2021), proposed for unsupervised domain adaptation in deep embedding spaces. The framework aligns the joint distribution $P(Z, Y)$ of the source and the target domains, where Z is the embedding space through a mapping function $g(.)$, and Y is the label space. For a discrete setting, let $\mu_s = \sum_i^{n_s} a_i\, \delta_{g(x^s_i), y^s_i}$ and $\mu_t = \sum_i^{n_t} b_i\, \delta_{g(x^t_i), y^t_i}$ be two empirical distributions on the product space of $Z \times Y$. Here $\delta_{g(x_i), y_i}$ is the Dirac function at the position $(g(x_i), y_i)$, and a_i, b_i are uniform probability weights, i.e. $\sum_i^{n_s} a_i = \sum_i^{n_t} b_i = 1$.

The 'balanced' OT problem (OT_b), as defined by Kantorovich (2006), seeks for a transport plan γ in the space of the joint probability distribution $\Pi(\mu_s, \mu_t)$, with marginals μ_s and μ_t, that minimizes the cost of transport from μ_s to μ_t, as:

$$\begin{aligned} OT_b(\mu_s, \mu_t) = & \min_{\gamma \in \Pi(\mu_s, \mu_t)} \sum_{i,j} \gamma_{i,j} c_{i,j} \\ & s.t. \quad \gamma \mathbf{1}_{n_t} = \mu_s, \gamma^T \mathbf{1}_{n_s} = \mu_t \end{aligned} \tag{1}$$

Here $c_{i,j}$ is an entry in a cost matrix $C \in R^{n_s \times n_t}$, representing the pair-wise cost (see Section 3.2), and $\mathbf{1}_n$ is a vector of ones with dimension n. Each entry $\gamma_{i,j}$ indicates the amount of transfer from location i in the source to j in the target.

The constraint on γ requires that all mass from μ_s is transported to μ_t. However, this can be alleviated through relaxation, leading to the 'unbalanced' OT (OT_u) (Benamou, 2003), as:

$$\begin{aligned} OT_u(\mu_s, \mu_t) = & \min_{\gamma \in \Pi(\mu_s, \mu_t)} \sum_{i,j} \gamma_{i,j} c_{i,j} + \Lambda\,; \\ & \text{where} \quad \Lambda = \epsilon\, \Omega(\gamma) + \lambda \left(\mathrm{KL}(\gamma \mathbf{1}_{n_t}, \mu_s) + \mathrm{KL}(\gamma^T \mathbf{1}_{n_s}, \mu_t) \right) \\ & s.t. \quad \gamma \geq 0 \end{aligned} \tag{2}$$

KL is the Kullback-Leibler divergence that allows the relaxation of the marginal constraint on γ. λ is the marginal relaxation coefficient. $\Omega(\gamma) = \sum_{i,j} \gamma_{i,j} log(\gamma_{i,j})$ corresponds to the entropic regularization term, which allows fast computation of the OT distances (Cuturi, 2013). ϵ is the entropy coefficient.

For models with a high-dimensional embedding space like ours, Fatras et al. (2021) propose to make the computation of OT losses scalable using the mini-batch OT. Thus, for every mini-batch, we sample an equal number of instances, given by the batch size m, from X^s_{train} and X^t_{train}, which makes $C \in R^{m \times m}$ and γ square matrices. As discussed by Fatras et al. (2021), since the transport plan at the mini-batch level is much less sparse, it may result in undesired pairings between instances if computed by Equation 1. To counteract this effect, we rely on the more robust version of OT as formulated in Equation 2. Thus, we adopt the *joint distribution entropy regularized unbalanced mini-batch OT* for our framework, henceforth simply referred to as OT. Note that this framework does not modify the underlying model architecture used for classification, but only introduces a new training strategy.

3.2 Neighborhood-aware OT (OT^{NN})

In the above joint distribution framework, the cost matrix C is expressed as the weighted combination of the costs in the embedding and the label spaces:

$$c_{i,j}(g(x_i^s), y_i^s; g(x_j^t), y_j^t) = \alpha\, d(g(x_i^s), g(x_j^t)) + \beta\, L(y_i^s, y_j^t) \tag{3}$$

$d(.,.)$ denotes the *embedding distance* (ED), which is a squared l_2 distance between the corresponding embeddings. $L(.,.)$ is *label-consistency loss* (LC), which is a cross-entropy loss that enforces a match between the label of the i^{th} source instance and that of the j^{th} target instance. α and β are scalar values. Minimizing the cost in Equation 3 results in aligning instances from the source and the target that simultaneously share similar representations and common labels.

We adapt C to account for k nearest neighbors of the target instances in X^t_{train} from the source X^s_{train}. Since BERT is not optimal for semantic similarity search (Reimers and Gurevych, 2019), we extract the neighbors using the Sentence-BERT (SBERT) model (Reimers and Gurevych, 2019). SBERT provides sentence embeddings that can be easily compared using cosine similarity. We hypothesize that allowing transfers to occur only from the corresponding neighbors in the source to the target should result in more effective learning.

For this, we explicitly assign the value $\max(C)$ to $c_{i,j}$ in C whenever the i^{th} source and j^{th} target instances are not neighbors, considering the nearest neighborhood space of k neighbors. Besides, we use the SBERT distances as the embedding distance in Equation 3. This distance, in addition to the label consistency term, ensures that γ is learned to allow a higher amount of transfer from neighbors in X^s_{train} that are simultaneously (i) closer in the SBERT space and (ii) share the same label with an instance in X^t_{train}, compared to the neighbors that are further away and/or have opposite labels.

Note that even though we use a neighborhood size of k, the target instances do not attend equally to all of their k neighbors. This is because if the distance between a target instance x_j^t and its top n^{th} neighbor (x_i^s) from the source, within the neighborhood size of k (i.e. $n < k$) is comparatively large, their corresponding (i, j)-th entry in C would have a larger value. This would comparatively reduce the transfer *even if they share common labels*. Thus, for a neighbor with the same label as the target instance, the higher its SBERT distance from the target instance, the lower the amount of transfer. This results in more flexibility where the model can learn from the relevant neighbors corresponding to every target instance.

In addition to the OT loss from Equation 2, we introduce the cross-entropy losses for the training instances from both X^t_{train} and X^s_{train} in the final loss function, as required by our classification task. Our final loss function is given by Equation 4. Here $g(.)$ encodes a given input using the pre-trained BERT encoder to the BERT embedding space by extracting the fine-tuned [CLS] token representation of the last hidden layer. $f(.)$ denotes the classifier, which is one fully connected layer. θ_s and θ_t are the weights assigned to the source and the target cross-entropy losses, respectively.

$$\begin{aligned}\mathrm{OT}^{NN} = \min_{\gamma,f,g} \quad & \theta_s \frac{1}{m}\sum_i L_s\left(y_i^s, f(g(x_i^s))\right) + \sum_{i,j}\gamma_{i,j}c_{i,j} \\ & + \Lambda + \theta_t \frac{1}{m}\sum_j L_t\left(y_j^t, f(g(x_j^t))\right)\end{aligned} \tag{4}$$

Solving the optimization problem: Following Damodaran et al. (2018), we adopt a two-step procedure to solve the above optimization problem at the mini-batch level. We first compute the optimal γ by fixing the model parameters of f and g.

$$\min_{\gamma} \sum_{i,j}\gamma_{i,j}\left(\alpha\, d(g_{sbert}(x_i^s), g_{sbert}(x_j^t)) + \beta\, L(y_i^s, y_j^t)\right) + \Lambda \tag{5}$$

We use the SBERT embeddings through the mapping function $g_{sbert}(.)$ here instead of the learned BERT embeddings to compute the ED loss. This is done so that the γ is updated based on the semantic proximity in the SBERT space. y_i^s and y_j^t are the ground truth labels for the instances x_i^s and x_j^t from X^s_{train} and X^t_{train}, respectively. In the next step, the model parameters of f and g are learned while fixing γ obtained from Equation 5, denoted as $\hat{\gamma}$.

$$\min_{f,g} \quad \sum_{i,j} \hat{\gamma}_{i,j} \left(\alpha\, d(g(x_i^s), g(x_j^t)) + \beta\, L(f(g(x_i^s)), y_j^t)\right)$$
$$+ \theta_s \frac{1}{m} \sum_i L_s \left(y_i^s, f(g(x_i^s))\right) + \theta_t \frac{1}{m} \sum_j L_t \left(y_j^t, f(g(x_j^t))\right) \tag{6}$$

The first part of Equation 6 allows the model to learn from the instances in X^s_{train} that are consistent in terms of both the embedding space (ED loss) and the label space (LC loss) with the instances in X^t_{train}. Here we use $g(.)$, instead of $g_{sbert}(.)$, to compute ED so that g learns from the SBERT space through $\hat{\gamma}$. For the LC loss, we use the predicted labels for x_i^s from the source and the actual labels y_j^t corresponding to x_j^t from the target. This is done to update the model parameters of f and g based on the target labels and bring source instances that have common labels closer to the target instances. We have provided an illustration of the training strategy of OT^{NN} in Figure 3 of Appendix A.

We propose different variants of OT^{NN}:

OT^{NN}: In this variant, we do not use the source cross-entropy loss term in Equation 4, thus effectively having $\theta_s = 0$.

OT$^{NN}_{\text{pre-select}}$: Prior to the training, we pre-select the k nearest neighbors from X^s_{train} corresponding to every instance in X^t_{train}, instead of training with all the source instances. Here also $\theta_s = 0$.

OT^{NN} + sloss: This is OT^{NN} with source cross-entropy loss (sloss), thus having $\theta_s = 1$.

OT$^{NN}_{\text{pre-select}}$ + sloss: This is similar to the second variant, with $\theta_s = 1$. Here, sloss is computed only on the pre-selected source instances.

4 Experimental Settings

4.1 Corpus Description

We perform experiments with three standard HS corpora, namely, *Waseem* (Waseem and Hovy, 2016), *Vidgen* (Vidgen et al., 2021), and *Ethos* (Mollas et al., 2022), as they are collected using different sampling strategies across varied platforms. Following Wiegand et al. (2019); Swamy et al. (2019), we use the labels of *hate* and *non-hate*, where the former involves all forms of hate.

Waseem is a Twitter corpus comprising hate against women and ethnic minorities. We obtain 10.9K tweets in total from the tweet IDs, of which 26.8% instances belong to the *hate* class. *Vidgen* is collected using a human-and-model-in-the-loop process aimed at making the corpus robust. It covers hate against diverse social groups, like blacks, women, muslims, immigrants, etc. with a total of 41144 instances, of which 53.9% is labeled as *hate*. *Ethos* comprises 998 instances from YouTube and Reddit, of which 43.4% are *hate* instances. Even with fewer instances, it is made diverse with an active learning-based sampling strategy, ensuring a balance with respect to different hateful aspects. See Appendix B for further details on the corpora.

For our experiments, we create two different versions of every corpus depending on its use as the source or the target, as presented in Table 1.

Corpus	Number of comments		
	Source setting		
	Train		
Waseem$_{\text{src}}$	8720		
Vidgen$_{\text{src}}$	32924		
Ethos$_{\text{src}}$	998		
	Target setting		
	Train	Validation	Test
Waseem$_{\text{tar}}$	400	100	1090
Vidgen$_{\text{tar}}$	400	100	4120
Ethos$_{\text{tar}}$	400	100	200

Table 1: Corpus statistics.

Source setting: In the absence of available standard splits, we randomly sample 80% of *Waseem* as the train set, resulting in 8720 instances. For *Vidgen*, we use the original corpus-provided train split of 32924 instances. Since *Ethos* has a relatively small size, we use the entire corpus for training, when used as the source. We call the source versions of these corpora as *Waseem*$_{\text{src}}$, *Vidgen*$_{\text{src}}$ and *Ethos*$_{\text{src}}$. Note that the source corpus is only used for training, while its validation set is not used for our experiments. Instead, we use the corresponding validation and test sets of the low-resource target corpus.

Target setting: In order to simulate a low-resource scenario for the target, we down-sample the original training instances of the corpora to 500 instances. This yields three low-resource target corpora, namely, *Waseem*$_{\text{tar}}$, *Vidgen*$_{\text{tar}}$ and *Ethos*$_{\text{tar}}$. Furthermore, we split each of them in the 80-20 ratio to obtain their respective low-resource train (400) and validation (100) sets. For the test set from *Waseem*$_{\text{tar}}$, we sample 10% of the original data, disjoint from the train and validation sets, given by 1090 instances. We use the original test split of 4120 instances for *Vidgen*$_{\text{tar}}$. For *Ethos*$_{\text{tar}}$, we randomly sample 20% of the data, disjoint from the previous set of 500 instances, as the test set.

4.2 Baselines

We compare our approach with the following baseline approaches:

Target-FT: We fine-tune the pre-trained BERT on the train set of the low-resource target corpus.

Seq-FT: Here, we sequentially fine-tune the BERT model first on the resource-rich source corpus and then on the low-resource target corpus.

Mixed-FT: Here, we fine-tune BERT on a mix of the source and target corpora. Since the target instances are limited, we first over-sample them. Then, for every mini-batch of size m, we randomly sample m training instances each from the source and the target. We then combine their cross-entropy losses for updating the model parameters, as:

$$\min_{f,g} \quad \theta_s \tfrac{1}{m}\sum_i L_s(y_i^s, f(g(x_i^s))) + \theta_t \tfrac{1}{m}\sum_j L_t(y_j^t, f(g(x_j^t))) \tag{7}$$

This is similar to Equation 4 without the OT^{NN} losses.

***k*NN-FT:** For every target instance, we retrieve top-k neighbors from the source, ranked with cosine similarities over SBERT embeddings. This yields a subset of source instances that are neighbors to the target instances. We then fine-tune the BERT model with the strategy used for Mixed-FT.

***k*NN ranking:** Here, we predict the labels of the target instances using a majority voting strategy. This voting is done over the labels associated with the top-*k* retrieved neighbors from the source based on their cosine similarities.

Weighted *k*NN: This uses a weighted voting of the top-*k* neighbors. Here we compute the sum of cosine similarities of neighbors associated with every class. The class with the highest score is returned as the predicted label of the target instance.

CE *k*NN$^+$ + SRC: This is the Cross-Encoder-based neighborhood framework *k*NN$^+$, proposed by Sarwar et al. (2022), as discussed in Section 2.2. For a fair comparison, we use the pre-trained BERT as the base representation. We first train CE *k*NN$^+$ on the source (SRC) and then with the target instances and their neighbors from the source.

PretRand: This is a transfer learning strategy proposed by Meftah et al. (2021) for low-resource domain adaptation. They jointly learn a pre-trained branch in the target model with a normalized, weighted, and randomly initialized branch. This is done so that the model can learn target-specific patterns while retaining the source knowledge. For a fair comparison, we use the pre-trained BERT as the base model, which is first fine-tuned on the source. For the random branch, following the approach, we add a BiLSTM layer and a Fully Connected layer over the final hidden layer from BERT. The final predictions are obtained using an element-wise sum of the predictions from the two branches.

OT: Finally, we use OT to transfer knowledge from the source to the target using both the ED and LC losses, similar to Equation 4. However, this is done *without* incorporating any neighborhood information in both the cost matrix and the computation of γ.

4.3 Hyper-parameters

We train all the models for 10 epochs initialized with the pre-trained BERT-base (Devlin et al., 2019) uncased model (Wolf et al., 2020), with a maximum sequence length of 128 tokens. We use the Adam optimizer with a learning rate of 5×10^{-5}. Besides, we perform hyper-parameter tuning for k and model selection using the best F1 scores over the respective target corpus validation sets. After the preliminary experiments, we set $\alpha = 0.05$, $\beta = 10$, $\epsilon = 0.2$, $\lambda = 0.5$, and $\theta_t = 10$ for all our experiments. We use a batch size of 32 for the OT^{NN} and the baselines, except CE-*k*NN$^+$. The latter inherently requires the batch size to be equal to the neighborhood size, as it provides query-neighborhood pairs as inputs to the model. See Appendix D for further details on the hyper-parameter tuning.

5 Results

5.1 Discussion

Table 2 shows the performance obtained with the baselines and the OT^{NN} variants across the test sets of three low-resource target corpora using different resource-rich source corpora. We also present the performance with Target-FT for reference. Following the prior work on HS detection (Sarwar et al., 2022; Attanasio et al., 2022), we use the F1 score of the hate class to report the performance, with an average F1 computed over five runs of the same experiments with different random initializations.

The results show that transferring knowledge from a resource-rich corpus to a low-resource corpus is generally helpful. The best scores in the

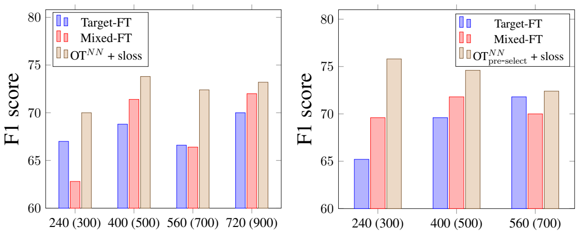
Table 2: F1 score (±std-dev) on the target corpus. The last four are the proposed OT^{NN} variants. **Bold** denotes the best, underline denotes the second-best scores in each column. * denotes the significantly improved scores compared to Seq-FT using the McNemar test (Dror et al., 2018; McNemar, 1947).

six respective settings of Table 2 are substantially higher than those from Target-FT. Furthermore, while the baseline methods show inconsistent performance across different settings, the proposed OT^{NN} variants yield the best performance in five out of six cases and the second-best in three cases. The baselines of Mixed-FT, *k*NN variants and CE *k*NN$^+$ achieve significant improvements compared to the vanilla Seq-FT for only 1 case, and PretRand achieves it for 2 cases. OT^{NN} variants, on the other hand, yield significant improvements in most cases; for instance, OT^{NN} has significantly improved scores in 5 out of 6 cases. Besides, the best scores from OT^{NN} variants improve over OT in 5 settings, while staying on par with OT in the remaining setting. This demonstrates that incorporating neighborhood information results in a more effective transfer.

When *Vidgen*$_{\text{src}}$ is used for transferring knowledge to *Ethos*$_{\text{tar}}$, Seq-FT yields the highest score (79.8). This is apparently because *Vidgen*$_{\text{src}}$ comprises a wide range of hateful forms directed towards different social groups. Since *Ethos*$_{\text{tar}}$ also involves hate against a variety of social groups, pretraining on all the source instances from *Vidgen*$_{\text{src}}$ for transfer learning, instead of training with the nearest neighbors, seems to be more helpful in this case. However, this is not the case when the transfer occurs from *Ethos*$_{\text{src}}$ to *Vidgen*$_{\text{tar}}$. This is likely because the *Vidgen* corpus involves adversarial instances that can easily fool an HS detection system trained on a different corpus. Besides, *Ethos*$_{\text{src}}$ has a subset of hateful forms and social groups covered by *Vidgen*. Therefore, a nearest neighborhood framework for transferring knowledge from *Ethos*$_{\text{src}}$ to *Vidgen*$_{\text{tar}}$ yields an improved performance, the highest score being 73.8 obtained by OT^{NN} + sloss, compared to 70.8 from Seq-FT.



(a) *Ethos*$_{\text{src}}$ to *Vidgen*$_{\text{tar}}$ (b) *Waseem*$_{\text{src}}$ to *Ethos*$_{\text{tar}}$

Figure 1: Performance with different sizes of the target train set. The total number of labeled instances available from the target is mentioned within the brackets, where the remaining instances are used as the target validation set.

Varying the size of X^t: We vary the size of the labeled target corpus available for training. We illustrate the cases of transferring knowledge from *Ethos*$_{\text{src}}$ to *Vidgen*$_{\text{tar}}$ in Figure 1(a), and from *Waseem*$_{\text{src}}$ to *Ethos*$_{\text{tar}}$ in Figure 1(b), with different OT^{NN} variants. For *Vidgen*$_{\text{tar}}$, we sample 300, 500, 700, and 900 instances. We use 80% for training, given by 240, 400, 560, and 720 instances, respectively, and the remaining 20% for validation. Since the *Ethos* corpus is small, we sample only 300, 500, and 700 instances as *Ethos*$_{\text{tar}}$, with the same proportions for training and validation. The target test set remains the same as in Table 1 for different training sizes. We observe that the OT^{NN} variants consistently improve the performance, with larger improvements obtained when the size of available target instances is lower. Mixed-FT, on the other hand, is inconsistent, and in some cases performs worse than Target-FT.

The improvements with OT^{NN} can be attributed to the fact that it can systematically *learn* the amount of transfer based on both the embedding distance and label consistency.

Table 3: Ablation study without the Embedding Distance (ED) /Label Consistency (LC) losses. F1 (±std-dev) on low-resource target corpus. **Bold** denotes the best, $\underline{\text{underline}}$ denotes the second-best score for each OT^{NN} variant.

Target instance: rt i am not sexist but girls who smoke are a big turn off even if your supermodel status its still a turn off.	
Instances	**GT**
Nearest neighbors from source using SBERT	
i do not actually care much for looks but the inflated sense of self importance that girls seem to have nowadays is rather obnoxious.	hate
totally agree. i could never find a woman or man attractive to go out with. .... i could nt be in a relationship with them as i am aromantic.	non-hate
every guy i know at work smoke at least 10 fags a day and i call them out. do not like it then do not do it.	non-hate
wow the truth is i did not get turned on until you mentioned cigar smoking men pissing on other men	non-hate
women have no redeeming features	hate
i am not sexist but women are dumb	hate
weed is stoner trash. if you are not a stoner guy, smoking this estrogen-filled garbage makes you a honorary one.	non-hate
maybe i am sexist because women are dumb	hate
women are less attracted to looks. they are far more attracted to high status and a dominant personality. the good news is you can acquire both of these.	non-hate
women without big t*ts are not attractive	hate
Nearest neighbors from source using OT^{NN}	
i am not sexist but women are dumb	hate
maybe i am sexist because women are dumb	hate
thrilled to have been born as the superior male gender	hate
men are superior than women in every single aspect	hate
women of color are not pleasant to look at	hate
leadership positions should only be occupied by men. that is the way to get things done.	hate
all women are created as equal b*tches	hate
all women should be suppressed	hate
this is the fact feminism is girlf*rts you cant unsmell	hate
women are devious	hate

Table 4: Qualitative analysis of an example with its top 10 nearest neighbors extracted using the SBERT and the learned OT^{NN} representations, where the source is *Vidgen*$_{\text{src}}$ and the target is *Waseem*$_{\text{tar}}$; GT: Ground Truth class.

5.2 Ablation Study

To analyze the importance of the constituent losses in OT^{NN}, we present an ablation study in Table 3 by removing the ED and the LC losses from the OT^{NN} variants. The best performances for each variant are obtained in 5 out of 6 cases when both the ED and the LC losses are incorporated. Besides, the second-best performances are obtained, in most cases, when we remove the ED loss. This suggests that while both losses are essential for an effective transfer, the LC loss contributes more towards the final performance than the ED loss.

5.3 Analysis of OT^{NN} Representations

We analyze the effect of training with OT^{NN} on the representation space by extracting the nearest neighbors of target instances. We rank these neighbors with cosine similarity over the learned OT^{NN} representations and check their ground truth classes. We compare them with the nearest neighbors obtained using SBERT representations. Table 4 contains an example of a hateful instance from *Waseem*$_{\text{tar}}$, and its top 10 nearest neighbors from *Vidgen*$_{\text{src}}$. We observe that the neighbors retrieved using the SBERT representations belong to both hate and non-hate classes. This is because SBERT is optimized mainly for semantic similarity, while they are sub-optimal in differentiating hateful instances from non-hateful ones. On the other hand, the neighbors obtained from OT^{NN} representations indicate that OT^{NN} brings instances across corpora, which are both semantically similar (the topic of women) and belong to the same class closer in the representation space, compared to those belonging to the opposite class.

In addition, we study the effect of the OT^{NN} representations by performing a simple majority voting of the top k nearest neighbors retrieved from the source with SBERT versus OT^{NN}. Figure 2 demonstrates the performance obtained on the target test set. Here the neighbors from the two representation spaces are ranked using cosine similarities. We can see that majority voting using the OT^{NN} representations achieves higher performance compared to that using the SBERT representations for different numbers of neighbors.

6 Conclusion and Future Work

In this work, we proposed a framework for transferring knowledge to a low-resource HS corpus by

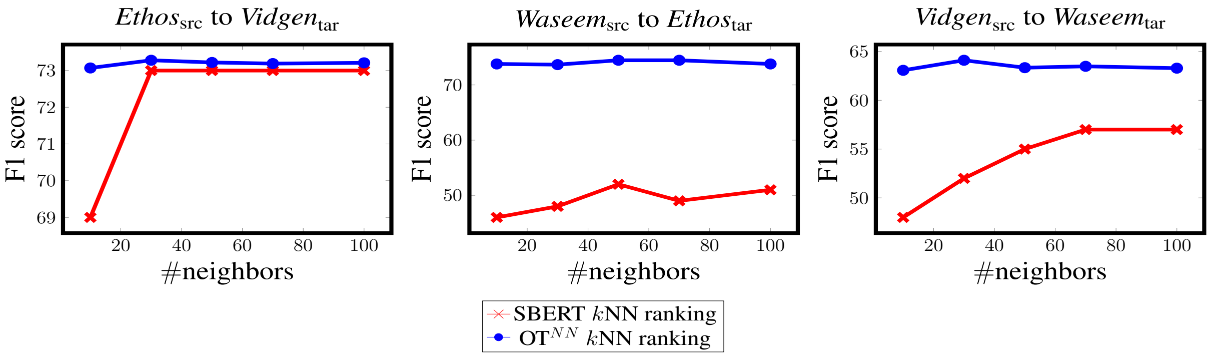

Figure 2: F1 using the majority voting of the k-Nearest Neighbors retrieved from SBERT and OT^{NN} representations.

incorporating neighborhood information with Optimal Transport. It allowed the model to flexibly learn the amount of transfer from the nearest neighbors based both on their proximity in a sentence embedding space and label consistency. Our framework yielded substantial improvements across HS corpora from varied platforms in low-resource settings. Besides, the qualitative analysis of its learned representations demonstrated that they incorporate both semantic and label similarities. This is different from sentence embedding representations, where semantically similar instances may have opposite labels.

Since our framework uses neighborhood information for transferring knowledge, it relies on the degree of proximity of the neighbors. However, if all of the source and target instances are very distant semantically, all the nearest neighbors from the source may have very low cosine similarity to the corresponding target instances. In such scenarios, the framework may yield limited improvements over the vanilla fine-tuning as the available neighborhood information would be much weaker. In such cases, the performance would mainly depend on the label consistency of the neighbors.

For future work, our framework can be explored for transferring knowledge from resource-rich languages, such as English, to low-resource languages. This can be done by extracting the cross-lingual neighbors using multilingual sentence embedding models like LaBSE (Feng et al., 2022). Besides, the framework can be applied for transferring knowledge in other text classification tasks, such as sentiment classification, bragging detection (Jin et al., 2022), etc., as the methodology is not restricted to only hate speech detection.

Ethical Considerations

The proposed approach intends to support more robust detection of online hate speech that can use the existing annotated resources for transferring knowledge to a resource with limited annotations. We acknowledge that annotating hateful content can have negative effects on the mental health of the annotators. The corpora used in this work are publicly available and cited appropriately in this paper. The authors of the respective corpora have provided detailed information about the sampling strategies, data collection process, annotation guidelines, and annotation procedure in peer-reviewed articles. Besides, the hateful terms and slurs presented in the work are only intended to give better insights into the models for research purposes.

Acknowledgements

This work was supported partly by the french PIA project “Lorraine Université d’Excellence”, reference ANR-15-IDEX-04-LUE. Experiments presented in this article were carried out using the Grid’5000 testbed, supported by a scientific interest group hosted by Inria and including CNRS, RENATER and several Universities as well as other organizations (see https://www.grid5000.fr). We are extremely grateful to Claire Gardent for taking time out to review the paper internally and Michel Olvera for his very helpful feedbacks regarding the work and for internally reviewing the paper. We would also like to thank the anonymous reviewers for their valuable feedbacks and suggestions.

Figure 3 presents an illustration of the proposed OT^{NN} training strategy.

B Corpus Details

The corpora used in our experiments are collected during different time periods, with different sampling strategies across varied online platforms. Following are some additional details about the corpora discussed in Section 4.1.

Waseem: This Twitter corpus, provided by Waseem and Hovy (2016), is sampled mainly using keywords containing common terms and slurs associated with hate against sexual, gender, religious, and ethnic minorities. It originally has three

Figure 3: Illustration of the training strategy in OT^{NN}. Even though the BERT encoder g and the classifier f are shared by both corpora, they are illustrated twice for better clarity by representing the two corpora separately. The presented softmax values obtained from f are simply examples provided for illustration. The figure is inspired by Damodaran et al. (2018).

classes: 'sexism', 'racism', and 'none'. However, since it is made available as tweet IDs, we observe that a major portion of the racist comments is removed by Twitter, and we could retrieve only 20 instances labeled as 'racism'. Due to the difference in the labeling schemes across corpora, we follow other prior work for cross-corpus evaluations (Wiegand et al., 2019; Swamy et al., 2019), and merge the original 'racism' and 'sexism' classes into the class *hate*. In total, we obtain 10.9K tweets, of which 26.8% instances belong to the *hate* class. A major portion of hateful comments in this corpus is subtle and do not involve profane words (Wiegand et al., 2019).

Vidgen: The *Vidgen* corpus (Vidgen et al., 2021) is dynamically generated using a human-and-model-in-the-loop process that is aimed at making the corpus robust to different forms of hate. These hateful forms are derogation, animosity, threatening language, support for hateful entities, and dehumanization. It covers hate directed against diverse social groups like blacks, women, jews, muslims, immigrants, arabs, disabled people, trans people, and others. It has adversarial content that can mislead the HS detection systems trained on other corpora, such as '*all women are created equal, except chinks*', '*the tea cup is bigger than the f*cking teapot*'. We use its version v0.2.3 containing a total of 41144 instances, where duplicates are removed, of which 53.9% is labeled as *hate*.

Ethos: This corpus (Mollas et al., 2022) consists of 998 comments from YouTube and Reddit, sampled using an active learning strategy, which ensures both diversity and balance with respect to different hateful aspects defined. One of the ways they ensure this is by keeping only one instance of multiple comments with similar meanings. For example, the comments '*I hate white people*' and '*I hate whites*' (Mollas et al., 2022) are similar, and only one of them is added. It includes hate directed towards diverse identities, such as gender, race, national origin, disability, religion, and sexual orientation. In this work, we use the binary version of this corpus with 43.4% *hate* instances.

C Data Preprocessing

We pre-process the corpora by removing the URLs, splitting the hashtags into constituent words using CrazyTokenizer[1], expanding contractions (e.g. i'll to i will), and removing the rarely occurring Twitter handles and numbers. We finally convert the instances into lower case.

D Implementation Details

For implementing the proposed OT^{NN} framework, we fine-tune the pre-trained BERT-base uncased model, implemented by Hugging Face (Wolf et al., 2020), having 110 million parameters, with the

joint distribution OT framework[2]. We encode an instance into the embedding space by obtaining the representations of the [CLS] token from the last hidden layer of BERT, which is a 768-dimensional vector in the BERT-base. We fine-tune the BERT model end-to-end for the classification task. Therefore, the [CLS] representations are the fine-tuned BERT representations. For incorporating the neighborhood information, we use the pre-trained SBERT sentence embeddings from 'all-mpnet-base-v2'[3] model, which is a sentence transformer model. For computing γ, we use the entropic regularized unbalanced OT solver using the Python Optimal Transport package[4] (Flamary et al., 2021) at the mini-batch level.

For the baselines of kNN-FT, kNN ranking, weighted kNN and the OT^{NN} variants, we select the number of neighbors (k) from the range {10, 30, 50, 70, 100, 200, 300, 400, 500} through tuning over the corresponding target validation sets with respect to the F1 score of the hate class with a random seed. We set α = 0.05 and β = 10 in Equation 3 and 5, and θ_s = 1 for OT^{NN} / OT$^{NN}_{\text{pre-select}}$ + sloss and θ_t = 10 in Equation 4, 6 and 7 for all the experiments. For OT^{NN} without sloss, we set θ_s = 0.

For CE kNN$^+$ + SRC, we perform experiments with the implementation provided to us by the authors and report the results for the neighborhood size of 10 in Table 2. Even though Sarwar et al. (2022) use 10 as the neighborhood size in their task of transfer learning in a cross-lingual set-up, we experiment with different neighborhood sizes (k values). The results are reported in Table 5. However, we could not increase the neighborhood size beyond 50 because of resource constraints. This is because a mini-batch in their framework comprises a query instance from the target and all its k neighbors from the source. Thus, the number of neighbors is limited by the mini-batch size, which usually needs to be kept small when fine-tuning large language models like BERT. We can observe from Table 5 that the performances obtained with different neighborhood sizes are similar.

We implement PretRand ourselves following the description provided by Meftah et al. (2021). This approach is evaluated by the authors on the tasks of part-of-speech tagging, chunking, named entity recognition, and morphosyntactic tagging. Therefore, the approach uses a sequence labeling model with pre-trained word embeddings and a BiLSTM-based feature extractor. However, for a fair comparison with our approach, we use the pre-trained BERT model as the feature extractor instead of the BiLSTM model for the pre-trained units. For the randomly initialized units, we follow the approach and add a BiLSTM layer over the last hidden layer of the BERT model. We first fine-tune the pre-trained BERT model, without the randomly initialized units, on the source corpus. We then fine-tune the model with the additional randomly initialized units on the target corpus. We use the Adam optimizer with a learning rate of 5×10^{-5} for the pre-trained BERT parameters. For the randomly initialized units, we use the Adam optimizer with a learning rate of 1.5×10^{-2} following Meftah et al. (2021).

E Computational Efficiency

We present the per epoch training time of Mixed-FT and OT^{NN} variants for different settings of the source and target corpora in Table 6. Mixed-FT is a baseline that involves training the pre-trained BERT model on the combination of the source and target corpora. For every mini-batch of size m, there are m instances sampled from each of the source and target corpora (Equation 7). This is the same mini-batch sampling that is followed in

Table 6: Per epoch training time in minutes for different settings.

OT^{NN}. We use one Nvidia GTX 1080 Ti GPU for our experiments. We can observe that OT^{NN} results in approximately the same computation time as taken by Mixed-FT in most of the settings as it does not change the model architecture, but only introduces a new training strategy. With the 'pre-select' variant, the computation time gets further reduced in a few settings. This is because, in this variant, the model only gets trained on a subset of pre-selected source instances based on the neighborhood size.

Bag-of-Vectors Autoencoders for Unsupervised Conditional Text Generation

Abstract

Text autoencoders are often used for unsupervised conditional text generation by applying mappings in the latent space to change attributes to the desired values. Recently, Mai et al. (2020) proposed Emb2Emb, a method to *learn* these mappings in the embedding space of an autoencoder. However, their method is restricted to autoencoders with a single-vector embedding, which limits how much information can be retained. We address this issue by extending their method to *Bag-of-Vectors Autoencoders* (BoV-AEs), which encode the text into a variable-size bag of vectors that grows with the size of the text, as in attention-based models. This allows to encode and reconstruct much longer texts than standard autoencoders. Analogous to conventional autoencoders, we propose regularization techniques that facilitate learning meaningful operations in the latent space. Finally, we adapt Emb2Emb for a training scheme that learns to map an input bag to an output bag, including a novel loss function and neural architecture. Our empirical evaluations on unsupervised sentiment transfer show that our method performs substantially better than a standard autoencoder.

1 Introduction

In conditional text generation, we would like to produce an output text given an input text. Hence, parallel input-output pairs are required to train a good supervised machine learning model on this type of task. Large-scale pretraining (Peters et al., 2018; Devlin et al., 2019; Lewis et al., 2020) can alleviate the necessity for training examples to some extent, but even this requires a substantial number of annotations (Yogatama et al., 2019). This is an expensive process and can introduce unwanted artifacts itself, which are henceforth learned by the model (Gururangan et al., 2018). For these reasons, there is substantial interest in unsupervised solutions. *Text autoencoders* (AEs) don't require labeled data for training, and are therefore a popular model for unsupervised approaches to many tasks, such as machine translation (Artetxe et al., 2018), sentence compression (Févry and Phang, 2018) and sentiment transfer (Shen et al., 2017). The classical text AE (Bowman et al., 2016) embeds the input text into a single fixed-size vector via the encoder, and then tries to reconstruct the input text from the single vector via the decoder. Single-vector embeddings are very useful, because they allow to perform conditional text generation through simple mappings in the embedding space, e.g. by adding a constant offset vector to change attributes such as sentiment (Shen et al., 2020). Recently, Mai et al. (2020) proposed Emb2Emb, a method that can *learn* these mappings directly in the embedding space of any pretrained single-vector AE. This is a powerful framework, because the AE can then be pretrained on unlimited amounts of unlabeled data before applying it to any downstream application. This concept, *transfer learning*, is arguably one of the most important drivers of progress in machine learning in the recent decade: These so-called *Foundation Models* (Bommasani et al., 2021) have revolutionized natural language understanding (e.g, *BERT* (Devlin et al., 2019)) and computer vision (e.g, *DALL-E* (Ramesh et al., 2021)), among others. Since Emb2Emb was designed to work with any pretrained AE, it was an important step towards their *scalability*.

However, as Bommasani et al. (2021) point out, another crucial model property is *expressivity*, the ability to represent the data distribution it is trained on. In this regard, single-vector representations are fundamentally limited; they act as a bottleneck, causing the model to increasingly struggle to encode longer text (Bahdanau et al., 2015). In this paper, we extend conditional text generation methods from single-vector bottleneck AEs to *Bag-of-Vector Autoencoders* (BoV-AEs), which encode text into a variable-size representation where the number of vectors grows with the length of the text. This

November 20–23, 2022. ©2022 Association for Computational Linguistics

gives BoV-AEs the same kind of representations as attention-based models. But this added expressivity comes with additional challenges: First, it can more easily overfit, leading to a non-smooth embedding space that is difficult to learn in. Secondly, as illustrated in Figure 1, in the single-vector case, an operation Φ in the vector space consists of a simple vector-to-vector mapping, and a single-vector loss. But with BoV-AEs, Φ needs to map a bag of vectors onto another bag of vectors, for which the single-vector mapping and loss are not applicable. In this paper, we demonstrate how such a mapping can be learned in the context of the $\mathrm{Emb2Emb}$ framework by making the following novel contributions: **(i)** We propose a regularization scheme for BoV-AEs, **(ii)** a neural mapping architecture Φ for $\mathrm{Emb2Emb}$, and **(iii)** a suitable training loss.

Empirically, we show on two unsupervised sentiment transfer datasets (Shen et al., 2017) of drastically different text lengths that BoV-AEs perform substantially better than standard AEs if the text is too long to be captured by one vector alone. Our ablation studies confirm that our technical contributions are crucial for this success.

In the following section, we review the $\mathrm{Emb2Emb}$ framework, before we introduce BoV-AE (Section 3) and its integration within $\mathrm{Emb2Emb}$ (Section 4).

2 Background: Emb2Emb

Embedding-to-Embedding ($\mathrm{Emb2Emb}$) (Mai et al., 2020) is a general framework for both supervised and an unsupervised conditional text generation. The core idea is to disentangle the specific task from the transition from the discrete text space to a continuous latent space (*plug and play*), allowing for larger-scale pretraining with unlabeled data.

The workflow of the framework is depicted in Figure 2. First, a text AE $\mathcal{A} = \mathrm{dec} \circ \mathrm{enc}$ is trained to map an input sentence from the discrete text space $\mathcal{X}$ to an embedding space $\mathcal{Z}$ via the encoder $\mathrm{enc} : \mathcal{X} \to \mathcal{Z}$, and back to $\mathcal{X}$ via a decoder $\mathrm{dec} : \mathcal{Z} \to \mathcal{X}$, such that $\mathcal{A}(x) = x$, typically trained via negative log-likelihood, $\mathcal{L}_{rec} = \mathrm{NLL}(\mathcal{A}(x), x)$. In contrast to other methods, $\mathcal{A}$ can in principle be any AE, opening the possibility for large-scale AE pretraining with unlabeled data. Second, task-specific training is performed only in the embedding space $\mathcal{Z}$ of the AE. To this end, the encoder is frozen, and a new mapping layer $\Phi : \mathcal{Z} \to \mathcal{Z}$ is introduced, which is trained to transform the embedding of the input $\mathbf{z}_x$ into the embedding of the predicted output $\hat{\mathbf{z}}_y$. The concrete loss $\mathcal{L}(\hat{\mathbf{z}}_y)$ depends on the type of task. In the supervised case, the true output is also encoded into space $\mathcal{Z}$, and the distance between the true embedding and the predicted embedding is minimized. In the unsupervised case, the loss needs to be defined for the specific task at hand. For example, for sentiment transfer, where the goal is to transform a negative review into a positive review while retaining as much of the input as possible, Mai et al. (2020) compose the loss as a combination of two loss terms[1], $\mathcal{L}(\hat{\mathbf{z}}_y) = \mathcal{L}_{sim}(\mathbf{z}_x, \hat{\mathbf{z}}_y) + \lambda_{sty}\mathcal{L}_{sty}(\hat{\mathbf{z}}_y)$. $\mathcal{L}_{sty}$ encourages $\hat{\mathbf{z}}_y$ to be classified as a positive review according to a separately trained sentiment classifier. $\mathcal{L}_{sim}$ encourages the output to be close to the input in embedding space, e.g. via euclidean distance. λ_{sty} is a hyperparameter that controls the importance of changing the sentiment of the predicted output.

A main question in $\mathrm{Emb2Emb}$ is how to choose the embedding space $\mathcal{Z}$. Mai et al. (2020) use a single continuous vector to encode all the information of the input, i.e. $\mathcal{Z} = \mathbb{R}^d$. This choice simplifies the mapping Φ to an MLP and the training loss to vector space distances, which is relatively easy to train. On the other hand, it limits the model in fundamental ways: The representation is *fixed-sized*, i.e., the representation cannot grow in size. Sequence-to-sequence models with a fixed-size bottleneck struggle to encode long text sequences (Bahdanau et al., 2015), which is a key reason why attention-based models are now standard practice in sequence-to-sequence models. Hence, it would be desirable to adapt $\mathrm{Emb2Emb}$ in such a way that $\mathcal{Z}$ contains *variable-sized* embeddings instead.

3 Bag-of-Vectors Autoencoder

We propose *Bag-of-Vectors Autoencoders* (BoV-AEs) which facilitate learning mappings in the embedding space. Following the naming convention by Henderson (2020), we refer to a bag of vectors as a (multi)-set of vectors that (i) can grow arbitrarily large, and (ii) where the elements are not ordered (a basic property of sets). A type of BoV representation that is used very commonly is found in Transformer (Vaswani et al., 2017)

[1] Their total loss includes an adversarial component that encourages the outputs of the mapping to stay on the latent space manifold. We leave adaptation of this component to the BoV scenario for future work.

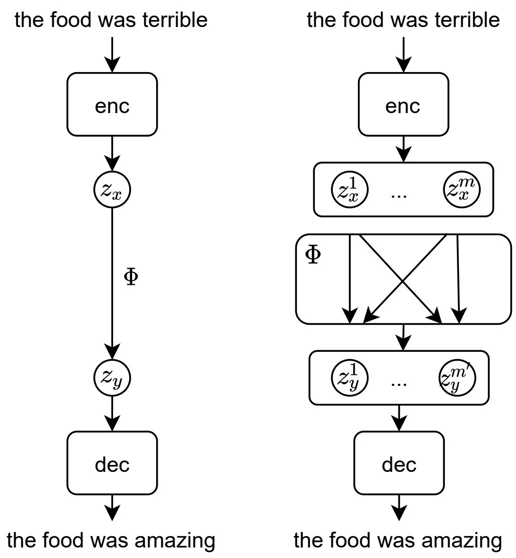

Figure 1: *Left*: In the standard setup, the representation consists of a single vector, requiring a simple vector-to-vector mapping to do operations in the vector space. *Right*: In BoV-AE, the representation consists of a variable-size bag of vectors, requiring a more complex mapping from one bag to another bag.

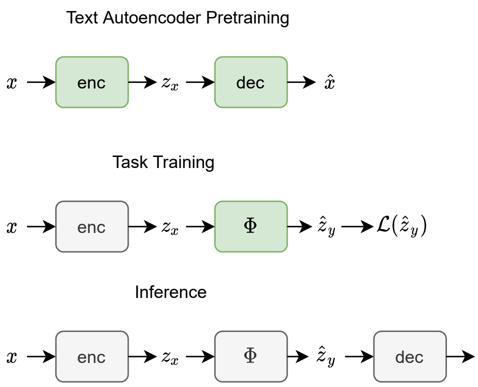

Figure 2: High-level view of the Emb2Emb framework. *Text Autoencoder Pretraining*: An autoencoder is trained on an unlabeled corpus, i.e., the encoder enc transforms an input text x into a continuous embedding $\mathbf{z}_x$, which is in turn used by the decoder dec to predict a reconstruction $\hat{x}$ of the input sentence. *Task Training*: The encoder is frozen (grey), and a mapping Φ is trained (green) on input embeddings $\mathbf{z}_x$ to output predictions $\hat{\mathbf{z}}_y$ such that it minimize some loss $\mathcal{L}(\hat{\mathbf{z}}_y)$. *Inference*: To obtain textual predictions $\hat{y}$, the encoder is composed with Φ and the decoder.

encoder-decoder models, where there is one vector to represent each token of the input text, and the order of the vectors does not matter when the decoder accesses the output of the encoder. In this work, we also rely on Transformer models as the backbone of our encoders and decoders. However, in principle, any encoder and decoder can be used, as long as the encoder produces a bag as output and the decoder takes a bag as input. Formally, $\mathcal{Z} = (\mathbb{R}^d)^+$, so the encoder produces a bag-of-vectors $\mathbb{X} = \{\mathbf{z}_1, ..., \mathbf{z}_n\} := \mathrm{enc}(x)$, where n is the number of vectors in the induced input bag.

3.1 Regularization

The fact that we use a BoV-based AE presents a major challenge: AEs have to be regularized to prevent them from learning a simple identity mapping where the input is merely copied to the output, which does not result in a meaningful embedding space. In fixed-size embeddings, this is for example achieved through under-completeness (choosing a latent dimension that is smaller than the input dimension) or through injection of noise, either at the input or in the embedding space. While there exists a lot of research on regularizing fixed-sized AEs, it is not clear how to achieve the same goal in a BoV-AE. Here, regularizing the capacity of each vector is not enough. As long as each vector can store a (constant) positive amount of information, a bag of unlimited size can still store infinite information. However, it is not clear to what extent the size of the bag needs to be restricted. By default, a standard Transformer model produces as many vectors as there are input tokens, but this is likely too many, as it makes copying from the input to the output trivial. Hence, we want the encoder to output fewer vectors. In the following we explain how this is achieved in BoV-AEs.

Ideally, we want the model to decide for itself on a per-example basis which vectors it needs to retain for reconstruction. To this end, we adopt *L0Drop*, a differentiable approximation to L0 regularization, which was originally developed by Zhang et al. (2021) for the purpose of speeding up a model through sparsification. The model computes scalar gates $g_i = g(\mathbf{z}_i) \in [0, 1]$ (which can be exactly zero or one) for each encoder output. After the gates are computed, we multiply them with their corresponding vector. Vectors whose gates are near zero (i.e., smaller than some $\epsilon > 0$) are removed from the bag entirely. An additional loss term, $\mathcal{L}_{L_0}(\mathbb{X}) = \lambda_{L0} \sum_i^n g_i$ encourages the model to close as many gates as possible, where the hyperparameter λ_{L0} controls the sparsity rate *implicitly*. However, in initial experiments, we found λ_{L0} difficult to tune, as it is very sensitive with respect to other hyperparameters. We instead employ a modified loss that seeks to *explicitly* match a certain target ratio r of open gates. Similar to the *free-bits* objective that is used to prevent the posterior collapse problem in VAEs (Kingma et al., 2016), the objective becomes

$$\mathcal{L}_{L_0}(\mathbb{X}) = \lambda_{L0} \max(r, \tfrac{1}{n} \textstyle\sum_i^n g_i). \tag{1}$$

By setting λ_{L0} to a large enough value (empirically, $\lambda_{L0} = 10$), we find that this objective reaches the target ratio r reliably for different r while at the same time reducing the reconstruction loss. This allows to compare different strengths of regularization while reducing the tuning effort substantially.

4 Emb2Emb with BoV-AEs

In the following we describe how to adapt the Emb2Emb model to BoV-AEs, i.e., how to generate an output bag $\hat{\mathbb{X}} = \{\hat{\mathbf{z}}_1, \ldots, \hat{\mathbf{z}}_n\}$ given an input bag $\mathbb{X}$ through the mapping $\Phi(\mathbb{X})$, and how to choose the loss function $\mathcal{L}(\hat{\mathbb{X}}, \mathbb{X})$. For example, in the case of style transfer, we want $\hat{\mathbb{X}}$ to be similar to $\mathbb{X}$.

4.1 Mapping Φ

In contrast to Mai et al. (2020), who use a single-vector embedding and hence Φ can be as simple as an MLP, in our work, Φ must be capable of producing a bag of vectors. The straight-forward choice for Φ is a Transformer decoder that uses cross-attention on the input BoV, and generates vectors autoregressively one at a time, formally $\hat{\mathbf{z}} = \text{Transformer}(\mathbf{z}_s, \hat{\mathbf{z}}_1, \ldots, \hat{\mathbf{z}}_{t-1}, \mathbb{X}), t \geq 1$, where $\mathbf{z}_s$ is the embedding of some starting symbol. Since the resulting sequence of vectors is still interpreted as a bag by the decoder and loss function, the ordering is irrelevant, but generating vectors autoregressively facilitates modelling the correlations between vectors.

Depending on the difficulty of the task, a generic Transformer decoder may be sufficient to learn the mapping, but for more difficult mappings and for larger bags (i.e. longer texts) appropriate inductive biases are needed. Based on the assumption that the output should be close to the input in embedding space, Mai et al. (2020) propose *OffsetNet* for the single vector case, which computes an offset vector to be added to the input. With a similar motivation, we propose a variant of pointer-generator networks (See et al., 2017), which allows the model to choose between copying an input vector and generating a new one. Instead of just copying, however, our model (Transformer++) allows to compute an offset vector to be added to the copied vector, analogous to (Mai et al., 2020). Formally, at each timestep t,

$$\hat{\mathbf{z}}_t = (1 - p_{gen})(\mathbf{z}_{copy} + \mathbf{z}_{\text{offset}}) + p_{gen}\mathbf{z}'_t, \tag{2}$$

where $\mathbf{z}'_t = \text{Transformer}(\mathbf{z}_s, ..., \hat{\mathbf{z}}_{t-1}, \mathbb{X})$. Intuitively, by controlling $p_{gen} \in (0, 1)$, the model makes the (soft) decision to either copy a vector from the input and add an offset, or to generate a completely new vector. Here, p_{gen} is a function of $\mathbf{z}'_t$ and the starting symbol which we treat as a context vector, $p_{gen} = \sigma(\mathbf{W}[\mathbf{z}_s; \mathbf{z}'_t])$. Similarly, $\mathbf{z}_{\text{offset}}$ is a one-layer MLP with $[\mathbf{z}'_t; \mathbf{z}_{copy}]$ as input. $\mathbf{z}_{copy}$ is determined through an attention function:

$$\mathbf{z}_{copy} = \sum_{i=1}^{|\mathbb{X}|} \alpha_i \mathbf{z}_i, \quad \mathbf{K} = \mathbf{W}_{cpy}\mathbf{X}, \tag{3}$$

$$\alpha_i = \text{softmax}(\mathbf{z}_s^T \mathbf{K})_i, \quad (\mathbf{X})_i := \mathbf{z}_i \tag{4}$$

where $\mathbf{W}_{cpy}$ is a learnable weight matrix. We refer to this model as Transformer++.

4.2 Generating Variable Sized Bags

The output bag is generated in an autoregressive manner. In the unsupervised case, it is not always clear how many vectors the bag should contain. However, due to the unsupervised nature, all information needed for computing the (task-dependent) training loss $\mathcal{L}(\hat{\mathbb{X}}, \mathbb{X})$ are also available at inference time. In this case, we can first generate some fixed maximum number N of vectors autoregressively, and then determine the optimal bag by computing the minimal (inference-time) loss value, $\mathbb{X}^* = \min_{l=1,\ldots,N} \mathcal{L}(\hat{\mathbb{X}}_{1:l}, \mathbb{X})$. This can be valuable for tasks where we do not have a good prior on the size of the target bag. During training, we minimize the loss locally at every step. But we don't necessarily care about the loss at very small or big bags, so we might want to weight the steps as $\mathcal{L}^{\text{total}}(\hat{\mathbb{X}}, \mathbb{X}) = \sum_{l=1}^{N} \mathbf{w}_l \mathcal{L}(\hat{\mathbb{X}}_{1:l}, \mathbb{X})$. Here, $\mathbf{w} \in \mathbb{R}_+^N$ could be any weighting, but it is more beneficial for training to only backpropagate from bag sizes that we expect to be close to the optimal output bag size. For instance, in style transfer, the output typically has about the same length as the input. Hence, for an input size of length n, a useful weighting could be

$$\mathbf{w}_l = \begin{cases} 1 & n - k \leq l \leq n + k \\ 0 & \text{otherwise} \end{cases}, \tag{5}$$

where k is the size of a window around the input bag size.

4.3 Aligning Two Bags of Vectors

As described in Section 2, unsupervised sentiment transfer involves two loss terms, $\mathcal{L}_{sty}$ and $\mathcal{L}_{sim}$. In order to adapt $\mathcal{L}_{sty}$ from the single vector case to the BoV case, we can simply switch from an MLP classifier to a Transformer-based classifier. For $\mathcal{L}_{sim}$, however, we need to switch to a loss function that is defined on sets. While there are well-known losses for the single-vector case, in NLP set-level loss functions are not well-studied.

Here, we propose a novel variant of the *Hausdorff* distance. This distance is commonly used in vision applications: as a performance evaluation metric in e.g. medical image segmentation (Taha and Hanbury, 2015; Aydin et al., 2020), or in vision systems as a way to compare images (Huttenlocher et al., 1992; Takács, 1998; Lin et al., 2003; Lu et al., 2001). More recently, variants (different from ours) of the Hausdorff distance have also been used as loss functions to train neural networks (Fan et al., 2017; Ribera et al., 2019; Zhao et al., 2021). In NLP, its use is very rare (Nutanong et al., 2016; Chen, 2019; Kuo et al., 2020). To the best of our knowledge, our paper is the first to present a novel, fully differentiable variant of the Hausdorff distance as a loss for language learning.

The Hausdorff distance is a method for aligning two sets. Given two sets $\mathbb{X}$ and $\hat{\mathbb{X}}$, their Hausdorff distance H is defined as

$$\mathrm{H}(\mathbb{X}, \hat{\mathbb{X}}) = \frac{1}{2}\operatorname{align}(\mathbb{X}, \hat{\mathbb{X}}) + \frac{1}{2}\operatorname{align}(\hat{\mathbb{X}}, \mathbb{X}) \quad (6)$$

$$\operatorname{align}(\mathbb{X}, \hat{\mathbb{X}}) = \max_{x\in\mathbb{X}} \min_{y\in\hat{\mathbb{X}}} \mathrm{d}(x, y) \quad (7)$$

Intuitively, two sets are close if each point in either set has a counterpart in the other set that is close to it according to some distance metric d. We choose d to be the euclidean distance, but in principle any differentiable distance metric could be used (e.g. cosine distance). However, the vanilla Hausdorff distance is very prone to outliers, and therefore often reduced to the *average Hausdorff distance* (Dubuisson and Jain, 1994), where

$$\operatorname{align}(\mathbb{X}, \hat{\mathbb{X}}) = \frac{1}{|\mathbb{X}|}\sum_{x\in\mathbb{X}} \min_{y\in\hat{\mathbb{X}}} d(x, y). \quad (8)$$

The average Hausdorff function is step-wise smooth and differentiable. Empirically, however, we find step-wise smoothness to be insufficient for the best training outcome. Therefore, we propose a fully differentiable version of the Hausdorff distance by replacing the min operation with softmin by modelling $\operatorname{align}(\mathbb{X}, \hat{\mathbb{X}}) =$

$$\frac{1}{|\mathbb{X}|}\sum_{x\in\mathbb{X}}\sum_{y\in\hat{\mathbb{X}}}\left(\frac{e^{(-d(x,y))}}{\sum_{y'\in\hat{\mathbb{X}}} e^{(-d(x,y'))}} \cdot d(x, y)\right). \quad (9)$$

This variant is reminiscent of the attention mechanism (Bahdanau et al., 2015) in the sense that a weighted average is computed, which has been very successful at smoothly approximating discrete decisions, e.g., read and write operations in the Differentiable Neural Computer (Graves et al., 2016) among many others.

5 Experiments

Our experiments are designed to test the following two hypotheses. **H1**: If the input text is too long to be encoded into a fixed-size single vector representation, BoV-AE-based Emb2Emb provides a substantial advantage over the fixed-sized model. **H2**: Our technical contributions, namely L0Drop regularization, the training loss, and the mapping architecture, are necessary for BoV-AE's success.

We evaluate our model on two unsupervised conditional text generation tasks: In Section 5.1, we show that **H1** holds even when the single-vector dimensionality is large (d=512). To this end, we create a new sentiment transfer dataset, Yelp-Reviews, whose inputs are relatively long. However, training on this dataset is computationally very demanding[2]. Therefore, we turn to a short-text style transfer dataset to test hypothesis **H2** (Section 5.2).

Additionally, we conducted experiments on abstractive sentence summarization (Rush et al., 2015). These provide evidence of the generality of our method, as well as the utility of the mapping architecture's copy mechanism. Due to space constraints, these are included in Appendix A.

For each of the experiments in this section, we provide full experimental details in Appendix B.

Evaluation metrics: In sentiment transfer, the goal is to rewrite a negative review as a positive review while keeping as much of the content as possible. Hence, two metrics are important, sentiment transfer ability and content retention. Following common practice (Hu et al., 2017; Shen

[2] Pretraining a model of this size until convergence took more than a month on a single 24GB GPU.

et al., 2017; Lample et al., 2019), we measure the former with a separately trained style classifier based on DistilBERT (Sanh et al., 2019), and content retention in terms of self-BLEU (Papineni et al., 2002) between the input and the predicted output. To allow comparison via a single score, we aggregate content retention and transfer accuracy (Xu et al., 2018; Krishna et al., 2020), per sentence (Krishna et al., 2020), and compute a single $score = \frac{1}{M}\sum_{i=1}^{M} \mathrm{ACC}(\hat{y}) \cdot \mathrm{BLEU}(\hat{y}, x)$ where x is the input sentence, $\hat{y}$ is the predicted sentence, and M is the number of data points. For readability, we multiply all metrics by 100 before reporting.

Autoencoder Pretraining: Since Emb2Emb is plug and play, the autoencoder pretraining can be decoupled from the downstream task, enabling large-scale pretraining on a general purpose corpus. While this would certainly be necessary to reach the best results possible, such an endeavor is very resource-intensive, making it impractical to conduct the kind of controlled experiments needed to support our hypotheses. Moreover, existing pretrained autoencoders such as BART (Lewis et al., 2020) cannot be used off-the-shelf because they weren't trained to have a smooth embedding space, for example using L0Drop. In Appendix C.2.2, we study the effect of adding an L0Drop layer inside BART and finetuning it for a few steps on the target task data. Although this works to some extent, this L0Drop layer can be expected to remove information which would be kept if it were trained in full large-scale pretraining, which we don't have the resources to do.

Therefore, we instead pretrain all autoencoders from scratch directly on the data of the target task. Models named **L0-r** denote L0Drop-based BoV-AE models that only differ in the target ratio r used in training. As a control, we always compare to a single vector **fixed**-size AE, which is obtained by averaging the vectors at the last layer of the encoder.

5.1 Yelp-Reviews

Our hypothesis is that AEs with a single vector bottleneck are unable to reliably compress the text when it is too long. Here, we test if this holds true even for a large single-vector model with d=512. To this end, we create the dataset *Yelp-Reviews*, which consists of strongly positive and strongly negative English restaurant reviews on Yelp (see Appendix B.4.1 for a detailed description). This dataset is very similar to Yelp-Sentences introduced by Shen et al. (2017). However, while Yelp-Sentences consists of single sentences of about 10 words on average, Yelp-Reviews consists of entire reviews of 52 words on average. For style transfer, we train a Transformer++ mapping using the loss described in Section 2. To obtain results at varying transfer levels, we train multiple times with varying λ_{sty}, resulting in multiple points for each model in Figure 3 and 6.

Results: The results (full graph shown in Figure 8 in the Appendix) indicate that even large single vector models (d=512) are unable to compress the text well; the NLL loss on the validation set of the fixed-size model is $\approx$3.9. **L0-0.05** is only slightly better than the fixed-size model, whereas **L0-0.1** already reaches a substantially lower reconstruction loss ($\approx$2.1). We evaluated the downstream sentiment transfer performance of Transformer++ with **L0-0.1**[3] and the fixed-size model, respectively. Figure 3 shows a scatter plot of the results, where results that are further to the top-right corner are better. We see that at a comparable transfer level, the BoV is substantially better at retaining the input content. This supports hypothesis **H1** that variable-size BoV models are particularly beneficial in cases where the text length is too long to be encoded in a single-vector.

5.2 Yelp-Sentences

In order to answer research question **H2**, we perform a large set of controlled experiments over our model's components. Due to the high computational demand, we turn to the popular Yelp-Sentences sentiment transfer dataset by Shen et al. (2017). Texts in this dataset are $\approx$ 10 words on average. As these sentences are much easier to reconstruct, we set the embedding size to d=32 so that the condition for hypothesis **H1** is still valid. Here, we again train BoV-AEs for a variety of target rates ($r = 0.2, 0.4, 0.6, 0.8$) and then evaluate their reconstruction and style transfer ability in the same fashion as for Yelp-Reviews. Finally, we investigate the impact of the differentiable Hausdorff loss and the window size. For completeness, we provide an analysis of the computational complexity of BoV-AE in Appendix C.2.1.

[3] We restrict our analysis to L0-0.1 because this dataset have is computationally demanding.

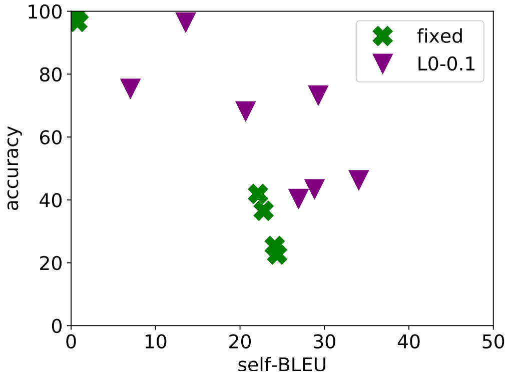

Figure 3: Style transfer on Yelp-Reviews.

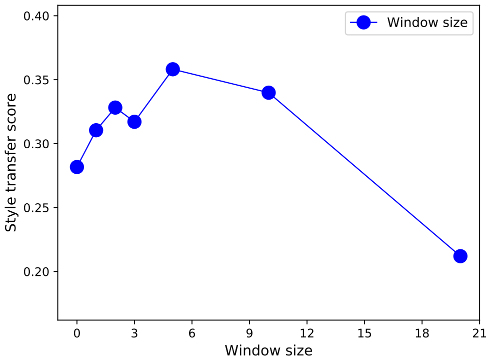

Figure 4: Style transfer score depending on the window size.

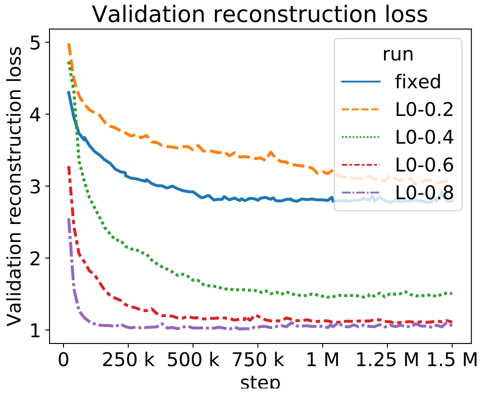

Figure 5: Reconstruction loss on the validation set for different AEs. **fixed**: A single vector obtained by averaging the encoder output vectors. **L0-r**: BoV-AEs with L0Drop target ratio r.

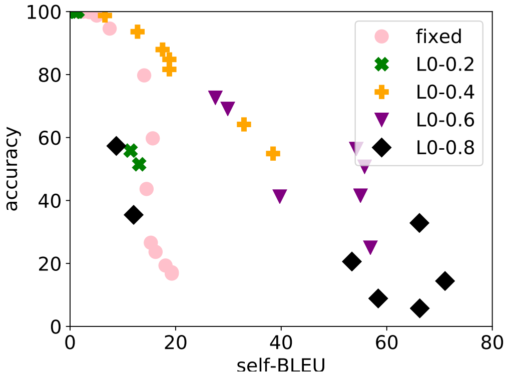

Figure 6: Style transfer performance on Yelp-Sentences of BoV models compared to a fixed-size AE for varying λ_{sty}. Further to the top (style transfer) and right (content retention) is better.

5.2.1 Reconstruction Ability

Figure 5 shows the reconstruction loss on the validation set for the fixed-size model compared to BoV models. The fixed-size AE does not reach satisfactory reconstruction ability, converging at an NLL loss value of about 3. In contrast, BoV models are able to outperform the fixed-size model considerably. As expected, higher target ratios lead to better reconstruction, because the model can use more vectors to store the information. Models with a higher target ratio also reach their optimal loss value more quickly. While **L0-0.6** approaches the best reconstruction value ($\approx$1.0) eventually, the model needs more than 1 million training steps to reach it. In contrast, **L0-0.8** needs less than 100k steps to converge, which could indicate that **L0-0.8** learns to copy rather then compress the input, resulting in a bad latent space. **L0-0.4** yields to a higher loss, but is still drastically better than the fixed size model. **L0-0.2** is not enough to outperform the fixed-size model. Overall, these results show we have the right settings for evaluating **H1** and **H2**, as 10 words is too long to be encoded well into a single vector of d=32, whereas a BoV-AE with a high enough target ratio r can fit it well.

5.2.2 Style Transfer Ability

Results are shown in Figure 6. Up to r=0.6, they correspond well to the reconstruction ability, in that BoV models with higher target ratios yield higher self-BLEU scores at comparable transfer abilities, outperforming the fixed-size model (**H1**). However, at r=0.8, the performance suddenly deteriorates at medium to high transfer levels. This supports the hypothesis that **L0-0.8** lacks smoothness in the embedding space due to insufficient regularization, which in turn complicates downstream training. This is the first piece of evidence that L0Drop is necessary for the success of our model (**H2**).

5.2.3 Ablation on Differentiable Hausdorff

In Section 4.3, we argue that the min operation should be replaced by softmin in order to facilitate backpropagation. Here, we test if the differentiable version is really necessary, that is, we compare Eq. 8 to Eq. 9. Like above, we train the two variants with different λ_{sty}, and then select the best style transfer score on the validation set. The difference is substantial: Average Hausdorff reaches 14.6, whereas differentiable Hausdorff reaches 24.2. We hypothesize that this discrepancy is due to the difficult nature of the style transfer problem, which requires carefully balancing the two objectives, content retention (via Hausdorff) and style transfer (via the classifier). This is easier when the objective functions are smooth, which is the advantage of differentiable Hausdorff.

5.2.4 Ablation on Window Size

The window size k determines which bag sizes around the input bag size we backpropagate from (cmp. Section 4.2). Here, we investigates its influence on the model's performance. Since the λ_{sty} hyperparameter is very sensitive to other model hyperparameters, we train with varying λ_{sty} for each fixed window size and report the best style transfer score for each window size. In Figure 4, we plot the style transfer score as a function of the window size. Our results indicate that increasing the window size from zero (score 28.2) is beneficial up to some point (k=5, score 35.8), whereas increasing by too much (k=20, score 21.2) is detrimental to model performance even compared to a size of zero. We hypothesize that backpropagating bags that are either very small or very large is detrimental because it forces the model to adjust its parameters to optimize unrealistic bags, taking away capacity for fitting realistic bags.

5.2.5 Qualitative Analysis

We hypothesize that standard autoencoders suffer from poor performance with Emb2Emb if the text is too long to be encoded into a single vector (**H1**). BoV-AEs were designed to alleviate this issue. Here, we conduct a qualitative analysis of 10 randomly selected model outputs on Yelp-Sentences. For comparability, we select models with similar levels of style transfer accuracy, namely the fixed size model with a performance of 59% accuracy and 17 points self-BLEU to **L0-0.4** with a performance of 55% accuracy and 38 points self-BLEU. We randomly sample 10 examples and show them in Table 1. By design of the Yelp-Sentences dataset (Shen et al., 2017), the inputs are sentences drawn from negative reviews, whose sentiment are supposed to be changed to positive. Note that due to how the dataset was constructed, some of the input sentences are already positive (#7) or just neutral (#2).

We observe several trends: **(1)** The fixed-sized model has a difficult time retaining the aspect discussed in the input sentence (#10: staff instead of location, #9: food instead of price), whereas the BoV-AE stays on topic. This is likely a consequence of the fixed-sized model's inability to encode the input well into a single vector, supporting **H1**. **(2)** The outputs of the fixed-sized models are often completely unusable (#1, #2) or nonsensical (#5, #9, #10), whereas the outputs of the BoV-AE are at least intelligible. **(3)** In absolute terms, the outputs of neither model are reliably grammatical or able to flip the sentiment. This is understandable since no large pretrained language model is used. This would be needed to produce coherent outputs (Brown et al., 2020), which then produces impressive outputs on style transfer (Reif et al., 2021). As we argue in Section 1, our paper contributes to the foundation for large scale pretraining of autoencoder models to be used in Emb2Emb.

6 Related Work

Manipulations in latent space: Besides Emb2Emb, latent space manipulations for textual style transfer are performed either via gradient descent (Wang et al., 2019; Liu et al., 2020) or by adding constant style vectors to the input (Shen et al., 2020; Montero et al., 2021). In computer vision, discovering latent space manipulations for image style transfer has recently become a topic of increased interest, in both supervised (Jahanian et al., 2020; Zhuang et al., 2021) and unsupervised ways (Härkönen et al., 2020; Voynov and Babenko, 2020). While these vision methods are similar to Emb2Emb conceptually, they differ from our work in important ways. First, they focus on the latent space of GANs (Goodfellow et al., 2014), which work well for image generation but are known to struggle with text (Caccia et al., 2020). Secondly, images typically have a fixed size, and consequently their latent representations consist of single vectors. Our work focuses on data of variable size, which may have important insights for modalities other than text, e.g. videos and speech.

Unsupervised conditional text generation: Modern unsupervised conditional text generation approaches are based on either **(a)** language mod-

els (LMs) or **(b)** autoencoders (AEs). **(a)** One type of LM approach explicitly conditions on attributes during pretraining (Keskar et al., 2019), which puts restrictions on the data that can be used for training. Another type adapts pretrained LMs for conditional text generation by learning modifications in the embedding space (Dathathri et al., 2020). These approaches work well because LMs are pretrained with very large amounts of data and compute power, which results in exceptional generative ability (Radford et al., 2019; Brown et al., 2020) that even enables impressive zero-shot style transfer results (Reif et al., 2021). However, in contrast to AEs, LMs are not designed to have a latent space that facilitates learning in it. We therefore argue that AE approaches could perform even better than LMs if they were given equal resources. This motivates our research. **(b)** A very common approach to AE-based unsupervised conditional text generation is to learn a shared latent space for input and output corpora that is agnostic to the attribute of interest (e.g., sentiment transfer (Shen et al., 2017), style transfer (Lample et al., 2019), summarization (Liu et al., 2019), machine translation (Artetxe et al., 2018)). However, in these approaches, the decoder is explicitly conditioned on the desired attribute that must be available for all data points, complicating pretraining on unlabeled data. To overcome this, Mai et al. (2020) recently proposed $\mathrm{Emb2Emb}$, which disentangles AE pretraining from learning to change the attributes via a simple mapping. Our paper makes an important contribution by improving the expressivity of $\mathrm{Emb2Emb}$ through variable-size representations.

7 Conclusion

Our paper addresses a fundamental research question: How do we learn text representations in such a way that conditional text generation can be learned in the latent space (e.g. $\mathrm{Emb2Emb}$)? We propose Bag-of-Vectors Autoencoders to overcome the fundamental bottleneck of single-vector autoencoders: Controlled experiments revealed that, thanks to our technical contributions, BoV-AEs perform substantially better at learning in their embedding space when the text is too long to be encoded into a single vector. This lays the foundation for learning conditional long-text generation models in a framework such as $\mathrm{Emb2Emb}$ in an unsupervised manner.
