Several proposals have been put forward in recent years for improving out-of-distribution (OOD) performance through mitigating dataset biases. A popular workaround is to train a robust model by re-weighting training examples based on a secondary biased model. Here, the underlying assumption is that the biased model resorts to shortcut features. Hence, those training examples that are correctly predicted by the biased model are flagged as being biased and are down-weighted during the training of the main model. However, assessing the importance of an instance merely based on the predictions of the biased model may be too naive. It is possible that the prediction of the main model can be derived from another decision-making process that is distinct from the behavior of the biased model. To circumvent this, we introduce a fine-tuning strategy that incorporates the similarity between the main and biased model attribution scores in a Product of Experts (PoE) loss function to further improve OOD performance. With experiments conducted on natural language inference and fact verification benchmarks, we show that our method improves OOD results while maintaining in-distribution (ID) performance.[1]

1 Introduction

Overfitting to the training data is a big obstacle in learning patterns that generalize to unseen data. Traditionally, this is diagnosed by monitoring the performance of a trained model on an in-distribution (ID) test set. However, a bigger challenge is when both the training and test data have the same non-generalizable patterns, emerged as spurious correlations between input features and output labels (Gardner et al., 2021). For instance, in the natural language inference (NLI) task, it is shown that the occurrence of some task-neutral words, like a negation in hypothesis, is highly correlated with a specific class (Gururangan et al., 2018). While high-capacity models can learn a generalized distribution of labels from the inputs, they are prone to spurious patterns, also known as dataset biases (Clark et al., 2019; He et al., 2019). A model could exploit these biases during fine-tuning, leading to a model that achieve high ID performance, while it is highly fragile in out-of-distribution (OOD) settings (Schuster et al., 2019; McCoy et al., 2020).

Besides trying to prevent these non-generalizable artifacts from entering the dataset (Liu et al., 2022), it is reasonable to seek for more robust learning methods. This has been the basis for a multitude of research works that encourage models to rely on truly generalizable patterns. Most of these methods are based on the assumption that the learning method will inevitably exploit biases if they are present in a training example (Clark et al., 2019; Sanh et al., 2020; Mahabadi et al., 2020; Utama et al., 2020; Ghaddar et al., 2021). Therefore, they discourage the main model from paying much attention to the examples which are correctly classified by a biased model. Recently, it is shown that this assumption is questionable in the way that for a significant number of cases, the main model does not follow the biased model in treating biased examples (Amirkhani and Pilehvar, 2021). Therefore, depriving the training algorithm from the examples which are detected to be biased is a waste of training data.

In this paper, we propose an alternative way to discard biased examples. Instead of considering the mere prediction of the biased model, we monitor the way the model processes each example by computing its attribution scores over the input tokens. With the resulting scores, we adjust the proportion of the loss function that is a cross-entropy loss (CE) versus a Product of Experts loss (PoE). If

the attribution scores are similar between the main and biased models, the loss becomes a PoE loss where a correct prediction from the biased model down-weights the contribution of the corresponding example. In contrast, dissimilarity between the scores suggests a different behaviour from the biased model and leads to a CE loss that only considers the main model's prediction. Experiments on natural language inference and fact verification demonstrate that our method significantly outperforms previous approaches in terms of OOD performance while preserving its ID performance.

2 Methodology

In this section we explain our debiasing solution for a given classification task with dataset $\mathcal{D}\{\boldsymbol{x_i}, y_i\}_{i=1}^{N}$. For the i^{th} training example, we denote the input sequence of tokens as $\boldsymbol{x_i}$ and the gold label as $y_i \in \{1, 2, ..., Y\}$ where Y is the number of classes. Specifically, the goal is to train a model—we denote it as the *main model*—on the training dataset ($\mathcal{D}$) so that it can also perform well on OOD datasets that do not necessarily share the same biases. Following other well-known paradigms for identifying biases in the dataset, we first need to design or train a *biased model* that employs shortcut methods to complete the task (Mahabadi et al., 2020; Sanh et al., 2020; Utama et al., 2020).

In what follows, we will first review the Product of Experts (PoE) method for bias reduction, which is based solely on the outputs of the main and biased models. Then we present our contribution to developing a novel debiasing method that takes into account not only the models' outputs but also their attribution scores.

Product of Experts. In the original Product of Experts (PoE) solution, the loss is based on combining the predictions of the main and biased model: $\sigma(f_B(\boldsymbol{x_i^b}))$ & $\sigma(f_M(\boldsymbol{x_i}))$ (Hinton, 2002; Mahabadi et al., 2020). The summation of the log-softmaxes ($\sigma(.)$) of both models combine the distributions so that the main would focus less on biased examples:

$$f_C(\boldsymbol{x_i}; \boldsymbol{x_i^b}) = \log(\sigma(f_B(\boldsymbol{x_i^b}))) + \log(\sigma(f_M(\boldsymbol{x_i})))$$

The PoE loss is the cross-entropy loss over the summation shown above:

$$\mathcal{L}_{\text{PoE}}(\theta_M; \theta_B) = -\log(\sigma(f_C^{y_i}(\boldsymbol{x_i}; \boldsymbol{x_i^b}))) \quad (1)$$

While PoE does produce promising results, training the main model only based on the biased model's output can undermine some instances that could have been helpful and non-biased. As stated in Amirkhani and Pilehvar (2021), correct prediction of an instance by the biased model does not necessarily imply that the instance is biased, as the behaviour of the two models might differ.

2.1 PoE with Saliencies

To determine how similarly the main model and bias model behave, we must compute the attribution scores of the input tokens for both models. Therefore, after fine-tuning the biased model, we compute the saliencies $\boldsymbol{S}$ using a gradient-based approach according to the *gradient*×*input* method (Kindermans et al., 2016):

$$\boldsymbol{S}_i = \left\| \frac{\partial y_i}{\partial \boldsymbol{h}_i^0} \odot \boldsymbol{h}_i^0 \right\|_2 \quad (2)$$

This method is based on the gradient of the logit of the output prediction y_i with respect to the input embeddings $\boldsymbol{h}_i^0$. We also obtain the main model saliencies during training. By computing the saliencies for both bias and main models, it is possible to estimate the contribution of each input token in a training instance to both models' predictions. Therefore, we can compute the inter-model similarity—between the saliencies of the two models; for instance, using the cosine similarity metric:

$$\rho = \frac{\boldsymbol{S}_{\text{Main}} \cdot \boldsymbol{S}_{\text{Biased}}}{\|\boldsymbol{S}_{\text{Main}}\| \, \|\boldsymbol{S}_{\text{Biased}}\|} \quad (3)$$

Since the saliencies defined in 2 can only have positive values, ρ will always be a number between 0 and 1. This would provide a complementary metric that shows how similar the two models behave on a specific example. Therefore, we can modify the original PoE loss function that only incorporates the output predictions and include the inter-model similarity in the debiasing loss function:

$$\begin{aligned}\mathcal{L}_{\text{PoE+Sals}}(\theta_M; \theta_B) = \rho^* \mathcal{L}_{\text{PoE}}(\theta_M; \theta_B) \\ +\alpha(1-\rho^*)\mathcal{L}_{\text{CE}}(\theta_M)\end{aligned} \quad (4)$$

where $\mathcal{L}_{\text{CE}}(\theta_M)$ is the cross-entropy (CE) loss on the main model. We also define ρ^* that adjusts the inter-model similarity (ρ) based on the PoE loss using the following formulation:

$$\begin{aligned}\rho^* &= \rho^{\exp(-\beta \mathcal{L}_{\text{PoE}}(\theta_M; \theta_B))} \\ &= \rho^{\exp(\beta \log(\sigma(f_C^{y_i}(\boldsymbol{x_i}; \boldsymbol{x_i^b}))))} \\ &= \rho^{\sigma(f_C^{y_i}(\boldsymbol{x_i}; \boldsymbol{x_i^b}))^{\beta}}\end{aligned} \quad (5)$$

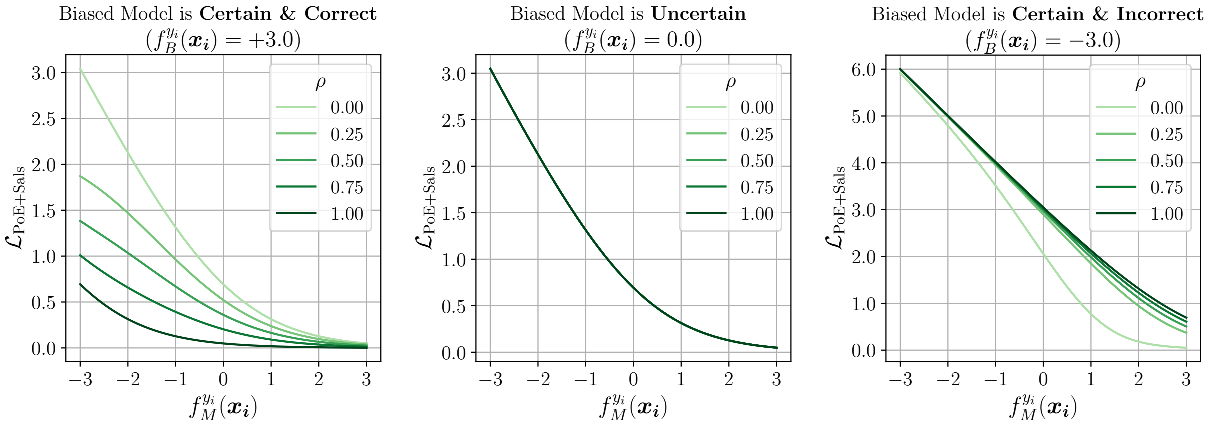

Figure 1: A visualization of our proposed loss function ($\mathcal{L}_{\text{PoE+Sals}}$) based on the main and biased models' prediction ($f_M^{y_i}(\boldsymbol{x_i})$ and $f_B^{y_i}(\boldsymbol{x_i})$) and the inter-model similarity (ρ). For a given input, when the biased model is correct and certain (left), the loss will be upweighted when the biased model differs from the main model in terms of saliency scores. However if the biased model returns a certain but incorrect prediction (right), the loss is downweighted if the main model is dissimilar and also returns a correct prediction. In an uncertain case (middle), the biased model does not affect the PoE loss (Sanh et al., 2020). In this case, the loss is converted to a CE loss based on the output of the main model.[3]

Where β is a positive hyperparameter for adjusting the combined prediction's ($\sigma(f_C^{y_i}(\boldsymbol{x_i}; \boldsymbol{x_i^b}))$) impact.

The intuition behind this adjustment is to upweight and increase the loss for an example where the main and biased models agree on the correct label but show a different behaviour in terms of token attribution scores (a.k.a. less inter-model saliency similarity scores, $0 < \rho < 0.5$). As an extreme case, if the biased model correctly classifies an example with a high output score ($\sigma(f_B^{y_i}(\boldsymbol{x_i^b})) \approx 1$), the main model's prediction would be ineffective in the original PoE loss, since the PoE model output probability is as follows:

$$\sigma(f_C^{y_i}(\boldsymbol{x_i}; \boldsymbol{x_i^b})) = \frac{\sigma(f_B^{y_i}(\boldsymbol{x_i^b}))\sigma(f_M^{y_i}(\boldsymbol{x_i}))}{\sum_{k=1}^{Y} \sigma(f_B^{k}(\boldsymbol{x_i^b}))\sigma(f_M^{k}(\boldsymbol{x_i}))}$$

Therefore, in the adjusted similarity stated in Eq. 5, the exponent would be approximately equal to one, which makes the adjusted similarity equal to the original cosine similarity. As a result, according to Eq. 4, if the models exhibit dissimilar explanations for their prediction ($\rho \approx 0$), the loss tends to be a cross-entropy loss[2] than a PoE loss. On the other hand, in case both models behave similarly on a given training example, i.e., $\rho \approx 1$, the example can be considered as one containing bias. Thus, the PoE loss renders this example as being less impactful during training. The left and right plots of Figure 1 respectively demonstrate[3] that having a higher similarity results in a loss function that is down- or up-weighted depending on the correctness of a certain biased model. Also with an uncertain biased model, the loss in Eq. 1 converts to a CE loss which is only based on the output of the main model.

3 Experiments

In this section, we will introduce the datasets, explain the experimental setup, and then demonstrate the results of our method.

3.1 Datasets

The experiments were carried out on two types of common NLU classification tasks: Natural Language Inference (NLI) and Fact Verification. For NLI, we used MNLI (Williams et al., 2018) as our in-distribution data and HANS (McCoy et al., 2020) for OOD evaluation. Note that the Matched development set is used for the ID evaluation in MNLI. In addition, because HANS has only two labels, entailment and not entailment, we consider outputs that are predicted contradictions or neutral as not entailment. For Fact Verification, we

It is important to note that the results of the methods that are used for comparison are not the results that were reported by the methods themselves but rather the scores that were obtained by replicating their implementation[5].

used FEVER (Thorne et al., 2018) and FEVER Symmetric-V1 (Schuster et al., 2019) for ID and OOD, respectively.[4]

3.2 Setup

In all the experiments, we used *BERT-base-uncased* (Devlin et al., 2019) as the main model to allow a fair comparison against other debiasing methods. However, the biased model differs depending on the task.

We used the TinyBERT model (Turc et al., 2019) for the NLI task, since its limited capacity makes it extremely susceptible to biased features in training examples (Sanh et al., 2020). For fact verification, a full 12-layer BERT-base model similar to the main model is fine-tuned using only the claim sentences from the training data. In both biased models, we compute and save their prediction logits and attribution scores across the entire training dataset so that they can be used as a frozen model during training. However, since the fact verification biased model is only trained on the claim sentences, the attribution scores are only calculated for the claim portion. Therefore, the similarities computed during the training procedure are limited to the claim segment alone.

For the generic fine-tuning hyperparameters, we adopted Sanh et al. (2020) recommendations: 3 epochs of training, a batch size of 32, an Adam optimizer (Kingma and Ba, 2015) with warmup and linear decay in its learning rate schedule, and a peak learning rate of 3e-5 or 2e-5 for MNLI or FEVER, respectively. But as for the specific hyperparameters in our approach, using sweeping over $\alpha \in \{0.01, 0.1, 0.2, 0.3, 0.5, 1.0\}$ and $\beta \in \{0.1, 0.3, 0.5, 1.0\}$, we set $\alpha = 1.0$, $\beta = 1.0$ for MNLI and $\alpha = 0.3$, $\beta = 0.1$ for training on FEVER.

All experiments were implemented using the HuggingFace Transformers library (Wolf et al., 2020) and performed on an RTX 3070 GPU machine. The results are the average of six runs with different seeds.

3.3 Results

The results of various debiasing techniques applied to the previously mentioned benchmarks are shown in Table Table 1. The baseline is fine-tuning the backbone model (BERT-base-uncased) with the commonly used cross-entropy loss, which provides high ID performance but lacks OOD. We also include four approaches from two different studies for additional comparison[5]. Two End-to-End solutions from Mahabadi et al. (2020), one utilizing Debiased Focal Loss (DFL) and the other employing PoE. The PoE and PoE+CE (PoE with a static weighted CE loss added) methods from Sanh et al. (2020) are similar to our approach of having a bi-

---

[4] In both FEVER and FEVER-Symmetric, replacement tokens are used in place of parentheses and brackets (e.g. "]" → "-RSB-"). This causes the BERT tokenizer to split the specified tokens into multiple segments, as there are no tokens in the BERT vocabulary that correspond to the replacement tokens. Therefore, we replace these tokens with the punctuation that corresponds to them so that BERT can tokenize the inputs with less undesirable segmentation. We apply this modification to other approaches that we have evaluated and compared.

[5] We could have included the compared methods' results from their respective papers as well as results from other approaches. However, in our empirical results we observed significant discrepancies between the results obtained from their source code and those reported. In this paper, we intend to report only the reproduced results, which is why the number of compared methods is limited.

ased model that is frozen, but they only rely on the predictions of the biased model and not the inter-model similarities.

It can be observed that the OOD performance of our method outperforms those of other approaches, without or with minimal loss of ID accuracy. On FEVER, our strategy improves SymV1 by nearly 2% while also slightly improving the ID performance. In MNLI, our strategy improves HANS to achieve high scores comparable to Sanh et al. (2020) PoE-only solution. However, the ID performance of Sanh et al. (2020) PoE-only falls short. While maintaining the same level of OOD performance, our solution achieves a minimum MNLI-m dev score that is acceptable.

As an ablation study, we also trained the procedure without using similarity values, resulting in a PoE+CE solution. Since we used a different biased model in FEVER than Sanh et al. (2020), we reported its results using the claim-only biased model configuration. However, we omitted MNLI results from our report because they are identical to Sanh et al. (2020) PoE+CE configuration. Having a claim-only biased model for FEVER rather than a TinyBERT model yields a substantial increase in OOD, as can be seen in the results. As a result, we can observe that even though adding a weighted CE to a PoE loss yields improvements in terms of ID performance in particular, the similarities could push even further and also improve OOD performance.

Another observation is the large standard deviations in OOD accuracy of all approaches, which is why we chose to execute 6 runs as also suggested by Sanh et al. (2020). Even so, it should be noted that our method still has a relatively low variance in HANS.

4 Conclusions

In this paper, we introduced a strategy for improving OOD performance by incorporating the similarity values between the token attribution scores of main and biased models into a Product of Experts (PoE) loss function. The gist of this approach is that it takes into account the decision-making process in addition to the output predictions of the main and biased models (which are often taken as the primary signal). By comparing our method to multiple recent debiasing methods on two widely-used NLU tasks, we demonstrated that our method improves performance on out-of-distribution data while preserving performance on in-distribution data. Future work could include exploring other loss formulations with Attribution Similarities that may produce better results. Additionally, it may be beneficial to investigate methods to reduce the variability of results, which is present in the majority of debiasing solutions.

Limitations

Due to the high variance in the accuracy scores, the main limitation of this approach (as well as the majority of other debiasing approaches) is the large number of seeds used to tune the hyperparameters. As a result, any type of tuning necessitates a multi-seed run, which requires multiple GPUs or many hours of training. Because of this constraint, we omitted working on larger scaled models or other types of PLMs.

Abstract

Sentiment analysis and opinion mining of the opinion-bearing text are important tasks in NLP. The Appraisal framework in systemic functional linguistics is a theory for analysing the linguistic patterns for expressing emotion and opinion. Manual annotation of appraisals however, requires linguistic expertise, and is costly and time-consuming. In this paper, we study how to automatically identify and tag appraisal text segments. We formulate the problem as a sequence tagging problem and propose a novel approach, Adaptive Appraisal (A^2), which employs task and sentiment adapters on pre-trained language models for sequence appraisal tagging. Experiments on user comments, blogs and microblogs show that A^2 outperforms baseline models and achieves good performance for cross-domain and cross-lingual settings. Source code for A^2 is available at: https://github.com/ltian678/AA-code.git

1 Introduction

With the development of the Web technology, opinion-bearing user generated texts such as reviews, users comments, blogs and microblogs are widespread. Sentiment analysis and opinion mining on such texts are prominent NLP tasks that have attracted extensive research studies in the literature (Liu, 2022). On the other hand, the Appraisal framework (Martin and White, 2003) is a systemic functional linguistic theory describing how language is used by writers or speakers to express emotion and opinion. The Appraisal framework consists of three subsystems: 1) Attitude, which includes personal emotion, judgement and evaluation of entities; 2) Engagement, which regards one's own opinions or with respect to others; and 3) Graduation, which describes strength of the attitude and engagement expressed.

Appraisal annotated resources have been used for deeper sentiment and emotion analysis (Whitelaw et al., 2005) than simple sentiment classification, but building such resources manually requires significant linguistic expertise and is time-consuming (Read and Carroll, 2012; Kolhatkar et al., 2020). Automated appraisal tagging would be extremely beneficial to support annotation and analysis efforts by expert linguists. To our best knowledge, the only publicly available appraisal annotated corpus is the Simon Fraser University Opinion and Comments Corpus (SOCC) (Kolhatkar et al., 2020)[1], which is based on news comments. In creating the SOCC corpus, 663,173 user comments were collected, and expert linguists manually annotated 1,043 comments.

To the best of our knowledge, there has been no prior work leveraging machine learning for automatically tagging appraisals. We fill this gap in this paper. We especially target domains with voluminous opinionated texts but zero or very limited appraisal annotation resources, such as blogs and microblogs. Our research focuses on sequence tagging for cross-domain and cross-lingual texts with low resources. In the literature, various approaches for sequence tagging tasks have been reported, including transfer learning (Lee et al., 2018a), few-shot learning (Hofer et al., 2018) and multi-task learning (Changpinyo et al., 2018; Kann et al., 2018; Liu et al., 2018). However, none of the existing studies on sequence tagging consider zero-shot cross-domain or cross-lingual settings.

We propose a model for automatic Appraisal tagging. Our model A^2, namely Adaptive Appraisal, utilises joint task and sentiment adapters based on pre-trained language models for tagging appraisal segments in text sequences. Our model leverages the adapter-based transfer learning framework for cross-domain and cross-lingual appraisal tagging. Based on the pre-trained language model, we propose the task adapter for appraisal tagging across different domains. For instance, the language that

short Microblog posts use for expressing appraisals is very different from the language of long blog posts. It is therefore necessary to enable the adaptive ability from one domain to different domains. We further propose the sentiment adapter to capture the sentiment knowledge for appraisal tagging, capitalised on the strong correlation between appraisals and sentiments. Rather than employing appraisal annotations for sentiment analysis as in existing studies (Whitelaw et al., 2005), we propose to leverage the rich sentiment analysis resources for automatic appraisal tagging.

In this study, we seek to answer the following research questions.

- RQ1: Can we leverage the adapter-based framework for the within-domain appraisal tagging task?
- RQ2: Can the sentiment knowledge fused adapter improve the adapter-based framework for cross-domain appraisal tagging?
- RQ3: Can the sentiment knowledge fused adapter improve the adapter-based framework for the cross-lingual appraisal tagging task?

To summarise, our contributions are twofold: (1) we propose an adapter-based framework for appraisal tagging; and (2) we propose task and sentiment adapters to further enhance the framework for cross-domain and cross-lingual generalisation ability.

2 Related Work

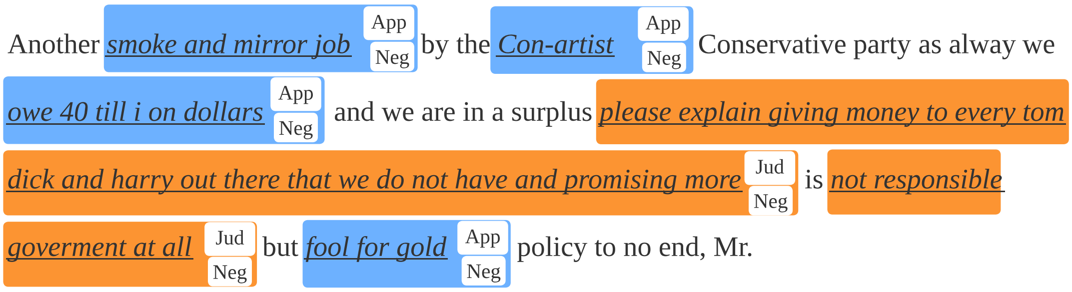
Our work is related to sequence tagging – such as named entiy recognition, semantic role labeling, where token sequences in the input text are tagged with class labels. Our work is especially related to the task of sequence tagging with low resources for training. In the literature, to address the issue of low resources, sequence taggers based on transfer learning (Lee et al., 2018a), few-shot learning (Hofer et al., 2018) and multi-task learning (Changpinyo et al., 2018; Kann et al., 2018; Liu et al., 2018) have been reported. Our research falls under transfer learning.

Various transfer learning strategies and techniques have been proposed for NLP tasks addressing the issue of scarce labelled data. Early transfer learning algorithms have addressed the target domain data scarcity problem and boosted the model‘s generalisation ability via learning domain-agnostic knowledge for transfer (Kim et al., 2015; Lee et al., 2018b). Modern pre-trained language models (e.g. BERT) have achieved the state-of-the-art performance for a range of Natural Language Processing (NLP) tasks via transfer learning by fine-tuning parameters for different tasks (Devlin et al., 2019; Radford et al., 2019; Liu et al., 2019; Li et al., 2019; Yin et al., 2020). Apart from cross-domain, cross-lingual transfer learning has also been investigated, in particular for part-of-speech tagging and dependency parsing (Ruder et al., 2019). Algorithms have been proposed for transfer learning tasks of low resource languages (Kim et al., 2017; Schuster et al., 2019). All these transfer learning frameworks require fine-tuning parameters of the full model to achieve knowledge transfer, which limits the capacity for models to adapt to many target domains.

Adapter-based transfer is a recently proposed parameter-efficient transfer learning mechanism for adapting a pre-trained model to a target task without fine-tuning all parameters. Adapter modules was originated from computer vision, to control the convolutions and adapt models to multiple domains (Rebuffi et al., 2017). Then, in NLP application, adapters have been widely used for quick adaption in combination with existing large language models to new tasks (Houlsby et al., 2019) and avoiding catastrophic forgetting issues (McCloskey and Cohen, 1989). Üstün et al. (2020) generated adapter parameters from language embeddings for multilingual dependency parsing. Pfeiffer et al. (2021) combined the information stored in multiple adapters for most robust transfer learning between monolingual tasks. As adapter modules have been proved effective for efficient transfer learning with large language models, we propose task and sentiment adapters for the cross-domain and cross-lingual appraisal tagging tasks.

3 The Appraisal Framework

Following the Systemic Functional Linguistics (SFL) theory (Eggins, 2004), the Appraisal framework is a theory describing the linguistic patterns for authors to express emotion and opinion. The Appraisal framework consists of three semantic systems including Attitude, Graduation and Engagement. Attitude is divided into three sub-systems: *Affect*, *Judgement* and *Appreciation*. *Affect* deals with a person's emotional reactions (e.g. happy,



Another smoke and mirror job App Neg by the Con-artist App Neg Conservative party as alway we owe 40 till i on dollars App Neg and we are in a surplus please explain giving money to every tom dick and harry out there that we do not have and promising more Jud Neg is not responsible goverment at all Jud Neg but fool for gold App Neg policy to no end, Mr.

Figure 1: Sample appraisal annotations from SOCC dataset ("App" = Appreciation, "Jud" = Judgement, "Neg" = Negative)

confident), *Judgement* deals with assessing people's behaviour (e.g. powerful, truthful), and *Appreciation* deals with constructing the value of things (e.g. fascinating, exciting). In this work, we focus on the three sub-systems of Attitude and their Polarity (*Positive*, *Negative* and *Neutral*). Figure 1 shows an example for appraisal annotations from the SOCC dataset (Kolhatkar et al., 2020); each span is labelled with an attitude and its polarity.

It should be noted that the linguistic Appraisal framework in this study is different from the Appraisal theory of emotion (Ellsworth and Smith, 1988). The Appraisal theory of emotion (Ellsworth and Smith, 1988) describes that emotions are the result of the way in which people appraise or evaluate events and situations in terms of their relevance and significance to their goals, needs and values. According to this theory, emotions are generated by the way in which people appraise events and situations, and the specific emotion that is generated depends on the type of appraisal that is made. The functional linguistic Appraisal framework (Oteíza, 2017) on the other hand, describes that emotions are the result of the way in which people use language to evaluate and interpret events and situations. The specific emotion that is generated depends on the specific linguistic patterns that are used.

4 Problem Statement

We frame our appraisal tagging task as a BIO sequence tagging problem (Ramshaw and Marcus, 1995), where segments are tagged with the Attitude labels of Affect, Appreciation and Judgement, and Polarity labels of Positive, Negative and Neutral. Let $S = (w_1, w_2, ..., w_l)$ be an input sentence, where w_i is the i-th token and l is the sequence length. The objective of the proposed model A^2 is to identify a set of attitude tags $T_{att} = (\text{B-Attitude}, \text{I-Attitude}, O)$ and a set of polarity tags $T_{pol} = (\text{B-Polarity}, \text{I-Polarity}, O)$ for each $w_i \in S$.

5 Methodology

The architecture of adaptive appraisal (A^2) model is shown in Figure 2. It comprises two modules: (1) a language model for automatic BIO tagging with two target tasks, and (2) a sentiment adapter for learning sentiment specific knowledge and a task adapter for generating task-specific representations.

5.1 The Adaptive Appraisal (A^2) Model

The model predicts Appraisal Attitude and Polarity labels simultaneously. For the input sequence $S = (w_1, w_2, ..., w_l)$, we first feed to adapter-based transformer to generate token embeddings.

$$v = \text{Adapter-Transformer}([\text{CLS}] \oplus w_1 \oplus ... \oplus w_l)$$
$$v = [CLS], Emb[w_1], ..., Emb[w_l]$$

Each token embedding(e.g. $Emb[w_1]$) is presented by a d dimensional vector, where BERT-based encoder $d = 768$. Then we get a list of token representations with sequence length l and dimension d, denoted as $v \in \mathbb{R}^{l \times d}$. For two different objectives, we pass the token representations to two separate multilayer perceptron (MLP), denoted as Φ_{att} and Φ_{pol}.

$$\begin{aligned}\Phi_{att} &= \sigma(XU) \\ \Phi_{pol} &= \sigma(XU) \\ Z &= \Phi_{att}\left(Emb[w_1], ..., Emb[w_l]\right) \\ Z' &= \Phi_{pol}\left(Emb[w_1], ..., Emb[w_l]\right)\end{aligned}$$

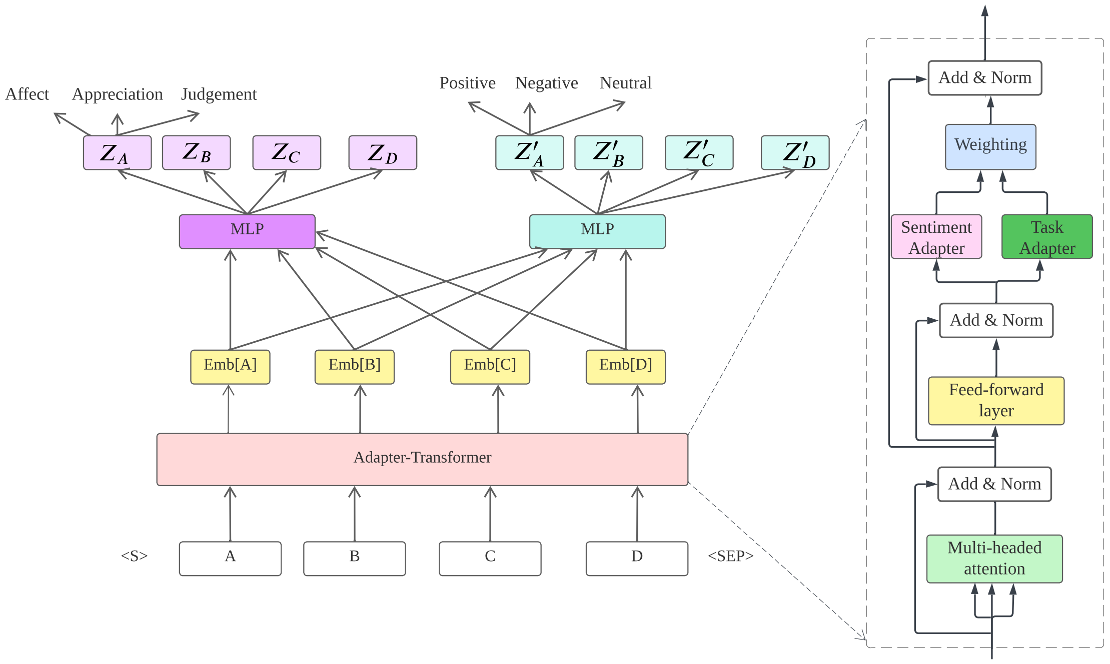


Figure 2: Overall architecture of Adapter-based Automatic Appraisal Framework ("A, B, C, D" are the tokens in the input sequence S)

where σ is ReLU (Agarap, 2018) activation function. U is the linear projection along the sequence length. Normalisation and biases are omitted for brevity. Due to the imbalance on our appraisal data, the dice loss (Li et al., 2020) has been adopted for token tagging tasks. To perform joint training with data D_{train} based on pre-trained language model on both the Attitude and Polarity labels, we minimise the overall loss:

$$\mathcal{L}^d_{att} = 1 - \frac{2p_d y_d + \gamma}{p_d^2 + y_d^2 + \gamma}$$

$$\mathcal{L}^d_{pl} = 1 - \frac{2p_d y_d + \gamma}{p_d^2 + y_d^2 + \gamma}$$

$$\mathcal{L} = \frac{1}{|\mathcal{D}_{train}|} \sum_{d \in \{D_{train}\}} \left(\mathcal{L}^d_{att} + \mathcal{L}^d_{pl} \right)$$

where λ is the L_2 regularisation parameters and Θ represents the parameters set. Following the dice loss setting, we set $\gamma = 1$, and p_d is the possibility of the data d belongs to the prediction y_d after the softmax function. $\mathcal{L}^d_{\text{att}}$ and $\mathcal{L}^d_{\text{pl}}$ are the loss functions for Attitude and Polarity labels, respectively. The reason for using the dice loss is to mitigate the impact of our imbalanced Appraisal labelled data.

5.2 Sentiment and Task Adapters

To develop a sentiment adapter and a task adapter, we followed an efficient adapter architecture recently proposed by Pfeiffer et al. (2021). They defined the adaptor structure by simply combining down and up projection with a residual connection. To examine whether sentiment knowledge can boost the performance of the appraisal tagging task, we propose employing a sentiment adapter on pre-trained language models. Furthermore, to capture task-specific knowledge, we propose employing a task adapter on pre-trained language models. The task adapter is trained with our appraisal training data D_{train}.

We denote sentiment-specific adaptive parameters Ω and task-specific adaptive parameters Ψ. In our architecture, we allocate the sentiment-specific adapter in parallel with our task-specific adapter after the feed-forward layer, followed by a ReLU activation at each layer l:

$$\Omega_l\left(\mathbf{h}_l, \mathbf{r}_l\right) = \mathbf{U}_l\left(\mathrm{ReLU}\left(\mathbf{D}_l\left(\mathbf{h}_l\right)\right)\right) + \mathbf{r}_l$$
$$\Psi_l\left(\mathbf{h}_l, \mathbf{r}_l\right) = \mathbf{U}_l\left(\mathrm{ReLU}\left(\mathbf{D}_l\left(\mathbf{h}_l\right)\right)\right) + \mathbf{r}_l$$

where $\mathbf{h}_l$ is the hidden states passing through the transformer architecture and $\mathbf{r}_l$ represents the residual at layer l. $\mathbf{D}_l$ is the projection presentation at layer l. To combine two adapters, we further introduce our simple yet effective adapter weight layer Θ, for each transformer layer l, the function denoted as:

$$\Theta_l = \alpha \Omega_l \left(\mathbf{h}_l, \mathbf{r}_l\right) + (1-\alpha)\, \Psi_l \left(\mathbf{h}_l, \mathbf{r}_l\right)$$

where α is the learned parameter and α can be different across transformer layers.

The sentiment adapter is fine-tuned with the sentiment datasets [2] at the sentence-level with negative log-likehood loss with $\mathcal{D}_{senti}$ as sentiment training set, as following:

$$\mathcal{L}_{senti} = -\frac{1}{|\mathcal{D}_{senti}|} \sum_{n=1}^{N} \log\left(p\left(y^n \mid x^n\right)\right)$$

5.3 Cross-lingual Inference

Follow the adapter-based cross-lingual framework MAD-X (Pfeiffer et al., 2020), we include a target language adapter when we transfer from English→Chinese and Chinese→English tasks. For instance, if we transfer from English→Chinese, we will plug in the Chinese adapter before the parallel task and sentiment adapters. Note that for cross-lingual tests, we also swap the base encoder from BERT to XLM-R to handle multi-lingual token embedding.

6 Datasets

For the cross-domain and cross-lingual appraisal tagging task, we conducted experiments on two datasets: the SOCC and POST datasets. The SOCC dataset comprises of 10,399 opinion news articles and 663,173 comments from the Canadian daily newspaper, *The Glove and Mail*. In addition to the raw text, the corpus includes specific annotations from multiple perspectives: negation, appraisal, constructiveness and toxicity. Among them, we used the appraisal annotations for our experiments. The POST dataset comprises of Twitter and Blog posts annotated with appraisals developed in-house following the same Appraisal Framework (Martin and White, 2003); it contains not only English text but also Chinese text. In the POST dataset, various spans of appraisals were annotated, as evaluation occurs at all levels of languages (words, phrases, clauses or entire sentence). In our experiments, we used the word and phrase level of labels. When there are phrases with more than one appraisal labels overlapping, we opted the longest span label.The data statistics of these two datasets are shown in Table 1 and Table 2.

7 Experiments and Results

7.1 Experiment Setup

A^2 is an adapter-based framework adding adapter modules to pre-trained language models; A^2(BERT) and A^2(RoBERTa) are based on language models, BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019), respectively. We compared the performance of A^2 framework models with following baseline models:

- Conditional Random Fields (CRF) (Lample et al., 2016) is a baseline that is widely used, feature-based model for a sequence tagging task.
- GLoVe+FFN is a baseline where tokens are encoded by the max and mean of GloVe (Pennington et al., 2014) [3] embeddings and followed by a feedforward neural network (FFN) for sequence labelling.
- BERT (Devlin et al., 2019) is a baseline based on the off-the-shelf BERT token embeddings, where we include further pre-training (BERT-PT) (Gururangan et al., 2020) and fine-tuning (BERT-FT) on a sentiment dataset.

Tweets	1,042	4.46
Tweets(CHN)	514	3.01

Table 3: Statistics of Appraisal expressions in different domains. Span length is counted by # of tokens.

- RoBERTa (Liu et al., 2019) is a baseline similar to BERT, where we include further pre-training (RoBERTa-PT) and fine-tuning (RoBERTa-FT) on a sentiment dataset.
- M-BERT is a baseline based on multilingual BERT.
- XLM-R (Conneau et al., 2019) is a baseline based on the multilingual language model XLM-R.

7.2 Implementation Details

We implemented our models in PyTorch using the HuggingFace library[4] and their pretrained BERT[5] and RoBERTa[6] models. Adapters in language models are implemented with the AdapterHub [7] package. The 100-dimension GloVe word embedding is applied for the GloVE+FFN model.

For the input sequence, we set maximum token length$=384$ and dropout rate $= [0.5, 0.6]$ for token embeddings. Learning rate is tuned in the range between $[1e^{-5}, 5e^{-5}]$ for BERT and $[1e^{-6}, 5e^{-6}]$ for RoBERTa based on the development set. All models use the Adam optimiser (Kingma and Ba, 2014), and our experiments are run using one A100 GPU with 40GB Memory.

7.3 Results

We evaluated A^2 for each attitude and polarity category. Each result is an average of three runs with different random seeds. For pre-training, we followed the procedures in (Gururangan et al., 2020) with masked LM loss. Table 4 and Table 5 present the in-domain test results on the SOCC and POST datasets, respectively.

As shown in the first group of both Table 4 and Table 5, compared with CRF and GloVe+FNN models, both BERT- and RoBERTa-based models yield better performance based on the average F1 scores on both datasets. This indicates that existing pre-trained language models have better capability to handle the appraisal tagging task. Moreover within the off-the-shelf language models, RoBERTa generally performs better than BERT.

The second group of both Table 4 and Table 5 shows the results of the continued pre-training and sequential fine-tuning language models. Comparing the performance of the first group of off-the-shelf language models, we found that our models with both strategies boost the performance further on all the Attitude (*Affect*, *Appreciation* and *Judgement*) labels and Polarity (*Positive*, *Negative* and *Neutral*) labels. The improved performance on the polarity labels especially implies that sentiment knowledge is useful for the appraisal tagging task. On the question of which strategy works better for this task, we observed that the continued pre-training strategy generally can bring better performance compared with the sequential fine-tuning strategy on both datasets in most of the cases except on the average F1 scores (e.g. 65.24% vs. 65.48%).

The main results of the appraisal tagging performance on our A^2 models are presented in the last group of both Table 4 and Table 5. As shown at the overall F1 score, both our A^2 models yield strong performance on these two datasets compared with all the other models. Note that we only fine-tuned the adapter parameters, which only apply to 15% of the overall number of parameters in the transformer-based language models.

7.4 Ablation Study

We compared the “jointly adap” approach of our A^2 framework (A^2) with the "sequentially adapt" approach in the literature (Pfeiffer et al., 2020), where the task-specific adapter is stacked on top of the sentiment-fused adapter (A$^2_{seq}$). As shown in the first group of Table 6, the joint adapters with weighting layer (A^2) gives better performance compared with stacking both adapters (A$^2_{seq}$) for the appraisal tagging task.

Furthermore, we conducted an ablation study to compare the performance of our A^2 framework against one without the task adapter (w/o T-Adpt) and one without the sentiment adapter (w/o S-Adpt). As presented in the second group of Table 6, the model with both sentiment and task adapters (A^2) performs the best and the sentiment adapter

A^2(RoBERTa)	74.86	74.45	71.62	74.50	78.18	79.45	70.95

Table 5: F1 scores of all models on the POST English test set (“PT” = pre-training, “FT” = fine-tuning)

brings major improvement to model performance on the POST test set, by delivering +8.23 and +8.2 F1 scores on Polarity labels, *Positive* and *Negative*, respectively.

The experiment results indicate that the joint adapter approach can fully leverage both sentiment-specific and task-specific information through our adapter architecture and sentiment knowledge can greatly enrich token semantics.

7.5 Cross-domain Performance

This set of experiments aim to answer our second research question (RQ2), "*Can the sentiment knowledge fused adapter improve the adapter-based framework for the cross-domain appraisal tagging?*". As shown in Table 3, the average appraisal expression length varies in different domains; for instance, Twitter appraisals (avg. 4 tokens) have less number of tokens compared with News Comment appraisals (avg. 6 tokens) and Blog appraisals (avg. 12 tokens). As the SOCC and POST datasets contain corpus from three different domains (Tweet, Blog and News Comment) we got 6 sets of cross-domain performance results in total: Tweet→Blog, Tweet→News Comment, Blog→Tweet, Blog→News Comment, News Comment→Tweet, and News Comment→Blog. For instance, under Tweet→Blog setting, we will use Tweet domain text as training and zero-shot testing the performance on Blog domain text. Table 7 shows the average F1 scores of the cross-domain performance results in the zero-shot setting.

When comparing the cross-domain performance of the baseline models (BERT and RoBERT) against the fine-tuned models (BERT-FT and RoBERT-FT), we observe that directly fine-tuning language models with a sentiment dataset does not always yield performance improvement. For example, while the BERT-FT improves its performance (from 0.61 to 5.58 of F1 score) than the BERT on the most of the cross-domain settings (except one ‘News Comment→Blog’ setting), the RoBERTa-FT worsens its performance (from -0.55 to -1.83 of F1 score) than the RoBERTa on the most of the cross-domain settings (except one ‘Tweet→News Comment setting). This result indicates that directly fine-tuning language models without considering domain specific vectors can hurt naive trans-

Model	Avg. F1	Affect	Appreciation	Judgement	Positive	Negative	Neutral

Model	eng→chn		chn→eng	
MBERT	68.11	61.07	72.64	52.12
XLM-R	70.71	63.77	76.06	56.69
A^2(MBERT)	69.45	64.33	71.54	61.78
A^2(XLM-R)	72.64	67.91	75.44	62.67

Table 8: Cross-lingual performance on the POST dataset (“eng” = English, “chn” = Chinese)

fer learning. On the other hand, our A^2(BERT) and A^2(RoBERTa) models achieve better performance than the fine-tuned models (BERT-FT, RoBERTa-FT) on all the six cross-domain settings. Moreover, the A^2(RoBERTa) model achieves consistently better performance than the A^2(BERT) model on all the six cross-domain settings.

When comparing the cross-domain performance (shown in Table 4 and Table 5) against the in-domain performance (shown in Table 7), we can see that all language models show substantial drop in performance. For example, on News Comments, the performance of the BERT-FT drops from 65.48 to 54.72 and 50.71 when it is originally trained on Tweet domain but test on News Comment domain. This demonstrates the challenge of the cross-domain task setting, which may contain a catastrophic forgetting issue, conflicting signals and domain requirements. However, when we incorporate adapters in A^2 framework, we observe that the performance gap diminishes significantly.

7.6 Cross-lingual Performance

Table 8 shows the cross-lingual performance results, from English to Chinese with tweets data and vice versa. To answer RQ3, "*Can the sentiment knowledge fused adapter improve the adapter-based framework for the cross-lingual appraisal tagging?*", we first fine-tuned the multilingual BERT (MBERT) and XLM-RoBERTa (XLM-R) models using the labels in the source language and applied them to the target languages with subword embeddings frozen.Then, we compared with them under a simple set up of our A^2 framework with plugging in a target language specific adapter. Both A^2(MBERT) and A^2(XLM-R) models demonstrate performance gains (avg. 6.96% and 5.06% for MBERT and XLM-R based) on the target language.

We can see when we transfer from source to target language, existing multilingual language models perform poorly. For example, with XLM-R, when we test out eng→chn, there is a huge performance drop from 76.06% to 63.77% on Chinese data. Both A^2 models are slightly under-perform (avg. 0.85%) the base language models when Chinese as the source language, which may due to the sentiment adapter trained with English data only. Note that the performance on the source language does not decrease as we only replace the language-specific adapter at the inference time.

8 Illustration of a prediction error

To provide a qualitative analysis for our approach, we showcase an example of an annotated sentence from the SOCC dataset in Table 9. We present our A^2 prediction v.s. the human annotations. The original sentence is a comment towards an article discussing the aboriginal of Canada [8]. Based on

Sentence	The author does not seem to have much of a clue in spite of her elevated status.
A^2 prediction	The author does not seem to have much Jud Neg of a clue in spite of her elevated status. App Neg
Gold annotation	The author does not seem to have much of a clue Jud Neg in spite of her elevated status.

Table 9: Illustration of a prediction error

the human annotations, the whole span of “does not seem to have much of a clue” labelled with *Judgement* Attitude and *Negative* Polarity. Our A^2 framework can accurately predict the *Judgement* Attitude and *Negative* Polarity labels but missing three following tokens. It also falsely tags the text segment, “elevated status” as *Appreciation* Attitude and *Negative* Polarity.

9 Conclusion

We have proposed A^2, an adapter-based framework for automatically tagging Appraisal expressions. We have designed task and sentiment adapters of a small number of additional parameters to improve the capacity of pre-trained language models for quick adaptation for cross-domain and cross-language settings.

Limitations

Our system is based on the pre-trained language models and therefore assumes that GPU resources are available. The system is designed for tagging short opinion-bearing texts and the maximum text length is set to 384 tokens. Moroever, our system only performed cross-lingual tests from English to Chinese and Chinese to English for experiments. This is mainly constrained by the dataset availability. To our best knowledge, the POST dataset is the only available resource in Chinese with appraisal annotations. It is desirable to conduct more experiments on a broader set of languages to evaluate the generalisability of the A^2 model for cross-lingual adaptation.

DREEAM: Guiding Attention with Evidence for Improving Document-Level Relation Extraction

Abstract

Document-level relation extraction (DocRE) is the task of identifying all relations between each entity pair in a document. Evidence, defined as sentences containing clues for the relationship between an entity pair, has been shown to help DocRE systems focus on relevant texts, thus improving relation extraction. However, evidence retrieval (ER) in DocRE faces two major issues: high memory consumption and limited availability of annotations. This work aims at addressing these issues to improve the usage of ER in DocRE. First, we propose DREEAM, a memory-efficient approach that adopts evidence information as the supervisory signal, thereby guiding the attention modules of the DocRE system to assign high weights to evidence. Second, we propose a self-training strategy for DREEAM to learn ER from automatically-generated evidence on massive data without evidence annotations. Experimental results reveal that our approach exhibits state-of-the-art performance on the DocRED benchmark for both DocRE and ER. To the best of our knowledge, DREEAM is the first approach to employ ER self-training[1].

1 Introduction

Document-level relation extraction (DocRE) has been recognized as a more realistic and challenging task compared with its sentence-level counterpart (Peng et al., 2017; Verga et al., 2018; Yao et al., 2019). In DocRE, an entity can have multiple mentions scattered throughout a document, and relationships can exist between entities in different sentences. Therefore, DocRE models are expected to apply information filtering to long texts by focusing more on sentences relevant to the current decision of relation extraction (RE) and less on irrelevant ones. To this end, existing studies retrieve *supporting evidence* (evidence hereafter, Yao et al., 2019), a set of sentences necessary for humans to identify the relation between an entity pair (Huang et al., 2021a,b; Xie et al., 2022; Xiao et al., 2022; Xu et al., 2022). As shown in Figure 1, to decide the *present in work* relation between *Prince Edmund* and *Blackadder*, reading sentences 1 and 2 should be sufficient. Although sentences 5 and 6 also mention the subject, they are irrelevant to the relation decision. Evidence of the relation triple (*Prince Edmund*, *present in work*, *Blackadder*) is thus defined as sentences 1 and 2.

The Archbishop

[1] "The Archbishop" is the third episode of the first series of the BBC sitcom ***Blackadder*** (***The Black Adder***). [2] It is set in England in the late 15th century, and follows the exploits of the fictitious ***Prince Edmund*** as he is invested as Archbishop of Canterbury amid a Machiavellian plot by the King to acquire lands from the Catholic Church. [3] ... [5] ***Edmund***, faced with the threat of assassination, attempts to escape to France into self-imposed exile; and in a later scene, two drunk knights overhear King Richard IV exclaiming "Who will rid me of this turbulent priest?" [6] The words attributed to King Henry II which led to Becket's death in 1170, and embark on a mission to murder ***Edmund***. [7] …

Subject: ***Prince Edmund***	**Relation**: ***present in work***
Object: ***Blackadder***	**Evidence: 1,2**

Figure 1: Example document and one of the relation triples from DocRED, where the i-th sentence is marked with [i] in the beginning. Mentions in bold italics are those of subjects and objects, whereas entity mentions other than subject and object are underlined.

Despite the usefulness of evidence, automatic evidence retrieval (ER) faces two major issues. Firstly, the existing approaches for ER are memory-inefficient. Previous systems tackle ER and DocRE as separate tasks, introducing extra neural network layers to learn ER with DocRE jointly (Huang et al., 2021a; Xie et al., 2022; Xiao et al., 2022). The ER module typically involves a bilinear classifier that receives entity-pair-specific embeddings and sentence embeddings as the input. To compute the evidence score of each sentence for each entity pair, the module must walk through all (entity pair, sentence) combinations. The computations signifi-

cantly increase memory consumption, particularly in documents with numerous sentences and entities. Secondly, the availability of human annotations of evidence is limited. To make matters worse, gold training data for DocRE are more expensive to annotate than those for their sentence-level counterpart. Despite the difficulty of obtaining human annotations, acquiring evidence annotations at a low cost has been underexplored. Although automatically collecting silver training data for RE by distant supervision (Mintz et al., 2009; Yao et al., 2019), locating evidence for a sliver RE instance in the document is nontrivial.

This work aims at alleviating these issues to improve the usage of ER in DocRE. To reduce the memory consumption, we propose **D**ocument-level **R**elation **E**xtraction with **E**vidence-guided **A**ttention **M**echanism (DREEAM), a memory-efficient approach for incorporating DocRE with ER. We adopt ATLOP (Zhou et al., 2021), a Transformer-based DocRE system widely used in previous studies (Xie et al., 2022; Tan et al., 2022a; Xiao et al., 2022), as the backbone. Instead of introducing an external ER module, we directly guide the DocRE system to focus on evidence. Specifically, we supervise the computation of entity-pair-specific local context embeddings. The local context embedding, formed as a weighted sum among all token embeddings based on attention from the encoder, is trained to assign higher weights to evidence and lower weights otherwise.

To compensate for the shortage of evidence annotations, we propose performing ER under a weakly-supervised setting. Specifically, we design a strategy to perform self-training with DREEAM on massive, unlabeled data. The data is obtained from distant supervision (distantly-supervised data hereafter) and thus is automatically annotated with relation labels but not evidence labels. We expect the knowledge about ER learned from the human-annotated data to generate and grow on the distantly-supervised data. To enable self-training, we first adopt a teacher model trained on human-annotated data to retrieve silver evidence from distantly-supervised data. Next, we train a student model on the data for RE while learning ER from the silver evidence. The student model is further finetuned on the human-annotated data to refine its knowledge. Experiments on the DocRED benchmark (Yao et al., 2019) show that with the help of ER self-training, DREEAM exhibits state-of-the-art performance on both RE and ER.

In short, the contributions of this work are: (1) We propose DREEAM, a memory-efficient approach to incorporate evidence information into Transformer-based DocRE systems by directly guiding the attention. DREEAM does not introduce any extra trainable parameters for ER while achieving good performance on both RE and ER. (2) We propose incorporating distantly-supervised RE training with ER self-training, which improves the performance on both tasks. To the best of our knowledge, DREEAM is the first DocRE system that enables joint training of ER and RE under a weakly-supervised setting.

2 Preliminary

2.1 Problem Formulation

Given a document D containing sentences $\mathcal{X}_D = \{x_i\}_{i=1}^{|\mathcal{X}_D|}$ and entities $\mathcal{E}_D = \{e_i\}_{i=1}^{|\mathcal{E}_D|}$, DocRE aims to predict all possible relations between every entity pair. Each entity $e \in \mathcal{E}_D$ is mentioned at least once in D, with all its proper-noun mentions denoted as $\mathcal{M}_e = \{m_i\}_{i=1}^{|\mathcal{M}_e|}$. Each entity pair (e_s, e_o) can hold multiple relations, comprising a set $\mathcal{R}_{s,o} \subset \mathcal{R}$, where $\mathcal{R}$ is a pre-defined relation set. We let the set $\mathcal{R}$ include ϵ, which stands for *no-relation*. Additionally, if an entity pair (e_s, e_o) carries a valid relation $r \in \mathcal{R}\backslash\{\epsilon\}$, ER aims to retrieve the supporting evidence $\mathcal{V}_{s,r,o} \subseteq \mathcal{X}_D$ that are sufficient to predict the triplet (e_s, r, e_o).

2.2 ATLOP

This section reviews ATLOP, the backbone of our proposed method.

Text Encoding Before encoding, a special token $*$ is inserted at the beginning and the end of each entity mention. Then, tokens $\mathcal{T}_D = \{t_i\}_{i=1}^{|\mathcal{T}_D|}$ within document D are encoded with a Transformer-based pretrained language model (PLM, Vaswani et al., 2017) to obtain token embeddings and cross-token dependencies. Although the original ATLOP adopts only the last layer, this work takes the average of the last three layers[2]. Specifically, for a PLM with d hidden dimensions at each transformer layer, the token embeddings $\boldsymbol{H}$ and cross-token dependencies $\boldsymbol{A}$ are computed as:

$$\boldsymbol{H}, \boldsymbol{A} = \mathrm{PLM}(\mathcal{T}_D), \tag{1}$$

---

[2] Pilot experiments showed that using the last 3 layers yields better performance than using only the last layer.

where $\boldsymbol{H} \in \mathbb{R}^{|\mathcal{T}_D| \times d}$ averages over hidden states of each token from the last three layers and $\boldsymbol{A} \in \mathbb{R}^{|\mathcal{T}_D| \times |\mathcal{T}_D|}$ averages over attention weights of all attention heads from the last three layers.

Entity Embedding The entity embedding $\boldsymbol{h}_e \in \mathbb{R}^d$ for each entity e with mentions $\mathcal{M}_e = \{m_i\}_{i=1}^{|\mathcal{M}_e|}$ is computed by collecting information from all its mentions. Specifically, `logsumexp` pooling, which has been empirically shown to be effective in previous studies (Jia et al., 2019), is adopted as: $\boldsymbol{h}_e = \log \sum_{i=1}^{|\mathcal{M}_e|} \exp(\boldsymbol{H}_{m_i})$, where $\boldsymbol{H}_{m_i}$ is the embedding of the special token $*$ at the starting position of mention m_i.

Localized Context Embedding To better utilize information from long texts, ATLOP introduces entity-pair specified localized context embeddings. Intuitively, for entity pair (e_s, e_o), tokens important to both e_s and e_o should contribute more to the embedding. The importance of each token is determined by the cross-token dependencies $\boldsymbol{A}$ obtained from Equation 1. For entity e_s, the importance of each token is computed using the cross-token dependencies of all its mentions $\mathcal{M}_{e_s}$. First, ATLOP collects and averages over the attention $\boldsymbol{A}_{m_i} \in \mathbb{R}^{|\mathcal{T}_D|}$ at the special token $*$ before each mention $m_i \in \mathcal{M}_{e_s}$ to get $\boldsymbol{a}_s \in \mathbb{R}^{|\mathcal{T}_D|}$ as the importance of each token for entity e_s. Then, the importance of each token for an entity pair (e_s, e_o), noted as $\boldsymbol{q}^{(s,o)} \in \mathbb{R}^{|\mathcal{T}_D|}$, is computed from $\boldsymbol{a}_s$ and $\boldsymbol{a}_o$ as:

$$\boldsymbol{q}^{(s,o)} = \frac{\boldsymbol{a}_s \circ \boldsymbol{a}_o}{\boldsymbol{a}_s^\top \boldsymbol{a}_o}, \tag{2}$$

where $\circ$ stands for the Hadamard product. $\boldsymbol{q}^{(s,o)}$ is thus a distribution that reveals the importance of each token for entity pair (e_s, e_o). Subsequently, ATLOP performs a localized context pooling,

$$\boldsymbol{c}^{(s,o)} = \boldsymbol{H}^\top \boldsymbol{q}^{(s,o)}, \tag{3}$$

where $\boldsymbol{c}^{(s,o)} \in \mathbb{R}^d$ is a weighted average over all token embeddings.

Relation Classification To predict the relation between entity pair (e_s, e_o), ATLOP first generates context-aware subject and object representations:

$$\boldsymbol{z}_s = \tanh(\boldsymbol{W}_s[\boldsymbol{h}_{e_s}; \boldsymbol{c}^{(s,o)}] + \boldsymbol{b}_s) \tag{4}$$

$$\boldsymbol{z}_o = \tanh(\boldsymbol{W}_o[\boldsymbol{h}_{e_o}; \boldsymbol{c}^{(s,o)}] + \boldsymbol{b}_o), \tag{5}$$

where $[\cdot;\cdot]$ represents the concatenation of two vectors and $\boldsymbol{W}_s, \boldsymbol{W}_o \in \mathbb{R}^{d \times 2d}$, $\boldsymbol{b}_s, \boldsymbol{b}_o \in \mathbb{R}^d$ are trainable parameters. Then, a bilinear classifier[3] is applied on the context-aware representations to compute the relation scores $\boldsymbol{y}^{(s,o)} \in \mathbb{R}^{|\mathcal{R}|}$:

$$\boldsymbol{y}^{(s,o)} = \boldsymbol{z}_s^\top \mathsf{W}_r \boldsymbol{z}_o + \boldsymbol{b}_r, \tag{6}$$

where $\mathsf{W}_r \in \mathbb{R}^{|\mathcal{R}| \times d \times d}$ and $\boldsymbol{b}_r \in \mathbb{R}^{|\mathcal{R}|}$ are trainable parameters. The probability that relation $r \in \mathcal{R}$ holds between entity e_s and e_o is thus $\mathrm{P}(r|s,o) = \sigma(y_r^{(s,o)})$, where σ is the sigmoid function.

Loss Function ATLOP proposes Adaptive Thresholding Loss (ATL) that learns a dummy threshold class TH during training, serving as a dynamic threshold for each relation class $r \in \mathcal{R}$. For each entity pair (e_s, e_o), ATL forces the model to yield scores above TH for positive relation classes $\mathcal{R}_P$ and scores below TH for negative relation classes $\mathcal{R}_N$, formulated as below:

$$\begin{aligned}\mathcal{L}_{\text{RE}} = &- \sum_{s \neq o} \sum_{r \in \mathcal{R}_P} \frac{\exp(y_r^{(s,o)})}{\sum_{r' \in \mathcal{R}_P \cup \{\text{TH}\}} \exp(y_{r'}^{(s,o)})} \\ &- \frac{\exp(y_{\text{TH}}^{(s,o)})}{\sum_{r' \in \mathcal{R}_N \cup \{\text{TH}\}} \exp(y_{r'}^{(s,o)})}.\end{aligned} \tag{7}$$

The idea of setting a threshold class is similar to the Flexible Threshold (Chen et al., 2020).

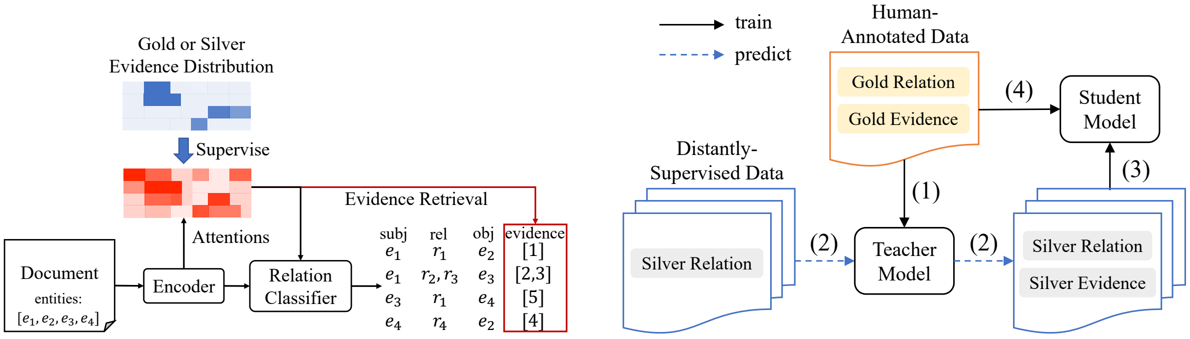
3 Proposed Method: DREEAM

To perform information filtering, ATLOP computes a localized context embedding based on attention weights from the Transformer-based encoder. The rationale is that cross-token dependencies are encoded as attention weights in Transformer layers. In this work, we propose DREEAM to enhance ATLOP with evidence. In addition to the automatically-learned cross-token dependencies, the attention modules are supervised to concentrate more on evidence sentences and less on others.

DREEAM can be employed for both supervised and self-training, sharing the same architecture with different supervisory signals, as shown in Figure 2 (a). Inspired by Tan et al. (2022a), we propose a pipeline to enable self-training of ER, with the data flow shown in Figure 2 (b). First, we train a teacher model on human-annotated data with gold relations and evidence labels. Next, we apply the trained teacher model to predict silver evidence for

---

[3] In practice, a grouped bilinear classifier (Zheng et al., 2019) is applied to save memory.



(a) Model architecture of DREEAM.

(b) Information flow of self-training using DREEAM.

Figure 2: Model architecture and the information flow during self-training. In (a), gold/silver evidence distributions come from human-annotations/the teacher model. In (b), arrows represent the direction of knowledge transfer.

the distantly-supervised data. Then, we train a student model on the distantly-supervised data, with ER supervised by the silver evidence. Finally, we finetune the student model on the human-annotated data to refine its knowledge. The rest of this section introduces the training processes of the teacher and student models, followed by the inference process.

3.1 Teacher Model

For each entity pair (s, o), we guide $\boldsymbol{q}^{(s,o)}$ with an evidence distribution to help generate an evidence-centered localized context embedding. While $\boldsymbol{q}^{(s,o)}$ yields token-level importance for e_s and e_o, we can obtain only sentence-level evidence from human annotations, as shown in Figure 1. To alleviate this gap, we sum the weight of each token within a sentence. Specifically, for a sentence $x_i \in \mathcal{X}_D$ consisting of tokens $t_{\text{START}(x_i)}, \ldots, t_{\text{END}(x_i)}$, we obtain the sentence-level importance as:

$$p_i^{(s,o)} = \sum_{j=\text{START}(x_i)}^{\text{END}(x_i)} q_j^{(s,o)}. \tag{8}$$

Collecting the importance of all sentences yields a distribution $\boldsymbol{p}^{(s,o)} \in \mathbb{R}^{|\mathcal{X}_D|}$ that expresses the importance of each sentence within the document.

We further supervise $\boldsymbol{p}^{(s,o)}$ for each entity pair (e_s, e_o) using a human-annotated evidence distribution computed from gold evidence. First, we define a binary vector $\boldsymbol{v}^{(s,r,o)} \in \mathbb{R}^{|\mathcal{X}_D|}$ for each valid relation label $r \in \mathcal{R}_{s,o} \subset \mathcal{R} \backslash \{\epsilon\}$ that records whether each sentence $x_i \in \mathcal{X}_D$ is evidence of the relation triple (e_s, r, e_o) or not. For example, if x_i is evidence of (e_s, r, e_o), then $v_i^{(s,r,o)}$ is set to 1, and otherwise 0.

Next, we marginalize all valid relations and normalize the marginalized vector to obtain $\boldsymbol{v}^{(s,o)}$:

$$\boldsymbol{v}^{(s,o)} = \frac{\sum_{r \in \mathcal{R}_{s,o}} \boldsymbol{v}^{(s,r,o)}}{\sum_{r \in \mathcal{R}_{s,o}} \mathbf{1}^\top \boldsymbol{v}^{(s,r,o)}}, \tag{9}$$

where $\mathbf{1} = (1, 1, \ldots, 1) \in \mathbb{R}^{|\mathcal{X}_D|}$ is an all-ones vector. The rationale behind Equation 9 is that modules before the relation classifier are not explicitly aware of specific relation types. We thus guide attention modules within the encoder to produce relation-agnostic token dependencies.

Loss Function Our purpose is to guide $\boldsymbol{p}^{(s,o)}$ with human evidence $\boldsymbol{v}^{(s,o)}$ to generate an evidence-focused localized context embedding $\boldsymbol{c}^{(s,o)}$. To achieve this, we train the model with Kullback-Leibler (KL) Divergence loss, minimizing the statistical distance between $\boldsymbol{p}^{(s,o)}$ and $\boldsymbol{v}^{(s,o)}$:

$$\mathcal{L}_{\text{ER}}^{\text{gold}} = -D_{\text{KL}}(\boldsymbol{v}^{(s,o)} || \boldsymbol{p}^{(s,o)}). \tag{10}$$

During training, we balance the effect of ER loss with RE loss using a hyper-parameter λ:

$$\mathcal{L}^{\text{gold}} = \mathcal{L}_{\text{RE}} + \lambda \mathcal{L}_{\text{ER}}^{\text{gold}}. \tag{11}$$

3.2 Student Model

We employ the system trained on human-annotated data as a teacher model to support ER self-training on massive data. The data, obtained from relation distant-supervision (Mintz et al., 2009), contains noisy labels for RE but no information for ER. We train a student model on the data. Supervision of the student model, similar to that of the teacher model, consists of two parts: an RE binary cross-entropy loss and an ER self-training loss.

In general, predictions from the teacher model are adopted as the supervisory signal for ER training. First, we let the teacher model infer on the distantly-supervised data, thereby yielding an evidence distribution over tokens $\hat{\boldsymbol{q}}^{(s,o)}$ for each entity pair (e_s, e_o). Next, we train the student model to reproduce $\hat{\boldsymbol{q}}^{(s,o)}$ for each entity pair (e_s, e_o).

Loss Function The objectives of self-training are identical to those of supervised training. We train ER of the student model using a KL-divergence loss similar to Equation 10:

$$\mathcal{L}_{\mathrm{ER}}^{\mathrm{silver}} = -D_{\mathrm{KL}}(\hat{\boldsymbol{q}}^{(s,o)} || \boldsymbol{q}^{(s,o)}), \tag{12}$$

where $\boldsymbol{q}^{(s,o)}$ is the student model's evidence distribution over tokens regarding entity pair (e_s, e_o), computed from Equation 2.

There are two notable differences between $\mathcal{L}_{\mathrm{ER}}^{\mathrm{silver}}$ and $\mathcal{L}_{\mathrm{ER}}^{\mathrm{gold}}$. Firstly, the supervisory signal of $\mathcal{L}_{\mathrm{ER}}^{\mathrm{gold}}$ is sentence-level, while that of $\mathcal{L}_{\mathrm{ER}}^{\mathrm{silver}}$ is token-level. The gap results from the availability of token-level evidence distributions. On human-annotated data, it is untrivial to obtain token-level evidence distributions from sentence-level annotations. On distantly-supervised data, however, the evidence distribution over tokens can be easily obtained from predictions of the teacher model. We thus adopt token-level evidence distributions to provide supervision from a micro perspective for ER self-training. Secondly, $\mathcal{L}_{\mathrm{ER}}^{\mathrm{gold}}$ is computed only on entity pairs with valid relation(s), while $\mathcal{L}_{\mathrm{ER}}^{\mathrm{silver}}$ is computed over all entity pairs within the document. The design choice is based on the low reliability of relation labels on distantly-supervised data. As these relation labels are collected automatically, it is possible that some of the annotated relations are irrelevant to the document. Therefore, it is hard to tell which relations are valid and which are not from the automatic annotations. For this reason, we compute the loss from all entity pairs to prevent missing important instances.

The overall loss is balanced by the same hyper-parameter λ in Equation 11:

$$\mathcal{L}^{\mathrm{silver}} = \mathcal{L}_{\mathrm{RE}} + \lambda \mathcal{L}_{\mathrm{ER}}^{\mathrm{silver}}. \tag{13}$$

After training on the distantly-supervised data, the student model is further finetuned using the human-annotated data to refine its knowledge about DocRE and ER with reliable supervisory signals.

3.3 Inference

Following Zhou et al. (2021), we apply adaptive thresholding to obtain RE predictions, selecting relation classes with scores higher than the threshold class as predictions. For ER, we apply static thresholding and choose sentences with importance higher than a pre-defined threshold as evidence.

Statistics	Human	Distant
# of documents	3,053/998/1,000	101,873
# of relation types	97	97
Avg. # of ent. per doc.	19.5	19.3
Avg. # of sent. per doc.	8.0	8.1
Avg. # of ment. per ent.	1.3	1.3
Avg. # of rel. per doc.	12.5	14.8
Avg. # of evi. per rel.	1.6	-

Table 1: Data statistics of DocRED. *Human* stands for human-annotated data and *Distant* stands for distantly-supervised data. The abbreviations *doc.*, *ent.*, *sent.*, *ment.*, *rel.*, and *evi.* stand for document, entity, sentence, mention, relation, and evidence sentences, respectively.

We further incorporate the **inference-stage fusion** strategy proposed by Xie et al. (2022). Specifically, for each predicted relation triple (e_s, r, e_o) associated with evidence prediction $\mathcal{V}_{s,r,o}$, we create a pseudo-document $\hat{D}_{s,r,o}$ by collecting only evidence sentences $x_i \in \mathcal{V}_{s,r,o}$. Then, we feed pseudo-documents into the trained model to re-score the relation triples. To aggregate the predictions from the pseudo-documents and the entire document, we adopt a blending layer that contains only one parameter τ representing a threshold. Each triple (e_s, r, e_o) is chosen as the final prediction only if the summation of its scores on the entire document and pseudo-documents is higher than τ. We adjust τ to minimize the binary cross-entropy loss of RE on the development set. For more details, we refer the readers to the original paper (Xie et al., 2022).

4 Experiments

To evaluate DREEAM, we conduct experiments under supervised and weakly-supervised settings.

4.1 Setting

Dataset We conduct experiments on DocRED (Yao et al., 2019)[4], the largest dataset for DocRE with human annotations. As shown in Table 1, DocRED contains a small portion of human-annotated data and a large portion of distantly-supervised data made by aligning Wikipedia articles with the Wikidata knowledge base (Vrandečić and Krötzsch, 2014). In this work, we directly adopt the distantly-supervised data provided in DocRED.

Configuration We implement DREEAM based on Hugging Face's Transformers (Wolf et al., 2020).

Table 2: Evaluation results on development and test sets of DocRED, with best scores **bolded**. The scores of existing methods are borrowed from corresponding papers. We group the methods first by whether they utilize the distantly-supervised data or not, then by the PLM encoder.

Following previous work, we evaluate the performance of DREEAM using BERT$_{\text{base}}$ (Devlin et al., 2019) and RoBERTa$_{\text{large}}$ (Liu et al., 2019) as the PLM encoder. The parameter for balancing ER loss with RE loss is set to 0.1 for BERT$_{\text{base}}$ and 0.05 for RoBERTa$_{\text{large}}$ when training both the teacher and the student model, chosen based on a grid search from $\lambda \in \{0.05, 0.1, 0.2, 0.3\}$. We train and evaluate DREEAM on a single Tesla V100 16GB GPU when utilizing BERT$_{\text{base}}$ and on a single NVIDIA A100 40GB GPU when utilizing RoBERTa$_{\text{large}}$. Details about hyper-parameters and running time are provided in Appendix A.

Evaluation During inference, sentences x_i with $p_i > 0.2$ computed from Equation 8 are retrieved as evidence. For the evaluation, we adopt official evaluation metrics of DocRED (Yao et al., 2019): Ign F1 and F1 for RE and Evi F1 for ER. Ign F1 is measured by removing relations present in the annotated training set from the development and test sets. We train our system five times, initialized with different random seeds, and report the average scores and standard error of these runs.

4.2 Main Results

Table 2 lists the performance of the proposed and existing methods. We select the best-performing model on the development set to make predictions on the test set and submit the predictions to CodaLab for evaluation[5].

Performance of the Student Model Table 2 shows that the student model outperforms existing systems on RE by utilizing the distantly-supervised data. In particular, when adopting BERT$_{\text{base}}$ as the PLM encoder, DREEAM performs better than KD-DocRE (Tan et al., 2022a), the previous state-of-the-art system, by 0.6/1.0 points on Ign F1/F1 for the development set. On the test set, the improvement reaches 1.1 F1 points on both Ign F1 and F1. Notably, DREEAM utilizing BERT$_{\text{base}}$ even performs comparably with SSAN utilizing RoBERTa$_{\text{large}}$ under the weakly-supervised setting (Xu et al., 2021a). When adopting RoBERTa$_{\text{large}}$ as the PLM encoder, the advantage of DREEAM remains on both development and test sets. These results support our hypothesis that ER self-training improves RE, which has not been demonstrated by any previous work.

Performance of the Teacher Model The upper half of Table 2 shows that the teacher model trained

w/o both	62.13$_{\pm0.07}$	63.82$_{\pm0.08}$	47.13$_{\pm0.12}$

Table 3: Ablation studies evaluated on the DocRED development set.

on human-annotated data exhibits comparable performance to EIDER (Xie et al., 2022) on both RE and ER. Although there is a performance gap between DREEAM and SAIS, we attribute it to the difference in supervisory signals. While DREEAM incorporates RE with only relation-agnostic ER, SAIS is trained under three more tasks: coreference resolution, entity typing, and relation-specific ER (Xiao et al., 2022). These extra supervisory signals possibly contribute to the high performance of SAIS. Apart from the performance, our method has a critical advantage over previous ER-incorporated DocRE systems in memory efficiency. We provide a detailed discussion in Section 4.4.

Effectiveness of ER Self-Training Additionally, we observe that the student model leads the existing systems by a large margin on ER. As the first approach enabling weakly-supervised ER training, DREEAM utilizes considerable amounts of data without evidence annotation via self-training. The experimental results reveal that DREEAM improves over the state-of-the-art supervised approaches by approximately 2.0 points on Evi F1. Therefore, we conclude that our approach to ER self-training succeeds in acquiring evidence knowledge from the relation-distantly-supervised data with no evidence annotation.

4.3 Ablation Studies

This subsection investigates the effect of evidence-guided attention by ablation studies. All subsequent experiments adopt BERT$_{\text{base}}$ as the PLM encoder. We report scores without the inference-stage fusion strategy (Xie et al., 2022).

Teacher Model Firstly, we examine how guiding attention with evidence helps RE training on human-annotated data. We train a variant of our teacher model without ER training and evaluate its performance on the DocRED development set. In general, disabling ER training reduces the model to a baseline similar to ATLOP (Zhou et al., 2021)[6].

As presented in Table 3 (a), the RE performance of our system decreases without ER training. This observation supports the hypothesis that guiding attention with evidence is beneficial to improving RE. We further visualize the token importance $\boldsymbol{q}^{(s,o)}$ for some instances to investigate the effect of evidence-guided training and find that our method succeeds in guiding the attention to focus more on relevant contexts. The details can be found in Appendix B.

Additionally, we retrieve evidence from the ER-disabled model as sentences with importance higher than the pre-defined threshold. By doing so, we find that the Evi F1 is not far from its evidence-aware counterpart. This observation indicates that ER is a task highly coupled with RE.

Student Model Next, we investigate the student model trained on distantly-supervised data and fine-tuned on human-annotated data. The aim is to examine the effect of guiding attention with evidence at various stages of training. To this end, we remove ER supervisory signals from the student model during the training on distantly-supervised and human-annotated data. The baseline excludes ER supervision from both stages, pre-trained on distantly-supervised data and then finetuned on human-annotated data for only RE.

As shown in Table 3 (b), DREEAM without ER self-training performs comparably to the baseline, while DREEAM without ER fine-tuning performs comparably to the original model with no ablations. These results indicate that ER self-training is more essential than ER fine-tuning for the student model. On the one hand, we observe that disabling ER self-training on massive data causes a huge loss of evidence knowledge that cannot be recovered by finetuning on the much smaller evidence-annotated dataset. On the other hand, we can conclude that DREEAM succeeds in retrieving evidence knowledge from the data without any evidence annotation, demonstrating the effectiveness of our ER self-training strategy.

4.4 Memory Efficiency

This subsection discusses the memory inefficiency issue in previous ER approaches and shows how DREEAM solves it. Previous approaches regard

---

[6] The difference between ATLOP and our baseline is that our baseline utilizes the last three layers of PLM to obtain embeddings, whereas ATLOP adopts only the final layer.

Method	Memory (GiB)	Trainable Params. (M)
(a) without ER Module		
ATLOP (Zhou et al., 2021)	10.8	115.4
SSAN (Xu et al., 2021a)	6.9	113.5
KD-DocRE (Tan et al., 2022a)	15.2	200.1
(b) with ER Module		
EIDER (Xie et al., 2022)	43.1	120.2
SAIS (Xiao et al., 2022)	46.2	118.0
DREEAM (proposed)	11.8	115.4

Table 4: Memory consumption and the number of trainable parameters of DREEAM and existing methods.

ER as a separate task from RE that requires extra neural network layers to solve (Huang et al., 2021a; Xie et al., 2022; Xiao et al., 2022). To perform ER, all of them introduce a bilinear evidence classifier that receives an entity-pair-specific embedding and a sentence embedding as inputs. For example, EIDER computes an evidence score for sentence x_i with regard to entity pair (e_s, e_o) as below:

$$\mathrm{P}(x_i|e_s, e_o) = \sigma(\boldsymbol{x}_i \mathsf{W} \boldsymbol{c}^{(s,o)} + \boldsymbol{b}), \tag{14}$$

where $\boldsymbol{x}_i$ is a sentence embedding, $\boldsymbol{c}^{(s,o)}$ is the localized context embedding computed from Equation 3, W and $\boldsymbol{b}$ are trainable parameters. EIDER and other existing systems thus need to compute over all combinations of (sentence, entity pair). Specifically, consider a document D with n sentences $\mathcal{X}_D = \{x_1, x_2, \ldots, x_n\}$ and m entities $\mathcal{E}_D = \{e_1, e_2, \ldots, e_m\}$, yielding $m \times (m-1)$ entity pairs. To obtain evidence scores, EIDER must perform bilinear classification $n \times m \times (m-1)$ times via Equation 14, resulting in huge memory consumption. In contrast, DREEAM takes the summations of attention weights over tokens as evidence scores, thus introducing neither new trainable parameters nor expensive matrix computations. Hence, we see that DREEAM is more memory-efficient than its competitors.

Table 4 summarizes the memory consumption and the number of trainable parameters when utilizing BERT$_{\text{base}}$ as the PLM encoder for existing and proposed methods. Values are measured when training the systems using the corresponding official repositories with a batch size of four[7]. We observe that the memory consumption of DREEAM is only 27.4% of EIDER and 25.5% of SAIS. Notably, DREEAM also consumes less memory than KD-DocRE, underscoring the memory efficiency of our proposed method.

Statistics	DocRED	Re-DocRED

Table 6: Evaluation results on the test set of Re-DocRED, with best scores **bolded**. PLM encoder is aligned to RoBERTa-large. The scores of existing methods are borrowed from Tan et al. (2022b).

4.5 Performance on Re-DocRED

Although DocRED is a widely used benchmark, recent works have pointed out that annotations of the dataset are incomplete (Huang et al., 2022; Xie et al., 2022; Tan et al., 2022b). To paraphrase, many relation triples in DocRED are missing in human annotations, biasing the dataset with many false negatives. Tan et al. (2022b) thus proposed Re-DocRED, a more reliable benchmark for DocRE that revises DocRED to alleviate the false negative issue. In this subsection, we evaluate DREEAM on Re-DocRED to verify the soundness of our proposed method.

Similar to Section 4.2, we conducted experiments under two different settings: (a) a fully-supervised setting without distantly-supervised data and (b) a weakly-supervised setting utilizing distantly-supervised data. Notably, Re-DocRED introduces new relation triples without providing accurate evidence sentences. As shown in Table 5, compared with DocRED, the training set of Re-DocRED contains much more relation triples without evidence sentences. DREEAM trained on Re-DocRED could thus be inaccurate on ER, biased by the considerable amount of missing evidence. Therefore, during ER self-training of the student model, we adopt token evidence distributions predicted by a teacher model trained on DocRED as

---

[7] The value of EIDER is different from the original paper because we enable ER evaluations during training.

the supervisory signal. The student model is further finetuned on Re-DocRED to obtain more reliable knowledge about RE.

Table 6 compares the performance of DREEAM against existing methods. We observe that DREEAM outperforms existing methods under both the fully-supervised setting and the weakly-supervised setting. The observation indicates the soundness of our proposed method.

5 Related Work

DocRE Recent work has extended the scope of relation extraction task from sentence to document (Peng et al., 2017; Quirk and Poon, 2017; Yao et al., 2019). Compared with its sentence-level counterpart, DocRE is a more realistic and challenging setting, aiming at extracting both intra-sentence and inter-sentence relations. Although commonly-used benchmarks for DocRE include DocRED (Yao et al., 2021), CDR (Li et al., 2016) and GDA (Wu et al., 2019), only DocRED contains evidence annotation and massive pre-processed data obtained from relation distant supervision. Therefore, we adopt DocRED as our test bed.

Transformer-based DocRE Modeling DocRE with a Transformer-based system has been a popular and promising approach, outperforming its graph-based counterparts (Zeng et al., 2020, 2021; Xu et al., 2021b). One of the major topics of these systems is a better utilization of long-distance token dependencies captured by the PLM encoder. Zhang et al. (2021) formulate DocRE as a semantic segmentation task and introduce a U-Net (Ronneberger et al., 2015) on top of the PLM encoder to capture local and global dependencies between entities. Zhou et al. (2021) propose localized contextual pooling to focus on tokens relevant to each entity pair. Based on their work, Tan et al. (2022a) adopt an axial attention module to perform two-hop reasoning and capture the dependencies between relation triples. These designs provide no supervision on token dependencies, expecting the model to capture them implicitly during training. In contrast, we provide explicit supervision for token dependencies by utilizing evidence information.

ER in DocRE This study is not the first to incorporate evidence information into DocRE. Huang et al. (2021b) first report that heuristically selecting evidence sentences boosts the performance of DocRE systems. Huang et al. (2021a), Xie et al. (2022) and Xiao et al. (2022) train neural classifiers to automatically retrieve evidence together with RE. However, we perform ER with neither heuristic rules nor neural classifiers. Furthermore, our approach can be used for ER self-training on data without evidence annotations.

Distant Supervision Distant supervision has been widely adopted as a technique to generate automatically-labeled data for RE (Mintz et al., 2009; Quirk and Poon, 2017; Xiao et al., 2020). The method assumes that if a sentence contains an entity pair that participates in a known relation in a knowledge base (KB), the sentence probably expresses that relation. Thus unlabeled text can be aligned with a KB using entities as anchors, with each match distantly supervised by the relation described in the KB. Yao et al. (2019) apply the technique to annotate relations in documents automatically. In this work, we directly adopt those documents for ER self-training.

6 Conclusion

We have introduced methods to improve the usage of ER in DocRE. First, we propose DREEAM, a memory-efficient method to reduce the computation cost of ER. Unlike existing approaches that train an evidence classifier for ER, DREEAM directly supervises the attention to concentrate more on evidence than on others. Next, we propose to employ DREEAM in a weakly-supervised setting to compensate for the shortage of human annotations. Instead of gold evidence annotated by humans, we adopt evidence predictions from a teacher model trained on human-annotated data as the supervisory signal to realize ER self-training on unlabeled data. Experiments on the DocRED benchmark show that DREEAM exhibits state-of-the-art performance on both RE and ER, with the help of weakly-supervised training on data obtained from distant supervision of relations. Compared with existing approaches, DREEAM performs ER with zero trainable parameters introduced, thereby reducing the memory usage to 27% or less. The soundness of DREEAM is confirmed by conducting experiments on Re-DocRED, a revised version of DocRED.

In the future, we plan to transfer the evidence knowledge of DREEAM trained on DocRED to other DocRE datasets.

Limitations

A major limitation of this work is that our method can only retrieve relation-agnostic evidence. Unlike Xiao et al. (2022), DREEAM cannot specify evidence sentences for each relation label. Therefore, when an entity pair holds multiple relations, DREEAM retrieves the same evidence regardless of the relation type, even though the evidence may be correct for some of the relations but not for others.

Ethics Statement

In this work, we have proposed a method for incorporating ER into DocRE. Our approach directly supervises the weights of attention modules within a Transformer-based PLM encoder. Inside the research community, we hope our approach can provide a new viewpoint on the explainability of document-level relation extraction systems. Furthermore, a better DocRE system will benefit the research on other tasks, such as question answering and reading comprehension. In the real world, a DocRE system with good performance can help extract useful information from unstructured text, reducing human efforts and expenses. Furthermore, as our method is memory-efficient, it is also friendly to the environment.

We also have demonstrated a use case of our method in ER self-training, utilizing massive data obtained from relation distant-supervision. Although in this work, we directly adopt the data provided by Yao et al. (2019), it is possible to extend the scale of data by utilizing numerous unstructured texts. Utilizing a wide range of unstructured texts may expose our system to the risk of vulnerable data, potentially biasing our system in the wrong direction. To mitigate the problem, we encourage performing data pre-processing to detect and remove harmful contents before training.

A Hyper-Parameters and Runtime

We adopt AdamW as the optimizer (Loshchilov and Hutter, 2019) and apply a linear warmup for the learning rate at the first 6% steps. Important hyper-parameters are shown in Table 7, which are mainly borrowed from existing works. Specifically, we borrow hyper-parameters from Zhou et al. (2021) to train the teacher model and borrow those from Tan et al. (2022a) to train and finetune the student model. The only exception is the number of epochs for training the student model, which is determined by a grid search from $\{2, 5, 8, 10\}$.

The average running time spent for our system at each training stage is shown in Table 8. Note that we employ a single Tesla V100 16GB GPU when utilizing BERT$_{\text{base}}$ and a single NVIDIA A100 40GB GPU when utilizing RoBERTa$_{\text{large}}$.

B Visualization: Evidence-Guided Attention

As introduced in Section 3.1, evidence knowledge of DREEAM originates from sentence-level supervision. We hypothesize that sentence-level supervision, from a more macro perspective, should improve its micro counterpart of token-level focusing. To test the hypothesis, we examine the token-level evidence distribution for localized context pool-

Abstract

The information bottleneck (IB) principle has been proven effective in various NLP applications. The existing work, however, only used either generative or information compression models to improve the performance of the target task. In this paper, we propose to combine the two types of IB models into one system to enhance Named Entity Recognition (NER). For one type of IB model, we incorporate two unsupervised generative components, span reconstruction and synonym generation, into a span-based NER system. The span reconstruction ensures that the contextualised span representation keeps the span information, while the synonym generation makes synonyms have similar representations even in different contexts. For the other type of IB model, we add a supervised IB layer that performs information compression into the system to preserve useful features for NER in the resulting span representations. Experiments on five different corpora indicate that jointly training both generative and information compression models can enhance the performance of the baseline span-based NER system. Our source code is publicly available at `https://github.com/nguyennth/joint-ib-models`.

1 Introduction

Tishby et al. (1999) introduced the information bottleneck (IB) method to compress representation while preserving meaningful information. The method has been incorporated in many state-of-the-art (SOTA) deep models such as Variational Autoencoder (VAE) (Kingma and Welling, 2014; Rezende et al., 2014), and Deep Variational Information Bottleneck (Deep VIB) (Alemi et al., 2017). Those deep models can be divided into supervised generative models (e.g., Deep VIB) and unsupervised ones (e.g., VAEs) (Voloshynovskiy et al., 2019).

Both VAE and VIB have been applied to NLP applications. For example, Effland and Collins (2019) and Chen et al. (2018) proposed to use VAE in sequence labelling tasks such as POS tagging and NER. Meanwhile, Wang et al. (2022) used VIB to tackle OOV issues in NER. The two types of IB have also been employed in other tasks, such as dialogue response generation (Chen et al., 2022), parsing (Li and Eisner, 2019), paraphrase generation for MT (Ormazabal et al., 2022), and text summarisation (West et al., 2019), to name a few. Such previous work only used one type of IB model (either VAE or VIB) in their system, and it is unclear whether we can effectively combine the two types of IB models.

The NER task has been typically approached using sequence models such as BiLSTM (Lample et al., 2016) and BERT (Devlin et al., 2019; Lee et al., 2019; Beltagy et al., 2019). At the same time, we have seen the rise of span-based models (Sohrab and Miwa, 2018; Zheng et al., 2019; Tan et al., 2020; Xia et al., 2019; Xu et al., 2021; Fu et al., 2021; Li et al., 2021), which are simple and effective. Using a span-based model, we can directly represent and manipulate span representations.

This paper investigates the effects of combining the two IB types for the NER task. To that end, we jointly train the span-based NER system with two VAE components and one VIB component. The first VAE component is span reconstruction, used to reconstruct original spans. This component is similar to Sentence VAEs (Bowman et al., 2016), but the model learns only from spans instead of sentences. The second VAE one is syn-

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1984–1996
May 2-6, 2023

onym generation, used to generate synonym(s) of a span. We first collect synonyms of each span from an external knowledge base (KB) and then train a VAE model that can generate the corresponding synonyms given a span. By adding the synonym generation into the model, we indirectly inject semantic information from synonyms into the span representation. The last component is a VIB component (Mahabadi et al., 2021) introduced into the system to compress span representations while keeping useful features for NER.

We evaluate the proposed model on five different corpora: BC5CDR (Li et al., 2016), GENIA (Kim et al., 2003), MedMention-21st (Mohan and Li, 2019), NCBI Disease (Dogan et al., 2014), and ShARe/CLEFE (Suominen et al., 2013). For the synonym generation component, we identify synonyms of each span by performing exact matching against mentions in Unified Medical Language System (UMLS) (Bodenreider, 2004). Experimental results show that by incorporating the two IB types into a span-based NER, we can improve the performance over the baseline span-based model on BC5CDR-Disease, GENIA, MedMention, and NCBI datasets. In the case of GENIA–one of the most popular corpora for nested entities, the proposed model could perform favourably compared with current SOTA systems, even with the simple span-based baseline model without any recent enhancements like boundary detection (Tan et al., 2020; Xu et al., 2021). Furthermore, such boundary-enhanced models can benefit from our approach.

We additionally performed some analysis on the intermediate output of the proposed model. We observed that when jointly trained VAEs with a NER task, the latent variable is restructured satisfactorily towards the task. Similarly, posteriors estimated by the VIB component are clustered neatly even though the input information is compressed. Such distinguishable clusters are potentially helpful for entity linking (Liu et al., 2021). We also found that synonym generation helped improve the quality of span reconstruction and the NER performance.

In summary, the contributions of our paper are:

- This is the first study that investigates the impact of combining two IB methods on NER.
- Through experiments on five different corpora, we demonstrate that the joint model can improve the baseline performance in most cases.
- In-depth analyses on the intermediate output of the joint model indicate that each component plays a different role in enhancing span representations as expected.

2 Related Work

2.1 Span-based NER

Traditionally, sequence models such as BiLSTM (Lample et al., 2016) and BERT (Devlin et al., 2019; Lee et al., 2019; Beltagy et al., 2019) have been used to tackle the task of NER, producing state-of-the-art (SOTA) performance. However, those models could not perform on overlapping entities, i.e., a span has more than one named entity category or nested entities. To address this issue, Sohrab and Miwa (2018) proposed the span-based approach. In this approach, all possible spans are exhaustively generated given a specific span length. The span representation was calculated based on a pre-trained language model and then classified to a corresponding entity type by a linear layer. Following the suite, numerous studies have shown that span-based approaches to NER could produce SOTA performance (Zheng et al., 2019; Tan et al., 2020; Xia et al., 2019; Sohrab et al., 2019; Xu et al., 2021; Fu et al., 2021; Li et al., 2021; Yu et al., 2022).

Fu et al. (2021) designed SpanNER that learns the representation of a span based on its token representation and the span length embedding. SpanNER can also make ensemble predictions from both span-based and sequence labelling systems. Similarly, Yu et al. (2022) proposed SNER that represents a span by considering the context embedding from BERT, i.e., the CLS embedding. Ouchi et al. (2020) proposed to learn the similarity between spans using instance-based learning. The model will assign the class label based on its similar training span at inference time. Xu et al. (2021) used a supervised multi-head self-attention mechanism, where each head corresponds to one entity type, to construct the word-level correlations for each type.

Following the work mentioned above, this paper also focuses on span-based models. Our model, however, learns span representation differently. In particular, we update the span representation using span reconstruction and synonym generation. We then compress it by selecting relevant features using the IB method. It is noted that our model can potentially be incorporated into existing span-based models.

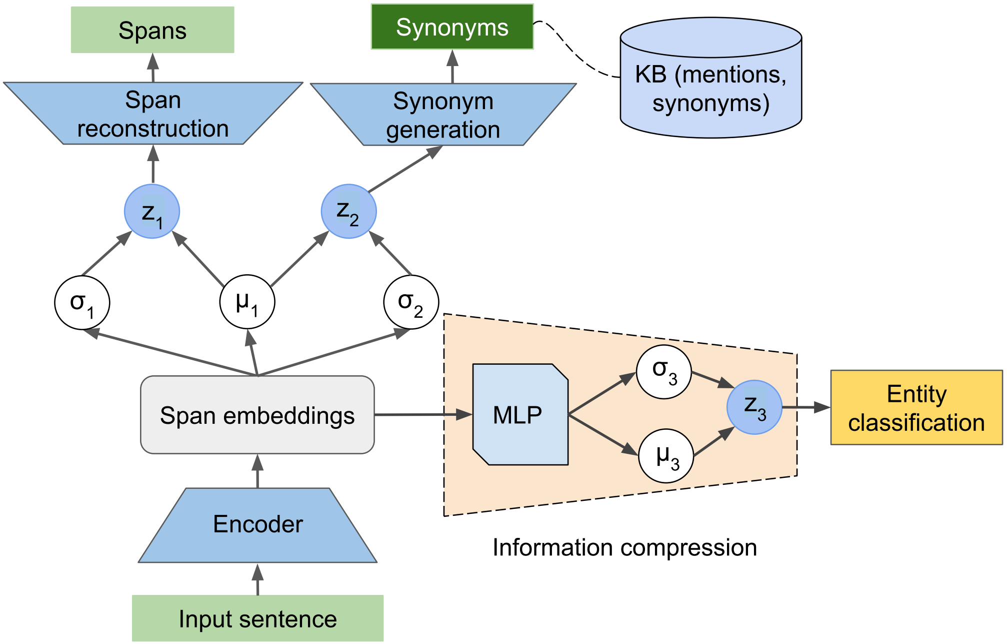

Figure 1: Span-based NER is jointly trained with one supervised VIB component: information compression, and two unsupervised VAE components: span reconstruction and synonym generation. The encoder is shared across the components. Synonyms are collected from an external knowledge base (KB).

2.2 Information Bottleneck in NLP

The Information Bottleneck (IB) method has been applied to various NLP applications. We divide those studies into two main groups: generative models and information compression models.

In the first group, we have studies that used IB as generative models, namely Variational Autoencoders (VAEs). Effland and Collins (2019) proposed a sequence labelling NER model that treats a neural CRF as the amortised approximate posterior in a discrete structured VAE. Meanwhile, Chen et al. (2018) applied neural variational methods to sequence labelling by combining a latent variable generative model and a discriminative labeller. VAEs were also employed in dialogue response generation (Chen et al., 2022) and relation extraction (Yuan and Eldardiry, 2021; Christopoulou et al., 2021).

The second group are studies that used IB as information compression, namely Variational Information Bottleneck (VIB). Mahabadi et al. (2021) was one of the first studies using VIB to finetune low-resource target tasks. Wang et al. (2022) employed the information bottleneck principle to tackle OOV issues in NER. Information compression was also used in parsing (Li and Eisner, 2019), paraphrase generation for MT (Ormazabal et al., 2022), research replication prediction (Luo et al., 2022), text classification (Zhang et al., 2022), improving the attention's reliability (Zhou et al., 2021) and text summarisation (West et al., 2019).

Unlike previous studies, we combine generative and information compression models for the task of NER. In our model, span reconstruction ensures that the span representation keeps the span information, while synonym generation makes similar synonyms have similar representations even in different contexts. Meanwhile, information compression helps suppress irrelevant features, addressing overfitting (if any). To the best of our knowledge, this is the first paper investigating such a joint system for span-based NER.

3 Methods

The overall framework of our model is illustrated in Figure 1. We first encode span embeddings using a transformer-based network. The output from the encoder is then used in three components: (1) entity classification that classifies input spans into an entity type or non-entity using a supervised VIB framework (Mahabadi et al., 2021); (2) span reconstruction that recovers input spans of gold entities; and (3) synonym generation that generates synonyms for a gold entity. Similarly to a multitask setting, we simultaneously train the three components. We only run the first component at the inference step to predict named entities.

3.1 Span Reconstruction and Synonym Generation

3.1.1 Encoder

Given an input sentence with n words: $\{w_0, w_1, ..., w_n\}$, we use a multi-layer transformer-based encoder (Devlin et al., 2019) to encode the sentence. As a result, we have the following contextualised sub-word vectors $\{\boldsymbol{v}_0, \boldsymbol{v}_1, ..., \boldsymbol{v}_m\}$. Similarly to Sohrab and Miwa (2018), we then exhaustively extract all possible spans with a maximum length of sl from the input sentence. Each span embedding is calculated as follows:

$$\boldsymbol{s}_{i,j} = \left[\boldsymbol{v}_i; \frac{\Sigma_{t=i}^{j} \boldsymbol{v}_t}{j-i+1}; \boldsymbol{v}_j \right], \tag{1}$$

where i and j are the start and end positions of the span, $\boldsymbol{v}_t$ is the embedding of the t-th sub-word, and $[;;]$ denotes the concatenation operation.

We then apply two linear layers on top of the span embeddings to construct the parameters of a posterior distribution $q(\boldsymbol{z}|\boldsymbol{s})$ using the following equations:

$$\begin{aligned} \boldsymbol{\mu} &= \boldsymbol{W}_{\mu}\boldsymbol{s} + \boldsymbol{b}_{\mu}, \\ \boldsymbol{\sigma}^2 &= \boldsymbol{W}_{\sigma}\boldsymbol{s} + \boldsymbol{b}_{\sigma}, \end{aligned} \tag{2}$$

where $\boldsymbol{\mu}$ and $\boldsymbol{\sigma}$ are the parameters of a multivariate Gaussian, representing the feature space of the span; $\boldsymbol{W}$ and $\boldsymbol{b}$ are weights and biases of the linear layers, respectively. The posterior distribution is approximated via a latent variable $\boldsymbol{z}$ using the reparameterisation trick (Kingma and Welling, 2014) as follows

$$\boldsymbol{z} = \boldsymbol{\mu} + \boldsymbol{\sigma}\boldsymbol{\epsilon}, \text{where } \boldsymbol{\epsilon} \sim \boldsymbol{\mathcal{N}}(0, 1). \tag{3}$$

In the case that we train both span reconstruction and synonym generation, we have different parameters of $\boldsymbol{\sigma}_1$ and $\boldsymbol{\sigma}_2$, respectively. To encourage span and synonyms to distribute closely, $\boldsymbol{\mu}$ is shared between them.

3.1.2 Decoders

Our decoder is an LSTM network that greedily reconstructs the input span or generates all the corresponding synonyms (if any) in an autoregressive manner. Given latent z from the encoder, we first use $\boldsymbol{z}$ to initialise the hidden state of the decoder via a linear layer transformation. We then form the input of the decoder with the teacher forcing strategy (Williams and Zipser, 1989), i.e., we concatenate $\boldsymbol{z}$ with the representation of each word w_t[1] in a given gold span (for span reconstruction) or a gold synonym (for synonym generation).

3.1.3 Learning

To train VAEs, we maximise the Evidence Lower BOund (ELBO) that includes two losses: the reconstruction loss and the Kullback-Leibler divergence (D_{KL}). The reconstruction loss is the cross entropy loss between an actual span and its reconstruction or synonym. The D_{KL} is calculated based on a prior distribution ($p(\boldsymbol{z})$) and the posterior distribution ($q(\boldsymbol{z}|\boldsymbol{s})$) produced by the decoder. In the case of span reconstruction (SR), the loss for a span s is

$$\begin{aligned} L_{SR}(\boldsymbol{\theta}_1, \boldsymbol{\phi}_1) = & \mathop{\mathbb{E}}_{\boldsymbol{z}_1 \sim q_{\boldsymbol{\phi}_1}(\boldsymbol{z}_1|\boldsymbol{s})} [\log(p_{\boldsymbol{\theta}_1}(\boldsymbol{s}|\boldsymbol{z}_1))] \\ & - D_{KL}(q_{\boldsymbol{\phi}_1}(\boldsymbol{z}_1|s) \parallel p_{\boldsymbol{\theta}_1}(\boldsymbol{z}_1)). \end{aligned} \tag{4}$$

Similarly, with the synonym generation (SG), the loss is

$$\begin{aligned} L_{SG}(\boldsymbol{\theta}_2, \boldsymbol{\phi}_2) = & \mathop{\mathbb{E}}_{\boldsymbol{z}_2 \sim q_{\boldsymbol{\phi}_2}(\boldsymbol{z}_2|\boldsymbol{s})} [\log(p_{\boldsymbol{\theta}_2}(\boldsymbol{s}|\boldsymbol{z}_2))] \\ & - D_{KL}(q_{\boldsymbol{\phi}_2}(\boldsymbol{z}_2|\boldsymbol{s}) \parallel p_{\boldsymbol{\theta}_2}(\boldsymbol{z}_2)). \end{aligned} \tag{5}$$

In Equations 4 and 5, $\boldsymbol{\theta}$ and $\boldsymbol{\phi}$ are weights and biases of the network, respectively. We attach a subscript to each parameter to denote that the parameter belongs to the span reconstruction component or the synonym generation one.

3.2 Entity Classification with Supervised IB

The main objective of the supervised IB is to preserve the information about the target class(es) in the latent while filtering out irrelevant information from the input (Voloshynovskiy et al., 2019). As a result, the objective loss function for supervised IB is based on the compression loss and the prediction loss, as shown in Equation 6.

$$\begin{aligned} L_{VIB}(\boldsymbol{\theta}_3, \boldsymbol{\phi}_3) = & \, \beta \mathop{\mathbb{E}}_{\boldsymbol{s}}[D_{KL}(p_{\boldsymbol{\theta}_3}(\boldsymbol{z}_3|\boldsymbol{s}), r(\boldsymbol{z}_3))] \\ & + \mathop{\mathbb{E}}_{\boldsymbol{z}_3 \sim p_{\boldsymbol{\theta}_3}(\boldsymbol{z}_3|\boldsymbol{s})} [-\log q_{\boldsymbol{\phi}_3}(y|\boldsymbol{z}_3)], \end{aligned} \tag{6}$$

where $r(\boldsymbol{z}_3)$ is an estimate of the prior probability $p_{\boldsymbol{\theta}_3}(\boldsymbol{z}_3)$, β is in a range of $[0, 1]$, and y is the true label of the input span. Similarly to previous equations, $\boldsymbol{\theta}_3$ and $\boldsymbol{\phi}_3$ are weights and biases of the network, respectively.

Following Mahabadi et al. (2021), we use a multi-layer perceptron (MLP) with two linear layers to compute the compressed representation of a span. We approximate $q_{\boldsymbol{\phi}_3}(y|\boldsymbol{z}_3)$ using another

---

[1] We pass a special start symbol as w_0.

linear layer. In particular, this layer is a binary classifier with a sigmoid function to predict the correct entity category of an input span. We use binary cross entropy (BCE) loss to compute the prediction loss (i.e., the second term of Equation 6) in our model.

3.3 Training Objective

We jointly train span reconstruction, synonym generation, and entity classification with the sum of the following optimisation objective for all the spans:

$$L = L_{VIB} + \gamma(L_{SR} + L_{SG}), \qquad (7)$$

where γ is a hyper-parameter with a range of $[0, 1]$. It is noted that during training, L_{VIB} is calculated for all spans, while L_{SR} and L_{SG} are calculated for gold spans only.

4 Experiments

4.1 Datasets

We conducted experiments on five different datasets: NCBI Disease (Dogan et al., 2014), BC5CDR (Li et al., 2016), ShARe/CLEFE (ShARe) (Suominen et al., 2013), GENIA (Kim et al., 2003), and MedMention-21st (MM) (Mohan and Li, 2019). Following previous work, we divided BC5CDR into BC5CDR-Disease (BC5-Dis) and BC5CDR-Chemical (BC5-Chem). To detect synonyms of each span, we only performed exact matching against mentions from UMLS (Bodenreider, 2004). In Table 1, we report the number of documents, the number of golden entities, and the percentage of golden entities that have synonyms in the UMLS (version 2017AA) of the experimental corpora. Since UMLS does not cover every entity, there are cases that an entity does not have any synonyms[2].

Corpus	Baseline	Joint model
BC5-Chemical	91.38	91.30
BC5-Disease	84.46	**85.25**
GENIA	76.93	**77.43**
MedMention-21st	62.78	**63.21**
NCBI	88.12	**88.29**
ShARe/CLEFE	80.88	80.77
Average	80.76	**81.04**

Table 2: F1 scores (%) on the test sets. Bold numbers indicate the joint model is better than the baseline.

4.2 Settings

Regarding the encoder, we employed the pre-trained SciBERT model (Beltagy et al., 2019). Regarding the decoder, we used an LSTM with one hidden layer; input vectors to the LSTM were extracted from resulting vectors trained on a combination of PubMed, PMC texts and the English Wikipedia (Pyysalo et al., 2013).

It is noted that before jointly training with the entity classification, we pre-trained the auxiliary components, i.e., span reconstruction and synonym generation in several epochs. The NER performance was measured based on the exact matching F1 scores calculated by the N2C2 Shared Task NER evaluation script (Henry et al., 2020). All hyper-parameter settings are detailed in Appendix A.

4.3 Results

Across all corpora, we compare the joint model in Figure 1 with a Baseline system that is a span-based model[3] using SciBERT, as reported in Table 2. With the GENIA corpus, we also collected the performance of other span-based SOTA systems for comparison, as shown in Table 3.

In Table 2, we can see that performance across the corpora differs. The proposed model produced better NER performance than the baseline ones

---

[2] In this case, we only lowercase texts in the data and UMLS before matching. Using other techniques to find synonyms in UMLS is beyond the scope of this paper.

[3] We used the span-based NER implementation by Trieu et al. (2020)

System	F1 score
Instance-based (Ouchi et al., 2020)	74.20
Boundary-aware (Zheng et al., 2019)	74.70
BENSC (Tan et al., 2020)	78.30
MHSA (Xu et al., 2021)	79.60
Baseline	76.93
Joint model	**77.43**

Table 3: F1 scores (%) on the GENIA testing set compared with other SOTA systems.

on four corpora. The exception happened with BC5CDR-Chemical and ShARe/CLEFE where the simple span-based model obtained higher F1 scores than the joint model. The corpora's characteristics are one possible reason for this. For BC5-Chemical, reconstructing chemical entities and finding their correct synonyms are more complex than the other entities (see Section 5.3). For ShAe/CLEFE, its documents are health records, not scientific papers like the others. On average, however, the joint model performed better than the baseline.

Results in Table 3 show that on the GENIA corpus, the joint model could perform better than (1) the baseline and (2) the two span-based models: the instanced-based NER model (Ouchi et al., 2021) and the boundary-aware one (Zheng et al., 2019). However, our model produced lower F1 scores than BENSC (Tan et al., 2020) and MHSA (Xu et al., 2021). This can be explained by the fact that both BENSC and MHSA specifically address nested entities by enhancing span boundary detection, while our model classifies all possible spans. Nevertheless, it is noted that our objective is not to improve the SOTA; we focus on investigating the joint model for the NER task anyway. Furthermore, our model can be incorporated into those span-based SOTA systems.

5 Analysis

5.1 Ablation Study

To evaluate the effect of each component on the proposed model, we ran the following settings on the development sets:

- SupVIB: the span-based model using the supervised IB entity classification.
- SupVIB_0: β was set to 0, meaning that the compression loss was not involved in the training stage. This setting is similar to the baseline setting, but the span embeddings are compressed by the MLP before being fed into the linear layer.
- SupVIB + SpanReco: we jointly trained span reconstruction with the SupVIB.
- SupVIB + SpanReco + SynGen (All): the full joint model with all three components.

From Table 4, we can observe the following. Firstly, using SupVIB, we could obtain higher F1 scores in most of the corpora than the baseline. The compression loss is important for SupVIB. In four over six corpora, setting $\beta = 0$ made the performance drop. Secondly, when we introduced the span reconstruction component alone into the model, except for MedMention-21st and NCBI, the component degraded the performance. We observed that SupVIB restructured embeddings differently than SupVIB+SpanReco, which probably affected the performance. Moreover, SupVIB was slightly better than SupVIB+SpanReco in distinguishing entities' boundaries.

When we introduced synonym generation into the model (i.e., the All setting), we could obtain better performance than the baseline model on five over six corpora. This indicates that indirectly injecting semantic information into the span representation is mostly helpful. The exceptions were with MedMention and ShARe/CLEFE, where the All setting produced a lower F1 score than the SupVIB+SpanReco.

By jointly training two types of IB, i.e., generative model and supervised IB, we could enhance the NER performance over the baseline on four out of six testing corpora. Especially with the two most complex, multi-category NER corpora, i.e., GENIA and MedMention-21, the joint model could outperform the baseline by a larger margin than the other corpora.

Lastly, looking at the last column in Table 4, i.e., the average F1 score across the corpora, we can see that the scores were increased from the top to the bottom. We, therefore, can confirm that adding the proposed components one after another helped improve the performance in general.

5.1.1 Impact of the Shared Parameters in VAEs

To encourage spans and their synonyms to distribute closely, we have $\boldsymbol{\mu}$ shared between the span reconstruction and the synonym generation, as in the aforementioned All model. Theoretically, we can also share $\boldsymbol{\sigma}$ between the two components. To investigate the impact of these shared parameters, we conducted two more experiments:

Setting	BC5-Chem	BC5-Dis	GENIA	MM	NCBI	ShARe	Avg.
Baseline	93.34	84.88	78.00	62.83	87.89	80.89	81.30
SupVIB_0	94.01	85.51	78.26	62.31	87.76	81.14	81.50
SupVIB	**94.05**	85.51	78.36	63.00	87.70	81.65	81.71
SupVIB + SpanReco	93.69	85.23	78.22	**63.63**	88.05	81.56	81.73
All	93.78	**85.56**	**79.30**	63.39	**88.41**	81.11	**81.93**
All (w/ shared $\boldsymbol{\sigma}$)	93.87	85.33	78.90	63.21	87.62	80.93	81.64
All (w/o shared $\boldsymbol{\mu}$ and $\boldsymbol{\sigma}$)	93.49	85.03	78.97	61.85	87.89	**81.78**	81.50

Table 4: F1 scores (%) on the development sets produced by different settings. All is the Joint model in Tables 2 and 3. The last column is the average score across the corpora. Bold numbers indicate the best performance in each corpus.

- All with shared $\boldsymbol{\sigma}$: the full model in which the two VAE components share $\boldsymbol{\mu}$ and $\boldsymbol{\sigma}$.
- All without shared $\boldsymbol{\mu}$ and $\boldsymbol{\sigma}$: the full model in which each VAE component has its own (i.e., independent) $\boldsymbol{\mu}$ and $\boldsymbol{\sigma}$.

From the last two rows in Table 4, we can see that the All model with shared $\boldsymbol{\sigma}$ made the F1 scores drop across the corpora (except for the BC5CDR-Chemical) compared with the All model. This is expected because sharing $\boldsymbol{\mu}$, i.e., sharing the mean of the two distributions, is more reasonable than sharing both of the parameters, i.e., sharing both the mean and the variance of the two distributions. However, when we have the independent $\boldsymbol{\mu}$ and $\boldsymbol{\sigma}$, there is no common pattern in the performance. Compared with the All model, the All without shared $\boldsymbol{\mu}$ and $\boldsymbol{\sigma}$ model produced lower scores on most of the corpora, except for the ShARe/CLEFE one. On average, the shared $\boldsymbol{\mu}$ setting (i.e., the All model) was superior to the other two.

5.2 NER Error Analysis

We classified false positive predictions by NER models into two classes:

- Category errors: denote predictions that have correct spans but wrong category,
- Span errors: denote predictions that have incorrect spans.

Regarding the BC5CDR, NCBI, and ShARe/CLEFE corpora, all false positives are due to span errors since these corpora have only one NER category. We report the percentage of span errors in false positives on the development sets of these corpora in Table 5. On BC5-Chemical and ShARe/CLEFE, the proposed model produced more span errors than the baseline one. This situation somehow aligns with the exceptionally lower performance of the proposed model on the two corpora reported in Table 2.

Corpus	Baseline	All
BC5-Chemical	**6.48**	6.50
BC5-Disease	15.21	**13.52**
NCBI	12.76	**12.36**
ShARe/CLEFE	**18.02**	19.23

Table 5: Percentage of span errors on the development sets. The lower the number, the better the model.

Corpus	Category Error		Span Error	
	Base	All	Base	All
GENIA	126	**115**	**4,133**	4,411
MM	2,447	**2,028**	37,148	**34,747**

Table 6: Number of category errors and span errors on the development sets. Base means the Baseline model. The lower the number, the better the model.

In cases of MedMention-21st and GENIA, we report the number of category and span errors in Table 6. We can see that the proposed model produced fewer category errors than the baseline one on both corpora. We hypothesise that the synonym generation component attributed to this improvement; the semantic information provided by the component enhanced the ability to distinguish named entities' categories of the All model. Moreover, we find that categories in GENIA are more ambiguous than those in MedMention-21st. For example, it is difficult to distinguish between "Cell line" and "Cell type" or between "Protein" and "DNA". This can explain the lower reduction of category errors in GENIA than in MedMention-21st.

Table 6 also shows that the proposed model could help reduce span errors on MedMention-21st but not on GENIA. We think that the effectiveness of our model depends on the annotation schemes. As mentioned above, the GENIA cor-

Corpus	SupVIB+ SpanReco	All
BC5-Chemical	0.0066	0.0051
BC5-Disease	0.0092	**0.0243**
GENIA	0.3902	**0.4479**
MedMention-21st	0.0612	**0.1482**
NCBI	0.1244	**0.2228**
ShARe/CLEFE	0.0033	**0.1283**

Table 7: BLEU-2 scores of span reconstruction on the development set of each corpus.

pus contains gene/protein-related entities, of which the boundary of an entity is more specially defined than those in MedMention-21st. As a result, detecting correct spans in GENIA is more challenging than in MedMention. For example, the All model detected "HBxAg - specific synthetic polypeptides" as a Protein entity while the correct span should be "HBxAg" only.

Nevertheless, the span errors accounted for a majority of the false positives across all corpora, indicating that an enhanced-boundary approach can help alleviate the situation.

5.3 Generation Quality

To evaluate the generation quality of the VAEs component, we calculated BLEU-2 scores of the reconstructed gold entities on the development set of each corpus. From Table 7, we can see that using synonym generation helped improve the BLEU scores in almost corpora. This indicates that semantic information from the synonym generation component is useful for the NER task and the span reconstruction.

In Table 8, we show examples where having synonym generation, i.e., the All model, could reconstruct original entities much better than SupVIB+SpanReco. In all examples, the reconstructed spans by the All model are more meaningful and fluent than those by SupVIB+SpanReco.

Among the six corpora, reconstructing chemical entities is the most challenging task, especially with short-form chemicals such as PPA (Phenylpropanolamine). When looking for synonyms of these entities in UMLS, we only did exact matching without checking any semantics. Therefore, there are cases in which we found UMLS synonyms for these abbreviations, but their full forms are completely different. For example, some UMLS synonyms of PPA are "primary progressive aphasia", "primary progressive apraxia of speech", and "Mesulam syndrome", which are not relevant to "Phenylpropanolamine"—the correct full form of the chemical PPA. Nevertheless, we observed that the All model usually reconstructed an abbreviation if the original entity is an abbreviation, while the SupVIB+SpanReco did it very randomly. For example, in row 9 in Table 8, given an abbreviation of "PPA", the All model could generate the exact full form given span, while SupVIB+SpanReco generated "antidepressant"–an incorrect full form for "PPA".

5.4 Entity Posteriors

We further explore the effect of the proposed model by inspecting its intermediate values, which are posteriors z generated by the VAE and VIB components.

5.4.1 Span Reconstruction and Synonym Generation

We plot the resulting posteriors z_1 of gold entities on the development set in a 2D space using tSNE (van der Maaten and Hinton, 2008) in two cases: (i) Only VAEs: when we only train span reconstruction and synonym generation, and (ii) our joint model. We observed that across the settings, thanks to the target task of NER, z_1 was satisfactorily restructured, i.e., posteriors of entities in the same category are clustered together. This phenomenon is more visible in the case of GENIA and MedMention-21[4] than in the other corpora since the two corpora have more than one named entity categories, as illustrated in the first row of Figure 2. In Figures 2a and 2c, entities are scattered over the space. Meanwhile, in Figures 2b and 2d, points in the same category are grouped. We can conclude that after simultaneously training VAEs and NER (the All model), we have better clusters than only training VAEs (Only VAEs).

5.4.2 Supervised IB

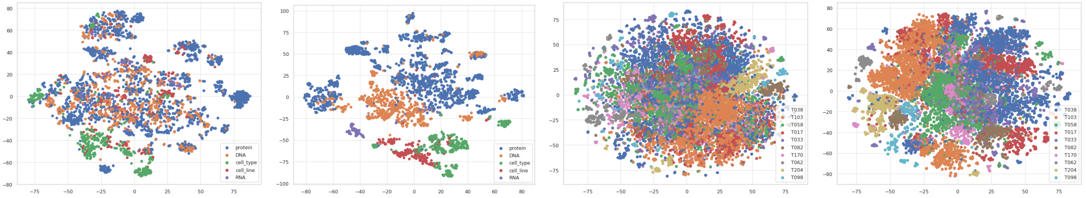
Similarly, we plot the gold entity embeddings and their posteriors z_3 estimated by the supervised IB in the second row of Figure 2. We can see in Figures 2e and 2h that initially, the gold entity embeddings are not clustered very well. In contrast, their posteriors are neatly grouped as illustrated in Figures 2f and 2h. These clusters look even more distinguishable than those by z_1, i.e., Figures 2b and

---

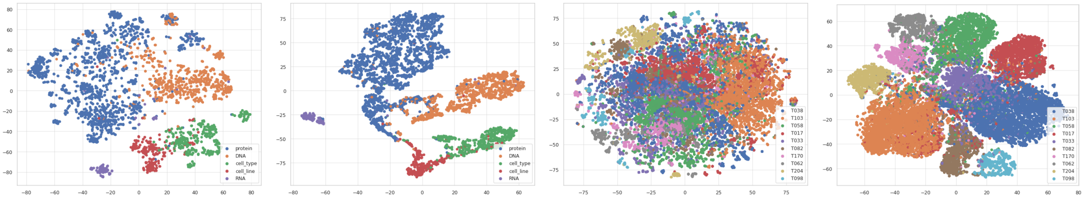
[4] We only show embeddings of the top-10 named entity categories in MedMention-21.

No.	Original span	SupVIB + SpanReco	All
1	nervous fibers	central channel	nervous muscles
2	renal failure	pain failure	renal failure
3	immunomodulatory therapy	Cg therapy	antiviral therapy
4	central hydrophobic core	central its carbon	central temporal core
5	pulmonary veins	liver ganglion	pulmonary vein
6	fibre degeneration	hearing loss	macular degeneration
7	cardiac inter - beat	cardiac - time coil	cardiac - - range
8	volatile compounds	translational compounds	volatile compounds
9	PPA	antidepressant	PPA
10	autoimmune lymphoproliferative syndrome	ankylosing lymphoproliferative syndrome	autoimmune lymphoproliferative syndrome

Table 8: Some examples to show that the synonym information is helpful to span reconstruction.



(a) GENIA: Only VAEs (b) GENIA: The joint model (c) MM21: Only VAEs (d) MM21: The joint model



(e) GENIA: Input to VIB (f) GENIA: Output by VIB (g) MM21: Input to VIB (h) MM21-Output by VIB

Figure 2: Visualisation of entity posteriors on the development set of GENIA and MedMention-21. Points in the same colour indicate entities in the same category. First row: posteriors from the generation models. Second row: the embeddings of entities input to VIB and the corresponding posteriors by VIB.

2d. This phenomenon is understandable because z_3 is approximated based on supervised learning while z_1 is based on unsupervised one.

These visualisations also demonstrate the effectiveness of the supervised IB method. While reducing the input representation size, the method can still reserve relevant features about the target classes. As a result, we can have smaller but more meaningful representations than the original ones. Such neat clusters are potentially helpful for entity linking (Liu et al., 2021).

6 Conclusion

We introduced a joint span-based NER model consisting of three components: VAE-based span reconstruction, VAE-based synonym generation, and VIB-based NER. Each component plays a different role in learning span representation. The VIB-based NER tries to preserve the information about the target NER category in the estimated latent while filtering out irrelevant information from the input. The model is forced to keep contextualised span information when having the span reconstruction component. Meanwhile, the synonym generation component indirectly injects semantic information about a span's synonyms. When testing on five different corpora, we found that the joint model could perform better than the baseline.

The proposed model focuses on learning span representation, which is applicable not only to span-based NER but also to other span-based tasks such as event coreference resolution (Lu and Ng, 2021) and question answering (Li and Choi, 2020). We plan to apply our model to such tasks in the future.

Limitations

We find two main limitations of the proposed model. Firstly, we need synonyms for each gold entity to train the synonym generation component. Unfortunately, this requirement is unsuitable for many NER corpora, such as CoNLL 2012 and ACE2005. One possible way to go around this is to treat the coreferences of an entity (if any) as synonyms. Secondly, similarly to some span-based NER models, our model suffers from a considerable number of all possible spans. We can alleviate this limitation by detecting spans' boundary (Tan et al., 2020; Xu et al., 2021) before classifying spans. We, however, leave those as future work.

Acknowledgements

We would like to thank Dr. Hai-Long Trieu for his help and fruitful comments on the initial implementation of the paper. This paper is based on results obtained from a project JPNP20006, commissioned by the New Energy and Industrial Technology Development Organization (NEDO).

A Hyper-parameter settings

In Table 9, we show the hyper-parameter values used in our experiments. In both SupVIB+SpanReco and All settings, we trained VAEs in 10 epochs before introducing NER into the models. Our models were finetuned on NVIDIA Tesla V100 GPUs with 16GB of RAM using Optuna (Akiba et al., 2019). Depending on the size of the corpus, we ran different numbers of trials, which were in the range of [5,15].

Hyper-parameter name	Value
β	[1e-6, 1e-4]
γ	[1e-6, 1e-4]
Latent size	[512, 768, 1024]
Input size of the LSTM encoder	200
Output size of the LSTM decoder	256
NER learning rate	[1e-5, 3e-4]
VAE learning rate	[1e-4, 1e-3]
Batch size	16
Maximum length of a span	14
Maximum sentence length	512
Number of epochs	20
Number of epochs to pretrain VAEs	10

Abstract

The research carried out so far in detecting abusive content in social media has primarily focused on overt forms of hate speech. While explicit hate speech (HS) is more easily identifiable by recognizing hateful words, messages containing linguistically subtle and implicit forms of HS (as circumlocution, metaphors and sarcasm) constitute a real challenge for automatic systems. While the sneaky and tricky nature of subtle messages might be perceived as less hurtful with respect to the same content expressed clearly, such abuse is at least as harmful as overt abuse. In this paper, we first provide an in-depth and systematic analysis of 7 standard benchmarks for HS detection, relying on a fine-grained and linguistically-grounded definition of implicit and subtle messages. Then, we experiment with state-of-the-art neural network architectures on two supervised tasks, namely implicit HS and subtle HS message classification. We show that while such models perform satisfactory on explicit messages, they fail to detect implicit and subtle content, highlighting the fact that HS detection is not a solved problem and deserves further investigation.

1 Introduction

The rising mass of communication through social media further exacerbates harmful consequences of online hate speech. As a result, social media have faced mounting pressure from civil rights groups demanding to ramp up their enforcement of anti-hate speech policies, so that to monitor and limit this kind of content. In the latest years, numerous methods have been developed to automatically identify this type of utterances expressing hateful or abusive content on social media using Natural Language Processing methods. A variety of datasets have also been built, exemplifying various manifestations of this harmful content (Poletto et al., 2021). However, most of the research carried out so far on this topic has focused on overt forms of hate speech. Explicit hate speech is more easily identifiable by recognizing a clearly hateful word or phrase. Only recently, a few works (Hartvigsen et al., 2022; Wiegand et al., 2022, 2021a; ElSherief et al., 2021; Jurgens et al., 2019; Waseem et al., 2017) have started to focus on implicitness, where circumlocution, metaphor, or stereotypes are used to intentionally convey hatred towards a particular group. In those messages, hatefulness can be captured only by understanding their global meaning, as well as contextual information.

In this paper, we carry out an in-depth analysis of implicit HS in standard benchmarks for HS detection. Additionally, we define the notion of *Subtle HS* that puts forward hateful meanings elusively relying on human perception and through the use of complex syntactic structures. In our study, we collect messages from 7 available datasets for HS detection that cover different topics and are extracted from different social media platforms, and we enrich them with the following three-layer annotation: HS/non HS, Explicit/Implicit and Subtle/Non Subtle. We also provide a fine-grained annotation for implicit HS messages with 18 implicit properties such as irony, exaggeration, metaphor, and rhetorical question, among others. The newly created resource named ISHate (Implicit and Subtle Hate speech) provides a rich and variegate benchmark for pushing forward research on implicit and subtle hateful messages, and constitutes a challenging test-bed to evaluate computational approaches.[1] Additionally, we evaluate SOTA and competitive baseline classifiers to detect both implicit and subtle HS in ISHate, showing that current methods fail to effectively detect implicit and subtle HS messages due to their peculiar nature.

NOTE: This paper contains examples of language which may be offensive to some readers. They do

2 Related Work

In the latest years, there has been significant research on abusive language and hate speech detection using Natural Language Processing (NLP) methods (e.g., Xu et al. (2012); Dadvar et al. (2013); Poletto et al. (2021); Bohra et al. (2018); Corazza et al. (2020); Zampieri et al. (2019a); Caselli et al. (2020, 2021)). A few works focus on subtypes of HS, such as Warner and Hirschberg (2012) that tackles the recognition of antisemitism, or Waseem and Hovy (2016); Badjatiya et al. (2017); Gambäck and Sikdar (2017) that investigate predictive features to identify HS in the form of racism and sexism. In this context, several challenges and shared tasks have also been organized over the years, that made datasets and resources for multiple languages available (for a survey, see Poletto et al. (2021)). Research studies carried out so far have mostly focused on overt forms of hate speech, while very few works address the issue of implicit and subtle HS (ElSherief et al., 2021). However, several works show awareness of the problem. For instance, Warner and Hirschberg (2012) and Xu et al. (2012) discuss systems' limitations in identifying HS messages which are ambiguous, have patterns of emotional speech or lack context. Zhang and Luo (2018) and Corazza et al. (2020) highlight the complexity of recognizing hateful messages when the meaning is conveyed through sarcasm, stereotypes, complex syntactic structure, or non-explicit lexical patterns.

Among the few studies that attempted to address the issues of implicit and subtle detection, Caselli et al. (2020) defines a shared task to detect implicit and explicit abusive messages from AbusEval, a reannotated dataset based on OLID/OffensEval (Zampieri et al., 2019a). Benikova et al. (2018) paraphrases German HS tweets obtaining implicit and explicit messages to study classification methods. Dadvar et al. (2013) shows how taking user context improves cyberbullying detection with neither explicit profanities nor apparent neutral emotions. Jurgens et al. (2019) and Waseem et al. (2017) explain why explicitness, implicitness, and subtlety are typologies of abusiveness and encourage researchers to develop proactive technologies in this area. ElSherief et al. (2021) introduces a taxonomy of implicit hate speech and a benchmark corpus with fine-grained labels for each message. Hartvigsen et al. (2022) proposes a large-scale approach to automatically generate benign and implicit HS statements through the language model GPT3. Wiegand et al. (2021a, 2022) proposes resources to tackle implicitly abusive comparisons and abusive remarks, which are two subtypes of implicitness. Wiegand et al. (2021b) explains the key issues in the implicit abuse detection, as well as possible future directions to explore. Even though these studies set the basis to explore and model the issue of implicit HS, there is still large room for improvement, both in terms of creating adequate resources to investigate these aspects and in terms of computational approaches to address them.

3 HS, Implicitness and Subtlety

Hate Speech is defined as a direct attack against people – rather than concepts or institutions – based on protected characteristics (PC): race, ethnicity, national origin, disability, religious affiliation, caste, sexual orientation, sex, gender identity, and severe disease (Meta, 2022). We encompass in the concept refugees, migrants, immigrants, asylum seekers from the most severe attacks, and occupations when they are referenced along with PC, though commentary and criticism of immigration policies are excluded from HS. Following this definition, HS differs from related concepts mainly since it is specifically oriented to groups of people with PC as the main target (Poletto et al., 2021). In the following, we provide clear and operational definitions of explicit, implicit and subtle HS. Reported examples are extracted from the White Supremacy Forum (WSF) (de Gibert et al., 2018) and the CONAN (Chung et al., 2019) datasets, described in Section 4.

3.1 Explicit Hate Speech

Explicit HS is unambiguous in its potential to be abusive/hateful, such as language containing racial or homophobic slurs. Explicit HS uses words whose literal definition (taken from the dictionary) is hateful (ElSherief et al., 2021; Waseem et al., 2017; Caselli et al., 2020), as in Example 1.

1. *Negros are so dumb* . (WSF)

3.2 Implicit Hate Speech

According to the definitions of ElSherief et al. (2021), implicit HS does not immediately denote abuse/hate. Implicitness goes beyond word-related meaning, implying figurative language use such as irony, sarcasm, etc. (ElSherief et al., 2021; Benikova et al., 2018), generally hiding the real meaning, making it more difficult to grasp and undermining the collection of hateful messages (Hartvigsen et al., 2022; Waseem et al., 2017). Therefore, we deal with figurative meaning intended by the author rather than literal meaning of words that may be extracted from dictionaries.

In our extensive study on hate speech datasets, we identified 18 typical properties of implicitness relying on linguistics features (listed in Table 2). Among the most significant ones we have irony (Frenda et al., 2022), sarcasm (Potamias et al., 2020), black humor, metaphor (Choi et al., 2021; Gao et al., 2018), exaggeration (Troiano et al., 2018), rhetorical question, sentiment (Li et al., 2021), inference, lack of context (Dadvar et al., 2013), and lack of extralinguistic knowledge. Most of the implicit HS messages contain combinations of several properties, as in:

2. *Global Jewry did not want Brexit and are doing everything they can to sabotage it.* (CONAN)

Example 2 illustrates an interlacement of irony and exaggeration. Global Jewry represents a wordplay mixing Global Jury and Jews adding humorous content to the perception of Jewish people as a nation, while doing everything is hyperbolic pointing out that Jewish are extremely occupied by Brexit. The whole message is ironical as it emphasizes that Israel has its own interest in other country's affairs.

3. *I also , unfortuantely , spent 7-8th grade in a 95 % monkey house* (WSF)

In Example 3 there is an overlap of irony, exaggeration, and metaphor (underlined). *95 %* looks more like an exaggeration than a fact, while monkey house refers to the group of students and in the metaphor due to their skin color they are compared with monkeys.

4. *Are you sure that Islam is a peaceful religion?* (CONAN)

Example 4 interlaces rhetorical question, inference, and sentiment. The rhetorical question doubts about the peacefulness of Islam, expressing at the same time the author's take on it. As well as that, we may read negative inference between the lines.

3.3 Subtle Hate Speech

Subtle Hate Speech concerns hateful messages that are so delicate or elusive as to be difficult to analyze or describe, and that depend on an indirect method to deliver the meaning (Merriam-Webster, 2022). However, literal meanings (Roland et al., 1968; Bertrand, 1905) are of prime importance in subtle messages by contrast to implicit messages where we go beyond literal meanings (Waseem et al., 2017). Although implicitness and subtlety differ a lot at this point, we still rely on language users' perception (Grice, 1967, 1989; Korta and Perry, 2020) to understand implicit and subtle messages (Benikova et al., 2018). Despite the challenges in characterizing human perception schematically, in our study, the use of elements such as negations with positive clauses, conditionals, connectors, unrelated constructions, word order, and circumlocution can greatly affect the subtlety of a message. Cases of HS that convey the meaning directly and straightforwardly are non-subtle. As subtlety is even less studied than implicitness in the domain of HS (Breitfeller et al., 2019), and only considered as a related concept of implicitness in previous works (Jurgens et al., 2019; ElSherief et al., 2021; Hartvigsen et al., 2022), we analyze their interrelation, particularly whether one of these concepts is an umbrella term for the other.

First, we study whether explicit HS can convey the meaning in a subtle way, to accept or reject the idea that implicitness is a general term for subtlety. As can be seen from the example below, a message can be explicit and subtle at the same time:

5. *As a brit my knowledge of american law is somewhat lacking but even i know that this holder groid has committed treason* (WSF)

Example 5 is explicit as it literally conveys hateful meanings with the expression holder groid, but it is subtle as the intended hateful meaning is disguised by the first and second underlined constructions, pushing out the attention from the explicit hateful expression.

On the other side, we investigate whether subtlety is an umbrella concept for implicitness (whether all implicit messages are subtle by default). The following example shows an implicit non-subtle HS message:

6. *I 'm either in North Florida or Nigeria sometimes i can't tell the difference.* (WSF)

According to the definitions of explicitness and implicitness, this message is not explicit since it does not contain any hateful words, thus, it does not directly convey hateful meaning. However, it is hateful despite being more elaborated, as it includes certain figures of speech that trigger hateful meaning. The underlined expression in Example 6 represents antithesis, while the message itself is ironical. This message also lacks contextual information and extralinguistic knowledge. Although being implicit, this message is not subtle as the meaning is delivered plainly without any delusion or delicacy. Based on these considerations, we consider implicitness and subtlety as two separate concepts. To illustrate the difference between implicit non-subtle messages presented above and implicit subtle cases, consider the following example:

7. *I think it is a bit late to think to look after the saety and the future of white people in Southfrica* . (WSF)

We label it as implicit HS as it does not express hateful meaning explicitly via offensive words and it is ironic. It is also subtle as it starts with an introductory construction that makes the message more sophisticated and adds extra weight to it.

As can be expected, it is also possible to find non-hateful subtle or implicit sentences (such as ironic or sentimental texts). However, our work focuses on exploring implicitness and subtlety in the context of hate speech only, therefore those more general cases are not investigated.

4 The ISHate Dataset

Relying on the fine-grained definitions of HS provided in the previous section (explicit, implicit and subtle HS), we collect and enrich 7 available standard datasets for HS detection. As a result, we create the first benchmark for implicit and subtle HS detection on social media messages extracted from different sources.

4.1 Data Collection

Nearly all available resources of user-generated HS content are retrieved with a keyword-based approach, and mainly relying on a list of words with negative polarity (Poletto et al., 2021). However, with this strategy it is possible to extract mainly explicit HS expressions (as in the AbusEval dataset, Caselli et al. (2020)). Given that our study focuses on implicit and subtle HS, we prefer to explore resources collected from communities of users that are potentially prone to hate speech, or resources manually created using a systematic approach. In the following, we list the considered resources:

White Supremacy Forum Dataset (WSF) (de Gibert et al., 2018), that contains HS messages from Stormfront, scraped from the most influential white supremacist forum on the Web. The database is arranged in sub-forums and conversation threads.

HatEval (Basile et al., 2019), which is among the most well-known benchmark for HS detection. A combined approach is applied to collect hateful and misogynous tweets by monitoring potential victims of hate accounts, downloading the history of identified haters, and filtering Twitter streams with both neutral and derogatory keywords.

Implicit Hate Corpus (IHC) (ElSherief et al., 2021), annotated with explicit HS, implicit HS, and non-HS labels obtained from online hate groups on Twitter. The authors focused on eight ideological clusters of U.S., as Black Separatists, White Nationalist and Neo-Nazi. From this dataset we only extracted messages labeled as implicit HS, as it is one of our target categories.

ToxiGen (Hartvigsen et al., 2022), a dataset with benign and implicit toxic messages against minority groups. ToxiGen is machine-generated through the GPT3 language model and prompt programming. Similarly to IHC, we only extracted messages which were automatically labeled as implicit HS and human-validated as toxic by the authors. We did not consider unfinished generated sentences which make a part of implicit messages.

YouTube Video Comments Dataset (YouTube) (Hammer, 2017), that consists of YouTube comments posted under videos related to religion and politics. Differently from the other resources, the messages are annotated as "violent" or "clean".

CONAN (Chung et al., 2019), a dataset of HS messages and counter-narratives (CN) pairs for CN generation. Two native English speakers were asked to write 50 prototypical short texts, which NGO could later use to write their hate texts and counter-narratives. We believe that messages for which a CN can be provided might be richer in implicit content since a slur-based explicit HS message might produce very poor argumentative CN.

Multi-Target CONAN (MCONAN) (Fanton et al., 2021), a dataset of English HS/CN pairs comprising several hate targets. It is collected using a Human-in-the-Loop approach. A generative language model is refined iteratively by using data from the previous loops to generate new samples that NGOs experts review.

Before starting the annotation process with the fine-grained annotations (Explicit, Implicit and Subtle HS), we had to make sure that the definition of HS originally used to annotate such resources is consistent with ours. In the first annotation round, we checked the messages originally annotated as HS, and discarded the few ones that did not correspond to the definition of HS reported in Section 3. For the YouTube dataset, we also added the HS labels. While all the messages annotated as HS are directed to PC, it should be noted that the topics distribution and the writing quality might be different, given the heterogeneity of the selected resources. HS messages mostly target Islamism, Judaism, misogyny, multi-culturalism, racism, immigration, and refugees. Regarding time creation, WSF is made from threads posted between 2002 and 2017, ToxiGen's LM was trained with messages from 2016 to 2019, Hateval consists of messages of 2018, the YouTube comments were collected in 2017, while the IHC contains tweets from U.S. ideological clusters from 2015 to 2017.

4.2 Annotation Procedure

Following the annotation scheme described in Section 3, four graduate-level annotators with linguistics and computational linguistics competences carried out a pilot annotation study on a sample of 100 messages extracted from each of the above mentioned resources to converge to non-ambiguous annotation strategies. We calculate the Inter Annotator Agreement (IAA) on this sample, resulting in Cohen's κ=0.793 (Cohen, 1960) for the implicit layer (binary annotation Explicit/Implicit) and 0.730 for the subtlety layer (binary annotation Subtle/Non-Subtle). We also compute the IAA considering both layers simultaneously, that is, considering one layer of 4 classes (Implicit, Explicit, Subtle, Non-Subtle), obtaining a Cohen's κ of 0.734. In the reconciliation phase, we notice that most of the disagreements are due to the interlacement of subtlety and implicitness. For that reason, we also calculate an ordered weighted disagreement using Krippendorff's α to penalize less when the annotators agree at least on one of the layers (Artstein and Poesio, 2008). The Krippendorff's α is 0.757. Despite the complexity of the annotation task, obtained results are considered as strong agreement in a two-annotators setting. The rest of the annotations has then been carried out by two of the annotators mentioned above, which were provided with the final version of the annotation guidelines (containing the definitions of the target classes, i.e., subtlety and implicitness, and a discussion about borderline cases), together with a set of labeled examples.

Finally, the implicit properties annotations are added on top of the messages labeled as implicit as an additional annotation layer to highlight 18 linguistic features that implicitly convey hateful meaning. For this layer, annotations are carried out by one expert linguist.

4.3 Data Statistics

Table 1 shows statistics of the final dataset, reporting on the number of annotated HS messages for each resource and for the three annotation layers.

The ISHate collection consists of a total of 29116 messages, where 11247 are HS (further annotated with the Explicit/Implicit and Subtle/Non-subtle labels). For computational purposes, we provide a dataset split in three subsets, i.e., *train* (70%), *validation* (15%), and *test* (15%) sets. Each of the partition respects the distribution of all the annotation layers using stratified splitting. As can be seen, classes are unbalanced, each resource providing only a reduced number of implicit and subtle messages - as expected. Note that CONAN and MCONAN do not contain Non-HS messages, because their main objective is CN generation. As for IHC and ToxiGen, we only look through previously annotated implicit HS messages disregarding non hateful ones. Note also that ToxiGen claimed to contain only implicit adversarial messages, but according to our definitions and annotation guidelines many messages are considered as explicit and non-subtle by our annotators.

Table 2 shows the full distribution of the implicit properties relative to the implicit messages in ISHate. As it can be seen, Inference (58%), Context (48%), Sentiment (45%), Exaggeration (28%) and Irony (22%), are the most frequent properties of implicit HS messages, whereas Euphemism (4%), Circumlocution (3%), Metonymy (0.4%) and Synecdoche (0.08%) are the least recurrent. Note that one implicit message can be labeled with more than one property.

	Train		Dev		Test		CONAN	HatEval	IHC	MCONAN	ToxiGen	WSF	Youtube
Label	#	%	#	%	#	%							
Non-HS	12508	.614	2680	.614	2681	.614	0	7421	0	0	0	9342	1106
Explicit HS	7007	.344	1501	.344	1501	.344	324	3107	317	3344	183	987	1747
Implicit HS	866	.042	186	.043	186	.043	81	110	300	295	170	173	109

4.4 Data Augmentation

To overcome the problem of the unbalanced dataset, we propose oversampling and data augmentation (DA) methods for the minority classes using adversarial methods and generative models following (Mayer et al., 2020; Wei and Zou, 2019), and the GPT2 language model (Radford et al., 2019).

Replace Named Entities (RNE). It replaces a named entity (PER, LOC, ORG, and MISC) in the input sentence. A candidate NE in a sentence is replaced by another one according to a previously collected list of NEs (Mayer et al., 2020). Then, the most similar NE is selected by using pre-trained FastText embeddings (Bojanowski et al., 2016). In our use case, we notice that the number of NEs PER, LOC, and ORG are very few compared to MISC. This might be due to the fact that HS messages in our collection mostly target groups and not individuals. However, expressions like *muslims*, *jews*, or *blacks* are present in the MISC category and replaced, as in Example 8. As it can be noticed, the expression preserves its meaning, that is, the use of the rhetorical question to convey that Muslims are not considered as a part of society.

8. **Original**: *Have Muslims ever made a contribution to our society?* (CONAN)
   Augmented: *Have Moslem Arabs ever made a contribution to our society?*

Replace Scalar Adverbs (RSA). It replaces emphasising adverbs like *considerably* or *largely*, with another scalar adverb that might increase or decrease the emphasis of an adjective/verb.

9. **Original**: *I do like the outfit they dressed the simian in ; he looks so regal* (WSF)
   Augmented: *I do like the outfit they dressed the simian in ; he looks incredibly regal*

Example 9 is another implicit racist HS message that uses irony by combining *simian*, *dressed*, and *regal*. RSA replaces the scalar adverb, slightly increasing the emphasis of *regal* in the sentence.

Add Adverbs to Verbs (AAV). It adds modifiers to verbs to accentuate them. In this case, we use speculative adverbs like *certainly*, *likely*, *clearly*.

10. **Original**: *I wish we lived in a world in which only men could be doctors, lawyers, firemen, and teachers.* (MCONAN)
    Augmented: *I wish we lived in a world in which only men could plausibly be doctors, lawyers, firemen, and teachers.*

In Example 10, the meaning is made elusive by the use of the expression *I wish we lived*, the addition of *plausibly* alters the possibility of the verb “to be”, but keeps the misogyny meaning.

Replace Adjectives (RA). It replaces adjectives with their synonyms, as in:

11. **Original**: *If you look at an Alaskan malamute and a timber wolf that are two different species , they look a lot more alike than say a Congolese and a Swede .* (WSF)
    Augmented: *If you look at an Alaskan malamute and a timber wolf that are two unlike species , they look a lot more alike than say a Congolese and a Swede .*

Replace In-Domain Expressions (RI). It replaces a list of manually-crafted expressions often used in HS messages (not captured by the RNE) with other semantically similar expressions, as in Example 12. Here the word "migrants" is replaced by "foreigners" without adding hateful connotations. It would have been different to replace it with *aliens*, which is a derogatory term to refer to migrants.

12. **Original**: *migrants are entering the u.s. just to obtain welfare and other benefits .* (MCONAN)
Augmented: *foreigners are entering the u.s. just to obtain welfare and other benefits .*

Easy Data Augmentation (EDA). Given an input sentence, EDA randomly: *i)* replaces a non-stop word expression with a synonym using Wordnet; *ii)* inserts a synonym of a non-stop word in a random position; *iii)* chooses two words of the sentence and swaps their positions; *iv)* removes each word in the sentence with a certain probability. Only one of the four operations at a time is applied to a sentence.

13. **Original**: *A lot of white women are trying to create danger by drawing these other people into our countries .* (WSF)
Augmented: *A lot of our women are trying to create danger by drawing these other people into white countries .*

A parameter α expressing the percent of the words to be changed in a sentence is specified (in our setting, $\alpha = 0.1$ as in Wei and Zou (2019)).

Back Translation. It translates an input message into a different language to translate it back into the original language. We use the translation from English to Russian following (ElSherief et al., 2021).

14. **Original:** *As a nation , we are in desperate need for an immigration time out and a zero tolerance policy for those here illegally .* (WSF)
Augmented: *As a nation, we desperately need an immigration time-out and a zero-tolerance policy for those here illegally.*

Generative Models (GM). We fine-tune autoregressive generative language models with instances from our minority classes, i.e., explicit subtle, implicit non-subtle, and implicit subtle messages. To do so, we prefix this label on the text as a prompt. Then, language models are asked to generate messages starting with one of our fine-tuned prompts, as in Example 15. We use GPT2 (Radford et al., 2019) as a language model, fine-tuned for 4 epochs using learning rate of 3e-5, and batch size of 32. Additionally, we implement a human-in-the-loop approach revising the generated examples and re-annotating them in case the original label is no-more appropriate for the message.

15. **Input:** *Explicit Subtle HS:*
Augmented: *Explicit Subtle HS: In the end, it comes down to what women want from a man... If they want to play with whores, they can stay at home and have babies...*

Except for GM and BT, the same strategy is applied to augmentation methods to produce new messages. Preprocessing (e.g., Parts-of-Speech tagging and Named Entities Recognition) is carried out using Flair (Akbik et al., 2019) and NLTK (Bird and Loper, 2004) models, and allows to recognize possible candidate phrases to perform a replacement/addition. Then, a candidate phrase is perturbed by another one according to a list of adverbs, NEs, or adjectives based on domain data. We rely on FastText and WordNet Synsets to maintain the semantics of the augmented sentences with respect to the original one. The number of candidates to perform a replacement/addition and the number of replacement/additions per candidate are provided as parameters to these methods.

5 Evaluation

To show that implicit and subtle HS detection is still a very challenging task, we evaluate a set of state-of-the-art models for HS detection on the ISHate dataset. We propose two 3-label classification tasks:

- Task A (Non-HS/Explicit HS/Implicit HS)
- Task B (Non-HS/Non-Subtle HS/Subtle HS)

To this goal, we consider the following models:

Universal Sentence Encoder (USE) + SVM (Indurthi et al., 2019). First-ranked model on the HatEval benchmark (Basile et al., 2019). The USE (Cer et al., 2018) is a sentence embedding that encodes text into high dimensional vectors of 512 dimensions, trained on large data sources to provide an encoding method that works for various NLP tasks. An SVM classifier with RBF kernel and default parameters is then used for classification.

DeBERTa V3 (hate_speech18). SOTA model on the WSF dataset (de Gibert et al., 2018). For classification, a default HuggingFace implementation of a one-layer Feed Forward network is used on top of DeBERTa (He et al., 2021a,b), a transformer-based model. The model is later fine-tuned for 4 epochs (learning rate of 2e-5, batch size of 32).

BERT (Devlin et al., 2018). We use this language model to encode text sequences and classify them by adding a Feed-forward neural network on top.

HateBERT. A re-trained BERT model using over 1 million posts from banned communities on Reddit (Caselli et al., 2021) and then fine-tuned on our dataset. HateBERT obtained very promising results in the benchmarks HatEval, OffensEval (Zampieri et al., 2019b), and AbusEval (Caselli et al., 2020).

As for preprocessing, we replace long non-space character chains for only one occurrence, and delete digits, special symbols, and URLs.

5.1 Results

Table 3 reports on the results of the different models on the two tasks. On both tasks, all models show satisfactory performances when detecting overt forms of HS (Explicit HS and Non-Subtle HS classes), with DeBERTa outperforming the other models. The results obtained by all models for the Implicit HS and Subtle HS classes are much lower, and comparable to those obtained by ElSherief et al. (2021) (F1-score=.586) on the implicit class.

As a follow-up experiment, we apply the oversampling techniques (Section 4) on the minority classes of tasks A and B until balancing them with respect to the Explicit HS and Non-Subtle HS categories. The oversampling is performed on the training set only. The test set is the one of the original dataset, and is therefore unbalanced in order to evaluate the system on real class distribution and to avoid information leakage from train to test through augmentation methods. Tables 4a and 4b show the number of additional generated implicit/subtle messages and the resultant training set distribution per augmentation method, respectively.

Among all tested models, only HateBERT significantly improves its performance for detecting implicit messages combining all augmented data (ALL) (see Table 3). We also highlight that back translation (BT) better contributes to the performance on the implicit hate class for BERT, DeBERTa, and USE+SVM [2]. Performances surprisingly increase for the subtle class with USE+SVM+BT showing that back-translated messages provide diversity by rephrasing subtle examples without altering their meaning. Data generated with simpler augmentation methods as BERT+RNE and DeBERTa+RI also show slight improvements for subtlety. However, performances decrease on the implicit class when applying data augmentation strategies GM and GM+Revised, and only slightly improve on the subtle class.

5.2 Error Analysis

To gain insights into the models' behaviours, we manually analyse the classification errors of the best performing approaches, i.e., HateBERT+ALL and USE+SVM+BT for both tasks A and B. For the Non-HS/Explicit/Implicit classification, it is harder for HateBERT+ALL to differentiate implicit messages rather than explicit ones. Figure 1 in Appendix A shows the resultant embedding through t-SNE (van der Maaten and Hinton, 2008) approximation of all implicit messages of the test set, and two samples of the other two classes, showing how HateBERT+ALL is capable of separating the space in three different blobs for classification (Figure 1a), embedding well the human-annotated Explicit HS and Non-HS classes (Figure 1b), but badly encoding implicit annotated messages (instances spread over the explicit and non-hateful blobs). We also considered the F1-scores of the (Non-HS vs Implicit HS) and (Non-HS vs Explicit HS) classes, as if we had binary labels, obtaining an (F1-score=0.670) and (F1-score=0.850) on the target categories respectively, showing that implicit cases are harder to detect than explicit ones.

Among misclassified examples, we can find messages where the PC are not explicitly named (Example 16). Contextual knowledge is needed there to grasp that the target of the message is black people.

16. *I can picture him as that baby monkey on the ' save the rainforest comercial or whatever*

Additionally, from the misclassified messages we extract the most frequent implicit properties not captured by the classifier[3]. They concern Inference (53%), Context (41%), Sentiment (40%), Exaggeration (24%), Extralinguistic knowledge (24%).

For Subtle/Non Subtle message classification, we also plotted the USE embedding for the best

---

Table 4: Statistics on the train set with data augmentation.

model on this task (Figure 2 in Appendix A). However, it can be seen that USE+SVM+BT could not differentiate correctly on the subtle notion despite of the results reported in Table 6b. Example 17 is not predicted as subtle. It shows how the word order may influence our understanding. At a first glance, the part how stupid the Jews seems to have a different meaning from what the phrase actually conveys if we read it entirely. We may also notice a circumlocution in the second part of the message.

17. *I am insulted by how stupid the jews think we are until i see what they see by reading the posts amongst our so called , ' ' awakened brethren .*

6 Conclusions

In this paper, we have presented ISHate, the first benchmark dataset annotated with both implicit and subtle HS labels, which represents a challenging test-bed to evaluate computational approaches. We also provide a fine-grained annotation for implicit HS messages with 18 implicit properties which represent the relevant features that HS classifiers should possess to improve implicit HS detection. It has been created enriching 7 existing datasets for HS detection over different topics and from different social media. We have shown that current SOTA models fail to properly detect implicit and subtle HS messages as peculiar features connected to Sentiment, Inference, Context and Irony, as well as complex syntactic structure, cannot be properly understood. We also investigated data augmentation strategies to increase the number of instances for the minority classes. We show that - while they cannot be the ultimate solution to the lack of implicit and subtle examples - they still play a role in improving the systems' performances, in line with ElSherief et al. (2021). As for future work, we plan to propose alternative large-scale methods to collect implicit and subtle messages by targeting "hateful" users, manual creation (Wiegand et al., 2021a, 2022) or refining human-in-the-loop generative methods as in (Hartvigsen et al., 2022). Also, we will investigate features modeling implicit properties (Wallace et al., 2014; Troiano et al., 2018; Frenda and Patti, 2019) and new model architectures for HS detection (Nejadgholi et al., 2022).

Limitations

The main limitation of this paper lies in the intrinsic difficulty to provide a clear definition of the notions of Implicit HS and Subtle HS (given the limited number of definitions available in the literature for these notions), and, as a consequence, to build annotated resources. Enhancing the ISHate dataset with new instances requires future annotators to be experts in computational linguistics trained on our annotation guidelines through pilot annotations to keep the same level of agreement. This restricts crowdsourcing-like options, making the resource building process more expensive. Moreover, the complexity of the messages and of the considered categories makes the process time-consuming (i.e., a trained annotator requires 30sec. for explicit messages and 1.30min. for implicit/subtle messages on average). Even opting for generative and synthetic data augmentation approaches, they still require human-in-the-loop intervention and high computational resources to generate Implicit/Subtle HS messages on a big scale.

Ethics Statement

This paper contains examples of HS from existing linguistic resources for HS detection and which do not reflect the authors' opinions.

While our purpose is to prevent and curate social media resources from HS, the release of this dataset might still pose a potential misuse case. However, we still consider that effective classifiers for this task are necessary to tackle implicit and subtle online hate on scale and prevent the spreading of this harmful content online. Our work aims at making a step towards that objective and encourages the scientific community to investigate these aspects.

A Performance Details in Data Augmentation

Inspired by the ranked one augmentation strategy in ElSherief et al. (2021), i.e., a back-translation approach, we also test SOTA models on our dataset, ISHate, with the augmentation techniques described in Section 4.4. Each model is trained with the originally collected data described in Section 4.3 and additional data obtained from one augmentation strategy. At the end, we also evaluate each model using only non-augmented test data. Tables 6a and 6b show the experiments' results on tasks A and B.

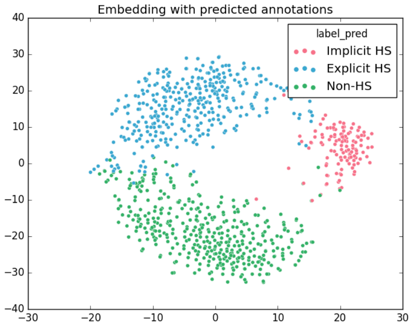
We further analyse the errors committed by the best performing model on task A. We took from Table 6a HateBERT+ALL and the third annotation layer described in Sections 3 and 4 to identify which are the most frequent implicit properties on task A miss-classified messages. Table 5 shows how Inference, Context, Sentiment, Exaggeration, and Extralinguistic knowledge are the most recurrent not captured devices.

	Implicit HS	
Implicit Property	#	%
Inference	44	53.659
Context	34	41.463
Sentiment	33	40.244
Exaggeration	23	28.049
Extralinguistic knowledge	20	24.390
Irony	17	20.732
Black humor	12	14.634
Visual signs	11	13.415
Metaphor	9	10.976
Rhetorical question	8	9.756
Antithesis	6	7.317
Humiliation	5	6.098
Sarcasm	5	6.098
Circumlocution	4	4.878
Fallacy	4	4.878
Euphemism	3	3.659

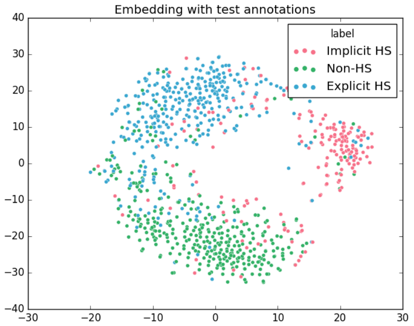
Table 5: Implicit properties of the messages that are not captured by HateBERT+ALL

.

We also analysed the embeddings of our best-performing models in tasks A and B (HateBERT+ALL and USE+SVM+BT, respectively) through t-SNE (van der Maaten and Hinton, 2008). Figures 1 and 2 show the text embeddings for sentences of the test set, labeled by both classifiers and annotators, for the implicit and subtle tasks.

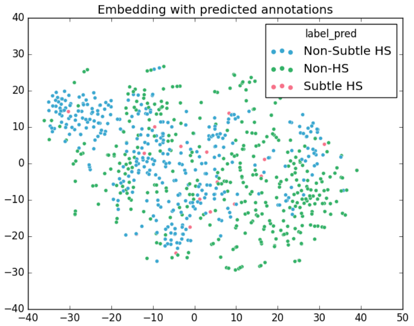


(a) Embedding using predicted annotations.

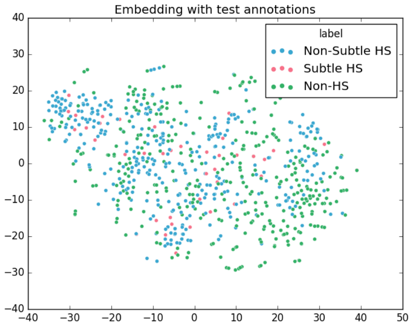


(b) Embedding using manual annotations.

Figure 1: Embedding of HateBERT + ALL in the test set of task A



(a) Embedding using predicted annotations.



(b) Embedding using manual annotations.

Figure 2: Embedding of USE+SVM+BT in the test set of task B

(b) Results of SOTA models using data augmentation on task B.

Table 6: Obtained results on tasks A and B by all models and different types of augmented data.

B Implicit Properties

In the following part, we provide a list of implicit properties with their definitions. All the examples illustrating implicit properties are used in implicit hateful messages and their descriptions are presented in the annotation guidelines.

Antithesis – the rhetorical contrast of ideas through parallel arrangements of words, clauses, or sentences (as in "action, not words" or "they promised freedom and provided slavery") (Merriam-Webster, 2022)

Black humor – humor marked by the use of usually morbid, ironic, grotesquely comic episodes; humor treating sinister subjects like death, disease, deformity, handicap or warfare with bitter amusement (Willinger et al., 2017)

Circumlocution – the use of an unnecessarily large number of words to express an idea (Merriam-Webster, 2022)

Context – the parts of a discourse that surround a word or passage and can throw light on its meaning (Dadvar et al., 2013)

Euphemism – the substitution of an agreeable or inoffensive expression for one that may suggest something unpleasant (Casas Gómez, 2009)

Exaggeration (hyperbole) – an act or instance of exaggerating something: overstatement of the truth (Troiano et al., 2018)

Extralinguistic knowledge – any knowledge that exists outside knowledge of the language. In other words, it refers to knowledge that an author or a recipient of a message may possess about the message itself or about the world, but which is not expressed by any linguistic means.

Fallacy – a false or mistaken idea; an often plausible argument using false or invalid inference (Merriam-Webster, 2022)

Humiliation – the embarrassment and shame a person feels when someone makes them appear stupid or when they make a mistake in public (Dictionary, 2022)

Inference – something that is inferred. The premises and conclusion of a process of inferring (Merriam-Webster, 2022)

Irony – the use of words to express something other than and especially the opposite of the literal meaning; incongruity between the actual result of a sequence of events and the normal or expected result (Potamias et al., 2020)

Metaphor – a figure of speech in which a word or phrase literally denoting one kind of object or idea is used in place of another to suggest a likeness or analogy between them (Choi et al., 2021; Gao et al., 2018)

Metonymy – a figure of speech consisting of the use of the name of one thing for that of another of which it is an attribute or with which it is associated (such as "crown" in "lands belonging to the crown") (Merriam-Webster, 2022)

Rhetorical question – a question not intended to require an answer, used mainly for dramatic effect (Frank, 1990)

Sarcasm – a mode of satirical wit depending on its effect on bitter, caustic, and often ironic language usually directed against an individual. Sarcasm differs from irony with one distinct characteristic: negativity. Sarcasm is mostly witty mockery having a negative connotation whereas irony does not represent negativity (Potamias et al., 2020)

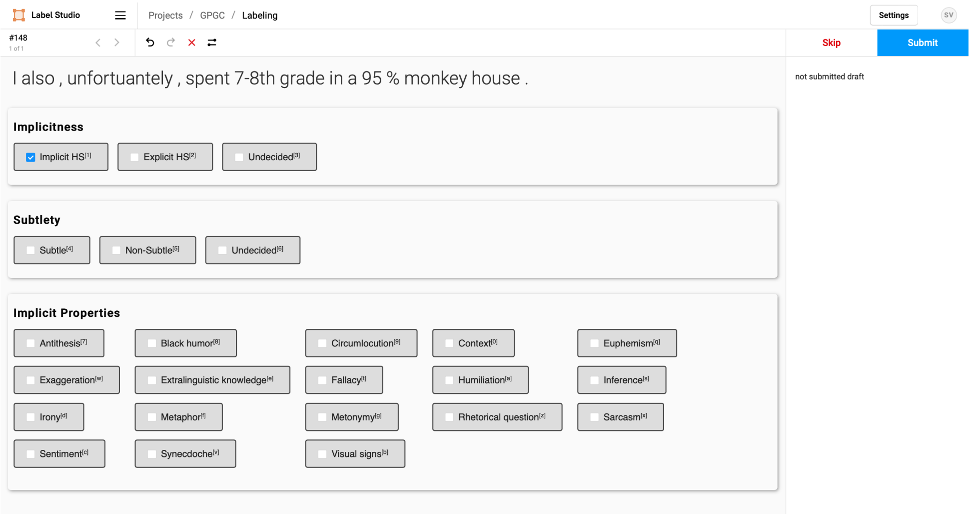
Sentiment – an attitude, thought, or judgment prompted by feeling; the emotional significance of a passage or expression as distinguished from its verbal context (Li et al., 2021)

Synecdoche – a figure of speech by which a part is put for the whole, the whole for a part, the species for the genus, the genus for the species, or the name of the material for the thing made (Merriam-Webster, 2022)

Visual signs – punctuation marks, quotes, and use of uppercase that play a role of support in hate messages.

C Annotation Tool Interface

Figure 3a demonstrates a screenshot of the annotation interface of the Label Studio tool used for the labeling process. According to the annotation scheme represented by three annotation layers (discussed in Section 3 and Subsection 4.2) Label Studio has three consecutive annotation steps. The first step consists in implicitness with three choices: Implicit HS, Explicit HS, Undecided, keeping in mind that the tool allows to filter Non-Hate out before starting the labeling process. The first choice of Implicit HS or Explicit HS brings in the appearance of the second step of subtlety with three choices: Subtle, Non-Subtle, Undecided. This step does not appear with an Undecided choice at the previous step. As well as that, the choice of Implicit HS triggers the appearance of the third step which consists of implicit properties being characteristic of only implicit messages. Figure 3b shows the shape of the resultant dataset after annotation.



I also , unfortuantely , spent 7-8th grade in a 95 % monkey house .

The annotation layer *hateful_layer* (Non-HS/HS) consists of the already provided labels of each HS corpus, with the exception of the Youtube dataset where we re-annotated it.

MTEB: Massive Text Embedding Benchmark

Niklas Muennighoff[1], **Nouamane Tazi**[1], **Loïc Magne**[1], **Nils Reimers**[2]*
[1]Hugging Face [2]cohere.ai
[1]`firstname@huggingface.co` [2]`info@nils-reimers.de`

Abstract

Text embeddings are commonly evaluated on a small set of datasets from a single task not covering their possible applications to other tasks. It is unclear whether state-of-the-art embeddings on semantic textual similarity (STS) can be equally well applied to other tasks like clustering or reranking. This makes progress in the field difficult to track, as various models are constantly being proposed without proper evaluation. To solve this problem, we introduce the Massive Text Embedding Benchmark (MTEB). MTEB spans 8 embedding tasks covering a total of 58 datasets and 112 languages. Through the benchmarking of 33 models on MTEB, we establish the most comprehensive benchmark of text embeddings to date. We find that no particular text embedding method dominates across all tasks. This suggests that the field has yet to converge on a universal text embedding method and scale it up sufficiently to provide state-of-the-art results on all embedding tasks. MTEB comes with open-source code and a public leaderboard at `https://github.com/embeddings-benchmark/mteb`.

1 Introduction

Natural language embeddings power a variety of use cases from clustering and topic representation (Aggarwal and Zhai, 2012; Angelov, 2020) to search systems and text mining (Huang et al., 2020; Zhu et al., 2021; Nayak, 2019) to feature representations for downstream models (Saharia et al., 2022; Borgeaud et al., 2022). Using generative language models or cross-encoders for these applications is often intractable, as they may require exponentially more computations (Reimers and Gurevych, 2019).

However, the evaluation regime of current text embedding models rarely covers the breadth of their possible use cases. For example, SimCSE (Gao et al., 2021b) or SBERT (Reimers and Gurevych, 2019) solely evaluate on STS and classification tasks, leaving open questions about the transferability of the embedding models to search or clustering tasks. STS is known to poorly correlate with other real-world use cases (Neelakantan et al., 2022; Wang et al., 2021). Further, evaluating embedding methods on many tasks requires implementing multiple evaluation pipelines. Implementation details like pre-processing or hyperparameters may influence the results making it unclear whether performance improvements simply come from a favorable evaluation pipeline. This leads to the "blind" application of these models to new use cases in industry or requires incremental work to reevaluate them on different tasks.

The Massive Text Embedding Benchmark (MTEB) aims to provide clarity on how models perform on a variety of embedding tasks and thus serves as the gateway to finding universal text embeddings applicable to a variety of tasks. MTEB consists of 58 datasets covering 112 languages from 8 embedding tasks: Bitext mining, classification, clustering, pair classification, reranking, retrieval, STS and summarization. MTEB software is available open-source[1] enabling evaluation of any embedding model by adding less than 10 lines of code. Datasets and the MTEB leaderboard are available on the Hugging Face Hub[2].

We evaluate over 30 models on MTEB with additional speed and memory benchmarking to provide a holistic view of the state of text embedding models. We cover both models available open-source as well as models accessible via APIs, such as the OpenAI Embeddings endpoint. We find there to be no single best solution, with different models dominating different tasks. Our benchmarking sheds light on the weaknesses and strengths of individual

models, such as SimCSE's (Gao et al., 2021b) low performance on clustering and retrieval despite its strong performance on STS. We hope our work makes selecting the right embedding model easier and simplifies future embedding research.

2 Related Work

2.1 Benchmarks

Benchmarks, such as (Super)GLUE (Wang et al., 2018, 2019) or Big-BENCH (Srivastava et al., 2022), and evaluation frameworks (Gao et al., 2021a) play a key role in driving NLP progress. Yearly released SemEval datasets (Agirre et al., 2012, 2013, 2014, 2015, 2016) are commonly used as the go-to benchmark for text embeddings. SemEval datasets correspond to the task of semantic textual similarity (STS) requiring models to embed similar sentences with geometrically close embeddings. Due to the limited expressivity of a single SemEval dataset, SentEval (Conneau and Kiela, 2018) aggregates multiple STS datasets. SentEval focuses on fine-tuning classifiers on top of embeddings. It lacks tasks like retrieval or clustering, where embeddings are directly compared without additional classifiers. Further, the toolkit was proposed in 2018 and thus does not provide easy support for recent trends like text embeddings from transformers (Reimers and Gurevych, 2019). Due to the insufficiency of STS benchmarking, USEB (Wang et al., 2021) was introduced consisting mostly of reranking tasks. Consequently, it does not cover tasks like retrieval or classification. Meanwhile, the recently released BEIR Benchmark (Thakur et al., 2021) has become the standard for the evaluation of embeddings for zero-shot information retrieval.

MTEB unifies datasets from different embedding tasks into a common, accessible evaluation framework. MTEB incorporates SemEval datasets (STS11 - STS22) and BEIR alongside a variety of other datasets from various tasks to provide a holistic performance review of text embedding models.

2.2 Embedding Models

Text embedding models like Glove (Pennington et al., 2014) lack context awareness and are thus commonly labeled as Word Embedding Models. They consist of a layer mapping each input word to a vector often followed by an averaging layer to provide a final embedding invariant of input length. Transformers (Vaswani et al., 2017) inject context awareness into language models via self-attention and form the foundation of most recent embedding models. BERT (Devlin et al., 2018) uses the transformer architecture and performs large-scale self-supervised pre-training. The resulting model can directly be used to produce text embeddings via an averaging operation alike Glove. Building on InferSent (Conneau et al., 2017), SBERT (Reimers and Gurevych, 2019) demonstrated it to be beneficial to perform additional fine-tuning of the transformer for competitive embedding performance. Most recent fine-tuned embedding models use a contrastive loss objective to perform supervised fine-tuning on positive and negative text pairs (Gao et al., 2021b; Wang et al., 2021; Ni et al., 2021b; Muennighoff, 2022). Due to the large variety of available pre-trained transformers (Wolf et al., 2020), there is an at least equally large variety of potential text embedding models to be explored. This leads to confusion about which model provides practitioners with the best performance for their embedding use case.

We benchmark both word embedding and transformer models on MTEB quantifying gains provided by often much slower context aware models.

3 The MTEB Benchmark

3.1 Desiderata

MTEB is built on a set of desiderata: **(a) Diversity:** MTEB aims to provide an understanding of the usability of embedding models in various use cases. The benchmark comprises 8 different tasks, with up to 15 datasets each. Of the 58 total datasets in MTEB, 10 are multilingual, covering 112 different languages. Sentence-level and paragraph-level datasets are included to contrast performance on short and long texts. **(b) Simplicity:** MTEB provides a simple API for plugging in any model that given a list of texts can produce a vector for each list item with a consistent shape. This makes it possible to benchmark a diverse set of models. **(c) Extensibility:** New datasets for existing tasks can be benchmarked in MTEB via a single file that specifies the task and a Hugging Face dataset name where the data has been uploaded (Lhoest et al., 2021). New tasks require implementing a task interface for loading the data and an evaluator for benchmarking. We welcome dataset, task or metric contributions from the community via pull requests to continue the development of MTEB. **(d) Reproducibility:** Through versioning at a dataset and software level, we aim to make it easy to repro-

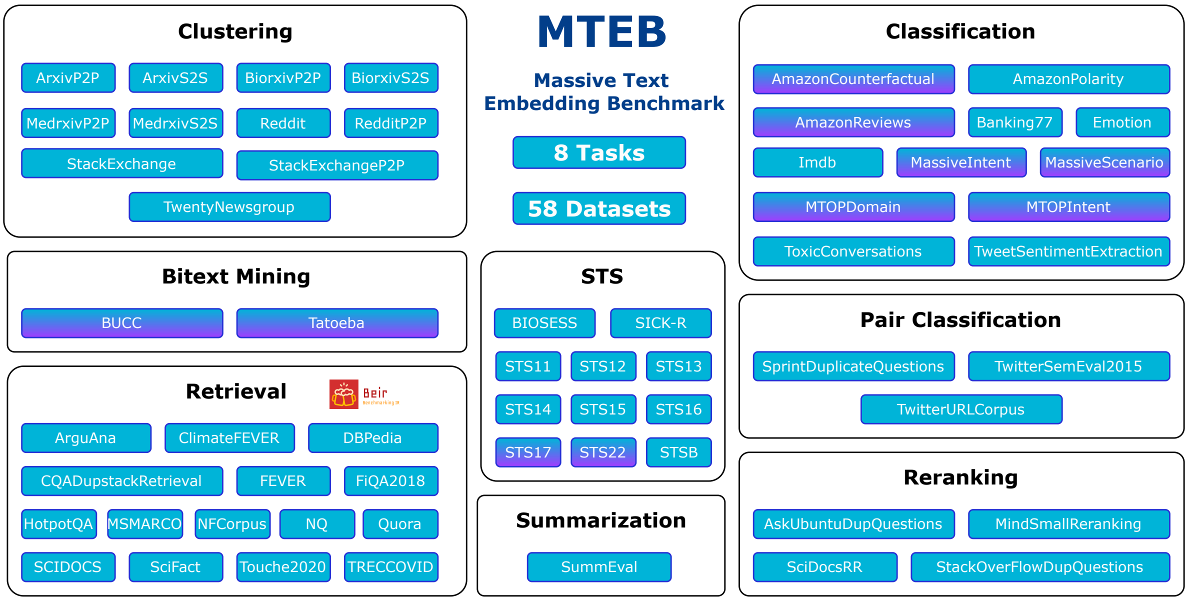

Figure 1: An overview of tasks and datasets in MTEB. Multilingual datasets are marked with a purple shade.

duce results in MTEB. JSON files corresponding to all results available in this paper have been made available together with the MTEB benchmark[3].

3.2 Tasks and Evaluation

Figure 1 provides an overview of tasks and datasets available in MTEB. Dataset statistics are available in Table 2. The benchmark consists of the following 8 task types:

Bitext Mining Inputs are two sets of sentences from two different languages. For each sentence in the first set, the best match in the second set needs to be found. The matches are commonly translations. The provided model is used to embed each sentence and the closest pairs are found via cosine similarity. F1 serves as the main metric for bitext mining. Accuracy, precision and recall are also computed.

Classification A train and test set are embedded with the provided model. The train set embeddings are used to train a logistic regression classifier with 100 maximum iterations, which is scored on the test set. The main metric is accuracy with average precision and f1 additionally provided.

Clustering Given a set of sentences or paragraphs, the goal is to group them into meaningful clusters. A mini-batch k-means model with batch size 32 and k equal to the number of different labels (Pedregosa et al., 2011) is trained on the embedded texts. The model is scored using v-measure (Rosenberg and Hirschberg, 2007). V-measure does not depend on the cluster label, thus the permutation of labels does not affect the score.

Pair Classification A pair of text inputs is provided and a label needs to be assigned. Labels are typically binary variables denoting duplicate or paraphrase pairs. The two texts are embedded and their distance is computed with various metrics (cosine similarity, dot product, euclidean distance, manhattan distance). Using the best binary threshold accuracy, average precision, f1, precision and recall are computed. The average precision score based on cosine similarity is the main metric.

Reranking Inputs are a query and a list of relevant and irrelevant reference texts. The aim is to rank the results according to their relevance to the query. The model is used to embed the references which are then compared to the query using cosine similarity. The resulting ranking is scored for each query and averaged across all queries. Metrics are mean MRR@k and MAP with the latter being the main metric.

Retrieval Each dataset consists of a corpus, queries and a mapping for each query to relevant documents from the corpus. The aim is to find these relevant documents. The provided model is used

---

[3] `https://huggingface.co/datasets/mteb/results`

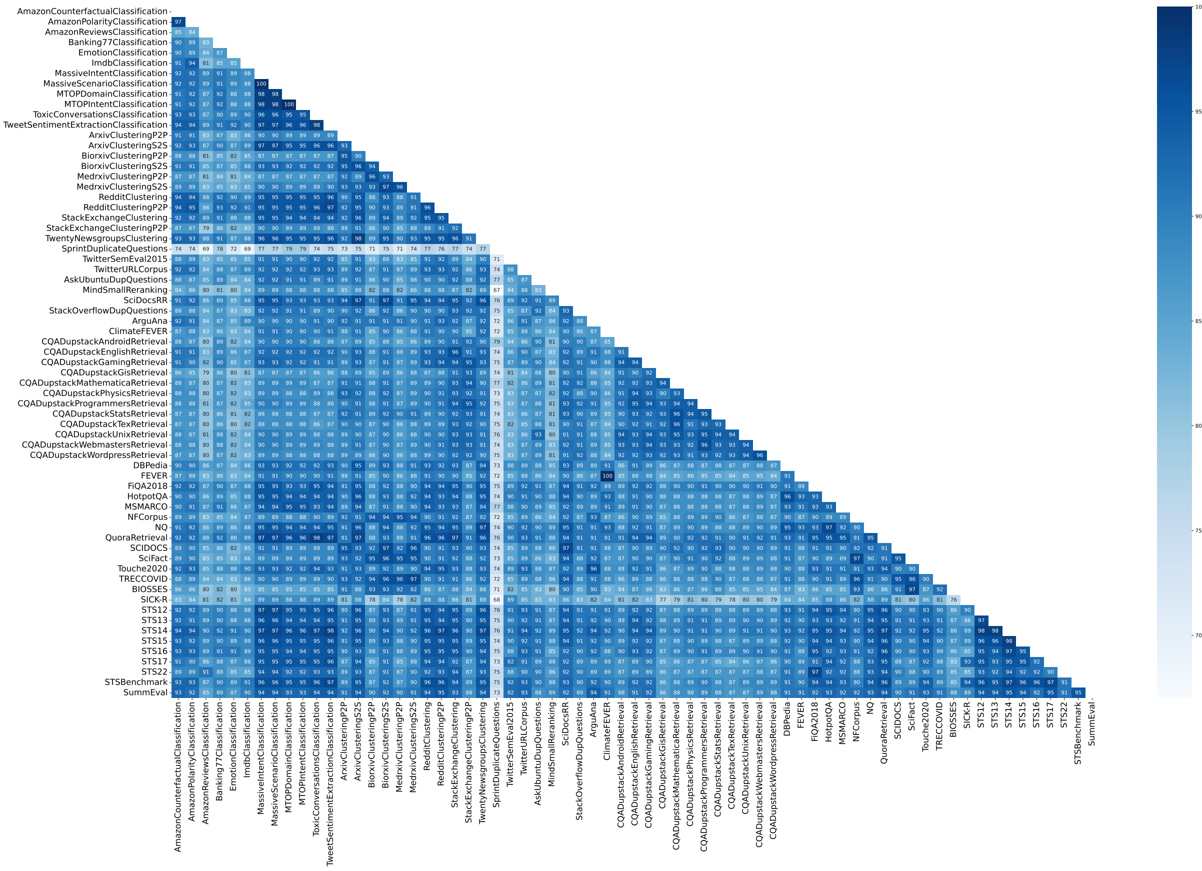

Figure 2: Similarity of MTEB datasets. We use the best model on MTEB STS (ST5-XXL, see Table 1) to embed 100 samples for each dataset. Cosine similarities between the averaged embeddings are computed and visualized.

to embed all queries and all corpus documents and similarity scores are computed using cosine similarity. After ranking the corpus documents for each query based on the scores, nDCG@k, MRR@k, MAP@k, precision@k and recall@k are computed for several values of k. nDCG@10 serves as the main metric. MTEB reuses datasets and evaluation from BEIR (Thakur et al., 2021).

Semantic Textual Similarity (STS) Given a sentence pair the aim is to determine their similarity. Labels are continuous scores with higher numbers indicating more similar sentences. The provided model is used to embed the sentences and their similarity is computed using various distance metrics. Distances are benchmarked with ground truth similarities using Pearson and Spearman correlations. Spearman correlation based on cosine similarity serves as the main metric (Reimers et al., 2016).

Summarization A set of human-written and machine-generated summaries are provided. The aim is to score the machine summaries. The provided model is first used to embed all summaries. For each machine summary embedding, distances to all human summary embeddings are computed. The closest score (e.g. highest cosine similarity) is kept and used as the model's score of a single machine-generated summary. Pearson and Spearman correlations with ground truth human assessments of the machine-generated summaries are computed. Like for STS, Spearman correlation based on cosine similarity serves as the main metric (Reimers et al., 2016).

3.3 Datasets

To further the diversity of MTEB, datasets of varying text lengths are included. All datasets are grouped into three categories:

Sentence to sentence (S2S) A sentence is compared with another sentence. An example of S2S are all current STS tasks in MTEB, where the similarity between two sentences is assessed.

Paragraph to paragraph (P2P) A paragraph is compared with another paragraph. MTEB imposes no limit on the input length, leaving it up to the

Table 1: Average of the main metric (see Section 3.2) per task per model on MTEB English subsets.

models to truncate if necessary. Several clustering tasks are framed as both S2S and P2P tasks. The former only compare titles, while the latter include both title and content. For ArxivClustering, for example, abstracts are concatenated to the title in the P2P setting.

Sentence to paragraph (S2P) A few retrieval datasets are mixed in a S2P setting. Here a query is a single sentence, while documents are long paragraphs consisting of multiple sentences.

Similarities across 56 MTEB datasets are visualized in Figure 2. Several datasets rely on the same corpora, such as ClimateFEVER and FEVER, resulting in a score of 1. Clusters of similar datasets can be seen among CQADupstack variations and STS datasets. S2S and P2P variations of the same dataset tend to also be similar. Scientific datasets, such as SciDocsRR, SciFact, ArxivClustering, show high similarities among each other even when coming from different tasks (Reranking, Retrieval and Clustering in this case).

4 Results

4.1 Models

We evaluate on the test splits of all datasets except for MSMARCO, where the dev split is used following Thakur et al. (2021). We benchmark models claiming state-of-the-art results on various embedding tasks leading to a high representation of transformers (Vaswani et al., 2017). We group models into self-supervised and supervised methods.

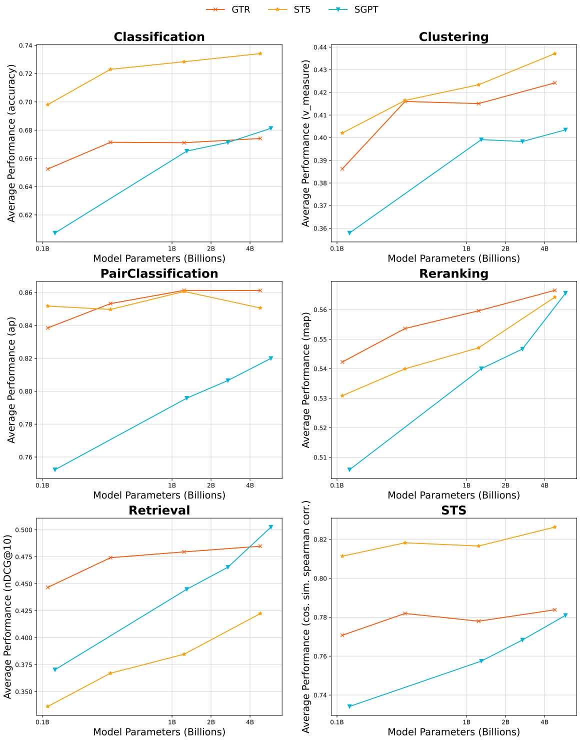

Figure 3: MTEB performance scales with model size. The smallest SGPT variant underperforms similar-sized GTR and ST5 variants. This may be due to the bias-only fine-tuning SGPT employs, which catches up with full fine-tuning only as model size and thus the number of bias parameters increases (Muennighoff, 2022).

Self-supervised methods (a) Transformer-based BERT (Devlin et al., 2018) is trained using self-supervised mask and sentence prediction tasks. By taking the mean across the sequence length (mean-pooling) the model can directly be used to produce text embeddings. SimCSE-Unsup (Gao et al., 2021b) uses BERT as a foundation and performs additional self-supervised training. **(b) Non-transformer**: Komninos (Komninos and Manandhar, 2016) and Glove (Pennington et al., 2014) are two word embedding models that directly map words to vectors. Hence, their embeddings lack context awareness, but provide significant speed-ups.

Supervised methods The original transformer model (Vaswani et al., 2017) consists of an encoder and decoder network. Subsequent transformers often train only encoders like BERT (Devlin et al., 2018) or decoders like GPT (Radford et al., 2019).

(a) Transformer encoder methods coCondenser (Gao and Callan, 2021), Contriever (Izacard et al., 2021), LaBSE (Feng et al., 2020) and SimCSE-BERT-sup (Gao et al., 2021b) are based on the pre-trained BERT model (Devlin et al., 2018). coCondenser and Contriever add a self-supervised stage prior to supervised fine-tuning for a total of three training stages. LaBSE uses BERT to perform additional pre-training on parallel data to produce a competitive bitext mining model. SPECTER (Cohan et al., 2020a) relies on the pre-trained SciBERT (Beltagy et al., 2019) variant instead and fine-tunes on citation graphs. GTR (Ni et al., 2021b) and ST5 (Ni et al., 2021a) are based on the encoder part of the T5 model (Raffel et al., 2020) and only differ in their fine-tuning datasets. After additional self-supervised training, ST5 does contrastive fine-tuning on NLI (Ni et al., 2021a; Gao et al., 2021b) being geared towards STS tasks. Meanwhile, GTR fine-tunes on MS-MARCO and focuses on retrieval tasks. MPNet and MiniLM correspond to fine-tuned embedding models (Reimers and Gurevych, 2019) of the pre-trained MPNet (Song et al., 2020) and MiniLM (Wang et al., 2020) models using diverse datasets to target any embedding use case.

(b) Transformer decoder methods SGPT Bi-Encoders (Muennighoff, 2022) perform contrastive fine-tuning of <0.1% of pre-trained parameters using weighted-mean pooling. Similar to ST5 and GTR, SGPT-nli models are geared towards STS, while SGPT-msmarco models towards retrieval. SGPT-msmarco models embed queries and documents for retrieval with different special tokens to help the model distinguish their role. For non-retrieval tasks, we use its query representations. We benchmark publicly available SGPT models based on GPT-NeoX (Andonian et al., 2021), GPT-J (Wang and Komatsuzaki, 2021) and BLOOM (Scao et al., 2022). Alternatively, cpt-text (Neelakantan et al., 2022) passes pre-trained GPT decoders through a two-stage process using last token pooling to provide embeddings from decoders. We benchmark their models via the OpenAI Embeddings API[4].

(c) Non-transformer LASER (Heffernan et al., 2022) is the only context aware non-transformer model we benchmark, relying on an LSTM (Hochreiter and Schmidhuber, 1997) instead. Similar to LaBSE, the model trains on parallel data and focuses on bitext mining applications.

---

[4] `https://beta.openai.com/docs/guides/embeddings`

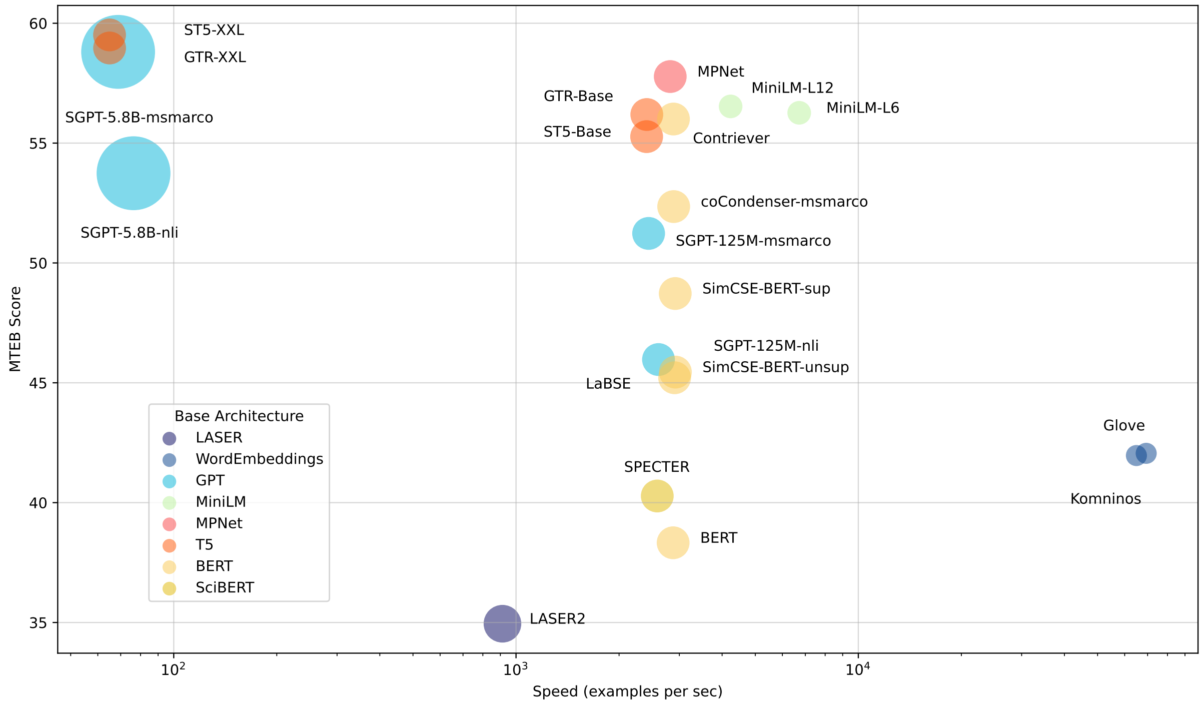

Figure 4: Performance, speed, and size of produced embeddings (size of the circles) of different embedding models. Embedding sizes range from 1.2 kB (Glove / Komninos) to 16.4 kB (SGPT-5.8B) per example. Speed was benchmarked on STS15 using 1x Nvidia A100 80GB with CUDA 11.6.

4.2 Analysis

Based on the results in Table 1, we observe that there is considerable variability between tasks. No model claims the state-of-the-art in all seven English tasks. There is even more variability in the results per dataset present in the appendix. Further, there remains a large gap between self-supervised and supervised methods. Self-supervised large language models have been able to close this gap in many natural language generation tasks (Chowdhery et al., 2022). However, they appear to still require supervised fine-tuning for competitive embedding performance.

We find that performance strongly correlates with model size, see Figure 3. A majority of MTEB tasks are dominated by multi-billion parameter models. However, these come at a significant cost as we investigate in Section 4.3.

Classification ST5 models dominate the classification task across most datasets, as can be seen in detail in the full results in the appendix. ST5-XXL has the highest average performance, 3% ahead of the best non-ST5 model, Ada Similarity.

Clustering Despite being almost 50x smaller, the MPNet embedding model is on par with the ST5-XXL state-of-the-art on Clustering. This may be due to the large variety of datasets MPNet (and MiniLM) has been fine-tuned on. Clustering requires coherent distances between a large number of embeddings. Models like SimCSE-sup or SGPT-nli, which are only fine-tuned on a single dataset, NLI, may produce incoherent embeddings when encountering topics unseen during fine-tuning. Relatedly, we find that the query embeddings of SGPT-msmarco and the Ada Search endpoint are competitive with SGPT-nli and the Ada Similarity endpoint, respectively. We refer to the public leaderboard[5] for Ada Search results. This could be due to the MSMARCO dataset being significantly larger than NLI. Thus, while the OpenAI docs recommend using the similarity embeddings for clustering use cases[6], the retrieval query embeddings may be the better choice in some cases.

Pair Classification GTR-XL and GTR-XXL have the strongest performance. Pair classification is closest to STS in its framing, yet models rank significantly differently on the two tasks. This

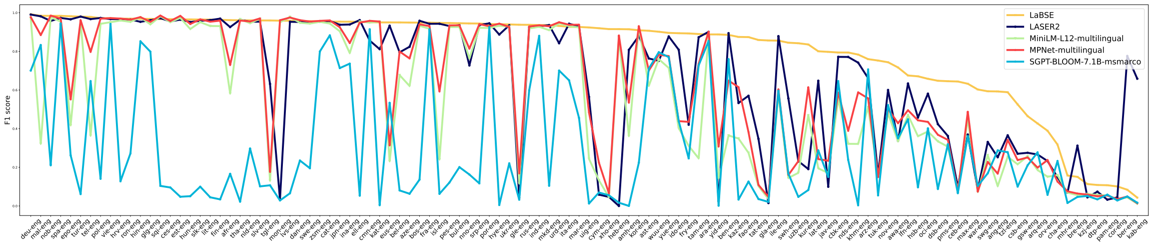
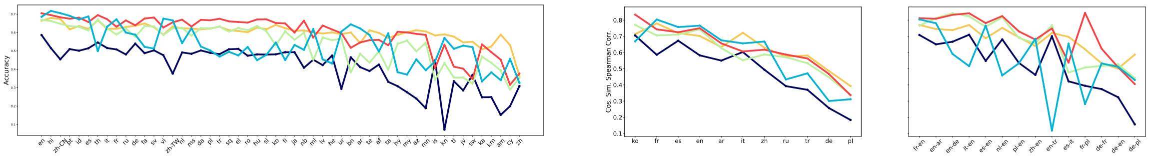
[6] `https://beta.openai.com/docs/guides/embeddings/similarity-embeddings`



(a) Bitext Mining on Tatoeba



(b) Multilingual Classification

(c) Multi- and Crosslingual STS

Figure 5: MTEB multilingual performance. Bitext mining is dominated by LaBSE, while classification and STS results are mixed. SGPT-BLOOM-7B1-msmarco tends to perform well on the languages BLOOM has been pre-trained on, such as Chinese, French and Portuguese.

highlights the importance of benchmarking on a diverse set of tasks to avoid blindly reusing a model for a different task.

Reranking MPNet and MiniLM models perform strongly on reranking tasks. On SciDocsRR (Cohan et al., 2020a) they perform far better than bigger models, which is likely due to parts of SciDocsRR being included in their training data. Our scale of experiments and that of model pre-training make controlling for data contamination challenging. Thus, we ignore overlap of MTEB datasets with model training datasets in MTEB scores. As long as enough datasets are averaged, we believe these effects to be insignificant.

Retrieval SGPT-5.8B-msmarco is the best embedding model on the BEIR subset in MTEB as well as on the full BEIR benchmark (Thakur et al., 2021; Muennighoff, 2022). The even larger 7.1B SGPT model making use of BLOOM (Scao et al., 2022) performs significantly weaker, which is likely due to the multilinguality of BLOOM. Models geared towards STS (SimCSE, ST5, SGPT-nli) perform badly on retrieval tasks. Retrieval tasks are unique in that there are two distinct types of texts: Queries and documents ("asymmetric"), while other tasks only have a single type of text ("symmetric"). On the QuoraRetrieval dataset, which has been shown to be largely symmetric (Muennighoff, 2022), the playing field is more even with SGPT-5.8B-nli outperforming SGPT-5.8B-msmarco, see Table 11.

STS & Summarization Retrieval models (GTR, SGPT-msmarco) perform badly on STS, while ST5-XXL has the highest performance. This highlights the bifurcation of the field into separate embedding models for retrieval (asymmetric) and similarity (symmetric) use cases (Muennighoff, 2022).

4.3 Efficiency

We investigate the latency-performance trade-off of models in Figure 4. The graph allows for significant elimination of model candidates in the model selection process. It brings model selection down to three clusters:

Maximum speed Word Embedding models offer maximum speed with Glove taking the lead on both performance and speed, thus making the choice simple in this case.

Maximum performance If latency is less important than performance, the left-hand side of the graph offers a cluster of highly performant, but slow models. Depending on the task at hand, GTR-XXL, ST5-XXL or SGPT-5.8B may be the right choice, see Section 4.2. SGPT-5.8B comes with the additional caveat of its high-dimensional embeddings requiring more storage.

Speed and performance The fine-tuned MPNet and MiniLM models lead the middle cluster making the choice easy.

4.4 Multilinguality

MTEB comes with 10 multilingual datasets across bitext mining, classification and STS tasks. We investigate performance on these in Figure 5. Tabular results can be found in Tables 12, 13 and 14.

Bitext Mining LaBSE (Feng et al., 2020) performs strongly across a wide array of languages in bitext mining. Meanwhile, LASER2 shows high variance across different languages. While there are additional language-specific LASER2 models available for some of the languages we benchmark, we use the default multilingual LASER2 model for all languages. This is to provide a fair one-to-one comparison of models. In practice, however, the high variance of LASER2's performance may be resolved by mixing its model variants. MPNet, MiniLM and SGPT-BLOOM-7B1-msmarco perform poorly on languages they have not been pre-trained on, such as German for the latter.

Classification & STS On multilingual classification and STS, the multilingual MPNet provides the overall strongest performance. It outperforms the slightly faster multilingual MiniLM on almost all languages. Both models have been trained on the same languages, thus bringing decision-making down to performance vs speed. SGPT-BLOOM-7B1-msmarco provides state-of-the-art performance on languages like Hindi, Portuguese, Chinese or French, which the model has seen extensively during pre-training. It also performs competitively on languages like Russian or Japanese that unintentionally leaked into its pre-training data (Muennighoff et al., 2022). However, it is not much ahead of the much cheaper MPNet. LASER2 performs consistently worse than other models.

5 Conclusion

In this work, we presented the Massive Text Embedding Benchmark (MTEB). Consisting of 8 text embedding tasks with up to 15 datasets each and covering 112 languages, MTEB aims to provide reliable embedding performance estimates. By open-sourcing MTEB alongside a leaderboard, we provide a foundation for further pushing the state-of-the-art of available text embeddings.

To introduce MTEB, we have conducted the most comprehensive benchmarking of text embeddings to date. Through the course of close to 5,000 experiments on over 30 different models, we have set up solid baselines for future research to build on. We found model performance on different tasks to vary strongly with no model claiming state-of-the-art on all tasks. Our studies on scaling behavior, model efficiency and multilinguality revealed various intricacies of models that should ease the decision-making process for future research or industry applications of text embeddings.

We welcome task, dataset or metric contributions to the MTEB codebase[7] as well as additions to the leaderboard via our automatic submission format[8].

6 Limitations of MTEB

While MTEB aims to be a diverse benchmark to provide holistic performance reviews, the benchmark has its limitations. We list them here:

1. Long document datasets MTEB covers multiple text lengths (S2S, P2P, S2P), but very long documents are still missing. The longest datasets in MTEB have a few hundred words, and longer text sizes could be relevant for use cases like retrieval.

2. Task imbalance Tasks in MTEB have a different amount of datasets with summarization consisting of only a single dataset. This means MTEB average scores, which are computed over all datasets, are biased towards tasks with many datasets, notably retrieval, classification and clustering. As MTEB grows, we hope to add more datasets to currently underrepresented tasks like summarization or pair classification.

3. Multinguality MTEB contains multilingual classification, STS and bitext mining datasets. However, retrieval and clustering are English-only. SGPT-BLOOM-7B1-msmarco is geared towards multilingual retrieval datasets and due to the lack thereof cannot be comprehensively benchmarked in MTEB. Further, MTEB does not contain any code datasets that could be used to benchmark code models (Neelakantan et al., 2022; Allal et al., 2023). It should be easy to extend MTEB with datasets, such as CodeSearchNet (Husain et al., 2019), TyDI QA (Clark et al., 2020), XOR QA (Asai et al., 2020) or MIRACL (Zhang et al., 2022).

4. Additional modalities Text embeddings are commonly used as input features for downstream models, such as in our classification task. This can involve other modalities, notably image content (Carvalho et al., 2018; Tan and Bansal, 2019; Muennighoff, 2020; Nichol et al., 2021; Saharia

---

[7] `https://github.com/embeddings-benchmark/mteb`

[8] `https://huggingface.co/spaces/mteb/leaderboard`

et al., 2022; Weinbach et al., 2022). We have focused solely on natural language applications and leave extensive benchmarking of text embeddings as inputs for other modalities to future work.

Acknowledgments

This work was granted access to the HPC resources of Institut du développement et des ressources en informatique scientifique (IDRIS) du Centre national de la recherche scientifique (CNRS) under the allocation 2021-A0101012475 made by Grand équipement national de calcul intensif (GENCI). In particular, all the evaluations and data processing ran on the Jean Zay cluster of IDRIS, and we want to thank the IDRIS team for responsive support throughout the project, in particular Rémi Lacroix.

We thank Douwe Kiela, Teven Le Scao and Nandan Thakur for feedback and suggestions.

A Datasets

Table 2 provides a summary along with statistics of all MTEB tasks. In the following, we give a brief description of each dataset included in MTEB.

A.1 Clustering

ArxivClusteringS2S, ArxivClusteringP2P, BiorxivClusteringS2S, BiorxivClusteringP2P, MedrxivClusteringP2P, MedrxivClusteringS2S These datasets are custom-made for MTEB using the public APIs from arXiv[9] and bioRxiv/medRxiv[10]. For S2S datasets, the input text is simply the title of the paper, while for P2P the input text is the concatenation of the title and the abstract. The cluster labels are generated using categories given to the papers by humans. For bioRxiv and medRxiv this category is unique, but for arXiv multiple categories can be given to a single paper so we only use the first one. For bioRxiv and medRxiv there is only one level of category (e.g. biochemistry, genetics, microbiology, etc.) hence we only perform clustering based on that label. For arXiv there is a main category and secondary category: for example "cs.AI" means the main category is Computer Science and the sub-category is AI, math.AG means the main category is Mathematics and the sub-category is Algrebraic Geometry etc. Hence, we create three types of splits:

(a) Main category clustering Articles are only clustered based on the main category (Math, Physics, Computer Science etc.). This split evaluates coarse clustering capacity of a model.

(b) Secondary category clustering within the same main category Articles are clustered based on their secondary category, but within a given main category, for example only Math papers that need to be clustered into Algebraic Geometry, Functional Analysis, Numerical Analysis etc. This split evaluates fine-grained clustering capacity of a model, as differentiating some sub-categories can be very difficult.

(c) Secondary category clustering Articles are clustered based on their secondary category for all main categories, so the labels can be Number Theory, Computational Complexity, Astrophysics of Galaxies etc. These splits evaluate fine-grained clustering capacity, as well as multi-scale capacities i.e. is a model able to both separate Maths from Physics as well as Probability from Algebraic Topology at the same time.

For every dataset, split and strategy, we select subsets of all labels and then sample articles from those labels. This yields splits with a varying amount and size of clusters.

RedditClustering (Geigle et al., 2021): Clustering of titles from 199 subreddits. Clustering of 25 splits, each with 10-50 classes, and each class with 100 - 1000 sentences

RedditClusteringP2P Dataset created for MTEB using available data from Reddit posts[11]. The task consists of clustering the concatenation of title+post according to their subreddit. It contains 10 splits, with 10 and 100 clusters per split and 1,000 to 100,000 posts.

StackExchangeClustering (Geigle et al., 2021) Clustering of titles from 121 stackexchanges. Clustering of 25 splits, each with 10-50 classes, and each class with 100-1000 sentences.

StackExchangeClusteringP2P Dataset created for MTEB using available data from StackExchange posts[12]. The task consists of clustering the concatenation of title and post according to their subreddit. It contains 10 splits, with 10 to 100 clusters and 5,000 to 10,000 posts per split.

TwentyNewsgroupsClustering[13] Clustering of the 20 Newsgroups dataset, given titles of article the goal is to find the newsgroup (20 in total). Contains 10 splits, each with 20 classes, with each split containing between 1,000 and 10,000 titles.

A.2 Classification

AmazonCounterfactual (O'Neill et al., 2021) A collection of Amazon customer reviews annotated for counterfactual detection pair classification. For each review the label is either "counterfactual" or "not-counterfactual". This is a multilingual dataset with 4 available languages.

Table 2: Tasks in MTEB

AmazonPolarity (McAuley and Leskovec, 2013) A collection of Amazon customer reviews annotated for polarity classification. For each review the label is either "positive" or "negative".

AmazonReviews (McAuley and Leskovec, 2013) A collection of Amazon reviews designed to aid research in multilingual text classification. For each review the label is the score given by the review between 0 and 4 (1-5 stars). This is a multilingual dataset with 6 available languages.

Banking77 (Casanueva et al., 2020) Dataset composed of online banking queries annotated with their corresponding intents. For each user query the label is an intent among 77 intents like ’activate_my_card’, ’apple_pay’, ’bank_transfer’, etc.

Emotion (Saravia et al., 2018) Dataset of English Twitter messages with six basic emotions: anger, fear, joy, love, sadness, and surprise.

Imdb (Maas et al., 2011) Large movie review dataset with labels being positive or negative.

MassiveIntent (FitzGerald et al., 2022) A collection of Amazon Alexa virtual assistant utterances annotated with the associated intent. For each user utterance the label is one of 60 intents like ’play_music’, ’alarm_set’, etc. This is a multilingual dataset with 51 available languages.

MassiveScenario (FitzGerald et al., 2022) A collection of Amazon Alexa virtual assistant utterances annotated with the associated intent. For each user utterance the label is a theme among 60 scenarios like ’music’, ’weather’, etc. This is a multilingual dataset with 51 available languages.

MTOPDomain / MTOPIntent Multilingual sentence datasets from the MTOP (Li et al., 2020) benchmark. We refer to their paper for details.

ToxicConversations Dataset from Kaggle competition[14]. Collection of comments from the Civil Comments platform together with annotations if the comment is toxic or not.

TweetSentimentExtraction Dataset from Kaggle competition[15]. Sentiment classification of tweets as neutral, positive or negative.

A.3 Pair Classification

SprintDuplicateQuestions (Shah et al., 2018): Collection of questions from the Sprint community. The goal is to classify a pair of sentences as duplicates or not.

TwitterSemEval2015 (Xu et al., 2015) Paraphrase-Pairs of Tweets from the SemEval 2015 workshop. The goal is to classify a pair of tweets as paraphrases or not.

TwitterURLCorpus (Lan et al., 2017) Paraphrase-Pairs of Tweets. The goal is to classify a pair of tweets as paraphrases or not.

A.4 Bitext Mining

BUCC (Zweigenbaum et al., 2016, 2017, 2018) BUCC provides big set of sentences ($\sim$ 10-70k each) for English, French, Russian, German and Chinese, along with associated pairs annotation. The annotated pairs here corresponds to a pairs of translated sentences, i.e. a sentence and its translation in the other language.

Tatoeba (Research) Tatoeba provides sets of sentences (1000 sentences each) for 112 languages with annoated associated pairs. Each pair is one sentence and its translation in another language.

A.5 Reranking

AskUbuntuDupQuestions[16] Questions from AskUbuntu with manual annotations marking pairs of questions as similar or dissimilar.

MindSmall (Wu et al., 2020) Large-scale English Dataset for News Recommendation Research. Ranking news article titles given the title of a news article. The idea is to recommend other news from the one you are reading.

SciDocsRR (Cohan et al., 2020b) Ranking of related scientific papers based on their title.

StackOverflowDupQuestions (Liu et al., 2018) Stack Overflow Duplicate Questions Task for questions with the tags Java, JavaScript and Python, ranking questions as duplicates or not.

A.6 Semantic Textual Similarity (STS)

STS12, STS13, STS14, STS15, STS16, STS17, STS22, STSBenchmark (Agirre et al., 2012, 2013)[17][18][19][20] Original STS benchmark, with scores from 0 to 5. The selection of sentences includes text from image captions, news headlines and user forums. In total they contain between 1,000 and 20,000 sentences. STS12 - STS16 and

---

[19] https://alt.qcri.org/semeval2016/task1/

[20] https://competitions.codalab.org/competitions/33835

STSBenchmark are monolingual english benchmarks. STS17 and STS22 contain crosslingual pairs of sentences, where the goal is to assess the similarity of two sentences in different languages. STS17 has 11 language pairs (among Korean, Arabic, English, French, German, Turkish, Spanish, Italian and Dutch) and STS22 has 18 language pairs (among Arabic, English, French, German, Turkish, Spanish, Polish, Italian, Russian and Chinese).

BIOSSES[21] Contains 100 sentence pairs from the biomedical field.

SICK-R (Agirre et al., 2014) Sentences Involving Compositional Knowledge (SICK) contains a large number of sentence pairs (10 0000) that are lexically, syntactically and semantically rich.

A.7 Summarization

SummEval (Fabbri et al., 2020) Summaries generated by recent summarization models trained on CNN or DailyMail alongside human annotations.

A.8 Retrieval

We refer to the BEIR paper (Thakur et al., 2021), which contains description of each dataset. For MTEB, we include all publicly available datasets: **ArguAna, ClimateFEVER, CQADupstack, DBPedia, FEVER, FiQA2018, HotpotQA, MSMARCO, NFCorpus, NQ, Quora, SCIDOCS, SciFact, Touche2020, TRECCOVID**.

B Examples

Tables 3-9 provide examples for each dataset for each task. For retrieval datasets, we refer to the BEIR paper (Thakur et al., 2021).

C Correlations

Figure 6 provides correlation heatmaps for model performance and MTEB tasks.

D Models

Table 10 provides publicly available model checkpoints used for MTEB evaluation.

E Additional results

Tables 11 until the end provide results on individual datasets of MTEB. The results are additionally available in json format on the Hugging Face Hub[22] and can be inspected on the leaderboard[23].

Dataset	Text	Label
AmazonCounterfactualClassification	In person it looks as though it would have cost a lot more.	counterfactual
AmazonPolarityClassification	an absolute masterpiece I am quite sure any of you actually taking the time to read this have played the game at least once, and heard at least a few of the tracks here. And whether you were aware of it or not, Mitsuda's music contributed greatly to the...	positive
AmazonReviewsClassification	solo llega una unidad cuando te obligan a comprar dos Te obligan a comprar dos unidades y te llega solo una y no hay forma de reclamar, una autentica estafa, no compreis!!	0
Banking77Classification	What currencies is an exchange rate calculated in?	exchange_rate
EmotionClassification	i feel so inhibited in someone elses kitchen like im painting on someone elses picture	sadness
ImdbClassification	When I first saw a glimpse of this movie, I quickly noticed the actress who was playing the role of Lucille Ball. Rachel York's portrayal of Lucy is absolutely awful. Lucille Ball was an astounding comedian with incredible talent. To think about a legend like Lucille Ball being portrayed the way she was in the movie is horrendous. I cannot believe...	negative
MassiveIntentClassification	réveille-moi à neuf heures du matin le vendredi	alarm_set
MassiveScenarioClassification	tell me the artist of this song	music
MTOPDomainClassification	Maricopa County weather forecast for this week	weather
MTOPIntentClassification	what ingredients do is have left	GET_INFO_RECIPES
ToxicConversationsClassification	The guy's a damn cop, so what do you expect?	toxic
TweetSentimentExtractionClassification	I really really like the song Love Story by Taylor Swift	positive

Table 3: Classification examples

Dataset	Text	Cluster
ArxivClusteringP2P	Finite groups of rank two which do not involve $Qd(p)$. Let $p > 3$ be a prime. We show that if G is a finite group with p-rank equal to 2, then G involves $Qd(p)$ if and only if G p'-involves $Qd(p)$. This allows us to use a version of Glauberman's ZJ-theorem to give a more direct construction of finite group actions on mod-p homotopy spheres. We give an example to illustrate that the above conclusion does not hold for $p \leq 3$.	math
ArxivClusteringS2S	Vertical shift and simultaneous Diophantine approximation on polynomial curves	math
BiorxivClusteringP2P	Innate Immune sensing of Influenza A viral RNA through IFI16 promotes pyroptotic cell death Programmed cell death pathways are triggered by various stresses or stimuli, including viral infections. The mechanism underlying the regulation of these pathways upon Influenza A virus IAV infection is not well characterized. We report that a cytosolic DNA sensor IFI16 is...	immunology
BiorxivClusteringS2S	Association of CDH11 with ASD revealed by matched-gene co-expression analysis and mouse behavioral	neuroscience
MedrxivClusteringP2P	Temporal trends in the incidence of haemophagocytic lymphohistiocytosis: a nationwide cohort study from England 2003-2018. Haemophagocytic lymphohistiocytosis (HLH) is rare, results in high mortality and is increasingly being diagnosed. Little is known about what is driving the apparent rise in the incidence of this disease. Using national linked electronic health data from hospital admissions and death certification cases of HLH that were diagnosed in England between 1/1/2003 and 31/12/2018 were identified using a previously validated approach. We calculated incidence...	infectious diseases
MedrxivClusteringS2S	Current and Lifetime Somatic Symptom Burden Among Transition-aged Young Adults on the Autism Spectrum	psychiatry and clinical psychology
RedditClustering	Could anyone tell me what breed my bicolor kitten is?	r/cats
RedditClusteringP2P	Headaches after working out? Hey guys! I've been diagnosed with adhd since I was seven. I just recently got rediagnosed (22f) and I've been out on a different medication, adderall I was normally taking vyvanse but because of cost and no insurance adderall was more affordable. I've noticed that if I take adderall and workout...	r/ADHD
StackExchangeClustering	Does this property characterize a space as Hausdorff?	math.stackexchange.com
StackExchangeClusteringP2P	Google play services error DEBUG: Application is pausing, which disconnects the RTMP client. I am having this issue from past day with Google Play Services Unity. What happens is, when I install app directly ot device via Unity, the Google Play Services work fine but when I upload it as beta to play store console and install it via that then it starts to give " DEBUG: Application is pausing, which disconnects the RTMP client" error. I have a proper SHA1 key.	unity
TwentyNewsgroupsClustering	Commercial mining activities on the moon	14

Table 4: Clustering examples

Dataset	Sentence 1	Sentence 2	Label
SprintDuplicateQuestions	Franklin U722 USB modem signal strength	How do I know if my Franklin U772 USB Modem has a weak signal ?	1

Abstract

We propose a novel gradient-based attack against transformer-based language models that searches for an adversarial example in a continuous space of token probabilities. Our algorithm mitigates the gap between adversarial loss for continuous and discrete text representations by performing multi-step quantization in a quantization-compensation loop. Experiments show that our method significantly outperforms other approaches on various natural language processing (NLP) tasks.

1 Introduction

Deep neural networks achieve impressive results, but their vulnerability to adversarial attacks causes major security threats and is a concern when interpreting or explaining model predictions.

In computer vision, the most successful attack methods use gradient-based optimization techniques (Carlini and Wagner, 2017; Madry et al., 2018). They minimize adversarial loss function that encourages the prediction error and imperceptibility of a generated example.

Development of optimization-based attacks in NLP is much more challenging due to the discrete nature of text. Recent methods (Guo et al., 2021; Yuan et al., 2021) overcome this limitation by performing a gradient descent in the continuous space of token representations and eventually quantizing them into discrete text.

A quantization of a token can significantly change its embedding and cause an undesired change of the loss value, degrading the adversarial example. To our knowledge, all existing optimization-based NLP attacks quantize all tokens in a text at once, which creates a considerable gap between adversarial loss for continuous and discrete text representations.

In this paper, we propose MANGO[1] (Multi-step quANtization Gradient-based adversarial Optimizer): a novel optimization-based attack against Transformer (Vaswani et al., 2017) language models that mitigates the aforementioned gap by performing multi-step quantization in a quantization-compensation loop. MANGO quantizes continuous token representations one by one and reoptimizes the adversarial example after each quantization to compensate undesired degradation of adversarial loss value. The construction of MANGO introduces interesting problems that are addressed in Section 3. MANGO achieves superior performance in various NLP tasks, outperforming recent white-box (optimization-based) and black-box attacks.

2 Related Work

Adversarial attacks can be roughly divided into two categories: white-box attacks that have access to the internal model's states (e.g. gradient) and more common black-box attacks that only know outputs of the model. In our paper, we focus on a white-box version of our MANGO attack. In Appendix D, we develop a version of MANGO that can be used in the loosened black-box setting.

Black-Box Methods Most black-box NLP attacks define a space of character or word replacements and heuristically search it for an adversarial example (Yoo et al., 2020). The search space is limited with semantic ad hoc constraints (e.g. limiting edit distance or restricting possible replacements to synonyms) to preserve the attack's imperceptibility. Such constraints disallow some specific perturbations (e.g. replacing a word with its antagonist even if the semantics is preserved in the context of other perturbations) and tend to generate semantically incorrect examples (Morris et al., 2020a).

White-Box Methods Many white-box methods use gradients to guide a heuristic search in a space of text perturbations (Ebrahimi et al., 2018; Cheng et al., 2019; Xu and Du, 2020). Recent methods take a step further and perform gradient descent

optimization. They aim to find an example that minimizes the adversarial loss function, which encourages the prediction error and the imperceptibility of the attack. Because the similarity and fluency of an example are controlled by a powerful external model used in the loss, optimization-based methods do not require hand-crafted semantic constraints, making them more flexible than black-box ones.

Adapting gradient descent in NLP attacks is a challenging problem due to the discrete nature of the optimized text. Yuan et al. (2021) overcome this issue by performing optimization in the continuous space of token embeddings and replacing each token with a possibly new token, which embedding is the closest to the optimized one. An alternative approach is the GBDA method (Guo et al., 2021) that optimizes a continuous distribution of stochastic one-hot vectors and repeatedly samples adversarial examples from the optimized distribution until it fools the attacked model.

Quantization Both methods mentioned above quantize all continuous representations of tokens to a text at once. Quantization of a single token may significantly change its embedding and cause an undesirable change of adversarial loss value. When quantizing all tokens at once, the changes accumulate to a considerable gap between adversarial loss for continuous and discrete text representations (see Section 6). Our MANGO mitigates this gap.

3 MANGO

This section describes our MANGO method. Unlike other optimization-based methods that quantize all token representations at once, MANGO constitutes an entirely new algorithm that quantizes a token and compensates for the resulting change in an adversarial loss value in a step-by-step manner. The construction of MANGO introduces interesting problems that are addressed in the **Optimization**, **Vector Selection** and **Candidates Selection** paragraphs and are further evaluated in Section 5.

Continuous Token Representation The first learnable layer of Transformer takes as input a sequence of tokens $x = (t_1, ..., t_n)$, where $t_i \in 2^{|V|}$ has a single non-zero binary value at index k indicating that it represents the k-th token in vocabulary V.

Similarly to Guo et al. (2021), we relax the input sequence x and replace one-hot encodings t_i with probability vectors π_i. Because the first learnable Transformer layer is a simple linear layer, it can take probability vectors as input without any modification.

A probability vector π_i constitutes probability distribution over tokens from V.

In the embedding layer, the Transformer embeds probability vectors with the function e:

$$e(\pi_i) = \sum_{j=1}^{|V|} (\pi_i)_j E_j, \tag{1}$$

where E_j is the embedding vector of the j-th token. If π_i is quantized, meaning it is a one-hot vector representing some token k, function e simply looks up the k-th embedding: $e(\pi_i) = E_k$. In MANGO, π_i is a probabilistic vector, and its embedding $e(\pi_i)$ is a mixture of embeddings of all tokens weighted by their probabilities π_i. We parameterize π_i with logits Θ_i and a standard softmax function σ, so that $\pi_i = \sigma(\Theta_i)$ and $x = \sigma(\Theta)$ for $\Theta = (\Theta_1, ..., \Theta_n)$.

Loss function Let $m : X \rightarrow \mathbb{R}^{|Y|}$ be a classifier that outputs logit vectors and properly predicts a label $y \in Y$ for some datapoint $x \in X$, meaning that $\arg\max_k m(x)_k = y$. An adversarial example is a sample $x' \in X$ that is imperceptible (according to specified criteria) from x but changes the output of the model. In an optimization-based setting, searching for an adversarial example is usually defined as a minimization of an adversarial loss function.

Following Guo et al. (2021), we compose our adversarial loss $\mathcal{L}$ as a combination of margin loss l_m, fluency loss l_f, and similarity loss l_s:

$$\mathcal{L}(x') = l_m(m, x', y) + \lambda_f l_f(g, x') + \lambda_s l_s(g, x', x), \tag{2}$$

where λ_f and λ_s are the coefficients used to balance the losses and g is a reference model.

Margin loss l_m encourages model m to missclassify x' by a margin κ:

$$l_m(m, x', y) = \max(m(x')_y - \max_{k \neq y} m(x')_k + \kappa, 0).$$

Fluency loss l_f promotes x' with a high probability of being generated by a causal language model g that predicts the next token distribution:

$$l_f(g, x') = -\sum_{i=1}^{n} \sum_{j=1}^{|V|} (\pi_i)_j g(\pi_1, ..., \pi_{i-1})_j.$$

Similarity loss l_s is based on BERTScore (Zhang et al., 2020) and captures the semantic similarity between x and x' using contextualized embeddings of tokens $\phi_g(x) = (v_1, ..., v_n)$ and $\phi_g(x') =$

$(v'_1, ..., v'_n)$ produced by the reference model g :

$$l_s(g, x', x) = -\sum_{i=1}^{n} w_i \max_j v_i^T v'_j,$$

where w_i is the inverse frequency of token t_i.

Quantization-Compensation Loop MANGO algorithm searches for a x' that minimizes $\mathcal{L}$, quantizing and compensating it step by step. Algorithm 1 introduces the idea of MANGO.

In the first line, the parameters Θ of x' are initialized, so that $\Theta'_{ij} = C \cdot (x_i)_j$ for some constant C. Each loop starts with **optimization** of x' with respect to $\mathcal{L}$. Then **vector selection** is performed to select π'_i from x' which will be quantized in the current step. Given π'_i, MANGO performs **candidates selection** and selects m the most promising tokens $c_1, ..., c_m$ to which x'_i can be quantized. In the 6th line, each candidate c_j is evaluated by computing $\mathcal{L}$ for a sequence x' with vector π'_i quantized to c_j. Finally, π'_i is quantized to the best c_j chosen from the previous step. Quantized π'_i will no longer be updated during optimization. MANGO repeats lines 2-7 until all vectors in x' are quantized.

Algorithm 1: MANGO

```
Data: adversarial loss $\mathcal{L}$ (eq. 2)
Result: sentence $x'$ that minimizes $\mathcal{L}$
1 initialize $x' = (\pi'_1, ..., \pi'_n)$
2 while $x'$ is not fully quantized do
3     optimization: optimize parameters of $x'$
4     vector selection: select probabilistic
        vector $\pi'_i$ from $x'$ for quantization
5     candidates selection: select $m$ tokens
        candidates from $\pi'_i$
6     evaluate these $m$ candidates with loss $\mathcal{L}$
7     quantize $\pi'_i$ to best evaluated token
```

Optimization We optimize x' with the Adam optimizer (Kingma and Ba, 2014) which is reset after each quantization (see Section 5). This allows x' to rapidly change its trajectory to compensate for the degradation of $\mathcal{L}$. The initial number of optimization steps is S, but it decreases by a factor of 2 in each loop to reduce computational costs.

Vector Selection In line 4th, we choose vector π'_i with the highest entropy (see Section 5), because its quantization will introduce the most significant change to x' and is likely to increase the loss value the most. Intuitively, we want such degrading quantizations to occur early in the algorithm, because the more vectors are not quantized yet, the larger capacity x' has to compensate for degradation by finding another local minimum of $\mathcal{L}$.

Candidates Selection In this phase, we select m tokens that can be used to quantize the probability vector π'_i with possibly a small degradation of $\mathcal{L}$. Quantization of π'_i with token k is a step $q_k = (-(\pi'_i)_1, -(\pi'_i)_2, ..., 1 - (\pi'_i)_k, ..., -(\pi'_i)_n)$ in the π'_i space. As π'_i is likely to be in the proximity of its local minimum with respect to $\mathcal{L}$, we want the step q_k to have (1) the lowest norm $\|q_k\|$ possible and (2) follow the direction of the local (minus) gradient. We use this intuition in the formulation of the token score s_k, which is a weighted mean of the probability $(\pi'_i)_k$ and the direction score d_k:

$$s_k = \lambda_{prob}(\pi'_i)_k + (1 - \lambda_{prob})d_k. \tag{3}$$

Note that $(\pi'_i)_k$ is inversely proportional to $\|q_k\|$. We define d_k as cosine similarity between q_k and the local (minus) gradient (see Section 5):

$$d_k = \frac{q_k \left(-\nabla_{\pi'_i}\mathcal{L}(x')\right)^T}{\|q_k\| \cdot \|\nabla_{\pi'_i}\mathcal{L}(x')\|} \tag{4}$$

We then select m tokens with the highest scores s_k.

4 Experiments

In this section, we evaluate MANGO on various NLP tasks and compare it to recent NLP attacks.

Baselines We compare our method with the latest white-box GBDA attack (Guo et al., 2021), as well as recent black-box attacks implemented in TextAttack (Morris et al., 2020b): BERT-Attack (Li et al., 2020), BAE (Garg and Ramakrishnan, 2020) and TextFooler (Jin et al., 2020). To emphasize the importance of multi-step quantization, we evaluate the Naive version of MANGO that performs quantization in one step. MANGO, Naive and GBDA attacks use identical loss. All hyperparameters are listed in appendix A.

Tasks We attack BERT models from TextAttack fine-tuned on three text classification tasks: AG News (Zhang et al., 2015), Yelp Reviews (Zhang et al., 2015), IMDB (Maas et al., 2011), and MNLI task for natural language inference, (Williams et al., 2018). In MNLI p., an attack is allowed to modify only the premise, and in MNLI h., only the hypothesis. For each task, we randomly select 1000 attack targets from the training set. We use a training set as it provides more challenging targets and is more relevant to Adversarial Training (Bai et al., 2021).

Task	Method	Adv.	Adv. prob.	USE sim.	BERTScore	Δ perp.	Δ gram.	# queries

Table 1: Results for black-box and white-box methods. We report: the initial training accuracy of BERT model (under Task); training accuracy under attack (Adv.); probability of ground-truth label prediction under attack (Adv. prob.); similarity between the original and perturbed text computed with USE (Cer et al., 2018) (USE sim.) and with F1 BERTScore (BERTScore); percent change in perplexity computed with GPT-2 (Radford et al., 2019) (Δ perpl.); increase in the number of grammar errors (Δ gram.) obtained with LanguageTool (github.com/jxmorris12/language_tool_python); average number of queries to a victim model (# queries). We omit results for TextFooler on MNLI p., as it has not generated any adversarial example. We also report standard deviation for each result, except adversarial accuracy as it is simply the percent of successful attacks. Our MANGO method achieves superior results on most tasks while maintaining high semantic similarity and grammar fluency. The best results for Adv. are **bold**.

Results Results can be found in Table 1. Our MANGO substantially reduces the training accuracy of the BERT model in all tasks, while maintaining a high level of semantic similarity to the original input. The attacks of MANGO are difficult (low Adv. prob., which indicates that model misclassifies an example by a large margin), fluent (low Δ perp.) and do not flaw the grammatical correctness (low Δ gram.).

In almost all settings, MANGO outperforms other attacks in terms of training accuracy, which we believe to be the fairest metric for comparing optimization-based methods with black-box ones due to inherent design biases (see Appendix B).

MANGO surpasses the recent state-of-the-art optimization-based GBDA attack in terms of most considered metrics: in terms of Adv. acc. and BERTScore on 4/5 tasks and in terms of USE sim., Δ perpl. and Δ gram. on 5/5 tasks.

Moreover, MANGO achieves considerably better results than its Naive version, emphasizing the importance of multi-step quantization.

Qualitative Results We provide qualitative analysis of a few adversarial examples generated by BAE, GBDA, and MANGO in Appendix C.

5 Ablation Study

In this section, we evaluate three solutions from Section 3 that improve the core idea of multi-step quantization:

1. selection of probability vector to quantization by maximal entropy (instead of minimal entropy, which seems more natural choice),
2. scoring token candidates by weighted mean of token probability and gradient direction score (eq. 4),
3. resetting optimizer after every quantization.

Figure 1 compares different MANGO settings. We may observe that selection of probability vector for quantization by maximal entropy ("max entropy") is better than selection by minimal entropy ("min entropy"). Resetting the optimizer after every quantization enhances the performance for both "max entropy" and "min entropy" settings. Finally, we see that MANGO benefits from using both token's probability and gradient direction to score token candidates.

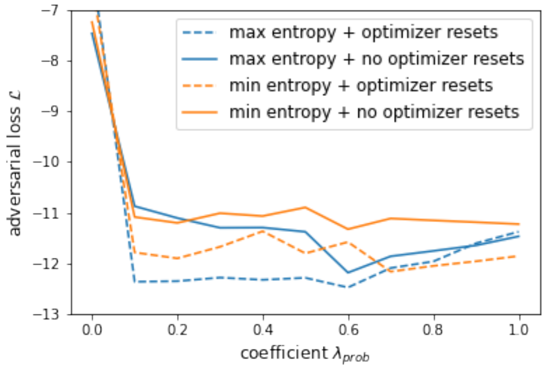

Figure 1: Final adversarial losses for different MANGO setting. "max entropy + optimizer resets" stands for a version of MANGO that selects probability vector for quantization by maximal entropy and resets optimizer after every quantization. Rest of the names follow the same pattern. We also present the influence of the coefficient λ_{prob} used in token candidates scoring function (eq. 4). Loss values are averaged over 10 samples from IMDB dataset.

6 Visualization of Quantization Gap

To visualize the quantization gap between adversarial loss for continuous and discrete text representations, we compared adversarial losses of MANGO, GBDA and a Naive version of MANGO that does not use multi-step quantization. The comparison can be found in Figure 2. We observe that the Naive method converges to the lowest value loss in the optimization phase, but the value explodes after quantization. The GBDA method, which samples probability vectors that resemble discrete one-hot vectors using Gumbel-softmax (Jang et al., 2017), reaches a higher minimum, but its quantization gap is much smaller than that of Naive method. Finally, in the case of MANGO, we observe sudden peaks and slow declines of loss values that correspond to the quantization-compensation loop, in which the quantization of single tokens is followed by the compensation of the quantization gap. After optimization, MANGO continues to quantize tokens step by step further decreasing the loss. MANGO obtains a significantly lower final adversarial loss than GBDA and Naive, avoiding the quantization gap.

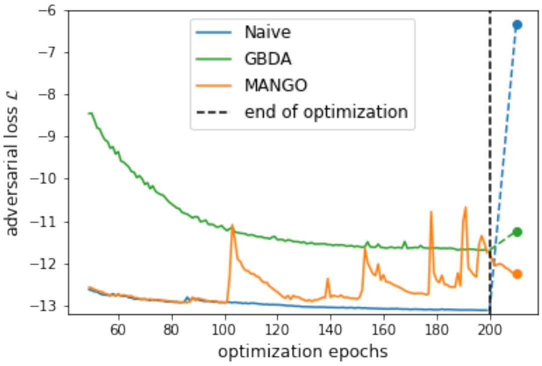

Figure 2: Adversarial loss for epochs 50-200 of optimization for Naive, GBDA and MANGO methods. The vertical dashed line shows the end of optimization. Naive and GBDA methods immediately quantize the tokens, while MANGO do it step by step. The rightmost points shows the final adversarial loss value. We observe that after optimization, MANGO continues to quantize tokens step by step and eventually reaches the best adversarial loss value. Loss values are averaged over 9 samples from IMDB dataset.

7 Conclusion

We developed MANGO, a novel optimization-based attack against Transformer models that mitigates the gap between adversarial loss for continuous and discrete text representations using a quantization-compensation loop. MANGO achieves superior results on various NLP tasks, outperforming recent black-box and optimization-based attacks.

Limitations

One limitation is that the number of queries of MANGO to the attacked model depends on the length of the input sequence. Therefore, MANGO may suffer a long attack time on datasets with long sequences (like IMDB or Yelp).

Moreover, MANGO is restricted only to token replacement. The inability to insert or remove tokens can lead to reduced attack performance.

The most important limitation is the white-box nature of MANGO that excludes it from applications when the internal model's states cannot be known. To partially circumvent this limitation, we propose Gray MANGO - a version of MANGO that can be used in the loosened black-box setting, which we call gray-box setting (see appendix D).

A Hyperparameters

MANGO To save computational resources during **candidates selection**, we use the dynamic number of candidates m. We rescale the candidate scores s_k to $[0, 1]$ and take at most $M = 5$ candidates whose scores differ from the best score at most by a threshold $T = 0.5$: $s_k \geq \max_j s_j - T$. We use $\lambda_{prob} = 0.5$ in Equation (4).

White-Box Attacks MANGO, Naive and GBDA methods use the loss function Equation (2) with the same parameters $\lambda_s = 20$, $\lambda_f = 1$, $\kappa = 5$ (taken from Guo et al. (2021)) for all tasks, except Yelp, where they use $\lambda_s = 10$. As a reference model g, we used the GPT-2 model downloaded from the official GBDA repository. We set $C = 10$ for initialization of the adversarial sample parameters. The number of optimization epochs $S = 100$ for all models and the batch size in GBDA was set to 10.

Black-Box Attacks We take TextFooler, BertAttack, and BAE implementations from TextAttack (Morris et al., 2020b) along with their original parameters. For fair comparison, we set the USE similarity threshold to the lowest value (0.2) used along these methods. Following the GBDA paper, we slightly modify the BertAttack method to mitigate its problem with subtokens and extremely long time of attack.

B Comparison Fairness

When comparing the results of optimization-based (MANGO, GBDA, Naive MANGO) and black-box methods (TextFooler, Bert-Attack, BAE), we should note that black-box methods stop perturbing text as soon as they fool the model, while optimization-based attacks minimize adversarial loss (that encourage them to fool the model by some margin) for some fixed number of steps. The former improves similarity metrics (USE sim., BERTScore) and the latter highly decreases the model's prediction on ground-truth labels (Adv. prob.), increasing the difficulty of generated sample. Therefore, we believe that training accuracy under attack (Adv.) is the fairest metric to make a direct comparison between optimization-based and classic black-box methods.

C Attack Examples

To draw some insights into MANGO performance, we compared examples generated by BAE, GBDA and MANGO. We chose all the sentences from AG News and MNLI hypothesis that were successfully perturbed by the three considered methods and on which the methods obtained USE cosine similarity score greater than 0.9. We then sampled two sentences from AG News and two from MNLI hypothesis tasks. To avoid cherry-picking, we fixed a seed and sampled only once. Examples can be found in table 2 and in table 3. We are careful in drawing any conclusion from the qualitative results, however, there seems to be a trend consistent with the result from table 1 and our observations from appendix B: BAE perturbs less words than GBDA and MANGO, but also achieves lower confidence of the mislassified label.

D Gray MANGO

To circumvent the white-box nature of MANGO attack, we additionally develop Gray MANGO: a version of MANGO that can be used in the loosened black-box setting, which we call gray-box setting.

Gray-Box Setting Gray MANGO is not strictly a black-box attack, as it requires the attacked model to take probability vectors and needs access to token vocabulary V. Transformer-based models satisfy these assumptions: they usually share the same V and their embedding function e can be used for both one-hot and probability vectors. However, to avoid misconception, we call this loosened black-box setting a grey-box setting.

Zeroth-Order Optimization Gray MANGO is based on Zeroth-Order Optimization (ZOO) (Nesterov and Spokoiny, 2017). The idea of ZOO is to approximate the gradient using only zeroth order loss values. In computer vision, Chen et al. (2017) developed a ZOO-based attack that significantly outperforms other black-box attacks. We believe that this success can be transferred to the NLP domain. Berger et al. (2021) have proposed an NLP attack that uses a discrete version of ZOO, but the results were unsatisfactory. Our Gray MANGO method is the first to successfully adapt the continuous version of ZOO in NLP attacks.

Formulation The main modification with respect to MANGO is the use of the zeroth-order gradient approximation of the gradient $\nabla_{\Theta'}\mathcal{L}(x')$ (Liu et al.,

Table 2: Attack examples sampled from AG News dataset.

2020):

$$\widetilde{\nabla}_{\Theta'}\mathcal{L}(x') = \frac{1}{K}\sum_{i=1}^{K}\frac{\mathcal{L}(\sigma(\Theta' + \mu u_i)) - \mathcal{L}(x')}{\mu}u_i,$$

where u_i is a noise sampled from the normal distribution, μ is the scale factor and $\sigma(\Theta' + \mu u_i)$ is x' with noise μu_i added to its parameters Θ'.

As $\widetilde{\nabla}_{\Theta'}\mathcal{L}(x')$ is unstable, we set $\lambda_{prob} = 1$ and use AMSGrad variant of Adam (Chen et al., 2019) without reset after every quantization. To reduce the high dimensionality of x', which is an issue in ZOO (Wang et al., 2018), we disallow replacement of the original token with tokens that have a cosine similarity of GloVe (Pennington et al., 2014) embedding lower than 0.

Hyperparameters We use almost the same parameters as for MANGO (see appendix A), but with $\lambda_{prob} = 1$, $S = 140$ and $\lambda_s = 80$. To save computational resources, we set $S = 100$ for the IMDB and Yelp datasets. Based on small grid search, we set the noise scaling parameter $\mu = 0.1$.

BAE	neutral (96%)	**hypothesis:** consensus decision makers are not important to first things.
GBDA	neutral (98%)	**hypothesis:** key decision makers are noted fairchild – emery associates.
MANGO	neutral (99%)	**hypothesis:** older ahlers are also important in this regard.

Table 3: Attack examples sampled from MNLI hypothesis task.

Results We evaluated the Gray MANGO method and compared it to vanilla MANGO. Results can be found in table 4.

Gray MANGO, which is the first method to incorporate continuous ZOO in NLP attack, performs competitively with other black-box attacks in terms of training accuracy reduction, but struggles to keep adversarial examples similar to original texts. We believe that the performance of Gray MANGO may be greatly elevated by a more thorough design of ZOO components (Liu et al., 2020). This may be an interesting topic for future research.

Abstract

Recent years have witnessed interest in Temporal Question Answering over Knowledge Graphs (TKGQA), resulting in the development of multiple methods. However, these are highly engineered, thereby limiting their generalizability, and they do not automatically discover relevant parts of the KG during multi-hop reasoning. Relational graph convolutional networks (RGCN) provide an opportunity to address both of these challenges – we explore this direction in the paper. Specifically, we propose a novel, intuitive and interpretable scheme to modulate the messages passed through a KG edge during convolution based on the relevance of its associated period to the question. We also introduce a gating device to predict if the answer to a complex temporal question is likely to be a KG entity or time and use this prediction to guide our scoring mechanism. We evaluate the resulting system, which we call TwiRGCN, on a recent challenging dataset for multi-hop complex temporal QA called *TimeQuestions*. We show that TwiRGCN significantly outperforms state-of-the-art models on this dataset across diverse question types. Interestingly, TwiRGCN improves accuracy by 9–10 percentage points for the most difficult ordinal and implicit question types.

1 Introduction

Question answering (QA) is a key problem in natural language processing and a long-lasting milestone for artificial intelligence. A large class of approaches for QA makes use of knowledge graphs (KG), which are multi-relational graphs representing facts (KGQA). Temporal KGs (TKG) represent facts that are only valid for specific periods of time as *(subject, relation, object, time range)*, for example, *(Franklin D Roosevelt, position held, President of USA,* $[1933, 1945]$*)*. The problem of answering questions that require temporal reasoning over TKGs (TKGQA) is a special case of KGQA that specifically focuses on the following challenge: temporal questions constrain answers through temporal notions, e.g., “*who was the first president of US during WW2?*” Developing systems for temporal QA is of immense practical importance for many applications. It is considered a more challenging problem than KGQA (Bhutani et al., 2019; Saxena et al., 2020), where questions are typically about persistent, non-temporal facts (e.g., place of birth), with only a small portion of the questions requiring any temporal reasoning (Jia et al., 2018a).

Even though a variety of models have been proposed for the TKGQA recently, they suffer from the following problems: 1) they are either highly engineered toward the task (Jia et al., 2021; Chen et al., 2022) or 2) they do not incorporate graph structure information using Graph Neural Networks (GNN) (Mavromatis et al., 2021; Shang et al., 2022; Saxena et al., 2021). We explore the following hypotheses in this paper: 1) a simple GNN-based solution could generalize better and offer higher performance than highly engineered GNN-based, and TKG embedding-based models; 2) a multi-layer GNN model could do multi-hop reasoning across its layers; 3) not all edges (temporal facts) are equally important for answering temporal questions (see Figure 1), so GNN solutions could benefit from temporally weighted edge convolutions.

Following the aforementioned hypotheses, we develop a novel but architecturally simple TKGQA system that we call “Temporally weighted Relational Graph Convolutional Network” (TwiRGCN). It is based on the Relational Graph Convolutional Network (RGCN) proposed by Schlichtkrull et al. (2018). TwiRGCN introduces a question-dependent edge weighting scheme that modulates convolutional messages passing through a temporal fact edge based on how relevant the time period of that edge is for answering a particular question. In RGCN, convolution messages from all TKG edges are weighted equally. But all edges are not equally important for answering temporal

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2049–2060
May 2-6, 2023

questions. For example, in Figure 1, to answer the question "*Who was the first president of the US during WW2?*" the edge with Bill Clinton has little relevance for answering the question. But, regular RGCN would still weigh all edges equally. We address this shortcoming through our proposed modulation. We impose soft temporal constraints on the messages passed during convolution, amplifying messages through edges close to the time period relevant for answering the question while diminishing messages from irrelevant edges. This leads to better, more efficient learning as we are not confusing our model with unnecessary information, as evidenced by our significantly improved performance without the need for any heavy engineering. We explore two different strategies for our convolutional edge weighting, which show complementary strengths. Our experiments establish that TwiRGCN significantly outperforms already strong baselines on *TimeQuestions*. Our contributions are:

- We propose TwiRGCN, a simple and general TKGQA system that computes question-dependent edge weights to modulate RGCN messages, depending on the temporal relevance of the edge to the question.
- We explore two novel and intuitive schemes for imposing soft temporal constraints on the messages passed during convolution, amplifying messages through edges close to the time relevant for answering the question while diminishing messages from irrelevant edges. We also propose an answer-gating mechanism based on the likelihood that the answer is an entity or time.
- Through extensive experiments on a challenging real-world dataset, we find that TwiRGCN substantially outperforms prior art in overall accuracy, and by 9–10% on the implicit and ordinal type questions — categories that require significant temporal reasoning.
- We augment *TimeQuestions* with a TKG and release both code and data at https://github.com/adi-sharma/TwiRGCN.

2 Related Work

Most KGQA systems have focused on answering questions from simple (i.e., 1-hop fact-based questions) (Berant et al., 2013) to multi-hop complex questions requiring multi-fact reasoning (Sun et al., 2019; Saxena et al., 2020). However, only a small fraction of these questions require any temporal reasoning (Jia et al., 2018a). Recent efforts have tried to overcome this gap by proposing models as well as datasets to explicitly focus on temporal reasoning. We review these below.

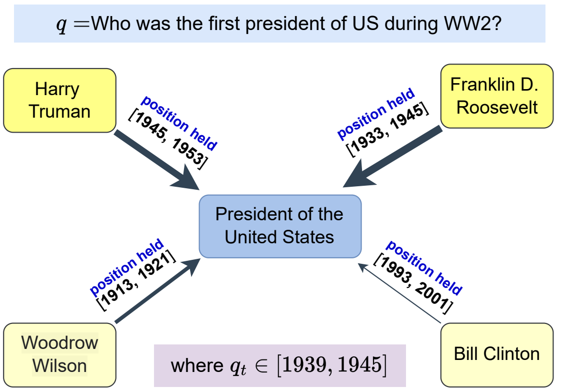

Figure 1: An illustrative example of how our temporal gating described in Section 4.2 modulated the incoming graph convolution messages for one node depending on the time period of interest for the question. The thickness of an edge here is proportional to the value of the temporal edge weight $m_{tq}^{(e)}$ for that edge. In this example, the entities *Franklin D. Roosevelt* and *Harry Truman*, who were presidents during WW2 $[1939, 1945]$ get the top two highest weights, while *Woodrow Wilson*, who was president during WW1 $[1914, 1918]$ gets a smaller edge weight. In contrast, *Bill Clinton*, whose time period is unrelated to the question, gets a much lower edge weight. Thus, contributing very little to the convolution update of the 'President of the US' node.

Temporal KGQA methods: One line of work uses temporal constraints along with hand-crafted rules to find the answer (Bao et al., 2016; Luo et al., 2018; Jia et al., 2018b). A recent class of models has leveraged advances in TKG embedding methods for answering questions on Temporal KGs. CronKGQA (Saxena et al., 2021) does this by posing a question as a TKG completion problem and finds the answer using the TComplex (Lacroix et al., 2020) score function and BERT (Devlin et al., 2018) question embedding to complete the fact. TempoQR (Mavromatis et al., 2021) uses additional temporal supervision to enrich TKG embeddings, followed by a transformer-based decoder (Vaswani et al., 2017). TSQA (Shang et al., 2022) on the other hand estimate the time in the question and uses it to enrich TKG embeddings for finding the answer. SubGTR (Chen et al., 2022) infers question-relevant temporal constraints using TKG embeddings and applies them as filters to score entities in the question subgraph. Although we, too, use pre-trained TKG embeddings to initialize our generalized RGCN, we use the GNN framework to take advantage of the structural information in the KG in ways that they do not. Recent work (Teru et al., 2020) shows that GNN-based models can encode any logical rule corresponding to a path in the knowledge graph. We refer to this as structural information that shallow embedding-based models cannot access.

RGCN based QA systems: Graph neural networks are increasingly being used in QA systems not specifically meant for temporal reasoning. GraftNet (Sun et al., 2018) uses personalized PageRank to collect a query-relevant subgraph from a global KG, then an RGCN to predict the answer from the relevant subgraph. PullNet (Sun et al., 2019) loops over and expands GraftNet's subgraph to do multi-hop reasoning. EXAQT (Jia et al., 2021) is the system closest to ours: it addresses TKGQA and also uses an RGCN. The RGCN for answer prediction which works on the question subgraph is very similar to that in GraftNet. EXAQT augments it with dictionary matching, heavy engineering, and additional category information. In contrast, TwiRGCN uses a straightforward temporally weighted graph convolution followed by answer gating, as described in Section 4, while still achieving superior performance (see Section 5.3). More details in Section 5.2.

3 Preliminaries

3.1 Temporal Knowledge Graphs (TKG)

KG: Multi-relational graphs with entities (eg: Barack Obama, USA) as nodes and relations r between entities $\{s, o\}$ (e.g., president of) represented as typed edges between nodes. Each edge of this graph, together with endpoint nodes, represents a fact triple $\{s, r, o\}$, e.g., $\{\text{Barack Obama}, \text{president of}, \text{USA}\}$.

TKG: Numerous facts in the world are not perpetually true and are only valid for a certain time period. A TKG represents such a fact as a quadruple of the form $\{s, r, o, [t_{st}, t_{et}]\}$, where t_{st} is the start time and t_{et} is the end time of validity of the fact, e.g., $\{\text{Barack Obama}, \text{president of}, \text{USA}, [2009, 2017]\}$.

3.2 Question Answering on TKGs

Given a question q specified in natural language form and a TKG $\mathcal{G}$, TKGQA is the task of finding the answer to q based on the information that is available (or can be derived) from $\mathcal{G}$. A subgraph of $\mathcal{G}$ is a subset of its nodes with induced edges. In this paper, we assume each question is already associated with a subgraph $\mathcal{G}_q$ relevant to the question. We define $\mathcal{G}_q = (\mathcal{V}_q, \mathcal{R}_q, \mathcal{T}_q, \mathcal{E}_q)$ as the subgraph of $\mathcal{G}$ associated with a question $q \in \mathcal{Q}$, where $\mathcal{Q}$ represents the set of all questions. Each edge $e \in \mathcal{E}_q$ represents a fact $\{v_i, r, v_j, [t_{st}, t_{et}]\}$, where $v_i, v_j \in \mathcal{V}_q$ are entity nodes, $r \in \mathcal{R}_q$ is the relation between them and $t_{st}, t_{et} \in \mathcal{T}_q$ are the start and end times for which the fact is valid.

3.3 Relational Graph Convolutional Networks

Given a KG, each node v_i is initialized to a suitable embedding $h_{v_i}^{(0)}$ at layer 0.Thereafter, Schlichtkrull et al. (2018) propose to update node embeddings $h_{v_i}^{(l+1)}$, at layer $(l+1)$, as follows:

$$h_{v_i}^{(l+1)} = \sigma\left(\sum_{r \in \mathcal{R}} \sum_{j \in \mathcal{N}_i^r} \frac{W_r^{(l)} h_{v_j}^{(l)}}{|\mathcal{N}_i^r|} + W_0^{(l)} h_{v_i}^{(l)}\right) \quad (1)$$

where $\mathcal{N}_i^r$ is the set of neighbors of node v_i that are connected via relation edges of type r, $\mathcal{R}$ is the set of relations, $W_r^{(l)}$ are weight matrices associated with each relation type r and layer l. They are initialized using a basis decomposition method.

4 Proposed Method: TwiRGCN

In this section, we develop and describe TwiRGCN ("Temporally Weighted Relational Graph Convolutional Network"), our model for TKGQA.

4.1 Embedding for questions and KG facts

Question embedding: We pass the question text through a pre-trained encoder-only language model (LM) to obtain a question embedding. In particular, we prepend a [CLS] token to the input question and feed it into BERT (Devlin et al., 2019), and then use its output-layer [CLS] embedding as the question embedding q_B. We enable LM fine-tuning during training.

TKG preprocessing for RGCN initialization: We initialize entity and time embeddings using pre-trained TComplEx (Lacroix et al., 2020) embeddings.[1] To obtain these for the *TimeQuestions* dataset (Jia et al., 2021), we first construct a 'background KG' $\mathcal{G} = \bigcup_{q \in \mathcal{Q}} \mathcal{G}_q$ which is the union of all question subgraphs $\mathcal{G}_q$ in the train dataset. As in most temporal KGQA works, we discretize time to a suitable granularity (in our dataset, a year).[2] The graph on which TwiRGCN is run represents every entity as a node v_i and time as edge attribute t_j. Their initial (layer-0) RGCN embeddings $h_{v_i}^{(0)}$ and h_{t_j}, are set to the entity and time embeddings

---

[1] TComplEx is known to provide high-quality embeddings, but other TKG embedding methods such as TimePlex (Jain et al., 2020) can also be used.

[2] TwiRGCN can be extended to TKGQA datasets that do not provide subgraphs through recently proposed subgraph selection methods (Chen et al., 2022; Shang et al., 2022).

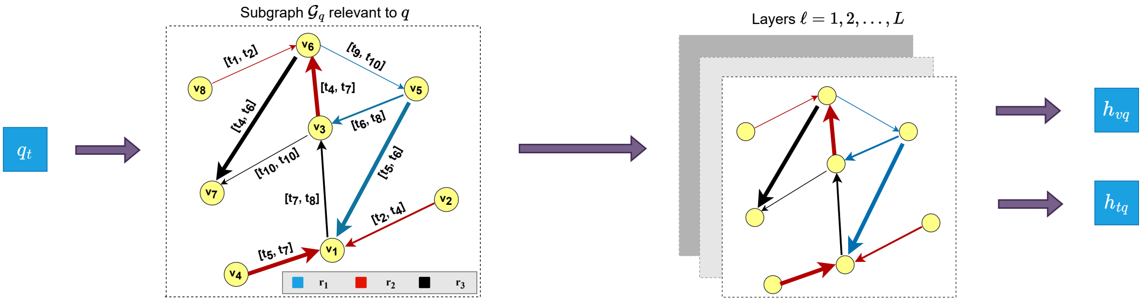

Figure 2: **Left:** Shows temporally weighted convolutional message passing described in Section 4.2 happening across a subgraph G_q for one layer. For the same, we get question-dependent temporal edge weights $m_{tq}^{(e)}$ using *question time*, q_t (described in 4.3). **Right:** As discussed in Section 4.2, embeddings are propagated in the subgraph G_q for a fixed number of layers (L) and hidden units of the final layer are pooled to get entity prediction, h_{vq}. We get time prediction, h_{tq}, by pooling the updated embeddings for all unique times in G_q.

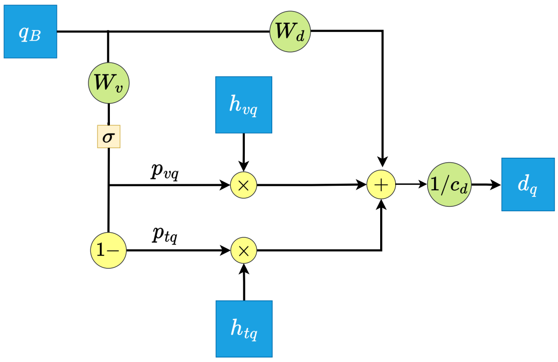

Figure 3: Predicting the answer based on gating entity prediction (h_{vq}) and time prediction (h_{tq}) of a subgraph G_q based on the likelihood that the answer is either an entity (p_{vq}) or time (p_{tq}) given question q, respectively. Details in Section 4.4.

obtained from TComplEx, respectively. We refer to h_{tj} as $h_{st}^{(e)}$ and $h_{et}^{(e)}$ depending on t_j appearing as start or end time for edge e, respectively. When $e = (i, r, j)$, we will use superscript (i, r, j) in place of (e).

4.2 Temporally modulated edge weights

Having available the question subgraph, and the initial entity and time embeddings, our system applies a temporally weighted graph convolution on the local subgraph to enable answering questions that require complex temporal reasoning over a KG. To achieve this, we introduce a question-dependent temporal edge weight $m_{tq}^{(i,r,j)} \in [-1, 1]$ for modulating the convolutional message passed through edge e valid from time $t_{st}^{(i,r,j)}$ to $t_{et}^{(i,r,j)}$ connecting node v_i to v_j via relation r, $\{v_i,\ r,\ v_j,\ [t_{st}^{(i,r,j)}, t_{et}^{(i,r,j)}]\}$ which assigns a weight to that edge depending on how relevant the time period of e is for answering question q. Then, motivated by Eqn. (1), we update the hidden state for a node v_i in the temporal KG at layer $(l+1)$ as:

$$h_{v_i}^{(l+1)} = \sigma\Bigg(W_0^{(l)} h_{v_i}^{(l)} + \sum_{r \in \mathcal{R}} \sum_{j \in \mathcal{N}_i^r} m_{tq}^{(i,r,j)} \frac{W_r^{(l)} h_{v_j}^{(l)}}{|\mathcal{N}_i^r|}\Bigg). \quad (2)$$

See Figure 1 for an example update for one node.

As shown in Figure 2, after passing messages across a subgraph G_q over L such layers, we pool the hidden states from the final layer of all nodes in G_q to get h_{vq}, the entity prediction. Similarly, we pool the updated embeddings for all unique times in G_q to get h_{tq}, the time prediction. We describe in Section 4.4 how we use h_{vq} and h_{tq} to get the final predicted answer from our model. We use mean pooling in this work, but any other pooling operation can also be used.

4.3 Edge weighting formulations

We explore two different formulations for computing $m_{tq}^{(i,r,j)}$, namely *average* and *interval*, and discuss the motivations behind the two approaches. In Section 5, we empirically show that the inductive bias inherent in each of the two approaches makes them excel at different types of temporal reasoning while giving similar performance overall. We also provide an intuitive explanation of how the edge weighting formulations of the two approaches explain the difference between their empirical results. We first project the question embedding q_B, using a learned projection matrix W_{tq}, to find the *question time* embedding $q_t = W_{tq} q_B$. In the following, $m_{tq}^{(i,r,j)} = m_{tq}^{(e)}$ is the weight for edge e.

4.3.1 TwiRGCN (average)

In this variant, we calculate the edge modulation m_{tq} as the cosine similarity between the question time embedding, and the average of the embeddings for the start and the end time of an edge:

$$m_{tq}^{(e)} = \cos\left(\frac{h_{st}^{(e)} + h_{et}^{(e)}}{2}, q_t\right). \quad (3)$$

This formulation gives a high weight to an edge if the question time falls close to the middle of the time interval for an edge. For example, if the edge times are [2008, 2012] and the question time is 2010, the edge is weighted highly.

4.3.2 TwiRGCN (interval)

In this variant, $m_{tq}^{(e)}$ is defined as the mean of two cosine similarities: (1) the cosine similarity between the start time of the edge and the learned question time embedding, and (2) the cosine similarity between the end time of the edge and the learned question time embedding. Formally,

$$m_{tq}^{(e)} = \frac{\cos(h_{st}^{(e)}, q_t) + \cos(h_{et}^{(e)}, q_t)}{2}. \quad (4)$$

This formulation weighs an edge highly if question time t_q lies within the time interval of the edge.

Generality beyond temporal reasoning While we developed TwiRGCN for temporal reasoning, the edge weighting is more general and could extend to the case where q_t is a "goal" embedding for any goal-directed task.

4.4 Answer type gating

Question answering over TKGs may involve questions whose answer is an entity (e.g., *Who was ...?*) or whose answer is a time (e.g., *When did ...?*). We hypothesize that it should be possible to predict whether the answer to a question is an entity or a time based on the text of the question; making such a prediction helps filter out (or down-weight) a portion of the nodes in that graph that are less likely to be the answer. Toward this hypothesis, we introduce a gating mechanism that learns the likelihood that the answer is an entity p_{vq} or a time p_{tq} given the question:

$$p_{vq} = 1 - p_{tq} = \sigma(w_v q_B), \quad (5)$$

where w_v transforms q_B to a scalar and σ is the sigmoid function that ensures $0 \leq p_{vq} \leq 1$. As shown in Figure 3, we then compute a prediction embedding d_q for question q as a gated sum of the entity prediction and time prediction (see Section 4.2 and Figure 2) added to the question embedding:

$$d_q = \frac{1}{c_d}[p_{vq}h_{vq} + p_{tq}h_{tq} + W_d q_B], \quad (6)$$

where c_d is a constant hyperparameter and W_d is the weight for transforming q_B to the dimension of the entity and time embeddings. Having the prediction embedding d_q, we rank candidate answers (entities and times from the global TKG) based on their similarity to d_q.

Category	Question
Explicit	*Which team won the 2010 F1 world championship?* *What honour did Agatha Christie win in 1971?*
Implicit	*Who did Kevin Garnett play for before Celtics?* *Where was Leonardo Da Vinci when he died?*
Temporal	*What years did the team with fight song Steelers polka win the Superbowl?* *What year did Sam Elliott and Kathryn Ross marry?*
Ordinal	*What was the first satellite to maintain orbit around the earth in space?* *What is the third book of the twilight series?*

Table 1: Examples of questions from each category in *TimeQuestions* dataset, discussed in Section 5.1.

Training We score all possible answer entities and times as a cosine distance with the prediction embedding (d_q), scaled using a constant hyperparameter. We take a softmax over all these scores and train using the cross-entropy loss.

5 Evaluation

5.1 Dataset

Earlier works on TKGQA use the automatically generated CronQuestions dataset (Saxena et al., 2021). A recent analysis, however, shows that this dataset comes with several limitations that stem from its automatic construction method (Chen et al., 2022). Specifically, there are spurious correlations in the dataset that can be exploited by different models to achieve high accuracy (e.g., Mavromatis et al. (2021) report more than 90% accuracy overall and 99% in some categories on this dataset). Therefore, we base our experiments on a recent more challenging dataset, namely *TimeQuestions* (Jia et al., 2021), where the aforementioned models perform poorly (as seen in Table 3).

TimeQuestions has $13.5k$ manually curated questions divided into the train, valid, and test splits containing $7k$, $3.2k$, and $3.2k$ questions, respectively. The questions fall under four types: 'Explicit,' 'Implicit,' 'Temporal,' and 'Ordinal,' based on the type of temporal reasoning required to answer the questions. We show some examples of questions from each of these categories in Table 1. We augment this dataset with question-specific subgraphs generated from WikiData in the final step of the answer graph construction pipeline proposed by Jia et al. (2021). We preprocess all the obtained facts to the *(subject, relation, object, [start*

Dataset	Question
ComQA	*Who played Dumbledore in the 5th harry potter film?*
Complex-Web-Questions	*What is the name of the club the subject of "golden shoes" played for in 2010?*
Graph-Questions	*What sports were in both the 1912 summer Olympics and the 2008 Olympic games?*
LC-QuAD 2.0	*What is the start time for Heidi Klum has spouse as Seal?*
Free917	*What is the price of a 2012 jeep wrangler sport?*

Table 2: Examples of questions requiring temporal reasoning from KGQA datasets (see Section 5.1).

time, end time]) format, and restrict all times to years, a format used by most contemporary TKGs. We create a "background KG" described in Section 4.1 as a union of all subgraphs in the train set. This background KG contains $240k$ facts, $118k$ entities, and 883 relations. We include this augmented *TimeQuestions* dataset and associated code at https://github.com/adi-sharma/TwiRGCN.

Temporal subsets of KGQA datasets: *TimeQuestions* is a compilation of temporal questions from different KGQA datasets. We show the results in Table 4 on a subset of 5 such datasets included in the test set of *TimeQuestions* namely, ComQA (Abujabal et al., 2019), ComplexWebQuestions (Talmor and Berant, 2018), GraphQuestions (Su et al., 2016), LC-QuAD 2.0 (Dubey et al., 2019), and Free917 (Cai and Yates, 2013). Table 2 shows representative examples from these 5 datasets.

5.2 Baseline methods

We compare TwiRGCN against a spectrum of existing methods, including EXAQT, other TKGQA methods, and non-temporal KGQA methods.

Non-temporal KGQA methods: We include Unicorn (Pramanik et al., 2021), which uses Group Steiner Trees for answering questions. We test on two RGCN-based approaches for KGQA, namely, GRAFT-Net (Sun et al., 2018), which attends over relations of neighborhood edges based on the question, and PullNet (Sun et al., 2019), which extends GRAFT-Net for multi-hop questions.

TKGQA methods: We also compare against TKGQA methods CronKGQA (Saxena et al., 2021) and TempoQR (Mavromatis et al., 2021) recently proposed for the CronQuestions dataset. In contrast to TwiRGCN, these do not leverage the powerful GNN framework. CronKGQA frames QA as a KG completion problem to complete the fact the question is interested in, using the TComplex score function and BERT question embedding. TempoQR, on the other hand, enriches pre-trained TKG embeddings with additional supervision from the dataset and uses a transformer (Vaswani et al., 2017) based decoder to predict the final answer.

EXAQT: Jia et al. (2021) propose EXAQT, which is hitherto the best performer on *TimeQuestions*. It is also an RGCN-based TKGQA model that utilizes the GRAFT-Net framework. But in contrast to our model, EXAQT is heavily engineered. It utilizes the ground truth question category information from the dataset at train and test time, so it always knows whether the answer is temporal or belongs to another category. In contrast, our model learns the likelihood that the answer is an entity or time without any explicit supervision through our gating mechanism described in Section 4.4. EXAQT also uses explicit temporal signals from the question, extracted through a dictionary matching-based method using predefined temporal words such as ‘before’, ‘after’, ‘first’, ‘last’, ‘during’, etc. It then enriches its embeddings by utilizing the above in a multi-step end-to-end process. In contrast, our models do not have access to any such information with only a straightforward temporally weighted graph convolution followed by answer gating, as described in Section 4.

5.3 Results

TwiRGCN achieves new state-of-the-art: We compare the accuracy (Hits@1) for different Temporal KGQA models across all question categories found in *TimeQuestions* in Table 3. From this table, we see that our models TwiRGCN (average) and TwiRGCN (interval) achieve significant improvements of up to 3.3% overall absolute accuracy over the previous state-of-the-art model, EXAQT. Additionally, TwiRGCN (average) gets a 9.8% improvement over EXAQT in the ordinal category and TwiRGCN (interval) improves over EXAQT by 9.1% in the implicit category. The questions in both these categories require significant temporal reasoning to find the correct answer. Both models also show a marked improvement of up to 3.4% in the explicit question category.

TwiRGCN (average) vs (interval): Even though the two TwiRGCN variants achieve comparable overall accuracy, they do so in different ways, showing complementary strengths. TwiRGCN (average) achieves a 2.4% improvement over TwiRGCN (interval) in the ordinal category, while TwiRGCN (interval) improves over TwiRGCN (average) for

	Overall	Explicit	Implicit	Temporal	Ordinal
PullNet (Sun et al., 2019)	0.105	0.022	0.081	0.234	0.029
Uniqorn (Pramanik et al., 2021)	0.331	0.318	0.316	0.392	0.202
GRAFT-Net (Sun et al., 2018)	0.452	0.445	0.428	0.515	0.322
CronKGQA (Saxena et al., 2021)	0.462	0.466	0.445	0.511	0.369
TempoQR (Mavromatis et al., 2021)	0.416	0.465	0.36	0.4	0.349
EXAQT (Jia et al., 2021)	0.572	0.568	0.512	0.642	0.42
TwiRGCN *(average)*	**0.605**	**0.602**	0.586	0.641	**0.518**
TwiRGCN *(interval)*	**0.603**	0.599	**0.603**	**0.646**	0.494

Table 3: Comparison of Hits@1 for different Temporal KGQA methods on *TimeQuestions* dataset (Section 5.3). Interestingly, TwiRGCN improves accuracy over SOTA by 3.3% overall and by 9-10% for the most difficult ordinal & implicit question types.

	TwiRGCN	**EXAQT**
ComQA	**0.413**	0.292
ComplexWebQuestions	**0.728**	0.515
GraphQuestions	**0.382**	0.323
LC-QuAD 2.0	0.71	**0.732**
Free917	0	**0.17**

Table 4: Results for EXAQT and TwiRGCN on temporal subsets of well-known KGQA datasets, as discussed in Section 5.3. TwiRGCN beats EXAQT by a high margin up to 21% on ComQA, ComplexWebQuestions, and GraphQuestions, which include questions requiring multi-hop reasoning.

	With gating	**W/o gating**
TwiRGCN (average)	0.605	0.597
TwiRGCN (interval)	0.603	0.597

Table 5: Results of ablation study to see contributions of answer gating described in Section 4.4 on overall Hits@1. We that it contributes about 0.7% on average to the overall accuracy of our models

Temporal Distance from q_t	
Median	**5**
=0	18.3%
≤5	51.5%
≤20	74.8%

Table 6: The median temporal distance from learned q_t to extracted time is just 5 years, while we predict an exact match 18.3% of the time (discussed in Section 5.4).

the implicit and temporal question types. We intuitively explain this behavior as a consequence of their edge weighting function m_{tq}. In TwiRGCN (average), m_{tq} (defined in Eqn. (3)) is at its peak when the average time of edge is close to the question time, enabling it to reason between the temporal ordering of facts more effectively. Thus, helping it better answer ordinal questions of the type *first*, *fourth* or *last occurrence*, etc. In contrast, m_{tq} for TwiRGCN (interval), as defined in Eqn. (4), helps answer questions that require temporal reasoning over specific times rather than just a temporal ordering of facts, which are mainly present in the implicit and temporal categories.

Temporal subsets of KGQA datasets: As mentioned earlier, *TimeQuestions* is a compilation of temporal questions from different KGQA datasets. To provide a finer-grained comparison, we compare TwiRGCN to our most competitive baseline, EXAQT, on these subsets. We show the results in Table 4. TwiRGCN outperforms EXAQT by a high margin of up to 21% in Hits@1 on the *ComQA*, *ComplexWebQuestions*, and *GraphQuestions* datasets. These three datasets contain questions requiring complex multi-hop reasoning. In contrast, we are competitive but perform slightly worse than EXAQT on *LC-QuAD 2.0*, a templated dataset created from SPARQL queries, and *Free917* that primarily consists of quantity-based questions. These results show our model's generalizability and superior performance over our primary baseline on complex multi-hop questions. They also identify a failure mode for questions whose answers are quantities (explored in Section 5.4).

5.4 Analysis

Here we explore how our models behave qualitatively and look at example cases where they perform well and cases where they do not.

Ablation for answer gating: To understand the contribution of the proposed answer gating method described in Section 4.4, we perform an ablation study by removing answer gating from Eqn. (6). By comparing columns of Table 5 we can infer that our proposed answer gating contributes about 0.7% on average to the overall accuracy of our models.

How accurate is predicted question time? We predict a question time embedding q_t close to the time of interest for answering question q, as described in Section 4.3. Here we analyze the effectiveness of this prediction by getting the time with embedding closest to q_t. We then use regex-based time extraction on questions and can extract time for 1199 questions in the test set. As seen in Table 6, out of a time range of 2916 years (including BC and AD years), our median distance from learned question time to extracted time is just 5 years while we predict an exact match 18.3% of the time. Ad-

Ground Truth	Prediction	TwiRGCN (average)		TwiRGCN (interval)	
		with gating	w/o gating	with gating	w/o gating
Entity	Time	3.18 %	7.28 %	3.23 %	4.53 %
Time	Entity	7.99 %	6.88 %	7.3 %	7.82 %

Table 7: Percentage of questions for which answer is an entity but our model incorrectly predicts time and vice versa. We analyze this in Section 5.3 with and w/o answer gating to show that our proposed answer gating helps in reducing such mistakes.

	Hits@1	**Hits@2**	**Hits@3**
EXPLICIT			
EXAQT	0.568	0.602	0.618
TwiRGCN	**0.602**	**0.618**	**0.628**
IMPLICIT			
EXAQT	0.512	0.575	0.612
TwiRGCN	**0.603**	**0.622**	**0.637**
ORDINAL			
EXAQT	0.42	0.47	0.49
TwiRGCN	**0.518**	**0.542**	**0.553**

Table 8: Effects of increasing k for Hits@k. As discussed in Section 5.4, TwiRGCN significantly outperforms EXAQT across categories of questions even as k is increased.

Temporal (Hits@1)	**±0**	**±1**	**±3**
EXAQT	0.642	0.653	0.667
TwiRGCN (average)	0.641	0.649	0.671
TwiRGCN (interval)	**0.646**	**0.659**	**0.682**

Table 9: Effects of increasing the answer temporal window on model performance for Temporal type questions. As discussed in Section 5.4, TwiRGCN (interval) gets even more accurate relative to EXAQT as we increase the temporal tolerance window.

ditionally, for 51.5% of the questions the distance is ≤5 years, while it is ≤20 years for ∼75% of the questions. Our simple-to-learn q_t which is just a linear transform of q_B works reasonably well. Better q_t would result in even more performance improvements. We leave that for future work.

Dominant errors: We do an error analysis over quantity-type questions, a challenging query class. Neither EXAQT nor TwiRGCN perform well on quantity-type questions. Out of a total of 224 quantity questions, EXAQT gets 0.1% accuracy while TwiRGCN gets 0.05%. This is because current TKGQA models treat quantities such as "2.55" or "16,233" as independent entities, instead of scalar numeric values. Additionally, from Section 5.3, we reconfirm that current TKGQA models fail on this bucket, so future work can direct special attention here. Examples: "*What was Panama's fertility rate in 2006?*" A: 2.55; "*What was the population of Bogota in 1775?*" A: 16,233.

Reducing answer type mistakes: In this study, we estimate TwiRGCN's propensity to make answer type mistakes. We define these mistakes as questions where the answer was an entity, but our model predicted a time or vice versa. From Table 7 we see that our answer gating mechanism mentioned in Eqn. (5) helps reduce such mistakes. For TwiRGCN (average), gating cuts entity-to-time mistakes by more than half.

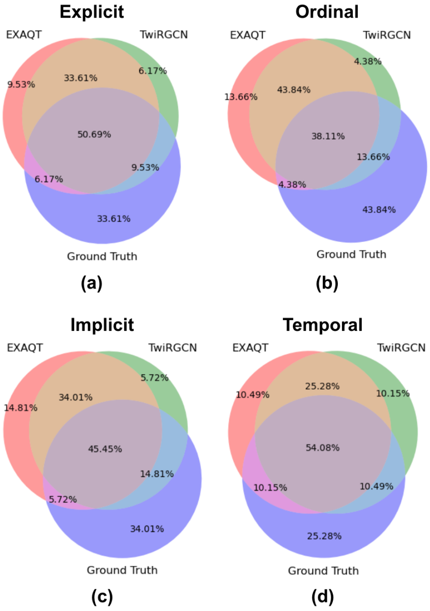

Figure 4: Venn diagrams for the prediction overlap of EXAQT, ground truth and our best model for each category. As described in Section 5.4, for Explicit, Implicit, and Ordinal question types TwiRGCN gives the right answers for most questions that EXAQT answers correctly, while correctly answering a much larger set that EXAQT gets wrong.

Increasing k for Hits@k: We extend the analysis in Table 3 increasing k from 1 to 3 for Hits@k on *TimeQuestions*. From Table 8 we see that the performance of TwiRGCN is robust to increasing k. It significantly outperforms EXAQT across categories even as k is increased for Hits@k.

Increasing temporal tolerance window: In Table 9, we explore the effects of increasing the time window for marking an answer correct for temporal questions. This means if the ground truth answer is 1992, and the predicted answer is 1990 for a question, it will be marked as incorrect in the ±1 column and correct in the ±3 column. We find that our model, specifically TwiRGCN (interval) gets even more accurate relative to EXAQT as we increase the temporal tolerance window. This implies that TwiRGCN is robust at ranking gold answers high up, even if they do not achieve rank 1.

Prediction overlap: We study the overlap of predictions between EXAQT, TwiRGCN, and ground truth. As seen in Figure 4, for Explicit, Implicit, and Ordinal question types our model gives the right answers for most questions that EXAQT answers correctly (missing less than 6% on average), while correctly answering a much larger set that EXAQT gets wrong. This split is more even between the two models for the temporal-type questions.

6 Conclusion

In this paper, we proposed TwiRGCN, a TKGQA system that employs a novel, temporally weighted graph convolution for answering questions that require complex temporal reasoning over a TKG. TwiRGCN modulates the convolutional messages through a TKG edge based on the relevance of the edge time interval to the question. We present two temporal weighting schemes with complementary strengths, intuitively explained through their simple formulations. We also propose an answer gating system for incorporating the pooled entity and time embeddings from TwiRGCN in the prediction, based on the likelihood that the answer is a time or an entity, given the question. Despite its relative simplicity, TwiRGCN gives significantly superior TKGQA accuracy on a challenging dataset compared to more heavily engineered baselines.

7 Limitations

TwiRGCN is limited by the need for relevant subgraphs for each question to be provided in the dataset. Such subgraphs have been provided in the *TimeQuestions* dataset used in the current work, but that may not be true for all TKGQA datasets. This limitation may be addressed for datasets that do not provide subgraphs through recently proposed subgraph selection methods (Chen et al., 2022; Shang et al., 2022; Jia et al., 2021), but we leave that exploration for future work.

TwiRGCN: Temporally Weighted Graph Convolution for Question Answering over Temporal Knowledge Graphs
(Appendix)

A Additional Analyses

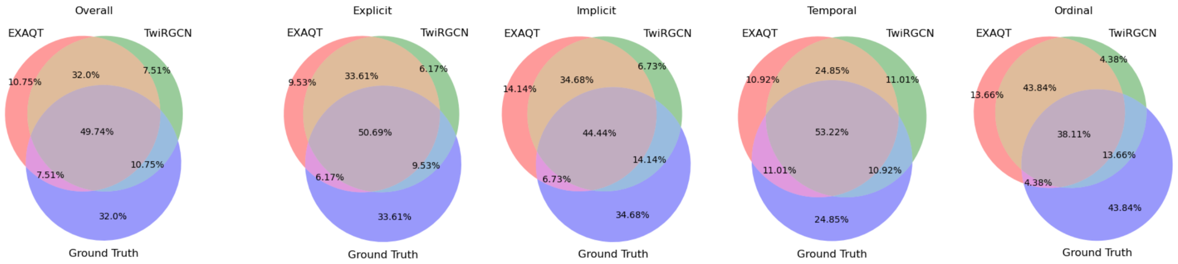
A.1 Complete prediction overlap

In Figure 5, we extend our analysis in 5.4 by providing the complete prediction overlap for both our models with EXAQT and ground truth across all question categories in *TimeQuestions*.

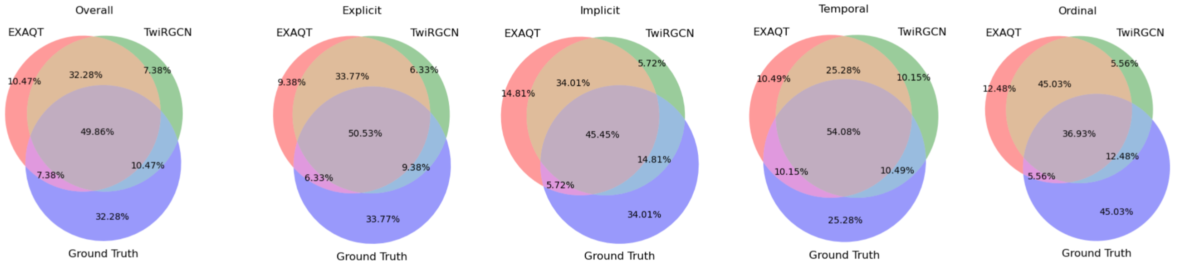
B Hyperprameters

We use the following hyperparameters:
- Number of layers, $L = 2$
- $c_d = 3$
- train batch size = 32
- valid batch size = 5
- LR = 0.00004
- Decay for LR = 0.4 every 10 epochs
- Cosine distance scaling constant for training (described in Section 4) = 30

Model and program execution details:
- Number of parameters = 2,223,833
- 11GB Nvidia GPU used with cudatoolkit 11.1
- Time per training epoch = 1:04 min
- Number of epochs to convergence on average = 50
- Early stopping used and implemented in code with patience = 10
- Validation overall Hits@1 for TwiRGCN (average) = 0.606
- Validation overall Hits@1 for TwiRGCN (intervall) = 0.602
- Performance is fairly stable around current hyperparameters without much tuning, except for LR decay rate. We used around 5–7 training runs with different decay settings to get the current rate. TwiRGCN is stable around current settings.
- Hyperparameters were tuned by manually inspecting loss behavior. Final values were selected based on a sustained, stable good performance on the test set for 3 runs.



(a) TwiRGCN (average)



(b) TwiRGCN (interval)

Figure 5: Venn diagrams for the prediction overlap of EXAQT, ground truth, and our two models TwiRGCN (average) in (a) and TwiRGCN (interval) in (b), as discussed in Appendix A.1.

ZELDA: A Comprehensive Benchmark for Supervised Entity Disambiguation

Marcel Milich
Humboldt-Universitat zu Berlin
marcelmilch@gmx.de

Alan Akbik
Humboldt-Universitat zu Berlin
alan.akbik@hu-berlin.de

Abstract

Entity disambiguation (ED) is the task of disambiguating named entity mentions in text to unique entries in a knowledge base. Due to its industrial relevance, as well as current progress in leveraging pre-trained language models, a multitude of ED approaches have been proposed in recent years. However, we observe a severe lack of uniformity across experimental setups in current ED work, rendering a direct comparison of approaches based solely on reported numbers impossible: Current approaches widely differ in the data set used to train, the size of the covered entity vocabulary, and the usage of additional signals such as candidate lists. To address this issue, we present ZELDA, a novel entity disambiguation benchmark that includes a unified training data set, entity vocabulary, candidate lists, as well as challenging evaluation splits covering 8 different domains. We illustrate its design and construction, and present experiments in which we train and compare current state-of-the-art approaches on our benchmark. To encourage greater direct comparability in the entity disambiguation domain, we open source our benchmark at https://github.com/flairNLP/zelda.

1 Introduction

Entity disambiguation (ED) is the task of disambiguating textual mentions of entities to a corresponding unique entry in a knowledge base. For instance, the entity mention "NBA" might refer to one of several organizations with this abbreviation, such as "National Basketball Association" or "National Boxing Association". ED resolves these ambiguities and creates links between a knowledge base of unique entities and the various ways an entity may be referred to in text. It is the core component in the larger task of entity linking (EL), which includes the identification of entity mentions in text, often handled by a named entity recognition (NER) system.

Recent progress in the field is driven by advances in large language models (Shen et al., 2021; Sevgili et al., 2022), pushing the scores on standard evaluation datasets to new heights. These models are typically trained in a supervised manner. Unlike many other NLP tasks with relatively few target classes, such as sentiment analysis or part-of-speech tagging, ED may have millions of target classes, since each entity in a knowledge base is modeled as a distinct class. Accordingly, most current state-of-the-art ED approaches are trained over very large amounts of annotated text data that often is automatically derived from Wikipedia.

Lack of uniformity in experimental setup. However, while a number of standard evaluation datasets exist to measure final ED accuracy, such as the AIDA-B test split of the popular AIDA dataset for newswire data (Hoffart et al., 2011), we observe that no such standardization exists for the data used to train ED systems. To illustrate this disparity, refer to Table 1 for an overview of current state-of-the-art approaches, published numbers and their respective training setups.

As Table 1 shows, approaches use different amounts of training data (ranging from 2 to 20 million "snippets" of annotated text), sourced from different Wikipedia versions using different sampling methodologies, and in some cases augmented with weak labels. Importantly, there is a stark difference in the size of the entity vocabulary for which approaches are trained, ranging from models that disambiguate a few thousand entities to models that handle over 6 million. Approaches also typically leverage so-called "candidate lists" that contain all possible disambiguation targets for textual mentions and so greatly narrow the search space. Prior work (see Section 2) has shown that each of these factors greatly influences the accuracy of an otherwise identical ED system (Broscheit, 2019; Wu et al., 2020; Févry et al., 2020; Orr et al., 2021; De Cao et al., 2021).

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2061–2072
May 2-6, 2023

Table 1: Differences in the signal used to train current state-of-the-art ED approaches and their reported accuracy on the AIDA-B evaluation dataset. Differences include: the number of snippets used to train each approach, the definition of what constitutes a "snippet", the Wikipedia version the data is sourced from, and -importantly- the size of the entity vocabulary and quality of the candidate lists used ("HF" are lists by Hoffart et al. (2011), "GH" lists by Ganea and Hofmann (2017), and "PPR" lists by Pershina et al. (2015)).

Lack of direct comparability. With this paper, we argue that these differences in training setup impair our ability to directly compare approaches based solely on published numbers on evaluation datasets. For instance, Table 1 shows that LUKE (Yamada et al., 2022) slightly outperforms the comparatively simple approach by FEVRY (Févry et al., 2020) on AIDA-B; but since FEVRY is trained to cover a much larger set of entities, we cannot know if the difference in evaluation score is due to algorithmic differences in both approaches, or simply a function of the signal used to train them.

Contributions. We argue that -much like in most other NLP tasks- we require a uniform experimental setup to evaluate large ED models. To this end, we present ZELDA, a comprehensive benchmark for supervised entity disambiguation. The benchmark consists of 95k full text paragraphs from Wikipedia, annotated with mention boundaries and disambiguation targets, and integrates 8 existing ED datasets from various domains as evaluation splits. ZELDA defines a fixed entity vocabulary of 822k entities, together with fixed candidate lists and entity descriptions. In this paper:

1. We analyze training setups in recent state-of-the-art ED approaches, and derive desiderata for a uniform training benchmark (Section 2).
2. We present the ZELDA benchmark, the design goals that inform our sampling methodology to create it, and its properties (Section 3).
3. We compute evaluation scores for baselines and three state-of-the-art approaches to present standardized scores and illustrate the usefulness of our benchmark (Section 4).
4. We make our benchmark available to the research community as an open source project.

We hope that the public release of ZELDA will encourage future ED works to leverage our benchmark, and thus facilitate greater direct comparability of future ED approaches.

2 Analysis of Training Setups

ED approaches employ large language models to embed an entity mention, its textual context and additional features. To decode, approaches typically either use variants of softmax classification (Broscheit, 2019; Févry et al., 2020; Yamada et al., 2017; Orr et al., 2021; Ayoola et al., 2022), generative decoding (De Cao et al., 2021) or retrieval-based models that compute the pairwise similarity of an embedded mention and a textual description for each target entity (Ravi et al., 2021).

Rather than focus on the algorithmic differences of these approaches, this section analyzes current state-of-the-art approaches from the point of view of their respective training setups.

2.1 Training Data

Size of training dataset. Approaches are typically trained over short snippets of text with annotated entity mentions, derived from Wikipedia page links. The number and length of these snippets varies greatly across approaches. For instance, as Table 1 shows, Ayoola et al. (2022) train their model with 20 million snippets of 512 tokens length, while De Cao et al. (2021) train with 9 million snippets of 100 token length. Orr et al. (2021) train on single sentences only, and use a comparatively small set of 5.7 million snippets. The sampling methodology to derive these snippets from Wikipedia is seldom described in detail and bespoke to each paper.

While we could find few ablation experiments in prior work, Broscheit (2019) presents an experimental evaluation in which he trains his proposed approach over two different datasets sampled from Wikipedia, one with 8.8 million and one with 2.4 million snippets. The difference in dataset size is due to a threshold parameter for frequent entities in his sampling method. Surprisingly, he finds that the model trained on the smaller dataset yields significantly better results on AIDA-B. He believes this may be because his computational resources limited training on the large dataset to only 4 epochs, whereas on the small dataset he could train for 14.

Single-mention vs multi-mention data. The number of snippets is only partly illustrative of the training signal, as the number of mentions dramatically differs per setup. In "single-mention" data as used by Barba et al. (2022) and De Cao et al. (2021), each snippet only contains a single annotated entity mention (indicated with a *dagger* asterisk in Table 1). In "multi-mention" data on the other hand, more than one mention might be annotated, thus potentially greatly increasing the training signal.

Optional augmentation with weak labels. One particularity of Wikipedia text is that within an article, usually only the first mention of an entity is marked with a page link. In fact, Orr et al. (2021) estimate that 68% of mentions are unlabeled. For this reason, many works use "weak labeling" methods to annotate unlabeled mentions (Orr et al., 2021; Ayoola et al., 2022; Broscheit, 2019) in Wikipedia articles. These methods dramatically increase the number of labeled mentions per text snippet, but may introduce errors into the training data. This naturally impacts the performance of ED: for instance, Orr et al. (2021) find that their model performs better on rare and unseen entities but worse on frequent ones when using weak labels.

Wikipedia version of training data. Table 1 also shows that the data is sourced from different Wikipedia versions. This poses problems as the entity set covered by Wikipedia grows significantly over time (Gillick et al., 2019). Further, the information contained in Wikipedia is constantly updated (such as which person currently holds which political office), potentially giving advantages to models trained on a Wikipedia version from a similar point in time as the evaluation data.

2.2 Entity Vocabulary

As Table 1 shows, published approaches also differ in their entity vocabulary, i.e. the number of unique entities they can resolve, ranging from 128k (Yamada et al., 2017) to about 6 million entities (Févry et al., 2020; Ayoola et al., 2022). While a very large entity set is desirable for a general-purpose ED system, a smaller vocabulary tuned to an evaluation dataset will likely result in better evaluation numbers. This intuition is supported by experiments by Wu et al. (2020) who found that a model trained to handle an entity set specific to their evaluation dataset outperforms a general-purpose model trained to handle 5.9M Wikipedia entities.

2.3 Candidate Lists

Most state-of-the-art ED approaches employ *candidate lists* that contain for each mention string a set of sensible entity candidates (Sevgili et al., 2022).

	Domain	Doc. Type	# Docs	∅ length	# Entities	# Mentions
Evaluation Splits						
AIDA-B	news	articles	231	201 tokens	1,538	4,485
TWEEKI	tweets	short texts	500	16 tokens	639	860
REDDIT-POSTS	forum posts	short texts	377	20 tokens	524	705
REDDIT-COMMENTS	forum comments	short texts	360	41 tokens	483	638
WNED-WIKI	Wikipedia	articles	318	315 tokens	5,293	6,747
WNED-CWEB	web	pages	320	1,433 tokens	4,467	11,116
SLINKS-TOP	web	short texts	904	35 tokens	899	904
SLINKS-SHADOW	web	short texts	904	35 tokens	902	904
SLINKS-TAIL	web	short texts	902	35 tokens	902	902
Training Split						
ZELDA-TRAIN	Wikipedia	paragraphs	95k	527 tokens	822k	2.6M

Table 2: Descriptive statistics of the training and evaluation splits of ZELDA. Note that the statistics reported for evaluation splits may differ slightly from previous literature as a consequence of our normalization procedure.

The model then classifies over the small list rather than the whole entity set. The advantage of this approach is that it greatly narrows the search space and speeds up computation. A drawback however is that these candidate lists must be created separately and that incomplete lists lower the upper bound of what an ED approach can achieve: if the correct entity is not included in the candidate list of a mention, correct classification is not possible.

Prior work showed that the choice of candidate lists significantly impacts overall results. For instance, the lists of Pershina et al. (2015) were found to be exceptionally well-tailored to the AIDA-B evaluation dataset, with high recall and low ambiguity for its entities (Yang et al., 2018). As Table 1 shows, both Févry et al. (2020) and Yamada et al. (2022) find that their models improve significantly when using these lists instead of the more generic lists by Hoffart et al. (2011) and Ganea and Hofmann (2017) respectively. Unfortunately, some approaches such as Févry et al. (2020) also employ custom lists that are not released.

2.4 Domain-Specific Features

It is possible to tailor ED systems to achieve better results on individual domains.

Page titles. Févry et al. (2020) and Orr et al. (2021) disambiguate entities in news articles, and present a custom approach for constructing snippets: instead of only taking a token window around an entity mention, they also add the title and first two sentences of the article as additional context, reasoning that these texts contain salient information that pertains to the whole article. However, such custom contexts can only be defined for individual domains (e.g. tweets for instance do not have titles) and are therefore challenging to integrate for general-purpose ED systems.

Domain-specific data. In addition to large Wikipedia-derived datasets, many works also incorporate domain-specific data into their training or fine-tuning. While many available evaluation datasets are limited to small test splits, some popular datasets also define training splits. A well-known example is AIDA, which next to AIDA-B defines a train split consisting of 20k sentences and covering 30k entities. Table 1 shows (in column "additional features") that all models either present ablations in which AIDA-TRAIN is included, or include this data by default. The numbers clearly show that including domain-specific data improves overall results. However, prior works have shown that fine-tuning to a particular domain degrades performance on other datasets (Yamada et al., 2022; De Cao et al., 2021; Le and Titov, 2019).

2.5 Additional Features

Some ED approaches leverage additional sources of information (Shen et al., 2021; Sevgili et al., 2022). In particular, *entity descriptions* are concise textual summaries of the "meaning" of each entity, and a core component of all ED approaches that follow a retrieval-based approach (Ravi et al., 2021). *Entity type information* equips each entity with semantic type as additional signal. Finally, some approaches employ *knowledge base (KB)* information to decode multiple mentions in a text paragraph such that overall entity relatedness is observed (Ayoola et al., 2022; Orr et al., 2021).

3 The ZELDA Benchmark

We create ZELDA to enable analysis and direct comparison of large ED models. Refer to Table 2 for an overview. We start by selecting and normalizing appropriate evaluation datasets (Section 3.1), upon which we define a methodology to sample training data that satisfies several objectives (Section 3.2). To ensure broad applicability, we also produce candidate lists and entity descriptions (Section 3.3).

3.1 Selection of Evaluation Splits

Desiderata. Our analysis of Section 2 showed that there are many ways to tailor the training setup to a specific evaluation dataset: one might employ domain-optimized candidate lists, include domain-specific features, use an optimized entity vocabulary, or optimize the process of sampling Wikipedia for training data. With ZELDA, we seek to minimize opportunities for such domain-specific engineering to place greater focus on evaluating algorithmic rather than engineering components. We also seek an evaluation setup that not only produces a single score, but facilitates more granular analysis of the capabilities of large ED models.

We therefore sought evaluation datasets that both span a broad range of domains (web pages, newswire text, social media) as well as isolate specific challenges in ED. To facilitate distribution, we limited our search to freely available datasets.

Selected datasets (Table 2). We chose the following 8 datasets for inclusion:

- AIDA-B is the test split of AIDA, the most commonly used ED dataset. It contains 231 manually annotated Reuters news articles.

- TWEEKI (Harandizadeh and Singh, 2020) is a collection of 500 randomly selected and hand-annotated tweets.

- Two datasets from Botzer et al. (2021), referred to as REDDIT-COMMENTS and REDDIT-POSTS respectively, that consist of top-scoring posts and comments from the internet forum Reddit. We use the "gold" subset of this dataset, i.e. all annotations in which all three annotators agreed.

- Two datasets from Guo and Barbosa (2018), referred to as WNED-WIKI and WNED-CWEB respectively, that cover the domains of Wikipedia articles and web pages. We include these datasets because they include annotation of the difficulty of each document on a scale from 0 to 1. This enables analyses of approaches as a function of estimated difficulty, as we show in Section 4.

- Three datasets from Provatorova et al. (2021), created specifically to analyze three classes of mention ambiguities: (1) SLINKS-TOP contains only easy cases in which the correct disambiguation is the most frequent sense of a mention. (2) SLINKS-SHADOW is the opposite and contains only difficult cases in which the correct disambiguation of a mention is "overshadowed" by a more popular entity. (3) SLINKS-TAIL contains only "long tail" entities that are very rare in Wikipedia.

Normalization. We unify these datasets in two ways: First, since these datasets were created at different times, we update entity annotations to the most recent version of Wikipedia (October, 2022). Second, as datasets are provided in various formats, we convert them into two commonly used standard formats, namely CoNLL and JsonL.

3.2 Training Data

Desiderata. We define a sampling methodology to create training data to balance two objectives: our first goal is to evaluate entity disambiguation for "broad entity coverage" approaches that derive large-scale training data from Wikipedia. However, if the training data is too large, model training becomes to costly for thorough analyses of design choices and hyperparameters; with the exception of the work by Févry et al. (2020), we find such analyses to be rare in current literature. For this reason, our second goal is to limit the overall size of the training dataset.

Sampling process (Algorithm 1). To balance these two goals, our sampling process starts from the vocabulary of all entities in the evaluation splits, which we refer to as the test entity set E_t. Our sampling seeks to find at least a minimal number of training examples for these entities, set by the *threshold* parameter. Following prior analyses by Vasilyev et al. (2022), we set the threshold to 10, meaning that each entity in the test set should appear at least 10 times in the training data. However, this is only possible for entities that do appear this often in the source Wikipedia data; for long-tail entities that appear fewer times, we select as many examples as possible.

Our sampling selects entire Wikipedia paragraphs for inclusion into the training dataset. The reason for choosing paragraphs as atomic document type is threefold: (1) Unlike fixed-length token windows that center on one particular entity, paragraphs typically consist of multiple full sentences that provide natural context for entity mentions. (2) By choosing random paragraphs instead of full articles, we limit overall dataset size and introduce more textual variety as opening paragraphs of Wikipedia articles were observed to often have similar wording (Le and Titov, 2019). (3) Paragraphs contain mentions to many other entities outside of E_t. These entities are naturally skewed and added to the overall entity vocabulary of ZELDA.

Data preprocessing. We leverage the Kensho Derived Wikimedia Dataset[1], derived from the Wikipedia dump of December 2019. This dataset is preprocessed such that redirect-, disambiguation- and list-pages are removed, the text is cleaned and articles are divided into sections. Here, each section corresponds to one paragraph of text. We discard common section types that typically contain little text (such as the "Bibliography" and "External Links" sections common to Wikipedia articles). To ensure that all annotations are consistent with our evaluation splits, we update entity annotations to the most recent version of Wikipedia and discard those for which no article exists anymore.

Resulting training data. This set is randomized and sampled using Algorithm 1, yielding a training data set of 95k paragraphs spanning on average 527 tokens. It contains a total of 2.6 million mentions covering a vocabulary of 825k distinct entities, which we refer to as ZELDA-TRAIN. See Table 2 for descriptive statistics.

3.3 Additional Structured Information

We provide *candidate lists* that we derive with a general approach from the Kensho Wikimedia dataset, the Wikilinks web corpus (Singh et al., 2012) and the "also known as" information from Wikidata. For all mentions in these sources we list and count all entities that they refer to and filter entities from these lists that are not contained in the ZELDA entity vocabulary (details in Appendix A.3). Moreover we derive the most-frequent-sense baseline (MFS) by choosing, for every mention, the entity that this mention refers to the most often.

We also provide standardized *entity descriptions*: For each entity we extract the opening paragraph of its Wikipedia article as its description.

4 Experiments

We showcase the ZELDA benchmark by training a set of baselines and state-of-the-art approaches on ZELDA-TRAIN, and comparatively evaluating them on our evaluation splits.

Algorithm 1: Paragraph sampling

```
input  : Set of sections $S$, test entity set $E_t$
output : Filtered list of sections $\hat{S}$

$threshold \leftarrow 10$;
$counter_e \leftarrow 0$ for $e$ in $E_t$;
while $E_t \neq \emptyset$ do
    $s$ = random.sample($S$);
    if $E_t \cap s.links \neq \emptyset$ then
        $\hat{S}$.add($s$);
        for $e$ in $s.links$ do
            $counter_e \leftarrow counter_e + 1$;
            if $counter_e \geq threshold$ then
                $E_t$.remove($e$)
            end
        end
    end
end
return $\hat{S}$
```

4.1 Evaluated Approaches

We compare 8 different models, as listed in Table 3:

Simple baselines. We include two baseline approaches. The first is MFS, a simple most-frequent-sense baseline that assigns each mention to its most commonly observed entity. The second is CL-RECALL, which calculates the upper bound reachable with our provided candidate lists: for each mention, the gold entity is assigned if it is included in the candidate list.

Simple softmax classifier (FEVRY). We include a reimplementation of the approach by Févry et al. (2020) in two variants: FEVRY_{CL} uses our candidate lists, while FEVRY_{ALL} does not use any lists to restrict the search space. The approach leverages a simple softmax classification head trained on top of a transformer model that takes as input a text snippet. Despite its simplicity, it was found to be surprisingly competitive. We reimplemented the approach as Févry et al. (2020) did not release their code. However, since our train set is much smaller we use `bert-base-uncased` instead of just a 4-layer transformer and adapt the hyperparameters to our setting (see Appendix A.1)

LUKE. We train two variants of LUKE (Yamada et al., 2022), the current state-of-the-art approach for several benchmark datasets. It trains a language model with entity embeddings, and employs a global decoding mechanism to decode mentions

Table 3: Results of our experiments. Bold scores indicate the best scores of all the trained models. Underlined scores represent the best scores among the classification-based models.

in a given text snippet by order of confidence. Each classified mention is used as a feature to better classify the remaining mentions in a snippet. For training, they distinguish between *pre-training* in which entity embeddings are learned, and an optional final epoch of *fine-tuning* in which they are frozen. We train one model only with pre-training (LUKE$_{PRE}$) and one with fine-tuning (LUKE$_{FT}$).

We use their publicly available code[2] to train our two models. For direct comparison to the FEVRY model, we use `bert-base-uncased` instead of `bert-large-uncased` (utilized in Yamada et al. (2022)) and slightly adapt their hyperparameters to our setting, see Appendix A.1.

GENRE. We also train two variants of GENRE (De Cao et al., 2021), a generative approach that formulates ED as a sequence-to-sequence problem. A given input text with flagged mention boundaries is input, from which an entity title is generated. To ensure that the generated sequence is a valid title, GENRE uses a prefix-tree generated from all entity titles in the data to constrain the generation process. GENRE does not use candidate lists during training but in inference the prefix tree can be derived from the candidate lists. We call this variant GENRE$_{CL}$.

We use their publicly available code[3] to train our two models. Instead of the `bart-large` model we use the `bart-base` version to make the comparison more fair. We adapt the recommended hyperparameters to our setting (see Appendix A.1).

4.2 Results

Table 3 breaks down the accuracy of each model for each of the evaluation splits, and provides a single macro-averaged accuracy score for all data. We make a number of interesting observations:

Different ranking of approaches. Most importantly, we arrive at a starkly different ranking of approaches compared to published numbers on AIDA-B as listed in Table 1 where GENRE is one of the lowest-scoring models. In contrast, in our evaluation the two GENRE models clearly outperform all other considered models in most evaluation splits.

Impact of candidate lists. We note that our general-purpose candidate lists derived from Wikipedia score unevenly across domains. As our CL-RECALL baseline shows, our lists have a high upper bound on evaluation splits covering Wikipedia and social media domains, but a relatively low upper bound on splits from the domains of web pages or news text. We also note that of the classification-based approaches, only FEVRY$_{ALL}$ does not use candidate lists, but scores best.

Moreover, the overall best-scoring approach GENRE is trained without candidate lists. But during prediction, the better-scoring variant GENRE$_{CL}$ employs candidate lists, while GENRE$_{ALL}$ does not. This indicates using candidate lists only for prediction, but not training, may be a worthwhile approach to further explore.

Hard-to-disambiguate entities. On the SLINKS-SHADOW dataset of "overshadowed" entities, FEVRY$_{ALL}$ outperforms GENRE. One possible interpretation is that a generative approach naturally favors decoding into the most prominent sense, as the generated entity title will be most similar to the mention text. On the other hand, classification-based approaches are not influenced by string similarity of entity and mention text, potentially leading to better performance here.

In Table 4, we additionally list the scores on the brackets for WNED-WIKI provided by Guo and Barbosa (2018). The table shows that accuracy scores of all models steadily decrease from left (the

LUKE$_{FT}$	0.915	0.904	0.863	0.803	0.778	0.738	0.622	0.562	0.773
GENRE$_{CL}$	0.971	0.942	0.912	0.856	0.878	0.869	0.869	0.797	0.887

Table 4: Accuracy measured for best approaches on different *difficulty brackets* of WNED-WIKI. The lowest scores are observed for the most difficult bracket "[0.4 - 0.3]".

easiest bracket) to right (the hardest bracket). As we see this is not caused by a the CG-recall on WNED-WIKI which is independent from the brackets. This indicates that there remains much room for improving ED performance on ZELDA even when leveraging candidate lists during prediction.

4.3 Discussion

Our evaluation showed that the generative GENRE approach outperforms all classification-based approaches, and a simple direct classification approach without candidate lists as second-best performing approach overall. This indicates that equalizing the training signal, removing opportunities for domain-specific engineering, and evaluating across diverse evaluation splits may yield more insights into which algorithmic approach is best-suited to train large ED models.

However, we must also caution against overinterpreting this ranking: due to the large training times for each of these models, we did not explore any hyperparameters. Instead, we used default parameters whenever possible, and in the case of LUKE and FEVRY changed the underlying transformer to the same model, for more direct comparability. Models were only trained for as long as our computational resources allowed. Upon publication of the benchmark we anticipate that authors will explore better hyperparameters for their respective approaches, which may change the ranking (see Limitations section).

5 Related Work

Prior work has addressed aspects of evaluating ED.

Standardized evaluation. GERBIL (Röder et al., 2018) standardizes ED evaluation over multiple datasets in a unifying framework, but does not define the training data and thus only focuses on comparing already-trained models. Similarly, a range of prior works have sought to refine and standardize ED evaluation (Waitelonis et al., 2019; Nait-Hamoud et al., 2021; Noullet et al., 2021; Odoni et al., 2019; van Erp and Groth, 2020; Braşoveanu et al., 2018). In contrast, ZELDA defines the full experimental setup, including training data, the entity vocabulary and other training signals.

Manually labeled training data. A few existing ED datasets not only define a test set, but also a training split. An example discussed in this paper is the AIDA dataset. Other datasets include TAC-KBP2010 (Ji and Grishman, 2011), which is not available anymore, and a zero-shot dataset from Logeswaran et al. (2019). However, these datasets are too small and cover too few entities for evaluation of large ED approaches.

Deriving training data from Wikipedia. All current state-of-the-art approaches derive their training data from Wikipedia, though the exact process is often not thoroughly described and/or provided to the public. One exception is the BLINK corpus created by Wu et al. (2020) that is used in other works. However, this corpus consists only of single-mention snippets and cannot be used for approaches that train global decoders, like LUKE.

Most similar to our sampling method is from Orr et al. (2021). The authors sample a small Wikipedia subset by sampling for the mentions of the KORE50 benchmark (Hoffart et al., 2012). Unlike our approach, they sample all occurrences of each mention and sample only single sentences, yielding 520k sentences for only 144 mentions.

6 Conclusion

We presented the ZELDA benchmark to unify experimental setups across large ED approaches, and conducted an evaluation of various approaches. We find that given the exact same training signal, approaches compare differently than published numbers suggest. We release the datasets, our sampling and preprocessing scripts and our FEVRY reimplementation to the research community as an open source project available at `https://github.com/flairNLP/zelda`. Additionally, we integrate our benchmark into the open source NLP framework FLAIR (Akbik et al., 2019).

We hope that this will encourage present and future ED works to compare algorithmic differences on a more equal setting and thus help generate insights to further advance the field of ED.

7 Limitations

As discussed in Section 4.3, an important limitation of our experimental evaluation is our lack of hyperparameter exploration of published approaches. Given the effort required to train large ED models and the many involved hyperparameters, we believe that only the original authors of their respective approaches can perform a meaningful search of hyperparameters for our benchmark, limiting us to best-effort parameters from prior literature. It is therefore possible if not likely that the respective authors of the approaches we compare might arrive at better numbers than the ones presented here.

Regarding the ZELDA benchmark itself, we note that it is designed to evaluate supervised ED approaches. As we sampled the dataset to contain at least 10 annotations for each entity in the ZELDA test splits whenever possible, it is unclear whether ZELDA is useful for evaluating the currently growing family of zero-shot ED models (Logeswaran et al., 2019; Wu et al., 2020). Finally, our training corpus is relatively small compared to some other Wikipedia corpora used in prior approaches. While we made this design choice purposefully to enable faster training times and hopefully more exploration of hyperparameters by future works, we cannot be certain whether rankings obtained on ZELDA transfer to approaches trained on orders of magnitude of more data.

A Appendix

A.1 Training Parameters and Times

Our training parameters are informed by recommended parameters of prior works, adapted to the smaller training dataset size of ZELDA-TRAIN. In some cases, we adapted parameters across approaches for greater comparability, for instance by using the same transformer model for both LUKE and FEVRY. Across all approaches, we use the following parameters: We train all models for 6 epochs with a mini-batch size of 64 and a learning rate of 5e-5. The remaining hyperparameters are specific to each model:

FEVRY. The remaining parameters in FEVRY follow the recommendations from the paper, i.e. we use the Adam optimizer (Kingma and Ba, 2015) with a linear warmup for the first 10% of training and gradient clipping. However, the smaller dataset allowed us to look at more context. We split paragraphs of ZELDA into snippets of 400 tokens (Fevry: 256) and use an entity embedding size of 200 (Fevry: 256). Training FEVRY$_{ALL}$ took around 5h per epoch and for FEVRY$_{CL}$ 2.5h per epoch on a single Nvidia 3090ti GPU, respectively.

LUKE. We run experiments with both one-stage and two-stage training in LUKE. In one-stage training, we use for all epochs the same learning rate and do not fix the transformer weights. The entity masking rate is set to 30%. In two-stage training (LUKE$_{CL}$), we do fine-tuning in the last training epoch where we fix the entity embeddings and set the entity masking rate to 90%. To ensure comparability to FEVRY we set the entity embedding size to 200. For the remaining parameters we stick to the ones of the original LUKE which can be found in detail in table 4 and 5 of Yamada et al. (2022). Paragraphs of ZELDA are divided into snippets with ≤ 512 tokens. Training LUKE took roughly 2h per epoch on a single Nvidia 3090ti GPU.

GENRE. Apart from the parameters that we already discussed, we take all default parameters from the original paper. The parameters can best be found in the released code[4]. Since GENRE takes much longer to train than the other models and processes mentions individually we gave the model less context: We split context 500 chars to the left and 500 chars to the right of each mention (a context of roughly 190 tokens). At inference we use a beam size of 10 and a maximum number of 15 decoding steps as in the original paper. Training GENRE took around 16 hours on two Nvidia 3090ti GPUs per epoch.

A.2 Model Parameters

Our models have the following number of parameters: Both LUKE and FEVRY use a `bert-base-uncased` transformer model (110M parameters), a projection layer (768 × 200 ≈ 153k parameters) and the entity embedding layer (200 × 825k ≈ 165M parameters), and thus have about 274M parameters in total. GENRE adds a decoder with 768 × 51197 ≈ 39M parameters to its underlying transformer and thus has a total of 178M parameters.

A.3 Candidate Lists

We derive the candidate lists with a straightforward approach from three sources: Wikipedia Kensho, WikiLinks and Wikidata. The first two are text corpora with entity annotations derived from page links. As each page link has a mention string (the so-called "anchor text") and a target Wikipedia

---

[4] `https://github.com/facebookresearch/GENRE/blob/main/scripts_genre/train.sh`

page, we can simply go through both datasets and collect all mentions and their targets. To ensure that the entity titles are up-to-date, we check with calls to the Wikipedia API if the titles lead to an existing Wikipedia page and discard them if not. This yields a set of [mention, entity] tuples. We aggregate and count these tuples.

Using the Wikidata API, we retrieve for each entity in our vocabulary the corresponding Wikidata page. From this page, we extract aliases from the "also known as" field. We interpret all aliases as additional mentions to an entity, leading to another set of [mention, entity] tuples that we aggregate with the first list. To cover a broader range of mentions we add the lower cased version and version without blanks and special characters of each mention to the tuple set.

GLADIS: A General and Large Acronym Disambiguation Benchmark

Abstract

Acronym Disambiguation (AD) is crucial for natural language understanding on various sources, including biomedical reports, scientific papers, and search engine queries. However, existing acronym disambiguation benchmarks and tools are limited to specific domains, and the size of prior benchmarks is rather small. To accelerate the research on acronym disambiguation, we construct a new benchmark named GLADIS with three components: (1) a much larger acronym dictionary with 1.5M acronyms and 6.4M long forms; (2) a pre-training corpus with 160 million sentences; (3) three datasets that cover the general, scientific, and biomedical domains. We then pre-train a language model, *AcroBERT*, on our constructed corpus for general acronym disambiguation, and show the challenges and values of our new benchmark.

1 Introduction

An acronym is an abbreviation formed from the initial letters of a longer name. For instance, the following two sentences contain the acronym *“AI”*: (1) *This is the product’s first true **AI** version, and it understands your voice instantly.* (2) *In the United States, the **AI** for potassium for adults is 4.7 grams.* The long forms (or expanded forms) for the same acronym are *“Artificial Intelligence”* and *“Adequate Intake”*, respectively.

Acronym Disambiguation (AD) is the task of mapping a given acronym in a given sentence to the intended long form. Acronym disambiguation is crucial for downstream tasks such as information extraction, machine translation, and query analysis in search engines (Jain et al., 2007; Islamaj Dogan et al., 2009). Acronym disambiguation is also important for humans: acronyms may make a text more difficult to understand for readers who are not familiar with the specific domain. A study on a Microsoft question answering forum found that only 7% of the acronyms co-occur with their corresponding long forms, which confuses the readers about the meaning of a text (Li et al., 2018).

ID	Long Form	Popularity	Domain
1	***Artificial Intelligence***	★★★★★	Computer Science
2	*Adequate Intake*	★★★★	Food and Nutrition
3	*Aromatase Inhibitor*	★★★	Chemistry
4	*Apoptotic Index*	★★★	Biomedicine
5	*Asynchronous Irregular*	★★★	Neuroscience
6	*Amnesty International*	★★	Organization
7	*Anterior Insula*	★★	Biomedicine
8	*Air India*	★★	Organization
9	***Article Influence***	★★	Science
......			
2243	*Agricultural Implement*	★	Agriculture

Table 1: Long form candidates for the acronym *“AI”* from our acronym dictionary. The SciAD benchmark (Veyseh et al., 2020) only includes two long terms (black) in the scientific domain. The popularity is the occurrence frequency in our collected corpora.

Acronym Disambiguation has received more attention in the past few years. The first step in acronym disambiguation is usually the creation of a dictionary, i.e., a mapping of each acronym to one or more long forms. Early systems extracted acronyms and their definitions automatically from texts by rule-based (Schwartz and Hearst, 2002) or supervised (Nadeau and Turney, 2005) methods. Once a dictionary is available, acronym disambiguation methods expand acronyms in a given text by capturing the contexts for specific domains, e.g., the enterprise domain (Li et al., 2018), biomedical texts (Jin et al., 2019), and scientific papers (Charbonnier and Wartena, 2018). Madog (Veyseh et al., 2021) was the first general and web-based system, recognizing and expanding acronyms across multiple domains. Several benchmarks have also been constructed, including for the biomedical area (Suominen et al., 2013) and the scientific area (SciAD, Veyseh et al., 2020). Several methods fine-tuned SciBERT (Beltagy et al., 2019) on SciAD to disambiguate acronyms in scientific documents (Pan et al., 2021; Zhong et al., 2021; Li et al., 2021).

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2073–2088
May 2-6, 2023 ©2023 Association for Computational Linguistics

Although these works have significantly advanced the progress of acronym disambiguation, they suffer from three main limitations. First, most existing dictionaries (and benchmarks) focus on one specific domain. In real-world applications, however, the input text may be general, cross-domain, or of an unspecified domain (as in search engine queries). Second, existing dictionaries are limited in size. For example, there are only two long forms for the acronym *"AI"* in SciAD (Table 1), which is constructed from arXiv. However, we find that the two long forms *"Asynchronous Irregular"* and *"Anterior Insula"* also appear in scientific papers on arXiv (Girardi-Schappo et al., 2019; Vadovičová, 2014), and the acronym *"AI"* also appears separately without the long form in sentences. In our work, we actually find at least 2 243 different long forms for *"AI"*. Besides, SciAD suffers from the problem of data leakage, because the train and test sets have overlapping pairs of acronym and long form. Finally, current general AD systems such as MadDog (Veyseh et al., 2021) rely on static word embeddings and LSTMs (Long Short Term Memory (Hochreiter and Schmidhuber, 1997)). Thus, they do not leverage pre-training on large corpora, which drives the current state of the art in most NLP tasks with contextual embeddings like BERT (Devlin et al., 2018).

With this work, we aim to improve Acronym Disambiguation along two dimensions: First, we automatically construct GLADIS, a **G**eneral and **L**arge **A**cronym **DIS**ambiguation benchmark that includes a larger dictionary, a pre-training corpus and three datasets covering the general, biomedical, and scientific domains. Our dictionary contains 1.5M acronyms and 6.4M long forms, which trumps existing dictionaries by a factor of 3. We complement this dictionary by three domain-specific datasets for acronym disambiguation, which are adapted from three existing human-annotated and crowd-sourced datasets (Mohan and Li, 2018; Onoe and Durrett, 2020; Veyseh et al., 2020). The pre-training corpus has 160 million sentences with acronyms, collected from the Pile dataset (Gao et al., 2020) with a rule-based algorithm (Schwartz and Hearst, 2002). Second, we propose AcroBERT, the first pre-trained language model for general acronym disambiguation. Our experiments show that this model outperforms existing systems across multiple domains. Our code and data are available at `https://github.com/tigerchen52/GLADIS`.

2 Related Work

2.1 Acronym Identification and Disambiguation

To expand acronyms, there are usually two subtasks: Acronym Identification (AI), which creates a dictionary of acronyms and their definitions from a given document, and Acronym Disambiguation (AD), which aims to link acronyms in the input text to the correct long forms from a dictionary.

The study of acronym identification has a long history. Early work observed that acronyms and their long forms appear frequently together in a document, as in *"Artificial Intelligence (AI)"*. Based on this pattern, many approaches identify and extract acronyms by using rules (Yeates et al., 2000; Larkey et al., 2000; Pustejovsky et al., 2001; Park and Byrd, 2001; Yu et al., 2002; Schwartz and Hearst, 2002; Adar, 2004; Ao and Takagi, 2005; Okazaki and Ananiadou, 2006; Sohn et al., 2008; Veyseh et al., 2021) or supervised methods (Chang et al., 2002; Nadeau and Turney, 2005; Kuo et al., 2009; Movshovitz-Attias and Cohen, 2012; Liu et al., 2017; Wu et al., 2017; Zhu et al., 2021). In our work, we build on previous work (Schwartz and Hearst, 2002) for Acronym Identification, and focus mainly on disambiguation.

As for acronym disambiguation, early solutions manually designed features to score each pair of acronyms and long forms, by either unsupervised (Jain et al., 2007; Henriksson et al., 2014) or supervised machine learning (Pakhomov et al., 2005; Yu et al., 2007; Stevenson et al., 2009; Finley et al., 2016; Li et al., 2018). Later, deep learning approaches were introduced to the task, using embeddings to represent word sequences. The methods can be categorized as static embedding-based (Wu et al., 2015; Li et al., 2015; Charbonnier and Wartena, 2018) and dynamic embedding-based (Jin et al., 2019; Pan et al., 2021; Zhong et al., 2021; Li et al., 2021), where the former generates fixed representations for words in a pre-defined vocabulary and the latter can represent arbitrary words dynamically based on specific contexts. One main limitation of these methods is that they are domain-specific systems that can be applied only to a certain field such as the biomedical domain or scientific documents. To generalize the system, Ciosici and Assent (2018) presented the Abbreviation Expander, and Veyseh et al. (2021) proposed MadDog, both of which can be used in multiple domains. In this paper, we improve over the performance of these systems by adapting transformer-based methods and pre-training strategies.

2.2 Existing benchmarks

Most current public datasets for acronym expansion are focused on a particular domain, such as the biomedical domain (Suominen et al., 2013; Wen et al., 2020) or science (Charbonnier and Wartena, 2018; Veyseh et al., 2020). Some works adopt two domain-specific datasets for better evaluations (Ciosici et al., 2019; Veyseh et al., 2022). The main limitation of these benchmarks is two-fold: first, their acronym dictionaries are rather small. For instance, the average number of candidates per acronym in the SciAD benchmark (Veyseh et al., 2020) is 3.15 while in our benchmark the number is greater than 200. Second, there are no AD evaluation sets that cover multiple domains. We also note that, in SciAD, the train and test sets have overlapping pairs of acronym and long form. For example, the pair ⟨*CT, Computed Tomography*⟩ appears in the training, validation, and test sets.

3 Constructing GLADIS

Our GLADIS benchmark consists of three components: a dictionary, a pre-training corpus, and three domain-specific datasets.

3.1 Dictionary and Pre-training Corpus

We propose an acronym dictionary that addresses the shortcomings of existing dictionaries (Section 2.2) by being (1) cross-domain and (2) large in size. To construct this dictionary, we apply rule-based extraction on a large set of corpora that contain acronym definitions. In this process, we can also obtain a large number of sentences containing acronyms as the pre-training corpus.

Input Corpora. For the textual data source, we use the Pile dataset (Gao et al., 2020), an 825 GiB English corpus constructed from 22 diverse high-quality subsets (see the details of Pile in Appendix A.1). We also make use of structured knowledge from knowledge bases, namely the Alias Table from Wikidata and the Concept Names from UMLS. Both of them contain alternate names for canonical entities, and these may be acronyms or not. To consider only the acronyms, we produce pairs of the canonical name and an alternate name in the form *"canonical form (alternate name)"*. The rule-based algorithm will then decide whether to extract an acronym or not. Table 2 shows the statistics of our sources. They cover a wide range of domains including Web pages, books, scientific and biomedical papers, legal documents, etc.

Table 2: Sources for acronym extraction. All corpora except Wikidata Alias and UMLS Concept are from Pile (Gao et al., 2020).

Acronym Extraction. To extract acronyms from the textual sources, we use the rule-based algorithm proposed by Schwartz and Hearst (2002). It assumes that acronyms follow a predictable pattern, e.g., *long form (acronym)* or *acronym (long form)*, and then uses rules to extract candidate pairs by identifying parentheses and surrounding tokens. Experimental results show that this simple algorithm achieves 95% precision and 82% recall, averaged over two datasets. As the method has good results at low time complexity, we decided to not adopt more sophisticated methods. Some extracted samples are shown in Table A2 in the appendix. A manual evaluation on a random sample of 100 extracted sentences yields a precision of 94%.

Dictionary Construction. Next, we build a large-scale acronym dictionary with frequencies (popularity) by merging the extracted outputs. This merger may regroup duplicate long forms for an acronym, e.g., *"convolutional neural network"*, *"convolutional-neural network"* or *"convolutional neural networks"*. Therefore, we merge long forms that are identical after stemming and removing punctuation. In our case, the above three forms are merged into *"convolutional neural network"*. We keep the most frequent, unpreprocessed, long

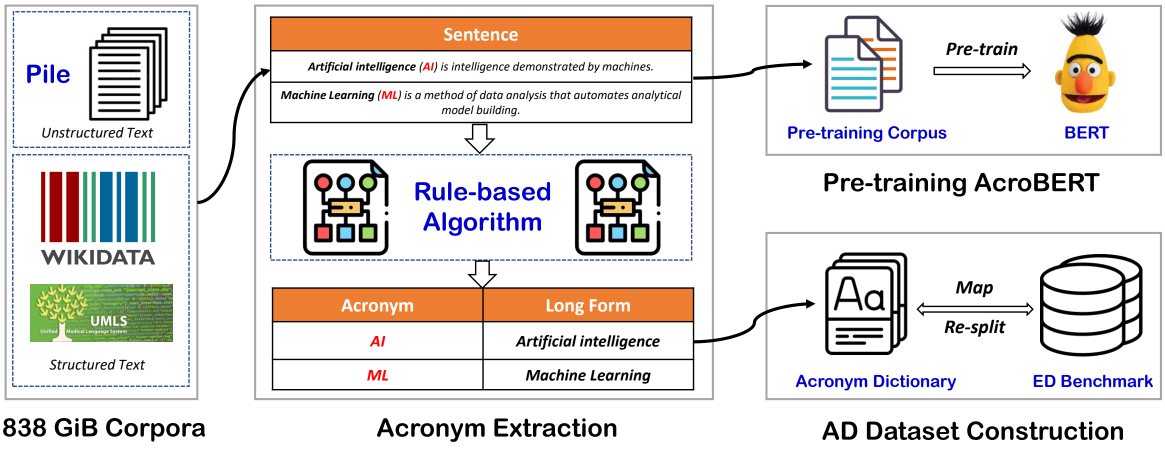

Figure 1: Framework of our benchmark construction. The *"ED"* in the lower right corner means *"Entity Disambiguation"*.

	train	valid	test	unique short form	long forms per acronym	overshadowed ratio
General	13,269	7,024	7,125	1,147	248	29.8%
Scientific	28,023	14,134	14,066	2,922	262	68.7%
Biomedical	6,295	3,150	3,149	2,909	278	27.4%

Table 3: Statistics of our new Acronym Disambiguation Benchmark. The last column shows the ratio of overshadowed samples in the dataset: long forms with the same acronym but not the most popular one.

	Short Form	Long Form	Avg
SciAD (2020)	732	2,308	3.15
MadDog (2021)	426,389	3,781,739	8.87
Ours	1,542,819	6,381,257	4.14

Table 4: Statistics for three acronym dictionaries. The "Avg" column shows the average number of long forms per acronym.

form as the canonical name in our dictionary, discarding other forms. There are still some noisy long forms that cannot be merged, caused by typos and nested acronyms (see Section 7). However, a manual evaluation on a sample shows that 94% of the long forms are clean. If the long forms are weighted by their frequency, the percentage of clean forms increases to 97%. Most notably, all most frequent long forms for a given acronym were clean in our sample. The statistics of our dataset are shown in Table 4. Our resource will be the largest publicly available dictionary for acronyms that covers various domains.

Pre-training Corpus. While building the dictionary, we can also collect the sentences that contain acronyms for pre-training. For example, the following sentence contains the acronym *ELEC*: *"Christie, some legislators and the state Election Law Enforcement Commission (**ELEC**), have joined the comptroller in voicing support for the elimination of the loophole."* For pre-training, the long form *Election Law Enforcement Commission* is removed, and we then force the model to restore the long form from our constructed dictionary, based on the input sentence and the acronym. In total, we collect a pre-training corpus with ~160 million sentences. More examples are shown in Table A2.

3.2 Acronym Disambiguation Dataset

We use our acronym dictionary to construct new, larger datasets for evaluating AD systems. To automatically construct the datasets, we adapt the existing two Entity Disambiguation datasets by replacing the long form of entity with the acronym. For example, one sentence in Medmentions (Mohan and Li, 2018) contains the long form of Cerebral Blood Flow: *"The reconstructed volume was then compared with corresponding magnetic resonance images demonstrating that the volume of reduced **Cerebral Blood Flow** agrees with the infarct zone at twenty-four hours"*. The dataset provides the unique ID of this long form in UMLS (*C1623258*), and we use it to find the acronym *CBF* in UMLS.

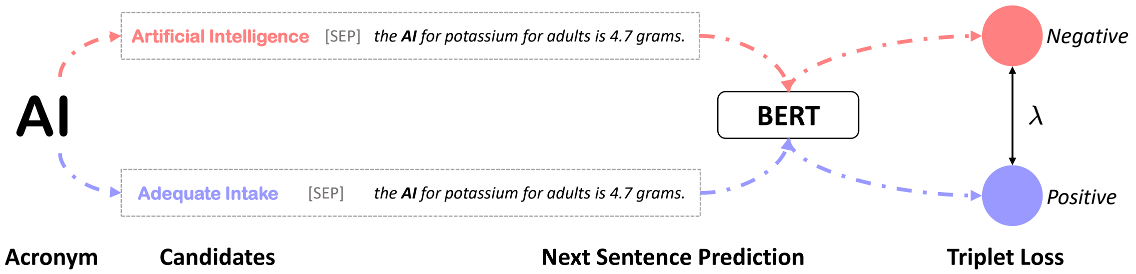

Figure 2: The pre-training strategy of AcroBERT. λ is a margin between positive and negative pairs, here $\langle$*Adequate Intake, AI*$\rangle$ and $\langle$*Artificial Intelligence, AI*$\rangle$.

Therefore, a new sample can be obtained by replacing the long form with its corresponding acronym.

Specifically, we use the following human-annotated and crowd-sourced datasets:

WikilinksNED Unseen Mentions (Onoe and Durrett, 2020) is an Entity Disambiguation dataset, i.e., a set of text documents that have mentions of entities, together with a reference knowledge base (KB) that contains, for each entity, one or several names. WikilinksNED Unseen Mentions re-splits the WikilinksNED dataset (Eshel et al., 2017) to ensure that all mentions in the validation and test sets do not appear in the training set. This is a large-scale, crowd-sourced ED dataset from websites in various fields, which is significantly noisier and more challenging than prior datasets. The reference KB is Wikidata (or Wikipedia), and we adapt this WikilinksNED Unseen Mentions to an AD dataset in the **general** domain.

Medmentions (Mohan and Li, 2018) is an entity disambiguation dataset of 4,392 PubMed papers that were annotated by professional and experienced annotators in the biomedical domain. The reference KB is UMLS (Bodenreider, 2004), and this is a **biomedical** dataset.

SciAD (Veyseh et al., 2020) is the previously mentioned acronym disambiguation dataset in the **scientific** domain.

SciAD is already an AD dataset, and we only re-split it to avoid data leakage. As for the two ED datasets, they both provide a unique ID to the reference KB for each long form. We then replace the long forms with the acronyms from their corresponding reference KB, i.e., Wikidata and UMLS. To make sure this replacement is correct, we apply the rule-based algorithm (Schwartz and Hearst, 2002) to the pair of long form and acronym again for verification. We manually checked 100 random sentences constructed in this way and did not find problematic cases. Hence, this semi-synthetic construction results in a dataset of natural text in which the long form and the acronym are mutually replaceable in the context. Besides, the pair is added to our dictionary with a frequency of 1 if it does not appear in our dictionary. For the WikilinksNED dataset, we use the taxonomy of YAGO 4 (Pellissier Tanon et al., 2020) to label each long form with a top-level class. For example, *"rhythm and blues"* is a `CreativeWork` and *"United States Navy"* is an `Organization`.

We then partition the three datasets separately into training, test, and validation set, ensuring that the acronyms in the training set do not appear in the validation and test sets. We repartition the datasets at the ratio of 6:2:2. Table 3 gives the statistics of this new benchmark. It is not only larger but also more challenging than existing benchmarks, because acronyms in our benchmark have more than 200 candidates on average. Moreover, it contains many *overshadowed forms* (Provatorova et al., 2021), which means that an acronym has to be disambiguated to a long form that is not the most popular long form for that acronym. For example, *"Adequate Intake"* is overshadowed by the more popular form *"Artificial Intelligence"* for the acronym *"AI"*.

4 AcroBERT

We can now capitalize on our dictionary and pre-training corpus to propose a new method for acronym disambiguation. It takes as input (1) a dictionary of acronyms with their long form(s), and (2) a large-scale corpus that contains acronyms (we assume that the boundaries of the acronym have already been recognized). Our goal is to pre-train a language model for acronym disambiguation, which has a strong generalizability across multiple domains.

Model	**General**				**Scientific**				**Biomedical**				**Avg**	
	Dev		Test		Dev		Test		Dev		Test			
	F1	Acc	F1	Acc	F1	Acc	F1	Acc	F1	Acc	F1	Acc	F1	Acc

Table 5: Performances of the unsupervised setting across different models, measured by macro F1 and Accuracy.

The Pre-training Strategy of BERT. We adapt the BERT model for our purpose. BERT is pre-trained by using two unsupervised tasks, Masked Language Model (MLM) and Next Sentence Prediction (NSP). The Masked Language Model task randomly masks some percentage of the input tokens, and then forces the model to predict the masked tokens, similar to a cloze task. The Next Sentence Prediction task asks the model to predict whether one sentence follows the other.

The Next Sentence Prediction task can be used to predict, from the input text (e.g., *"This is the product's first true **AI** version, and it understands your voice instantly."*), the correct long form (*"Artificial Intelligence"*). Here, the model learns to judge whether the input context that contains the acronym *"AI"* is coherent with the long form *"Artificial Intelligence"*. The Masked Language Model task can memorize the correlation of tokens between the context sequence and long form. Thus, the model learns that the phrase *"Artificial Intelligence"* often co-occurs with *"product"* or *"understand"*.

However, we find that this naive technique does not perform well (see the ablation studies in Table A4). We believe that the reason is that the acronym is usually ambiguous with many candidates (as shown in Table 1), so that the model has difficulties predicting the correct long form by only using the cross-entropy loss of the binary classification. We also observe that the Masked Language Model loss is so small that the model focuses on adapting the Next Sentence Prediction task only.

AcroBERT. To mitigate the weaknesses of the original BERT, we pre-train an adapted BERT, called AcroBERT, by slightly adjusting the Next Sentence Prediction task. The framework is shown in Figure 2. It aims to bring the positive sample pairs closer together, and to push apart the negative sample pairs. We find that already such a simple model can perform very well. For each pair of a candidate long form and a sentence with an acronym, we compose an input for the Next Sentence Prediction task as *"*`[CLS]` *long form* `[SEP]` *sentence* `[SEP]`*"*. Then, we obtain representations of this sequence by applying BERT to this new input. The final hidden vector $\mathbf{e}^{\texttt{[CLS]}} \in \mathbb{R}^H$ of the first input token (`[CLS]`) is used as the aggregate representation, where H is the dimension of the hidden vector. Next, the scores for the binary classification are:

$$\mathrm{P}(y) = \mathrm{softmax}(\mathbf{e}^{\texttt{[CLS]}}\mathbf{W}), y \in \{0, 1\} \qquad (1)$$

where $\mathbf{W} \in \mathbb{R}^{H \times 2}$ is a trainable matrix initialized with the weights of the original BERT, and the label 0 signifies that this pair of sentences are coherent. We use $d = \mathrm{P}(y = 1)$ as the distance between the candidate and the context, and we want the distances of negative pairs to be larger than for positive pairs. For this, we use a triplet loss function that aims to assign higher scores to the correct candidates that match the topic of the input sentence while reducing the scores of irrelevant candidates:

$$\mathcal{L} = \max\left\{0, \lambda - d_{\text{neg}} + d_{\text{pos}}\right\} \qquad (2)$$

where λ is the margin value, and d_{pos} and d_{neg} are the distances for positive and negative pairs, respectively.

The negatives in this triplet framework can be randomly sampled from the dictionary. However, we observe that such random negatives contribute less to the training and result in slower convergence because the initial model can easily distinguish these triplets. Therefore, it is crucial to select harder triplets that are active and beneficial to the training. For this purpose, we introduce a certain number of ambiguous negatives to each mini-batch, e.g., *"Artificial Intelligence"* can be added to the input context as an ambiguous negative sample for the positive pair *"Adequate Intake* `[SEP]` *In the United States, the **AI** for potassium for adults is 4.7 grams."* Through the pre-training step, AcroBERT is able to identify the correct long form with the most consistent theme from numerous candidates based on the input context.

5 Experiments

In this section, we compare AcroBERT empirically to other acronym disambiguation approaches.

5.1 Experimental Settings

Datasets. We use the following datasets for evaluation: Our GLADIS benchmark consists of three subsets covering the General, Scientific, and Biomedical domains. This benchmark is more challenging than prior work due to a large number of ambiguous long forms: each acronym has around 200 candidates on average. We also evaluate AcroBERT on two existing datasets: UAD (Ciosici et al., 2019) and SciAd (Veyseh et al., 2020). They are general and scientific AD datasets, respectively. We reuse the test set of Medmentions but use the UMLS as the target dictionary. We refer to them as **datasets with fewer candidates** because they have fewer candidates per acronym. The average numbers of candidates per acronym are 2.1, 3.1, and 34.2, respectively. See Appendix A.2 for more details on the datasets.

Benchmark Settings. We design two benchmark settings for the unsupervised and supervised scenarios respectively. In the *unsupervised setting*, each model is evaluated on the test sets without access to train and validation sets. In the *fine-tuned setting*, each model is first fine-tuned on train sets and then evaluated on test sets. We focus on the unsupervised setting because it demonstrates that AcroBERT can achieve considerable performances across several domains even without any annotated samples.

Competitors. We compare our approach to the following publicly available competitors: BM25 (Robertson et al., 1995), FastText (Bojanowski et al., 2017), MadDog (Veyseh et al., 2021), BERT (Devlin et al., 2018), BioBERT (Lee et al., 2020), SciBERT (Beltagy et al., 2019). Besides, we introduce a Popularity-Ours baseline that uses the frequency of long forms of our collected pre-training datasets. We do not compare to general entity linking methods, because prior work has already found that general systems like AIDA (Hoffart et al., 2011) tend to lag behind acronym disambiguation models by 10-30 absolute percentage points (Li et al., 2018). See Appendix A.3 for details on the competitors.

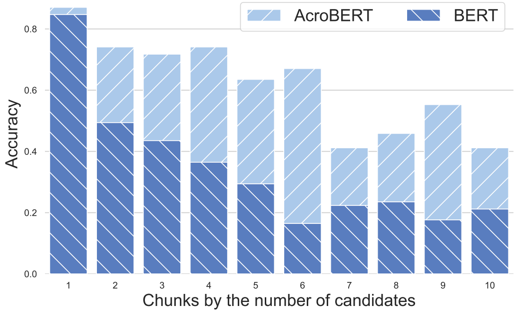

Figure 3: Robustness evaluation of hard samples on the General test set. The samples are divided evenly into ten chunks according to the number of candidates of each sample (results on the other two sets are shown in Figure A1 in the appendix).

Implementation Details. All approaches are implemented with PyTorch (Paszke et al., 2019) and HuggingFace (Wolf et al., 2020) by using one NVIDIA Tesla V100S PCIe 32 GB Specs. For pre-training, we use the parameters in the original BERT to initialize AcroBERT, and then pre-trained on our collected datasets with ~160 million samples for one epoch. The margin of triplet loss is 0.2 and the number of ambiguous negatives is 2 for each mini-batch. See more details in Appendix A.4.

Inference. For the inference stage, every pair of a context sentence and a candidate with the matching short form in the dictionary constitutes an input to the Next Sentence Prediction task. The language model produces a score for each candidate and we select the one with the highest score as the final predicted output.

Metrics. We evaluate the models by precision, recall, and macro F1. These metrics are defined in detail in Section A.5

5.2 Results

5.2.1 Overall Performance

Unsupervised Setting. Table 5 shows the experimental results in the unsupervised setting. We first observe that our AcroBERT significantly outperforms the baselines across the three domains. For example, AcroBERT can improve the original BERT by more than 30 absolute percentage points of F1 on average on our benchmark. Second, the naive popularity method comes second on this

	General				Scientific				Biomedical				Avg	
	Dev		Test		Dev		Test		Dev		Test			
	F1	Acc	F1	Acc	F1	Acc	F1	Acc	F1	Acc	F1	Acc	F1	Acc
BERT (2018)	53.8	70.7	54.9	53.1	13.5	9.9	14.3	10.4	9.8	12.4	9.4	7.5	26.0	27.3
SciBERT (2019)	32.4	38.6	33.6	27.7	22.7	19.4	23.4	17.7	31.2	35.6	31.0	28.3	29.5	27.9
BioBERT (2020)	26.0	23.6	25.7	20.3	11.2	9.7	12.4	9.0	24.0	21.8	20.2	16.8	19.9	16.9
AcroBERT	**72.9**	**76.1**	**71.0**	**76.1**	**28.7**	**34.9**	**29.0**	**27.6**	**62.5**	**62.4**	**60.3**	**69.2**	**54.1**	**57.7**

Table 6: Performances of fine-tuned setting across different models, measured by macro F1 and Accuracy.

benchmark, most likely because it contains a limited number of overshadowed terms. However, it performs badly on the scientific dataset. We assume that this is because this dataset contains 68.7% of overshadowed terms (as shown in Table 3).

Besides, we conduct experiments on existing datasets, namely UAD (Ciosici et al., 2019) and SciAD (Veyseh et al., 2020). Although our method performs consistently well, we relegate this experiment to the appendix B.2 due to the weaknesses of the datasets (small size or data leakage).

Fine-tuned Setting. In this experiment, every pre-trained language model is fine-tuned on the training set by the triplet loss, as introduced in the pre-training step. Negatives are randomly sampled from ambiguous long forms for the correct label, and the results are shown in Table 6. BERT, SciBERT, and BioBERT perform better in their respective fields. However, our AcroBERT achieves the best result across the three fields on average, which demonstrates the effectiveness of the pre-training strategy. One might think that it is unfair that AcroBERT uses the pre-training corpus, while the other models do not. However, there is no other pre-trained model for general disambiguation. Our approach is the first that capitalizes on large-scale corpora and pre-training.

As for the inference speed, AcroBERT has to be run once for every possible long form, which may take some time if there are thousands of long forms, e.g., the acronym AI. However, this runtime can be reduced drastically if one cuts off the less frequent long forms per acronym. Limiting the number of long forms to 23 per acronym, e.g., reduces the worst-case runtime by a factor of 100, while still keeping the recall at 90%.

5.2.2 Robustness Evaluation

Our GLADIS benchmark is more challenging than existing acronym disambiguation datasets due to the much larger acronym dictionary, which means more candidates per acronym. To measure the robustness of acronym disambiguation systems against more candidates, we sort the samples in the dataset in descending order of the number of candidates per acronym, and divide them evenly into 10 chunks. For example, samples in the first chunk have 1.58 candidates on average while that number is 2159 for the last chunk. The experimental results are shown in Figure 3. As expected, the performance of BERT and AcroBERT decreases as the number of candidates increases. The same goes for the other two subsets, as shown in Appendix B.3. However, AcroBERT consistently outperforms BERT on each data chunk, which shows that AcroBERT is able to select the correct long form among the numerous candidates.

Model	Popular	Overshadowed	Avg
BERT (2018)	13.3	12.7	13.0
SciBERT (2019)	11.6	8.1	9.9
BioBERT (2020)	2.1	1.0	1.6
AcroBERT	**61.9**	**33.4**	**47.7**

Table 7: Robustness evaluation of overshadowed entities on General test set,measured by Accuracy.

Moreover, the challenge with our GLADIS benchmark comes from overshadowed samples, which are harder to disambiguate. To validate the robustness of the models, we divide the General test set into two parts: Popular and Overshadowed, as described in Section 3.2. Next, we compare different language models in the unsupervised setting. As shown in Table 7, our AcroBERT performs best on both the Popular and the Overshadowed subset. We conclude that AcroBERT is more robust against ambiguous and overshadowed samples in acronym disambiguation task.

6 Conclusion

In this paper, we have presented GLADIS, a challenging benchmark for Acronym Disambiguation, which includes a larger dictionary, three datasets from the general, scientific, and biomedical domains, and a large-scale pre-training corpus. We have also proposed AcroBERT, a BERT-based model that is pre-trained on our collected acronym documents, which can significantly outperform other baselines across multiple domains, and which is more robust in the presence of very ambiguous acronyms and overshadowed samples. For future work, we aim to enhance the performance of AcroBERT on the overshadowed cases, which is crucial for the acronym disambiguation task.

7 Limitations

We see two main limitations of our work. First, although the current acronym dictionary is of relatively high quality, it still contains a small fraction of duplicate long forms due to typos (as in *"Convlutional Neural Network"*), morphological changes (as in *"Convolutional Neuronal Network"*) and nested acronyms (as in *"convolutional NN"*). A manual evaluation of 100 randomly chosen long forms from the three datasets in GLADIS shows that 6% of them are noisy. At the same time, the frequency of these noisy forms is much lower than that of the standard long forms: all noisy forms in the sample taken together appear 100 times in the corpus – compared to 31k times for the clean forms. Thus, the percentage of clean forms, weighted by their frequency, is 97%. A good AD system should select the most frequent one among noisy forms for an acronym, and in our sample none of the most frequent forms was noisy.

A second limitation of our approach is that the performance of the current AcroBERT system on the Scientific dataset still needs improvement. We are considering to introduce more pre-training data from this domain to address this issue.

Ethics Statement

This work presents GLADIS, a free and open benchmark for the research community to study Acronym Disambiguation, which consists of three components: a dictionary, a pre-training corpus, and three domain-specific datasets. The dictionary and pre-training corpus are collected from the Pile dataset (Gao et al., 2020), which is a public dataset under the MIT license. The three domain-specific datasets are adapted from SciAD (Veyseh et al., 2020), WikilinksNED Unseen Mentions (Onoe and Durrett, 2020) and Medmentions (Mohan and Li, 2018), respectively. They all allow sharing and redistribution. The source datasets and their publications will be credited on our GitHub page, and their licenses will be mentioned both on the Web page and in the downloads of GLADIS.

A Details of the Experimental Settings

A.1 Details of the Pile Dataset

Pile (Gao et al., 2020) is an 825 GiB English text corpus designed to train large-scale language models, which is constructed from 22 diverse high-quality academic or professional sources. Pile is constructed from existing or newly introduced datasets, and we present these sources here. **Pile-CC** is a collection of web pages, metadata and texts, which is extracted from jusText (Endrédy and Novák, 2013). **Books3** is a book dataset of fiction and nonfiction books derived from Bibliotik [1]. **Project Gutenberg** has classic Western literature derived from PG-19 (Rae et al., 2019). **OpenSubtitles** provides a large corpus of English subtitles from movies and television shows collected by Tiedemann (2016). **DeepMind Mathematics** is a collection of many different types of mathematics questions (Saxton et al., 2018). **BookCorpus2** is an expanded version of BookCorpus (Zhu et al., 2015), a corpus of books from the web. **EuroParl** is a corpus of parallel text in 11 languages from the proceedings of the European Parliament(Koehn, 2005). **Enron Emails** is a large set of email messages, which contains 619,446 messages belonging to 158 users (Klimt and Yang, 2004).

A.2 Details of the Experimental Datasets

We use the following benchmarks for Acronym Disambiguation:

Our GLADIS benchmark consists of three subsets covering the General, Scientific, and Biomedical domains. It is a very challenging benchmark, due to a large number of ambiguous long forms, as described in Section 3.2.

- **General** has 45K samples gathered from the WikilinksNED Unseen Mentions (Onoe and Durrett, 2020).
- **Scientific** is adapted from SciAD (Veyseh et al., 2020) with 56K samples, and the long forms in the original dataset are mapped to the new acronym dictionary. We re-split the training, validation and test sets to assure there are no overlaps.
- **Biomedical** includes 12K samples obtained from Medmentions (Mohan and Li, 2018).

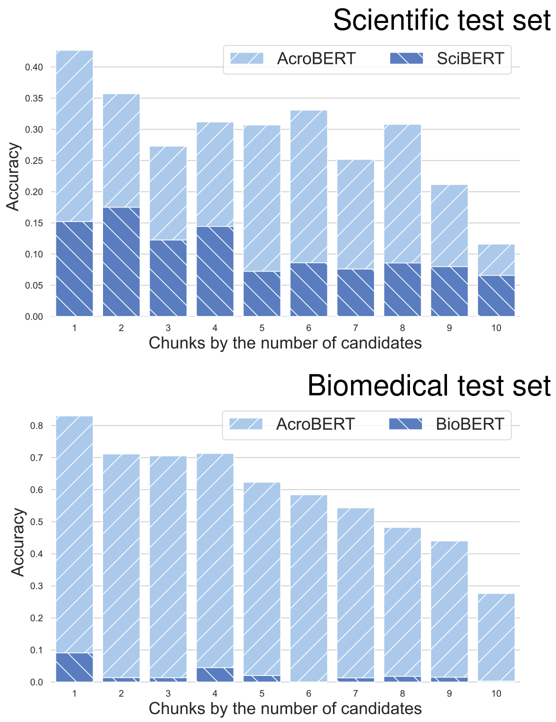

Figure A1: Robustness evaluation of hard samples on Scientific and Biomedical test set. The samples are divided evenly into ten chunks according to the number of candidates of each sample.

Datasets with fewer candidates per acronym.

- **UAD** (Ciosici et al., 2019) is gathered from the English Wikipedia and we use the manually labeled 7K samples for evaluation.
- **SciAD** (Veyseh et al., 2020) is a human-annotated dataset for the scientific domain with 62K samples gathered from the ArXiv preprint papers, and the validation set with 6K samples is used for experiments.
- **Biomedical-UMLS** is a dataset with 3K samples obtained from the test set in our benchmark by using the UMLS concepts as the acronym dictionary

The average candidates per acronym for the three datasets are 2.1, 3.1, and 34.2, respectively.

A.3 Competitors

We compare our approach to the following publicly available competitors:

- BM25 (Robertson et al., 1995) is a classical ranking function in information retrieval.

---

Model	UAD		SciAD		Biomedical-UMLS		Avg	
	F1	Acc	F1	Acc	F1	Acc	F1	Acc
BERT (2018)	**89.3**	91.1	54.1	57.2	38.0	32.7	60.5	60.3
SciBERT (2019)	74.8	78.4	**65.6**	71.7	54.9	50.3	65.1	66.8
BioBERT (2020)	66.2	68.2	19.7	22.4	37.4	31.4	41.1	40.7
AcroBERT	88.8	**93.7**	58.0	**72.0**	**67.5**	**65.3**	**71.4**	**77.0**

Table A1: Performances on benchmarks with fewer candidates, measured by macro F1 and Accuracy.

- Popularity-Ours is a baseline that uses the frequency of long forms of our collected pre-training datasets.

- BERT (Devlin et al., 2018) is a strong baseline, which pre-trains contextual language models on large corpora. The scores for the NSP task can be used for the acronym disambiguation.

- FastText (Bojanowski et al., 2017) is a character-level embeddings and can produce representations for arbitrary words. In this experiment, we first represent the input sentence and candidates by the sum of word embeddings from FastText. Then, all candidates are ranked by their cosine similarity score.

- MadDog (Veyseh et al., 2021) is a web-based acronym disambiguation system for multiple domains. It first creates chunks in which all samples with the same acronyms are assigned to the same chunks. After, a separate Bi-LSTM model is trained for each chunk. To deploy the MadDog server, it needs at least 125 GB of disk space and 70 GB of RAM memory [2].

- BioBERT (Lee et al., 2020) is a biomedical language representation model mainly pre-trained on PubMed Abstracts and PMC Full-text articles, which is a strong baseline in the biomedical domain.

- SciBERT (Beltagy et al., 2019) is a scientific language model based on BERT pre-trained on a large multi-domain corpus of scientific publications, which can improve performance on downstream scientific NLP tasks.

A.4 Implementation Details

All approaches are implemented with PyTorch (Paszke et al., 2019) and HuggingFace (Wolf et al., 2020). When pre-training AcroBERT, the model is initialized by the parameters in the original BERT, and then pre-trained on our collected datasets for one epoch. In total, there are ~160 million samples in this corpus, covering various domains. The batch size is 32, and we use Adam (Kingma and Ba, 2014) with a learning rate $2e-5$ for optimization. The learning rate is exponentially decayed for every 10,000 steps with a rate of 0.95. The margin of triplet loss is 0.2 and the number of ambiguous negatives is 2 for each mini-batch.

For the fine-tuning stage, each competitor model is initialized with the pre-trained parameters from HuggingFace, and we use AcroBERT after pre-training for comparison. All models are fine-tuned by using the Triplet loss. All parameters of each model are fine-tuned in this experiment, across all domains by using the same hyper-parameters. The batch size is 8 and the learning rate is among $[1e-5, 8e-6, 6e-6, 4e-6, 2e-6]$ for the Adam optimizer. The model that has the best performance on the validation set among the 5 learning rates is evaluated on the test set. We use one NVIDIA Tesla V100S PCIe 32 GB Specs.

A.5 Metrics

Acronym disambiguation can be seen as a classification problem, where the input is (1) a dictionary of acronyms and (2) a sentence with an acronym. Each long form for that acronym from the dictionary is considered a class, and the acronym disambiguation has to choose the correct class. We evaluate the models by precision, recall, and macro F1. There are two ways to calculate the macro F1: "F1 of Averages" and "Averaged F1". The first computes the F1 value over the arithmetic means of precision and recall, while the second computes the F1 value for each class, and then averages them. Some prior works adopt the first method. However, this method gives a higher weight to popular classes, and it may thus unfairly yield a high score if the model works well on these popular classes

Table A3: Case study of predicted results by BERT and AcroBERT.

only (Opitz and Burst, 2019). Therefore, we use the Averaged F1 across classes as our metric, which is more robust towards the error type distribution. That is:

$$\text{Precision}_i = \frac{\text{TP}_i}{\text{TP}_i + \text{FP}_i}, i \in \{1, 2, ..., n\} \quad \text{(A.1)}$$

$$\text{Recall}_i = \frac{\text{TP}_i}{\text{TP}_i + \text{FN}_i}, i \in \{1, 2, ..., n\} \quad \text{(A.2)}$$

$$\text{F1} = \frac{1}{n} \sum_{i=1}^{n} \frac{2 \times \text{Precision}_i \times \text{Recall}_i}{\text{Precision}_i + \text{Recall}_i} \quad \text{(A.3)}$$

B Additional Experiments

B.1 Ablation Study

In this experiment, we validate the effectiveness of the pre-training strategy in AcroBERT, which adopts a triplet loss with negative samples from ambiguous candidates. Every model is initialized with the parameters of the original BERT, and we use various strategies for pre-training: only Masked Language Model, only Next Sentence Prediction, and the combination of the two and the triplet framework in AcroBERT. Each strategy is pre-trained on our collected corpus for 300K steps and then the corresponding model is evaluated on the three validation sets. The results (in Table A4) show that the strategy of AcroBERT is most beneficial for the acronym disambiguation, as it performs the best on average. The Next Sentence Prediction task is more important than the Masked Language Model task. Even if MLM is not used, the impact on the model is not significant, which means the

Strategy	**General**		**Scientific**		**Biomedical**		**Avg**	
	F1	Acc	F1	Acc	F1	Acc	F1	Acc
Triplet framework in AcroBERT	**61.2**	**64.2**	**18.8**	**18.4**	9.1	10.1	**29.7**	**30.9**
MLM + NSP of the original BERT	45.7	55.7	15.8	14.9	**10.2**	**11.4**	23.9	27.3
only NSP	52.4	58.7	15.1	12.4	6.1	6.5	24.5	25.9
only MLM	11.2	14.4	2.7	3.5	1.4	1.5	5.1	6.5

Table A4: Ablation studies for different pre-training strategies after 300K steps across three validation sets, measured by macro F1 and Accuracy.

original BERT has already learned it well.

B.2 Experiments on Benchmarks with Fewer Candidates

As mentioned before, one drawback of the prior AD benchmark is that the magnitude of the acronym dictionary is small, which is not consistent with practical applications. In this experiment, we therefore valid the performance of AcroBERT on datasets with fewer candidates. The results are shown in Table A1, and we observe that AcroBERT can achieve the best average scores across three datasets again, which demonstrates the generalization capability of our AcroBERT. On the other hand, the lead of our model is not as substantial as before. This is because there are fewer candidates per acronym, and AcroBERT is particularly well-suited for identifying the correct one among a large number of candidates.

B.3 Robustness Evaluation for Many Candidates

Similar to Section 5.2.2, we analyse the robustness of AcroBERT on the other two domains. Each test set is divided evenly into 10 chunks by the number of candidates. The first chunk has the least number of candidates while the last chunk has the most, up to more than 2K. Figure A1 shows the experimental scores on the Scientific and Biomedical test set. We observe that for the first chunk, SciBERT and BioBERT are on par with our AcroBERT. However, AcroBERT outperforms the two significantly when the number of candidates get larger.

B.4 Case Study

Table A3 shows case studies of the outputs by BERT and AcroBERT. BERT often uses the memorized correlations of tokens for reasoning and this can cause errors. For example, *External Commercial Borrowings* are loans in India made by non-resident lenders in foreign currency to Indian borrowers [3]. BERT can determine this correct long form probably with help of the key phrase *"external financing"*. For the third case, *Peptic Ulcer Disease* is more consistent with the input context. However, BERT fails on it while AcroBERT benefits from the pre-training strategy and is able to distinguish different candidates based on contexts. For the fourth sample, both methods fail, most likely because of the low frequency of the long forms and the uninformative contexts.

Abstract

Pretrained multilingual language models (LMs) can be successfully transformed into multilingual sentence encoders (SEs; e.g., LaBSE, xMPNET) via additional fine-tuning or model distillation with parallel data. However, it remains unclear how to best leverage them to represent sub-sentence *lexical* items (i.e., words and phrases) in cross-lingual lexical tasks. In this work, we *probe* SEs for the amount of *cross-lingual lexical knowledge* stored in their parameters, and compare them against the original multilingual LMs. We also devise a simple yet efficient method for *exposing* the cross-lingual lexical knowledge by means of additional fine-tuning through inexpensive contrastive learning that requires only a small amount of word translation pairs. Using bilingual lexical induction (BLI), cross-lingual lexical semantic similarity, and cross-lingual entity linking as lexical probing tasks, we report substantial gains on standard benchmarks (e.g., +10 Precision@1 points in BLI). The results indicate that the SEs such as LaBSE can be 'rewired' into effective cross-lingual lexical encoders via the contrastive learning procedure, and that it is possible to expose more cross-lingual lexical knowledge compared to using them as off-the-shelf SEs. This way, we also provide an effective tool for harnessing 'covert' multilingual lexical knowledge hidden in multilingual sentence encoders.

1 Introduction

Transfer learning with pretrained Language Models (LMs) such as BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) offers unmatched performance in many NLP tasks (Wang et al., 2019; Raffel et al., 2020). However, despite the wealth of semantic knowledge stored in the pretrained LMs (Rogers et al., 2020; Vulić et al., 2020b), they do not produce coherent and effective sentence representations when used off-the-shelf (Liu et al., 2021c). To this effect, further specialization for sentence-level semantics – not unlike the standard task fine-tuning – is needed (Reimers and Gurevych, 2019; Li et al., 2020; Yan et al., 2021, *inter alia*). LMs get *transformed* into sentence encoders (SEs) via dual-encoder frameworks that leverage contrastive learning objectives (van den Oord et al., 2018; Musgrave et al., 2020), in supervised (i.e., leveraging labeled external data such as NLI or sentence similarity annotations) (Reimers and Gurevych, 2019; Vulić et al., 2021b; Liu et al., 2021a) or, more recently, fully unsupervised fine-tuning (Liu et al., 2021c; Gao et al., 2021) setups.

Following the procedures from monolingual setups, another line of research has been transforming multilingual LMs into *multilingual SEs* (Feng et al., 2022; Reimers and Gurevych, 2020), which enable effective sentence matching and ranking in multiple languages as well as cross-lingually (Litschko et al., 2022). The transformation is typically done by coupling **1)** LM objectives on monolingual data available in multiple languages with **2)** cross-lingual objectives such as Translation Language Modeling (TLM) (Conneau and Lample, 2019) and/or cross-lingual contrastive ranking (Yang et al., 2020). Such multilingual SEs consume a large number of parallel sentences for the latter objectives. Consequently, they outperform multilingual off-the-shelf LMs in cross-lingual sentence similarity and ranking applications (Liu et al., 2021d; Litschko et al., 2022). However, as we show in this work, such multilingual SEs may still lag behind traditional *static* cross-lingual word embeddings (CLWEs) when encoding sub-sentence *lexical items* (e.g., words or phrases) (Liu et al., 2021c) for cross-lingual lexical tasks (e.g., BLI).

In this work, we *probe* multilingual SEs for *cross-lingual lexical knowledge*, relying on standard semantic similarity tasks in cross-lingual setups as our '*lexical probes*' (Vulić et al., 2020b). We demonstrate that, due to their fine-tuning on multilingual and parallel data, they indeed store a

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2089–2105
May 2-6, 2023 ©2023 Association for Computational Linguistics

wealth of such knowledge, much more than what 'meets the eye' when they are used 'off the shelf'. However, this lexical knowledge needs to be *exposed* from the original multilingual SEs, (again) through additional fine-tuning. In other words, we show that multilingual SEs can be 'rewired' into effective cross-lingual *lexical encoders*, as illustrated in Figure 1. This rewiring is again done via a quick and inexpensive contrastive learning procedure: with merely 1k-5k word translation pairs, we successfully convert multilingual SEs into state-of-the-art bilingual lexical encoders for any language pair (present in a specific dataset).[1]

We probe the original LMs and SEs as well as demonstrate the usefulness of the proposed contrastive procedure for 'exposing' cross-lingual lexical knowledge on three standard lexical cross-lingual tasks using standard evaluation data and protocols: BLI, cross-lingual lexical semantic similarity (XLSIM), and cross-lingual entity linking (XL-EL). We show that the 'exposure' procedure is highly effective for both vanilla multilingual LMs (mBERT and XLM-R) and multilingual SEs (LABSE and XMPNET): e.g., we observe ≈+10 Precision@1 points gains on standard BLI benchmarks (Glavaš et al., 2019). Multilingual SEs offer substantially better cross-lingual lexical performance than vanilla LMs, both before and after being subjected to contrastive cross-lingual lexical fine-tuning (see Figure 1). This indicates that it is possible to expose more cross-lingual lexical knowledge from multilingual SEs than from their vanilla LM counterparts, likely owing to their additional exposure to parallel data.

Finally, inspired by Li et al. (2022), we validate that word vectors produced by cross-lingual lexical encoders (i.e., after the contrastive cross-lingual lexical 'exposure') can be effectively interpolated with static CLWEs (Artetxe et al., 2018) and offer even stronger performance in cross-lingual lexical tasks. Encouragingly, our cross-lingual lexical specialization of multilingual SEs (as well as the further interpolation with static CLWEs), yields particularly massive performance gains for pairs of low-resource languages, as demonstrated on the low-resource BLI benchmark (Vulić et al., 2019).

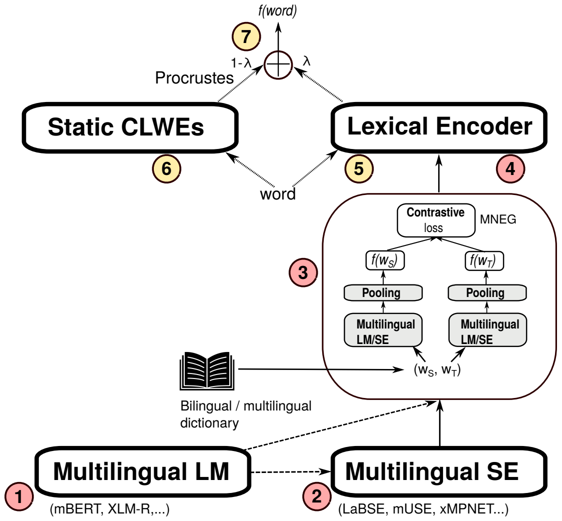

Figure 1: Illustration of the pipeline of exposing cross-lingual lexical knowledge from multilingual language models (LMs) and sentence encoders (SEs) (§2). Multilingual LMs (①) can be transformed into multilingual SEs (②) as done in previous work (Reimers and Gurevych, 2020; Feng et al., 2022). A contrastive cross-lingual lexical fine-tuning procedure (③) (requiring an external bilingual dictionary) can be applied on both ① and ②, yielding a fine-tuned cross-lingual lexical encoder (④). At inference, a word/phrase is encoded by the lexical encoder (⑤). In addition, its encoding can be interpolated with the corresponding static (cross-lingual) word embedding (⑥), producing the final embedding of the word/phrase (⑦). Before the interpolation, static CLWEs must be mapped into the vector space of the lexical encoder (④): to this end, we learn the standard orthogonal (Procrustes) projection matrix.

2 From Multilingual Sentence Encoders to Cross-Lingual Lexical Encoders

Motivation. The motivation for this work largely stems from the research on *probing and analyzing* pretrained LMs for various types of knowledge they (implicitly) store in their parameters (Ethayarajh, 2019; Jawahar et al., 2019; Rogers et al., 2020). In this paper, we focus on a *particular knowledge type*: cross-lingual lexical knowledge, and its extraction from multilingual LMs and SEs. The work combines two research threads, being inspired by the work on probing monolingual PLMs for lexical knowledge (Vulić et al., 2020b), as well as on interpreting representations in multilingual PLMs (Bjerva et al., 2019; Libovický et al., 2020; Beinborn and Choenni, 2020; Deshpande et al., 2022; Chai et al., 2022, *inter alia*).

Previous work also tried to prompt multilingual LMs for word translations via masked natural lan-

---

[1] Note that this is a typical requirement of standard mapping-based approaches for learning static cross-lingual word embeddings which excel in the BLI task (Mikolov et al., 2013; Conneau et al., 2018; Glavaš and Vulić, 2020).

guage templates (Gonen et al., 2020) and extract type-level word embeddings from LMs (i) directly without context (Vulić et al., 2020a, 2021a) or (ii) by averaging contextual embeddings over a large auxiliary corpus in the target language (Bommasani et al., 2020; Litschko et al., 2022). This existing body of work **1)** demonstrated that even sophisticated templates and extraction strategies cannot outperform cross-lingual word embedding spaces (e.g., induced from monolingual fastText vectors) in cross-lingual lexical tasks such as BLI (Vulić et al., 2020b) and **2)** did not attempt to expose cross-lingual lexical knowledge from multilingual SEs and compare it against the (same type of) knowledge extracted from vanilla multilingual LMs.

Multilingual Sentence Encoders. Off-the-shelf LMs contextualize (sub)word representations, but are unable to encode the precise meaning of input text out of the box. SEs – LMs fine-tuned via sentence-level objectives – in contrast, directly produce a precise semantic encoding of input text. A large body of work focuses on inducing multilingual encoders that capture sentence meaning across languages (Artetxe and Schwenk, 2019; Feng et al., 2022; Yang et al., 2020, *inter alia*).

The most popular approach obtains multilingual SEs (Reimers and Gurevych, 2020) by distilling the knowledge from the monolingual English SE teacher (trained on English semantic similarity and NLI data) into multilingual LM student (e.g., mBERT), using parallel sentences to guide the distillation process. SEs, being specialized for sentence similarity, encode sentence meaning more accurately and are useful in various (unsupervised) text similarity and ranking tasks, monolingually and across languages (Artetxe and Schwenk, 2019).

While SEs' primary purpose is sentence encoding, they can, in principle, be applied to sub-sentential text: words and phrases. In this work, we show that multilingual SEs can be turned into effective cross-lingual lexical encoders. We achieve this through additional cross-lingual lexical fine-tuning (Vulić et al., 2021a), requiring as supervision only a small set of word translation pairs.

2.1 Cross-Lingual Lexical Fine-Tuning

For a given language pair L_s-L_t, our contrastive cross-lingual lexical fine-tuning of multilingual encoders (LMs and SEs alike) requires a dictionary spanning N (typically $N \leq$ 5,000) word translation pairs, $\mathcal{D} = \{(w_{i,s}, v_{i,t})\}_{i=1}^{N}$.[2] We consider the translation pairs from $\mathcal{D}$ to be *positive examples* for the contrastive fine-tuning procedure. For each of the N source language words in the dictionary ($w_{i,s}$), we precompute a set of K hard negative samples: these are the L_t words that are the closest to $w_{i,s}$ in the representation space of the multilingual encoder, but not its direct translation $v_{i,t}$. For one-to-many and many-to-many seed dictionaries $\mathcal{D}$, the set K does not contain any L_t word paired with $w_{i,s}$. Let $f_\theta(\cdot)$, be the encoding function of the multilingual LM/SE, with θ as parameters, and let $S(\cdot,\cdot)$ be a function of similarity between two vectors. For a source word $w_{i,s}$, we select as hard negatives words v_t from L_t that have the highest $S(f_{\theta_0}(w_{i,s}), f_{\theta_0}(v_t))$ score, with θ_0 as the original encoder's parameters, before fine-tuning.

We encode all training words – those from the seed dictionary $\mathcal{D}$ and (at most) $N \cdot K$ precomputed hard L_t negatives – independently and *in isolation*. Concretely, for an input w with M subword tokens $[sw_1] \ldots [sw_M]$, we feed the sequence $[SPEC1][sw_1] \ldots [sw_M][SPEC2]$ into the multilingual encoder (with $[SPEC1]$ and $[SPEC2]$ as encoder's sequence start and end tokens, resp.), and take the average of the transformed representation (from the last Transformer layer) of the w's subword tokens as the w's encoding $f_\theta(w)$. Put simply, we process sub-sentential text input in the same way that multilingual SEs handle sentence-level input. We experimented with other encoding strategies from prior work, e.g., taking the representation of the sequence start token $[SPEC1]$ (Liu et al., 2021b; Li et al., 2022); in preliminary experiments, however, we obtained the best results by averaging subword representations.[3]

Following common practice in contrastive learning (Henderson et al., 2019; Vulić et al., 2021a), we define S as the scaled cosine similarity: $S(f_\theta(w_i), f_\theta(w_j)) = C \cdot cos(f_\theta(w_i), f_\theta(w_j))$, with C as the scaling constant. We then train in batches of B translation pairs, with the variant of the widely used multiple negatives ranking loss (MNEG) (Cer et al., 2018; Henderson et al., 2019, 2020) as the fine-tuning objective:

---

[2] Note that such bilingual dictionaries are one of the most widespread and cheapest-to-obtain resources in multilingual NLP (Ruder et al., 2019; Wang et al., 2022).

[3] Note that $[SPEC1]$ and $[SPEC2]$ are placeholders for the encoder's special tokens: e.g., in case of multilingual BERT [SPEC1] is the [CLS] token, while [SPEC2] is the [SEP] token.

$$
\begin{aligned}
\mathcal{L} = -&\sum_{i=1}^{B} S(f_\theta(w_i), f_\theta(v_i)) && \text{(positives)} \\
+&\sum_{i=1}^{B} \log \sum_{j=1, j\neq i}^{B} e^{S(f_\theta(w_i), f_\theta(v_j))} && \text{(in-batch negatives)} \\
+&\sum_{i=1}^{B} \log \sum_{k=1}^{K} e^{S(f_\theta(w_i), f_\theta(v_{k,i}))} && \text{(hard negatives)}
\end{aligned}
$$

where $v_{k,i}$ denotes the k-th hard negative from the language L_t for the L_s word w_i. MNEG combines the K hard negatives per each positive example with B-1 in-batch negatives (i.e., for a source language word $w_{i,s}$, each target language word $v_{j,t}$, $j \neq i$ from B is used as an in-batch negative of $w_{i,s}$). MNEG aims to reshape the representation space of the encoder by simultaneously (a) maximising the similarity for positive pairs – i.e., bringing closer together ('attracting') the words from the positive pairs and (b) minimising the similarity for (both in-batch and hard) negative pairs – i.e., pushing ('repelling') the words from negative pairs further away from each other).[4]

2.2 Interpolation with Static CLWEs

Li et al. (2022) recently showed that further performance benefits in the BLI task might be achieved by combining the type-level output of the encoding function *f* with static CLWEs, but they experimented only with multilingual LMs, and limited their analyses to the BLI task.

Static CLWEs and multilingual encoder-based representations of the same set of words can be seen as two different views of the same data point. Following Li et al. (2022), we learn an additional linear orthogonal mapping from the static cross-lingual WE space – e.g., a CLWE space induced from monolingual fastText embeddings (Bojanowski et al., 2017) using VECMAP (Artetxe et al., 2018) – into the cross-lingual space spanned by the multilingual encoder. The mapping transforms ℓ_2-normed d_1-dimensional static CLWEs into d_2-dimensional cross-lingual WEs obtained through the multilingual encoder (fine-tuned f_θ or original f_{θ_0}).

Learning the linear map $\boldsymbol{W} \in \mathbb{R}^{d_1 \times d_2}$, when $d_1 < d_2$,[5] is formulated as a Generalized Procrustes problem (Schönemann, 1966; Viklands, 2006). It operates on all (i.e., both L_s and L_t) words from the seed translation dictionary $\mathcal{D}$. To learn the mapping $\boldsymbol{W}$, for pairs from $\mathcal{D}$ we decouple L_s words $w_{i,s}$ from their L_t translations $v_{i,t}$ to create vector pairs $(clwe(w_{i,s}), f_\theta(w_{i,s}))$ and $(clwe(v_{i,t}), f_\theta(v_{i,t}))$ – with $clwe(w)$ as the static CLWE of w (e.g., its VECMAP embedding), and $f_\theta(w)$ its encoder-based representation – based on which we learn of the orthogonal mapping $\boldsymbol{W}$ (the so-called Procrustes method gives a closed-form solution). Unless noted otherwise, a final representation of an input word w is then computed as:

$$
(1-\lambda)\frac{clwe(w)\boldsymbol{W}}{\|clwe(w)\boldsymbol{W}\|_2} + \lambda\frac{f_\theta(w)}{\|f_\theta(w)\|_2}, \qquad (1)
$$

where λ is a tunable interpolation hyper-parameter, $clwe(w)$ denotes the static CLWE of w, and $f_\theta(w)$ the representation of w obtained with the (contrastively fine-tuned or original) multilingual LM/SE. This simple procedure yields an 'interpolated' shared cross-lingual WE space.

3 Experimental Setup

Multilingual Sentence Encoders. We probe two widely used multilingual SEs: **1)** Language-agnostic BERT Sentence Embedding (**LABSE**) (Feng et al., 2022) which adapts pretrained multilingual BERT (**MBERT**) (Devlin et al., 2019) into a multilingual SE; **2)** Multilingual **XMPNET** is a distillation-based adaptation (Reimers and Gurevych, 2020) of **XLM-R** (Conneau et al., 2020) as the student model into a multilingual SE, based on the monolingual English MPNet encoder (Song et al., 2020) as the teacher model. LABSE is the current state-of-the-art multilingual SE and supports 109 languages, while XMPNET is the best-performing multilingual SE in the Sentence-BERT repository (Reimers and Gurevych, 2019): For further technical details regarding the models in our comparison, we refer to the original papers.

Along with LABSE and XMPNET as SEs, we experiment with the original multilingual LMs – mBERT and XLM-R – using the the same training and evaluation protocols (see Figure 1 and §2), aiming to quantify: (i) the extent to which cross-lingual lexical knowledge can be exposed from LMs that have *not* been specialized for sentence-level semantics, as well as (ii) the increase in quality of lexical knowledge brought about with sentence-level specialisation (i.e., when multilingual LMs get transformed into multilingual SEs).

---

[4] In practice, we rely on the implementation of the MNEG loss from the SBERT repository `www.sbert.net` (Reimers and Gurevych, 2019); the default value $C = 20$ is used.

[5] The assumption $d_1 < d_2$ typically holds as fastText WEs are 300-dimensional while the dimensionality of standard multilingual LMs and SEs is $d_2 = 768$ or $d_2 = 1,024$.

Evaluation Tasks. We evaluate on the standard and diverse cross-lingual lexical semantic tasks treated as 'cross-lingual lexical probes'. In other words, we fine-tune the models to steer them towards becoming better lexical encoders and then we check how well they fare across a set of representative (intrinsic) lexical tasks which could be seen as such 'lexical probes'.

Task 1: Bilingual Lexicon Induction (BLI), a standard task to assess the "semantic quality" of static cross-lingual word embeddings (CLWEs) (Ruder et al., 2019), allows us to **1)** directly assess the extent to which cross-lingual word translation knowledge can be exposed from multilingual LMs and SEs and **2)** immediately test the ability to transform multilingual sentence encoders into bilingual lexical encoders. We run a series of BLI evaluations on two standard BLI benchmarks. **1)** GT-BLI (Glavaš et al., 2019), constructed semi-automatically from Google Translate, comprises 28 language pairs with a good balance of typologically similar and distant languages (Croatian: HR, English: EN, Finnish: FI, French: FR, German: DE, Italian: IT, Russian: RU, Turkish: TR). **2)** PanLex-BLI (Vulić et al., 2019) focuses on BLI evaluation for lower-resource languages, deriving training and test data from PanLex (Kamholz et al., 2014). We evaluate on 10 pairs comprising the following five typologically and etymologically diverse languages: Bulgarian (BG), Catalan (CA), Estonian (ET), Hebrew (HE), and Georgian (KA).

Standard BLI setups and data are adopted: 5k training word pairs are used as seed dictionary $\mathcal{D}$, and another 2k pairs as test data. Note that $\mathcal{D}$ is used to (i) contrastively fine-tune multilingual encoders (§2.1), (ii) learn the (baseline) static VecMap CLWE space, as well as to (iii) learn the projection between the static CLWE space and the representation spaces of multilingual encoders required to obtain the interpolated representations (§2.2). The evaluation metric is standard Precision@1 (P@1).[6] For PanLex-BLI, we also run experiments using smaller $\mathcal{D}$, spanning 1k pairs.

Task 2: Cross-Lingual Lexical Semantic Similarity (XLSIM) tests the extent to which lexical representations can capture the (human perception of) fine-grained semantic similarity of words across languages. We use the comprehensive XLSIM benchmark Multi-SimLex (Vulić et al., 2020a), which comprises cross-lingual datasets of 2k-4k scored word and phrase pairs over 66 language pairs. We evaluate on a subset of language pairs shared with the GT-BLI dataset: EN, FI, RU, FR.

The evaluation metric is the standard Spearman's rank correlation between the average of gold human-elicited XLSIM scores for word pairs and the cosine similarity between their respective word representations. To avoid any test data leakage, we remove all XLSIM test pairs from the bilingual dictionary $\mathcal{D}$ prior to fine-tuning and CLWE mapping.

Task 3: Cross-Lingual Entity Linking (XEL) is a standard task in knowledge base (KB) construction (Zhou et al., 2022), where the goal is to link an entity mention in any language to a corresponding entity in an English KB or in a language-agnostic KB.[7] We evaluate on the cross-lingual biomedical entity linking (XL-BEL) benchmark of Liu et al. (2021d): it requires the model to link an entity mention to entries in UMLS (Bodenreider, 2004), a language-agnostic medical knowledge base. We largely follow the XL-BEL experimental setup of Liu et al. (2021d) and probe the encoders first *without* any additional task-specific fine-tuning on UMLS data, and then *with* subsequent UMLS fine-tuning (i) only on the EN UMLS data, (ii) on all the UMLS data in 10 languages of the XL-BEL dataset.[8] Due to a large number of experiments, we again focus on the subset of languages in XL-BEL shared with GT-BLI: EN, DE, FI, RU, TR.

Static CLWEs and Word Vocabularies. As monolingual static WEs, we select CommonCrawl fastText vectors (Bojanowski et al., 2017) of the top 200k most frequent word types in the training data, following prior work on learning static CLWEs (Conneau et al., 2018; Artetxe et al., 2018; Heyman et al., 2019).[9] Static CLWEs are then induced via the standard and popular supervised mapping-based VecMap method (Artetxe et al., 2018), leveraging the seed dictionary $\mathcal{D}$. These CLWEs are used for interpolation with encoder-based WEs (see §2.2) but also as the baseline approaches for BLI and XLSIM tasks. We compute the type-level WEs from multilingual LMs and SEs for the same

---

[6] We observed very similar performance trends for P@5 and Mean Reciprocal Rank (MRR) as BLI measures.

[7] Following prior work (Liu et al., 2021b; Zhou et al., 2022), XEL in this work also refers only to entity mention *disambiguation*; it does not cover the mention detection subtask.

[8] See (Liu et al., 2021d) for additional details.

[9] CommonCrawl-based fastText WEs typically outperform other popular choice for monolingual WEs: Wikipedia-based fastText (Glavaš et al., 2019; Li et al., 2022). We note that the main trends in our results also extend to the Wiki-based WEs.

200K most frequent words of each language.

Technical Details and Hyperparameters. The implementation is based on the SBERT framework (Reimers and Gurevych, 2019), using the suggested settings: AdamW (Loshchilov and Hutter, 2018); learning rate of $2e\text{-}5$; weight decay rate of 0.01. We run contrastive fine-tuning for 5 epochs with all the models, with the batch size of $B = 128$ positives for MNEG. The number of hard negatives per each positive is set to $K = 10$ (see §2.1).[10] Since standard BLI and XLSIM datasets lack a validation portion (Ruder et al., 2019), we follow prior work (Glavaš et al., 2019) and tune hyperparameters on a *single* language pair from each dataset, and use those values in all other runs. The randomly selected language pairs are EN-TR for GT-BLI and CA–ET for PanLex-BLI.

All reported scores are the averages over 5 runs with 5 fixed random seeds.

Model Configurations. They are labelled as follows: **ENC-{noCL,+CL}** (λ), where (i) ENC denotes the input multilingual Transformer, which can be a multilingual LM (MBERT, XLM-R), or a multilingual SE (LABSE, XMPNET), (ii) 'noCL' refers to using the input model 'off-the-shelf' without any contrastive lexical fine-tuning, while '+CL' variants apply the contrastive fine-tuning, and (iii) λ is the factor that defines the interpolation with the static CLWE space, obtained with VECMAP (see Figure 1 and §2.2). Note that $\lambda = 1.0$ implies no interpolation with static CLWE space, i.e., WEs come purely from the multilingual LM/SE.

Important Disclaimer. We note that the main purpose of the chosen evaluation tasks and experimental protocols is not necessarily achieving state-of-the-art performance, but rather probing different model variants in different cross-lingual lexical tasks, and offering fair and insightful comparisons.

4 Results and Discussion

Bilingual Lexicon Induction (BLI). Table 1 displays our main BLI results, aggregated over all 28 language pairs of GT-BLI. Two trends hold across the board. First, multilingual SEs, LABSE and XMPNET, substantially outperform their multilingual LM counterparts, MBERT and XLM-R. The gains are visible in all four experimental configurations (with/without contrastive cross-lingual lexical specialisation × with/without interpolation with the VECMAP CLWE space). This confirms our intuition that multilingual SEs, having been (additionally) trained on parallel data (Feng et al., 2022; Reimers and Gurevych, 2020), should better reflect the cross-lingual alignments at the lexical level than off-the-shelf multilingual LMs, which have not been exposed to any cross-lingual signal in pretraining. The poor cross-lingual lexical alignment in the representation spaces of MBERT and XLM-R also reflects in the fact that with those encoders, we only surpass the baseline VECMAP performance by a small margin (+1.1 for XLM-R, +1.6 for MBERT) after subjecting them to contrastive lexical fine-tuning *and* interpolating their word encodings with VECMAP WEs.

The behavior of SEs, on the other hand, is much more favorable. LABSE, for example, surpasses baseline VECMAP performance with interpolation alone, even without the contrastive lexical fine-tuning. When contrastively fine-tuned (and then interpolated with VECMAP) both LABSE and XMPNET surpass the baseline VECMAP performance by a much wider margin (+6.4 and +5.2, respectively). This implies that contrastive fine-tuning exposes more of the high quality cross-lingual lexical knowledge from multilingual SEs.

Both (i) contrastive cross-lingual lexical learning (+CL) and (ii) interpolation with VECMAP consistently improve the performance for all four encoders: we reach peak scores by combining contrastive fine-tuning and interpolation with static CLWEs (+CL (λ)). Contrastive fine-tuning crucially contributes to the overall performance: compared to interpolation alone (noCL (λ)), +CL (λ) brings an average gain of over 6 BLI points.

Table 2 shows the BLI results on 10 low(er)-resource language pairs from PanLex-BLI. While overall relative trends are similar to those observed for high(er)-resource languages from GT-BLI (Table 1), the gains stemming from cross-lingual contrastive lexical fine-tuning are substantially larger in this case. The best-performing configuration – contrastive fine-tuning and interpolation (+CL (0.4)) applied on LaBSE – surpasses VECMAP by 11 BLI points on average (compared to 6 points on GT-BLI), with gains for some language pairs (e.g., HE-KA, ET-HE) approaching the impressive margin of 20 BLI points. This finding indicates that cross-lingual lexical knowledge stored in multilingual SEs is even more crucial when dealing

---

[10] We also tested K=$\{20, 30, 50\}$. They slow down fine-tuning while yielding small-to-negligible performance gains.

Multilingual LMs		mBERT				XLM-R

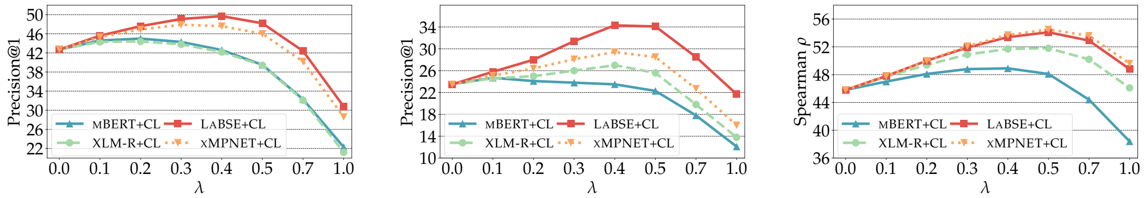
Table 3: P@1 scores over 10 language pairs from the PanLex-BLI dataset of Vulić et al. (2019) when $|\mathcal{D}| = 1k$, with different model variants based on LaBSE (see §3). Highest scores per row are in **bold**.

with lower-resource languages.

In Table 3 we compare the results of LaBSE (as the best-performing multilingual SE) against VecMap on PanLex-BLI in a scenario with less external bilingual supervision: $|\mathcal{D}| = 1k$. Interestingly, in this setup LaBSE already substantially outperforms VecMap out of the box (noCL (1.0)); contrastive lexical fine-tuning (+CL (1.0)) and interpolation with VecMap embeddings (+CL (0.5)) again bring further substantial gains, and we again observe a strong synergistic effect of the two components: +CL (1.0) yields gains over noCL (1.0) for 9/10 language pairs, and +CL (0.5) results in further boosts for all 10 pairs. Further, the contrastively fine-tuned LaBSE seems to be much more resilient to training data scarcity than VecMap: reduction of the training dictionary size from 5k to 1k reduces the performance of LaBSE +CL (λ) by 27% (from 34.7 to 25.2 P@1 points) compared to a massive performance drop of almost 70% for VecMap (from 23.5 to mere 7.4 P@1). In sum, the BLI results already indicate the wealth of lexical knowledge 'hidden' in multilingual SEs, which must be 'exposed to surface'.

Cross-Lingual Lexical Semantic Similarity (XLSIM). The average XLSIM results are summarized in Table 1. They again corroborate one of the main findings from BLI experiments: multilingual SEs store more cross-lingual lexical knowledge than



(a) GT-BLI (b) PanLex-BLI (c) Multi-SimLex (XLSIM)

Figure 2: Average scores across different interpolation values λ for the BLI task on **(a)** GT-BLI and **(b)** PanLex-BLI, and **(c)** the XLSIM task on Multi-SimLex. $|\mathcal{D}| = 5k$. Additional results are in Appendix B and C.

Table 4: A summary of results in the XEL task on the biomedical XL-BEL benchmark of Liu et al. (2021d). We show the results of the better-performing LM (XLM-R), and the more lightweight multilingual SE (XMPNET).

multilingual LMs. This is validated by substantial gains of SEs over corresponding LMs across all configurations in Table 1. Interestingly, due to their contrastive learning objectives on sentence-level parallel data (Feng et al., 2022), LABSE and XMPNET provide very strong XLSIM results when used off-the-shelf (noCL (1.0)), outperforming the CLWE VECMAP embeddings. Contrastive lexical fine-tuning with 5k word translation pairs (+CL (1.0)) in this case does not bring any gains. However, the opposite is true for multilingual LMs: contrastive cross-lingual lexical fine-tuning on only 5k word translation pairs brings large benefits in the XLSIM task (e.g., compare noCL (1.0) and +CL (1.0) configurations for MBERT and XLM-R), and turns them into more effective lexical encoders. This result corroborates a similar finding from prior work in monolingual setups (Vulić et al., 2021a). Finally, interpolation with static CLWEs benefits the final XLSIM performance of all four underlying multilingual encoders: interpolated vectors ($\lambda = 0.5$) yield highest scores across the board, substantially surpassing gains both VECMAP and WEs from fine-tuned encoders ($\lambda = 1.0$).

Interpolation with Static CLWEs. A more detailed analysis over different λ values for BLI and XLSIM, summarized in Figure 2, reveals that interpolation can bring large performance gains, especially for λ in the $[0.3, 0.5]$ interval. The optimal λ value is, however, task- and even dataset-dependent. For instance, for low-resource BLI on PanLex-BLI more knowledge comes from the multilingual encoders as VECMAP CLWEs are of lower quality for such languages: in consequence, the optimal λ value 'moves away' from the static CLWEs towards encodings obtained by fine-tuned multilingual SE. We also note that larger benefits from interpolation are observed when VECMAP CLWEs are combined with contrastively fine-tuned multilingual SEs than with LMs: cf., the large gains in Figure 2b and in Table 3 for the LABSE +CL model variant.

Cross-Lingual Entity Linking (XEL). Experiments on XL-BEL (Liu et al., 2021d), summarized in Table 4, demonstrate that additional contrastive tuning with word or phrase pairs can greatly boost performance of multilingual LMs: even fine-tuning with 5k word translation pairs without any domain-specific knowledge yields strong benefits for XLM-R. As expected, using a much larger and domain-specific external database UMLS yields much higher scores and is more crucial for performance. In fact, contrastively fine-tuning on UMLS generally improves XEL performance with all four underlying models. Again, we observe that SE-based (XMPNET) configurations outperform the respective LM-based (XLM-R) configurations across the board. This finding again indicates that multilingual SEs store more cross-lingual lexical knowledge than multilingual LMs: this difference is particularly salient when the models are used off-the-shelf without any additional contrastive fine-tuning, and xMPNET retains the edge over XLM-R even after task-specific fine-tuning with the UMLS-based domain-specific knowledge.

What is more, for FI, RU, and TR, the multilingual xMPNET-based variants match or surpass the performance of respective XEL models trained on top of monolingual LMs (e.g., for FI, a model based on the Finnish BERT) reported by Liu et al. (2021d). This further validates our hypothesis that multilingual SEs store rich multilingual lexical knowledge, which is then also exposed in domain-specific (multilingual) UMLS fine-tuning, yielding performance gains. Contrastive fine-tuning on UMLS synonyms (+CL+UMLS variants) expectedly outpeforms fine-tuning on (5k) general-domain word translations (+CL), indicating that in specialized domains, if available, in-domain cross-lingual lexical signal should be exploited.

4.1 Summary and Discussion

Since the exposure of knowledge is done through very knowledge-light tuning which also improves representations of lexical items not covered in the dictionaries used for the adaptive fine-tuning, this suggests that the knowledge is stored in the parameters of the large models (both LMs and SEs), but it is more easily 're-purposed' through fine-tuning for SEs. One might posit that the SEs have an 'unfair' advantage over LMs as the primary purpose of the SEs, even before is encoding text items (i.e., sentences) for semantic similarity and search. In this paper, we verify the extent of that advantage for lexical-level encodings/embeddings (as representations of lexical knowledge): while exposing (i.e., re-purposing) works for both model types, they do not reach the same performance peaks and benefits for lexical tasks where such lexical encodings are a paramount. We leave fine-tuning with LM-style objectives for other types of tasks beyond lexical similarity and search for future work.

5 Conclusion and Future Work

We investigated strategies to probe and expose cross-lingual lexical knowledge from pretrained models, including multilingual language models (LMs) and multilingual sentence encoders (SEs). Based on an extensive probing experiments on a suite of cross-lingual lexical tasks, we verified that multilingual SEs (e.g., LaBSE, xMPNET) are superior to multilingual LMs (mBERT, XLM-R) in terms of stored cross-lingual lexical knowledge. We empirically validated that the SEs store more lexical knowledge than 'what meets the eye' when they are used off-the-shelf, but this knowledge must be exposed from them. To this end, we proposed new methods to further fine-tune their representations based on contrastive learning to 'rewire' the models' parameters and transform them from LMs and SEs into more effective cross-lingual lexical encoders. These lexical encoders yield gains for all underlying models, and are especially significant for resource-poor languages and in low-data learning regimes. While this work focused on two widely used state-of-the-art multilingual SEs, the contrastive framework is versatile and model-independent and can be applied on top of other multilingual SEs in future work. We will also investigate other more sophisticated contrastive learning strategies, look into ensembling of knowledge extracted from different SEs, and expand our probing experiments to more tasks and languages.

We also thank the three anonymous reviewers for their extremely substantial and in-depth reviews with a large number of helpful suggestions.

Limitations

This work focuses on lexical specialization of multilingual encoders, off-the-shelf LMs (experiments with mBERT and XLM-R Base) and, in particular multilingual encoders specialized for sentence-level semantics (experiments with LaBSE and xMPNET). While these are all widely used models, they are arguably among the smaller pretrained multilingual encoders. Due to computational constraints, we have not evaluated the effectiveness of the proposed cross-lingual lexical specialisation for larger multilingual LMs, e.g., XLM-R-Large (Conneau et al., 2020) or mT5 (Large, XL, and XXL) (Xue et al., 2021). It is possible that these larger multilingual LMs would close (some of) the performance gap w.r.t. multilingual SEs. Such large LMs, however, are effectively available to fewer researchers and practitioners. Our work includes less resource-demanding LMs and SEs, making their lexically specialized variants that we offer more widely accessible.

Lexical input (i.e., words or phrases) are provided to each multilingual encoder fully *"in isolation"* (see §2), without any surrounding context. However, the alternative of using external corpora and *averaging-over-context* (Litschko et al., 2022), which we have not evaluated in this work for clarity and space constraints, might yield slightly improved task performance. Nonetheless, the 'in isolation' approach has been verified in previous work (Vulić et al., 2021a; Litschko et al., 2022; Li et al., 2022) as very competitive, and is more lightweight: **1)** it disposes of any external text corpora and is not impacted by the external data; **2)** it encodes words more efficiently due to the absence of context. Moreover, it allows us to directly study the richness of cross-lingual information stored in the encoders' parameters, and its interaction with additional cross-lingual signal from bilingual lexicons.

The contrastive cross-lingual lexical fine-tuning we proposed in this is work is *bilingual*. It leverages a small bilingual dictionary $\mathcal{D}$ for each language pair and specializes the multilingual encoders (LMs and SEs) independently for each language pair. Assuming interest in cross-lingual lexical tasks between all pairs of N_L languages, this entails $\frac{N_L \cdot (N_L - 1)}{2}$ fine-tuning procedures and as many resulting bilingual models. Although our contrastive fine-tuning is relatively fast and lightweight, given that it leverages at most 5k translation pairs, for large N_L it could easily exceed the computational and time budget for most users. On a high level, our work again outlines the advantages as well as disadvantages between **1)** more versatile massively multilingual models that serve multiple languages without any further adaptation, and **2)** better-performing but typically less modular and less versatile models adapted (i.e., *bilingually specialized*) from the multilingual models (Bapna and Firat, 2019; Parović et al., 2022).

Intuitively, for each bilingually fine-tuned model, we evaluate the performance for that respective language pair. Currently, we do not investigate the spillover effects that a bilingual lexical fine-tuning of multilingual encoders could have on lexical representations of other languages. Such an analysis, planned for future work, would be particularly interesting in the context of low-resource languages, unseen from the point of view of cross-lingual lexical fine-tuning, and in particular closely related low-resource languages. For instance, if we are doing cross-lingual lexical fine-tuning for language pairs involving Turkish, are there spillover benefits for low(er)-resource Turkic languages such as Uyghur or Kazakh?

Finally, we acknowledge that our choice of lexical tasks as probing tasks is non-exhaustive: we put focus on standard tasks from previous work on (multilingual) lexical semantics that are especially convenient as cross-lingual lexical probes: such tasks directly test and compare the quality of cross-lingual lexical representations obtained via different methods; see §4.1 again.

A List of Languages

The list of languages used in this work, along with their ISO 639-1 codes, is available in Table 5.

B BLI Results across Individual Language Pairs

Additional experiments and analyses over individual language pairs and other λ values, which further support the main claims of the paper, have been relegated to the appendix for clarity and compactness of the presentation in the main paper:

Table 6. It provides results over all 28 language pairs in GT-BLI with 2 multilingual LMs and 2 multilingual SEs in the *noCL* variant without contrastive fine-tuning.

Table 7. It provides results over all 28 language pairs in GT-BLI with 2 multilingual LMs and 2 multilingual SEs in the *+CL* variant with contrastive fine-tuning.

Table 8. It provides results over all 28 language pairs in GT-BLI and across different λ values with the LABSE +noCL variant.

Table 9. It provides results over all 28 language pairs in GT-BLI and across different λ values with the LABSE +CL variant.

C XLSIM Results across Individual Language Pairs

Table 10. It provides results over selected 6 language pairs from Multi-SimLex with 2 multilingual LMs and 2 multilingual SEs in the *noCL* variant without contrastive fine-tuning.

Table 11. It provides results over selected 6 language pairs from Multi-SimLex with 2 multilingual LMs and 2 multilingual SEs in the *+CL* variant with contrastive fine-tuning.

Table 12. It provides results over selected 6 language pairs from Multi-SimLex and across different λ values with the XMPNET +noCL variant.

Table 13. It provides results over selected 6 language pairs from Multi-SimLex and across different λ values with the XMPNET +CL variant.

D Models and Evaluation Data

URLs to the models used in this paper are provided in Table 14. Training and test data for all three tasks (BLI, XLSIM, XEL) is available online:

- GT-BLI is available here: `https://github.com/codogogo/xling-eval`
- PanLex-BLI: `https://github.com/cambridgeltl/panlex-bli`
- Multi-SimLex [XLSIM]: `https://multisimlex.com/`
- XL-BEL [XEL]: `https://github.com/cambridgeltl/sapbert`

Our code is based on PyTorch, and relies on the following two widely used repositories:

- `sentence-transformers`: `www.sbert.net`
- `huggingface.co/transformers/`

Table 6: Individual P@1 scores (×100%) for all 28 language pairs in the GT-BLI dataset of Glavaš et al. (2019), with multilingual LMs and SEs used 'off-the-shelf' *without contrastive fine-tuning* (§2). See §3 for the description of different model configurations/variants. $|\mathcal{D}| = 5k$. The number in the parentheses denotes the value for λ (see §3): the value of 1.0 effectively means 'no interpolation' with static VECMAP CLWEs.

Pento-DiaRef: A Diagnostic Dataset for Learning the Incremental Algorithm for Referring Expression Generation from Examples

Philipp Sadler[1] and **David Schlangen**[1,2]

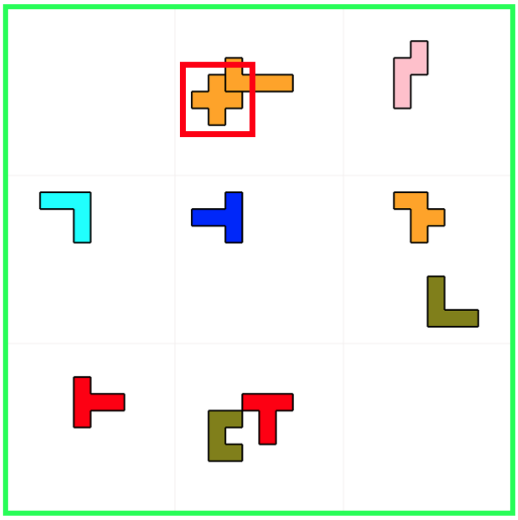
`firstname.lastname@uni-potsdam.de`

Abstract

NLP tasks are typically defined extensionally through datasets containing example instantiations (e.g., pairs of image i and text t), but motivated intensionally through capabilities invoked in verbal descriptions of the task (e.g., “t is a description of i, for which the content of i needs to be recognised and understood”). We present Pento-DiaRef, a diagnostic dataset in a visual domain of puzzle pieces where referring expressions are generated by a well-known symbolic algorithm (the “Incremental Algorithm”), which itself is motivated by appeal to a hypothesised capability (eliminating distractors through application of Gricean maxims). Our question then is whether the extensional description (the dataset) is sufficient for a neural model to pick up the underlying regularity and exhibit this capability given the simple task definition of producing expressions from visual inputs. We find that a model supported by a vision detection step and a targeted data generation scheme achieves an almost perfect BLEU@1 score and sentence accuracy, whereas simpler baselines do not.

1 Introduction

Being able to effectively and efficiently *refer* to objects is a central component of human language competence (van Deemter, 2016). The computational task of referring expression generation (REG) goes beyond the production of image descriptions (as in image captioning), in that it is a *uniquely identifying* description that needs to be produced, given a specific situation. In the formulation of Krahmer and van Deemter (2012), the REG task involves reasoning over all relevant objects in a scene, in order to determine what would make a description uniquely identifying. Additionally, maxims of efficiency (Grice, 1967) predict that it is a *minimal* natural language expression that should be preferred. The *Incremental Algorithm* (IA) (Dale and Reiter, 1995) is a well-known classic symbolic algorithm that tries to realise these desiderata. For example given a reference target and various distractors as in Figure 1 (an example of the domain chosen in this paper (Pentomino, Golomb (1996); Zarrieß et al. (2016); Kennington and Schlangen (2017))), then the Incremental Algorithm (IA) produces “Take the X”, achieving the desired uniquely identifying reference by mentioning only the shape and *not* also color and position.



(a) *“Take the orange X in the top”*

(b) *“Take the X”* (omit color and position)

Figure 1: An example board with a referring expression (b) as produced by the Incremental Algorithm (IA) (minimal wrt. a preference order); and an unnecessarily verbose reference (a) (that still is uniquely referring). The reference target is highlighted with bounding box; images regions separated by addition of lines.

Can such a reference strategy be learned by neural generation models from visual inputs alone? This is a question that is typically not systematically challenged in language generation from images (Kazemzadeh et al., 2014; Yu et al., 2016; Mao et al., 2016; Plummer et al., 2015; Luo and Shakhnarovich, 2017), as in natural scenes (such as in the RefCOCO dataset (Yu et al., 2016)), it has been shown that descriptions can be produced

Pento-DIARef (Ours)	REG	Image	BBox	Text (IA-RE)	Color-Shapes, Positions, IA-REs

Table 1: The most relevant datasets in comparison to Pento-DIARef. In contrast to Liu et al. (2019) we study the task of REG (which avoids models to exploit language inputs) and add generalization tests for the output expressions.

based on the recognition of only parts of the image (Agrawal et al., 2016); our dataset is designed to make this impossible. Schlangen (2021) observed that in typical settings in the field of natural language processing, the connection between an underlying natural language capability and a learned model is only an indirect one. It rests on how well the dataset from which the model was induced does indeed exemplify the assumed underlying task—of which typically only a verbal description is given—and in turn on the extent to which the task represents the capability.

In this work we study how a intensionally defined task (in the distinction of Schlangen (2021)) for which a verbal and theoretically motivated description is given (through a symbolic algorithm) can be learned from its extensional exemplification. Our contention is that the use of synthetic data (Johnson et al., 2017; Liu et al., 2019; Lake and Baroni, 2018; Ruis et al., 2020; Wu et al., 2021) offers the opportunity to strengthen the link, insofar as guarantees can be given on the exemplification relation. More specifically, we choose the Incremental Algorithm (Dale and Reiter, 1995) for the data generation process, which itself comes with a motivation through recourse to underlying fundamental conversational capabilities (appeal to Gricean maxims, Grice (1967)). Our contributions are as follows:[1]

- We create a novel synthetic dataset, Pento-DIARef, of examples that pairs visual scenes with generated referring expressions;
- examine two variants of the dataset, representing two different ways to exemplify the underlying task;
- and evaluate an LSTM-based baseline (Mao et al., 2016), a transformer (Vaswani et al., 2017) and a modified version with region embeddings (Tan and Bansal, 2019) on them.

2 Related Work

Compositional Reasoning. Lake and Baroni (2018) introduced a systematic benchmark to test the generalization capabilities of recurrent neural networks through the use of compositional splits and found that these models fail “spectacularly”. Ruis et al. (2020) extended the task of mapping text commands to actions (Navigation) by conditioning the learner additionally on a symbolic world state. Later (Wu et al., 2021) provided a curated dataset along with new dimensions for generalizability testing. Our work follows the idea of generalization testing through compositional datasets in language and vision settings where training examples are composed in such a way that the models are exposed towards all property values of objects, but not to all the possible combinations of them, so that they can be tested on unseen combinations. In contrast to their work we use images instead of symbolic world states as the input.

Diagnostic Datasets. For the generation of the synthetic data we took inspiration from Johnson et al. (2017) who created a “diagnostic dataset” for visual question answering to test for model limitations. They draw 3D objects on a 2D plane and systematically use templates to create questions about the objects to avoid biases that occur in “common” datasets. Later Liu et al. (2019) convert the questions to referring expressions to test systematically for referring expression comprehension (REC). They claim that the models’ performance on the dataset proves that they “work as intended”. In this work we study this aspect as well but on the mirroring task of REG which avoids models to exploit hints from the language inputs (Table 1).

Program Learners As a related idea Pi et al. (2022) suggest to train language models on text outputs of “executable programs” (which could be a symbolic algorithm). They focus on the pretraining paradigm and aim to induce reasoning capabilities into language models to enhance their usefulness for downstream tasks. Our work is more specifically focused on the question whether a neural model is able to learn the underlying capabilities that are exhibited by a symbolic algorithm in a vision and language domain. Same et al. (2022) showed that such rule-based algorithms are still a useful approach for REG in natural settings.

3 Pento-DIARef Task and Dataset

We present a **D**iagnostic dataset of IA **Ref**erences in a **Pento**mino domain (Pento-DIARef) that ties extensional and intensional definitions more closely together, insofar as the latter is the generative process creating the former (Schlangen, 2021). In this chapter we describe the task (§3.1) and how it is tied to the Incremental Algorithm (§3.2) via the generation process (§3.3) and present our compositional splits (§3.6) for generalization testing.

3.1 Task Description

Given as input an $x_i = (v_i, b_i)$, representing a Pentomino board v_i as in Figure 1 and a bounding box b_i (indicating the target piece), a model f has to produce a referring expression y_i (as it would be generated by IA) as shown in Figure 2. Formally, this can be described either as a classification task $\text{argmax}_{y_i} P(y_i|x_i)$ when y_i is considered a whole sentence or more generally as a conditional language modeling task $P(w_t|w_{<t}, x_i)$ with $y_i = \{w_0, ..., w_T\}$ where T is the length of the expression. We present models for both of these interpretations in Section 5.1.

3.2 The Incremental Algorithm (IA)

The Algorithm 1 , in the formulation of (Krahmer and van Deemter, 2012), is supposed to find the properties that uniquely identify an object among others given a preference over properties. To accomplish this the algorithm is given the property values $\mathcal{P}$ of distractors in M and of a referent r. Then the algorithm excludes distractors in several iterations until either M is empty or every property of r has been tested. During the exclusion process the algorithm computes the set of distractors that do *not* share a given property with the referent and stores the property in $\mathcal{D}$. These properties in $\mathcal{D}$ are the ones that distinguish the referent from the others and thus will be returned.

Algorithm 1 The IA on symbolic properties as based on the formulation by van Deemter (2016)

```
Require: A set of distractors $M$, a set of property
    values $\mathcal{P}$ of a referent $r$ and a linear preference
    order $\mathcal{O}$ over the property values $\mathcal{P}$
$\mathcal{D} \leftarrow \emptyset$
for $P$ in $\mathcal{O}(\mathcal{P})$ do
    $\mathcal{E} \leftarrow \{m \in M : \neg P(m)\}$
    if $\mathcal{E} \neq \emptyset$ then
        Add $P$ to $\mathcal{D}$
        Remove $\mathcal{E}$ from $M$
return $\mathcal{D}$
```

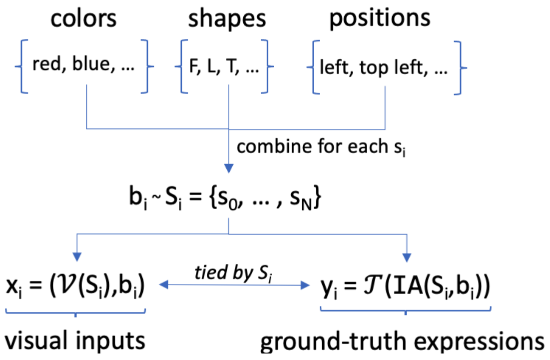

Figure 2: The general generation process for our synthetic datasets as defined by the task.

The algorithm has a meta-parameter $\mathcal{O}$, indicating the *preference order*, which determines the order in which the properties of the referent are tested against the distractors. In our domain, for example, when *color* is the most preferred property, the algorithm might return BLUE, if this property already excludes all distractors. When *shape* is the preferred property and all distractors do *not* share the shape T with the referent, T would be returned. Hence even when the referent and context are the same, different preference orders might lead to different expressions (Krahmer et al., 2012). We choose the preference order of *color, shape and position* for the algorithm; we leave experimenting with other orders to future work.

3.3 Data Generation

The inputs x_i for the task consist of two parts: the visual representation of the scene v_i and a bounding box around the target piece b_i. For the automatic generation of these inputs we make use of *symbolic board* representations $S_i = \{s_0, ..., s_N\}$ where N is the number of pieces on a board and s_i is a tuple of *color*, *shape* and *position* values e.g. (ORANGE,X,TOP). We define a mapping function $\mathcal{V}(S_i) \rightarrow v_i \in \mathbb{R}^{W \times H \times C}$ for rendering a board and sample uniformly from the symbols to select a target piece $b_i \sim S_i$ (for which we know the bounding box via $\mathcal{V}$). For simplicity, we use b_i to refer to the target bounding box in the visual domain or the target piece in the symbolic domain respectively.

As the ground-truth expressions we define $y_i = \{w_0, ..., w_T\}$ where T is the length of the expression and w_i is a word in the vocabulary. Again we make use of the symbolic piece representations (the same as above) to automatically generate the ground-truth by using the Incremental Algorithm. We apply the IA on the symbolic piece representations S_i and the target symbol b_i to select a set of property values $\mathcal{D}_i = \text{IA}(S_i, b_i)$ from the target b_i (Algorithm 1). These property values $\mathcal{D}_i$ are the shape, color or position values that are supposed to distinguish the target piece from other ones on the board. Finally, we define a mapping function $\mathcal{T}(\mathcal{D}_i) \rightarrow y_i$ to produce the ground-truth expression by filling the property values into pre-defined templates. The result of this process is a pairing of image and text, as you would find it for example in a captioning dataset (Johnson et al., 2016), albeit not collected from annotators but rather synthetically generated. In the following, we give more information on $\mathcal{V}$ and $\mathcal{T}$.

3.4 $\mathcal{V}$: Rendering the Pentomino boards

The symbolic piece representations in S_i are rendered as visual inputs v_i. We implement the rendering function $\mathcal{V}(S_i)$ that paints the symbolic pieces according to their shape and color values with black borders onto a board of 30×30 same-sized tiles. This underlying grid is projected onto 224×224 pixels. The exact tile coordinates of the pieces are determined by dividing the board into 9 distinct areas: one for each piece position value. To ensure that all pieces fit on the board, we allow maximal 2 pieces in a single area. We rotate and place the pieces one after the other into these areas by uniformly sampling tile coordinates that fall into the area that aligns to the piece position value. If two pieces collide during the placement, then we sample the coordinates again until they fit next to each other.

3.5 $\mathcal{T}$: Surface realization of IA outputs

The IA returns properties $\mathcal{D}_i$ of a target piece that distinguish it from other pieces. This list of properties is then transformed into a natural language expression. We define a mapping function $\mathcal{T}$ that inserts the property values into one of 7 different templates (Appendix C), for example "Take the *[color]* piece". We call these templates *expression types*. The mapping function selects the template based on the number of properties and the preference order: color, shape and then position. The word order in the templates is aligned with the preference order. We only use this order here to focus on the semantic correctness of the generation and leave mixing in additional variants like "Take the *[shape]* that is *[color]* in *[position]*" to future work. Altogether the property values and the templates lead to a vocabulary of 38 words—an extremely small vocabulary, which however as we are not targeting lexical complexity here is not a problem.

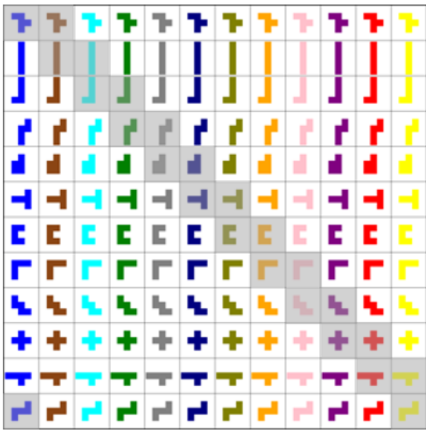

Figure 3: The shape and color combinations in grey are never seen during training, but only during evaluation.

3.6 Compositional Generalization

We make use of a synthetic dataset to guarantee the independence of properties and thus control, among other things, the compositionality of the learning task. There are 12 conventional names for the shapes which are roughly inspired by visual similarity to letters like *F*, *T*, *Y* etc. (Golomb, 1996). We sidestep the question of producing natural descriptions ("the one that looks like a boomerang") for the shapes and assume that these letter names can be produced. Furthermore, the pieces can appear in one of 12 different colors and the position can be approximated with 9 different spatial expressions (Appendix A.1, A.2). The permutation of colors, shapes and positions leads to $12 \cdot 12 \cdot 9 = 1296$ symbolic pieces to choose from for the composition of boards and the selection of targets. Now we create the training data from only $|S_{\text{train}}| = 840$ of the overall 1296 possible piece symbols and leave the remaining ones as a "holdout". These holdout pieces are specifically used to test the models' generalisation along three different dimensions, as in the following.

Piece appearances *(ho-color, 756 examples)*. The target piece shapes are combined with new colors with respect to the training set (Figure 3). For each of the 12 shapes we hold out 2 colors (val,test). Then we generate for each shape-color combination one board for each position and expression type.

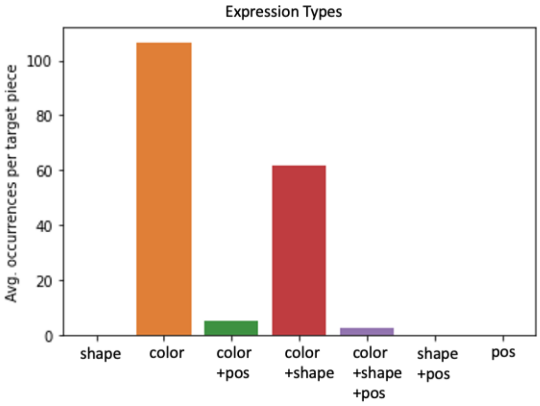

Figure 4: In the NAIVE dataset the synthesized examples highly prefer the generation of the two templates that only mention either the *(color)* or *(color,shape)* of a target piece. Some templates appear almost never [*(shape)*, *(shape,pos)*] or indeed never [*(pos)*].

Piece positions *(ho-pos, 840 examples)*. In these examples the target pieces are shown at new positions with respect to the training set. For each of the pieces we hold out 2 positions (val,test). Then we generate for the holdout combinations one board for each expression type.

Expression types *(ho-uts, 840 examples)*. We test that expression types are not attributed to specific pieces and show them in new contexts that leads to new expressions types wrt. the training set. For each of the pieces we hold out 2 expression types (val,test) and create corresponding boards.

4 What data is necessary to learn the IA?

The learned models have to generate an expression with exactly those property values (not more and not less) that the IA would produce. We hypothesise that learning the iterative set logic process and the preference order (either implicitly or explicitly) from text and visual inputs alone constitutes a challenging task for them, especially because given 12 shapes, 12 colors and 9 (discrete) positions for a piece (minus the combinations we excluded for holdout), then there are already around 20 billion possibilities to produce a board with 4 pieces on it.

Thus we make use of the fact that the generation process is fully under our control and directly ask what kind of data distribution is necessary to learn this task. We experiment with two different dataset variants: The first variant (§4.1) relies on an unconstrained sampling of symbolic pieces for each board while the second variant (§4.2) is designed to be more informative through a curated selection process.

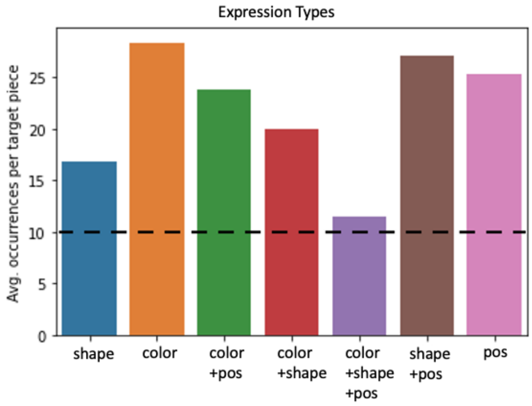

Figure 5: The DIDACT dataset is fairly balanced with respect to the expressions types. The figure shows the average count of expression types for each target piece after generating with ETOS. The dashed line indicate the distribution without the extra target selection.

4.1 NAIVE: Unconstrained Sampling

This process is meant to model the "naive" creation of a board by randomly sampling and placing pieces, as a person might do when setting up a board. We create these examples by randomly filling boards with pieces: First, we decide on the number of pieces that go on the board by sampling N from a uniform distribution over the integers 4–10. Then we sample uniformly with replacement $\{s_0, ..., s_N\}$ from the 840 symbolic pieces that are available for training. From the resulting symbolic board S_i we choose one piece, again uniform random, as the target piece b_{i_0}. Finally, we generate the input pairing (x_i, y_i) as described above.

We add one further constraint: We re-use the visual board v_i and pair it with 3 other target pieces $\{b_{i_1}, b_{i_2}, b_{i_3}\}$ chosen from S_i without replacement, so that a model *cannot* perform well by memorizing the (x_i, y_i) pairings alone, because then there are 4 identical visual boards with different targets that lead to (most likely) different expressions. This leads to 4 examples (x_j, y_j) per visual board with $x_j = (v_{i_0}, b_j)$. We repeat this procedure $42,000$ times which leads to $148,000$ training examples in total. The quantitative evaluation shown in Figure 4 reveals that here a model is most of the times confronted with expressions that only mention the *color* value or the *color and shape* of the target piece. The orange bar indicates that there are on average 100 examples (board and target) for each of the possible 840 target pieces where the color alone uniquely identifies the piece. So for around 84K samples in this dataset, a sentence like "Take the [blue, red, green,...] piece" would be correct.

4.2 DIDACT: Expression Oriented Sampling

The goal of the alternative sampling process is to ensure that examples of all *output* types are represented in the dataset, in a balanced way. We assume that this results in a more "didactic" dataset from which the underlying relation between input and desired output can more easily be induced. The idea is to directly choose the distractors of a target piece in such a way that the wanted expression type has to be produced. For example, when the target piece is (ORANGE, X, TOP) and the expression type is supposed to be *Take the [shape]*, then we construct a set of distractors where some share color and position, but none is of shape X. We call this approach *expression type oriented sampling* (ETOS) (details in Appendix B.1). This method allows us to confront the learner with all the possible expressions about the same amount of times. Thus each target piece is seen on 50 different boards resulting in $840 \cdot 50 = 42,000$ boards (Table 2).

Yet again we avoid that (x_i, y_i) pairs can be simply memorized and select as before 3 other pieces as the targets $\{b_{i_1}, b_{i_2}, b_{i_3}\}$ which leads to $148,000$ examples in total. The consequences of the extra target selection within this method are twofold: Firstly, the distribution is a bit shifted towards the NAIVE approach as shown in Figure 5 because we randomly select the target, and more importantly there might be now expressions produced that were actually intended for the holdout *(ho-uts)*. We remove such "unintended" examples from the training set so that there are $128,526$ examples for training (Table 3). Whereby the guarantees we can make for this "DIDACTic" dataset are that:

Target pieces appear with different distractors. Each target piece symbol for training appears on average in 153 contexts as a target.

On the same board occur different target pieces. We choose 3 additional pieces as targets apart from the one for which the board was initially intended.

Target pieces appear also on other boards. Each symbolic piece appears on average in $1,075$ contexts, which is more often than as a target.

5 Learning the Incremental Algorithm

Our goal in producing the collection of scenes was to ensure that a model f must indeed be based on features of the x_i that we care about (that is, which figure in the desired capability), namely the need to indeed compare the perceivable target piece and distractor properties. The IA (§3.2) achieves this by a hard-coded loop structure over symbols which (a) compares the objects (b) sticks to a preference order (c) preemptively stops when all distractors are excluded and (d) outputs the uniquely identifying properties (or all properties in ambiguous cases).

Dataset / Num. of	TPS	pET	Bords per pET	Boards Total
NAIVE	840	7	-	42,000
DIDACT	840	5	10	42,000
ho-uts val	840	1	1	840
ho-uts test	840	1	1	840
ho-color val	108	7	1	756
ho-color test	108	7	1	756
ho-pos val	120	7	1	840
ho-pos test	120	7	1	840

Table 2: The number of target piece symbols (TPS) and possible expression types (pET) per TPS for the NAIVE, DIDACT and holdout datasets. Although the number of the resulting NAIVE and DIDACT boards is with $42,000$ the same, the boards are generated with different techniques: either with random uniform sampling (NAIVE; the number of boards per pET and TPS is not controlled for) or expression type oriented sampling (DIDACT; 10 boards for each pET and TPS).

	NAIVE dataset	DIDACT dataset
Number of Boards	42,000	42,000
TPS per Board	4	4
Number of Samples	168,000	168,000
Validation	10,000	10,000
Testing	10,000	10,000
Training	148,000	148,000
Filtered	128,526	-

Table 3: The number of samples for each dataset and training split. For each board we chose 4 target piece symbols (TPS) (incl. the originally intended target piece in the DIDACT dataset) resulting into $168,000$ samples for both datasets. From this overall samples we choose $10,000$ for validation and testing. In addition, we exclude the training samples of the DIDACT for which an expression is to be produced that should reserved for the *ho-uts* testing. This is not done for the NAIVE dataset because here we train on possibly all expression types.

In the following, we present our neural models (§5.1) and the conducted experiments (§5.3) to test if neural language generators are indeed able to acquire such a "programatic" capability by the simple task definition of producing expressions from visual inputs. The generation models f will be trained on the basis of (x_i, y_i) pairs only. We train two common network architectures for this task of which one is an LSTM-based approach to REG proposed by Mao et al. (2016) for natural scenes and the other is a transformer (Vaswani et al., 2017). In addition, we propose a variant for processing the inputs along with a simple classifier-based baseline.

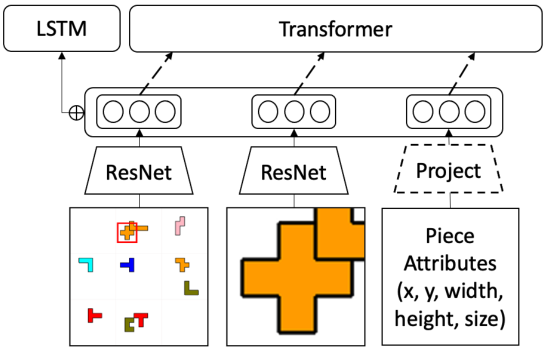

Figure 6: The encoding of the visual scene, target piece and its attributes as proposed by Mao et al. (2016). The dashed lines indicate the transformers' information flow.

5.1 Models

LSTM. Mao et al. (2016), who present a model of REG in natural scene images, embed the scenes and the referent within them with a pre-trained VGG (Liu and Deng, 2015). We follow their procedure but use the 512 dimensional embeddings after global average pooling of a ResNet-34 (He et al., 2016) and fine-tune all of its layers because our images look very different to the ones from the pre-training on ImageNet (Deng et al., 2009). We cut out the target piece using the bounding box information. Then the piece snippet is dilated with 5 context pixels and up-scaled to the size of the board image. We additionally randomly shift the snippet by 0-5% of the pixels in either direction horizontally or vertically (fill-color is white). The target piece and board image embeddings are then concatenated together with five location and size features of the target. The resulting 1029-dimensional feature vector is fed to an LSTM at each time step to condition the language production (using greedy decoding). We reduce the word embedding dims to 512 because our vocabulary is very small and apply an Adam optimizer (Kingma and Ba, 2015).

Transformer. For comparison with Mao et al. (2016) we resize, augment and encode the target piece and visual board with a ResNet-34 in the same way as described before. Then the image embeddings are fed into the transformer (Vaswani et al., 2017) individually (not concatenated) as "visual words" together with the target piece attributes embedding as shown in Figure 6 to compute an intermediate representation of the inputs altogether. This "memory" embedding is then fed into the decoder to generate the RE using masked self-attention as in other machine translation tasks. For the variable length expressions we use a padding symbol and ignore prediction at padded positions during loss computation. We reduced the original capacity of the model to avoid overfitting and applied a learning rate scheduling strategy as described by Vaswani et al. (2017), using an AdamW optimizer (Loshchilov and Hutter, 2019).

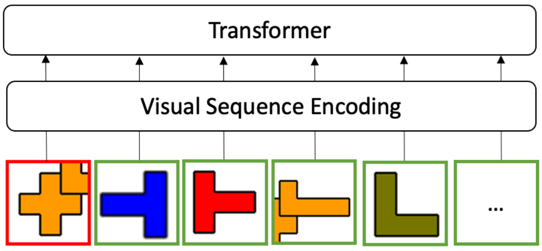

Figure 7: An exemplary visual input sequence for the Transformer+VSE model. The target is highlighted with a red and the distractors with a green border.

Transformer+VSE. We assume that the transformer should be particularly capable of generating IA-like expressions because self-attention might allow it to learn the required piece-wise comparison operation. The self-attention mechanism has already been proven powerful for other image-related tasks (Li et al., 2020; Zhang et al., 2021; Jaegle et al., 2021). Therefore we follow Tan and Bansal (2019) and implement a *visual sequence encoding* (VSE) mechanism. For this we cut out each piece on the board to produce a sequence of piece snippets as shown in Figure 7 and project the visual features onto the models' input dimensions $\hat{f}_j$ and add region embeddings $\hat{p}_j$ to them that contain the snippets size and location information:[2]

$$\hat{f}_j = \text{LayerNorm}(W_F f_j + b_F) \qquad (1)$$

$$\hat{p}_j = \text{LayerNorm}(W_P p_j + b_P) \qquad (2)$$

$$v_j = (\hat{f}_j + \hat{p}_j + \hat{t}_j)/3 \qquad (3)$$

To let a model distinguish between target and distractor "words" in the input sequence we add a type embedding $\hat{t}_j$, similar to word embeddings, and normalize. Furthermore, we have a variable amount of pieces on the board (between 4 and 10), but a transformer model assumes a fixed-size input sequence (per batch, during training). Thus we indicate "padding" pieces with a padding index in the sequence as implemented in PyTorch (Paszke et al., 2019) and use images with all zeros for them.

---

[2] b_F, b_P are bias terms of the linear projections

Classifier+VSE	DIDACT	91	79	77	60	76	40	44	14

Table 4: The match rates for unigrams (BLEU@1) and whole sentences (SentA) on the test splits. The *in-dist.* samples are from the DIDACT dataset because these are more balanced with respect to the expression types.

Classifier+VSE. The representations of the VSE might already capture enough information to perform the task. Therefore we test this assumption by training a simple linear sentence classifier just on top of the concatenated embeddings. The classifier has to predict the correct sentence out of the 1,689 possible ones. This framing is similar to that often used in visual question answering (Hudson and Manning, 2019), where the possible answers are framed as classes in a classification task.

5.2 Metrics

We use the well known and commonly reported precision-based BLEU@1 metric for evaluation because this is simple metric for word matching when having only a single reference. In addition, we compute the *sentence-wise accuracy* (SentA) that indicates how often a prediction does exactly match the single reference so that the order of the words matters. As an example in Appendix E the model erroneously produces “Take the i top in the top left”. We ignore the starting words “Take the” for the evaluation when they occur in both the prediction and the ground-truth, because then they are uninformative about the real performance.

5.3 Experiments

We perform separate training runs on both a NAIVE (§4.1) and DIDACT (§4.2) dataset for a maximum of 100 epochs and perform 10 validation runs during an epoch. Over all validation runs we save the three best performing models with respect to the BLEU@1 score using greedy decoding. We stop the training when the model does not improve anymore after 20 validation runs. For evaluation we choose the model with more epochs if the scores are the same. The training objective is to minimize the cross-entropy between the predicted and the ground-truth expression given by the Incremental Algorithm (IA).

6 Results and Discussion

NAIVE versus DIDACT. The results in Table 4 show that even the worst performing model trained on the DIDACT dataset (LSTM 31% in-dist) *is still performing better* than the best performing model trained on the NAIVE dataset (Transformer+VSE 29% in-dist) over all SentA scores (except ho-uts). This indicates that a well controlled data generation procedure is essential to perform well on this task, or conversely, that none of the learning algorithms can guess at the underlying minimality constraint from the unconstrained data alone. The SentA scores for the NAIVE-based models indicate that these often perform only about by chance (picking 1 of 7 templates leads to a score of 14%) on the compositional splits (highest 25% and avg. 18%). These splits contain all expression types in equal amounts and we find that these NAIVE models tend to produce only a few expression types.

Input triplets versus VSE. The results show that for both datasets a significant increase in performance is achieved by using VSE which includes a vision detection step. For the Transformer+VSE model the BLEU@1 scores double from 27% to 59% on the in-distribution test data. The simple Classifier+VSE model performs similarly well as the other models *without* VSE. This is reasonable because with VSE the visual encoder must *not* operate on two different image resolutions anymore: one for the (up-scaled) target piece and one for the whole context image. The VSE detection step “frees” capacities that would be necessary to correctly identify the content of the context image.

Classifier+VSE versus others. Almost all models struggle to perform well on both the compositional (<54% SentA) and the in-dist. test data (<77% SentA). Thus the Classifier+VSE establishes a relative high baseline on most of the test sets (76%/40%/44%) but only performs about by chance (14%) at the *ho-uts* data (which contains unseen expression types). The Transformer+VSE model is the only one that exceeds the high Classifier+VSE baseline by achieving almost perfect scores (91% SentA) over all categories when trained on the DIDACT data.

Effect of individual input features. We perform an ablation study to measure the impact of particular input features on the SentA scores. We do so by replacing the individual parts of the visual sequence encoding of our best model with noise sampled from a standard gaussian. We see that the visual embeddings are essential to generate the correct referring expression as the sentence-wise accuracy drops to 1% (Table 5). A similar performance drop is seen for the type embeddings where the accuracy is only 1-2%. A different impact is measured, when the region embeddings are replaced with random noise; here the accuracy is still around 40-44%. This is reasonable, because in only 4 of the 7 expression templates, the position (and therefore the region embeddings) are relevant.

Effect of DIDACTic training. We have a closer look on the tendencies of the models to produce certain expression types on the test data. For this we applied a parser to the predicted expressions of the models and counted the expression type occurrences. This provides insights, if a model tends to "overfit" on specific expression types. For example as the surface structure of the *color* expression types is seen in majority of cases during training, a model might simply try to produce *Take the [color] piece* and insert the referent color. We do not check for the correctness of the produced expressions here. The measures show that the LSTM model trained on the NAIVE dataset has converged on a behavior that produces in the majority of cases the *color* or *color+shape* expression type (Figure 8). This is reasonable as this is the majority class in the random sampling data. Only the DIDACT dataset let's them pick up on other expression types more regularly. The Transformer+VSE produces on the DIDACT test dataset rather balanced amounts of expression types (as these are given in the test data).

7 Conclusion and Future Work

In this work we presented the diagnostic dataset Pento-DIARef to study the question whether neural models can learn the RE production strategy of the Incremental Algorithm (IA). A symbolic algorithm that is motivated by the appeal to the hypothesises capability of "elimination of distractors" (through the application of Gricean maxims).

	Sentence-wise Acc. (in %) ↑			
Transformer+VSE	in-d.	ho-color	ho-pos	ho-uts
w/o visual emb.	1	1	1	1
w/o type emb.	2	1	2	2
w/o region emb.	44	42	41	40
full model	91	91	91	92

Table 5: The ablation study performed on the test dataset shows that the visual and type embeddings contain the crucial information for the RE generation.

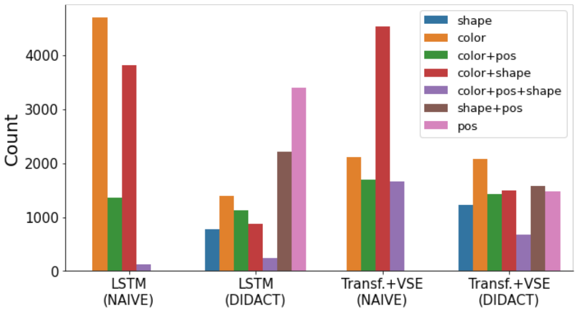

Figure 8: Produced expression types on the *in-dist.* split.

We found through the better control on scene complexity that an unconstrained sampling method (NAIVE) does not provide enough information for a neural model to pick up on the underlying regularity and to exhibit the desired capability, while an output oriented sampling process (DIDACT) does. This indicates that the generalizability in this task and domain is not given by the capabilities of the learner alone but is strongly determined by the learning examples. We evaluated a classic LSTM-based model and a modern transformer (that have to process two different image resolutions) and observed that these still struggle even on the more informative dataset (DIDACT). We proposed a modification of the input processing that comes with a detection step (VSE) and observed that this leads to a strong baseline and allows the transformer to converge. This indicates that object detection is an essential requirement to perform well on this task.

In future work we want to evaluate more models on our diagnostic dataset to find potential weaknesses. An interesting question is whether a PLM (Brown et al., 2020) might have picked up such Gricean constraints and would be able to recognise their desirability from being prompted with only a few examples. We also plan to explore to what extent our best model is applicable to more realistic settings following *Sim-to-Real* approaches (Peng et al., 2018).

Limitations

Limits on visual variability and naturalness. The Pentomino domain can only serve as an abstraction for referring expression generations in visual domains. The amount of objects is limited to 12 different shapes and the number of colors is reduced to 12 as well. The positions are chosen to be discrete and absolute while real-world references might include spatial relations which we leave for further work. Furthermore, the pieces show no texture or naturalness, but are drawn with a solid color fill and a simple black border. Various lightning conditions that might impact a vision detection system are avoided. We left the evaluation of the proposed models on more realistic dataset for further work.

Limits on variability of the referring expressions. We only explored expressions that are generate by the Incremental Algorithm with one fix preference order of color, shape and position although we are aware of the fact that preference order might vary between subjects (Krahmer et al., 2012). Moreover, we choose a fix property value order (color is mentioned before shape is mentioned before position) for the realisation of the template's surface structure and left the exploration for a higher variability to further work.

Limits possible claims about human capabilities. As this work is on synthetic dataset created by an algorithm, any claims about human capabilities, and about a model's ability to acquire those, are only made indirectly, via the quality of the original algorithm.

A Experiment details

We trained each of our models on a single GeForce GTX 1080 Ti (11GB).

A.1 The vocabulary

The vocabulary includes the following 38 words:

- 12 shapes: F, I, L, N, P, T, U, V, W, X, Y, Z
- 12 colors: red, orange, yellow, green, blue, cyan, purple, brown, grey, pink, olive green, navy blue
- 6 position words: left, right, top, bottom, center (which are combined to e.g., right center or top left)
- 4 template words: Take, the, piece, at
- 4 special words: <s>, <e>, <pad>, <unk>

A.2 The piece colors (RGB-values)

Name	HEX	RGB
red	#ff0000	(255, 0, 0)
orange	#ffa500	(255, 165, 0)
yellow	#ffff00	(255, 255, 0)
green	#008000	(0, 128, 0)
blue	#0000ff	(0, 0, 255)
cyan	#00ffff	(0, 255, 255)
purple	#800080	(128, 0, 128)
brown	#8b4513	(139, 69, 19)
grey	#808080	(128, 128, 128)
pink	#ffc0cb	(255, 192, 203)
olive green	#808000	(128, 128, 0)
navy blue	#000080	(0, 0, 128)

Table 6: The colors for the Pentomino pieces. We also have 2 two-word colors: olive green and navy blue.

A.3 Uniform distribution of piece properties

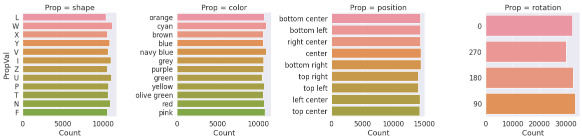

Figure 9: The occurrences of property values of target pieces in the DIDACT training data are almost uniform.

Our expression type oriented sampling strategy achieves an almost uniform distribution of piece color, shapes and positions (even rotations) as shown in Figure 9. We ignore the rotation property, but apply it to make the task harder. The model has to become invariant to the rotation.

B Data Generation

B.1 DIDACT dataset generation details

To construct this data, we iterate over all possible training symbols in S_{train} and set them as the target piece b_i directly (Table 2). Then we sample a symbolic board S_i (that includes the target) from the set of possible symbolic boards that lead to a wanted expression type u_i. For this we define the generator function $\mathcal{G}(u_i, b_i)$ that finds all possible symbolic boards that will be mapped by $\mathcal{T}$ so that $\{S_{u_i} | \mathcal{T}(\textsc{ia}(S_{u_i}, b_i)) \in \mathcal{Y}(u_i)\}$ where $\mathcal{Y}(u_i)$ is the collection of expressions that are represented by the template u_i, for example "Take the *[red, blue, green,...]* piece". In a sense $\mathcal{G}$ is the inverse of $\mathcal{T}$.

This method allows us to confront the learner with all the possible expressions about the same amount of times. We perform the example generation 10 times for each target piece and the according 5 training expression types (see §3.6 for holdouts). Finally, we generate the input pairing (x_i, y_i) as described in §3.1. Thus each target piece is seen on 50 different boards resulting in $840 \cdot 50 = 42,000$ boards. Yet again we avoid that (x_i, y_i) pairs can be learnt by heart and select as before 3 other pieces as the targets $\{b_{i_1}, b_{i_2}, b_{i_3}\}$ which leads to $148,000$ samples in total of which we filter the unintended ones (Table 3).

B.2 Holdout generation details

For the *ho-color* and *ho-pos* splits we additionally allow to choose distractors from the 840 symbolic pieces of the training split, because otherwise the distractor set of possible piece might become empty e.g. for the *ho-pos* split we have the target pieces only on a subset of possible positions, but need to place distractors in additional positions to produce all expression types.

C Expression Types

There are 3 expression types that are used when only a single property value of the target piece is returned by the Incremental Algorithm (IA):

- *Take the [color] piece*
- *Take the [shape]*
- *Take the piece at [position]*

Then there are 3 expression types that are selected when two properties are returned:

- *Take the [color] [shape]*
- *Take the [color] piece at [position]*
- *Take the [shape] at [position]*

And finally there is one expression type that lists all property values to identify a target piece:

- *Take the [color] [shape] at [position]*

In the following we exemplify the generated boards for each of the expression types.

C.1 Take the [color] piece

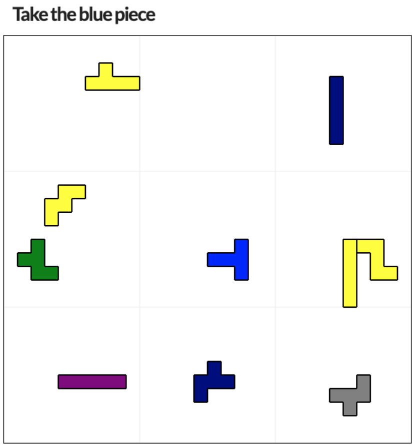

Figure 10: A sample board with the target piece (`T,blue,center`) for this expression type.

Mention the **color** excludes all. We add distractors with any shape or position, but a different color.

C.2 Take the [shape]

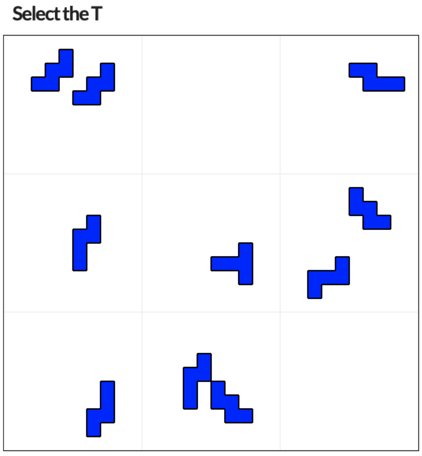

Figure 11: A sample board with the target piece (`T,blue,center`) for this expression type.

Mention the ~~color~~ does not exclude any. Mention the **shape** excludes all. We add distractors with the same color, but different shape and at any position.

C.3 Take the piece at [position]

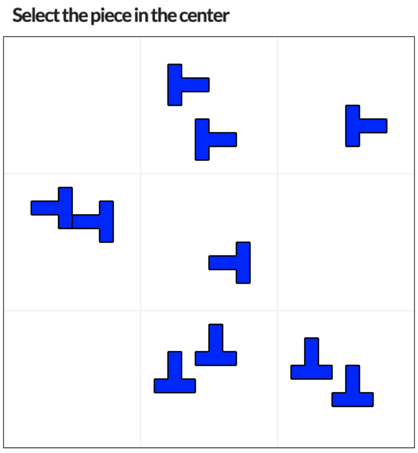

Figure 12: A sample board with the target piece (`T,blue,center`) for this expression type.

Mention the ~~color~~ does not exclude any. Mention the ~~shape~~ does not exclude any. Mention the **position** excludes all. We add distractors with the same color and shape, but at a different position.

C.3.1 Take the [color] [shape]

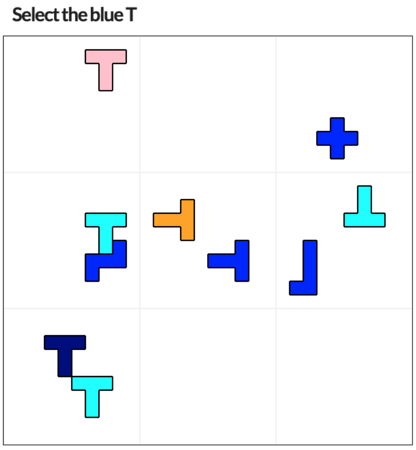

Figure 13: A sample board with the target piece (`T,blue,center`) for this expression type.

Mention the **color** excludes some, but not all. Mention the **shape** excludes the rest. We add some distractors with the same color (but different shape) and some distractors with the same shape (but different color) at any position.

C.3.2 Take the [color] piece at [position]

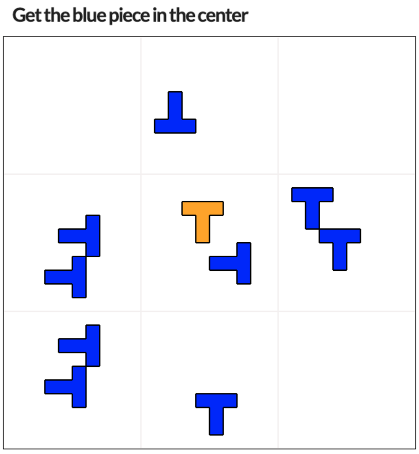

Figure 14: A sample board with the target piece (`T,blue,center`) for this expression type.

Mention the **color** excludes some, but not all. Mention the ~~shape~~ does not exclude any. Mention the **position** excludes the rest. We add some distractors with the same color (but different position) and some with the same position (but different color) and the same shape.

C.3.3 Take the [shape] at [position]

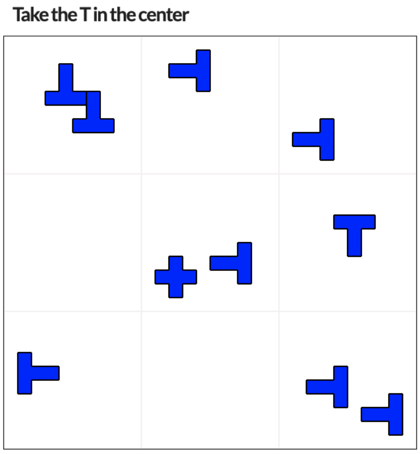

Figure 15: A sample board with the target piece (`T,blue,center`) for this expression type.

Mention the ~~color~~ does not exclude any. Mention the **shape** excludes some, but not all. Mention the **position** excludes the rest. We add distractors with the same color and some with the same shape (but different position) and some with the same position (but different shape).

C.3.4 Take the [color] [shape] at [position]

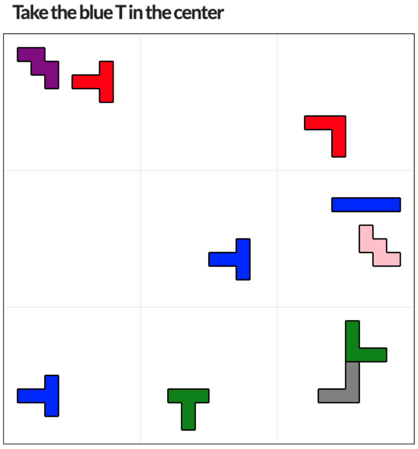

Figure 16: A sample board with the target piece `(T,blue,center)` for this expression type.

Mention the **color** excludes some, but not all. Mention the **shape** excludes some, but not all. Mention the **position** excludes the rest. We add one distractor that has the same color and shape (but a differen position) and one distractor that has the same color (but a different shape and position) and any other distractors. This requires at least 3 distractors.

D Model Details

D.1 LSTM

Parameters: 53, 201, 327 (127 MB)
GPU RAM: 3, 423 MiB (Batch 24; VE)

E Error Analysis

Our best Transformer+VSE model predicts 1, 119 of 12, 436 evaluation expressions wrong meaning that the prediction does not match the reference perfectly. Here 425 errors (213 data, 77 ho-pos, 65 ho-color, 70 ho-uts) are expression predictions where the target piece is the one for which the board was initially designed for and 694 (all data) are cases where we picked an additional target randomly.

E.1 First-class errors

Error types	color	shape	pos	ungram.
data	4	5	180	24
ho-color	2	13	47	5
ho-pos	5	5	58	9
ho-uts	4	15	43	9

Table 10: The error types for the first-class errors

For the 425 first-class errors 213 of the errors are related to cases where the model mentions more properties of the target piece, although this would be unnecessary. In 47 cases the model produces an expressions that is not necessarily incorrect, but not grammatical.

E.2 Second-class errors

Error types	color	shape	pos	ungram.
data	30	56	524	90

Table 11: The error types for the second-class errors

For the 694 second-class errors 179 of the errors are related to cases where the model mentions in addition the position, color or shape of the target piece, although this would be unnecessary. In 90 cases the model produces an expressions that is not necessarily incorrect, but not grammatical.

Mitigating Exposure Bias in Grammatical Error Correction with Data Augmentation and Reweighting

Hannan Cao*   Wenmian Yang†   Hwee Tou Ng*

Abstract

The most popular approach in grammatical error correction (GEC) is based on sequence-to-sequence (seq2seq) models. Similar to other autoregressive generation tasks, seq2seq GEC also faces the exposure bias problem, i.e., the context tokens are drawn from different distributions during training and testing, caused by the teacher forcing mechanism. In this paper, we propose a novel data manipulation approach to overcome this problem, which includes a data augmentation method during training to mimic the decoder input at inference time, and a data reweighting method to automatically balance the importance of each kind of augmented samples. Experimental results on benchmark GEC datasets show that our method achieves significant improvements compared to prior approaches.[1]

1 Introduction

Grammatical error correction (GEC) is the task of correcting errors in a source sentence and generating a well-written and grammatically correct target sentence. Good results have been achieved by state-of-the-art GEC systems (Rothe et al., 2021; Stahlberg and Kumar, 2021) based on the sequence-to-sequence (seq2seq) transformer (Vaswani et al., 2017) architecture.

Generally, the seq2seq models are optimized to predict the next token given all previous context tokens at each time step. During training, the ground truth tokens are used as the context, i.e., the so-called teacher forcing mechanism. However, during inference, the context is the previous tokens predicted by the model. As a result, the contexts at training and inference time are drawn from different distributions. This discrepancy is called *exposure bias* (Ranzato et al., 2016), which causes the model to make inferences under conditions that it has not met during training and causes errors to accumulate during inference.

Table 1: Example decoder inputs produced by different methods. Each method's deviations from the actual decoder input are shown in **bold**.

Currently, the exposure bias problem has attracted much attention in autoregressive text generation. For example, in neural machine translation (NMT), some work (Ranzato et al., 2016; Mihaylova and Martins, 2019; Zhang et al., 2019) addresses this problem by utilizing sentence-level metrics, randomly injecting noise into the training samples as the augmented decoder input, or randomly replacing tokens in the training samples with predicted tokens as the augmented decoder input. Although GEC is a text generation task like NMT, it emphasizes more on proposing correct edits. Therefore, feeding artificially augmented sentences into decoder input during training may produce a different distribution compared with the actual decoder input at inference time.[2] As a result, those generated errors may never happen, making the augmented sentences less effective in the GEC task. As illustrated in Table 1, the augmented decoder input using noise injection or random sampling differs from the actual decoder input.

To address the exposure bias problem more effectively in GEC, we propose a data augmentation approach, which reduces the difference in distribution of the samples between training and inference in an intuitive way. Specifically, we first collect the beam search output generated by the GEC model as the augmented sentences, which mimic the actual decoder input at inference time. Then, during training, the ground-truth and augmented sentences are both fed as input to the decoder, thus reducing the difference in distribution of the samples between training and inference.

Moreover, previous work (Zhang et al., 2019; Bengio et al., 2015) shows that adjusting the noise density during training can better address the exposure bias problem. Since different beam search candidates contain different noise densities (i.e., the error density in GEC), and affect the model performance to varying extent, each candidate should be treated unequally. Therefore, we further propose a data-reweighting method, which automatically learns sampling probability for different augmented sentences dynamically. Specifically, our reweighting approach learns a data scorer through reinforcement learning, which learns the sampling probability for each augmented sentence.

The contributions of our paper are as follows:

- We empirically demonstrated that the exposure bias problem exists in the top-performing seq2seq GEC models, and addressing them helps to improve performance.

- We propose a novel data manipulation approach in GEC, including a data augmentation approach that mitigates the distribution gap between training and inference, and a data reweighting approach that automatically learns the sampling probability for each kind of training samples. No previous work uses data reweighting to tackle exposure bias.

- To the best of our knowledge, our data manipulation approach is the first work that addresses the exposure bias problem regardless of the evaluation metrics in seq2seq GEC.

- Experimental results show that our data augmentation approach significantly reduces the exposure bias problem and improves the performance of seq2seq GEC models.

2 Related Work

This section briefly introduces recent related research in the literature.

2.1 Exposure Bias

Exposure bias has been mostly studied in NMT. Bengio et al. (2015) replace the ground truth word by sampling randomly from the previous predicted words during training. Zhang et al. (2019) further inject noise into the training examples at both word level and sentence level, and select sentence level candidates based on the BLEU score (Papineni et al., 2002). Instead of injecting random noise to the ground truth sentences during training, our data augmentation method treats model-generated sentences as the augmented decoder input to mitigate the difference in distribution of samples between training and inference.

Ranzato et al. (2016) utilize Mixed Incremental Cross-Entropy Reinforce to optimize the model using metrics used at test time (e.g., BLEU) directly. Many similar works (Shao et al., 2018; Saunders et al., 2020) have also been proposed in NMT. For GEC, Sakaguchi et al. (2017) address the exposure bias problem by using reinforcement learning to directly optimize the GEC model towards the GLEU score (Napoles et al., 2015). Compared to Sakaguchi et al. (2017), we do not optimize the GEC model using reinforcement learning, and we address the exposure bias problem effectively where GLEU score is not used.

2.2 Data Reweighting

Many methods have been developed for reweighting or selecting a subset of data suitable for training a model (Franceschi et al., 2018; Chen et al., 2017; Wu et al., 2018; Shu et al., 2019; Wang et al., 2020; Lichtarge et al., 2020). Specifically, Lichtarge et al. (2020) propose an offline reweighting method for GEC, which reweights each training sentence in the previous stage of training based on the perplexity difference between the current and previous checkpoint. Wang et al. (2020) use a reweighting method to learn the sampling distribution for different languages in multilingual machine translation. In contrast, our method is an online reweighting method which dynamically adjusts the error density of the augmented sentences according to different model states.

3 Method

In this section, we first briefly introduce a baseline GEC system in Section 3.1. Then, we introduce our data manipulation method in Section 3.2.

3.1 A Baseline GEC system

Let x be the ungrammatical source sentence and y be the corrected grammatical target sentence. For a seq2seq GEC model parameterized by θ, the goal is to minimize the negative log-likelihood (NLL) for a set of M sentence pairs $\{\langle x^{(i)}, y^{(i)}\rangle\}_{i=1}^{M}$, as follows:

$$l(x, d, y; \theta) = -\sum_{t=1}^{L_y}\sum_{k=1}^{|V|} \mathbb{1}\{y_t = k\}\cdot \log P(y_t = k|d_{<t}, x; \theta) \tag{1}$$

$$L_{NLL}(\theta) = \frac{1}{M}\sum_{i=1}^{M} l(x^{(i)}, y^{(i)}, y^{(i)}; \theta) \tag{2}$$

where x is the source sentence, d is the decoder input of the seq2seq model, y is the target sentence, L_y is the length of the target sentence, $|V|$ is the vocabulary size of the target language, y_t is the t-th target token, $\mathbb{1}\{\cdot\}$ is the indicator function, and $P(\cdot|\cdot)$ is the conditional probability with model θ.

Given trained parameters $\hat{\theta}$, the hypothesis sentence $\hat{y}$ is generated using beam search to select the candidate with the highest probability, as follows:

$$\hat{y} = \arg\max_{y}\{P(y|x; \hat{\theta})\} \tag{3}$$

3.2 Data Manipulation

We propose a data manipulation method that mitigates the difference in contexts during training and inference to improve performance. In particular, our method consists of two parts: A data augmentation method that generates augmented sentences based on beam search to mimic the decoder input distribution during inference, and a data reweighting method that assigns sampling probability for augmented sentences. The overview of our approach is shown in Figure 1.

We will first introduce the data augmentation method in Section 3.2.1 and then introduce the data reweighting method in Section 3.2.2.

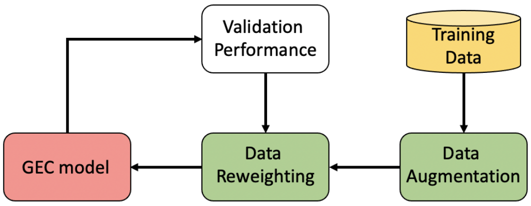

Figure 1: Overview of the proposed data manipulation method to mitigate exposure bias in GEC.

3.2.1 Data Augmentation

To reduce the distribution gap of decoder input during training and inference, we propose to add augmented sentences into the decoder input during training. These augmented sentences are generated by beam search using the model parameters from the checkpoint of the previous stage[3], which mimic the decoder input at inference time.

More specifically, we generate augmented sentences by feeding the source sentence x to the model parameterized by θ, and choose the top n output sentences $\{y_j\}_{j=1}^{n}$ with the highest probabilities generated by beam search.

As the decoder input must have the same length as the target during training, we first align the augmented sentences $\{y_j\}_{j=1}^{n}$ with the corresponding target sentence y according to linguistically-enhanced Damerau-Levenshtein alignment (Felice et al., 2016) by the ERRANT toolkit.[4] Then, we remove the excess tokens and add paddings for the missing tokens. The padded augmented sentences are denoted as $\{\bar{y}_j\}_{j=1}^{n}$. We collect $(x, \{\bar{y}_j\}_{j=1}^{n}, y)$ to form an augmented dataset D_{aug}.

Intuitively, for a well-trained GEC model, candidates with higher probability to be generated usually have lower error densities[5]. Therefore, different candidates affect the model performance unequally. To better capture the effect of different augmented sentences, we assign a separate weight for each augmented sentence, and the loss function is formulated as follows:

$$L_{EB}(\theta) = l(x, y, y; \theta) + \sum_{j=1}^{n} \alpha_{x,j} \cdot l(x, \bar{y}_j, y; \theta) \tag{4}$$

where $\alpha_{x,j}$ represents the weight for the jth augmented sentence for source sentence x. We set

---

[3] Following prior work (Stahlberg and Kumar, 2021), we train the GEC model in three stages, and load the checkpoint of the second stage

[4] https://github.com/chrisjbryant/errant

[5] We verified this in Table 5 in Section 4.4

$\sum_{j=1}^{n} \alpha_{x,j} = 1$, so that all the augmented sentences are treated equally as the original sentence.

3.2.2 Data Reweighting

The ideal way to train an optimal GEC model using Eq. 4 is to determine the optimal value for each $\alpha_{x,j}$. However, this can be computationally costly. To efficiently weight each augmented sentence, we use the averaged weight γ_j to approximate each individual weight $\alpha_{x,j}$, where $\gamma_j \sim E_{\alpha_j}$ and E_{α_j} represents the expectation of $\alpha_{x,j}$, calculated by

$$E_{\alpha_j} = \mathbb{E}_j[\alpha_{x,j}, x \in D_{train}]$$

Therefore, we reformulate Eq. 4 as:

$$L_{EB}(\theta) = l(x, y, y; \theta) + \sum_{j=1}^{n} \gamma_j \cdot l(x, \bar{y}_j, y; \theta) \tag{5}$$

Previous work (Zhang et al., 2019; Bengio et al., 2015) has demonstrated that varying noise density (error density in GEC) according to the training state of the model can effectively address the exposure bias problem. Therefore, we use the sampling probability β_j to approximate γ_j and propose to dynamically adjust β_j according to the model θ. Specifically, we design a learnable data scorer $P(j; \psi)$, parameterized by ψ to modify the training objective which we use to learn θ, so as to maximize the validation performance. Here $j \in \{1, ..., n\}$ indicates the index of the augmented sentence (index 1 indicates the sentence generated with the highest probability in beam search, and so on). More specifically, in the training process, $P(j; \psi)$ is used as the probability to sample an augmented sentence at index j such that the validation loss is minimized.

The final objective is written as follows:

$$\begin{aligned} \psi^* &= \operatorname*{argmin}_{\psi} L(\theta^*(\psi), D_{dev}) \text{ where} \\ \theta^*(\psi) &= \operatorname*{argmin}_{\theta} \sum_{(x,d,y)} L_{EB}(\theta, \psi) \end{aligned} \tag{6}$$

and $L_{EB}(\theta)$ in Eq. 5 is reformulated as:

$$\begin{aligned} L_{EB}(\theta, \psi) = {} & l(x, y, y; \theta) + \\ & \sum_{j=1}^{n} \mathbb{1}\{j = s_i\} \cdot l(x, \bar{y}_j, y; \theta) \end{aligned} \tag{7}$$

where $s_i \in \{1, ..., n\}$ represents the sampled index based on the learned probability $P(j; \psi)$ for each index j [6].

During training, we optimize θ and ψ iteratively. We first optimize the data scorer ψ with fixed θ. To update the data scorer, we use reinforcement learning with a reward function that approximates the effect of the training data on the model's development set performance.

Specifically, our *environment* is the model state θ and model input (x, d, y). Our *agent* is the data scorer network ψ. We formulate our *reward* as:

$$\begin{aligned} & R(j; \theta_t) \\ & = \cos(\nabla_\theta L_{dev}(D_{dev}; \theta_t) \cdot \nabla_\theta L_{train}(j; \theta_t)) \end{aligned} \tag{8}$$

where $L_{dev}(D_{dev}; \theta_t)$ denotes the validation loss calculated by Eq. 2, $L_{train}(j; \theta_t)$ represents the training loss for different kinds of augmented sentences, and $\cos(\cdot)$ denotes the cosine similarity of the two vectors.

Algorithm 1: Data reweighting method

        $\theta \leftarrow$ GradientUpdate($\theta$, $g_\theta$)
    end
end
```

---

[6] We use torch.multinomial function from the PyTorch package to sample one candidate at a time.

To capture the combined effect of augmented sentence and the original training sentence to the model's performance, we calculate $L_{train}(j;\theta_t)$ as follows:

$$L_{train}(j;\theta_t) = l(x, y, y; \theta) + l(x, \bar{y}_j, y; \theta_t) \quad (9)$$

Intuitively, this reward makes the data scorer upweight the training data that have a similar gradient direction as the development data (Wang et al., 2020).

According to the REINFORCE algorithm (Williams, 1992), the update rules for the data scorer become:

$$\psi_t \leftarrow \psi_{t-1} + R(j;\theta_t) \cdot \nabla_\psi \log P(j;\psi) \quad (10)$$

After obtaining ψ, we update θ by:

$$\theta_t \leftarrow \theta_{t-1} - \nabla_\theta \sum_{(x,d,y)} L_{EB}(\theta, \psi) \quad (11)$$

The training algorithm is shown in Algorithm 1. Note that we do not calculate the validation gradient in every training step, since it is too computationally expensive for the GEC task. Instead, we calculate the validation gradient for every f steps. Specifically, we first sample validation data and f batches of training data from the validation and the training set, respectively. Then, we obtain validation gradient g_{dev} based on the current model weights θ. For each batch of training data, we further calculate the reward for the data scorer using Eq. 8 and update the data scorer using the REINFORCE algorithm. After updating the data scorer, we apply the output from ψ to Eq. 7 and use this sampled loss to update the model θ with the same f batches of training data.

In this paper, we use a single-layer embedding network followed by a softmax layer as the data scorer networks ψ, and a transformer-based framework as our model θ. More details are given in Section 4.2.

4 Experiments

In this section, we report the effectiveness of our data manipulation approach.

4.1 Data and Model Configuration

Following (Kaneko et al., 2020; Stahlberg and Kumar, 2021), we build our GEC model based on the transformer-big architecture (Vaswani et al., 2017). To compare with state-of-the-art approaches in GEC, which pre-train with synthetic data, we follow (Stahlberg and Kumar, 2021) to generate C4_{200M} which contains 200 million synthetic parallel sentences. We use C4_{200M} to pre-train our GEC model, and use the combination of NUCLE (Dahlmeier et al., 2013), FCE (Yannakoudakis et al., 2011), and CLang-8 (Rothe et al., 2021) to train our GEC model, using an encoder-decoder shared vocabulary of 10K byte pair encoding tokens.[7]

We evaluate the effectiveness of our data manipulation method on two datasets: the CoNLL-2014 test set (Ng et al., 2014) and the BEA-2019 test set (Bryant et al., 2019). The W&I training set is used for fine-tuning. The development dataset is the CoNLL-2013 dataset (Ng et al., 2013) (W&I dev) when evaluating on the CoNLL-2014 test set (BEA-2019 test set).

4.2 Experimental Setup

We build our GEC model using the fairseq toolkit (Ott et al., 2019). All experiments are carried out on one NVIDIA A100 GPU. We use the MaxMatch scorer (Dahlmeier and Ng, 2012) to evaluate performance on the CoNLL-2014 test set and the ERRANT scorer (Bryant et al., 2019) to evaluate performance on the BEA-2019 test set. We report the average scores of three runs, and use a one-tailed sign test with bootstrap resampling to carry out statistical significance tests. We generate the augmented samples with a beam size of 5, and choose all five predictions for each training sentence as augmented samples for both CoNLL-2014 test set and BEA-2019 test set.

Baselines. We evaluate the performance of our method by comparing against five baseline methods. We apply our method and all the baseline methods to the checkpoint before fine-tuning.[8] **CE:** Fine-tuning the model using cross entropy loss. **SS:** Fine-tuning the model using the scheduled sampling method (Bengio et al., 2015). **RN-Word:** Fine-tuning the model by randomly injecting noise at word level (Zhang et al., 2019). **RN-Sent:** Fine-tuning the model by our modified version of sentence-level noise injection (Zhang et al., 2019) to better adapt to the GEC task. Specifically, we choose a noisy sentence with the smallest edit-

---

[7] More training details are given in Appendix A.7.

[8] The model checkpoint has been pre-trained first on C4_{200M} and then further trained on the combination of NUCLE, FCE, and CLang8.

RN-Sent	71.8	50.8	66.3	71.7	67.3	70.8
Ad-Bridge	71.4	50.5	66.0	71.0	67.6	70.4
DA	73.6	47.4	66.3*	72.6	66.0	71.1
+RE-DP	73.7	47.5	66.4	72.8	65.8	71.3
DM	74.0	48.1	**66.8***†	73.1	65.5	**71.5**

Table 3: Experimental results (in %) on the CoNLL-2014 and BEA-2019 test sets. DA represents fine-tuning the model using only the data augmentation approach mentioned in Section 3.2.1 where each γ_j in Eq. 5 is set to $1/n$. DM represents fine-tuning the model using our proposed data manipulation method (including both data augmentation and data reweighting). Statistically significant improvements ($p < 0.01$) over CE and DA are marked as * and † respectively. Since the BEA-2019 test set is a blind test set, we are unable to carry out statistical significance tests on it.

The performance of our data manipulation method is shown in Table 3.[9] All methods which aim to mitigate the exposure bias problem (i.e., SS, RN-Word, RN-Sent, Ad-Bridge, DA, and DM) outperform CE on both CoNLL-2014 and BEA-2019 test sets. This shows the importance of addressing the exposure bias problem in GEC.

Furthermore, our DM method outperforms all baseline methods on both test sets. Specifically, on the CoNLL-2014 test set, DM achieves an $F_{0.5}$ score of 66.8%, which is 0.5% higher than RN-Sent. On the BEA-2019 test set, DM achieves an $F_{0.5}$ score of 71.5%, which improves by 0.7% compared to RN-Sent. DM performs better since it is able to better approximate the decoder input distribution at inference time and adjust the amount of errors automatically based on the model θ.

We also compare DM with state-of-the-art seq2seq GEC systems in Table 2. Specifically, we show the performance of a single DM model and an ensemble of eight analogously trained DM models. Among all the transformer-big single systems, our method achieves the best $F_{0.5}$ scores on both CoNLL-2014 and BEA-2019 test sets, surpassing (Stahlberg and Kumar, 2021) by 0.2% and 1.1%, respectively. Although Rothe et al. (2021) achieve $F_{0.5}$ scores of 68.9% and 75.9% on the CoNLL-2014 and BEA-2019 test set respectively, they adapt the T5-xxl model with 11 billion parameters, whereas our transformer-big model only uses 220 million parameters (2% of the size of T5-xxl model). The corresponding $F_{0.5}$ scores of (Rothe et al., 2021) for their T5-base model with

CE	Surveillance technology will help to prevent ~~the~~ family to loss their member, especially the elderly and the children ~~which~~ who need to be pay more attention to.
RN-Sent	Surveillance technology will help to prevent ~~the~~ family to loss their ~~member~~ members, especially the elderly and the children ~~which~~ who need to be pay more attention to.
DM	Surveillance technology will help to prevent ~~the~~ family ~~to~~ from ~~loss~~ losing their ~~member~~ members, especially the elderly and the children ~~which~~ who need to be pay more attention to.

Table 4: Examples of the error accumulation problem, with the predictions taken from CE, RN-Sent, and DM models. Red texts show the correct edits.

220 million parameters are 65.1% and 69.4% for the CoNLL-2014 and BEA-2019 test set respectively.

Our DM ensemble achieves an $F_{0.5}$ score of 68.5% on the CoNLL-2014 test set and reaches an $F_{0.5}$ score of 74.8% on the BEA-2019 test set, which is close to the best performance achieved by (Stahlberg and Kumar, 2021). Note that Stahlberg and Kumar (2021) have used more than 540 million synthetic sentence pairs to pre-train their transformer big model, while we only use 200 million synthetic sentence pairs. Note that the current best $F_{0.5}$ scores achieved by an ensemble approach (Qorib et al., 2022) on the CoNLL-2014 and BEA-2019 test sets are 69.51% and 79.90% respectively. However, we have not included them in Table 2 as Qorib et al. (2022) combine sequence-to-sequence models with sequence-tagging models.

4.4 Effect of Reweighting

We analyze the sampling distribution for each augmented sentence in Figure 2, and show the error density (in terms of the number of edits required to correct to grammatical sentence) for each augmented sentence in Table 5. Specifically, the error density is measured by the average number of edits required to transform an augmented sentence into the target sentence.

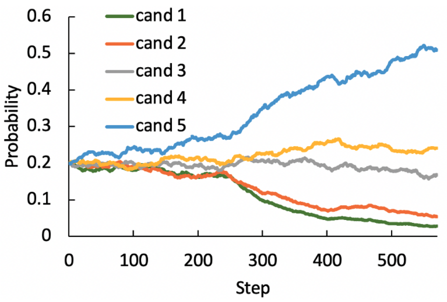

Figure 2: The sampling probability of augmented sentences during training.

As shown in Table 5 and Figure 2, the sampling probability for candidates with higher error density keeps increasing during training. This shows that as training progresses, candidates with higher error density play a more important role in training the model, which supports the hypotheses from (Zhang et al., 2019; Bengio et al., 2015).

Compared to RE-DP[10] which uses a static error density to train the model, our DM method achieves better performance by dynamically adjusting the error density according to the model θ. This further confirms that a varying error density is more

---

[10] We show the detailed settings of RE-DP in Appendix A.2.

Sentence	err%	e/s
WI train	67.1	3.45
BS-1	54.8	2.64
BS-2	90.7	2.18
BS-3	95.6	2.24
BS-4	96.9	2.30
BS-5	98.5	2.39
RN-Sent	-	7.82

Table 5: Statistics of the W&I training set and different augmented sentences. BS-x denotes the sentence which is the beam search candidate at position x. e/s is the number of edits per sentence calculated on erroneous sentences. err% is the percentage of erroneous sentences in the entire set. The err% for RN-Sent varies according to the different training epochs, with the details given in Appendix A.1.

effective in addressing the exposure bias problem.

4.5 Effect on Exposure Bias

In this section, we first present representative examples to illustrate the error accumulation problem in GEC. Then we conduct comprehensive studies to show the effectiveness of our method in addressing the exposure bias problem.

4.5.1 Effect on Error Accumulation

In Example 1 from Table 4, the CE model fails to correct “Many” to “Much” (since “surveillance” is an uncountable noun, “Much” should be used instead of “Many”). Failing to correct this error causes the CE model to also fail to correct “are” to “is”, which illustrates the error accumulation problem. Although RN-Sent and DM model also fail to correct “Many” to ‘Much”, they successfully correct “are” to “is”. This shows that both RN-Sent and DM are better able to address the error accumulation problem caused by exposure bias.

In the second example, the output generated by CE, RN-Sent, and DM all fail to correct “family” to “families”. For the output of CE, this further causes the model to fail to correct “to loss” to “from losing” and “member” to “members”. For RN-Sent, failing to correct “family” to “families” causes the model to fail to correct “to loss” to “from losing”, but it successfully corrects “member” to “members”. For the DM model, it is able to recover from failing to correct “family” to “families” and successfully corrects both “to loss” to “from losing” and “member” to “members”. Therefore, the error accumulation problem is better addressed by our DM approach.

Source	Her impressive physique ~~asa~~ as well as her ~~extraorinbary~~ extraordinary faculties as a rumba dancer will not be forgotten.
DA	Her impressive physique asa well as her extraorinbary faculties as rumba dancer will not be forgotten.
DM	Her impressive physique asa well as her ~~extraorinbary~~ extraordinary faculties as a rumba dancer will not be forgotten.

Table 6: Examples of the error accumulation problem, with the predictions taken from the DA and DM model. Red texts show the correct edits.

In Table 6, we show example output produced by the DA and DM model. The source sentence contains the following three errors: change “asa" to "as", change "extraorinbary" to "extraordinary", and insert "a" before “rumba”. Failure to correct the first error causes DA to fail to correct "extraorinbary" to "extraordinary" and to fail to insert "a" before “rumba”. However, DM successfully corrects the last two errors even when it fails to correct the first error.

4.5.2 Length and Edit Analysis

In this section, we further analyze the effect of our method on reducing the error accumulation problem, which tends to be more severe with longer sentences or sentences that require more edits. Therefore, we analyze the performance with respect to different lengths of the source sentence and different numbers of edits in the gold annotation in Figure 3.

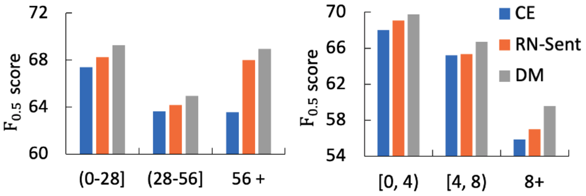

Figure 3: Performance comparison on the CoNLL-2014 test set with respect to different lengths of the source sentence, and different numbers of edits in the gold annotation. *Left:* source sentence length; *Right:* number of edits in the gold annotation.

Our method consistently improves over both CE and RN-Sent in all cases. The improvement is larger when the length of the source sentence is greater than 56, or the number of edits in the gold reference is greater than 8. This further shows that our method effectively addresses the error accumulation problem and that our improvement is mainly obtained by addressing the exposure bias problem.

4.5.3 Performance Analysis

This section further compares DM's capability of addressing the exposure bias problem against other baseline methods.

We consider the exposure bias problem to be better addressed when the predicted probability for the ground truth token is higher, under the condition that previously predicted tokens are generated by the model itself (i.e., not the ground truth). To evaluate how the exposure bias problem is addressed, we further design an experiment, which is an improved version of Zhang et al. (2019).

Specifically, we first generate noisy sentences by feeding the source sentences from the CoNLL-2014 test set to the model checkpoint before fine-tuning. We then generate the padded noisy sentences using the same procedure described in Section 3.2.1. Subsequently, we use different models (model A and model B in Table 7) to decode the same source sentence by using the padded noisy sentences as the decoder input. Let N be the number of ground truth tokens whose probabilities in the predicted distributions produced by model B are greater than those produced by model A. The win ratio is calculated by dividing N by the total number of tokens in the gold sentences. The results are shown in Table 7.

Win ratio A B	CE	DM
SS	69.99%	35.26%
RN-Word	73.54%	39.04%
RN-Sent	76.41%	37.64%
DM	89.41%	-

Table 7: The win ratio of model B over model A.

From Table 7, we observe that more than 89% of the target tokens' predicted probabilities of our DM model are greater than the CE model, indicating that our DM method greatly reduces the exposure bias problem. Moreover, compared to the DM model, all the other models are shown to have a win ratio of less than 40%. This shows that our method better addresses the exposure bias problem in GEC.

5 Conclusion

In this paper, we propose a novel data manipulation approach that includes both data augmentation and data reweighting to mitigate the exposure bias problem for seq2seq GEC models. Our core idea is to inject realistic augmented sentences into the decoder input and to automatically sample the augmented sentences. We show the effectiveness of our method which achieves significant improvements on both the CoNLL-2014 and BEA-2019 test sets.

6 Limitations

While our proposed approach is language-independent, we have only tested our approach on the English GEC task.

A Appendix

A.1 Error Density of RN-Sent

We adopt a similar approach to measure the error density in RN-Sent when training on the W&I training set. Specifically, our DM method only requires one epoch to converge, while RN-Sent requires seven epochs to converge. The average edits for each augmented sentence is 7.82, and the probability of creating augmented sentences is shown in Table 8.

epoch	p
1	0.01
2	0.02
3	0.03
4	0.05
5	0.07
6	0.11
7	0.17

Table 8: Probability of creating augmented sentences for each epoch.

The high edits per sentence generated by RN-Sent confirm that the augmented sentence generated through random noise injection has a bigger gap between actual decoder input and less efficiently addresses the exposure bias problem. Note that the original decay hyper-parameter is set to 5,800, with a maximum 40,000 updates[11]. Since our model is trained for 7 epochs (690 updates), we adjust the decay hyper-parameter to 100 accordingly.

A.2 RE-DP Setting

When using RE-DP to reweight each augmented sentence, we follow the setting in (Lichtarge et al., 2020). Specifically, we treat D_{aug} as the base dataset D^-, and D_{train} as the target dataset D^+. For a trained GEC model θ_{train}, it has been firstly pre-trained on C4$_{200\text{M}}$ and then trained on the combination of NUCLE, FCE, and CLang-8 dataset. We first obtain the model θ^- by fine-tuning θ_{train}

---

[11] `https://github.com/ictnlp/OR-NMT#results-and-settings-on-wmt14-english-german-translation-task`

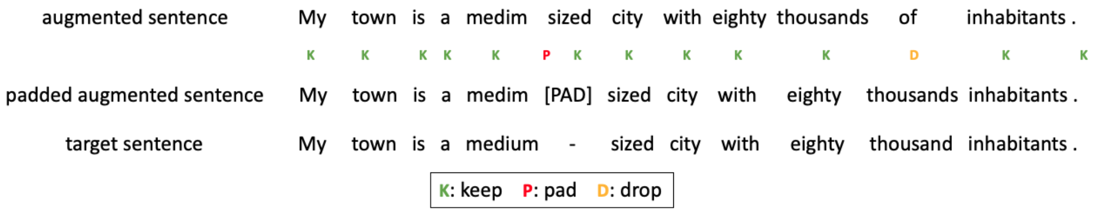

Figure 4: Illustration of the padding mechanism.

on D^- with the following loss function:

$$L_{RE-DP} = \sum_{j=1}^{n} l(x, \bar{y}_j, y; \theta)$$

The model θ^+ is obtained by further fine-tuning θ^- on D^+ using Eq. 2. Based on θ^- and θ^+, we calculate the perplexity of each augmented sentence. The weight $\alpha_{x,j}$ for each augmented sentence is calculated by the 'delta-perplexity-rank' method proposed in (Lichtarge et al., 2020). We then normalize $\alpha_{x,j}$, such that $\sum_{j=1}^{n} \alpha_{x,j} = 1$, and use Eq. 4 to fine-tune θ_{train}.

A.3 BLEU vs Edit Distance

We compare the performance of using BLEU to select sentence-level oracle with the performance of using edit distance to select sentence-level oracle in Table 9.

	CoNLL-2014	BEA-2019
BLEU	65.5	70.0
EDIT	66.3	70.8

Table 9: $F_{0.5}$ score on the CoNLL-2014 and BEA-2019 test sets. BLEU: represents selecting sentence-level oracle with the highest BLEU score. EDIT: represents selecting sentence-level oracle with the smallest edit distance.

A.4 Padding Mechanism

In Figure 4, we illustrate the padding mechanism introduced in Section 3.2.1.

A.5 Dataset Usage

The usage of different datasets for different setups is summarized in Table 10. Specifically, the W&I test set contains 4,477 sentences and the CoNLL-2014 test set contains 1,312 sentences.

A.6 Experimental Details

In this part, we will introduce the software packages we have used and the implementation details.

	CoNLL-2014	BEA-2019
Pre-training	$C4_{200M}$	
Training	NUCLE, FCE, CLang-8	
Fine-tuning	W&I train	W&I train
Validation	CoNLL-2013	W&I dev
Test	CoNLL-2014	W&I test

Table 10: Dataset usage for different setup cases.

Software configuration All models are implemented based on the Fairseq[12] and PyTorch packages. More specifically, we use Python 3.7 and PyTorch 1.7.1.

Implementation details When calculating the reward for the data scorer in Eq. 8, we use all the validation data to calculate the validation gradient.

To balance efficiency and performance, we set the update frequency f in line 3 of Algorithm 1 to 250 and 220 when fine-tuning for CoNLL-2014 and BEA-2019, respectively. The update frequency is selected from the range {250, 300} with a step size of 10 using grid search.

A.7 Hyper-Parameters and Computational Budget

We list the hyper-parameters for pre-training and training in Table 11. The hyper-parameters to fine-tune the model with the DM approach are shown in Table 12 . Specifically, pre-training takes 202 hours to converge, and training takes 0.6 hours to converge. Fine-tuning on the W&I training set takes 0.4 hours to converge.

A.8 Performance on CWEB-S/G and JFLEG Test Sets

We show the performance on the CWEB-S/G and JFLEG test sets in Table 13. When testing on the CWEB-S/G test set, we follow the setting in Cao et al. (2021) to extract the CWEB-train and CWEB-dev data. We use CWEB-train as the fine-tuning set

Abstract

Large-scale vision-language pre-trained (VLP) models are prone to hallucinate non-existent visual objects when generating text based on visual information. In this paper, we systematically study the object hallucination problem from three aspects. First, we examine recent state-of-the-art VLP models, showing that they still hallucinate frequently, and models achieving better scores on standard metrics (e.g., CIDEr) could be more unfaithful. Second, we investigate how different types of image encoding in VLP influence hallucination, including region-based, grid-based, and patch-based. Surprisingly, we find that patch-based features perform the best and smaller patch resolution yields a non-trivial reduction in object hallucination. Third, we decouple various VLP objectives and demonstrate that token-level image-text alignment and controlled generation are crucial to reducing hallucination. Based on that, we propose a simple yet effective VLP loss named ObjMLM to further mitigate object hallucination. Results show that it reduces object hallucination by up to 17.4% when tested on two benchmarks (COCO Caption for in-domain and NoCaps for out-of-domain evaluation).

1 Introduction

Thanks to the advancement of large pre-trained Language Models (LMs) and Vision-Language Pre-training (VLP) methods, models are able to achieve surprisingly good performance in vision-conditioned text generation, e.g., image captioning. However, large LMs are found to generate unfaithful or nonsensical texts given the source input (Ji et al., 2022), which is called hallucination. The hallucination problem is also inherited by VLP models (Alayrac et al., 2022), as they are still LMs that can understand visual information. VLP models often generate fluent and seem appropriate sentences if we only see the text, but wrong when taking the visual input into consideration. One major type of hallucination in VLP is known as object hallucination (Rohrbach et al., 2018), where models generate texts containing non-existent or inaccurate objects from the input images. Object hallucination in VLP models essentially limits their performance and raises safety concerns for industrial applications. For example, in biomedical image captioning (Pavlopoulos et al., 2019), object hallucination reduces the accuracy of diagnosis and may lead to severe consequences for the patient. Despite the limitations and risks caused by object hallucination, this problem has not been studied in contemporary VLP works yet.

To narrow down the aforementioned research gap, in this paper, we systematically investigate four fundamental research questions about object hallucination: 1) how much do modern VLP models hallucinate? 2) how do different forms of image encoding affect object hallucination? 3) what are the effects of common VLP objectives on object hallucination? and 4) how to mitigate object hallucination in VLP models?

For our first question, we examine recent state-of-the-art VLP models on the image captioning task. To evaluate object hallucination, we adopt and expand the CHAIR (Caption Hallucination Assessment with Image Relevance) metric proposed by Rohrbach et al. (2018). Results show that these models still hallucinate frequently with ∼10% of the generated sentences containing at least one hallucinated object. This problem becomes much severer when generating sentences given out-of-domain images. Furthermore, we discover that the widely used optimization method SCST (Rennie et al., 2017) could lead to more hallucination, even if it improves standard metrics like CIDEr (Vedantam et al., 2015).

For our second question, to investigate how different types of image encoding in VLP influence hallucination, we ablate three commonly

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2136–2148
May 2-6, 2023

used ones, including region-based, grid-based, and patch-based (Kim et al., 2021). Surprisingly, we find that patch-based features perform the best and smaller patch resolution yields a non-trivial reduction in object hallucination.

Thirdly, we analyze the effects of commonly adopted vision-language pre-training objectives on object hallucination. Specifically, we decouple and combine the image-text contrastive (ITC) loss, the image-text matching (ITM) loss with and without hard negatives, and the image-conditioned language modeling (ICLM) loss. Counter-intuitively, although ITC and ITM help to bring apart dissimilar images and texts, results show that they do not contribute much to alleviating object hallucination. The generative ICLM loss is the main influential factor of object hallucination and different pre-training datasets lead to distinctive model behaviors. More detailed analysis is described in Section 5.3.

Finally, we propose a simple yet effective new vision-language pre-training loss, namely object-masked language modeling (ObjMLM), to further mitigate object hallucination by enhancing the alignment and restriction between text tokens and visual objects during generation. Code and evaluation setups are released: `https://github.com/wenliangdai/VLP-Object-Hallucination`.

Overall, our contributions are three-fold:

- This is the first paper that systematically studies state-of-the-art VLP models on the object hallucination problem, proving that it is still far from resolved and previous methods that improve standard metrics may reflect in worse hallucination.
- We thoroughly investigate the influence of different VLP losses and image encoding methods on object hallucination. Our findings could be valuable for future work to build more responsible VLP systems.
- We present a new pre-training objective ObjMLM to mitigate object hallucination. Experimental results show that it reduces object hallucination by 17.4% without introducing extra training data.

2 Related Work

2.1 Hallucination in Deep Learning

Generally, the term *hallucination* denotes the appearance of undesirable output that is unfaithful to the conditional input (Maynez et al., 2020), even though it may appear to be fluent or reasonable. In the multimodal field, the hallucination phenomenon refers to the prediction of non-existent or incorrect objects (e.g., in object detection or image captioning) and is called *object hallucination* (Rohrbach et al., 2018; Biten et al., 2022). Despite the success of large pre-trained models, they still suffer the hallucination problem, which degrades the performance and largely hinders practical applications (Ji et al., 2022).

Many works have been proposed to mitigate hallucination in recent years. Nie et al. (2019) applied data refinement with self-training to improve the equivalence between the input and the paired text in the data-to-text generation task. Zhang et al. (2021b) and Zhang et al. (2020) proposes scene graph learning methods to ground the process of visual captioning to reduce hallucination. Ma et al. (2020) reconstruct generated sentences from localized image regions. Xiao and Wang (2021) proposed the uncertainty-aware beam search as an add-on technique to the original beam search, in both image captioning and data-to-text generation. To reduce hallucination in dialog systems, Shuster et al. (2021) introduced knowledge augmentation and Dziri et al. (2021) presented a post-processing method to refine generated outputs. Su et al. (2022) augment models with answer-related information predicted by a machine reading comprehension module to reduce hallucination in the generative question answering task.

2.2 Vision-Language Pre-training

The research on vision-language pre-training (VLP) has progressed vastly in recent years. Due to the demand for large-scale data, most VLP methods use self-supervised pre-training objectives to utilize image-text pairs crawled from the web. In the beginning, BERT (Devlin et al., 2019)-style VLP models (Lu et al., 2019; Tan and Bansal, 2019; Li et al., 2020b; Chen et al., 2020; Yu et al., 2021a; Shen et al., 2022) are trained to perform multimodal understanding tasks, using objectives like image-text matching and masked language modeling. Later, encoder-decoder architectures are introduced to additionally handle multimodal generation tasks with a causal language modeling loss (Li et al., 2021b; Yu et al., 2021b; Lin et al., 2021; Cho et al., 2021; Ding et al., 2021; Li et al., 2022; Wang et al., 2022a). Another line of research uses a dual-stream architecture (Radford et al., 2021; Jia et al., 2021; Zhai et al., 2022; Yao et al., 2022) with separate image and text encoders aligned together through an image-text contrastive loss. They improve the performance of various multimodal downstream tasks by a large step.

Alayrac et al. (2022) show that fatal object hallucination can happen naturally or be provoked by the adversarial prompting in modern VLP models. However, in previous works, how different VLP strategies influence the faithfulness of generated text given images has not been studied. Moreover, the effects of using different types of image encoding are also unclear, including region-based (Li et al., 2020c; Zhang et al., 2021a; Hu et al., 2022), grid-based (Wang et al., 2022b), and patch-based (Kim et al., 2021; Li et al., 2021a).

3 Evaluation Setup

In this section, we first introduce the CHAIR evaluation metric and our proposed improvements to it in Section 3.1. Then, in Section 3.2, we describe two datasets used for evaluation and explain how to calculate CHAIR scores under such settings.

3.1 Evaluation Metric

To automatically measure object hallucination, we adopt the CHAIR (Caption Hallucination Assessment with Image Relevance) metric proposed by Rohrbach et al. (2018). CHAIR calculates what proportion of generated object words are not in the image (i.e., hallucinated) according to the ground truth. CHAIR has two variants: CHAIR$_i$ (instance-level) and CHAIR$_s$ (sentence-level), which are formulated as follows:

$$\mathrm{CHAIR}_i = \frac{\#\,\{\text{hallucinated objects}\}}{\#\,\{\text{all objects in prediction}\}},$$

$$\mathrm{CHAIR}_s = \frac{\#\,\{\text{hallucinated sentences}\}}{\#\,\{\text{all sentences}\}}.$$

As formulated, CHAIR$_i$ represents the proportion of hallucinated objects over all golden objects in all data samples. It can be seen as the probability of a generated object to be a hallucination. On the other hand, CHAIR$_s$ measures the proportion of generated sentences that contain at least one hallucinated object. Therefore, to calculate CHAIR$_i$ and CHAIR$_s$, we need a pre-defined list of golden object categories to recognize objects in the text. We illustrate dataset-specific calculation details in Section 3.2.

3.2 Evaluation Datasets

To evaluate models' performance on object hallucination with CHAIR, we adopt two widely used benchmarks: Microsoft COCO Caption (Lin et al., 2014) and NoCaps (Agrawal et al., 2019). For all models, the COCO Caption training set is used for the finetuning of the image captioning task, and COCO Caption test set and NoCaps valid set are used for in-domain and out-of-domain evaluation, respectively. In the following, we introduce statistics of each dataset and how to calculate CHAIR on them.

3.2.1 COCO Caption

The COCO Caption (Lin et al., 2014) is a large-scale and widely used dataset for the training and evaluation of the image captioning task. We use the Karpathy split (Karpathy and Fei-Fei, 2017), in which 82K, 5K, and 5K images are in the train, validation, and test sets, respectively. Each image is annotated with at least five ground truth captions.

To calculate CHAIR scores on this dataset, we follow the setting proposed in Rohrbach et al. (2018). In practice, we first tokenize each sentence and then singularize each word. Then, we use a list of synonyms from Lu et al. (2018) to map fine-grained objects to the pre-defined 80 coarse-grained MSCOCO object categories (e.g., mapping "puppy", "chihuahua", "poodle" to the "dog" category). The purpose of doing this mapping is to ensure that we do not detect hallucinated objects by mistake. For example, when the ground-truth caption only has the "puppy" object, the CHAIR metrics will undesirably consider the "dog" object generated by models as a hallucinated object if we do not perform the mapping.

3.2.2 NoCaps

The NoCaps (Agrawal et al., 2019) dataset aims to evaluate models trained on the training set of COCO Caption to examine how well they generalize to a much larger variety of visual concepts, i.e., unseen object categories. There are 4,500 images in the validation set and 10,600 images in the test set. Images are taken from the Open Images V4 (Kuznetsova et al., 2020) dataset, which contains 600 object classes. Due to the unavailability of ground truth captions of the test set, we use the valid set of NoCaps.

To calculate CHAIR scores on NoCaps, we setup a similar setting as used in COCO Caption. Specifically, we map the fine-grained classes defined in

Model	CIDEr Optim (SCST)	# Pretrain Image-Text Pairs	COCO Caption Karpathy Test						NoCaps Validation Out-of-domain

Table 1: Image captioning results of recent state-of-the-art VLP models (Li et al., 2020c; Zhang et al., 2021a; Li et al., 2022; Wang et al., 2022a) on the COCO Caption Karpathy test set and NoCaps validation set. Here, B@4, C, M, S, and CH denote BLEU-4, CIDEr, METEOR, SPICE, and CHAIR, respectively. CIDEr Optim indicates whether the SCST CIDEr optimization is used or not. All results are generated by using their officially provided checkpoints and hyper-parameters, * means the model is finetuned by us as the provided one is broken. † denotes the model also uses unimodal data besides image-text pairs.

NoCaps to coarse-grained categories based on the hierarchical object relationship[1] to improve the effectiveness of CHAIR metrics. We only add two types of object categories to our final object list: 1) super-categories that have sub-categories, and 2) object categories that have neither super-category nor sub-categories. Eventually, we construct a list of 139 coarse-grained object categories from the 600 classes.

4 Object Hallucination in VLP Models

Benefitting from the vast advancement of various VLP methods, the performance of image captioning has been improved a lot by following a pretrain-then-finetune schema. Generally, the performance is measured by metrics like CIDEr (Vedantam et al., 2015), SPICE (Anderson et al., 2016), METEOR (Banerjee and Lavie, 2005), and BLEU (Papineni et al., 2002), which consider the semantic and syntactic similarity or n-gram-based fluency between the model generated and ground truth captions. However, the faithfulness of captions generated by VLP models is neglected.

In this section, we provide a thorough analysis of recent VLP models to investigate how much they hallucinate when generating text conditioned on visual information. The results are shown in Table 1. Models are finetuned on the COCO Caption training set and evaluated on both the COCO Caption test set and the NoCaps valid set.

Ground Truth: "A green garbage can has an orange face on it."

VinVL$_{Base}$ w/o SCST: "A green waste container with a face painted on it."

VinVL$_{Base}$ w/ SCST: "A green waste container with a picture of a **dog** on it."

Ground Truth: "A dresser with all of the drawers closed and something on top."

OFA$_{Large}$ w/o SCST: "A dresser with a bunch of drawers on it."

OFA$_{Large}$ w/ SCST: "A chest of drawers with a **mirror** on top of it."

Figure 1: Comparison of image captioning examples generated by VinVL$_{Base}$ and OFA$_{Large}$ with and without the SCST CIDEr optimization. Red color denotes the occurrence of object hallucination.

Overall, we observe two noteworthy insights. Firstly, similar to the findings in Rohrbach et al. (2018), for all CHAIR scores, they are not proportional to standard evaluation metrics. Although standard metrics (e.g., the cosine similarity in CIDEr) could potentially penalize the wrong object prediction, they do not directly reflect faithfulness. Captions can still have good scores from standard metrics as long as they contain sufficient accurate objects to fulfill coverage, even if hallucinated objects exist. For example, VinVL$_{Large}$ achieves higher CIDEr and BLEU-4 scores than VinVL$_{Base}$, but its CHAIR scores are also higher.

---

[1] `https://github.com/nocaps-org/image-feature-extractors/blob/master/data/oi_categories.json`

Therefore, it is important to have a supplementary metric like CHAIR to reflect faithfulness besides other metrics.

Secondly, the Self-Critical Sequence Training (SCST) (Rennie et al., 2017) for the CIDEr optimization method harms the faithfulness of generated captions. SCST is a reinforcement learning algorithm that has been widely adopted as the second-stage finetuning after the standard cross-entropy optimization for image captioning (Anderson et al., 2018; Zhou et al., 2020; Li et al., 2020c; Zhang et al., 2021a; Hu et al., 2022; Wang et al., 2022a). It calculates the reward based on the CIDEr score by sampling captions during training without the need of another baseline. Although SCST can significantly boost performance on previous standard metrics, it encourages models to generate more hallucinated objects in the captions. For example, applying SCST improves the CIDEr score by 11.1 and BLEU-4 score by 2.7 for VinVL$_{Base}$, yet it also increases 0.9 CHAIR$_s$ score on the COCO Caption dataset.

While Rennie et al. (2017) also observed this phenomenon by testing small scale models, we show that SCST hurts VLP models less. When the model is pre-trained very well, the side effect of SCST is alleviated (e.g., the OFA large model). Moreover, we demonstrate that this problem becomes more serious on out-of-domain images. For the VinVL$_{Base}$ model, there are 10.9% more generated captions containing at least one hallucinated object after using SCST. We speculate that the CIDEr-based optimization encourages models to generate more words or phrases that have higher cosine similarities to the ground truth captions in the vision-language representation space, which can be plausible but not faithful.

We show a case study in Figure 1. After finetuned by SCST, models will take a bigger risk to generate more detailed yet incorrect information (e.g., in the second example in Figure 1, the sentence with hallucination generates the detailed information "mirror", which cannot be found in the image). This will further amplify the object hallucination problem on out-of-domain images, as models may have lower confidence in unfamiliar visual concepts.

5 Probing Image Encoding Methods and VLP Objectives

In this section, we systematically study two determinants in VLP that are intuitively influential to the severity of the object hallucination problem. Firstly, we study how different types of image encoding affect object hallucination, as they are the key components of models to interpret visual information. Specifically, we ablate three encoding approaches including region-based, grid-based, and patch-based. Secondly, we analyze how different VLP objectives influence object hallucination. We ablate three commonly used ones: image-text contrastive (ITC), image-text matching (ITM), and image-conditioned language modeling (ICLM). Implementation details are described in Appendix A.

5.1 Model Architecture

CLIP. CLIP (Radford et al., 2021) is a dual-stream VLP model that consists of an image encoder and a text encoder. It is pre-trained on 400 million image-text pairs data using a cross-modal contrastive loss. Specifically, CLIP explores the image encoder with different sizes of two architectures[2], including the ResNet (He et al., 2016) and the Vision Transformer (ViT) (Dosovitskiy et al., 2021). The resulting image and text encoders are aligned in the same multimodal feature space.

BERT. BERT (Devlin et al., 2019) is a Transformer (Vaswani et al., 2017) model pre-trained on a large corpus by the masked language modeling (MLM) and sentence permutation losses. It is shown to have excellent performance on various downstream tasks after finetuning. Moreover, BERT can also handle generation tasks when the self-attention layers are restricted to the left-to-right direction to generate text auto-regressively. In this paper, we refer to this variant as BertLM.

We design a flexible architecture that can plug in various visual encoders and fit modern VLP objectives without introducing extra influential factors. As shown in Figure 4, the model consists of two parts, a visual encoder to encode images and a text decoder to generate sentences conditioned on the image representations. We use two separate modules rather than a unified single-stream model, as it is convenient to alter the visual encoder while keeping the text decoder the same. Specifically,

---

ViT-L/14	290M	120.7	6.4	11.6	59.8	24.2	33.5

Table 2: Results of different types of visual encoders with the same BertLM text decoder on the COCO Karpathy test set and NoCaps validation set (out-of-domain).

for region-based image features, we explore the Faster R-CNN object detector (Ren et al., 2015) with two different backbones: the ResNet-101 used in BUTD (Anderson et al., 2018) and the ResNeXt-152 (Xie et al., 2017) used by Zhang et al. (2021a). They are both pre-trained on COCO (Lin et al., 2014) and Visual Genome (Krishna et al., 2016) datasets for object detection. For the grid-based and patch-based image features, we use the CLIP ResNet variants and CLIP ViT variants, respectively. The reason for using CLIP is that all its variants are pre-trained on the same data and there is a wide range of different model sizes. For all visual encoders, we use the same BertLM as the text decoder.

5.2 Effects of Different Image Features

Recognizing visual objects correctly is crucial for avoiding object hallucination. In Table 2, we compare the performance of different visual encoders with the same text decoder on COCO (in-domain) and NoCaps (out-of-domain) datasets.

Overall, patch-based visual encoders attain the best performance in terms of avoiding object hallucination. Models with grid features hallucinate more frequently when achieving comparable CIDEr scores to the other models. For example, on COCO, RN50×16 has a similar CIDEr score to ViT-B/16 but higher CHAIR_s, which is also observed between RN50×64 and ResNeXt-152. We conjecture that the inductive biases (Cohen and Shashua, 2017) of the Convolutional Neural Network (CNN), such as locality and translation invariance, weaken the connection of different characteristics of a single object and thus lead to more hallucination. Oppositely, regional or patch-level features are obtained by directly dividing images into different parts and further associating them through positional embeddings. In addition, we see that a smaller patch resolution helps to reduce object hallucination without enlarging the model size.

VLP Objectives	COCO Karpathy Test			NoCaps Val Out-of-domain		
	C↑	CH_i↓	CH_s↓	C↑	CH_i↓	CH_s↓

(c) + (i)	**125.1**	**4.9**	**8.8**	**94.5**	**7.9**	**12.5**

Table 3: Comparison of the effects of different VLP objectives and their combination on object hallucination.

For region-based visual encoders, although they achieve modest results on COCO with relatively small model sizes, their performance of object hallucination on out-of-domain images drops dramatically. One important reason is that the output of such encoders only contains representations of detected visual objects rather than the whole image, which may amplify detection errors as there is much less context. Moreover, as the object detector is pre-trained separately from the whole model and its parameters are fixed during finetuning, this gap could also aggravate object hallucination on unseen images.

5.3 Effects of Different VLP Objectives

Based on the best performing ViT-L/14 baseline, we explore three commonly used vision-language pre-training objectives and their variants that could potentially affect object hallucination.

5.3.1 Pre-training Datasets

We explore two pre-training datasets with image-text pairs: 1) the VG Caption from the Visual Genome (Krishna et al., 2016) dataset, which contains 10K images and each image has multiple corresponding descriptions; and 2) a more large-scale dataset CC3M (Sharma et al., 2018) that contains three millions of image-text pairs.

5.3.2 Image-Text Contrastive (ITC) Loss

The cross-modal contrastive loss is shown to be fairly effective in representation learning (Tian et al., 2020; Sigurdsson et al., 2020) and VLP (Radford et al., 2021; Li et al., 2021a, 2022). It aligns the visual and textual representations into the same multimodal feature space by shortening the distance between an image and a text if they are paired, or enlarging if they are not.

Counter-intuitively, as shown in Table 3 (b), ITC has negligible influence on the faithfulness of generated captions. We speculate that it only enhances the model's understanding of global-level representations rather than token-level alignment between images and texts. To verify, we further test the ITC with a more fine-grained token-level late interaction (ITC_{Late}) proposed by Yao et al. (2022). As shown in Table 3 (c), ITC_{Late} is more effective than the vanilla ITC and slightly reduces object hallucination. We think this benefits from the word-patch alignment ability enabled by ITC_{Late}.

5.3.3 Image-Text Matching (ITM) Loss

ITM is a widely used objective in VLP (Li et al., 2020a; Chen et al., 2020; Zhou et al., 2021). It is a binary classification task that aims to make the model learn whether an image and a sentence are paired or not. Based on that, ITM with hard negatives (ITM_{Hard}) is introduced to increase the difficulty of the task, which is shown to be very effective on representation learning (Kalantidis et al., 2020; Robinson et al., 2021; Li et al., 2021b). We follow the ITM loss proposed by Li et al. (2022), in which an in-batch negative example is sampled either uniformly (normal negative) or from the similarity distribution of image-text pairs computed by ITC (hard negative).

The results are exhibited in Table 3 (d) (e). Both ITM and ITM_{Hard} are not highly correlated with the object hallucination problem. They only slightly reduce hallucination in generated texts on out-of-domain images. Although the ITM_{Hard} can be seen as an analogy to the object hallucination problem (plausible but not correct) in a global and discriminative way, it has a negligible effect on reducing hallucination for downstream generative tasks.

5.3.4 Image-Conditioned Language Modeling

Various image-conditioned language modeling losses have been proposed in the VLP research, in the form of masked language modeling (MLM) (Sun et al., 2019; Tan and Bansal, 2019; Su et al., 2020), text infilling (Dai et al., 2022; Wang et al., 2022a), prefix LM (Wang et al., 2022b), and causal LM (Hu et al., 2022). This is one of the most crucial pre-training losses to activate the cross-modal text generation ability for the VLP model.

COCO Caption

"Several boats docked at a floating dock at a marina.",
"Several boats sitting on a docking station on the water.",
"A bunch of speedboats near a harbor with flags from all over the world.", etc.

Visual Genome Caption

"A dock in a city.", "Long silver dock in water."
"Very blue, calm water in marina.", "The water is calm."
"A dock is floating on the water.", "Row of docked boats.", etc.

Figure 2: Comparison of ground truth captions in COCO and Visual Genome datasets for the same image.

Ground Truth: "A soccer ball is next to a wall.", "A soccer ball that is placed on the ground.", etc.

ViT-L/14 w/o VG: "A close up of a soccer ball on a **table**."

ViT-L/14 w/ VG: "A close up of a soccer ball on the ground."

Ground Truth: "A large black printer seems to have a piece of paper in it sideways.", "A large printer with paper coming out of it", etc.

ViT-L/14 w/o VG: "A pair of **scissors** sitting on top of a piece of paper."

ViT-L/14 w/ VG: "A large black machine."

Figure 3: Comparison of generated captions with or without the image-conditioned language modeling pre-training on the VG dataset before finetuning.

We first examine the causal LM loss, which is exactly the same loss as the image captioning loss, but used in the pre-training on a much larger scale. Surprisingly, as shown in Table 3 (f), although pre-training on the VG Caption does not improve previous standard metrics like CIDEr, it helps to reduce object hallucination by a large margin when compared to (a).

There are two reasons behind this performance lift. Firstly, as described in Figure 2, for each image, VG contains more captions than COCO.

Each caption in VG is much shorter and only describes one specific aspect of the image, unlike the global descriptions in COCO. Therefore, pre-training on VG and then finetuning on COCO is a fine-to-coarse process. It enables models to first accurately describe different parts of an image and connect these clues together at a higher viewing point. Secondly, due to the nature of the short length of VG captions, the model becomes slightly more cautious. On average, after adding VG data in the pre-training, there are 0.08 and 0.24 fewer objects generated in each caption on COCO and NoCaps, respectively. This observation aligns with the sentence simplification method proposed by Biten et al. (2022), which simplifies sentences to augment data and further mitigate object hallucination. Figure 3 illustrates VG's effects on generated samples. The model is more faithful but more likely to lack some details when it is not confident.

For CC3M, we observe a leap in all metrics. It improves the general image translation ability of the model, which can be seen as large-scale data augmentation. This indicates that seeing a sufficient amount of data and co-occurrence of various objects during pre-training help to mitigate object hallucination to some extent. However, data augmentation may not be the key to drastically tackle object hallucination. As discussed in Section 4, object hallucination still happens frequently even if the model is pre-trained on large-scale data. Therefore, we believe that enhancing the controllability of vision-conditioned text generation would be a promising future direction. More case studies are exhibited in Appendix B.

6 Object Masked Language Modeling

Based on the findings in Section 5, we propose a simple yet effective pre-training objective to mitigate object hallucination by improving object-level image-text alignment. It is named Object Masked Language Modeling (ObjMLM). As shown in Figure 4, ObjMLM can be seen as a variant of the MLM loss by masking all the objects in the text that appear in the image. For each sentence, we mask the object words and phrases as defined in the object category lists of both COCO and NoCaps by performing exact matching. Similar to the whole word masking (Cui et al., 2021), we conduct whole object masking so that there will be only one `[MASK]` token to replace each object.

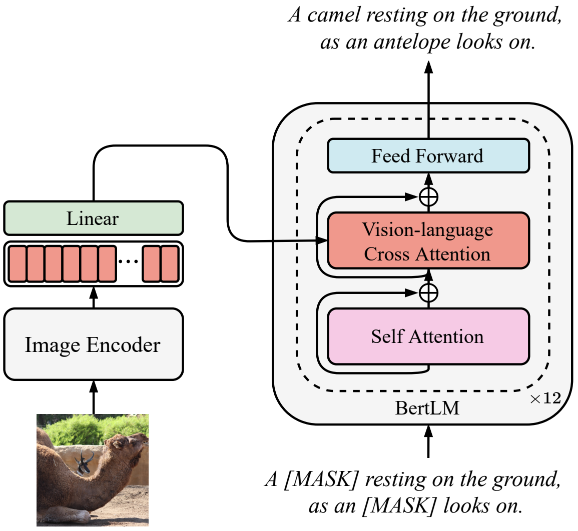

Figure 4: An overview of the model architecture and the training of our proposed ObjMLM. We use the same architecture as described in Section 5 to show the effectiveness of ObjMLM. Here, the image encoder can be one of the region-based, grid-based, or patch-based variants as described in Section 5.2. For ObjMLM, we use the ViT-L/14.

Compare the results shown in lines (h) and (i) of Table 3, by plugging ObjMLM into an existing VLP setting, the CHAIR$_s$ score is reduced by 17.4%. This is a non-trivial improvement without introducing more pre-training data. To further validate ObjMLM's effectiveness, we replace it by the standard MLM loss with a 15% masking rate. However, it only reduces CHAIR$_s$ by 1.7%, which is not significant. We conjecture that ObjMLM adds a constraint that indirectly controls the model to only generate objects that are visible in the input image. Additionally, ObjMLM enhances the model's recognition ability when describing the spatial relationship between objects, which is a common scenario that causes hallucinations frequently.

7 Conclusion

This paper systematically studies the objection hallucination phenomenon in VLP models, which is a severe problem but neglected in contemporary VLP works. We find that recent large VLP models still hallucinate frequently. Moreover, the widely used SCST method harms the faithfulness of generated sentences in image captioning, even if it improves previous standard metrics. Furthermore, we discover that image encoding matters and the patch-based input with smaller resolution helps mitigate object hallucination. Finally, we ablate commonly used VLP losses and show that token-level image-text alignment and controllability of the generation are crucial. We further propose a new loss named ObjMLM, which reduces object hallucination by 17.4% for an existing VLP setting. We believe our findings are beneficial for future work to build more responsible VLP models.

Limitations

We understand that the hallucination problem is a big research topic and it is not just limited to object hallucination. In this paper, we focus on the investigation and mitigation of object hallucination, leaving other types of hallucination in VLP for future work. Another limitation is that for the discussion of recent VLP models in Section 4, we only study those whose pre-trained checkpoints are publicly available. For the non-released ones, we cannot pre-train them by ourselves due to the lack of large-scale GPU power and private pre-training datasets.

A Implementation Details

Our experiments are implemented in the PyTorch framework (Paszke et al., 2019). For both pre-training and finetuning, we use 8 Nvidia V100 GPUs. As mentioned in Section 5.1, we use the official CLIP checkpoints provided on GitHub. For the text decoder BertLM, we initialize model weights from the bert-base-uncased checkpoint with 110M parameters. For the finetuning on COCO Caption, we use a batch size of 512 and train the models with the AdamW optimizer (Loshchilov and Hutter, 2019) for 10 epochs with a learning rate of 5×10^{-5} and a weight decay of 1×10^{-2}. The learning rate is decayed linearly after each epoch with a rate of 0.85. For the pre-training of text generation losses (LM and ObjMLM), we keep the same hyper-parameters with a learning rate warmup within the first epoch. For ITC and ITM losses, we increase the batch size to 1024 as they tend to have a better performance with more negative samples.

Abstract

Memes can sway people's opinions over social media as they combine visual and textual information in an easy-to-consume manner. Since memes instantly turn viral, it becomes crucial to infer their intent and potentially associated harmfulness to take timely measures as needed. A common problem associated with meme comprehension lies in detecting the entities referenced and characterizing the role of each of these entities. Here, we aim to understand whether the meme glorifies, vilifies, or victimizes each entity it refers to. To this end, we address the task of *role identification of entities in harmful memes*, i.e., detecting who is the 'hero', the 'villain', and the 'victim' in the meme, if any. We utilize `HVVMemes` – a memes dataset on US Politics and Covid-19 memes, released recently as part of the CONSTRAINT@ACL-2022 shared-task. It contains memes, entities referenced, and their associated roles: hero, villain, victim, and other. We further design `VECTOR` (Visual-semantic role dEteCToR), a robust multi-modal framework for the task, which integrates entity-based contextual information in the multi-modal representation and compare it to several standard unimodal (text-only or image-only) or multi-modal (image+text) models. Our experimental results show that our proposed model achieves an improvement of 4% over the best baseline and 1% over the best competing stand-alone submission from the shared-task. Besides divulging an extensive experimental setup with comparative analyses, we finally highlight the challenges encountered in addressing the complex task of semantic role labeling within memes.

1 Introduction

Due to their pervasive nature, online social media platforms have emerged as a conducive medium for information exchange. Unfortunately, their democratic nature has fostered unabated dissemination of hate speech (MacAvaney et al., 2019), misinformation (Wu et al., 2019), fake news (Aldwairi and Alwahedi, 2018), propaganda (Da San Martino et al., 2020), and other harmful content. Such information manifests itself in various ways, and more recently, in the form of *memes*. Though typically intended to burlesque and lampoon world events, political outlook, or daily routine, an ostensibly innocuous meme can readily become a multi-modal cause of distress with a dexterous blend of images and texts. Due to their viral nature and ability to circumvent censorship (Mina, 2014), social media instigators and hatemongers are increasingly using memes as a powerful medium for disseminating spiteful content. Therefore, investigating the dark side of memes has risen as a pertinent research problem both in industry and academia (Sharma et al., 2020a; Pramanick et al., 2021a).

Figure 1: Examples of `heroes`, `villains` and `victims`, as portrayed within memes.

Motivation. While there have been many studies that have analyzed memes through the lens of emotions (Sharma et al., 2020a), sarcasm (Kumar and Garg, 2019), hate speech (Zhou et al., 2021; Kiela et al., 2020), misinformation (Zidani and Moran, 2021), offensiveness (Suryawanshi et al., 2020),

May 2-6, 2023

and harmfulness (Pramanick et al., 2021a,b), there has been much less focus on analyzing semantic roles present within memes. Understanding these roles is critical for comprehending memes and narrative framing of various social entities. Caricaturing these entities with nefarious motives can lead to misinformation propagation, social calumny, and hatred towards minority communities. In addition to the dark portrayals, memes sometimes depict the sorrowful state of certain entities, illustrate their heroism, etc. Consider the memes in Fig. 1. The meme in Fig. 1 (a) portrays Jill Stein and the Green Party as *heroes* for their feminist views. Fig. 1 (b) draws a comparison between Adolf Hitler and Donald Trump, thus portraying the latter as a *villain* for his anti-immigrant views. Fig. 1 (c), on the other hand, depicts the plight of Ola and Uber drivers, who are out of work and *victims* of the lock-downs due to the COVID-19 pandemic. Thus, through depictions of heroism, villainy, and victimization, memes act as an alluring means to spread entity-relevant information and opinions.

Challenges. Despite growing interest in analyzing memes, identifying the underlying connotations for the entities framed therein remains a challenging task (Sharma et al., 2022b). Memes are obscure due to their highly cryptic semantics, and satirical content (Sabat et al., 2019). Moreover, categorizing the entities as a hero, a villain, or a victim requires real-world, contextual, temporal, spatial, and commonsense knowledge, which makes the task highly complex and subjective even for humans. Therefore, off-the-shelf multi-modal models that stand out well on conventional visual-linguistic tasks often flounder for memes as they are presumably inept to comprehend and capture the veiled information and multi-modal nuances present in a meme (Kiela et al., 2020).

Our Contributions. In this work, we propose a powerful approach to tackle the novel task of identifying the roles (the hero, the villain, and the victim) of the entities present in memes.

We model the problem as a role identification task and report the results for several unimodal and multi-modal baselines to benchmark the task (and the dataset) and assess its feasibility. We then proffer `VECTOR` a vision and commonsense enriched version of DeBERTa (He et al., 2020) for the task at hand. As meme text often contains satirical content, which tends to contradict the meme image, it is necessary to consider mutual information from both modalities. Also, meme content is often stated in a non-obvious way, necessitating commonsense and world knowledge. Thus, our `VECTOR` attempts to infuse the relevant visual and commonsense knowledge with linguistic representations. Utilizing ConceptNet (Speer et al., 2017), we generate an entity-relevant knowledge graph to represent commonsense knowledge relevant to the meme. Moreover, we employ a distinct multi-modal information fusion strategy based on Optimal Transport. We appropriate Optimal Transport-based Kernel Embedding (OTKE) (Mialon et al., 2021) for cross-modal correspondence. This technique by Mialon et al. (2021) marries the concepts of optimal transport theory with kernel techniques to provide robust and adaptable cross-modal adaptation. Our qualitative analysis underscores the importance of vision and commonsense knowledge integration, as `VECTOR` outperforms several competitive baselines.

Our contributions are summarized as follows:[1,2]

1. **Bench-marking `HVVMemes`:** We bench-mark the `HVVMemes` via ten baselines with various unimodal and multi-modal systems.
2. **Multi-modal system for identifying the hero, the villain, and the victim:** We develop `VECTOR` (Visual-semantic role dEteCToR), a knowledge enriched multi-modal system that integrates entity-based knowledge in the multi-modal representations.
3. **Extensive evaluation:** We report sizeable gains as part of our examination of `VECTOR` against state-of-the-art models and shared-task submissions.
4. **Detailed Analysis:** Along with the ablation investigations, we provide detailed qualitative and quantitative analysis.

2 Related Work

Online Harmfulness. Due to the exponential rise of harmful content on various social media platforms, the research community has piqued its curiosity toward related studies. Some of them are based on online trolling (Ortiz, 2020; Cook et al., 2018), cyber-bullying (Kim et al., 2021; Kowalski et al., 2014), cyber-stalking (Abu-Ulbeh et al., 2021), and hate speech (MacAvaney et al., 2019; Zhang and Luo, 2018). Other studies character-

ize the correlation of racial and ethnic discrimination in the online and offline world (Relia et al., 2019). Cheng et al. (2017) examined the psycho-sociological outlook of online users toward online trolling behavior analysis. Few noteworthy investigations include characterizing homophily for self-harm due to eating disorders (Chancellor et al., 2016; Wang et al., 2017) using logistic regression and snow-ball sampling, and suicide-ideation (Burnap et al., 2015; Cao et al., 2019) via linguistic, structural, affective and socio-psychological features. For a significant period, most of these studies have been dominated by text-oriented investigation while obscuring knowledge about other modalities.

Characterising Online Targets. Another research direction focuses on aspects such as relevance, stance, hate speech, sarcasm, and dialogue acts within hateful exchanges on Twitter in conventional and multi-task settings (Zainuddin et al., 2017; Gautam et al., 2020; Ousidhoum et al., 2019). Zainuddin et al. (2018) addressed it by proposing neural networks with word embeddings. In contrast, the aspect-based sentiment was studied while addressing data sparsity, classification accuracy, and sarcastic content identification (Zainuddin et al., 2019). Shvets et al. (2021) demonstrated the efficacy of a generic concept extraction module for detecting the targets of hate speech. A few other studies on characterizing targets in harmful communication (Sap et al., 2020; Mathew et al., 2021) addressed social bias and hate speech explainability for targeted protected categories. Ma et al. (2018) used a hierarchical stack bidirectional gated recurrent units to detect targets and associated sentiments. A similar objective was studied in (Mitchell et al., 2013) but was formulated as sequence tagging in low-resource settings. Silva et al. (2016) used sentence structure to capture hate speech targets on social media to address detection and prevention. Most of these studies either focused on one primary designated target or emphasized detecting the association of sentiment while ignoring the affective spectrum. As observed in the literature (Shvets et al., 2021), such approaches may not generalize well across domains.

Studies on Memes. A significant influx of memes from online fringe communities, such as Gab, Reddit, and 4chan, to mainstream platforms, such as Twitter and Instagram, resulted in a massive epidemic of intended harm (Zannettou et al., 2018). Conventional visual features alongwith multimodal associativity was explored towards detecting memes in (Sharma. and Pulabaigari., 2020; Sharma et al., 2020b). Several datasets capturing offensiveness (Suryawanshi et al., 2020), hatefulness (Kiela et al., 2020; Gomez et al., 2020), and harmfulness (Pramanick et al., 2021b), have been curated. Detecting memetic harmfulness and targeted categories are discussed in (Pramanick et al., 2021b). Commonsense knowledge (Shang et al., 2021), web entities, racial cues (Pramanick et al., 2021b; Karkkainen and Joo, 2021), and other external cues have also been explored for detecting offense, harm, and hate speech in memes. Participatory events like the Facebook Hateful Meme Challenge (Kiela et al., 2020) have laid a strong foundation for community-level initiatives for detecting hate speech in memes. As part of this challenge, several interesting approaches utilising meta information, attentive interactions, and adaptive loss are attempted in the multimodal setting (Das et al., 2020; Sandulescu, 2020; Zhou et al., 2020; Lippe et al., 2020). Most of these efforts either address the detection tasks at various levels for harmfulness; see a recent survey (Sharma et al., 2022a) or design *ensemble* techniques lacking cost-optimality. However, as per our knowledge, no stand-alone approach reliably addresses the fine-grained task of understanding the roles of specific entities referred to within memes. We intend to address these aspects by seeking a robust and generalizable multimodal framework.

Domain	**# Memes**	**# Entity References**				
		Hero	Villain	Victim	Other	Total
COVID-19	3381	200	747	407	3065	4419
US Politics	3552	288	1641	544	3242	5715

Table 1: Summary of statistics for # memes and entities referenced within them in `HVVMemes` (Sharma et al., 2022b). Original train/val/test split ratio of 80:10:10 (%) for memes was preserved.

3 Dataset

We employ `HVVMemes`, a dataset released as part of CONSTRAINT@ACL-2022. It contains English memes on two topics: $3,552$ memes about COVID-19 (C) and $3,381$ memes related to US Politics (P). The dataset primarily captures connotative roles: hero, villain, and victim, for different entities referenced within memes. Table 1 shows a summary

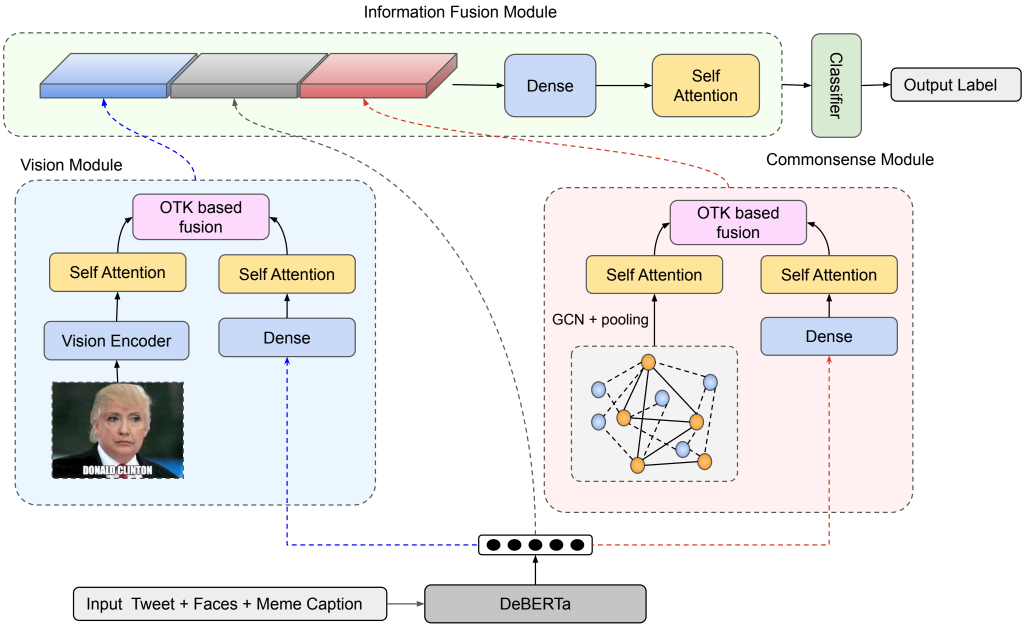

Figure 2: Schematic diagram of `VECTOR`. The *vision module* (left) consists of a ViT based image encoder and *commonsense module* (right) leverages GCN-based commonsense knowledge graph embedding. *Information fusion* module (top) fuses corresponding outputs toward final classification. OTK: Optimal Transport-based Kernel.

of `HVVMemes`.[3] In general, most of the entities referenced in the memes do not have any connotation associated (C: $3,065$, P: $3,242$) and are categorised as *other*. Amongst the key categories under consideration, *villain* has the most candidate references (C: 747, P: $1,641$), followed by *victim* (C: 407, P: 544), and finally *hero* (C: 200, P: 288), within a total of $3,381$ and $3,552$ memes for COVID-19 and US Politics, respectively. This highlights the realistic trends on social media.

4 Proposed Approach

This section outlines our proposed model `VECTOR` (Visual-semantic role dEteCToR) and its varied components. As previously noted, role detection for memetic entities is challenging and requires real-world, contextual, and commonsense knowledge. Thus, we propose a neuro-symbolic approach that integrates commonsense-enriched modelling via graph (KG) structure into the language modelling-based architecture (Zhang et al., 2021). KG's can be considered as discrete symbolic knowledge, which we leverage along with multimodal neural modelling. As shown in Fig. 2, `VECTOR` houses two primary sub-modules. The Vision Module leverages cross-modal interaction between the visual-linguistic signals to grasp optimal contextual information. The Commonsense Module integrates commonsense cues through an entity-based knowledge graph. Lastly, the Information Fusion Module coalesces the information obtained via attention-based fusion. In the following subsections, we go over the specifics of each module.

Text Module: We use DeBERTa (He et al., 2020) as our backbone model as it gives the best results amongst the text-only baselines (see Table 2). Aside from the text encoded in the meme, additional verbal information can be gleaned from memes. Evidence by Blaier et al. (2021) suggests that utilizing meme captions improves hateful meme identification results. Furthermore, additional cues such as the person, the location, and the entities present in the meme are helpful for downstream tasks. Thus, we use such ancillary information along with the OCR text. For image captioning, we make use of the recently released OFA model (Wang et al., 2022). For face identification, we use the same technique as the one by Kun et al. (2022). The OCR text, the entity name, the image caption, and the identified face *labels* are concatenated and passed to the DeBERTa model. We take the final layer representation $Z \in \mathbb{R}^{l \times d}$ to fuse information from other sub-modules.

Vision Module: Meme contents often contain contradicting text and image pairs. Therefore, it

---

[3] For additional details, please refer to the shared-task paper (Sharma et al., 2022b).

is required to incorporate information from these modalities to understand memes. Instead of using the traditional cross-modal attention to facilitate interaction between the two modalities, we utilize an optimal transport-based kernel interaction (Mialon et al., 2021). To begin with, we use a Vision Transformer (Dosovitskiy et al., 2020) for generating the image representations $E_m \in \mathbb{R}^{l_m \times d_m}$. The text and the image representations undergo dimensionality reduction by non-linear transformation, followed by a self-attention layer (Vaswani et al., 2017) as given by equations 1. This spawns vectors $Z'_m, E'_m \in \mathbb{R}^{l \times d'}$. We concatenate these two vectors and pass them to the Optimal Transport-based Kernel Embedding (OTKE) layer to bring about cross-modal interaction. It transforms the feature vectors to a Reproducing Kernel Hilbert Space (RKHS) (Berlinet and Thomas-Agnan, 2004) followed by a weighted pooling scheme using weights determined by the transport plan between the set and a trainable reference. Such a fusion technique provides a theoretically grounded adaptive vector for the task. This yields vector $Z_m \in \mathbb{R}^{l \times d'}$, given by equation 2 below:

$$Z'_m = S\left(\frac{ZZ^T}{\sqrt{d}}\right)Z \quad E'_m = S\left(\frac{E_m E_m^T}{\sqrt{d_m}}\right)E_m \quad (1)$$

$$Z_m = OTKE([Z'_m : E'_m]) \quad (2)$$

Commonsense Module: Due to their cryptic nature, identifying the intent of a meme is challenging. Their satirical and non-obvious way of conveying a message often requires commonsense comprehension. Thus, in our commonsense module, we generate a commonsense knowledge graph based on the entities in the meme. Similarly to (Shang et al., 2021), we extract all the nouns and noun phrases in the meme OCR and the meme caption. We extract commonsense relation pairs having confidence > 2 from ConceptNet (Speer et al., 2017) for all the noun chunks from memes. Noun chunks, commonsense entities, and the meme entity in question form the nodes of the commonsense graph. Each noun chunk from the OCR text is connected. The same applies to the noun chunks in the meme caption. A special aggregator token connects OCR and caption-based nodes. Thus, for each entity $e_{ij} \in E_i = \{e_{i1}, e_{i2}, \dots, e_{in}\}$, we have a commonsense graph $G_{ij} = (V_{ij}, E_{ij})$, where V_{ij} and E_{ij} are the nodes and the edges of the graph.

The graph having edges between various entities, noun chunks, and nouns, being undirected, represents a generic "connectivity". Therefore, an edge between nodes A and B indicates that they have some association. By doing this, we wanted to capture the commonsense-based 'proximity' of different entities/concepts within the vectorized space for common sense concepts. V_{ij} represents a set node (or vertices) constituting a commonsense graph corresponding to each entity.

For each node in the commonsense graph, we generate an embedding of size d_g using the last layer representations from DeBERTa. In order to facilitate the interaction between the nodes, the commonsense graph goes through two rounds of graph convolutions (Kipf and Welling, 2017) followed by a max-pooling operation to spawn an aggregated graph embedding $E_g \in \mathbb{R}^{d'}$. Similarly to the vision module, the textual representations Z and the commonsense graph representation E_g undergo non-linear transformation and dimensionality reduction followed by self-attention (Vaswani et al., 2017). This generates contextual vectors $Z'_g, E'_g \in \mathbb{R}^{l \times d'}$, respectively. Finally, the commonsense knowledge is infused in the language representations using OKTE, generating the final vector $Z_g \in \mathbb{R}^{l \times d'}$.

Information Fusion Module: Each of the modules mentioned above integrates salient information in the language representations. The information fusion module aggregates the knowledge obtained from all other modules using attention-based mutual interaction (Vaswani et al., 2017). Concretely, we concatenate the vectors of Z, Z_m, and Z_g and pass them through a round of dimensionality reduction and non-linear transformations. Then, we use a self-attention mechanism so that the information obtained from each component interacts with one another. The final generated vector $Z'_c \in \mathbb{R}^{l \times d}$ is passed to a classifier with a softmax activation to predict the final labels.

5 Baselines

Unimodal Systems: We use a variety of text-based and image-based models as our baseline systems. Starting with the text baselines, we use **BERT** (Devlin et al., 2019), and variants thereof such as **DistilBERT** (Sanh et al., 2019), **RoBERTa** (Liu et al., 2019), **XLNet** (Yang et al., 2019), and **DeBERTa** (He et al., 2020). For the image-based baselines, we start with a representation based on **ResNet-50** (He et al., 2016), followed by **Vision Transformer (ViT)** (Dosovitskiy et al., 2020) and **SWIN** (Liu et al., 2021), which is hierarchical ver-

sion of ViT that uses shifted windows. We also include the recently proposed **ConvNeXT** (Liu et al., 2022) and **BEiT** (Bao et al., 2021), which uses self-supervised pre-training of Vision Transformers.

Multi-modal Systems: We use various variants of multi-modal pre-trained systems from the MMF Framework. **MMF Transformer** is a library Transformer model that uses visual and language tokens with self-attention. **MMBT:** multi-modal Bi-transformer (Kiela et al., 2019) captures the two modalities' intra-modal and inter-modal dynamics. **ViLBERT** is a vision and language BERT (Lu et al., 2019), a strong model with the task-agnostic joint representation of images and text. **ViLBERT CC** is pre-trained on conceptual captions (Sharma et al., 2018) based pretext task. **Visual BERT** (Li et al., 2019), also pre-trained using MS COCO (Lin et al., 2014), implicitly aligns the input text and regions in the input image using self-attention. CLIP (Radford et al., 2021) leverages image–text contrastive pretraining.

6 Experiments

Experimental Details We present benchmarking results in Table 2, comparison with the shared-task submissions (c.f. Table 4) averaged over five independent runs, while for the ablation study in Table 3, we compare the *best* check-points for different `VECTOR` component-wise evaluations to assess the performance bounds, on the *diversified* test set. We use precision, recall, and F1 for individual classes, and macro-averaged for the overall assessment.[4]

Comparative Analysis. ▷ **Unimodal Models:** Despite the evident glorification cues within the *Hero* references in memes, large pre-trained models are observed to depict limitations. This can be observed from Table 2, wherein significantly low performance is observed for strong models like DistilBERT, BERT, and XLNet, with F1 scores of 0.132, 0.158, and 0.123, respectively. On the other hand, RoBERTa enhances the class-specific F1 score by about 0.05 absolute points, which suggests the efficacy the exhaustive hyperparameter tuning can induce. Finally, DeBERTa-based unimodal systems yield the highest optimal F1 scores among all unimodal models evaluated. The scores observed are 0.250 and 0.237 for the base and the large variants, respectively.

For the *Villain* category, BERT can be observed (c.f. Table 2) to yield relatively better performance as against Hero detection, with an F1 score of 0.464. This is in contrast to the sub-par performances by DistilBERT, RoBERTa, and XLNet, yielding 0.415, 0.433, and 0.432 F1 scores, respectively. As with the Hero detection, DeBERTa-base and large models outperform the other models for both text and vision modalities.

Interestingly, none of the text-only models, except for DeBERTa large, could beat the F1 score of 0.395 for DeBERTa-base. The lower performance is primarily due to inadequate categorical representation within the dataset. Moreover, the inherent complexity in distinguishing villains from victims confuses the model. The modelling efficacy solicited for such a scenario is suggested by over 0.10 absolute point enhancement by DeBERTa-large, which has 4X more backbone parameters

---

than DeBERTa-base.

Other category, having the majority representation with over 6K unique references within memes, projects the highest F1 scores with an average of 0.879. Finally, the overall Macro-F1 scores reflect the category-wise trend observed, with DeBERTa large leading with an F1 score of 0.540. DeBERTa-base follows it with 0.509 and the rest with an average F1 score of 0.444.

For intuitive reasons, the visual modality, not indicative of complex role semantics, yields poor performance compared to text-only models. As a result, none of the image-only models (ConvNext, ViTBEiT, and SWIN) are observed to make any headway in correctly detecting a Hero reference in memes (c.f. Table 2). At the same time, except for the Villain category, a simple ResNet-based model outperforms, albeit with fine margins, the rest of the models within the categories Victim and Other, with F1 scores of 0.097 and 0.883, respectively. This highlights the efficacy of global image representations against tokenized (or patched) ones for factoring visual features, especially where there is not much visual-linguistic grounding to be leveraged. On average, the image-only models can project a paltry F1 score of 0.324.

▷ **Multi-modal Models.** Several state-of-the-art multimodal systems, on average, are observed to yield a Macro-F1 score of 0.416, which lies between the text-only (0.444) and the image-only (0.324) models. Besides the category-wise performance trend being similar to the one observed for unimodal models, multimodal systems like VisualBERT and MMBT yield the highest Macro-F1 scores of 0.468 and 0.447, respectively. This is likely due to the joint attentive modelling, multimodal pre-training using standard datasets like MS COCO, and fine-tuning adopted by these models. Other competitive models like CLIP, ViLBERT, and MM Transformer achieve Macro-F1 scores of up to 0.342, 0.421, and 0.405, respectively. This either suggests that the image component induces additional noise within the models or that the existing multimodal systems do not effectively capture the complex pragmatics that semantic role-labeling in memes solicits. The former is less likely, as intuitively, memetic visuals do provide minor yet decisive semantics toward holistic assimilation of the meme's message. Our proposed approach `VECTOR`, is observed to address the required cross-modal association by achieving impressive F1 scores across different roles and a 0.581 Macro-F1 score, which induces an enhancement of almost 4% and 12 % over DeBERTa large (unimodal best) and VisualBERT (multimodal best), respectively.

Ablations Results. Table 3 depicts ablation results, wherein the basic early-fusion setup involving DeBERTa and ViT performs well for *villain* category with 0.55 F1 score. Adding meme-image captions enhances the *hero* predictions and overall accuracy marginally by 1% each. Face labels, although, significantly enhance the prediction of *villain* and *victim*, suggesting lexical and semantic utility via *face labels*. The overall performance remains unchanged due to compromised *hero* predictions. Besides yielding balanced scores, adding a commonsense module elevates hero prediction distinctly to 0.36, effectively indicating its utility, especially for the under-represented role category. Finally, `VECTOR` with OTK-based embedding yields optimal cross-modal correspondence, as observed from the best performances across roles and metrics evaluated, showcasing the constituting feature's utility towards addressing the given task. Although *not* averaged over multiple runs, the *best* model check-point for `VECTOR` is observed to yield an impressive overall macro-F1 score of 0.60, which is the best score observed across experiments, suggesting an upper-bound for `VECTOR`'s performance.

Comparison to Previous Work. Table 4 showcases the best-performing systems from

	Original	Proposed	VisualBERT
Hero	–	–	–
Villain	[jeffrey epstein, donald trump]	[donald trump]	[jeffrey epstein, donald trump]
Victim	[13 year old girl]	[13 year old girl]	[13 year old girl]
Other	–	[jeffrey epstein]	–

Figure 3: Error analysis for VECTOR and VisualBERT.

CONSTRAINT@ACL-2022's shared-task. Since all of the shared-task submissions used ensemble techniques of multiple models, we present their best individual model results for a fair comparison with our proposed model: VECTOR. The macro-F1 score varies by 0.334 points across the participants, emphasizing model selection. We can draw parallels between Table 2 and Table 4 with Logically, c1pher, smontariol, and zhouziming using DeBERTa, RoBERTa, VisualBERT, and VisualBERT, respectively. They exhibit marginal improvements using loss-weighting techniques and additional classification layers. Our model VECTOR performs more consistently, especially with the class-wise scores of *Hero* (c.f. Table 2), establishing its efficacy across the category types and limited categorical data representation. Besides class-wise consistency, VECTOR outperforms other shared-task submissions as a stand-alone system. Also, despite being relatively complex, VECTOR produces consistent class-wise and better overall performance, suggesting marginal yet robust modelling capacity facilitated by VECTOR's vision + common-sense module's interaction with the textual signals.

Statistical Significance. We performed a bootstrapping significance test w.r.t the proposed model (VECTOR), and the previous best solution by team Logically (Kun et al., 2022) via random sampling with replacement strategy, with N=1000 over 1000 simulations, and observed a 'p-value' of 0.0410. This indicates a subtle yet encouraging confidence margin in the model predictions. This could be likely due to better predictions across the four categories, including 'hero', which most of the other models compared are empirically observed to struggle at. These aspects corroborate the semantic-role label-agnostic characteristics of the proposed model.

	Original	Proposed	VisualBERT
Hero	–	–	–
Villain	[barack obama]	[barack obama]	[barack obama, donald trump, daily wire]
Victim	[donald trump]	[donald trump]	–
Other	[daily wire]	[daily wire]	–

Figure 4: Interpretability analysis for VECTOR; proposed model and VisualBERT; best multimodal baseline.

Error Analysis. The example depicted in Fig. 3 insinuates 'donald trump' and 'jeffrey Epstein's as *villains* while *victimizes* a '13 year old girl'. Visually, there isn't much to consider towards adjudicating the former two entities as villains, except the expressions of 'jeffrey Epstein's exuding somewhat *sinister* looks. Whereas *vilifying* connotation is implied primarily by the embedded text. Now, although VECTOR predicts the roles of 'donald trump' and '13 year old girl' correctly as *villain* and *victim*, respectively, it fails to detect 'jeffrey epstein as a *villain* and categorizes it as an *other*. This example highlights the limitations of VECTOR in terms of its inherent modality-specific biases. A ViT-based image encoder, due to its disparate patch-wise processing, and self-attention across the input patches, leads to noisy visual attention. On the other hand, VisualBert-based predictions replete with pre-trained common-sense semantics are better positioned for this case to capture the required semantic indicators, a portion of *epstein's* facial expression in this case. Also, as the dataset is well-stocked with examples where 'Donald trump' is *vilified*, both models being compared assign the role of *villain* to 'donald trump'.

7 Interpretability

The predictive capacity of VECTOR can be assessed by comparing its interpretability with that of VisualBERT, the best-performing baseline. We investigate a reasonably complex example depicted in Fig 4, for which VECTOR accurately predicts all the entity roles, but VisualBERT wrongly predicts all of them, as *villains*. Attention map for VECTOR reveals that it primarily attends to the face of 'barack obama', while leveraging other contextual cues, likely via the common-sense and visual description-based signals, leading to a correct assignment of roles. On the other hand, VisualBERT, having a Faster R-CNN-based image encoder, primarily pretrained for the common object-detection task, fails to uniquely attend to different semantically referred entities within the meme image and additionally adds noisy features related to objects like a *tie*, without any additional contextual knowledge. This validates `VECTOR`'s superior discriminatory capacity and interpretability over VisualBERT.

8 Generalizability

Since, the test set consists of all unique memes, there is a higher chance that there are many entities as part of it that are not seen during the training stage. Table 2 attests to the `VECTOR`'s potential to succeed across different roles. This suggests that `VECTOR` can adapt to the domain-specific nuances offered by the variety and complexity associated with visual-semantic roles within memes. Through the results observed in this work, we attempt to highlight that existing *standard* approaches either have inconsistent performances across the roles: hero, villain, victim, and other, or yield low scores for particular role categories (c.f. Table 2), which corroborates their limitations. On the other hand, `VECTOR` yields a balanced performance and generalizes reasonably well for the least represented class in the dataset (*hero*).

9 Conclusion

This paper addresses a recently proposed task of identifying the roles of entities in harmful memes and discusses its challenges. We further presented numerous unimodal and multi-modal baselines to benchmark `HVVMemes`. Moreover, we proffer `VECTOR`, a contextual knowledge-enriched multimodal framework that bolsters the multi-modal representations with entity-based external knowledge using a cross-modal attention scheme. `VECTOR` shows noteworthy improvements over the baselines, thus justifying contextual knowledge inclusion. As for future investigations, we plan to conceive a more symbolic system with graph-based entity linking, commonsense knowledge, and visual concepts.

10 Limitations

As noted in the discussion dedicated to *Error Analysis*, several entities tend to dominate specific roles within the dataset due to the realistic representation of the harmful referencing in memes. This not only biases the model against their generalizability but also poses challenges towards modelling entity-independent role detection hypotheses for a diverse set of entities. This especially calls for building models regularized to address such biases and more participatory initiatives toward curating better and more large-scale datasets.

11 Ethics and Broader Impact

Reproducibility. We present detailed hyperparameter configurations in Appendix A.

User Privacy. The information depicted/used does not include any personal information. Copyright aspects are attributed to the dataset source.

Biases. As per the authors, any biases found in the dataset are unintentional (Sharma et al., 2022b), and by conducting the study on this dataset we do not intend to cause harm to any group or individual. We acknowledge that detecting harmfulness can be subjective, and thus it is inevitable that there would be biases in gold-labelled data or in the label distribution. This is addressed by the dataset curators by using general keywords about US Politics, and also by following a well-defined schema, which sets explicit definitions for annotation.

Misuse Potential. Our approach can be potentially used for ill-intended purposes, such as biased targeting of individuals/communities/organizations, etc. that may or may not be related to demographics and other information within the text. Intervention with human moderation would be required to ensure that this does not occur.

Intended Use. We make use of the existing dataset in our work in line with the intended usage prescribed by its creators and solely for research purposes. This applies in its entirety to its further usage as well. We do not claim any rights to the dataset used or any part thereof. We believe that it represents a useful resource when used appropriately.

Environmental Impact. Finally, large-scale models require a lot of computations, which contribute to global warming (Strubell et al., 2019). However, in our case, we do not train such models from scratch; rather, we fine-tune them on a relatively small dataset.

A Implementation Details and Hyperparameter Values

We train all the models using PyTorch on an actively dedicated NVIDIA Tesla V100 GPU, with 32 GB dedicated memory, CUDA-11.2, and cuDNN-8.1.1 installed. For the unimodal models, we import all the pre-trained weights from the `TORCHVISION.MODELS`,[5] a sub-package of the PyTorch framework. We randomly initialise the remaining weights. Sharma et al. (2022b) re-annotate the HarMeme dataset (Pramanick et al., 2021b) by collecting annotator responses for different roles different entities within memes take. The re-annotated memes may or may not have harmful implications, contrary to the distinction modelled as part of original curation. However, they portray various entities within different contexts implying glorification, vilification, and victimisation. For most of our experiments, we use Adam optimiser (Kingma and Ba, 2015) with a learning rate of $1e^{-4}$ or $1e^{-5}$, a weight decay of $1e^{-5}$ and a Cross-Entropy (CE) loss as the objective function. We optimized our models to obtain hyper-parameter settings (c.f. Table 5) and early-stop to preserve our best state convergence. On average, it took approx. 2:30 hours to train a typical multi-modal neural model on a dedicated GPU system.

B Additional details of `HVVMemes`

B.1 Edge Case

Most memes are intended to project harmless mockery toward various sections of society. Such memes do not imply heroes, villains, or victims; instead, they disseminate harmless humour and trivial opinions. Therefore, Sharma et al. (2022b) do not presume any implications regarding these connotations and categorise them as ‘other’, a fourth *neutral* category, unless expressed otherwise in the meme. A depiction of such a scenario can be observed in Fig. 5. In this meme, it is unclear if Donald Trump is being vilified for being reluctant to use a mask or if the meme expresses a benign attempt at mocking his physical appearance with sarcasm. Additionally, since no background information would suffice to facilitate its complete assimilation, it is categorised as *other*.

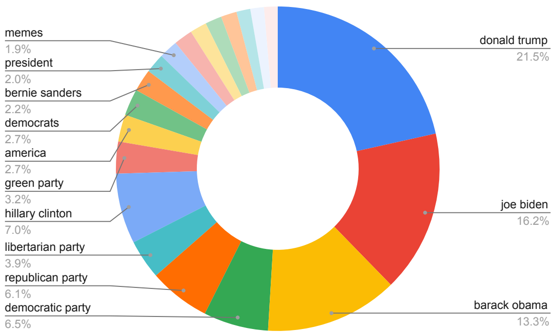

Figure 6: Entity distribution - US Politics.

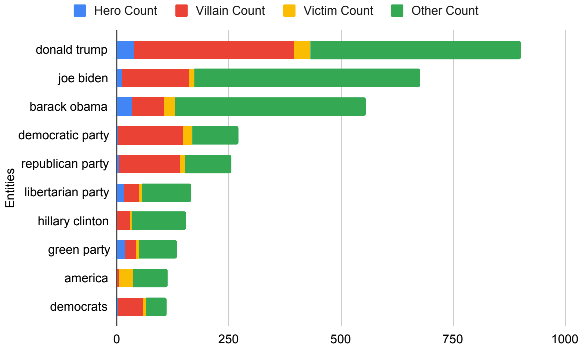

Figure 7: Entity-role distribution - US Politics.

B.2 Analysing Different Entities and Roles

Figure 5: Edge case

Regardless of the connotations and domains in which various entities are referred, only a handful of entities/topics dominate pivotal referencing in memes. The entities in *COVID-19* memes predominantly focus on *Coronavirus*, *Donald Trump*, *mask*, *COVID-19*, and *work from home*. The entities of *Donald Trump*, *Joe Biden*, *Barack Obama*,

---

[5] http://pytorch.org/docs/stable/torchvision/models.html

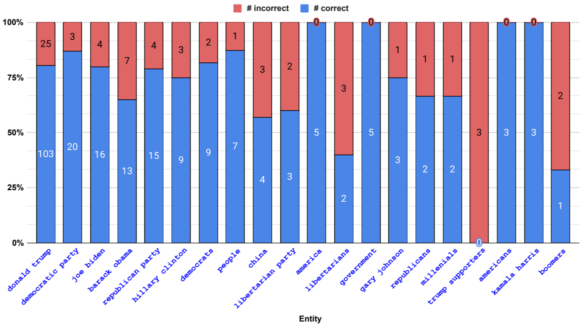

Figure 8: Entity role prediction summary for `HVVMemes`'s (combined) test set. X-axis: Top 20 entities referenced; Y-axis: True positive rate (Recall). Values depicted at the center of each portion for each bar depicts corresponding total counts.

Democratic Party, and *Republican Party* crowd the US Politics memes, as shown in Fig. 6. Such trends highlight the key figures and real-world topics that dominated memetic communication on social media during the period this dataset was compiled, which coincided with the onset of the global COVID-19 pandemic and contemporary US Politics. In COVID-19 memes, we observe that entities like *Donald Trump* and *China* are referenced almost equally within the vilifying and neutral contexts. In contrast, entities like *Corona beer*, *introverts*, and *Tom Hanks*, are invariably referenced in neutral contexts through irony, satire, or benign humour. Similar trends are observed in US Politics memes (Fig. 7), wherein entities like *Donald Trump*, *Democratic Party*, *Republican Party*, and *Democrats* observe almost equivalent referencing as *villain* and *others*. Interestingly, as shown in Fig. 7, US Politics related memes depict a higher propensity towards vilification than that of COVID-19, as most of the prominent entities encountered are vilified at least once in the dataset.

C Entity Role Prediction Analysis.

Careful analysis of the role predictions for various entities elicits the correlation between the role-wise distribution and the test set predictions for different entities. This correlation can be observed from Fig. 8, wherein entities like *Donald Trump, Democratic Party, Joe Biden, Republican Party, Democrats*, etc., which have a *true positive rate* (recall) of atleast 75%, are specifically the ones that have relatively balanced role-wise distribution for the roles of *villain* and *other* within `HVVMemes`, (see Fig. 4 (main content). Interestingly, a lower but role-wise balanced representation within `HVVMemes`, does not appear to deter `VECTOR` from yielding an impressive recall of 90% for an entity such as *Democrats*, which have a total of approximately 125 samples in the training set. On the other hand, for entities like *Barack Obama, China, Libertarian Party, Libertarian*, etc., the memetic portrayal is significantly skewed-in as an *other*, suggesting distinct role-wise imbalance within memes that `VECTOR` failed to accommodate, highlighting its limitations. Further, there are entities like *America, Government, Americans, Kamala Harris*, etc., that register a 100% recall. Role-wise distributions for such cases highlight a distinct majority of neutral connotations within both training and test splits via *other* category, essentially suggesting possible biases within the role-prediction modelling setup. Entity *Trump Supporters* is also observed to be present within the training set via another similar referencing *Donald Trump Supporters*, which has a 1:5 ratio of villain/victim:other. This is complemented by the predominant yet balanced referencing of an independent entity *Donald Trump*. This could lead to the model being confused for such entities as is depicted in Fig. 8.

Systematic Investigation of Strategies Tailored for Low-Resource Settings for Low-Resource Dependency Parsing

Abstract

In this work, we focus on low-resource dependency parsing for multiple languages. Several strategies are tailored to enhance performance in low-resource scenarios. While these are well-known to the community, it is not trivial to select the best-performing combination of these strategies for a low-resource language that we are interested in, and not much attention has been given to measuring the efficacy of these strategies. We experiment with 5 low-resource strategies for our ensembled approach on 7 Universal Dependency (UD) low-resource languages. Our exhaustive experimentation on these languages supports the effective improvements for languages not covered in pretrained models. We show a successful application of the ensembled system on a truly low-resource language Sanskrit.[1]

1 Introduction

Recently, the supervised learning paradigm has dramatically increased the state-of-the-art performance for the dependency parsing task for resource-rich languages (Chen and Manning, 2014; Dyer et al., 2015; Kiperwasser and Goldberg, 2016; Dozat and Manning, 2017; Kulmizev et al., 2019). However, only a handful of resource-rich languages are able to take advantage, and many low-resource languages are far from these benefits (Joshi et al., 2020; More et al., 2019a; Zeman et al., 2018).

In literature, several strategies have been proposed to enhance performance in low-resource scenarios, such as data augmentation (Şahin and Steedman, 2018; Gulordava et al., 2018), cross/monolingual pretraining (Conneau et al., 2020; Peters et al., 2018; Kondratyuk and Straka, 2019), sequential transfer learning (Ruder et al., 2019), multitask learning (Nguyen and Verspoor, 2018), cross-lingual transfer (Das and Sarkar, 2020) and self-training (Rotman and Reichart, 2019; Clark et al., 2018). However, not much attention has been given to measuring the efficacy of the existing low-resource strategies well-known to the community for low-resource dependency parsing (Vania et al., 2019). This is essential to assess their utility for low-resource languages (Hedderich et al., 2021) before inventing novel ways to tackle data sparsity.

In this work, we systematically explore 5 pragmatic strategies for low-resource settings on 7 languages. We experiment with low-resource strategies such as data augmentation, sequential transfer learning, cross/mono-lingual pretraining, multitask learning and self-training. We investigate: (1) How is the trend in performance of each strategy across various languages? Whether the choice of best performing variant of each strategy is language dependent? (2) We integrate the best performing variant of each strategy and call the resulting system as the ensembled system. Do all the strategies contribute towards performance gain in the ensembled system? How well does this ensemble approach generalize across multiple low-resource languages? (3) How far can we push a purely data-driven ensemble system using the best-performing low-resource strategies? Can this simple ensemble approach outperform the state-of-the-art of a low-resource language? We argue that while it may sound like a simple application of techniques well known to the community; it is non-trivial to select the best performing combination for a target low-resource language.

Our exhaustive experimentation empirically establishes the effective generalization ability of the ensembled system on 7 languages and shows average absolute gains of 5.2/6.2 points Unlabelled/Labelled Attachment Score (UAS/LAS) over strong baseline (Dozat et al., 2017). Notably, our ensembled system shows substantial improvements for the languages not covered in pretrained models. Finally, we show a successful application of the ensembled system on a truly low-resource

language Sanskrit. We find that the ensembled system outperforms the state-of-the-art system (Krishna et al., 2020a) for Sanskrit by 1.2 points absolute gain in terms of UAS and shows comparable performance in terms of LAS (§ 3).

2 Investigation of Strategies Tailored for Low-resource Settings

We explore 5 strategies specially tailored for low-resource settings on 7 languages, and integrate the best performing strategy of each category in our ensembled system (Table 1). We utilize Dozat and Manning (2017) as a base system for all the experiments, henceforth referred to as BiAFF.

Language selection criteria: We choose low-resource languages with less than 2,500 training samples from 4 different typological families such that each language belongs to a unique sub-family. In order to accommodate a low-resource tailored pretraining (Sandhan et al., 2021), we choose languages that have explicit morphological information. Additionally, we divide the set of languages into the languages covered/not-covered in the multilingual language model's pretraining: (1) Covered: Arabic (ar), Greek (el), Hungarian (hu) (2) Not covered: Wolof (wo), Gothic (got), Coptic (cop) and Sanskrit (san).

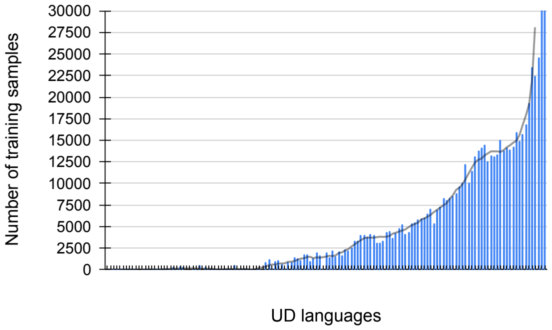

Figure 1: Plot for number of training samples vs. UD languages available in UD-2.6.

Figure 1 illustrates the number of training samples available for all UD languages in UD-2.6. Hedderich et al. (2021) ask "How low is low-resource?" and suggest that the threshold of low-resource is task and language-dependent. The low-resource settings can be seen as a continuum of resource availability due to the absence of a hard threshold. More efforts should focus on evaluating low-resource strategies across multiple languages for a fair comparison between these strategies. Therefore, we select a threshold for the languages with less than 2,500 training samples (Figure 1). We restrict ourselves to the setting where the target low-resource language does not have a high-resource related language that could possibly facilitate the positive cross-lingual or zero-shot transfer (Vulić et al., 2019; Pires et al., 2019; Søgaard et al., 2018; de Lhoneux et al., 2018; Smith et al., 2018). Thus, we do not consider low-resource languages with only a test set available. Also, we do not consider cross-lingual transfer (Duong et al., 2015; Ahmad et al., 2019; Vania et al., 2019; Das and Sarkar, 2020) strategy in our study.

Dataset and metric: For each of these 7 low-resource languages from Universal Dependencies (UD-2.6) (de Marneffe et al., 2021), following Rotman and Reichart (2019), we use 500 data points for training (allocating equal power to each language for fair comparison) and the original dev/test split as dev/test set. Additionally, 1000 morphologically tagged data points (without dependency annotations) are used for self-training and pretraining. We use sentence level macro averaged UAS/LAS metric for evaluation.

Hyper-parameters: For SeqTraL variants, we use the exact same encoder as Ma et al. (2018) with 2 Bi-LSTM layers and decoder with fully connected layer followed by softmax layer. For the ensembled system, we adopt BiAFF's codebase by Ma et al. (2018) with the hyper-parameters setting as follows: the batch size as 16, training iterations as 100, a dropout rate as 0.33, the number of stacked Bi-LSTM layers as 2, learning rate as 0.002 and the remaining parameters as the same as Ma et al. (2018). We release our codebase publicly under creative-common licence.

Computing Infrastructure Used: We primarily use RTX-2080, 12 GB GPU memory, 4352 GPU Cores computing infrastructure for our experiments.

Sequential Transfer Learning (SeqTraL): Following Sandhan et al. (2021), we pretrain three encoders (similar to BiAFF) on three sequence labelling auxiliary tasks and integrate them with the BiAFF encoder using a gating mechanism. We adapt these pretrained encoders with various optimization schemes, proposed for reducing a catastrophic forgetting (French, 1999; McCloskey and

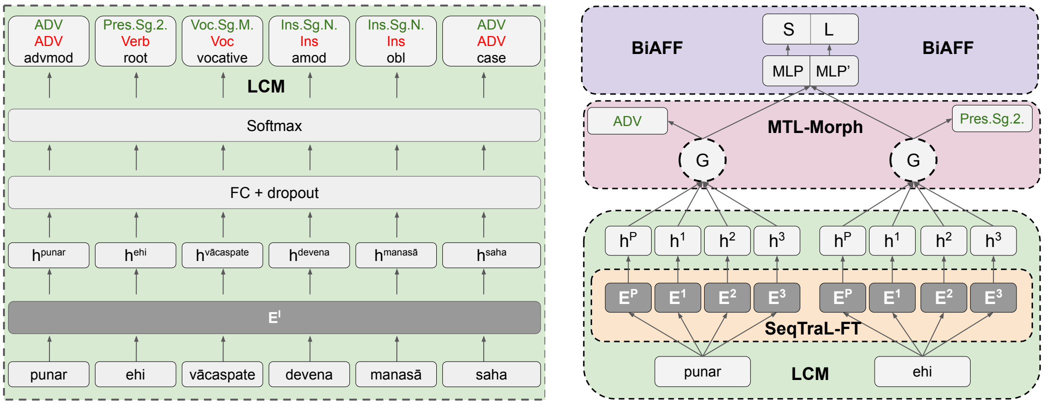
Table 1: Evaluation of low-resource strategies on 7 languages. Experiments are first performed on dev set to find best performing combination of strategies for each language. The best results from strategies from each family are bold and statistically significant compared to its peer baselines belonging to the same family as per t-test ($p < 0.01$). The second last block shows ablations when the best variant from each family is added to the ensembled system. For example, +Data. aug. refers to the system with the best variant from all 5 strategies. The best performing system as per dev set is finally compared with BiAFF on the test set. XLM-R is not compatible with 3 languages and case information of Gothic (*got*) language is missing; hence we do not report their results.

Cohen, 1989). **SeqTraL-FE:** We treat newly integrated layers as Feature Extractors (FE) by freezing them. **SeqTraL-UF:** Gradually Unfreeze (UF) these new layers in the top to down order (Howard and Ruder, 2018; Felbo et al., 2017). **SeqTraL-DL:** The discriminative learning rate (DL) is used for newly added layers (Howard and Ruder, 2018), the learning rate is decreased from top-to-bottom layers. **SeqTraL-FT:** The default learning rate is used to fine-tune all newly added layers.

Cross/mono-lingual Pretraining: We experiment with two multilingual pretrained models, namely, the multilingual BERT (Devlin et al., 2019, **mBERT**) based system (Kondratyuk and Straka, 2019) and the XLM-Roberta (Conneau et al., 2020, **XLM-R**) based system (Nguyen et al., 2021). We also consider supervised pretraining specially tailored for low-resource dependency parsing (Sandhan et al., 2021, **LCM**) which essentially combines three sequence labelling auxiliary tasks. We pretrain it on 1,000 morphologically tagged data points without dependency annotations.

Self-training: Another line of modelling focuses on self-training (Goldwasser et al., 2011; Clark et al., 2018; Rybak and Wróblewska, 2018) to overcome the bottleneck of task-specific labelled data. Earlier attempts failed to prove effectiveness of self-training for dependency parsing (Rush et al., 2012). However, Clark et al. (2018, **CVT**) and Rotman and Reichart (2019, **DCST**), show successful application, thus, we consider these two systems. Also, we generate dependency data by applying a pretrained BiAFF system on 1000 unlabelled data points. We augment this predicted data with gold data and retrain BiAFF in **Self-Train** setting.

Multi-task Learning: We simultaneously train BiAFF and a sequence labelling based auxiliary task in a multi-task setting (**MTL**). We experiment with the following auxiliary tasks: prediction of the morphological label (**MTL-Morph**), dependency relation between a word and its head (**MTL-Label**) and the case label (**MTL-Case**).



(a) (b)

Figure 2: The ensembled system for Sanskrit. Translation: "Oh Vācaspate! Come again with divine mind".

Data Augmentation: Şahin and Steedman (2018) introduce **Cropping:** delete some parts of a sentence to create multiple short meaningful sentences, and **Rotation:** permute the siblings of headword restricted to a set of relations. Both operations modify a set of words or configurational information; however, they do not change the dependencies. **Nonce:** Gulordava et al. (2018) propose to create nonce sentences by substituting a few words which share the same syntactic labels. For each variant, we use additional 1,000 augmented data points.

Results on multilingual experiments: Table 1 first reports results of all 5 strategies on dev set of 7 languages. Next, the second last block of Table 1 (Prop. system) shows ablations on dev set where the best variant from each family is gradually added into the ensembled system. For example, +*Data.aug.* row refers to the system with the best variant from all 5 strategies. Finally, the best performing system as per dev set is compared with BiAFF on the test set. We observe that (1) the best performing variant from augmentation, SeqTraL and MTL families is language dependent. (2) DCST variant of self-training wins over its peer for all the languages. (3) XLM-R outperforms for the languages which are covered in its pretraining (except Sanskrit[2]) and LCM outperforms for the rest of the languages which are truly low-resource. (4) Notably, we find effective generalization ability of the proposed approach on languages covered in cross-lingual pretraining (only pretraining helps) and for the rest of the languages (pretraining, MTL and SeqTraL helps).

3 Application on Sanskrit

Data: We use two standard benchmark datasets available for Sanskrit. We use 1,700, 1,000 and 1,300 sentences (prose domain) from the Sanskrit Treebank Corpus (Kulkarni et al., 2010, STBC) as train, dev and test set, respectively. We also evaluate on the Vedic Sanskrit Treebank (Hellwig et al., 2020, VST) consisting of 1,500 , 1,024 and 1,473 sentences (poetry-prose mixed) as train, dev and test data, respectively. For both data, the final results on the test set are reported using systems trained with combined gold train and dev set.

Baselines: We use More et al. (2019b, **YAP**) and Chang et al. (2016, **L2S**) from transition-based dependency parsing family. Dozat and Manning (2017, **BiAFF**) is a graph-based approach with BiAFFINE attention mechanism. Krishna et al. (2020a, **MG-EBM**) extends Krishna et al. (2020b, **Tree-EBM-F**) using multi-graph formulation. Systems marked with (*) are hybrid systems which leverage linguistic rules from Pāṇini.

The ensembled system: Figure 2 shows the ensembled system for Sanskrit as per Table 1. It consists of two steps, namely, pretraining (**LCM** 🟩) and integration. As shown in Figure 2a, **LCM** pretrains three encoders $E^{(1)-(3)}$ using three independent auxiliary tasks, namely, morphological label prediction, case label prediction and relation label prediction. Thereafter, as shown in Figure 2b, these pretrained encoders are integrated with the BiAFF encoder $E^{(P)}$ using a gating mechanism as employed in Sato et al. (2017). We use **SeqTraL-FT** 🟧 optimization scheme to update the weights

---

[2] Maybe due to limited coverage of corpus for Sanskrit.

of these four encoders. Next, **MTL-Morph** ■ component adds morphological tagging as an auxiliary task to inject complementary signal in the model. Finally, the combined representation of a pair of words in passed to **BiAFF** ■ to calculate probability of arc score (S) and label (L).

Table 2: Results on test set for Sanskrit. *Hybrid* systems, marked with (*) use extra-linguistic knowledge and are not directly comparable with our system. Our results are statistically significant compared to BiAFF as per t-test ($p < 0.01$). Results are averaged over 3 runs.

Results: On STBC, the ensembled system outperforms the state of the art *purely data-driven* system (BiAFF) by 2.8/3.9 points (UAS/LAS) absolute gain. Interestingly, it also supersedes the performance of the *hybrid* state of the art system (Krishna et al., 2020a, **MG-EBM**) by 1.2 points (UAS) absolute gain and shows comparable performance for LAS metric. We observe that performance of transition-based systems (**YAP/L2S**) is significantly low compared to graph-based counterparts (**BiAFF/Ours**). We also obtain a similar performance trend for VST data. The VST data is a mixture of dependency labelled trees from both poetry and prose domain. As a result, the overall performance for VST is low compared to STBC due to loss of configurational information.[3]

4 Conclusion and Discussion

We focused on low-resource dependency parsing for multiple languages. We found that our ensembled system can benefit the languages not covered in pretrained models. While multi-lingual pretraining (mBERT and XLM-R) is helpful for the languages covered in pretrained models, LCM pretraining (which simply uses an additional 1,000 morphologically tagged data points) is helpful for the remaining languages. Thus, these findings would help community to pick strategies suitable for their language of interest and come up with robust parsing solutions. Specifically for Sanskrit, our ensembled system superseded the performance of the state-of-the-art *hybrid* system MG-EBM* by 1.2 points (UAS) absolute gain and showed comparable performance in terms of LAS.

Limitations: We could not evaluate on complete UD due to limited available compute resources (single GPU), hence we selected 7 representative languages for our experiments.

Ethics Statement: We do not foresee any ethical concerns with the work presented in this manuscript.

Acknowledgement

We thank Amba Kulkarni for providing Sanskrit dependency treebank data, Anupama Ryali for Śiśupālavadha dataset. We are grateful to Amrith Krishna (Uniphore) for helping us with the initial discussions on this work. We thank Tushar Sandhan (IIT Kanpur), Narein Rao (IIT Kanpur), Rathin Singha (UCLA) and the anonymous reviewers for their constructive feedback towards improving this work. The work of the first author is supported by the TCS Fellowship under the Project TCS/EE/2011191P. The work was supported in part by the National Language Translation Mission (NLTM): Bhashini project by Government of India.

Compositional Generalisation
with Structured Reordering and Fertility Layers

Abstract

Seq2seq models have been shown to struggle with compositional generalisation, i.e. generalising to new and potentially more complex structures than seen during training. Taking inspiration from grammar-based models that excel at compositional generalisation, we present a flexible end-to-end differentiable neural model that composes two structural operations: a fertility step, which we introduce in this work, and a reordering step based on previous work (Wang et al., 2021). To ensure differentiability, we use the expected value of each step, which we compute using dynamic programming. Our model outperforms seq2seq models by a wide margin on challenging compositional splits of realistic semantic parsing tasks that require generalisation to longer examples. It also compares favourably to other models targeting compositional generalisation.[1]

1 Introduction

Many NLP tasks require translating an input object such as a sentence into a structured output object such as a semantic parse. Recently, these tasks have been approached with seq2seq models with great success. However, seq2seq models also have been shown to struggle *out-of-distribution* on compositional generalisation (Lake and Baroni, 2018; Finegan-Dollak et al., 2018; Kim and Linzen, 2020; Hupkes et al., 2020), i.e. the model fails on examples that contain unseen compositions or deeper recursion of phenomena that it handles correctly in isolation.

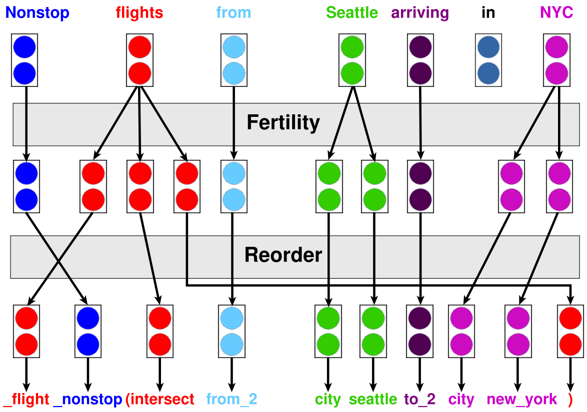

Figure 1: We model structural seq2seq tasks as the composition of differentiable fertility and phrase reordering layers. The model is trained end-to-end without direct supervision of the two structural layers.

Consider the example in Fig. 1. Arguably, any model that produces the given semantic parse from the input in a generalisable way has to capture the correspondence between fragments of the input and fragments of the output, at least implicitly. This is challenging because of structural mismatches between input and output. For example, the fragment contributed by “flights" is discontinuous and intertwined with the rest of the semantic parse.

In contrast to seq2seq models, grammar-based models such as synchronous context-free grammars (SCFGs) (Lewis and Stearns, 1968; Chiang, 2007) explicitly capture the compositional process behind the data and therefore perform very well in compositional generalisation setups. They can also model common structural mismatches like the one shown in the example. However, grammar-based models are rigid and brittle and thus do not scale well.

In this work, we take inspiration from grammar-based models and present an end-to-end differentiable neural model that is both flexible and generalises well compositionally. Our model consists of two structural layers: a phrase reordering layer originally introduced by Wang et al. (2021) and a fertility layer, new in this work, which creates zero or more *copies* of the representation of any input token. We show how to compose these layers to achieve strong generalisation.

We use a simple decoder and essentially translate each token after the fertility and reordering layers

independently into one output token. We found this to lead to better generalisation than using an LSTM-based decoder. The simple decoder also makes it easy to integrate grammar constraints to ensure well-formed outputs, e.g. in semantic parsing.

Most seq2seq models tend to predict the end of the sequence too early on instances that are longer than seen in training (Newman et al., 2020). Our model overcomes this by explicitly predicting the length of the output sequence as a sum of fertilities.

We first demonstrate the expressive capacity and inductive bias of our model on synthetic data. We then evaluate on three English semantic parsing datasets (Geoquery, ATIS, Okapi) and a style transfer task (Lyu et al., 2021). We clearly outperform seq2seq models both with and without pretraining in structural generalisation setups, particularly when the model has to generalise to longer examples. Our model also compares favourably with existing approaches that target structural generalisation, and we obtain state-of-the-art results on the structural style transfer tasks.

To summarise, our main contributions are:

- an efficient differentiable fertility layer;
- a flexible end-to-end differentiable model that composes two structural operations (fertility and reordering) and achieves strong performance in structural generalisation tasks.

2 Related Work

Fertility The concept of fertility was introduced by Brown et al. (1990) for statistical machine translation to capture that a word in one language is often consistently translated to a certain number of words in another language. Tu et al. (2016) and Malaviya et al. (2018) incorporate fertility into the attention mechanism of seq2seq models. Cohn et al. (2016); Gu et al. (2016) use heuristic supervision for training their fertility models. In contrast to prior work, we learn an explicit fertility component jointly with the rest of our model.

Monotonic alignment Related to fertility is the concept of monotonic alignment, i.e. an alignment a that maps output positions to input positions such that for any two output positions $i < j$, $a(i) \leq a(j)$. Monotonic alignments are usually modelled by an HMM-like model that places the monotonicity constraint on the transition matrix (Yu et al., 2016; Wu and Cotterell, 2019), leading to a runtime of $O(|\mathbf{x}|^2|\mathbf{y}|)$ with $\mathbf{x}$ being the input and $\mathbf{y}$ the output. Raffel et al. (2017) parameterise the alignment using a series of Bernoulli trials and obtain a training runtime of $O(|\mathbf{x}||\mathbf{y}|)$. Our approach also has $O(|\mathbf{x}||\mathbf{y}|)$ runtime.

Compositional generalisation There is a growing body of work on improving the ability of neural models to generalise compositionally in semantic parsing. Good progress has been made in terms of generalisation to new lexical items (Andreas, 2020; Akyürek and Andreas, 2021; Conklin et al., 2021; Csordás et al., 2021; Ontañón et al., 2022) but structural generalisation remains very challenging (Oren et al., 2020; Bogin et al., 2022).

Herzig and Berant (2021) use a neural chart parser and induce latent trees with an approach similar to hard EM. Their model assumes that one input token corresponds to a single leaf in the tree. Zheng and Lapata (2022) re-encode the input and partially generated output with a transformer for every decoding step to reduce entanglement and show considerable gains in structural generalisation.

There has also been work inspired by quasi-synchronous grammars (QCFGs, Smith and Eisner (2006)). Shaw et al. (2021) heuristically induce a QCFG and create an ensemble of a QCFG-based parser and a seq2seq model. Qiu et al. (2021) use similar QCFGs for data augmentation for a seq2seq model. Our approach does not require constructing a grammar. Finally, Kim (2021) introduces neural QCFGs which perform well on compositional generalisation tasks but are very compute-intensive.

Closest to our work is that of Wang et al. (2021) who reorder phrases and use a monotonic attention mechanism on top. Our approach differs from theirs in several important aspects: (i) we use fertility instead of monotonic attention, which parameterises alignments differently; (ii) we apply the fertility step first and *then* reorder the phrases, so our model can directly create alignments where output tokens aligned to the same input token do not have to be consecutive; (iii) we predict the length as the sum of the fertilities and not with an end-of-sequence token; (iv) they use an LSTM-based decoder network whereas we found that a simpler decoder can generalise better.

3 Background

3.1 Structured Attention

We often want to model the relationship between input $\mathbf{x}$ of length n and output $\mathbf{y}$ of length l by means of a latent variable Z. In particular, we assume that $Z \in \mathcal{Z} \subseteq \mathbb{B}^{n \times l}$ is a boolean alignment matrix. We want to predict $\mathbf{y}$ from a representation produced by a function $g(Z, \mathbf{x})$. In this case, the marginal distribution

$$P(\mathbf{y}|\mathbf{x}) = \mathbb{E}_{P(Z|\mathbf{x})} P(\mathbf{y}|g(Z, \mathbf{x})) \tag{1}$$

can be intractable to compute because $\mathcal{Z}$ often has exponential size in $\mathbf{x}$. In some important cases however we can formulate a similar but tractable model by using *structured attention* (Kim et al., 2017) which 'pushes' the expectation inside the model:

$$P(\mathbf{y}|\mathbf{x}) \approx P(\mathbf{y}|g(\tilde{Z}, \mathbf{x}))$$

where $\tilde{Z} = \mathbb{E}_{P(Z|\mathbf{x})} Z$ is now a 'soft' rather than a boolean matrix. Note that $\tilde{Z}_{ij} = P(Z_{ij} = 1|\mathbf{x})$ is a marginal probability that often can be efficiently computed with a dynamic programme if $P(Z|\mathbf{x})$ is factorisable. We will use such an approach for our model.

3.2 Marginal Permutations

In this section, we briefly review the method of Wang et al. (2021) that we use in our model.

Wang et al. (2021) build on bracketing transduction grammars (Wu, 1997) and show how to compute a distribution over separable permutations (Bose et al., 1998). A permutation is separable, iff it can be represented as a permutation tree. Some permutations are not separable. The internal nodes of a permutation tree are labelled as $\wedge$ or $\triangle$ and are interpreted as operations: $\wedge$ concatenates the values it receives from its left child with the value from its right child, whereas $\triangle$ concatenates them in reverse order. For example, the permutation tree $t = (\triangle\,(\wedge\, a\, b)\,(\triangle\, c\, d))$ represents the permutation $abcd \rightarrow dcab$. Let $R_t(i, j) = 1$ if the permutation described by tree t maps position i to position j, otherwise $R_t(i, j) = 0$.

Wang et al. (2021) show how to compute the expected permutation matrix $\tilde{R}_{i,j} \triangleq \mathbb{E}_{P(t|\mathbf{x})} R_t(i, j)$ in polynomial time with a CYK-style algorithm if $P(t|\mathbf{x})$ factors according to the CYK chart. Crucially, the expected permutation can also be interpreted as a distribution over alignments, where $\tilde{R}_{i,j}$ is the *marginal probability* that position i aligns to position j. We will use this alignment distribution as a building block in our model.

4 Overview of the Approach

In this section, we give a general overview of our approach and defer the details to Sections 5 and 6.

Conceptually, we want to model the transduction from input $\mathbf{x}$ of length n into output $\mathbf{y}$ of length l as the composition of two edit operations. First, we apply a *fertility* step, in which we decide for each token what its fertility is, i.e. how many *copies* we make of it. Assigning fertility of 0 corresponds to deleting the token. This step yields an *intermediate* sequence of tokens. We then reorder them using permutation trees (see Section 3.2). In the last step, we individually translate these tokens into the output tokens. Fig. 1 shows an example where the fertility step and reordering apply to vector representations of tokens.

The fertility step and the reordering can be represented as boolean matrices $F \in \mathbb{B}^{n \times l}$ and $R \in \mathbb{B}^{l \times l}$, respectively. These matrices denote alignments between the sequences before and after the operation. For example, $F_{i,j} = 1$ means that input token i aligns to intermediate token j, i.e. j is one of the copies of i.

With this conceptualisation, we would ideally use the following probabilistic model $P(\mathbf{y}|\mathbf{x})$:

$$P(\mathbf{y}|\mathbf{x}) = \mathbb{E}_{\underbrace{P(F|\mathbf{x})}_{\text{Fertility}}} [\mathbb{E}_{\underbrace{P(R|\mathbf{x}, F)}_{\text{Reordering}}} \underbrace{P(\mathbf{y}|\mathbf{x}, F, R)}_{\text{Decoder}}]$$

At training time, the true fertility values are unknown but we observe the length l of $\mathbf{y}$, so we condition on it:

$$P(\mathbf{y}|\mathbf{x}) = P(l|\mathbf{x}) \cdot \mathbb{E}_{P(F,R|\mathbf{x},l)} P(\mathbf{y}|\mathbf{x}, F, R) \tag{2}$$

where $P(l|\mathbf{x})$ can be computed with dynamic programming relying on the fertility model, as we explain in the next section.

Computing the marginal likelihood and the gradients is intractable. Instead of computing the likelihood exactly, one could sample and use a score function estimator (Williams, 1992) but the resulting gradient estimates have high variance.

Instead, we use structured attention as discussed in Section 3.1 and 'push' the expectations inside the model:

$$\mathbb{E}_{P(F,R|\mathbf{x},l)} P(\mathbf{y}|\mathbf{x}, F, R) \approx P(\mathbf{y}|\mathbf{x}, \tilde{F}, \tilde{R}) \tag{3}$$

with $\tilde{F} = \mathbb{E}_{P(F|\mathbf{x},l)} F$ and $\tilde{R} = \mathbb{E}_{P(R|\mathbf{x},\tilde{F})} R$. $\tilde{F}$ and $\tilde{R}$ now represent 'soft', differentiable versions of fertility and reordering. They approach their discrete counterparts as $P(F|\mathbf{x},l)$ and $P(R|\tilde{F},\mathbf{x})$ become peakier, which tends to happen over the course of training. We can view $(\tilde{F}\tilde{R})_{i,j} = \sum_k \tilde{F}_{i,k}\tilde{R}_{k,j}$ as a probability of aligning i to j in the composition of the operations.

A tendency to memorise larger chunks of the output might contribute to poor compositional generalisation (Hupkes et al., 2020). In order to avoid this, we use a simple decoder that generates each output token independently. A first attempt might look like this:

$$P(\mathbf{y}|\mathbf{x},\tilde{F},\tilde{R}) = \prod_{i=1}^{l}\sum_{j,k} P(\mathbf{y}_i|\mathbf{x}_j)\tilde{F}_{j,k}\tilde{R}_{k,i} \tag{4}$$

where the summation over j and k marginalises over all possible alignments to output position i.

Distinguishing copies The independence assumptions in Eq. (4) imply that $P(\mathbf{y}_i|\mathbf{x}_j)$ will have the same distribution for *all* copies of x_j, i.e. the model cannot express a preference to translate the first copy of *Seattle* to `city` and the second copy to `seattle` in Fig. 1. To enable this, we distinguish different copies of an input token.

We do this by defining F not as a matrix but as a tensor $F \in \mathbb{B}^{n\times l\times d}$ where d is some fixed maximum fertility value. Let $F_{i,j,u} = 1$ iff intermediate token j is the u-th copy of input token i. For example, in Fig. 1, $F_{4,6,1} = 1$ and $F_{4,7,2} = 1$. With this definition of F (and accordingly defined $\tilde{F}$), we can define a stronger decoder:

$$P(\mathbf{y}|\mathbf{x},\tilde{F},\tilde{R}) = \prod_{i=1}^{l}\sum_{j,k,u} P(\mathbf{y}_i|\mathbf{x}_j,u)\tilde{F}_{j,k,u}\tilde{R}_{k,i}$$

where we now additionally marginalise over which copy of the input sequence we are translating.

5 Fertility and Alignment

In this section we describe how to compute $\tilde{F} = \mathbb{E}_{P(F|\mathbf{x},l)}F$, i.e. the expected alignment that results from the fertility step given that the intermediate token sequence will have length l.

In the previous section, we looked at the fertility step mostly from the perspective of an alignment between the input tokens and the intermediate tokens. However, the fertility step is *parameterised* as assigning a fertility value $f_i \in 0,\ldots,d \in \mathbb{N}$ to every token x_i. We now show how to compute $\tilde{F}$ efficiently as a function of the distribution over fertility values $P(\mathbf{f}|\mathbf{x})$.

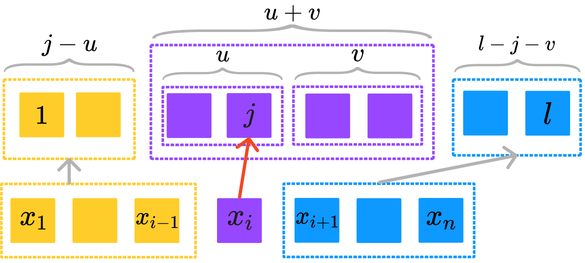

Figure 2: Efficiently computing the marginal probability that the u-th copy of i is at position j. We partition the intermediate sequence into four parts, and marginalise over all possible ways of choosing v.

We denote the alignment that follows from $\mathbf{f}$ as $F(\mathbf{f})$, i.e. $F(\mathbf{f})_{i,j,u} = 1$ iff intermediate token j is the u-th copy of token i. $\tilde{F}$ can be expressed as:

$$\tilde{F} = \mathbb{E}_{P(F(\mathbf{f})|\mathbf{x},l)}F(\mathbf{f}) \tag{5}$$

where we assume that the fertility values are independent of each other conditioned on $\mathbf{x}$:

$$P(F(\mathbf{f})|\mathbf{x}) \triangleq P(\mathbf{f}|\mathbf{x}) \triangleq \prod_{i=1}^{n} P(f_i|\mathbf{x})$$

Note that conditioning on the output length l in Eq. (5) introduces inter-dependencies between the values. In order to compute $\tilde{F}_{i,j,u}$, we need to marginalise over all possible assignments to the fertility vector $\mathbf{f}$ which satisfy $F(\mathbf{f})_{i,j,u} = 1$. We do this with a dynamic programming algorithm that is similar to the forward/backward algorithm for HMMs (Baum, 1972).

Computing marginals We characterise the situations where $F(\mathbf{f})_{i,j,u} = 1$ as the integer solutions to a set of equations (see also Fig. 2). First, in order for intermediate token j to be the u-th copy of i, there should be $j-u$ intermediate tokens generated by input tokens preceding i:

$$f_1 + \ldots + f_{i-1} = j - u \tag{6}$$

Second, the fertility f_i has to be at least u. We capture this by requiring

$$f_i = u + v \tag{7}$$

with $v \geq 0$. Finally, the input tokens following i have to contribute the remaining $l-j-v$ intermediate tokens:

$$f_{i+1} + \ldots + f_n = l - j - v \tag{8}$$

We then compute the probability of creating a sequence of length l, where the j-th intermediate token is the u-th copy of i, by marginalising over v (dropping $\mathbf{x}$ for readability):

$$P(F(\mathbf{f})_{i,j,u} = 1, f_0 + \ldots + f_{n+1} = l) \tag{9}$$
$$= \sum_{v=0}^{\min(l-j,d-u)} P(f_0 + \ldots + f_{i-1} = j - u) \times$$
$$P(f_i = u + v) P(f_{i+1} + \ldots + f_{n+1} = l - j - v)$$

We handle the boundary cases with $i = 1, i = n$ by adding dummy variables f_0 and f_{n+1} and setting $P(f_0 = 0) = P(f_{n+1} = 0) = 1$.

In order to compute Eq. (9), we also compute 'forward' probabilities $P(f_0 + \ldots + f_i = h)$ and 'backward' probabilities $P(f_i + \ldots + f_{n+1} = h)$ for all i, h. This can be done recursively:

$$P(f_0 + \ldots + f_i = h) =$$
$$\sum_{r=0}^{d} P(f_i = r) P(f_0 + \ldots + f_{i-1} = h - r)$$

Finally, $\tilde{F}_{i,j,u} = 1/P(f_0 + \ldots + f_{n+1} = l) \times P(F(\mathbf{f})_{i,j,u} = 1, f_0 + \ldots + f_{n+1} = l)$ because $\tilde{F}_{i,j,u}$ was defined in Eq. (5) by conditioning on the length l. We provide pseudo-code for all steps in Appendix A.

Runtime The runtime of the fertility step is dominated by computing Eq. (9). Note that v has a range of at most d, thus, we can compute the probabilities for all i, j, u in $O(n \cdot l \cdot d^2)$ time. Eq. (9) can be computed in parallel for each i, j, u.

6 Composing Fertility and Reordering

We will now describe in detail how $P(F|\mathbf{x})$ and $P(R|\mathbf{x}, \tilde{F})$ are defined and how the fertility and reordering layers are composed.

6.1 Fertility Layer

The fertility layer takes a desired output length l and a sequence of vectors $\mathbf{x}_1, \ldots, \mathbf{x}_n$ as input (GloVe embeddings (Pennington et al., 2014) in our case) and returns a marginal alignment $\tilde{F}$ (see Section 5) and a sequence of vectors $\mathbf{h}_1, \ldots, \mathbf{h}_l$ for use as input to the next layer. We compute the distribution over fertilities by first encoding $\mathbf{x}_1, \ldots, \mathbf{x_n}$ with a bidirectional LSTM, yielding a sequence of hidden states $\mathbf{h}^f_1, \ldots, \mathbf{h}^f_n$. We then model $P(f_i|\mathbf{x}) = \text{softmax}_\tau(\text{MLP}^f(\mathbf{h}^f_i))$, where τ is the temperature parameter of the softmax.

We use $\tilde{F}$ (Eq. (5)) as a form of structured attention to compute the input to the reordering layer:

$$\mathbf{h}_j = \sum_{i,u} \tilde{F}_{i,j,u}(\mathbf{x}_i + \mathbf{w}_u)$$

where $\mathbf{w}_u$ is a learned embedding indicating that j is a u-th copy of some token. Intuitively, $\mathbf{h}_j$ for an intermediate token j represents the corresponding token in the input sequence and also indicates *which* copy of that token it is.

6.2 Reordering Layer

Given the output $\mathbf{h}_1, \ldots, \mathbf{h}_l$ from the fertility layer, the reordering layer computes the alignment distribution $\tilde{R}$ as the expected permutation following Wang et al. (2021). This procedure involves populating a CYK-style chart with scores. We first run a bidirectional LSTM with a skip connection over $\mathbf{h}$ and compute a contextualised representation of the tokens after the fertility step:

$$\mathbf{h}^r_i = [\text{LSTM}^r(\mathbf{h}_{\leq i}), \text{LSTM}^r(\mathbf{h}_{\geq i})] + \mathbf{h}_i$$

Based on these representations, we compute scores for the chart following Stern et al. (2017).

6.3 Decoder

Our decoder factors as follows (see Section 4):

$$P(\mathbf{y}|\mathbf{x}, \tilde{R}, \tilde{F}) = \prod_{i=1}^{l} \underbrace{\sum_{j,k,u} P(\mathbf{y}_i|\mathbf{x}_j, u) \tilde{F}_{j,k,u} \tilde{R}_{k,i}}_{P(\mathbf{y}_i|\mathbf{x}, \tilde{R}, \tilde{F})}$$

$P(\mathbf{y}_i|\mathbf{x}_j, u)$ conditions only on the original input token and on the index indicating which copy of this token we are translating. For this reason, we contextualise the *input* with a bidirectional LSTM with a skip connection:

$$\mathbf{h}'_j = \rho[\text{LSTM}^d(\mathbf{x}_{\leq j}), \text{LSTM}^d(\mathbf{x}_{\geq j})] + \mathbf{x}_j \tag{10}$$

with ρ as hyperparameter.

We experiment with three versions of the decoder. In (i), we parameterise $P(\mathbf{y}_i|\mathbf{x}_j, u)$ as $P(\mathbf{y}_i|\mathbf{x}_j, u) = \text{softmax}(W_u\text{MLP}(\mathbf{h}'_j))$. In (ii), we additionally use a copy mechanism (Gu et al., 2016). In (iii), we use an autoregressive variant where we encode $\mathbf{y}_{<i}$ with an LSTM, defining $P(\mathbf{y}_i|\mathbf{y}_{<i}, u) = \text{softmax}(W_u\text{MLP}(\mathbf{h}'_j + \text{LSTM}(\mathbf{y}_{<i}))$.

6.4 Training

As mentioned in Section 4, at training time we condition on the observed length l of $\mathbf{y}$: $P(\mathbf{y}|\mathbf{x}) = P(l|\mathbf{x})P(\mathbf{y}|\mathbf{x}, \tilde{F}, \tilde{R})$ with $\tilde{F}$ conditioned on l. We use a weighted version of the log likelihood as the objective function:

$$\sum_i \lambda_1 \log P(l^i|\mathbf{x}^i) + \log P(\mathbf{y}^i|\mathbf{x}^i, l^i)$$

with i ranging over the training examples.

For the semantic parsing tasks, we found it necessary to give our model a reasonable starting point in terms of alignments. We encourage it to respect high-confidence automatic alignments during the first m training epochs by adding the following term to our objective function:

$$\lambda_2 \sum_{(i,j)\in\mathcal{A}} \log \sum_{k,u} \tilde{F}_{i,k,u}\tilde{R}_{k,j}$$

where $\mathcal{A}$ is the set of alignments with a posterior probability of at least χ according to an IBM-1 alignment model (Brown et al., 1993).

Initialising an alignment model with alignments from a simpler model was a common strategy in statistical machine translation (Och and Ney, 2003).

6.5 Inference

In order to make predictions with a trained model, we want to compute the most likely output $\mathbf{y}$ given the input $\mathbf{x}$. It is convenient to treat the length as a discrete variable and use the same algorithm for computing $\tilde{F}$ as derived for training. We therefore search for $\arg\max_{\mathbf{y}} P(\mathbf{y}|\mathbf{x}) = \arg\max_l P(l|\mathbf{x})P(\mathbf{y}^l|\mathbf{x}, l)$ with $\mathbf{y}^l = \arg\max_{\mathbf{y}} P(\mathbf{y}|\mathbf{x}, \tilde{F}, \tilde{R})$. For any given l we can easily find $\mathbf{y}^l$ in versions (i) and (ii) of the decoder:

$$\mathbf{y}_i^l = \arg\max_{\mathbf{y}_i} P(\mathbf{y}_i|\mathbf{x}, \tilde{R}, \tilde{F})$$

For version (iii) of the decoder, we use greedy search instead. It would be too costly to compute $\mathbf{y}^l$ for all l, so we explore only the top k most likely lengths.

Grammar-based decoding In executable semantic parsing, we want to produce only well-formed outputs, which can be characterised by a context-free grammar G. In practical applications, this grammar is needed to execute the query, so there is little extra engineering effort in using it for decoding. We search for

$$\mathbf{y}^l = \arg\max_{\mathbf{y}\in L(G)} P(\mathbf{y}|\mathbf{x}, l)$$

Because of the simple decoder we can do this exactly by applying a modified version of Viterbi CYK. Unlike in parsing though, the string is not observed because it is exactly what we are looking for. Therefore, we fill all entries from i to i in the chart C with $C_{A,i,i} = \max_{A\to a\in G} P(y_i = a|\mathbf{x}, \tilde{R}, \tilde{F})$. We then continue with the normal Viterbi CYK with weights of 1 on all other rules.

7 Evaluation

7.1 Synthetic Data

In order to probe the expressive capacity and inductive bias of our model, we evaluate on mirroring task $T = \{(w, ww^R)|w \in \Sigma^*\}$, e.g. $abc \to abccba$. The challenge is that the length of the dependency between output tokens grows with the length of the example. Models are trained on examples with input lengths 3 to 9, and tested in two setups. In the first setup (Length), the model has to generalise to examples with lengths 11 to 20; we use examples with length 10 as validation data. In the second setup (unseen combination, UC), the model only sees the symbols `x`, `y` and `z` grouped together as `xyz` on the input side at training time. The model is tested on examples that contain `x`, `y` or `z` adjacent to other symbols. See Appendix B.1 for further details on the setup.

We compare our model without copying (F→R) with a variant that first applies the reordering and then the fertility step (R→F) and autoregressive variants of the two (AR F→R and AR R→F). As baselines, we also compare with an LSTM-based seq2seq model with attention and a Transformer with relative positional embeddings, which was previously shown by Csordás et al. (2021) to perform well at compositional generalisation. AR R→F has similarities to Wang et al. (2021) who first reorder and then use an autoregressive decoder with monotonic attention.

Results Table 1 shows mean accuracy across 5 random initialisations. The accuracy of the relative Transformer and the LSTM-based seq2seq model drops sharply for longer inputs. In contrast, F→R and AR F→R generalise perfectly even to much longer examples. In the UC setup, F→R outperforms the rest by a wide margin. Interestingly, all

Model	Accuracy					
		Length				UC
	dev	11	12	13	14 - 20	test
Transformer	82.0	3.0	0.0	0.0	0.0	42.0
LSTM	**100.0**	94.3	67.9	6.9	0.0	0.1
R→F	0.0	0.0	0.0	0.0	0.0	1.3
AR R→F	90.0	85.7	89.8	87.5	80.5	1.2
F→R	**100.0**	**100.0**	**100.0**	**100.0**	**100.0**	**79.9**
AR F→R	**100.0**	**100.0**	**100.0**	**100.0**	**100.0**	32.1

Table 1: Exact match accuracy on the mirroring task.

autoregressive models struggle in this setup, including AR F→R which obtained perfect accuracy in the Length setup. This is consistent with the hypothesis that autoregressive models tend to memorise entire chunks (Hupkes et al., 2020).

Expressivity of F→R and R→F For this task, an input token corresponds to two output tokens that may be arbitrarily far apart from each other. F→R can learn this alignment because this can be captured by a separable permutation (see Section 3.2) following the fertility step duplicating every input token. In contrast, R→F and AR R→F cannot represent the correct alignment directly because the fertility step is applied only after the reordering, leading to alignments between an input token and a *contiguous span* in the output. However, in theory, they can represent this alignment *implicitly* through the LSTM (Eq. (10)). The evaluation shows that this does not work reliably in practice: we find that R→F gets stuck in bad local minima and fails completely on the task. While AR R→F performs well in the Length setup, it is weak in the UC setup.

7.2 Geoquery

Geoquery (Zelle and Mooney, 1996) is a standard dataset for semantic parsing and has recently been used to evaluate to what extent semantic parsers are capable of generalising to (i) structurally unseen queries (template split), and (ii) structurally unseen long examples. We follow the setup of Herzig and Berant (2021), using the variable-free FunQL representation (Kate et al., 2005), a copy mechanism, and evaluate with execution accuracy.

Model	iid	Template	Length
Seq2Seq ‡ (HB)	78.5	46.0	24.3
Seq2Derivation (HB)	72.1	54.0	24.6
BART-base‡ (HB)	87.1	67.0	19.3
Span (HB)	78.9	65.9	41.4
Span + lexicon (HB)	86.1	82.2	63.6
Liu et al. (2021)‡	-	**84.1**	-
Wang et al. (2021)‡	75.2*	43.2*	-
R→F	**89.1**±1.0	80.4±1.2	68.6±1.4
R→F ‡	83.5±0.7	73.0±1.6	49.2±5.1
F→R	88.6±3.3	79.9±2.5	**68.8**±5.2
F→R ‡	80.7±2.3	68.7±4.3	53.4±5.9
AR F→R ‡	81.1±1.0	52.8±3.3	37.6±1.8

Table 2: Accuracy on different splits of Geoquery. HB is Herzig and Berant (2021) and ‡ refers to systems that do not enforce well-formedness of the output. * Wang et al. (2021) use exact match accuracy and anonymise named entities instead of copying.

Results Table 2 shows the results on the different splits. We report means and standard deviations of 5 random initialisations. Our method performs well across the different splits, and in particular on the length split that evaluates a challenging form of compositional generalisation. As an ablation, we remove the grammar-based decoding. We notice a considerable drop in accuracy but it still outperforms the baselines. The drop in accuracy is slightly bigger out-of-distribution than in-distribution.

In line with the experiments on synthetic data, AR F→R and the approach of Wang et al. (2021) drastically lose accuracy when going from in-distribution to the compositional generalisation setups. This provides further evidence that a strong decoder can hinder compositional generalisation.

In contrast to the experiments on synthetic data, R→F and F→R perform comparably. Manual inspection of the data shows that good alignments on this dataset can be obtained even with the stronger assumption on possible alignments made by R→F.

7.3 ATIS

ATIS (Dahl et al., 1994) is a semantic parsing datasets for flight bookings. In comparison to Geoquery, the queries tend to be longer and the word order is more flexible. We use the variable-free FunQL notation as annotated by Guo et al. (2020). Apart from the original iid test split, we create a length split: Semantic parses with fewer than 4 conjuncts form the training set, parses with exactly 4 conjuncts form the development set and the test set contains instances with more than 4 conjuncts. Details on the split and preprocessing are in Appendix B.3.

We compare our model with finetuned BART-base (Lewis et al., 2020), an LSTM-based seq2seq model with attention and the relative Transformer

Model	iid	Length
LSTM seq2seq	76.52±1.66	4.95±2.16
LSTM seq2seq‡	75.98±1.30	4.95±2.16
Rel. Transformer‡	75.76±1.43	1.15±1.41
BART-base‡	**86.96**±1.26	19.03±4.57
F→R	74.15±1.35	**35.41**±4.09
F→R ‡	68.26±1.53	29.91±2.91

Table 3: Accuracy on different splits of ATIS.

Model	Calendar	Document	Email
BART-base‡	36.7±3.0	2.7±2.1	20.5±9.8
F→R	**69.5**±13.9	**42.4**±5.7	**55.6**±2.7
F→R ‡	57.2±19.9	36.1±5.6	43.9±3.8

Table 4: Accuracy on length splits by domain on Okapi.

(Csordás et al., 2021). We also run a version of the LSTM-based model with a large beam of size 50 and filter our instances that are not well-formed; the resulting outputs are well-formed at least 99.7% of the time.

Results Table 3 shows mean accuracy and standard deviations of 5 random initialisations. While on the iid split, our approach does not quite reach the same accuracy as the baselines, it outperforms them on the compositional length split by a margin of more than 16 points. Without grammar-based decoding, we again observe a noticeable loss in accuracy but we still substantially outperform BART on the length split. Constraining the output to be grammatical does not appear as beneficial for the LSTM baseline.

7.4 Okapi

Hosseini et al. (2021) introduce a semantic parsing dataset for evaluating compositional generalisation on three domains (document, calendar, email). Since template splits were not found to be challenging, we focus on generalising to longer examples. Models are trained on short examples with up to 3 'parameters' (such as filtering based on an attribute or ordering results) and are tested on examples with more parameters (at least 4 for the calendar and email domain and at least 5 for the document domain). The splits are described in Appendix B.4. In contrast to the other datasets we consider, Okapi is noisy because it was collected with crowd workers. This presents an additional challenge.

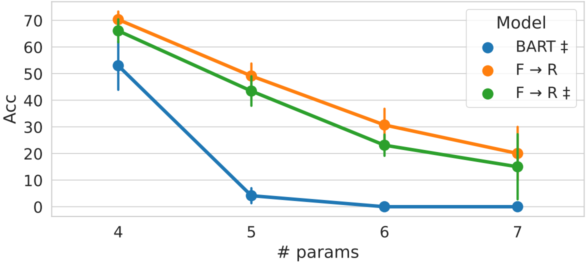

Figure 3: Accuracy on the document domain of Okapi by number of parameters in the gold logical form.

Results Table 4 shows the results of our model with copying from 5 random initialisations. F→R outperforms fine-tuned BART-base by a large margin, in particular on the challenging split of the document domain.

Fig. 3 shows the accuracy on the development and test set of the document domain as a function of the number of parameters in the gold logical form. BART performs relatively well when applied to examples with one more parameter than seen in the training set but then its performance drops sharply. F→R is more accurate and its accuracy also drops much slower with the number of parameters. We notice different failure modes for the two models: on the test set, BART deviates by 5.4 tokens on average from the gold length, whereas F→R deviates only by 1.0 tokens on average. This is in line with the observations of Newman et al. (2020) that seq2seq models systematically predict the end of sequence token too early on long out-of-distribution examples. Our results suggest that predicting length as a sum of fertilities is more robust towards this shift in distribution.

7.5 Style Transfer

In addition to being important for compositional generalisation, structural inductive biases can help when only little data is available. We evaluate our model in such a scenario on the style transfer tasks of Lyu et al. (2021). A model is given an English sentence and asked to reformulate it to conform with a certain 'style'. We focus on the tasks identified as challenging by Lyu et al. (2021): *active to passive* (2462 training examples), *adjective emphasis* (627 examples) and *verb emphasis* (1081 examples).

For the emphasis tasks, the word to be emphasised is provided in the input. Following Kim (2021), to incorporate it, we add a special learned embedding vector to the embedding of that token.

Transfer Type	Approach	BLEU-1	BLEU-2	BLEU-3	BLEU-4	METEOR	ROUGE-L	CIDEr
Active to passive	GPT-2 (Lyu et al., 2021)	47.6	32.9	23.8	18.9	21.6	46.4	1.820
	Seq2seq (Kim, 2021)	83.8	73.5	67.3	59.8	46.7	77.1	5.941
	Neural QCFG (Kim, 2021)	83.6	77.1	71.3	66.2	49.9	80.3	6.410
	Human (Lyu et al., 2021)	93.1	88.1	83.5	79.5	58.7	90.5	8.603
	F→R	**92.1**±1.3	**85.4**±1.5	**79.7**±1.7	**74.6**±1.9	**55.9**±0.5	**86.0**±1.1	**7.610**±0.130
Adj. emphasis	GPT-2 (Lyu et al., 2021)	26.3	7.9	2.8	0.0	11.2	18.8	0.386
	Seq2seq (Kim, 2021)	50.5	29.6	18.4	11.9	24.2	51.4	1.839
	Neural QCFG (Kim, 2021)	67.6	50.6	39.3	31.6	37.3	68.3	3.424
	Human	83.4	75.3	67.9	66.1	52.2	81.1	6.796
	F→R	**78.3**±1.4	**61.9**±0.7	**49.9**±1.3	**40.5**±1.4	**43.0**±1.0	**69.1**±0.6	**4.268**±0.170
Verb emphasis	GPT-2 (Lyu et al., 2021)	30.9	17.0	9.5	4.1	14.0	29.2	0.593
	Seq2seq (Kim, 2021)	52.6	38.9	29.4	21.4	29.4	46.4	2.346
	Neural QCFG (Kim, 2021)	66.4	51.2	40.7	31.9	37.0	**58.9**	3.227
	Human (Lyu et al., 2021)	64.9	56.9	49.3	42.1	43.3	69.3	5.668
	F→R	**68.4**±0.6	**52.7**±0.6	**41.6**±0.7	**32.8**±0.6	**37.4**±0.4	**58.9**±0.4	**3.498**±0.121

Table 5: Results on the hard style transfer tasks from Lyu et al. (2021). All models except for GPT2 use copying.

Results Table 5 shows the results comparing our F→R model to previous work based on three random initialisations. We achieve state-of-the-art results on all style transfer tasks on all metrics. The improvement compared to prior work is strongest for the active-to-passive task and weakest for the verb emphasis task, where our model ties with Kim (2021) in terms of ROUGE-L.

8 Conclusion

We presented a flexible end-to-end differentiable model for structured NLP tasks. It predicts the output sequence from the input by composing a fertility layer with a reordering layer. The evaluation shows that our model performs well in structural generalisation setups, in particular when the model has to generalise to longer examples than seen during training. In contrast, the accuracy of standard seq2seq models drops sharply on longer examples.

The efficient fertility layer introduced in this work may be useful in other scenarios as well, e.g. in non-autoregressive machine translation, or for (unsupervised) sentence compression when the fertility is restricted to 0 or 1. Future work could also investigate other structured layers and the best ways of composing and training them.

9 Limitations

The fertility layer is efficient but a limitation of the model presented in this paper is the high runtime complexity of the reordering layer. It makes it impractical for long output sequences (e.g. more than 50 tokens). While the structured reordering step can represent many permutations of practical interest, we observed a small number of cases where our model could not produce the correct permutation. We note that our approach is modular and the reordering layer could be replaced by a faster one with fewer restrictions in future work, e.g. based on one-to-one matchings.

While our method obtains strong accuracy in compositional generalisation setups without contextualised encoders, it remains an open question how different ways of integrating contextualised encoders affect the performance of our method in compositional generalisation setups. In addition, it is an open question how a *pretrained decoder* would influence our model's ability to generalise compositionally since we found that a non-pretrained LSTM-based decoder can be detrimental.

Algorithm 1 Forward

```
Require: f $\in \mathbb{R}^{n\times d}$, normalised over the second axis, output sequence length $l$
function FWD(f, $l$)
    Init fwd $\in \mathbb{R}^{n\times l}$ with zeros
    for $h$ in range(0, d) do                          ▷ Base case
        fwd[0, h] = f[0, h]
    for $i$ in range(1, n) do                          ▷ Recursion
        for $h$ in range(0, $l$) do
            for $r$ in range(0, min(d, h+1)) do
                fwd[i, h] += fwd[i-1, h-r] × f[i, r]
    return fwd
```

Algorithm 2 Marginals

```
Require: f $\in \mathbb{R}^{n\times d}$, normalised over the second axis, output sequence length $l$
function MARGINALS($f, l$)
    Init F $\in \mathbb{R}^{n\times l\times d}$ with zeros
    fwd = fwd(f, $l$)
    bwd = rev(fwd(rev(f),$l$))
    for $i$ in range(0, n-1) do
        for $j$ in range(0, $l$) do
            for $u$ in range(1, min(d, j+1+1)) do
                for $v$ in range(0, min(d-u, $l$-j)) do
                    F[i, j, u] += fwd[i, j+1-r1] ×
                        f[i,u+v]×bwd[i+1,$l$-(j+1+v)]
    divide all entries in F by fwd[i, $l$]
    return F
```

A Pseudo code

We present the algorithms for computing $\tilde{F}$ in python-style pseudo code, using 0-based indexing and `range(i,k)` refers to the integers $i, \dots, k-1$. As in the main paper, d refers to the maximum fertility value (hyperparameter).

Algorithm 1 shows how to compute all forward probabilities. If `rev(f)` reverses matrix `f` on the first dimension (e.g. like `torch.flip`), then we can compute the backward probabilities as `rev(fwd(rev(f), l))`. Algorithm 2 shows how $\tilde{F}$ can be computed.

B Data, grammars, pre- and post-processing

B.1 Synthetic data

In both setups, we generate 4000 training examples, 200 development examples and 1000 test examples. We use an alphabet size of $|\Sigma| = 11$ for the Length setup and $|\Sigma| = 11 + 3$ for the UC setup to accommodate for `x,y,z`. Symbols are chosen uniformly at random. In the Length setup, we choose the length of the example uniformly at random. In the UC setup, we do so as well but with probability 0.2 we insert an `xyz` cluster if this does not exceed the maximum length.

In the UC setup, we use development data from the training distribution.

We do not use grammar-based decoding or copying on the synthetic data.

B.2 Geoquery

We remove all parentheses in the logical forms, as they can be restored in post-processing. We also remove quotes around named entities in preprocessing to enable copying (`'texas'` becomes `texas`) and restore them in post-processing. Following Herzig and Berant (2021), we only allow copying of named entities and do not copy predicate symbols (e.g. `river`).

We use the grammar of Wong and Mooney (2006) for decoding as provided by Guo et al. (2020).

B.3 ATIS

We found that a naive length split led to having very few examples in the training set that used a date since both the month and the day count as one conjunct each. Therefore, we created 33 templates with three conjuncts based on existing ATIS examples (with four or more conjuncts) that contain dates and add 8 instances of each template with randomly chosen dates to the training set. In addition, we removed any exact duplicate samples from the data.

Similarly to Geoquery, we remove those parentheses that can be deterministically recovered in post-processing. However, in contrast to Geoquery the parentheses for `or` and `intersection` need to be kept because the arities of those operators are not fixed. We run all our experiments on this representation of ATIS.

For grammar-based decoding we use the “typed" grammar provided by Guo et al. (2020) and do not use the copy mechanism.

B.4 Okapi

We found there was too much distributional overlap in the original length split provided by Hosseini et al. (2021) and therefore use our own split:

For the document domain, our development set contains examples with 4 parameters, and the test

Dataset	Split/Version	Train	Dev	Test
Geoquery	iid	540	60	280
	template	544	60	276
	length	540	60	280
ATIS	iid	4465	497	448
	length	4017	942	331
Okapi/length	Calendar	1145	200	1061
	Document	2328	412	514
	Email	2343	200	991
Style transfer	active to passive	2462	136	137
	adjective emphasis	627	34	35
	verb emphasis	1081	60	60

Table 6: Number of examples per dataset/split.

set contains examples with at least 5 parameters. For the other two domains, there is insufficient data for such out-of-distribution development sets. Therefore, we chose our test set to contain all examples with at least 4 parameters and our development sets to consist of 95% in-distribution data and 5% of examples from the the examples with 4 parameters (which makes the bulk of the test distribution).

We manually create a grammar of well-formed logical forms for the three domains of Okapi (included in the code).

B.5 StylePTB

For comparability, we also tokenise on whitespace following Kim (2021). We do not restrict the output of the model with a grammar.

C Details on evaluation metrics

We provide code for all evaluation metrics in our repository/dependencies.

Geoquery We use the code of Herzig and Berant (2021) to compute execution accuracy (`https://github.com/jonathanherzig/span-based-sp`).

ATIS We allow for different order of conjuncts between system output and gold parse in computing accuracy. We do this by sorting conjuncts before comparing two trees node by node.

Okapi We follow Hosseini et al. (2021) and disregard the order of the parameters for computing accuracy. Since Hosseini et al. (2021) did not make their evaluation code publicly available, we use our own implementation. Our implementation uses sets and does not punish a model for predicting a correct parameter multiple times. For example, if the gold logical form contains `FILTER message.isRead eq False`, a necessary condition for a prediction to count as correct is that it must contain this string *at least* once.

StylePTB We follow Kim (2021) and use `https://github.com/Maluuba/nlg-eval` (commit `7f79930`) for all evaluation metrics, ensuring that BLEU, ROUGE and METEOR are scaled to 0 - 100.

D Hyperparameters

We provide a configuration file for each of our models with the chosen hyperparameters in our code repository (`configs/`). We set the maximum fertility value d to $d = 4$ for all datasets except for the style transfer tasks where we set it to $d = 3$.

At test time, we explore the top $k = 5$ most likely lengths when using grammar-based decoding. Without grammar-based decoding we used $k = 1$ as using $k = 5$ provided little improvement.

Many but not all instances of Geoquery require identity permutations. We found this to lead to the issue that the model gets stuck in a very steep local minimum within the first epoch where it would predict only identity permutations. We fixed this issue by reducing the learning rate in the feedforward network that predicts the scores for the permutation trees to 1×10^{-6}.

D.1 Hyperparameter selection

We select hyperparameters using a combination of manual selection and a random search. We optimise hyperparameters for accuracy on the development set of compositional generalisation splits, where available, (Length setup for the synthetic data, template split for Geoquery), and then use those hyperparameters for all splits of a (domain of a) dataset.

The high variance in accuracy across random initialisations often observed in compositional generalisation setups makes it difficult to tune hyperparameters even if an out-of-distribution development set exists. We restrict random hyperparameter search to two random seeds. After the hyperparameter search, we pick the two most promising configurations (according to (execution) accuracy), pick a new random seed and train them again to choose the one which provides the most stable accuracy (approximated as the highest accuracy on the new seed). We then run the main experiments

Dataset	Model	# params
Mirror	F→R and R→F	1.019
	AR F→R and AR R→F	1.12
	LSTM	3.187
	Transformer	33.067
Geoquery	F→R and R→F	2.541
	AR F→R	2.765
ATIS	LSTM	4.669
	Transformer	58.468
	F→R	3.511
Okapi/Calendar	F→R	2.466
Okapi/Document	F→R	2.468
Okapi/Email	F→R	2.485
Style/Active to passive	F→R	2.814
Style/Adjective emphasis	F→R	2.698
Style/Verb emphasis	F→R	3.133

Table 7: Number of parameters in millions in our models.

with the chosen hyperparameters and completely new random seeds.

We randomly sample 20 configurations per hyperparameter search. Since this procedure is expensive, we do not run train our models fully to convergence. The bounds of the hyperparameter search are reported in our repository.

For all our models, we initially chose hyperparameters manually, and then ran a random hyperparameter search as described above. If the manually chosen hyperparameters resulted in same or better performance (on the development set) on average, we kept those, and otherwise used the ones found by the hyperparameter search.

For example, on Geoquery, we noticed a particular sensitivity to hyperparameters, and the manually selected hyperparameters for F→R performed best with low variance, whereas for R→F, the hyperparameters found by the random search were better than the manually chosen ones. We think this sensitivity is at least in part caused by the small size of the dataset.

Style transfer In contrast to the other tasks we evaluate on, we did not run a hyperparameter search for the style transfer tasks and use the same manually determined hyperparameters for F→R across all style transfer tasks.

E Computing infrastructure and runtime

All experiments were run on GeForce GTX 1080 Ti or GeForce GTX 2080 Ti with 12GB RAM and Intel Xeon Silver or Xeon E5 CPUs.

The runtime of one run contains the time for training, evaluation on the devset after each epoch and running the model on the test set. We show the runtime the models we train in Table 8.

Dataset	Model	Epochs	Runtime
Mirror	F→R	7	8 min
	R→F	20	8 min
	AR F→R	20	30 min
	AR R→F	20	20 min
	Transformer	200	15 min
	LSTM	60	4 min
Geo	F→R	100	20 min
ATIS	F→R	100	11-12h
	Transformer	20	10 min
	LSTM	20	10 min
	BART	50	1.3h
Okapi / Calendar	F→R	70	1 h
	BART	40	15 min
Okapi / Document	F→R	70	1.5 h
	BART	60	30 min
Okapi / Email	F→R	70	1.5 h
	BART	40	30 min
Active → Passive	F→R	60	1 h
Adj. emphasis	F→R	60	20 min
Verb emphasis	F→R	60	30 min

Table 8: Average total runtime of the models we train. For comparison on Geoquery, Herzig and Berant (2021) report a runtime of 2 hours on comparable hardware to ours.

F Additional results

Geoquery Table 10 shows *exact match* accuracy of our models for comparison and Table 11 shows results on the development set.

ATIS Table 13 shows results on the development set. Table 12 shows the average deviation from the gold length.

Okapi Table 14 shows results on the development set.

StylePTB Table 9 shows results on the development set.

Transfer Type	BLEU-1	BLEU-2	BLEU-3	BLEU-4	METEOR	ROUGE-L	CIDEr

Investigating Multi-source Active Learning for Natural Language Inference

Ard Snijders[1] **Douwe Kiela**[2] **Katerina Margatina**[3]
[1]University of Amsterdam [2]Stanford University [3]University of Sheffield
`ardsnijders@gmail.com`

Abstract

In recent years, active learning has been successfully applied to an array of NLP tasks. However, prior work often assumes that training and test data are drawn from the same distribution. This is problematic, as in real-life settings data may stem from several sources of varying relevance and quality. We show that four popular active learning schemes fail to outperform random selection when applied to unlabelled pools comprised of *multiple* data sources on the task of natural language inference. We reveal that uncertainty-based strategies perform poorly due to the acquisition of collective outliers, i.e., hard-to-learn instances that hamper learning and generalization. When outliers are removed, strategies are found to recover and outperform random baselines. In further analysis, we find that collective outliers vary in form between sources, and show that hard-to-learn data is not always categorically harmful. Lastly, we leverage dataset cartography to introduce difficulty-stratified testing and find that different strategies are affected differently by example learnability and difficulty.

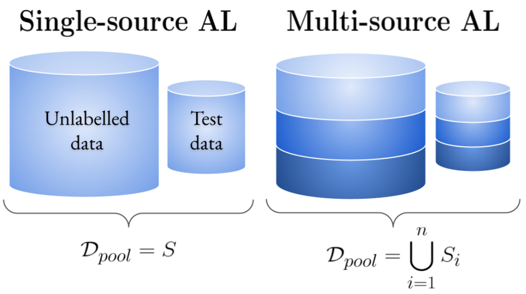

Figure 1: The pool of unlabelled data consists of a source S, or multiple sources $\bigcup_i S_i$, for the *single-source* and *multi-source* AL setting, respectively. The in-domain test set follows the same distribution of sources.

1 Introduction

In recent years, active learning (AL) (Cohn et al., 1996) has emerged as a promising avenue for data-efficient supervised learning (Zhang et al., 2022). AL has been successfully applied to a variety of NLP tasks, such as text classification (Zhang et al., 2016; Siddhant and Lipton, 2018; Prabhu et al., 2019; Ein-Dor et al., 2020; Margatina et al., 2022), entity recognition (Shen et al., 2017; Siddhant and Lipton, 2018; Lowell et al., 2019), part-of-speech tagging (Chaudhary et al., 2021) and neural machine translation (Peris and Casacuberta, 2018; Liu et al., 2018; Zhao et al., 2020).

However, these works share a major limitation: they often implicitly assume that unlabelled training data comes from a single *source*[1] (Houlsby et al., 2011; Sener and Savarese, 2018; Huang et al., 2016; Gissin and Shalev-Shwartz, 2019; Margatina et al., 2021). We refer to this setting as *single-source AL*. The single-source assumption is problematic for various reasons (Kirsch et al., 2021). In real-life settings we have no guarantees that all unlabelled data at our disposal will necessarily stem from the same distribution, nor will we have assurances that all examples are of consistent quality, or that they bear sufficient relevancy to our task. For instance, quality issues may arise when unlabelled data is collected through noisy processes with limited room for monitoring individual samples, such as web-crawling (Kreutzer et al., 2022). Alternatively, one may have access to *several* sources of unlabelled data of decent quality, but incomplete knowledge of their relevance to the task-at-hand. For instance, medical data may be collected from various different physical sites (hospitals, clinics, general practitioners) which may differ statistically from the targte distribution due to e.g. differences in patient demographics. Ideally, AL methods should be robust towards these conditions in order to achieve adequate solutions.

---

[1] Throughout the paper, we use the term "*source*" to describe the varying domains of the textual data that we use in our experiments. More broadly, "different sources" refers to having data drawn from different distributions.

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2187–2209
May 2-6, 2023 ©2023 Association for Computational Linguistics

In this work, we study whether existing AL methods can adequately select relevant data points in a *multi-source scenario* for NLP. We examine robustness by evaluating AL performance in both in-domain (ID) and out-of-domain (OOD) settings, while we also conduct an extensive analysis to interpret our findings. A primary phenomenon of interest here concerns *collective outliers*: data points which models struggle to learn due to high ambiguity, the requirement of specialist skills or labelling errors (Han and Kamber, 2000). While such outliers were previously found to disrupt several AL methods for visual question answering (Karamcheti et al., 2021), their impact on text-based tasks remains under-explored. Given the wide body of work on the noise and biases that pervade NLI (Bowman et al., 2015; Williams et al., 2017; Gururangan et al., 2018; Poliak et al., 2018; Tsuchiya, 2018; Geva et al., 2019; Liu et al., 2022), we may reasonably assume popular NLI datasets to suffer from collective outliers as well.

Concretely, our contributions can be summarised as follows: **(1)** We apply several popular AL methods in the under-explored multi-source, pool-based setting on the task of NLI, using RoBERTa-large (Liu et al., 2020) as our acquisition model, and find that no strategy consistently outperforms random selection (§5). **(2)** We seek to explain our findings by creating datamaps to explore the actively acquired data (§6.1) and show that uncertainty-based acquisition functions perform poorly due to acquisition of collective outliers (§6.2). **(3)** We examine the effect of training data difficulty on downstream performance (§7.1) and after thorough experiments we find that uncertainty-based AL methods recover or even surpass random selection when hard-to-learn data points are removed from the pool (§7.2). **(4)** Finally, we introduce difficulty-stratified testing and show that the *learnability* of acquired training data affects different strategies differently at test-time (§7.3). Our code is publicly available at `https://github.com/asnijders/multi_source_AL`.

2 Related Work

Multi-source AL for NLP While AL has been studied for a variety of tasks in NLP (Siddhant and Lipton, 2018; Lowell et al., 2019; Ein-Dor et al., 2020; Shelmanov et al., 2021; Margatina et al., 2021; Yuan et al., 2022; Schröder et al., 2022; Margatina et al., 2022; Kirk et al., 2022; Zhang et al., 2022), the majority of work remains limited to settings where training data is assumed to stem from a single source. Some recent works have sought to address the issues that arise when relaxing the single-source assumption (Ghorbani et al., 2021; Kirsch et al., 2021; Kirsch and Gal, 2021), though results remain primarily limited to image classification. Moreover, these works study how AL fares under the presence of *corrupted* training data, such as duplicating images or adding Gaussian noise, and they do not consider settings where sampling from multiple sources may be *beneficial* due to complementary source attributes. He et al. (2021) examine a multi-domain AL setting, but they focus on leveraging common knowledge between domains to learn a *set* of models for a set of domains, which contrasts with our single-model pool-based setup. Closest to our work, Longpre et al. (2022) explore pool-based AL over multiple domains and find that some strategies consistently outperform random on question answering and sentiment analysis. However, the authors crucially omit a series of measurements, as they instead perform *a single AL iteration*, limiting the effectiveness of AL, while complicating comparison with our results.

Dataset Cartography Karamcheti et al. (2021) employ dataset cartography (Swayamdipta et al., 2020) and show that a series of AL algorithms fail to outperform random selection in visual question answering due to the presence of collective outliers. Zhang and Plank (2021) apply datamaps to AL and introduce the cartography active learning strategy, identifying that examples with poor learnability often suffer from label errors. Our work contrasts with both of these works in that we show that hard-to-learn data is not always unequivocally harmful to learning. Moreover, both works only examine learnability of *training* examples, whereas we also consider how learnability of acquired data affects model performance at test-time.

3 Single & Multi-source Active Learning

We assume a warm-start, pool-based AL scenario (Settles, 2010) with access to a pool of *unlabelled* training data, $\mathcal{D}_{pool}$, and a seed dataset of labelled examples, $\mathcal{D}_{train}$. During each iteration i of AL, we first train a model $\mathcal{M}$ with $\mathcal{D}_{train}$ and then use it in conjunction with some acquisition function $\mathcal{A}$ to select a new batch of unlabelled examples $\mathcal{D}_{batch}$ from $\mathcal{D}_{pool}$ for labelling. Upon labelling, these examples are removed from $\mathcal{D}_{pool}$

and added to $\mathcal{D}_{train}$, after which a new round of AL begins.

$$\mathcal{D}^{i+1}_{train} = \mathcal{D}^{i}_{train} \cup \mathcal{D}^{i+1}_{batch}$$
$$\mathcal{D}^{i+1}_{pool} = \mathcal{D}^{i}_{pool} \setminus \mathcal{D}^{i+1}_{batch}$$

Single-source AL For single-source AL, we assume that $\mathcal{D}_{pool}$ is a set of unlabelled data that stems from a single source S, i.e. $\mathcal{D}_{pool} = S$.

Multi-source AL For multi-source AL, we assume that $\mathcal{D}_{pool}$ comprises a union of distinct sources $S_1, S_2, ..., S_n$ such that $\mathcal{D}_{pool} = \bigcup_{i=1}^{n} S_i$.

3.1 Data Acquisition

An acquisition function $\mathcal{A}$ is responsible for selecting the most *informative* unlabelled data from the pool, aiming to improve over random sampling. We use a set of acquisition functions which we deem representative for the wider AL toolkit: Monte Carlo Dropout Max-Entropy, (**MCME**; Gal et al., 2017) is an uncertainty-based acquisition strategy where we take the mean label distribution over T Monte-Carlo dropout (Gal and Ghahramani, 2015) network samples and select the k data points with the highest predictive entropy. Bayesian Active Learning by Disagreement, (**BALD**; Houlsby et al., 2011) is an uncertainty-based acquisition strategy which employs Bayesian uncertainty to identify data points for which many models disagree about. Discriminative Active Learning (**DAL**; Gissin and Shalev-Shwartz, 2019) is a diversity-based acquisition function designed to acquire a training set that is indistinguishable from the unlabelled set.

3.2 Analysis of Acquired Data

At each data acquisition step, we seek to examine what kind of data each acquisition function has selected for annotation. Following standard practice in active learning literature (Zhdanov, 2019; Yuan et al., 2020; Ein-Dor et al., 2020; Margatina et al., 2021) we profile datasets acquired by strategies via acquisition metrics. Concretely, we consider the *input diversity* and *output uncertainty* metrics. We provide more details in Appendix A.1.

Input Diversity To evaluate the diversity of acquired sets in the input space, we follow Yuan et al. (2020) and measure input diversity as the Jaccard similarity between the set of tokens from the acquired training set $\mathcal{D}_{train}$ and the set of tokens from the *remainder* of the unlabelled pool $\mathcal{D}_{pool}$. This function assigns *high* diversity to strategies acquiring samples with *high* token overlap with the unlabelled pool, and vice versa.

Output Uncertainty To approximate the output uncertainty of an acquired training set $\mathcal{D}_{train}$ for a given strategy, we follow Yuan et al. (2020) and use a model trained on the *entire dataset* to compute predictive entropy of all the examples in the dataset that we want to examine. The model is trained on all training data as this grants more accurate uncertainty measurements.

4 Experimental Setup

Data We perform experiments on Natural Language Inference (NLI), a popular classification task to gauge a model's natural language understanding (Bowman et al., 2015). We construct the unlabelled pool from three distinct datasets: **SNLI** (Bowman et al., 2015), **ANLI** (Nie et al., 2019) and **WANLI** (Liu et al., 2022). We consider **MNLI** (Williams et al., 2017) as an out-of-domain set to evaluate the transferability of actively acquired training sets. For more details see Appendix A.2.

Experiments We apply AL with two distinct end-goals: **in-domain** (ID) generalization, where the same source(s) are used for both the unlabelled pool $\mathcal{D}_{pool}$ and the test set $\mathcal{D}_{test}$, and **out-of-domain** (OOD) generalization, where we evaluate on the test set of an external source of which no training data was present in the unlabelled pool.

Constructing multi-source pools For multi-source AL, the unlabelled pool comprises the *union* of the SNLI, ANLI and WANLI training sets. During model selection, we similarly assume the union of SNLI, ANLI and WANLI validation sets. For both training and validation data we down-sample sources to the minority source size to obtain pools with even shares per source. We sub-sample *training data* for each source to reduce experiment runtimes. This yields a pool of 60K unlabelled training examples comprised of 20K shares of each source.

AL Parameters We assume an initial seed training set of size $|\mathcal{D}^{i=0}_{train}| = 500$ and an acquisition size $k = 500$, such that k examples are acquired per round of AL. We perform 7 rounds of AL: the final actively acquired labelled dataset $\mathcal{D}^{i=7}_{train}$ comprises 4K examples. We run each experiment 5 times with different random seeds to account for stochasticity in parameter initializations.

5 Results

5.1 AL over single sources

We first provide single-source AL results in Figure 2. AL has mixed performance across sources; it fails to consistently outperform random selection on SNLI and WANLI, though most strategies tend to outperform random on ANLI. However, none of the strategies consistently outperform others across sources. Moreover, the extent of improvement over the acquisition phase varies between tasks; e.g., for SNLI, strategy curves are close and the accuracy improvement from 500 to 4K examples is small. This is also reflected in test outcomes (Table 1), with models performing similarly across sources.

Observing Table 2,[2] we find that uncertainty-based methods (BALD, MCME) tend to acquire the most uncertain data points, as expected. Still, differences between strategies are small for WANLI and ANLI. Conversely, RANDOM and DAL tend to acquire data with greater diversity in the input space, but again variance across methods is low. Here, observed homogeneity in the input space may explain why test outcomes lie closely together: if the acquired training sets per strategy are very similar, we should expect to see similarly small differences in test outcomes for models trained on them. Relating these outcomes to the per-source learning curves in Figure 2, however, we observe no clear relation between metric results and performance outcomes: *acquiring uncertain or diverse data does not seem to be predictive of AL success throughout the acquisition process.*

5.2 AL over multiple sources

Next, we provide the results of our multi-source setting, as described in §3, and observe that again AL fails to consistently outperform random sampling on the aggregate ID test set of SNLI, ANLI and WANLI (Figure 3, bottom left). We also evaluate on the OOD MNLI that was not present in the unlabelled training data (Figure 3, top left) and still find that *AL fails to outperform* RANDOM.

Analyzing the acquired data in terms of input diversity, uncertainty and label distributions (Table 2) There do not appear to be clear relations between metric outcomes and strategy *performance* other-

wise, i.e., acquiring diverse or uncertain batches does not seem to lead to higher performance.

6 Dataset Cartography for AL Diagnosis

Our findings in both single and multi-source AL settings, for both in-domain and out-of-domain evaluations, showed poor performance of all algorithms (§5). We therefore aim to investigate if the answer for the observed AL failure may lie in the presence of so-called *collective outliers*: examples that models find hard to learn as a result of factors, such as high ambiguity, underspecification, requirement of specialist skills or labelling errors (Han and Kamber, 2000). Collective outliers can be identified through dataset cartography (Swayamdipta et al., 2020), a post-hoc model-based diagnostic tool which plots training examples along a so-called *learnability spectrum*.

6.1 Creating Datamaps

Dataset Cartography assumes that the learnability of examples *relative* to some model can be quantified by leveraging *training dynamics*, where for each example we measure at fixed intervals (1) the mean model *confidence* for the gold-truth label throughout training and (2) the *variability* of this statistic. After gathering these statistics we can plot datasets on a **datamap**: a 2D graph with mean confidence on the Y-axis and confidence variability on the X-axis. The resulting figure enables us to identify how data is distributed along a *learnability spectrum* (see an example in Figure 4).

We construct datamaps by training a model on the entire pool, i.e. 60K examples in total. Every $\frac{1}{2}$ epoch we perform inference on the full training set to get per-example confidence statistics, where the prediction logit corresponding to the gold-truth label serves as a proxy for model confidence. Variability is computed as the standard deviation over the set of confidence measurements. Following Karamcheti et al. (2021), we classify examples along four difficulties via a threshold on the mean confidence value p (Figure 4). We provide more details in the Appendix A.5.

6.2 Strategy Maps for Multi-source AL

We show the datamaps for random sampling and the MCME acquisition functions on the multi-source AL setting in the top row of Figure 4 (see Appendix A.5 for all datamaps). Examining the first datamap, it appears that *randomly sampling from all sources in equal proportions tends to yield predominantly easy-to-learn instances*, with diminishing amounts of ambiguous and hard-to-learn instances. Conversely, we find that MCME acquires considerably more examples with moderate to low confidence, suggesting a *tendency to acquire hard and impossible examples*. Note that these outcomes mirror the findings by Karamcheti et al. (2021) for VQA. Observing the per-difficulty acquisition over time (Figure 4 bottom row), we observe that BALD

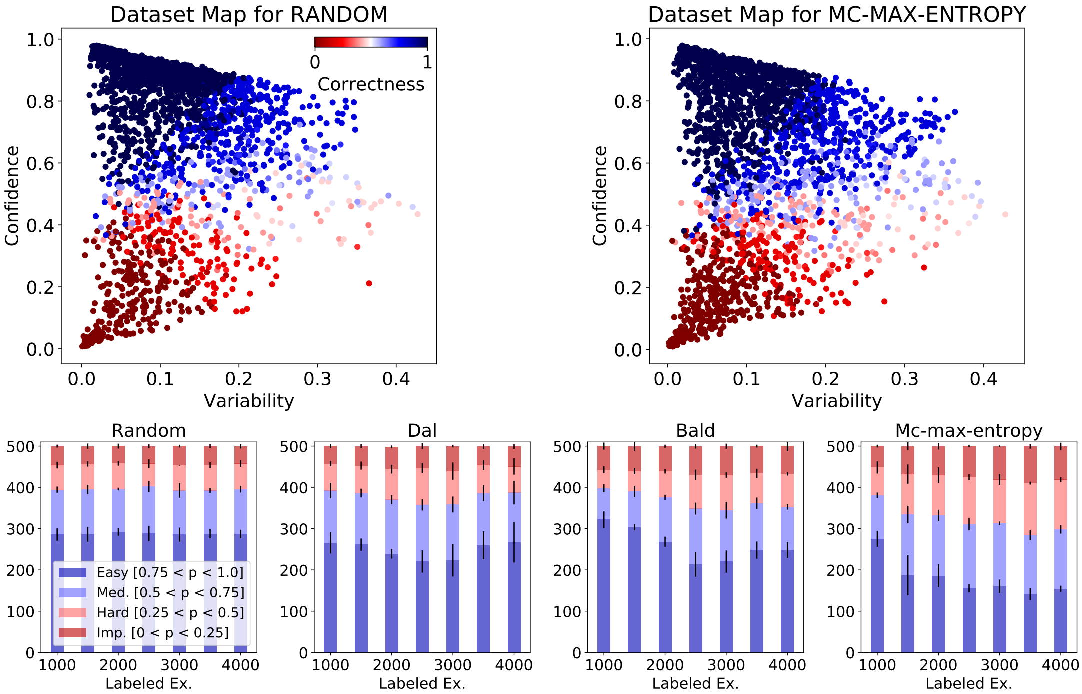

Figure 4: Top row: Strategy maps for RANDOM and MCME for **multi-source** AL. *Correctness* denotes how often the model predicts the correct label. Bottom row: Acquisition by difficulty over time for RANDOM, DAL, BALD and MCME. We provide additional datamap plots in the appendix (Section A.5).

and MCME *initially favour easy examples*, but as more examples are acquired, we observe a *shift towards medium, hard and impossible examples*. One explanation for these trends is that in early phases of AL, models have only been trained on small amounts of data. At this stage, model confidence is still poorly calibrated and consequently confidence values may be noisy proxies for uncertainty. As the training pool grows, model confidence will more accurately reflect example difficulty enabling uncertainty-based strategies to identify difficult data points.

7 Stratified Analysis on Data Difficulty

We begin our analysis of collective outliers by exploring impossible data points in the three NLI datasets we use; SNLI, ANLI and WANLI. We denote as impossible data points those that yield a confidence value in the range $0 \leq p \leq 0.25$ (§6.1). We provide some examples in Table 4 and in the Appendix A.7. We find that impossible examples from SNLI and WANLI are more prone to suffer from label errors and/or often lack a clear correct answer, which may explain their poor learnability. Conversely, we find impossible ANLI examples to exhibit fewer of these issues - we hypothesize that their difficulty follows rather from requirement of advanced inference types, e.g. identifying relevant information from long passages and numerical reasoning about dates of birth and events.

7.1 Examining the effect of training data difficulty

Now that we are able to classify training examples as easy, medium, hard and impossible (§6.2), we proceed to explore the effect of data difficulty on learning and per-source outcomes. In this set of experiments, we aim to answer the research question: *What data would the most beneficial training set consist of, in terms of data difficulty per example?* We conventionally (i.e., non-AL experiment) train RoBERTa-large on training sets of various difficulties. Each training set comprises 4K examples, i.e. the same amount of examples that would be acquired after all rounds of AL. We consider the following combinations of data: **EM**, **EMH**, **MH**, **HI** and **EMHI**, where **E** denotes *easy*, **M** *medium*, **H** *hard* and **I** *impossible* examples.[3]

---

[3] For a given run, examples are sampled from each difficulty in equal proportion. For instance, when training on the *easy-medium* (**EM**) split the training set comprises 2K easy-to-learn instances and 2K medium-to-learn instances.

Table 4: Impossible NLI training examples. **GT** denotes the gold truth label; **P** denotes the model prediction and **Conf.** denotes the prediction confidence. We provide more examples per source in the appendix (Section A.7).

Results We provide test results for all combinations of training data difficulty in Table 5. We first observe that models trained only on **HI** data consistently perform the worst, resulting in a drop of up to ~50%(!) points in accuracy compared to the **EM** split for SNLI and ~40% for MNLI. Surprisingly, we find that models trained on **MH** perform worse than splits that include *easy* examples, except for ANLI. Intuitively, this makes sense: of all datasets, ANLI features the most difficult examples, and thus it is plausible that hard-to-learn instances translate to more learning gains than easy ones. The **EMHI** split slightly underperforms relative to the **EM** and **EMH** splits. Otherwise, we do not observe great differences between the latter two splits. In the second part of Table 5, we compute the average performance for easy test sets (SNLI $\cup$ MNLI), hard (ANLI $\cup$ WANLI) and all test sets combined. We can now observe very clear patterns. The more difficult data points we include in the training set, the more the performance on an easy test set drops (AVG-EASY$\downarrow$). Similarly, when testing on a harder test set, the more difficult the training data the better (AVG-HARD$\downarrow$), but without including data points that are characterized as *impossible*. *Overall, we observe a strong correlation between training and test data difficulty, and we conclude that we should train models on data of the same difficulty as the test set, while always removing data points that are impossible to be learned from the model (i.e. collective outliers).*

7.2 Ablating Outliers for AL

Having uncovered the effects of data difficulty on learning outcomes, we now examine *how the presence or absence of hard and impossible instances affects AL strategy success*. Specifically, we repeat our multi-source AL experiment (§5.2) whilst excluding hard and impossible (**HI**) examples from $\mathcal{D}_{pool}$. Employing datamap statistics, we compute the product of an example's mean confidence and its variability for the entire unlabelled pool, after which we exclude the 25% of examples with the smallest products, following Karamcheti et al. (2021). Examples are filtered out for each source dataset separately to preserve equivalence in source sizes.

Results Examining the learning curves (Figure 3, right) and the final test results (Table 3, left), it appears that *excluding **HI** examples particularly affects the performance of uncertainty-based acquisition strategies* (MCME and BALD): across sources, both strategies do consistently *better*. Moreover, for ANLI, MCME clearly outperforms random selection and even achieves a higher accuracy compared to the non-ablated run. Similar results are obtained for the OOD MNLI dataset: *previously, none of the*

	SNLI	ANLI	WANLI	MNLI	AVG-EASY	AVG-HARD	AVG-ALL
EM	**85.95 $\pm$ 0.90**	36.85 $\pm$ 1.05	**68.34 $\pm$ 0.68**	**76.16 $\pm$ 2.32**	**81.06**	52.60	**66.83**
EMH	84.98 $\pm$ 0.56	37.84 $\pm$ 0.79	68.16 $\pm$ 0.66	75.50 $\pm$ 2.00	80.24	53.00	66.62
MH	76.32 $\pm$ 1.04	**39.11 $\pm$ 0.79**	63.56 $\pm$ 1.38	69.82 $\pm$ 6.10	73.07	**54.47**	62.20
HI	33.57 $\pm$ 1.60	34.00 $\pm$ 0.69	45.89 $\pm$ 3.85	32.69 $\pm$ 1.93	33.13	39.95	36.54
EMHI	79.12 $\pm$ 0.80	38.41 $\pm$ 0.57	64.52 $\pm$ 1.38	73.52 $\pm$ 0.07	76.32	51.47	63.89

Table 5: **Multi-source** test outcomes for training data of *varying difficulty*. Row headers denote difficulty splits, with **E** denoting *easy*, **M** *medium*, **H** *hard* and **I** *impossible* examples. Column headers denote the test set. We also compute the average over SNLI+MNLI (easy), ANLI+WANLI (hard) and all 4 datasets, respectively.

*strategies consistently outperformed random, but after ablating **HI** instances both* BALD *and* MCME *are either on par with random or outperform it.* Intuitively, under normal circumstances MCME and BALD tend to acquire more difficult examples than RANDOM or DAL, which typically leads to *poorer* models (§7.1). Therefore, we should expect to see *improvements* when these instances are ablated (i.e., removed).

7.3 Stratified Testing

Having established that some strategies acquire more hard and examples than others (§6.2), training on such examples can both hurt or help generalization (§7.1), and removal of this data can help strategies improve (§7.2), a question arises: Do strategies that predominantly acquire data of a certain difficulty also perform better on *test data* of that difficulty? To investigate this we introduce **stratified testing**: stratifying test outcomes *in terms of difficulty*. Here, we follow the approach as outlined in Section 6.1, but this time training a cartography model on the *test set* to obtain learnability measurements for each *test* example. This enables us to observe how strategies perform across test examples of varying difficulties.

Task	D	RANDOM	MCME	BALD	DAL
SNLI	**E**	95.4 | 95.0	95.0 | 93.3	95.5 | 94.8	93.7 | 94.6

Table 6: **Multi-source** strategy comparison (accuracy) for difficulty-stratified test outcomes between original training set and training set with hard-to-learn examples excluded. Test examples (D) belong to Easy (**E**), Medium (**M**), Hard (**H**) and Impossible (**I**) sets. Cell scheme to be read as *ablated* | *original*.

Results Table 6 shows the AL results for stratified testing for both *ablated* (i.e., **HI** removed) and the *original* setting. We observe in the pre-ablation experiments (right side) that RANDOM and DAL tend to do better on easy and medium data relative to MCME and BALD, while conversely they underperform when tested on hard and impossible examples. The same pattern also occurs also in the OOD setting (MNLI). In the ablation setting (left side), we find that across all sources, **HI** examples tends to yield a performance drop on hard and impossible examples for all strategies. Corroborating our previous analysis (§7.1), our findings here suggest that *it is essential to have data of the same difficulty in both unlabelled pool and in test set*. Next, we find that under ablation, RANDOM does moderately better on easy and medium, while DAL shows marginally lower test outcomes on medium and hard examples. For the uncertainty-based strategies, ablation tends to yield improvements across all difficulties, with MCME outperforming BALD on hard examples. We hypothesize that with **HI** instances absent, uncertainty-based methods select the "next-best" available data: medium examples which offer greater learning gains than easy ones. Overall, we find that post-ablation, BALD and MCME outperform both RANDOM and DAL across most difficulty splits.

8 Conclusion and Future Work

Our work highlights the challenge of successfully applying AL when the (training) pool comprises several sources which span various domains in the task of NLI. Similar to Karamcheti et al. (2021), we show that uncertainty-based strategies, such as MCME and BALD, perform poorly (§5) due to acquisition of collective outliers which impede successful learning (§6.2). However, these strategies recover when outliers are removed (§7.2). Practically, this suggests that uncertainty-based methods may fare well under more carefully curated datasets and labelling schemes, while alternative strategies (e.g. diversity-based) may be preferable in cases with poorer quality guarantees (e.g. data collection with limited budget for annotation verification). Next, we find that performance outcomes between strategies differ for test data of various difficulties (§7.3). On the one hand, this complicates strategy selection: it is unclear whether a strategy that performs well on hard data but poorer on easy data is preferable to a strategy with opposite properties. On the other hand, knowing which strategies work well for test data of a certain difficulty may be advantageous when the difficulty of the test set is known, in out-of-domain settings (Lalor et al., 2018).

Lastly, in contrast with Karamcheti et al. (2021) and Zhang and Plank (2021), we have shown that cases exist in which training examples in the hard-to-learn region do not hamper learning but are in fact pivotal for achieving good generalization (§7.1). Consequently, there may be value in refining existing cartography-based methods such that they can discriminate between useful and harmful hard-to-learn data. More broadly, our findings underscore the potential of understanding these phenomena for other NLP tasks and datasets.

Limitations

In our work, we have shown that standard AL algorithms struggle to outperform random selection in some datasets for the task of NLI, which is in fact rather surprising as a large body of work has shown positive AL results in a wide spectrum of NLP tasks. Still, we are not the first to show negative AL results in NLP, as Lowell et al. (2019); Karamcheti et al. (2021); Kees et al. (2021) have shown similar problematic behavior in the cases of text classification, visual question answering and argument mining, respectively.

More broadly, while AL outcomes have shown to not always reliably generalize across models and tasks (Lowell et al., 2019), we recognise that in our work several experimental conditions remain underexplored which warrant further attention. First, this work mostly examined point-wise acquisition functions; it remains unclear whether our outcomes hold for *batch-wise* functions. Similarly, it is unknown how the chosen model-in-the-loop affects strategy outcomes. We use RoBERTa-Large, a comparatively powerful large language model. Some authors hypothesize that as such models are already able to achieve great performance even with randomly labeled data, this could significantly raise the bar for AL algorithms to yield substantial performance improvements *on top* of a random selection baseline (Ein-Dor et al., 2020). Combined with the relative homogeneity of acquired batches between sources in terms of input diversity, this would explain why strategies tend to do similar across the board at test-time both in the presence and absence of hard-to-learn examples. Another factor tying into this is that small differences between results may be connected to the so-called inverse cold-start problem. This problem states that there may be cases where the initial seed set is too large, leaving comparatively little room for substantial improvements in sample efficiency. We leave further exploration of these variables to future work.

Another area within AL research which warrants further examination concerns the evaluation on out-of-domain datasets of which no data is present in the pool of unlabelled training data. Particularly, the majority of work typically assumes that acquisition is target-agnostic, i.e., target validation and test sets are assumed to be decoupled entirely from the acquisition process. This can be problematic as for different target sets, different subsets of the unlabelled training data may yield the best possible performance. Consequently, performance outcomes on *some* out-of-domain test data may not necessarily pose as reliable signals for determining the best strategy, for if a different target set had been chosen, a previously 'poor' performing strategy may suddenly achieve the best result. Despite this being a clear shortcoming of the existing AL toolkit, it remains an understudied area within AL research.

While this problem may be partially alleviated by evaluating strategies on a large and diverse array of target sets, the issue remains that current acquisition functions do not acquire data *with respect to the target set*. This problem becomes even more apparent in a *multi-source* setting, where depending on the target set at hand, acquiring data from the appropriate source(s) may be pivotal to achieve good performance. In such cases, we may want to explicitly regularise the acquisition process towards target-relevant training data. A small body of work has examined ways in which such target-aware acquisition could be formalized - most noticeably in the work of Kirsch et al. (2021), who introduce several methods to perform test-distribution aware active learning. While examination of such methods lies outside the scope of this work, we recognize its potential for future work on multi-source AL.

A Appendix

A.1 Analysis metrics

Following standard practice in active learning literature (Zhdanov, 2019; Yuan et al., 2020; Ein-Dor et al., 2020; Margatina et al., 2021) we profile datasets acquired by strategies via acquisition metrics. Concretely, we consider the *input diversity* and *output uncertainty* metrics.

Input Diversity Input diversity quantifies the diversity of acquired sets in the input space, meaning that it operates directly on the raw input passages. We follow (Yuan et al., 2020) and measure input diversity as the Jaccard similarity $\mathcal{J}$ between the set of tokens from the acquired training set $\mathcal{D}_{train}$, $\mathcal{V}$, and the set of tokens from the *remainder* of the unlabelled pool $\mathcal{D}_{pool}$, $\mathcal{V}\prime$, which yields:

$$\mathcal{J}(\mathcal{V}, \mathcal{V}\prime) = \frac{\mid \mathcal{V} \cap \mathcal{V}\prime \mid}{\mid \mathcal{V} \cup \mathcal{V}\prime \mid}$$

This function assigns *high* diversity to strategies acquiring samples with *high* token overlap with the unlabelled pool, and vice versa.

Output Uncertainty To approximate the output uncertainty of an acquired training set $\mathcal{D}_{train}$ for a given strategy, we train RoBERTa-large to convergence on the entire 60K training set. We then use the trained model to perform inference over $\mathcal{D}_{train}$. Following (Yuan et al., 2020), the output uncertainty of each strategy is computed as the mean predictive entropy over all examples x in its acquired set $\mathcal{D}_{train}$:

$$-\frac{1}{|\mathcal{D}_{train}|} \sum_{x \in \mathcal{D}_{train}} \sum_{c=1}^{C} p(y = c \mid x) \log p(y = c \mid x)$$

A.2 Datasets

As mentioned in the paper (§4), we perform experiments on Natural Language Inference (NLI), a popular text classification task to gauge a model's natural language understanding (Bowman et al., 2015; Williams et al., 2017). We recognize that NLI is somewhat artificial by nature - making it of lesser practical relevance for real-life active learning scenarios. However, recent work has sought to address shortcomings of existing NLI benchmarks such as SNLI (Bowman et al., 2015) and MNLI (Williams et al., 2017). This has lead to the emergence of novel approaches to dataset-creation such as Dynamic Adversarial Data Collection (ANLI, (Nie et al., 2019)) and worker-and-AI-collaboration (WANLI, (Liu et al., 2022)). As we seek to investigate how characteristics of data gathered through such alternative protocols may affect acquisition performance in a multi-source active learning setting, using NLI for our experiments is a natural choice. We construct the unlabelled pool from three distinct datasets: SNLI, ANLI and WANLI. Next, we consider the Multi Natural Language Inference (MNLI) corpus (Williams et al., 2017) as an out-of-domain challenge set to evaluate the transferability of actively acquired training sets. We provide datasets statistics in Table 7.

A.3 Training details & Reproducibility

We use RoBERTa-large (Liu et al., 2020) from Huggingface (Wolf et al., 2019) as our model-in-the-loop and optimize with AdamW (Loshchilov and Hutter, 2018), with a learning rate of $2e-6$ and a batch size of 32. We use Dropout with $p = 0.3$. Hyperparameters were chosen following a manual tuning process, evaluating models on classification accuracy. For the BALD and MCME strategies we use 4 Monte Carlo Dropout samples. Our framework is implemented in PyTorch Lightning; transformers are implemented using the. All experiments were ran on a single NVIDIA Titan RTX GPU. Trialling all acquisition functions for 7 rounds of active learning (assuming experiments are ran in series), for a single seed, requires approximately 21 hours of compute. See Table 8 for per-strategy runtimes.

A.4 Detailed Results

Acquisition Factor For the multi-source experiments we also plot the *acquisition factors*: a source-strategy-specific statistic which indicates how much data of a given source is acquired by some strategy, normalized by the share of that source in the unlabelled pool at the time of that acquisition round. This statistic is useful to interpret how much a strategy tends to acquisition of one source relative to others.

We normalize to correct for the effect that acquiring e.g. mostly SNLI data in an early round causes it to take up a relatively smaller share in the unlabelled pool in the next round, and by the simple consequence of there being fewer SNLI examples, they may have a lower likelihood to be acquired in those future rounds compared to examples from other sources.. As this could distort

Label Distributions

MNLI-m*	n/a	n/a	n/a	n/a	n/a	n/a	n/a	n/a	1.6K	1.7K	1.6K	4.9K

Table 7: Statistics for the used datasets. N = Neutral, E = Entailment, C = Contradiction. For MNLI, only a held-out test set was used, and thus statistics for the training and dev set are omitted. Since WANLI only has a train and test set, we split its test set in two equally sized subsets and use one half as our validation set.

	RANDOM	DAL	BALD	MCME
Runtime	190 ± 19	269 ± 15	350 ± 62	450 ± 90

Table 8: Total runtime per strategy in minutes. Scheme follows *mean* ± *standard error* format.

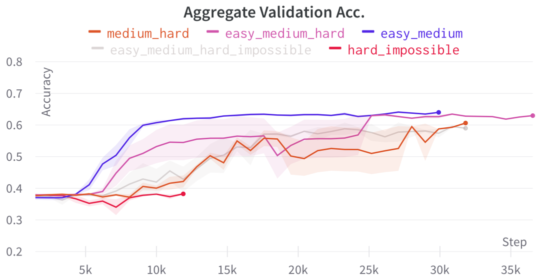

Figure 5: Aggregate validation accuracy for models trained on data of various difficulties. Training data difficulty appears to affect convergence speed: models trained on easier training sets converge earlier, whilst inclusion of hard and impossible models requires more steps to converge. In our experiments, models trained only on hard/impossible examples never surpass at-chance performance and suffer from model failure more often.

our impressions of the extent to which strategies acquire examples from different sources, we ideally want to correct for this.

We thus compute the acquisition factor for a given round as (1) the amount of source examples that were *actually* acquired by the strategy for that round, *divided* by (2) the amount of source examples that *would* be acquired under *random* sampling from the unlabelled pool at that point. For instance, if BALD has an acquisition factor of > 1 for SNLI, it means that it acquired more SNLI examples from the unlabeled pool than it *would* have under random sampling. Conversely, the Random sampling baseline will always have consistent acquisition factors of 1, since the quantities in the numerator and denominator will be approximately the same: random selection always acquire as much from a source as it would under random selection. See Figure 6 for a graphical explanation.[4]

A.5 Dataset Cartography

As mentioned in Section 6.1, we train a RoBERTa-large model on a training set comprised of the entire unlabelled pool of training examples, i.e. 60K examples in total.[5] Every $\frac{1}{2}$ epoch we perform inference on the full training set to get per-example confidence statistics, where the prediction logit corresponding to the gold-truth label serves as a proxy for model confidence. Variability is computed as the standard deviation over the set of confidence measurements. We stop training after 3 epochs or after no improvement in validation accuracy on the aggregate of validation sets was observed. Following Karamcheti et al. (2021), we classify examples along four difficulties via a threshold on the mean confidence value p.

Note on model discrepancy When studying the strategy maps, it is instructive to note that there exists a discrepancy between models which may distort the truthfulness of learnability measurements. That is, the cartography model that was used to obtain confidence/variability measurements

---

[4] Please note that these figures solely serve to support the textual explanation and should not be regarded as results otherwise.

[5] The AL experiments are simulations, where we have the ground truth labels for the data of the pool, but we consider them unlabelled. So in this case, we use the original labelled dataset to train the cartography model.

Task	Strategy	I-Div.	Unc.	N	E	C

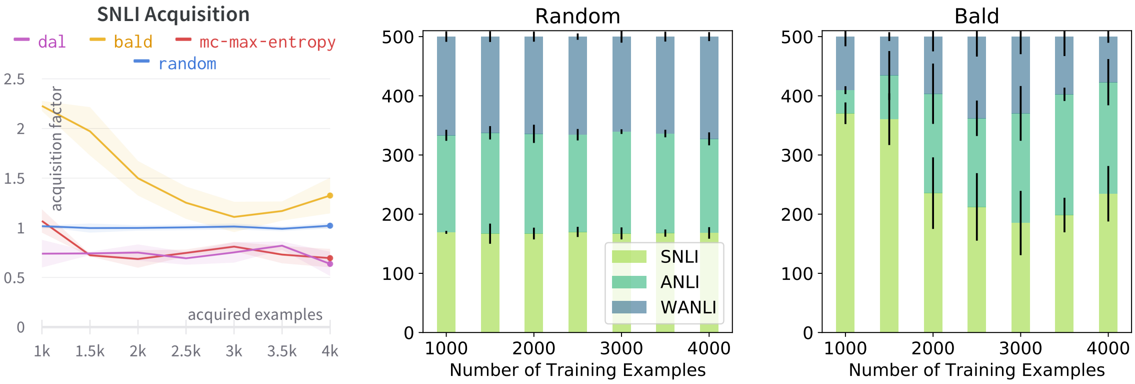
Table 9: Profiling strategy acquisitions for **single-source** and **multi-source** active learning in terms of mean input diversity (**I-Div.**), mean uncertainty (**Unc.**) and class distributions (**N**: *neutral*, **E**: *entailment*, **C**: *contradiction*) across seeds, following a *mean* ± *std* cell scheme. Each strategy is profiled *after* all rounds of active learning: $|\mathcal{D}_{train}| = 4K$.



(a) SNLI Acquisition factors

(b) Acquisitions by source

(c) Acquisitions by source

Figure 6: Acquisition factor explained. By design, random selection acquires a random sample of the unlabelled pool. Since the pool is initialized with even amounts of each source, random consistently acquires a uniform sample over sources, as can be seen in **(b)**. Consequently, the SNLI acquisition factor for Random steadily hovers around 1 in **(a)**. Conversely, BALD initially acquires mostly SNLI examples, as reflected by its high initial acquisition factor. This corresponds to its absolute acquisition statistics in **(c)**, where we note that initially BALD acquires predominantly SNLI.

for datamap construction was trained on the entire pool of 60K examples, whereas the model used during AL is exposed to at most 4K examples after completing all rounds of acquisition. Consequently, examples which were found to be easy by the cartography model are likely to be substantially more difficult for the AL model. As datamaps are inherently model-based, the generated strategy maps should be interpreted as skewed estimates of the true learnability spectra. While we recognize the potential value of preserving scale equivalence when using dataset cartography for analysis, we choose to follow Karamcheti et al. (2021) and intend to employ datamaps as a *post-hoc* diagnostic tool. In other words, we are interested in examining example learnability in an *absolute* sense (i.e. with respect to the entire pool) rather than a *relative* sense (with respect to the acquired data). Here,

Figure 7: In-domain multi-source Active Learning. The left-most graph represents the *learning curve* per strategy, plotting the validation performance as more labelled data is acquired. The middle graph plots the *acquisition factor* per source: how much a strategy acquires of a source, normalized by the share that source takes up in the wider data pool. Shaded regions indicate standard errors. Active learning fails to consistently beat random.

we also note that a model trained on a larger set of examples will likely more accurately reflect the true difficulty of examples. This is important if we want to draw new insights on the learnability of NLI datasets in a wider sense.

A.6 Impact of data difficulty on training time

We find that models quickly learn simple examples while requiring more iterations for complex ones (See Figure 5). A similar outcome was observed by Lalor et al. (2018) who employ item response theory for data difficulty estimation - interestingly however, their difficulty parameters are estimated via a human population, while our difficulty es-

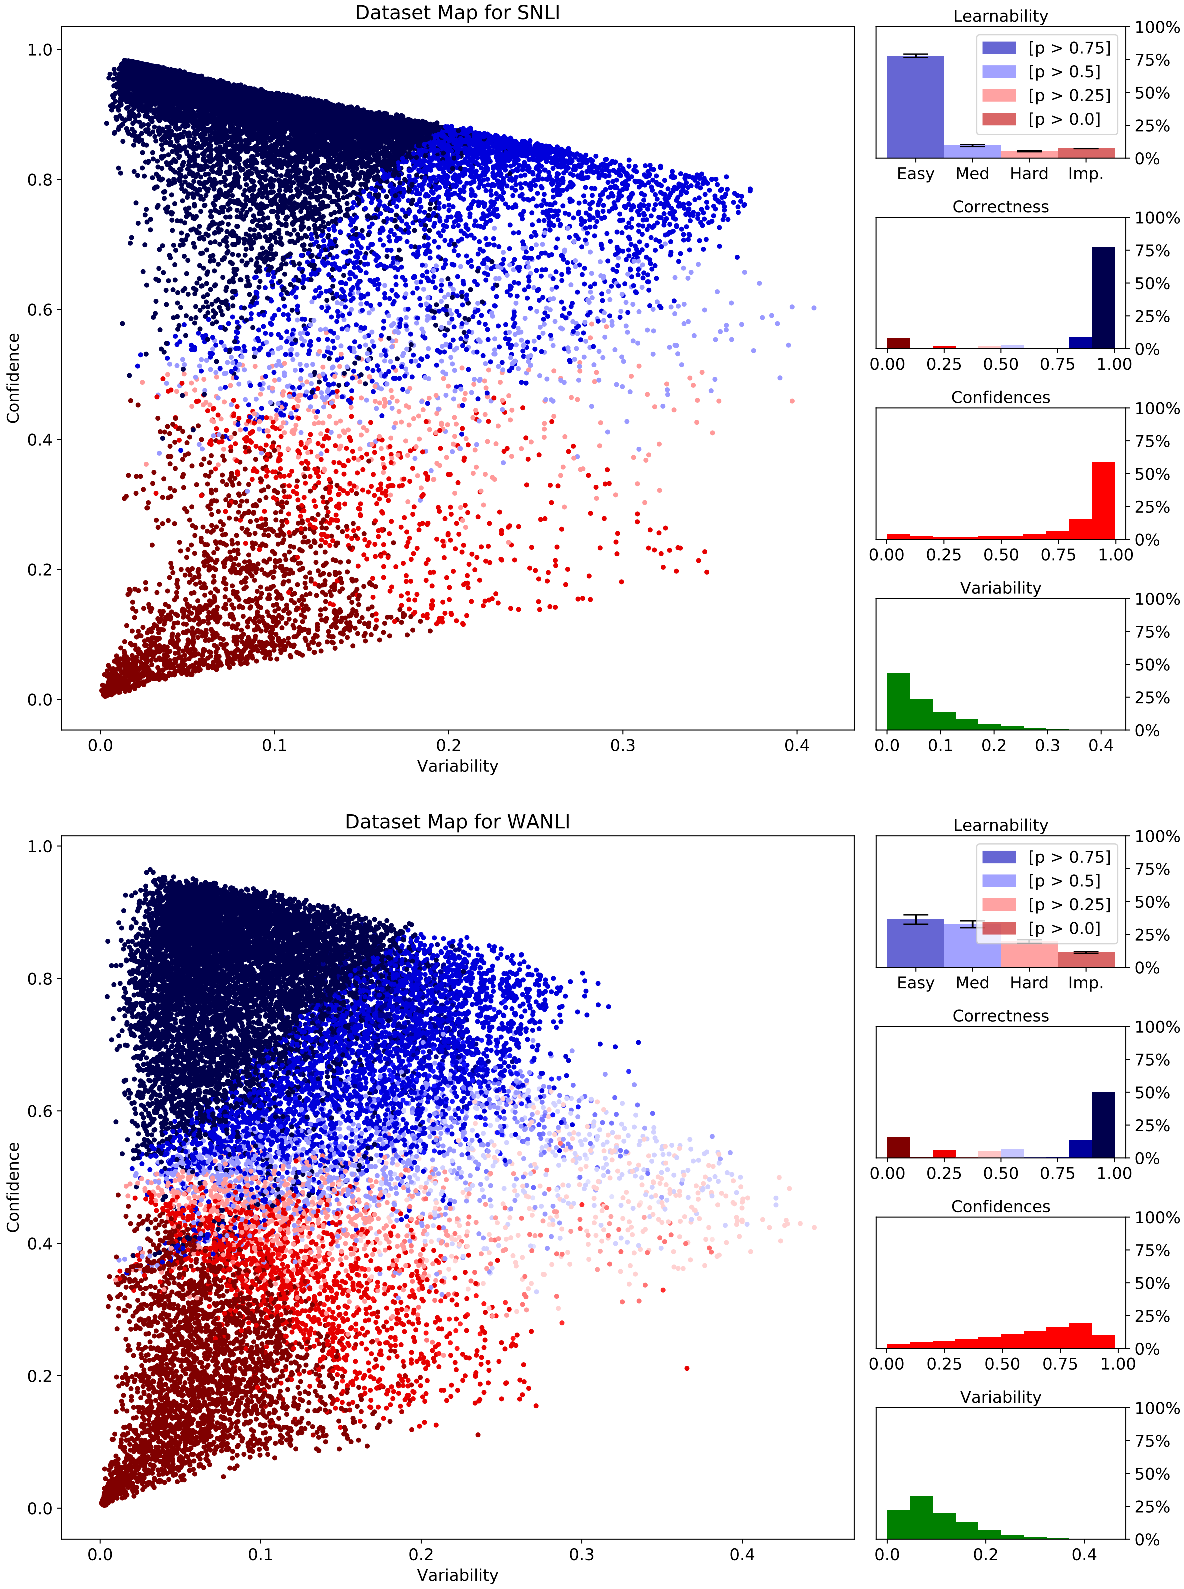

Figure 8: Dataset Maps for SNLI and WANLI training data. The majority of SNLI examples lie in the easy-to-learn region. For WANLI, datapoints are more evenly distributed across the learnability spectrum and exhibit greater variability.

timations follow directly from training dynamics. This echoes a similar finding by (Zhang and Plank, 2021), who show that cartography-based model confidence scores strongly correlate with human agreement on SNLI validation data. Similarly, it may be of interest to see whether examples which *many different* models identify as ambiguous correlate with human judgements of ambiguity, e.g. with respect to human label distributions (Nie et al., 2020; Chen et al., 2020), or annotator disagreement scores.

A.7 Hard-to-learn Data

In the tables below, we present various cases of hard-to-learn examples (i.e., collective outliers) for the NLI datasets we examine.

Abstract

Named Entity Recognition is a key Natural Language Processing task whose performance is sensitive to choice of genre and language. A unified NER model across multiple genres and languages is more practical and efficient through leveraging commonalities across genres or languages. In this paper, we propose a novel setup for NER which includes multi-domain and multilingual training and evaluation across 13 domains and 4 languages. We explore a range of approaches to building a unified model using domain and language adaptation techniques. Our experiments highlight multiple nuances to consider while building a unified model, including that naive data pooling fails to obtain good performance, that domain-specific adaptations are more important than language-specific ones and that including domain-specific adaptations in a unified model can reach performance close to training multiple dedicated monolingual models at a fraction of their parameter count.

1 Introduction

Identifying named entities, such as organization and people in text is a key NLP task situated upstream of other NLP tasks such as co-reference resolution (Ratinov and Roth, 2012; Dutta and Weikum, 2015; Miwa and Bansal, 2016; Luo and Glass, 2018) or relation extraction (Nguyen and Grishman, 2015; Zhong and Chen, 2021) and can enhance applications including information retrieval (Carpineto and Romano, 2012; Berger and Lafferty, 2017) and summarization (Cheng and Lapata, 2016; Liu and Lapata, 2019; Maddela et al., 2022; Hofmann-Coyle et al., 2022). However, it has been established that NER is very sensitive to genre differences (Augenstein et al., 2017; Agarwal et al., 2021),[1] with models trained on one genre performing poorly on a different one. As a result, multiple data sets were created to allow domain-specific models to be trained. Yet, domain adaptation especially across multiple genres has shown the promise that a single model could improve performance on multiple domains (Wang et al., 2020; Liu et al., 2021). Further, the advent of pretrained multilingual models (Wu and Dredze, 2019; Conneau et al., 2020) enables transfer across languages in an straightforward way by simply feeding heterogeneous language data in fine-tuning, making cross-lingual training feasible and a new dimension of adaptation available for exploration. Thus, performance on a specific genre and language pair could be improved by leveraging commonalities in training data across both genre and language dimensions, which is enabled by the significant amount of annotated data sets that are publicly available.

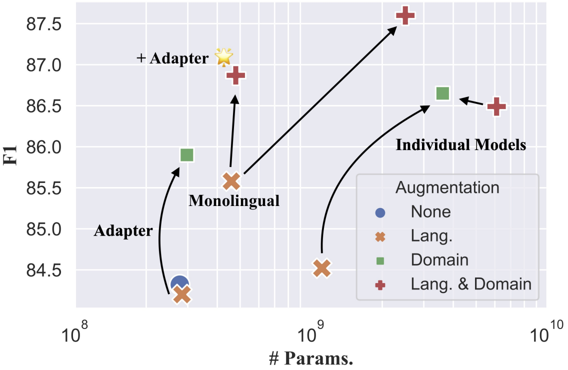

Figure 1: A graphic comparison of performance of language, genre and joint adaptation by demo parameter count.

The main research question becomes *what is the best way to leverage data from different languages and genres for NER* in this multilingual multi-domain setup? In this paper, we attempt to answer this question by using data sets available across multiple genres and languages to improve

---

performance across all data sets. To this end, we compile a collection of 22 data sets across 4 different languages and spanning 13 domains. To the best of our knowledge, this is the first attempt to building a unified multi-domain multilingual NER model.

We empirically explore our core research question through several experiments. First, we aim to identify whether sharing models or parts of the model across languages, domains or both is more beneficial in training. In general, simply pooling all the available data is likely sub-optimal as domain-specific differences in named entity mentions are useful to model, although using more data is usually more beneficial and can lead to improved robustness of the model. We explore several sharing techniques on top of state-of-the-art transformer-based encoders such as data pooling and mixture of experts methods, previously effective in cross-lingual learning, and language or domain specific adapter heads. Our results (Fig. 1) show that sharing genre information across languages is much more beneficial for performance than sharing language information across genres for all types of adaptation techniques.

Next, we compare monolingual encoders like RoBERTa, which can provide a better representation for text in each language, and multilingual encoders like XLM-R, which enables knowledge sharing from multiple languages, as starting points for fine-tuning NER models when genre and language annotated data is available. We find that the monolingual models pooling all the data from a particular language perform best and outperform their cross-lingual counterparts.

Throughout, we explore the trade-offs between the total number of model parameters and performance, which can bring practical benefits in terms of reduced maintenance and increased efficiency. We find that doing domain adaptation using adapter heads achieves a good trade-off between performance and parameter count and could represent the optimal solution in deploying a unified model.

Our contributions are as follows:

- Introducing the multilingual multi-domain NER setup;
- Extensive experiments on **13 domains** and **4 languages** using a variety of models and adaptation methods which highlight the best unified model architecture and show that modeling domains is more effective than languages;
- Analysis of the performance / efficiency trade-offs.

2 Data Sets

We create a collection of 22 data sets across 4 languages and 13 unique genres. For English, we use CoNLL-2003 (Tjong Kim Sang and De Meulder, 2003), Filings (Salinas Alvarado et al., 2015), OntoNotes-En (Hovy et al., 2006) with 6 genres (Pradhan et al., 2013; Wang et al., 2020) and Twitter (Ritter et al., 2011); for Chinese, we use MSRA (Levow, 2006), OntoNotes-Zh (Hovy et al., 2006) with 6 genres and Weibo (Peng and Dredze, 2015, 2016; He and Sun, 2017); for German, we use CoNLL-2003 (Tjong Kim Sang and De Meulder, 2003), Legal (Leitner et al., 2019) and Wikipedia (Balasuriya et al., 2009); for Spanish we use CoNLL-2002 (Tjong Kim Sang, 2002) and Wikipedia (Balasuriya et al., 2009). Note that not all languages contain the same genres and not all genres are present in each language, although there is overlap between genres and languages.

2.1 Statistics

We have a total of 502,720 training examples with 109,657 for validation and 105,255 for testing. We consider the following entity types: Person (`PER`), Organization (`ORG`), Location (`LOC`), and Miscellaneous (`MISC`), either removing extra types or collapsing them into the overarching parent entity class. We maintain the train/dev/test splits for all of these data sets and evaluate on test. Tab. 1 shows the number of training, validation and testing data points across each of the languages when domains in the language are combined. Here we can see that despite German and Spanish having few domains, the number of data points are in fact more than English and Chinese which have more domains.

Language	**Train**	**Dev**	**Test**
English	103,121	22,344	22,557
Chinese	67,129	15,672	11,314
German	234,297	50,471	50,611
Spanish	98,173	21,170	20,773
Total	502,720	109,657	105,255

Table 1: Data set statistics per language.

2.2 Entity-Type Mapping

The datasets do not have identical entity types. Thus, we apply pre-processing to standardize the

Language	Domain	ORG	PER	LOC	Dropped
English	Ritter	company	person, musicartist	geo-loc	N/A
	OntoNotes	N/A	N/A	N/A	TIME, CARDINAL, NORP, DATE, ORDINAL, QUANTITY, MONEY, PRODUCT, EVENT, PERCENT, WORK_OF_ART, LAW, LANGUAGE
German	Legal	UN, INN, GRT, MRK	RR, AN	LD, ST, STR, LDS	GS, RS, VO, LIT, VS, VT, EUN
Chinese	Weibo	ORG.NAM, ORG.NOM	PER.NAM, PER.NOM	LOC.NAM, LOC.NOM	N/A
	OntoNotes	N/A	PERSON	GPE	EVENT, NORP, TIME, FAC, QUANTITY, MONEY, CARDINAL, ORDINAL, LOC, LAW, WORK_OF_ART, PERCENT, LANGUAGE, PRODUCT

Table 2: Entity-type Mapping across data sets.

labels. Tab. 2 illustrates the pre-processing to map entities to the ORG, PER, LOC and MISC types. We do not list the simple mapping when the ORG, PER, LOC types exist themselves and blank spaces signify no mapping was done for the type. We reference previous work to map types to our subsets and also refer to the original data set paper to infer type mappings. Additionally, if a type does not map to any of the 4 types we train and evaluate on we drop the type as seen in the last column of the table.

3 Methods

To answer our core research question, we explore several methods inspired by approaches from both multilingual NER (Al-Rfou et al., 2015; Rahimi et al., 2019; Tedeschi et al., 2021) and multi-domain NER (Liu et al., 2020; Wang et al., 2020).

3.1 Multilingual Encoders

Pretrained multilingual encoders learn strong multilingual representation. In particular, we use XLM-R base (Conneau et al., 2020), a strong multilingual encoder.

3.1.1 Individual Models

The models consist of XLM-R base as the encoder, followed by the sequence tagging head in the form of a linear layer.

- **Data Pooling.** We fine-tune 1 model by naively pooling data from all languages and domains;
- **Per Lang.** We fine-tune 4 models using all data from each of the 4 languages;
- **Per Dom.** We fine-tune 1 model per domain using all data across all languages for that domain, resulting in 13 models (e.g., one CoNLL model trained using English, German and Spanish);
- **Per Lang. & Dom.** We fine-tune one model for each language and domain resulting in 22 models (e.g., CoNLL English, CoNLL German).

3.1.2 Mixture of Expert Models

Past multilingual NER research showed promising results using Mixture of Expert (MoE) (Shazeer et al., 2017) based models. MoE models are built on the premise that a set of experts can be parametrically learnt based on the training data without any explicit notion of matching an expert to a specific language or domain. MoE based models could be trained with a regular training setup (Jacobs et al., 1991), with gradient reversal methods (Ganin and Lempitsky, 2015) or with an adversarial loss (Chen and Cardie, 2018; Chen et al., 2019). We train MoE with regular training setup.

Given encoder output H for a sequence of length M, we introduce N experts, $E_i = FFN_i(H_t)$ with one hidden layer, where $i \in \{1, \dots, N\}, t \in \{1, \dots, M\}$, and a linear domain/language N-class classifier $C_{D/L} = Softmax(W_{C_{D/L}} H_{CLS})$. We take $\sum_i \alpha_i E_i$ with α_i from $C_{D/L}$ and feed it to a shared NER classifier. Thus experts are assigned at the sequence-level.[2] These are jointly trained in a multi-task learning setup with a cross-entropy NER loss $\mathcal{L}_{\text{NER}}^{\sum_i \alpha_i E_i}$ associated with all experts E_i and a Domain **(Dom. MoE)** or Language **(Lang. MoE)** prediction cross-entropy loss $\mathcal{L}_{D/L}$, yielding $\mathcal{L}_{\text{NER}}^{\sum_i \alpha_i E_i} + \mathcal{L}_{D/L}$. The loss is backpropagated through all the experts, both NER and domain/language classifier and the shared encoder.

3.1.3 Adapter Models

Research in multi-domain NER has found that adding private layers that are updated by data from

---

[2] We also experimented with token-level expert assignment, but observe worse results on the dev set.

each domain and shared layers updated by data from all domains is an effective way to improve multi-domain performance (Wang et al., 2020). Similar to the private layers explored in multi-domain NER, Adapters (Pfeiffer et al., 2020; Lin et al., 2020; Winata et al., 2021) used in conjunction with Transformer-based models demonstrated promise in further boosting the performance. We thus introduce adapter heads on top of the encoder. We leave variants of adapters that lie within each layer of the encoder (Houlsby et al., 2019; He et al., 2022) as future work.

The adapters A_i use the same model architecture (as MoE models), but are only updated by data from a given domain or language. It is equivalent to MoE with a predefined expert assignment. Fig. 2 shows the architecture of the adapter models used in our experiments.

Thus, for a given data point D_i the loss is computed as $\mathcal{L}_{\text{NER}}^{A_i}$ and only backpropagated through A_i, the NER classifier and the shared encoder.

- **Lang. Adp.** We create 4 adapter heads, one for each language and use the gold language label to pick the adapter;
- **Dom. Adp.** We create 13 adapter heads, one for each domain and use the gold domain label to pick the adapter;
- **Dom. Adp + DP.** We create 13 adapter heads and employ an auxiliary Domain Prediction objective $\mathcal{L}_{D/L}$ during training;
- **Dom. Adp + DP + SA.** In addition, we add a shared head which is updated for all examples, similar to the shared/private setup in (Wang et al., 2020) for multi-domain adaptation.

While adapters in each layer with frozen encoder performs on par with fine-tuning all parameters (Houlsby et al., 2019), it does not outperform it eithers. Thus, we also update the transformer layers as part of the training process. We also explored combining language and domain adapters but this resulted in worse performance and we omit it for brevity.

3.2 Monolingual Encoders

Finally, we explore monolingual encoders, which can provide a better representation of each language but are not able to transfer knowledge across languages. We identify monolingual BERT/RoBERTa versions for each of the 4 languages: English (Liu et al., 2019), Chinese (Cui et al., 2020), Spanish (de la Rosa et al., 2022), and German[3].

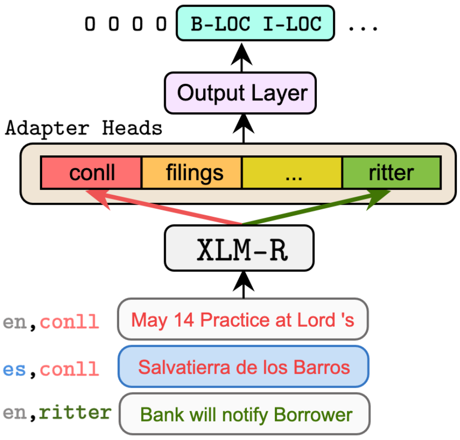

Figure 2: Our NER tagger with XLM-R encoder and domain adapters. Texts and adapter heads are color-coded to indicate the heads used for each domain.

- **Per Lang.** We fine-tune each monolingual encoder with all the NER data from the corresponding language, resulting in 4 models;
- **Per Lang. & Dom.** We fine-tune one model for each domain based on monolingual encoder, resulting in 22 models;
- **Dom. Adp.** We add domain adapters (**Dom. Adp.**, §3.1.3) to monolingual encoder. This results in 4 models, one for each language, with the number of adapters equal to the number of domains in each language.

3.3 Hyperparameters

We use the open-source Transformers library (Wolf et al., 2020) to facilitate reproducibility. For all experiments, we use a learning rate of 1e-5 on the AdamW optimizer (Loshchilov and Hutter, 2017), with no warm up, a batch size of 32 trained across 50 epochs on an NVIDIA V100 GPU. We use the same hyperparameters across all experiments to allow for comparability.

4 Results

We evaluate the models listed in §3 on all data sets. Tab. 3 illustrates the results averaged across languages obtained using F1 calculated with the CoNLL evaluation script. Granular results for each individual genre and language are in App. B. We treat the data pooling method in multi-lingual encoders as our baseline in terms of performance and number of parameters. Our findings are as follows:

---

[3] The model is taken from https://www.deepset.ai/german-bert

Models	**# param**	**en**	**zh**	**de**	**es**	**Avg.**
# Domains		9	8	3	2	
`Initiate with XLM-R (multilingual, base)`						
Data Pooling	×1.00	82.12	75.70	89.51	89.96	84.32
Per Lang.	×4.00	+0.54	+0.67	-0.27	-0.15	+0.2
Per Dom.	×13.00	+3.99	+4.45	+0.47	+0.40	+2.33
Per Lang. & Dom.	×22.00	+3.53	+4.27	+0.49	+0.38	+2.17
Lang. MoE	×1.02	+0.12	+0.47	0	+0.07	+0.17
Dom. MoE	×1.07	+0.51	+1.03	-0.36	-0.33	+0.21
Lang. Adp	×1.02	-0.09	+0.33	-0.37	-0.35	-0.12
Dom. Adp	×1.07	+1.95	+4.62	+0.26	-0.53	+1.58

Per Lang. & Dom.	×9.03	**+4.23**	+6.55	**+1.28**	**+1.05**	**+3.28**
Dom. Adp	×1.73	+3.05	**+6.61**	+0.22	+0.30	+2.55

Table 3: Results in macro-F1 for each language averaged across all domains within the language and overall average across the four languages. Number of parameters are relative to Data Pooling. **Bold** and underline indicate the best and second best performing models.

Domain vs. Language: In Fig. 1, we observe that across all types of methods (individual models, MoE and adapters), training models that leverage information about domain across languages is more beneficial when compared to sharing information across different genres in the same language, with gains of up to 1.70 – 2.13 F1. We hypothesize this result is due to the well documented sensitivity of NER to nuances specific to genres (Augenstein et al., 2017) such as entity distribution, document structure or capitalization patterns, whereas multilingual models manage to better preserve this information across languages. In addition, domain-specific models even perform slightly better than language- and domain-specific models (+0.16).

Adapters vs. MoE: When comparing methods, we observe that MoE techniques provide limited gains over data pooling (0.17–0.21) contrary to past cross-lingual experiments. The adapter heads provide bigger improvement compared to MoE with same number of parameters, while using shared layers and domain predictors as in multi-domain adaptation (Wang et al., 2020) fails to further boost performance. However, both adaptation strategies lag behind training domain specific models (+0.75), which however come with a much larger number of parameters (up to ×20) and added maintenance cost when deployed.

Monolingual vs. Multilingual Models: The monolingual results demonstrate that, if available, these models lead to better performance than their multilingual counterparts (+1.06 and +1.09 when comparing similar setups), which is natural as they have a better representation of each language. We find that the domain adapter method offers a good trade-off between performance (-0.73) and model size (×0.18), outperforming all models that perform adaptation across languages.

Impact of domain diversity: Finally we also observe that English and Chinese have much more diversity because of the number of domains, thus adding more capacity through the domain adaptation results in improved performance. However, since German and Spanish have fewer domains but an equal if not more training data points, we find that adding capacity is not necessarily helpful.

5 Conclusion and Future Work

This paper introduces the first extensive evaluation of multilingual multi-domain NER using a collection of 22 data sets spanning 4 languages. Through a series of experiments, we demonstrate that genre information is more important to be shared, even across languages, than sharing information from other genres in the same language. However, these cross-lingual methods are outperformed by domain adaptation over genres in monolingual models, if these models are available. We also explored trade-offs between model size and performance, showing that adapter heads strike a good balance, offering relatively little reduction in performance for an order of magnitude less parameters. For future work, we will explore additional experimental setups that include testing on domains or languages where limited or no data is available for training.

Limitations

Our research focuses on high-resource languages where annotated NER data sets and pretrained language models are available from only two language families. We have yet to explore how these findings translate to low resource languages or languages where annotated data sets are not available. We note that there are more domains available for English and Chinese, and since we are computing macro-F1 scores, the results over-emphasize performance on these languages, although Spanish and German show similar result patterns. Additionally, we only use 4 entity types (i.e., PER, ORG, LOC, MISC) across all datasets by dropping the other entities. Finally, due to limited computing resources and large number of experiments, we experiment with XLM-R base and thus do not compare with state-of-the-art results for each of these individual language/domain results which are usually obtained using XLM-R large.

Ethics Statement

We use publicly available data sets in our experiments with permissive licenses for research experiments. We do not release new data or annotations as part of this work.

A Data Set Details

In this section, we provide details about the statistics of the data sets, our hypothesis on what makes them challenging tasks and also pre-processing we perform to allow for reproducible results.

A.1 Statistics

A more in-depth look at the distributions of the domains across languages can be seen in Tab. 4 for German, Tab. 5 for Spanish, Tab. 8 for English, and Tab. 9 for Chinese. The tables show that English has the most diverse set of domain distribution, followed by Chinese, with a bulk of the data coming from MSRA, German, where Legal and Wiki constitute a large amount and Spanish, which is largely dominated by Wiki. The more diverse set of domains makes the language more challenging to achieve a consistently high average score, which is also evident in our results.

	conll2003	**legal**	**wiki**

B Fine-grained Results

In Tab. 3, we see the averaged results across domains for each language, however it is not easy to infer the performance on each for any given language. In an effort to provide more transparency, we provide the performance for each domain within a given language in Tab. 6, Tab. 7, Tab. 10, and Tab. 11.

Do Neural Topic Models Really Need Dropout?
Analysis of the Effect of Dropout in Topic Modeling

Abstract

Dropout is a widely used regularization trick to resolve the overfitting issue in large feedforward neural networks trained on a small dataset, which performs poorly on the held-out test subset. Although the effectiveness of this regularization trick has been extensively studied for convolutional neural networks, there is a lack of analysis of it for unsupervised models and in particular, VAE-based neural topic models. In this paper, we have analyzed the consequences of dropout in the encoder as well as in the decoder of the VAE architecture in three widely used neural topic models, namely, contextualized topic model (CTM), ProdLDA, and embedded topic model (ETM) using four publicly available datasets. We characterize the dropout effect on these models in terms of the quality and predictive performance of the generated topics.

1 Introduction

Dropout (Hinton et al., 2012) is used while training neural networks, by stochastically dropping out the activation of neurons to prevent complex co-adaptations of feature vectors (Baldi and Sadowski, 2013). The working of dropout is attributed to the implicit averaging over an ensemble of neural networks (Labach et al., 2019; Warde-Farley et al., 2014). It has been shown to be effective on supervised learning tasks to prevent overfitting (Srivastava et al., 2014).

As the volume of digital documents significantly increases with time, organizing them manually is becoming quite an inconvenient task. Because of the ability of topic models to learn a thematic structure from a set of documents in an unsupervised manner and label the documents with their corresponding dominant topics, the significance of topic models is enormous in this area (Hall et al., 2008; Adhya and Sanyal, 2022). But in the traditional topic models, not only the computation cost of the approximate posterior is very high but also for a small change in the modeling assumption, re-derivation of the inference method is needed. With greater flexibility and scalability than traditional topic models, a class of Neural Topic Models (NTMs) aim to leverage the potential of neural networks using the AEVB (Kingma and Welling, 2014) based inference technique. Following (Zhao et al., 2021), we refer to this class of models as VAE-NTMs where the training objective is to maximize the log-likelihood of the reconstruction of the input document while minimizing the KL-divergence of the learned posterior distribution of the latent space from a known prior distribution.

An earlier study by (Ha et al., 2019) of the dropout effect on two traditional topic models LDA (Blei et al., 2003) and BTM (Yan et al., 2013) shows that the correct choice of the dropout rate not only decreases the learning time of the models but also significantly improves the predictive performance and generalization for short texts. However, the study does not consider neural topic models.

In this work, we propose the use of dropout on VAE-NTMs as a hyperparameter in order to achieve much better performance in terms of topic coherence, topic diversity, and topic quality. We test this proposition on a range of standard VAE-NTM architectures. To the best of our knowledge, there has been no other study focusing specifically on the use of dropout in neural topic models. We have made our analysis publicly available[1].

In summary, our contributions are as follows:

1. We comprehensively show both quantitatively and qualitatively that topic quality undergoes a massive improvement with either very low or zero dropout settings in both the encoder and the decoder of a VAE-NTM.

2. We show that for VAE-NTMs the systematic choice of low dropout rates can lead to a sig-

nificant improvement in downstream tasks like document classification.

3. We study the dependence of dropout on the length of the input documents.
4. We present an empirical analysis for the increase in performance of VAE-NTMs with a decrease in dropout.

2 Task Formulation

Given a corpus $\{D_1, D_2, \ldots, D_N\}$ of N documents with vocabulary $\{w_1, w_2, ..., w_V\}$ of V words, topic models describe a document D_i as a distribution over K topics $\{\boldsymbol{\beta}_1, \boldsymbol{\beta}_2, ..., \boldsymbol{\beta}_K\}$, where an individual topic $\boldsymbol{\beta}_k$ is a distribution over V-words.

2.1 VAE Framework in Neural Topic Models

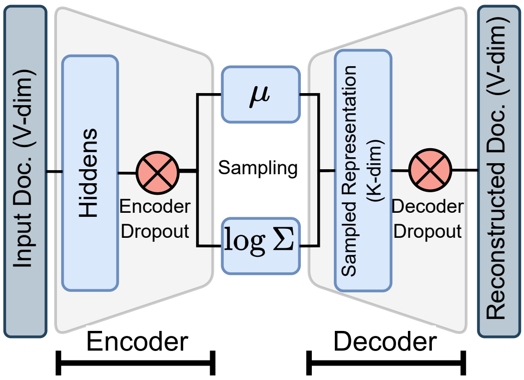

Figure 1: VAE framework in neural topic models.

Given an input sample $\mathbf{x}$, a VAE encoder learns the approximate posterior distribution $q_W(\mathbf{z}|\mathbf{x})$ where W is the encoder's weights that are to be learned and $\mathbf{z}$ is a latent variable. Given a sample $\mathbf{z} \sim q_W(\mathbf{z}|\mathbf{x})$, the VAE decoder learns the likelihood $p_{W'}(\mathbf{x}|\mathbf{z})$ where W' is the learnable decoder's weights.

In VAE-NTMs the input to the encoder is a document representation (e.g., bag-of-words) $\mathbf{x}_{V\times1}$. The encoder then returns the Gaussian parameters $(\boldsymbol{\mu}_{K\times1}, \boldsymbol{\Sigma}_{K\times1})$ that approximate the true posterior where K is the dimension of latent (topic) space, $\boldsymbol{\mu}_{K\times1}$ is the mean, and $\boldsymbol{\Sigma}_{K\times1}$ is the diagonal covariance matrix. Upon taking these Gaussian parameters as input, the decoder samples a latent representation $\mathbf{z}_{K\times1}$ from $\mathcal{N}(\boldsymbol{\mu}_{K\times1}, \boldsymbol{\Sigma}_{K\times1})$ using the reparametrization trick as follows:

$$\mathbf{z}_{K\times1} = \boldsymbol{\mu}_{K\times1} + \boldsymbol{\Sigma}^{\frac{1}{2}}_{K\times1} \odot \boldsymbol{\epsilon}_{K\times1}$$

where $\boldsymbol{\epsilon}_{K\times1} \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$ and $\odot$ represents the element-wise product. Then the document-topic distribution vector $(\boldsymbol{\theta}_{K\times1})$ is generated such that $\boldsymbol{\theta}_{K\times1} = \sigma(\mathbf{z}_{K\times1})$ where $\sigma(\cdot)$ is a softmax function. The input document-term distribution vector is reconstructed with the product of $\boldsymbol{\theta}_{K\times1}$ and $\boldsymbol{\beta}_{K\times V}$, the topic-word matrix, in the following manner:

$$\tilde{\mathbf{x}}_{V\times1} = \begin{cases} \boldsymbol{\beta}^T\boldsymbol{\theta} & \text{if } \boldsymbol{\beta} \text{ is normalized.} \\ \sigma\left(\boldsymbol{\beta}^T\boldsymbol{\theta}\right) & \text{if } \boldsymbol{\beta} \text{ is unnormalized.} \end{cases}$$

As shown in Figure 1, in the encoder, dropout is applied with probability E_p on the output of the hidden layer(s) of the multi-layer feed-forward neural network (FFNN). This output is then fed to two separate layers to get the approximate posterior $q_W(z|x)$. In the decoder, dropout is applied with probability D_p on the document-topic distribution vector $(\boldsymbol{\theta}_{K\times1})$, just before the reconstruction process.

2.2 Task Description

The goal is to measure the effect that dropout has on the *performance* of VAE-NTMs by varying the dropout rates from 0.0 to 0.6 in steps of 0.1, in both the encoder and the decoder. We have chosen 0.6 as the upper bound of the dropout rates for our experiments because it is the highest dropout rate used in any VAE-NTMs that we have considered as a baseline in this work. We measure performance using: *topic coherence*, *topic diversity*, and *topic quality*. We use NPMI (Lau et al., 2014; Röder et al., 2015) to measure topic coherence. Topic diversity (Dieng et al., 2020) shows the uniqueness of topics. Topic quality is the product of coherence and diversity (Dieng et al., 2020). As the automated topic model measures do not always accurately capture the quality of the topics (Hoyle et al., 2021), we also perform a manual evaluation of the topics and study their predictive performance on the document classification task.

3 Empirical Study

We perform all experiments in OCTIS (Terragni et al., 2021), which is an integrated framework for topic modeling.

3.1 Datasets

We have used four publicly available datasets in our experiments. Among them, **20NG**[2] and **BBC**

---

[2] `http://qwone.com/~jason/20Newsgroups/`

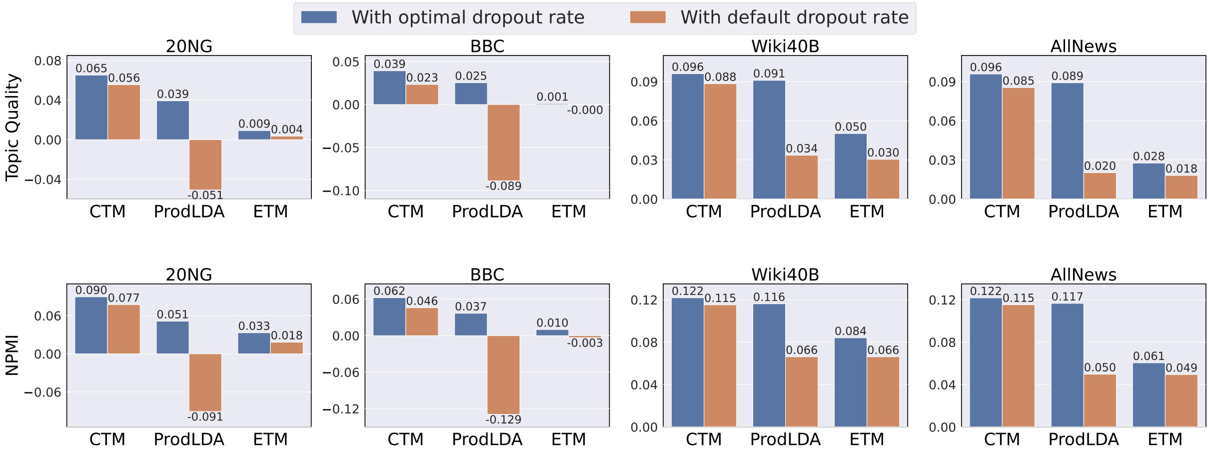

Figure 2: Topic quality and NPMI for different topic models with optimal dropout rate and default dropout rate.

(Greene and Cunningham, 2006) are already available in OCTIS in the pre-processed format while we added **Wiki40B** (Guo et al., 2020) and **AllNews** (Zhu et al., 2018) datasets further. The statistical descriptions of these datasets are mentioned in Table 1. Each corpus is split into train/valid/test sets in the ratio $70 : 15 : 15$. The validation set is used for early stopping.

Dataset	#Docs	Avg. #words	|Vocab|
20NG	16309	48.02	1612
BBC	2225	120.12	2949
Wiki40B	24774	541.08	2000
AllNews	49754	229.53	2000

Table 1: Statistics of the used datasets.

3.2 Models

We use the following three VAE-NTMs: **CTM** (Bianchi et al., 2021) which incorporates the contextualized documents embeddings with the neural topic models; **ProdLDA** (Srivastava and Sutton, 2017) which, unlike LDA, relaxes the simplex constraint over the topic-word matrix; (**ETM**) (Dieng et al., 2020) which incorporates word-embeddings in topic modeling to increase robustness in presence of stopwords.

For each of the four datasets, we compute the dropout rate that optimizes the topic quality of each model on that dataset. We train all three topic models for topic-count $K \in \{20, 50, 100\}$ with 30 epochs while keeping all hyperparameter values, except dropout, the same as in their original implementations. To ensure robustness, we average scores over 10 independent runs of each model. For comparison, we use the default dropout rates for each model as mentioned in the original papers that proposed the corresponding model. In Table 2, we show the default and the optimal dropout rates.

Model	20NG	BBC	Wiki40B	AllNews
CTM (0.2, 0.2)	(0.0, 0.0)	(0.0, 0.0)	(0.2, 0.1)	(0.0, 0.1)
ProdLDA (0.6, 0.6)	(0.1, 0.1)	(0.0, 0.0)	(0.1, 0.1)	(0.1, 0.1)
ETM (0.5, 0.0)	(0.0, 0.0)	(0.1, 0.0)	(0.0, 0.0)	(0.1, 0.0)

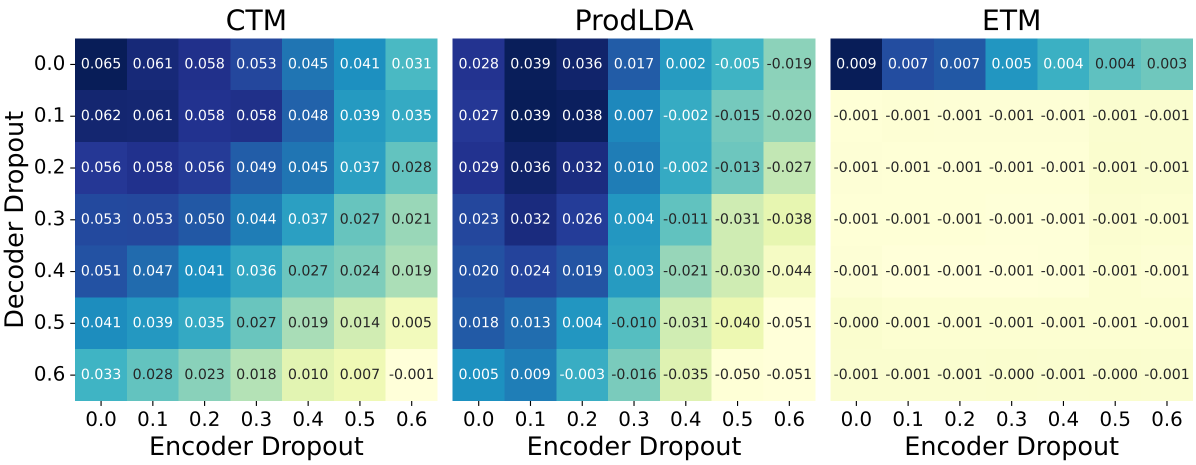
Table 2: For each of the datasets, the optimal dropout rates of all the models considering the highest topic quality are mentioned in the (E_p, D_p) format in the second through last columns. The default dropout rate is also specified for each model in the first column.

3.3 Results and Analysis

3.3.1 Quantitative Evaluation of Topic Quality

In Figure 2, we compare, for each dataset and each model, the topic quality and the NPMI respectively between the dropout-optimized model that gives the highest topic quality and the model with default dropout rates as mentioned in Table 2.

On **20NG**, the topic quality score for (CTM, ProdLDA, ETM) is improved from $(0.056, -0.051, 0.004)$ to $(0.065, 0.039, 0.009)$ by optimizing the dropout rate. For CTM, the increase in performance is around 16.07% whereas for the other two models it is over 100%. This is because the original implementation of CTM already uses a relatively low dropout rate, i.e.,



CTM

0.6	-0.001	-0.001	-0.001	-0.000	-0.001	-0.000	-0.001

Figure 3: Topic qualities on **20NG** for $(E_p, D_p) \in [0.0,\ 0.6] \times [0.0,\ 0.6]$ with a increment of 0.1.

0.2, for both the encoder and the decoder. The other two models show a significant increase in performance due to their large dropout in the baseline models.

Figure 3 shows that the topic quality on the **20NG** dataset for the VAE-NTMs generally produces better results on keeping the dropout rate for both the encoder and the decoder either to be zero or close to it, especially values like $\{0.0, 0.1\}$. Similar results have been found for the other datasets. Based on these observations, the topic quality is found to reduce with an increase in dropout rates in the encoder and decoder.

3.3.2 Qualitative Evaluation of Topic Quality

To qualitatively evaluate the models, we trained all of them for a topic count of 100 on the **20NG** dataset. We then aligned the topics for each pair of *(optimal-dropout model, default-dropout model)* for all three different models. We followed a two-step strategy for topic alignment. For a given pair of models, namely, one with optimal dropout and another with default dropout, with topics lists P and Q, respectively, we first construct a similarity matrix of the topic lists using Rank-biased Overlap (Webber et al., 2010) (RBO) which computes the similarity between two ordered lists by taking into consideration the rank of the individual elements. For example, for 100 topics, we get a matrix, $\mathbf{A} = (a_{ij})_{1 \le i,j \le 100}$ such that, $a_{i,j} = \text{RBO}\left(P[i], Q[j]\right)$. The RBO score lies in $[0, 1]$, where 0 represents no overlap and 1 implies exact overlap. In the final step, we iteratively select the pair of topics for which the similarity score is maximum and simultaneously exclude these two topics from further consideration, i.e. if $\left(P[i_1], Q[j_1]\right)$ and $\left(P[i_2], Q[j_2]\right)$ are two selected pairs then $(i_1 \neq i_2 \wedge j_1 \neq j_2)$.

In Table 3 we show the top words from *aligned* topics of all the models. '$*$' marked models have dropout optimized to give the highest topic quality while others use the default dropout rates as mentioned in Table 2. We see that dropout-optimized models output more interpretable topics.

3.3.3 Effect of Dataset Length

Among the input datasets on which we have experimented, the **20NG** dataset contains relatively short texts, while the others contain longer texts. (Ha et al., 2019) find that their dropout methods are not effective on long texts. But here we see that the performance of all VAE-NTMs decreases uniformly with the increase in the dropout rate, irrespective of the length of the dataset.

3.3.4 Document Classification

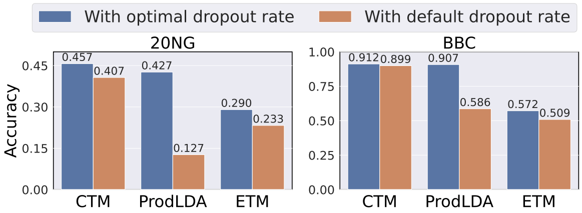

Figure 4: Accuracy for different topic models with optimal dropout and default dropout from Table 2.

We test the predictive performance of the topics produced by the models on a document classification task. We train the models on **20NG** and **BBC** corpora for K topics using the training subset. We represent each document as a K-dimensional document-topic vector and train an SVM, which is then tested on the test subset. We average the

Table 3: Some selected topics among 100 topics from **20NG**. '*' indicates models with optimal dropout. The dropout rate is mentioned in the (E_p, D_p) format. The more related words in a topic are highlighted in bold while less related ones are italicized.

accuracy scores over $K \in \{20, 50, 100\}$. Figure 4 shows that accuracy increases when we use the optimized dropout rates.

4 Theoretical Understanding of Results

Our experiments show that by tuning the dropout carefully, we can achieve a significant improvement in the performance of VAE-NTMs. Therefore, we argue that the dropout rate should be treated as an important hyperparameter and carefully selected based on the choice of the model as well as the dataset, especially in the case of VAE-NTMs. More precisely, in most cases, low dropout rates in the encoder and the decoder lead to higher performance than that achieved for higher dropout rates.

Standard dropout and other types of dropout have been extensively used in supervised learning techniques (Srivastava et al., 2014; Wu and Gu, 2015; Tompson et al., 2015; Devries and Taylor, 2017; Cai et al., 2019). The main prerogative of using dropout in the supervised scenario is to introduce noise while training so that the model can recognize the outliers in the testing phase. The drop in performance with high dropout that we see in our experiments is perhaps due to the fact that we are trying to learn a generative model of the data. Dropout makes the model robust against perturbations in the input data and thereby also prevents it from learning the characteristics of the input distribution accurately. This is probably why we see a drop in topic coherence and quality. In the case of document classification, if the topic model is trained with a high dropout, the document-topic vectors are of poor quality and the classifier gets trained on these vectors; this results in poor accuracy on the test documents. This setting is different from the usual supervised learning of neural classifiers where dropout is introduced directly in the classifier to prevent overfitting. We intend to analyze these aspects in more depth in the future.

5 Conclusion

We present a detailed study of the effect of the dropout rate on VAE-NTMs. We find that the model performance generally reduces with the increase in dropout rate in the encoder as well as the decoder.

Limitations

The following limitations are known and should be considered when applying the results of this work or relying on them in future studies: (1) Other variants of dropout can be applied to the VAE-NTMs. (2) Analysis of the dropout effect may be done for other VAE-NTMs as well. (3) Other downstream tasks may be formulated for further analysis.

A Appendix

A.1 Datasets

We run our experiments on the following datasets:

- **20NewsGroups (20NG)**[3] is a dataset of 18,846 documents from 20 different newsgroups posts. The **20NG** dataset is present in OCTIS, so it is already in pre-processed form. All the documents of this dataset have their corresponding category type as the document labels. The details about these categories are mentioned in Table 4.

- **BBC News (BBC)** (Greene and Cunningham, 2006) is a dataset of news articles from BBC. It is also accessible from OCTIS in pre-processed form. The documents of this dataset are categorized into 5 different categories which are *tech*, *business*, *entertainment*, *sports*, and *politics*. The details of these categories are mentioned in Table 5.

- **Wiki40B**(Guo et al., 2020) is a Wikipedia text dataset in 40+ languages, available in TensorFlow dataset format. In our experiment, we take a sample of 24,774 English documents from this dataset.

- **All the News (AllNews)**(Zhu et al., 2018) dataset consists of 50,001 news articles from 15 news publishers.

A.2 Pre-processing Steps

Using OCTIS, we convert each document to lowercase, remove the punctuations, lemmatize it, filter

---

[3] `http://qwone.com/~jason/20Newsgroups/`

the vocabulary with the most frequent 2000 terms, filter words with less than 3 characters, and filter documents with less than 3 words.

A.3 Topic Evaluation Metrics

1. **Coherence metric**: This measures how much the top words of the topics are relevant. Topic coherence (TC) for K topics each of which contains n top words can be calculated as:

$$\text{TC} = \frac{1}{K}\sum_{k=1}^{K}\frac{1}{{}^{n}C_2}\sum_{i=1}^{n}\sum_{j=i+1}^{n} f\left(w_i^{(k)}, w_j^{(k)}\right)$$

   Here, $f(\cdot,\cdot)$ is the Normalized Pointwise Mutual Information or NPMI (Lau et al., 2014) of the words $w_i^{(k)}$ and $w_j^{(k)}$ appearing in topic k:

$$f(w_i^{(k)}, w_j^{(k)}) = \frac{\log \frac{p(w_i^{(k)},w_j^{(k)})+\epsilon}{p(w_i^{(k)})p(w_j^{(k)})}}{-\log\left(p(w_i^{(k)}, w_j^{(k)}) + \epsilon\right)}$$

   where, $p(w_i^{(k)}, w_j^{(k)})$ is the probability of the co-occurrence of the words $w_i^{(k)}$ and $w_j^{(k)}$ in a boolean sliding window in topic k and $p(w_i^{(k)})$ and $p(w_j^{(k)})$ represents the probability of the occurrence of the individual words in topic k. ϵ is a small positive constant that is used to avoid zero in the $\log(\cdot)$ function.

2. **Diversity metric**: This measures how much the generated topics are different from each other. To measure the diversity score we have used the metric Topic Diversity (TD) (Dieng et al., 2020) which is defined as the proportion of the number of unique words appearing across all topics. It ranges between $[0, 1]$ where a value close to 0 implies repetitive topics and a value near 1 represents more diversification in the topics.

3. **Topic quality**: This is an overall metric that is defined as the product of the two metrics NPMI and TD.

In our experiments, we take the top 10 words for each topic (i.e., $n = 10$) to compute NPMI and TD scores.

A.4 Computing Infrastructure

Our experiments were run on a workstation with Intel® Xeon™ Gold 6326 CPU @ 2.90GHz, 256.0 GB RAM, NVIDIA A100 80GB PCIe, CUDA Version: 11.7 and Ubuntu 22.04 operating system.

A.5 Detailed Results

The detailed results of our experiments are given in Tables 6, 7, and 8. An asterisk ($*$) against a model in the above tables indicates that it is trained with the optimal dropout rate, and the absence of an asterisk indicates that the default dropout rate is used. The default dropout rate for **CTM** is taken from (Bianchi et al., 2021), for **ProdLDA** from (Srivastava and Sutton, 2017), and for **ETM** from (Dieng et al., 2020).

s.pezzelle@uva.nl

Abstract

This work studies the semantic representations learned by BERT for compounds, that is, expressions such as *sunlight* or *bodyguard*. We build on recent studies that explore semantic information in Transformers at the word level and test whether BERT aligns with human semantic intuitions when dealing with expressions (e.g., *sunlight*) whose overall meaning depends—to a various extent—on the semantics of the constituent words (*sun*, *light*). We leverage a dataset that includes human judgments on two psycholinguistic measures of compound semantic analysis: lexeme meaning dominance (LMD; quantifying the weight of each constituent toward the compound meaning) and semantic transparency (ST; evaluating the extent to which the compound meaning is recoverable from the constituents' semantics). We show that BERT-based measures moderately align with human intuitions, especially when using contextualized representations, and that LMD is overall more predictable than ST. Contrary to the results reported for 'standard' words, higher, more contextualized layers are the best at representing compound meaning. These findings shed new light on the abilities of BERT in dealing with fine-grained semantic phenomena. Moreover, they can provide insights into how speakers represent compounds.

1 Introduction

Compounds such as *sunlight* or *bodyguard* are an interesting benchmark to probe the semantic representations learned by any NLP models. On the one hand, compounds that are part of a language lexicon (i.e., lexicalized compounds; Gagné and Spalding, 2006) have their own (sets of) established meaning(s). As such, they are lexical items just like any other word. On the other hand, the semantic status of compounds is special since their meaning is the result of the combination of the meaning of two words (hence, the constituents). According to psycholinguistic evidence, this semantic relation does not disappear with lexicalization. Indeed, speakers actively combine constituent meanings when processing both novel and lexicalized compounds (Gagné and Spalding, 2009; Ji et al., 2011; Marelli and Luzzatti, 2012; Marelli et al., 2014).

In this work, we argue that NLP systems capable of faithfully representing word meanings should account for these aspects. For example, to acknowledge that the meaning of *handgun* relies more on the semantics of *gun* than of *hand* (indeed, a *handgun* is a type of *gun*). Or, that the meaning of *sunlight* is more directly recoverable from the semantics of its constituents (it is more transparent) than is the meaning of *muskrat* (which is very opaque).

Transformer-based encoders such as BERT (Devlin et al., 2019) are shown to produce word representations that align well with human semantic intuitions, particularly at their lower layers (Bommasani et al., 2020; Vulić et al., 2020). This suggests that these models are effective in encoding the meaning of a word, without any additional task-specific fine-tuning. However, these conclusions are based on evaluations that explore semantic relations between words, such as pairwise similarity patterns—not between words and their parts.

In parallel, BERT's contextualized embeddings have been leveraged for tasks that involve lexical composition. For example, to learn compound representations that are effective in predicting the *literality* of a compound or its semantic interpretation (Shwartz and Dagan, 2019). In this case, mixed results were reported. While BERT-based models are effective to judge, e.g., that *market* (but not *flea*) has a literal meaning in *flea market*, they are far behind humans in predicting, e.g., that *body part* stands for *part that makes up a body*. Crucially, these results were obtained by training a binary classifier on the top of BERT's embeddings. Since the encoder parameters were updated during learning, no conclusions can be drawn on the ef-

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2230–2241
May 2-6, 2023

fectiveness of BERT's embeddings in dealing with these and similar fine-grained semantic aspects.

In this work, we leverage a dataset that includes human judgments on two psycholinguistic measures of compound semantic analysis: lexeme meaning dominance (LMD) and semantic transparency (ST). The former quantifies the semantic weight of each constituent toward the compound meaning. For example, that *gun* has more semantic weight in *handgun* than *hand* does. The second evaluates the extent to which the compound meaning is recoverable from the semantics of the constituents. For example, that *handgun* is very transparent, while *muskrat* is much less so.

We test whether, and to what extent, the measures of LMD and ST that we obtain from BERT's representations of compounds and compound constituents align with human judgments. We carry out comprehensive experiments on model versions, contexts, pooling methods, layers.[1] We show that:

- BERT is moderately aligned with human intuitions on both measures, which confirms the effectiveness of the model in accounting for the fine-grained semantic aspects captured by LMD and ST. At the same time, LMD is substantially more predictable than ST;
- only representations extracted from words in a context (in a sentence), but not without a context (in isolation), are aligned with human intuitions, which reflects BERT's struggle to handle out-of-context words. Moreover, the highest correlations are achieved in higher, deeply contextualized layers. This could be due to the nature of the semantic evaluation subtending LMD and ST, which likely requires relying on a specific semantic interpretation of the compound rather than on abstract lexico-semantic information;
- both BERT$_{\text{base}}$ and BERT$_{\text{large}}$ outperform the GloVe (Pennington et al., 2014) baseline, with BERT$_{\text{large}}$ achieving the best results overall. This confirms the effectiveness of BERT models to represent word-level semantics, in line with previous work (Bommasani et al., 2020; Vulić et al., 2020);
- BERT accounts for the left and right constituents equally when representing the semantics of a compound. Moreover, these representations appear to encode the complex semantic and syntactic relation tying the constituents.

2 Related Work

2.1 Compound Semantics in Psycholinguistics

Compounds are one of the favorite subjects of psycholinguistic research. One of the reasons is that they are extremely productive: a new combination of two (or more) words can be generated at any time and get lexicalized through language use (Gagné and Spalding, 2006). Indeed, compounds have been considered to serve as a "backdoor into the lexicon" (Downing, 1977). While understanding novel compounds clearly involves accessing both the meaning of the constituents and the semantic relation tying them together, recent psycholinguistic evidence has shown that an active combination of the meaning of the constituent words is routinely in place also for lexicalized compounds (Gagné and Spalding, 2009; Ji et al., 2011; Marelli and Luzzatti, 2012; Marelli et al., 2014). Indeed, most psycholinguistic research in this field focuses on the constituents and their relation with compounds. For example, to study and quantify the role of frequency, semantic transparency, or headedness (Gagné and Spalding, 2009; Marelli et al., 2009; Marelli and Luzzatti, 2012; Juhasz et al., 2015).[2]

Recently, a few studies leveraging methods from NLP have been carried out to either reproduce or quantify some of these aspects. By typically using *static* embeddings (Mikolov et al., 2013; Pennington et al., 2014) and compositional models of distributional semantics (Mitchell and Lapata, 2010; Guevara, 2010), these approaches have proven successful in building compound representations that approximate, e.g., the different semantic and syntactic role of a compound's modifier and head, semantic transparency, plausibility of a novel combination or syntax-based categorizations (Günther and Marelli, 2016; Marelli et al., 2017; Günther and Marelli, 2019; Pezzelle and Marelli, 2020).

Though powerful, these methods have one crucial limitation, namely, they require training a set of parameters via supervised learning to obtain representations for compounds that are novel or simply not present in the corpus. Transformer-based encoders such as BERT (Devlin et al., 2019) lift this limitation. Without any additional training or

---

[2] Headedness refers to the property of having a head—in English, typically the right constituent. The left is the modifier.

fine-tuning, in fact, they can represent any novel or unseen word—provided that it can be divided into known subwords. Since compounds involve a meaningful combination of two constituents, they represent an interesting benchmark to test the representations by these models.

2.2 Word Representation in Transformers

A recent line of work started to investigate the type of semantic information encoded in the embeddings by pre-trained Transformer encoders. While this was a classical benchmark to evaluate static, word-level embeddings learned by previous generation models, e.g., word2vec (Mikolov et al., 2013) or GloVe (Pennington et al., 2014), the problem appears less trivial for current state-of-the-art NLP models (Westera and Boleda, 2019; Mickus et al., 2020; Lenci et al., 2022). Indeed, the embeddings by Transformer-based encoders are *contextualized*, i.e., affected by both the surrounding context and the position within a sentence. Moreover, they often represent subwords rather than whole words.

By means of a simple method to pool the various contextualized embeddings learned for a word into a single, static embedding, Bommasani et al. (2020) showed that these representations align with human judgments of semantic similarity better than how previous-generation ones do. In particular, lower layers perform the best, which reveals that these layers encode abstract, lexico-semantic information. Similar findings were reported by Vulić et al. (2020), who extended the investigation to other five languages than English. Taken together, these results are complementary to the findings that representations in higher layers tend to become more context-specific (Ethayarajh, 2019) and to better encode word senses (Reif et al., 2019).

Recent work (Shwartz and Dagan, 2019) leveraged BERT embeddings to obtain representations for compounds by means of (trained) lexical composition models—similarly to how it was done for compositional distributional semantic models. However, to the best of our knowledge, no work to date has explored how Transformer-based encoders represent compounds. The most relevant study in this direction is the one by Pinter et al. (2020), which focused on BERT's representations for blends (i.e., words such as *shoptics*, resulting from the merging of *shop* and *optics*) and included a comparison with novel compounds. They reported an overall high similarity between the compound and the constituents, slightly increasing through the layers.

By focusing on lexicalized compounds from a psycholinguistic angle, we are the first to study how BERT represents these complex expressions.

compound	**LMD [0,10]**	**ST [1,7]**
handgun	8.13 →	6.29 ↑
bodyguard	7.27 →	5.64 ↑
policeman	3.07 ←	6.13 ↑
wartime	3.47 ←	6.31 ↑
muskrat	7.53 →	2.80 ↓
primrose	7.93 →	2.00 ↓
milestone	3.36 ←	2.21 ↓
cheapskate	2.00 ←	2.00 ↓

Table 1: A few examples from the dataset with either high ↑ or low ↓ ST and either low ← or high → LMD. E.g., the meaning of *handgun* is deemed highly transparent and based more on the right than the left constituent.

3 Data

We use a psycholinguistic dataset of human judgments on compound LMD and ST (Juhasz et al., 2015). The dataset includes 629 lexicalized English compounds annotated by 189 participants for various variables.[3] LMD is a score that captures which of the two constituents of a compound is semantically dominant for the compound meaning. It ranges in [0,10], where 0 means totally dependent on the left constituent and 10 means totally dependent on the right constituent. In Table 1, we report a few examples from the dataset. As can be seen, compounds such as *handgun* or *muskrat* have a high LMD, i.e., the right constituent is semantically dominant. In contrast, compounds such as *policeman* or *milestone* have a low LMD, i.e., the left constituent is semantically dominant.

ST is defined as a score that quantifies the degree to which the meaning of a compound can be inferred or recovered from the meaning of the constituents: the higher the ST, the more transparent the compound. The compounds *handgun* and *wartime* in Table 1, for example, are fully transparent: both the constituents contribute to their meaning. In contrast, compounds such as *primrose* or *cheapskate* are fully opaque: neither of the two constituents contributes to its meaning.

Since only the compounds, but not the constituents, are provided in the dataset, we manually

---

[3] Such as LMD, ST, age of acquisition, and imageability.

annotate each compound (e.g., *handgun*) with its left (*hand*) and right (*gun*) constituents, so to obtain a dataset of $\langle$compound, left, right$\rangle$ triplets. While doing so, we decided to discard the pseudo-compound *mushroom*. We were left with 628 triplets, that we use in our experiments.

4 Method

We test whether, and to what extent, BERT's representations of compounds and compound constituents approximate human judgments on LMD and ST. To do so, we obtain word-level representations using two versions of BERT. We experiment with representations obtained by feeding the word either in isolation or in the context of a sentence. Moreover, building on previous work, we explore various pooling methods over BERT outputs.

4.1 Models

BERT (Devlin et al., 2019) is a Transformer-based model pre-trained on a large number of English texts. It is pre-trained using two learning objectives, i.e., Masked Language Modeling (MLM) and Next Sentence Prediction (NSP). MLM is about predicting some words that have been masked in the input. NSP is about predicting whether two concatenated sentences follow each other (or not).

We experiment with two versions of BERT, i.e., $\text{BERT}_{\text{base}}$ and $\text{BERT}_{\text{large}}$. The former has 12 encoder layers stacked on top of each other, 12 attention heads, and 110M parameters. At each layer, it learns 768-d embeddings. The latter has 24 layers, 16 attention heads, and 340M parameters. It learns 1024-d embeddings. For both models, we use HuggingFace (Wolf et al., 2020) implementations.[4]

4.2 Word-Level Representations

For each triplet in the dataset, we employ BERT models to obtain representations for the compound, the left constituent, and the right constituent. We henceforth use the general term *word* to refer to any of the items in a triplet. We obtain representations for words in two conditions, *no-context* (`NC`) and *in-context* (`C`), that we describe below.

No-Context (`NC`) In this condition, we obtain a single, static representation for a word (e.g., *snowboard*) by feeding it into the model in isolation, i.e., without any surrounding context. When fed with a single word, BERT outputs embeddings for the tokens which make it up (that result from the tokenization process), as well as for the special tokens [CLS] and [SEP] at the beginning and end of the sequence, respectively. Following previous work (Vulić et al., 2020), we explore 3 methods for obtaining a word representation. These methods differ with respect to what embeddings are taken into account when building such representation:

- `nospec` This method ignores the special tokens [CLS] and [SEP]. A word representation is built by averaging the embeddings of the tokens that make up the word (*snow*, *##board*);
- `withcls` This method builds a word representation by averaging the embedding for the special token [CLS] with the embeddings of the tokens making up the word (*snow*, *##board*);
- `all` This method builds a word representation by averaging all the embeddings that are output by BERT for the sequence, i.e., [CLS], [SEP], and the tokens making up the word.

In-Context (`C`) In this condition, we follow the method by Bommasani et al. (2020) to obtain a single, static representation of a word from the N contextualized embeddings produced by BERT for that word in context. First, we average the representations of the tokens that make up a given word—as in the `NC_nospec` setting. Second, we consider all the contextualized representations for a given word and aggregate them to obtain a single representation that is not dependent on a specific context. We do this by averaging the N contextual representations of a word $w_1, \ldots, w_N$:

$$w = mean(w_1, \ldots, w_N) \tag{1}$$

To obtain contextualized vectors, we sample sentences containing items from our 628 triplets from a cleaned English Wikipedia corpus.[5] For each word, we sample all the sentences in the corpus that contain it, up to a maximum of 100 unique instances per word. The average number of instances per word in our sample is 89.3 (min 1, max 100).

We henceforth simply refer to this setting as `C`.

Experimental details Within each setting, we therefore obtain a single 768-d ($\text{BERT}_{\text{base}}$) or 1024-d ($\text{BERT}_{\text{large}}$) embedding for each compound and

	`C`	*0.966 (21)*	**0.586 (21)**

Table 2: LMD. Results in **bold** and *italic* are the best and second-best in the column, respectively. Results are from a model's best-performing layer (in parentheses).

constituent in our dataset. This operation is performed for each layer of each model—i.e., 12 layers in BERT$_{\text{base}}$ (1-12) and 24 layers in BERT$_{\text{large}}$ (1-24). All representations are obtained by running a pre-trained BERT in inference mode, i.e., without fine-tuning or updating the model's weights.

Baseline As a baseline, we employ static embeddings by GloVe (Pennington et al., 2014). We use the 300-d embeddings from the version of the model trained with 6B tokens.[6] Since four compounds[7] were not found in GloVe's vocabulary, for this baseline we obtain results for 624 triplets.

4.3 Predicting Psycholinguistic Measures

LMD is a scalar in [0,10] that quantifies the relative semantic role of each constituent toward the meaning of the whole compound: The higher the value, the more the compound's semantics depends on the right constituent. Using BERT's representations for a ⟨compound, left, right⟩ triplet, we therefore operationalize LMD as follows:

$$LMD(c) = 5(R - L) + 5 \tag{2}$$

where c is the compound, L is the cosine similarity in [0,1] between the left constituent and the compound, $cos(left, compound)$, and R is the cosine similarity between the right constituent and the compound, $cos(right, compound)$. The scaling and addition operations make the values range in [0,10]. If $L = 0$ and $R = 1$, then $LMD(c) = 10$. *Vice versa*, if $L = 1$ and $R = 0$, $LMD(c) = 0$.

ST is a scalar in [1,7] that quantifies the degree to which the meaning of a compound can be inferred from the meaning of the constituents. The higher the value, the more the compound semantics can be inferred from the two constituents' meanings. Using BERT's representations for ⟨compound, left, right⟩, we operationalize ST as follows:

$$ST(c) = \frac{6(L + R)}{2} + 1 \tag{3}$$

where c, L, and R are defined as above. The scaling and addition operations make the values range in [1,7]. If $L = 1$ and $R = 1$, then $ST(c) = 7$. *Vice versa*, if $L = 0$ and $R = 0$, $ST(c) = 1$.

4.4 Evaluation

We evaluate the effectiveness of each model in approximating human LMD and ST by means of two metrics: mean absolute distance (MAE) and Spearman correlation (ρ) between the predicted and human values. For MAE, the lower the distance, the better. For ρ, the higher the correlation, the better.

In the next section, we report results by all models in all settings in approximating LMD and ST.

5 Results

5.1 Lexeme Meaning Dominance

In Table 2, we report the results by (the best layer of) each model on LMD in the various settings. Several key observations can be made. First, both BERT models achieve moderate positive correlation[8] (close to 0.6) with human judgments, with BERT$_{\text{large}}$ outperforming BERT$_{\text{base}}$ by some margin. On the one hand, this indicates that BERT's representations do a fairly good job in accounting for the relative semantic weight of each constituent in a (lexicalized) compound. On the other hand, it suggests that more data and parameters play a role in approaching human intuitions.

Second, BERT models outperform GloVe in terms of correlation. This indicates that BERT's embeddings not only encode sensible semantic information (in line with previous findings; see Bommasani et al., 2020; Vulić et al., 2020) but also align with human semantic intuitions to a greater extent than the previous-generation GloVe model. However, it is worth noting that BERT models outperform GloVe only in `C`, but not in `NC`. This clearly shows that BERT's embeddings have an advantage over GloVe's ones only when leveraging information in the surrounding context and reveals

---

[6] `https://nlp.stanford.edu/data/glove.6B.zip`

[7] Namely, *livelong*, *sunlamp*, *dunghill*, and *handclasp*.

[8] As per standard interpretation (Prion and Haerling, 2014), we consider ρ correlations from ±0.41 to ±0.60 as moderate.

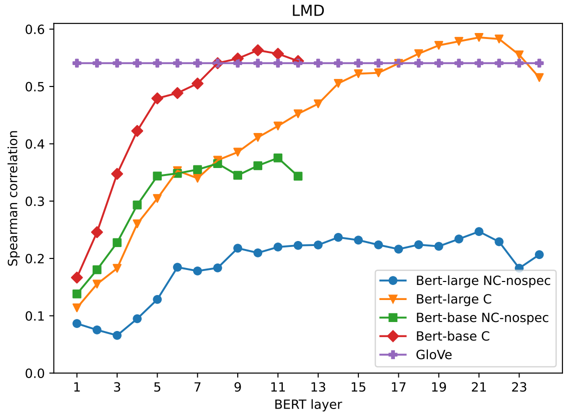

Figure 1: LMD. ρ against model layers. For out-of-context BERT models, we only report the best-performing `nospec` setting. Best viewed in color.

that BERT struggles to represent out-of-context words, likely due to its architecture and training regime. In A.1, we report that the lack of *any* surrounding context in `NC` is indeed detrimental to model representations, though sensible contextual information in `C` is needed to properly approximate LMD. Moreover, GloVe achieves the lowest MAE, which shows that these embeddings are effective in approximating the raw LMD values—though contextualized `C` BERT representations are better at capturing the overall pattern of similarity.[9]

Third, the pattern of correlation values over the model's layers highlights the importance of contextualization for compound representation. As can be seen in Figure 1, best-performing `C` BERT models show an almost constant increasing trend, with the highest correlation being achieved in high layers—layer 9 and 20 in BERT$_{\text{base}}$ and BERT$_{\text{large}}$, respectively. This is an opposite pattern compared to what was observed in previous work, where lower layers were found to encode most lexical semantic information (Bommasani et al., 2020; Vulić et al., 2020). These patterns do not necessarily contradict each other. Indeed, we argue that judging the semantic relationship between a compound (e.g., *handgun*) and its constituent words (*hand*, *gun*) might involve relying on a specific interpretation of the compound rather than on abstract lexico-semantic information. Since previous work showed that word senses are better encoded in deeper layers (Reif et al., 2019), this could explain why these layers are also good at capturing LMD. A similar—though flatter—trend is observed for `NC` models.

model	setting	metric (best layer)	
		MAE ↓	Spearman ρ ↑
GloVe	–	2.657	0.304
BERT$_{\text{base}}$	`NC_nospec`	0.953 (6)	0.316 (5)
	`NC_all`	1.129 (10)	0.234 (1)
	`NC_withcls`	0.989 (1)	0.275 (3)
	`C`	*0.899 (9)*	*0.415 (9)*
BERT$_{\text{large}}$	`NC_nospec`	0.989 (9)	0.195 (6)
	`NC_all`	1.118 (24)	0.113 (1)
	`NC_withcls`	1.024 (6)	0.139 (1)
	`C`	**0.876 (19)**	**0.476 (20)**

Table 3: ST. Results in **bold** and *italic* are the best and second-best in the column, respectively. Results are from a model's best-performing layer (in parentheses).

5.2 Semantic Transparency

In Table 3, we report the results by (the best layer of) each model on ST in the various settings. Several key observations can be made. First, both BERT models achieve moderate positive correlation with human judgments, with BERT$_{\text{large}}$ outperforming BERT$_{\text{base}}$. This indicates that BERT's representations are moderately effective in predicting the extent to which a compound meaning is recoverable from the meaning of its constituents and that more data and parameters help—indeed, the gap between the two BERT models is higher here than in LMD (0.06 vs 0.02). At the same time, the highest correlation achieved by BERT$_{\text{large}}$ (0.476) on ST is substantially lower than on LMD (0.586), which indicates that ST is more challenging to approximate compared to LMD.

Second, BERT models outperform GloVe on

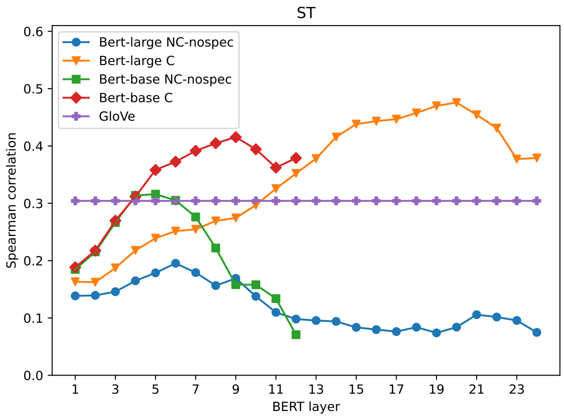

Figure 2: ST. ρ against model layers. For out-of-context BERT models, we only report the best-performing `nospec` setting. Best viewed in color.

---

[9] Recall that MAE measures the distance between the target and predicted values, while Spearman ρ quantifies strength and direction of association between the two ranked variables.

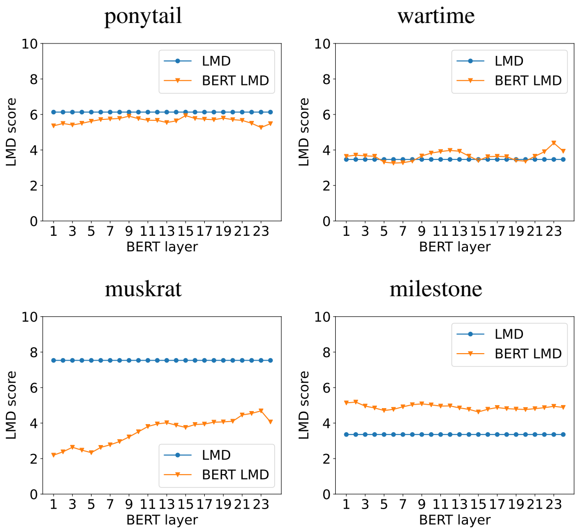

Figure 3: Examples where `C` BERT$_{\text{large}}$ is good (top) and bad (bottom) in approximating human LMD. From top left, clockwise: *ponytail*, *wartime*, *milestone*, *muskrat*.

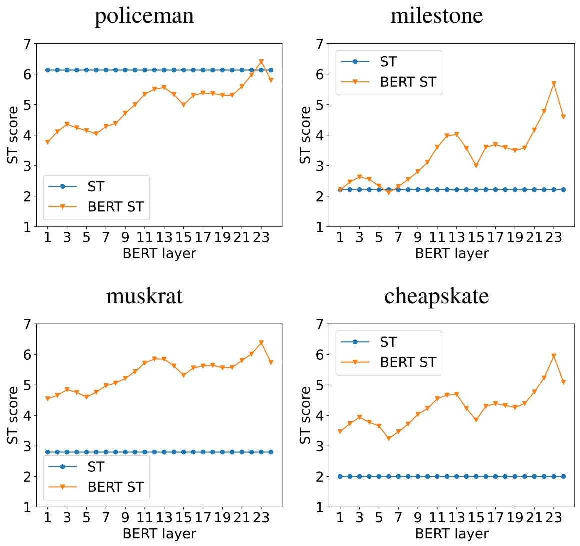

Figure 4: Examples where `C` BERT$_{\text{large}}$ is good (top) and bad (bottom) on ST. From top left, clockwise: *policeman*, *milestone*, *cheapskate*, *muskrat*.

both metrics. Though correlations are generally lower than in LMD, the gap between BERT models and GloVe is much more pronounced here. That is, BERT's contextualized embeddings have an even clearer advantage over previous-generation ones in modeling ST compared to LMD.

Third, as can be seen in Figure 2, the overall best results are achieved by `C` embeddings in high layers—layer 8 and 19 for BERT$_{\text{base}}$ and BERT$_{\text{large}}$, respectively—which replicates the findings for LMD. This confirms the role of context and contextualization for obtaining better representations of compounds.[10] Interestingly, in `NC` settings, BERT models show a different pattern compared to LMD, with correlation reaching a 'peak' within the first layers and then constantly decreasing. This suggests that decontextualized lexico-semantic information encoded in lower layers accounts for ST to some extent, on par with or even outperforming GloVe (this is the case for BERT$_{\text{base}}$ `NC_nospec`).

5.3 Examples

In Figure 3 we report some examples where the best-performing `C` BERT$_{\text{large}}$ is good (top) and bad (bottom) in approximating LMD. As can be seen, the distance between the predicted and human LMD is extremely low for *ponytail* and *wartime*, namely, a high-LMD (6.13) and a low-LMD (3.47) compound, respectively. In contrast, the distance is very large for high-LMD (7.53) *muskrat* and low-LMD (3.36) *milestone*. While the predicted LMD values are fairly stable over the layers for *ponytail*, *wartime*, and *milestone*, for *muskrat* the higher layers are better to approximate the real LMD by assigning an increasingly higher semantic weight to the *rat* lexeme. This could be due to the representation of *muskrat* becoming more 'aware'—through contextualization—of the semantic traits related to the animal domain, apparently less present in earlier layers. Also, it is interesting to note that for the compound *milestone*, which is 'exocentric' (i.e., the head is neither *mile* nor *stone*), BERT keeps predicting a conservative LMD value, which similarly weights the two constituents, over the layers. That is, contextualization does not make *mile* or *stone* become dominant in the compound (while, interestingly, human speakers consider *mile* as slightly dominant over *stone*).

In Figure 4, we report some good (top) and bad (bottom) cases for the same model in approximating ST. As can be seen, the distance between the predicted and human ST is very low for high-ST (6.31) *policeman* and low-ST (2.21) *milestone*. In contrast, the distance is large for low-ST (2.80) *muskrat* and low-ST (2.00) *cheapskate*. Moreover, it can be noted that higher layers are better than lower layers in approximating ST for *policeman*, which is highly transparent, while they are worse for *milestone*, *cheapskate*, and *muskrat*, which are very opaque. This goes hand in hand with a seemingly general trend observed in these examples:

---

[10] See the analysis in A.1 for further evidence of the role of sensible semantic context in approximating ST.

the more contextualization, the higher the ST. This could reflect a generalized increase of cosine similarity values through BERT's layers (as reported by Ethayarajh, 2019), which would lead in turn to a higher ST by virtue of how ST was operationalized; see Eq. 3. However, our results (see Figure 2) show that this increase does not correspond to a higher correlation with human judgments: indeed, correlation steadily decreases in the last 4 layers of BERT$_{\text{large}}$, where cosine similarities are highest.

Finally, while BERT struggles on both LMD and ST for *muskrat*, for *milestone* it struggles on LMD but does a good job on ST. This confirms that LMD and ST capture different semantic aspects: a good performance on one measure does not necessarily guarantee a good performance on the other.[11]

5.4 Which Factors Drive the Prediction?

To more formally investigate which factors contribute to higher predicted values of LMD and ST by the best performing model `C` BERT$_{\text{large}}$, we run two linear regression models in `R`—one for LMD, one for ST—using, for each compound, the predicted LMD/ST value by the best layers (21/20, respectively) as the dependent variable, and the following independent variables: (1) the number of tokens into which the compound was split by the tokenizer, e.g., 2 for *snowboard* (*snow*, *##board*); (2) the frequency of the compound in our dataset, i.e., the number of instances on the top of which the average representation was computed; (3) the compound concreteness; (4) the modifier (left constituent) concreteness; (5) the head (right constituent) concreteness. Concreteness values are extracted from Brysbaert et al. (2014).[12]

For LMD, both the concreteness of the head and the modifier—but not other variables—have a statistically significant role, though in the opposite direction: the higher the former, the higher the LMD (i.e., more weight to the head); the higher the latter, the lower the LMD (i.e., more weight to the modifier). This makes intuitive sense and shows that BERT assigns more 'weight' to concrete constituents. For ST, three variables have a statistically significant role in predicting higher values, and all in the same direction: the higher the number of tokens, the compound concreteness, and the modifier concreteness, the higher the ST. As for concreteness, this generally shows that BERT assigns higher similarities to concrete words. As for the effect of the number of tokens, this is an interesting finding, which reveals that BERT considers as more transparent those compounds than can be routinely broken into parts. The full tables reporting all the effects and corresponding coefficients and p-values can be found in A.2.

6 Analysis

6.1 LMD: Reversed Compounds

From the results reported in section 5.1, it appears that BERT is capable of obtaining sensible representations of compounds that encode the relation between the constituents and their respective semantic 'weight'. However, it might still be that the reported moderate correlations result from the model assigning a default high/low similarity to the constituents while being no or little aware of the semantic and syntactic (i.e., the modifier/head) relation which ties them. If that is the case, the model would consider, e.g., the contribution of *war* in *wartime* and *timewar* to be identical—though the meaning of the *reversed* compound would be intuitively very different. As such, we might expect a similar/same LMD value assigned by the model to these two compounds, and therefore a similar correlation with human judgments. Otherwise, if BERT represents a compound by genuinely accounting for the relationship between its constituents, the predicted LMD for the reversed compound (*timewar*) is likely to be different. As such, we might expect a much lower correlation with human intuitions.

In this analysis, we test this issue by re-running the LMD experiment on the *reversed* version of the compounds in our dataset, i.e., *wartime* > *timewar*, *bodyguard* > *guardbody*, etc. LMD is computed exactly as above, except that we replace the representation of the compound with that of its reversed version. Since (most of) these reversed compounds are unlikely to occur in standard *corpora* of texts, we experiment with `NC` representations. Moreover, we experiment with BERT$_{\text{base}}$ since it outperformed BERT$_{\text{large}}$ on this setting. As can be seen in Figure 5, the correlation for reversed compounds is much lower than the original one (0.11 vs 0.39). This is a good sign, which confirms that BERT does not rely on shortcuts when representing compound meanings and the relative weight of each constituent. Instead, it appears that the model can account for the semantic and syntactic relation

---

[11] Computing the correlation between LMD and ST human values in the dataset (-0.013) confirms this intuition.

[12] 23 compounds out of 628 were not present in the concreteness database and therefore excluded from the analysis.

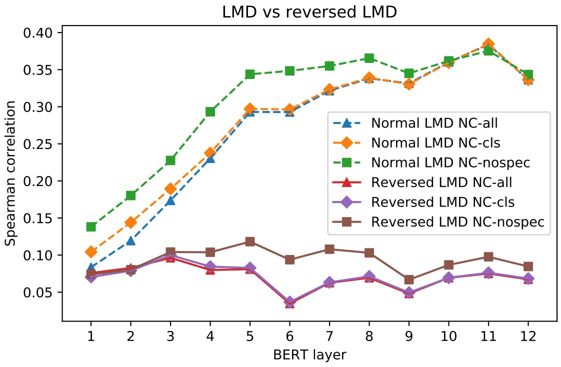

Figure 5: ρ for LMD vs LMD *reversed* values by out-of-context BERT$_{\text{base}}$ across layers. Best viewed in color.

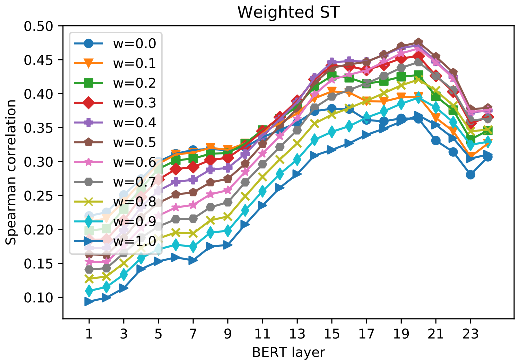

Figure 6: ρ for *weighted* ST by in-context BERT$_{\text{large}}$ across layers. Each weight stands for the weight assigned to the left constituent. Best viewed in color.

between the constituents, even when information from the surrounding context is not available.

6.2 ST: Weighted Constituents

From the results in section 5.2, it appears that BERT can approximate, to some extent, the degree to which the meaning of a compound is recoverable from the semantics of the constituents. When operationalizing ST we assumed that the two constituents are equally responsible for the overall ST—i.e., we computed the unweighted average between the two pairwise similarities. This way, a high (low) similarity between the compound and one of its constituents would not determine a high (low) ST on its own. This operationalization is in line with psycholinguistic literature, according to which we have a fully transparent compound when both lexemes contribute to its meaning and a fully opaque compound when neither of the two contribute (see, e.g., Libben, 1998). However, it is an open question whether BERT's compound representations do encode both constituents equally, or whether they disproportionately encode one constituent over the other. If the latter is the case, weighing one more than the other when computing ST would possibly result in a higher correlation with human judgments. If both constituents are equally represented in the compound embedding, instead, the unweighted version—our main experiment—would lead to the highest correlation.

In this analysis, we test this issue by computing a *weighted* version of ST where the left and right constituents are assigned different weights. For example, we assign weights 0.0 and 1.0 to the left and right constituent, respectively (in this case, only the right one, the compound's *head*, but not the left one, the *modifier*, will be responsible for ST); 0.1 and 0.9; 0.2 and 0.8; and so on. We experiment with all combinations of weights (including 0.5 and 0.5), which sums up to 11 versions of *weighted* ST.

Figure 6 reports the results of this analysis for the best-performing `C` BERT$_{\text{large}}$ model—note that the weight refers to the weight assigned to the left constituent. As can be seen, the highest correlation is achieved by the unweighted ST (weight 0.5) at layer 20. Since these are the results reported in Table 3, this finding confirms that both constituents are equally accounted for in the BERT's compound representation. Interestingly, weights that are close to 0.5 perform reasonably well (0.4 and 0.6 rank second and third, respectively), while correlation decreases the more we move away from this value.

Overall, the results of these two analyses confirm that BERT accounts for the left and right constituents equally when representing the semantics of a compound. Moreover, these representations seem to encode the complex semantic and syntactic relationship tying the compound constituents.

7 Conclusion

In this paper, we study how BERT represents the meaning of lexicalized compounds. We take a psycholinguistic angle and show that the model does a reasonably good job of making semantic judgments in line with those of human speakers. Since higher, more contextualized layers are shown to correlate best with human intuitions, we propose that speakers may access a specific, context-dependent representation when making these judgments. In future work, recent approaches to multimodal word representation in Transformers (Pezzelle et al., 2021) could be leveraged to test the role of visual grounding in compound semantics (Günther et al., 2020).

Limitations

Impact of the corpus To build contextualized representations for compounds, we sample sentences from a corpus of texts. A limitation of our work lies in the use of encyclopedic data only, which limits the number and variety of contextualized meanings a compound can have. Further attention should be paid to this aspect.

Operationalization of the measures While defining LMD and ST based on the cosine similarity between a compound and its constituent makes intuitive sense, it may not be the only (nor the best) way to operationalize the two measures. Further exploration on how to formally define them based on the model embeddings should be carried out.

Ethics Statement

Broader impact We do not see any serious ethical problem connected to this research. At the same time, we are aware of the risks associated with the development and use of large NLP models that we use in this research. Such risks include the environmental impact of the computational resources required for training and the encoding and possible amplification of biases present in the massive amounts of un-curated data the models learn from.

A Appendix

A.1 Templated Linguistic Contexts

In this analysis, we investigate the extent to which the disadvantage of `NC` compared to `C` in approximating LMD and ST is due to the lack of *any* linguistic context surrounding the compound and the constituent words.[13] Since BERT has probably seen very few examples of words out of context during training, it could be that the model is poor at handling words in isolation, which would have an impact on the resulting representations—and LMD/ST values. To test this issue, we consider the best-performing BERT$_{\text{large}}$ and use it to obtain a single, contextualized representation for words (either compounds or constituents) by embedding them in the following templated sentence: *This is a*

---

[13] We thank an anonymous reviewer for suggesting this analysis.

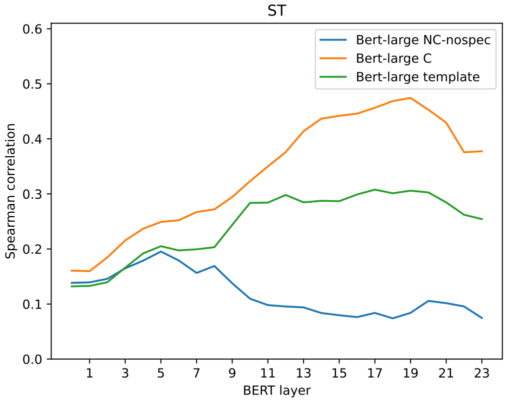

Figure 8: ρ for ST by BERT$_{\text{large}}$ `NC` (blue), `C` (orange), and `templated` (green). Best viewed in color.

`<word>`. This setting bears similarities with both `NC` and `C`. On the one hand, we compute a single representation for each word, similarly to `NC`. On the other hand, the representation of each word is contextualized (i.e., embedded in a linguistic context), though the surrounding context does not contain any meaningful semantic information. As such, we expect these representations to be better than `NC` by virtue of their higher similarity with standard training samples, but worse than `C` since they lack any sensible semantic information coming from the context surrounding the word at inference time.

The results follow the expected pattern. As can be seen in Figure 7 and 8, the correlation values obtained in the `templated` setting (best ρ for LMD: 0.491; best ρ for ST: 0.308) lie somehow in between `C` and `NC`. While this shows that embedding words in a sentence leads to a representational advantage over the out-of-context presentation (they clearly outperform `NC`), these representations are still far behind `C` and either on par with (ST) or neatly below (LMD) the GloVe baseline. This confirms that leveraging the meaningful linguistic context where compounds and constituents occur is crucial for obtaining sensible word representations that encode information on LMD and ST in line with human intuitions.

Abstract

We investigate in this paper how distributions of occupations with respect to gender is reflected in pre-trained language models. Such distributions are not always aligned to normative ideals, nor do they necessarily reflect a descriptive assessment of reality. In this paper, we introduce an approach for measuring to what degree pre-trained language models are aligned to normative and descriptive occupational distributions. To this end, we use official demographic information about gender–occupation distributions provided by the national statistics agencies of France, Norway, United Kingdom, and the United States. We manually generate template-based sentences combining gendered pronouns and nouns with occupations, and subsequently probe a selection of ten language models covering the English, French, and Norwegian languages. The scoring system we introduce in this work is language independent, and can be used on any combination of template-based sentences, occupations, and languages. The approach could also be extended to other dimensions of national census data and other demographic variables.

1 Introduction

Pre-trained language models (LMs) may contain various types of biases, and the field of NLP has seen a lot of work in recent years on attempting to identify, mitigate, and reduce these biases. Biases can originate both from the unlabeled texts used for pre-training these LMs, and from texts and annotations used for tuning downstream classifiers. LMs have become a cornerstone in most NLP model architectures, and the extent to which they reflect, amplify, and spread the biases present in their training data is still a problematic issue to be solved.

Several efforts in this direction have focused on *gender* as a variable (Touileb and Nozza, 2022; Touileb et al., 2021; Ousidhoum et al., 2021; Nozza et al., 2021; Touileb et al., 2020; Saunders and Byrne, 2020; Bhaskaran and Bhallamudi, 2019; Cho et al., 2019; Prates et al., 2018), also in correlation with occupations (Borchers et al., 2022; Touileb et al., 2022; Bolukbasi et al., 2016). While there have been several efforts on exploring the existing biases related to these demographic variables, most work approaches the task from a normative point of view (Blodgett, 2021), where equality between the demographic distributions is prioritized.

Although normativity in this aspect is crucial for certain applications, we argue that it is also interesting to explore the task from a descriptive perspective. This is especially interesting for occupations, since a descriptive and realistic view of society already contains gender disparities. We propose that national census data, in our case about gender-occupation distributions, can offer a reliable ground truth against which model predictions can be compared. Moreover, we argue for taking both normative and descriptive assessments into account, in order to give a broader picture of the representations of demographics within LMs. This has also been partly pointed out by Blodgett et al. (2020), who stress the importance of the connection between language and social hierarchies, which has not been taken into consideration in most previous work on bias in NLP.

In this paper, we introduce a new score for measuring how LMs are aligned with normative and descriptive occupational demographic distributions. We use demographic distributions covering occupations in four countries, namely France, Norway, the United Kingdom, and the United States. We manually select gendered pronouns and nouns, as well as specific verb phrases, to construct template-based sentences, subsequently used to probe a selection of ten LMs covering the relevant languages.

Our contributions include; (i) creating novel benchmark datasets for English, French, and Norwegian based on manually crafted templates to mea-

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2242–2248
May 2-6, 2023 ©2023 Association for Computational Linguistics

sure occupational gender biases, (ii) proposing a scoring system to measure normative and descriptive biases in LMs, and (iii) releasing our code and data for reproducibility.

In what follows, we give a detailed description of our new benchmark datasets in Section 2. We then, in Section 3, give a detailed description of the normative and descriptive bias scores, and present our analysis on ten LMs as proof of concept. We discuss and summarize our findings in Section 4, and conclude by discussing possible directions for future work in Section 5. The limitations of our work are discussed in the Limitations Section.

2 Benchmark datasets

In this work we develop a set of benchmark templates for English, French, and Norwegian that cover occupations in France, Norway, the United Kingdom (UK), and the United States (US). These templates are then used for probing different LMs. More details are given in what follows.

Occupations We retrieve country-specific lists of occupations and their associated (male/female) gender ratios from the national statistics bureaus of France, Norway, UK, and the US.[1] This resulted in 235 occupations from France,[2] 415 from Norway,[3] 325 from the UK,[4] and finally 314 occupations from the US.[5] All of these occupations were listed in either masculine singular or masculine plural form. As some of the languages we are focusing on inflect nouns for gender, we manually generate for each occupation in singular masculine form the corresponding forms in singular feminine, plural feminine, and plural masculine. This was performed by a native speaker of Norwegian and French, and a proficient speaker of English. Table 1 shows the top 5 female-dominated, male-dominated, and gender balanced occupations in each census data.

Templates Our work builds on the methodology of template-based probing. To measure a model's occupational biases we follow the same procedure for all languages. Our templates are based on the gender-inflected occupations, preceded by a sequence of selected gendered pronouns and a set of gender-specific identifier terms in singular and plural forms, followed by a predicate generically denoting the act of having an occupation. As an example, a template could be:

$$\underbrace{\text{The woman}}_{\text{gender-specific identifier}} \quad \underbrace{\text{worked as a}}_{\text{predicate}} \quad \underbrace{\text{nurse}}_{\text{occupation}}$$

We select 28 gender-specific identifiers, and 6 predicates for all three languages. The full list of gender-specific identifiers can be found in Table 2 and the list of predicates in Table 5 in Appendix A. Combining these identifiers and predicates with our country-specific occupations, we create a set of 12.726 template-based probes for French occupations, 69.720 for Norwegian, 50.700 for the UK, and 48.984 for the US.

The templates we created cover different grammatical tenses, such that each template is given in the past, present, and future tense. We have decided to include such a broad collection of variations to the templates to get a better representation of how occupations are correlated with genders, especially since research has shown that bias probes are sensitive to grammatical tense (Touileb, 2022).

3 Method

LMs trained with a masked language modelling objective are trained such that random tokens in the input training data are replaced with a placeholder token, `[MASK]`, which will subsequently be predicted by the trained model. Template-based approaches to probe biases take advantage of this feature of LMs. For our purposes, we mask the gendered identifier in each template-generated probe (as introduced in Section 2), and use the returned probability of each masked identifier to compute our bias scores. A masked version of the example template above would be:

$$\underbrace{\text{The [MASK]}}_{\text{gender-specific identifier}} \quad \underbrace{\text{worked as a}}_{\text{predicate}} \quad \underbrace{\text{nurse}}_{\text{occupation}}$$

Language models We select ten LMs covering the three languages English, French, and Norwegian. All models are available from the HuggingFace library (Wolf et al., 2020). We use four Norwegian models, four English models, and two French models. These are:

- NorBERT (Kutuzov et al., 2021): trained from scratch on the Norwegian newspaper corpus[6],

Table 1: Top 5 gender-dominated and gender-balanced occupations in census data from France (FR), Norway (NO), the United Kingdom (UK), and the United States (US). The occupations presented here are either dominated by more than 98% of either gender, or have a more balanced distribution (between 45% and 55%) between both female and male genders.

and Norwegian Wikipedia. The model comprises about two billion word tokens.

- NorBERT2[7]: the non-copyrighted subset of the Norwegian Colossal Corpus (NCC)[8] and the Norwegian subset of the C4 web-crawled corpus (Xue et al., 2021) were used to train this model from scratch. It comprises about 15 billion word tokens.
- NB-BERT_base (Kummervold et al., 2021): trained on the full version of the NCC corpus. This model used the architecture of the BERT cased multilingual model (Devlin et al., 2018). It comprises around 18.5 billion word tokens.
- NB-BERT_Large[9]: trained similarly to the NB-BERT_base model.
- BERT_base (Devlin et al., 2018) and BERT_Large: trained on English Wikipedia and Google's Books Corpus.
- RoBERTa_base (Liu et al., 2019) and RoBERTa_Large: trained on the BookCorpus, English Wikipedia, CC-news corpus (English news), OpenWebText dataset, and Stories dataset (a subset of the Common Crwal corpus).
- CamemBERT (Martin et al., 2020): trained on the OSCAR corpus (Ortiz Suárez et al., 2019), which is a multilingual corpus created by filtering the Common Crawl corpus.
- Barthez (Eddine et al., 2020): trained on the French part of the Common Crawl and Wikipedia, in addition to various smaller corpora (Eddine et al., 2020).

Scoring system The scoring system we introduce is the same for both bias scores. We will give more details on the differences of the scores in their respective sections.

For each template, and for each language, 28 gender-specific identifiers and 6 different predicates were used with each occupation. To compute the scores, we average over the gendered-identifiers and the predicates of the LMs' returned probabilities for each template. For each template, only one gender is represented (female or male). If the language inflects for gender, all components of a template reflect the gender in question, otherwise it is only reflected in the identifier.

We average the scores for a given occupation by gender, by summing and normalizing the probabilities of each identifier and the total probability

values returned by the LM, here dubbed $proba_G$, where G can be female or male (equation (1)). Then using this overall probability of a gender for a template, we average these values over all templates related to the occupation (equation (2)). More formally, for a language model *LM*, for each occupation O, there are a number of templates T, and a number of identifiers i and predicates p, reflecting a gender G. We define the bias score as follows:

$$proba_G = \frac{\sum_i T_p}{|i|} \tag{1}$$

$$score_O = \frac{\sum_{proba_G} T_O}{|T_O|} \tag{2}$$

Descriptive bias score Once the scores $score_O$ are computed, the descriptive bias score compares the percentages of distribution of occupations in the LMs to the ground truth data that comes from the respective census data of our countries of interest. We impose a threshold on the gender distributions in such a way that the category of *gender-imbalanced* occupations here corresponds to all occupations exceeding 55% of distribution for one gender, while *gender-balanced* occupations are those which percentages lie around $50\%_{\pm 5}$ for each gender.

Model	Normative	Descriptive
NorBERT	16.23	39.31

BARThez	6.45	37.08

Table 3: Normative and descriptive occupational bias scores.

We look at the extent to which this score aligns with the census data. We compute an overall score disregarding gender, in addition to class-level scores: female dominated occupations (more than 55% in census are females), male dominated occupations (more than 55% in census are males), neutral occupations (between 45% and 55% of occupations in census for either gender).

Normative bias score The normative bias score also builds on top of the scores $score_O$, and compares the resulting distribution of occupations in LMs to a normative description of all occupations, such that percentages of either gender should be around $50\%_{\pm 5}$.

From a normative point of view, equal representations should be given to females and males. Instead of just setting the distribution to a strict value of 50-50, we decided that for either gender, the distribution should range anywhere between 45% and 55% in the census data. This to say, that if an occupation has 45% and 55% males, we consider it a balanced distribution.

4 Results and discussion

Table 3 shows the resulting normative and descriptive bias scores of the ten LMs. All scores represent percentages, *i.e.,* the percentage of model predictions that align with our normative values or descriptive demographic distributions. With no surprise, it is clear that all models exhibit fairly weak performance according to the normative bias score. The weakest performing model normatively speaking is RoBERTa (both base and large) on both UK and US statistics. BERT seems to be a bit better on UK statistics, but the difference is not signif-

Model	Neutral	Female	Male

RoBERTa_Large_US	0.00	42.81	0.00
CamemBERT	0.00	0.00	34.10
BARThez	0.00	0.00	37.08

Table 4: Descriptive bias scores of gender-imbalanced and gender-neutral occupations. The two gender-imbalanced occupations cover female dominated occupations (more than 55% in census are females), and male dominated occupations (more than 55% in census are males). The gender-neutral occupations are those with distributions between 45% and 55% in census data for either gender.

icant. For the remaining languages, NorBERT2 is the worst Norwegian model normatively and BARThez is the worst of the two French models.

Results of the descriptive scores are in general higher. Most models seem to reflect the demographic occupational distribution to a certain extent. Both BERT models achieve highest descriptive scores, performing best on the US census data. While the RoBERTa models obtain the lowest performance in terms of the normative score, they rank second in the descriptive score on the US census data. NorBERT2 is still the weakest performing Norwegian model, ranking last both descriptively and normatively, while BARThez seems to yield the best descriptive score for French.

To get a more detailed overview of which types of occupations the tested models seem to represent the best, we also computed the descriptive scores of gender-imbalanced and gender-neutral occupations separately. Results can be seen in Table 4. Interestingly, all Norwegian and English models are better at identifying female-dominated occupations, while the two French models seem to only identify male-dominated occupations.

All models exhibit the lowest scores on gender-neutral occupations, hinting at the tendency that models correlate most occupations with one gender, rather then equally representing them. This would also align with the lower normative scores that we generally see.

Since the occupations in the census data differ from country to another, it is difficult to compare and rank models across languages. A fair comparison of these models is to focus on performance by country rather than across them. Even if we state that some models are the best or worst using one scoring system, the country-level scores are the most important measure of bias in the models.

5 Conclusion

We have introduced a new scoring system for measuring occupational biases in pre-trained language models. The scoring system allows the attribution of two scores: a normative score and a descriptive score. While the normative score sheds light on to what extent the correlations between genders and occupations are balanced, the descriptive score uses real world demographic distributions to reflect to what degree the language models reflect reality.

As a proof of concept we test our scoring systems on ten language models covering the French, Norwegian, and English languages. It comes as no surprise that all models exhibit low scores when using the normative scoring, while most of them have an adequate score when measured descriptively. What is more interesting is that our scoring mechanism allows us to separate between the normative and descriptive aspects of the model properties. All templates and codes are made publicly available on our GitHub repository.[10]

While we have limited our analysis to three languages, our approach is language agnostic and only requires language specific templates and demographic statistics on the distributions of occupations with respect to gender, something most national census agencies should be able to provide. Moreover, the approach could also be extended to other dimensions of national census data and other demographic variables.

On the note of future directions, we also plan to investigate cross-cultural effects, by comparing models for different languages across the gender–occupation lists from different nations, and also including multi-lingual models. Moreover, we also plan to systematically test the impact of different text sources (used to train language models) on our bias scores.

Limitations

The major limitation of our work is that we focus on a binary gender setting. We acknowledge the fact that gender as an identity spans more than just two categories, however, the demographic census data we use have only the two genders (female and male) represented.

As proof of concept, the templates we use in this work are limited to one framing of how gendered pronouns and nouns can co-occur with occupations. Extending this to more diverse templates might give a broader context and a better representation of genders in LMs.

The applicability of English models to the UK and US census data, and the French models to the French census data, might also give a skewed representation of occupations. Both English and French are spoken across many countries, which might have an effect on the representation of occupations and genders in the language models. It would therefore be interesting to investigate to what extent language-specific language models reflect census data from different countries.

Abstract

We propose two methods to make unsupervised domain adaptation (UDA) more parameter efficient using adapters, small bottleneck layers interspersed with every layer of the large-scale pre-trained language model (PLM). The first method deconstructs UDA into a two-step process: first by adding a *domain adapter* to learn domain-invariant information and then by adding a *task adapter* that uses domain-invariant information to learn task representations in the source domain. The second method jointly learns a supervised classifier while reducing the divergence measure. Compared to strong baselines, our simple methods perform well in natural language inference (MNLI) and the cross-domain sentiment classification task. We even outperform unsupervised domain adaptation methods such as DANN (Ganin et al., 2016) and DSN (Bousmalis et al., 2016) in sentiment classification, and we are within 0.85% F1 for natural language inference task, by fine-tuning only a fraction of the full model parameters. We release our code at *https://github.com/declare-lab/domadapter*.

1 Introduction

Fine-tuning pretrained language models (PLM) is the predominant method for improving NLP tasks such as sentiment analysis, natural language inference, and other language understanding tasks (Wang et al., 2018). However, fine-tuning forces us to modify all the parameters of the model and store one copy of the model for one task. Given the large size of current PLMs, this can be expensive. Furthermore, fine-tuning needs large-scale data to be effective and is unstable when using different seeds (Han et al., 2021).

A new approach to alleviate this is parameter-efficient fine-tuning – freezing the PLM parameters and fine-tuning only a small fraction of the parameters. Fine-tuning with adapters (Houlsby et al., 2019) is one of these methods in which small additional layers are tuned within each PLM layer. Fine-tuning with adapters has many advantages: performance comparable to full fine-tuning (He et al., 2021a), and robustness to different seeds and adversarial examples (Han et al., 2021).

Unsupervised domain adaptation (UDA) aims to adapt models to new domains and considers situations where labeled data are available only in the source domain and unlabeled data are available in the target domain. UDA methods in general have two components: The first reduces the divergence between the source and target domains, and the second reduces the loss corresponding to a particular task (Ramesh Kashyap et al., 2021a). However, they fine-tune a large number of parameters and are susceptible to catastrophic forgetting. Adapters (Houlsby et al., 2019) can help solve these problems. However, the benefits of using adapters fine-tuning for domain adaptation have been mostly overlooked. *How well can adapter fine-tuning perform across different domains and can we make domain adaptation more efficient?* In this work, we answer these questions and propose models to perform domain adaptation using adapters.

Adapters are known to perform well in low-resource scenarios where a small amount of supervised data is available in a new domain or language (He et al., 2021b; Pfeiffer et al., 2020b). In this work, using the principles of UDA, we propose to make domain adaptation more effective using unsupervised data from the target domain. We introduce two methods that we collectively call the **U** nsupervised **D** omain **A** daptation method using ada**pters** (UDAPTER). The first method is a two-step process: First, we learn *domain adapters* – where we use a divergence measure to bring two probabilistic distributions closer together. This helps us to learn representations that are independent of the

(a) (b) (c)

Figure 1: UDAPTER for a transformer layer l uses principles from unsupervised domain adaptation to make domain adaptation more parameter efficient. (a) The first method TS-DT-🔌 trains a Domain Adapter that reduces the marginal distribution between the domains (b) The task adapter is stacked on top of the domain adapter. and trained on an end task like sentiment analysis or natural language inference. The domain adapter is frozen during training. (c) The second method JOINT-DT-🔌 reduces the domain divergence and the task loss jointly.

domain from which they come. Second, we use the domain-invariant information learned as input to another task adapter that learns to perform an NLP task using labeled data from the source domain. We combine the two adapters by stacking them. The second method adds a single adapter without stacking, where we simultaneously reduce the divergence between domains and learn the task in the source domain.

Domain Adversarial Neural Networks (DANN) and Domain Separation Networks (DSN) are the most common methods for unsupervised domain adaptation in NLP (Ramesh Kashyap et al., 2021a). We compare our proposed methods with these strong baselines that fine-tune all model parameters, on Amazon (Blitzer et al., 2007) and the MNLI dataset (Williams et al., 2018) consisting of five domains each. UDAPTER performs better than all baselines. It achieves competitive performance compared to UDA methods by fine-tuning only a fraction of the parameters. In an era where large resources are spent to further pretrain language models on large amounts of unsupervised data to achieve domain adaptation (Gururangan et al., 2020), it is necessary to provide cheaper, faster solutions.

2 Method

Setup. We consider an NLP task (sentiment analysis) consisting of data $\mathcal{X}$ and labels $\mathcal{Y}$ (positive, negative). There exist two different distributions, called the source domain $\mathcal{D}_\mathcal{S}$ and the target domain $\mathcal{D}_\mathcal{T}$ over $\mathcal{X} \times \mathcal{Y}$. Unsupervised domain adaptation (UDA) consists of a model $\mathcal{C}$ that receives labeled input samples $\mathcal{X}_\mathcal{S} : (x_s, y_s)_{s=1}^{n_s} \sim \mathcal{D}_\mathcal{S}$ and unlabeled input $\mathcal{X}_\mathcal{T} : (x_t)_{t=1}^{n_t} \sim \mathcal{D}_\mathcal{T}$. The goal of UDA is to learn a model $\mathcal{C}$ such that we perform well in the NLP task for the target domain $\mathcal{D}_\mathcal{T}$.

The popular method in UDA is to learn representations that are invariant in the input domain and still have sufficient power to perform well in the source domain (Ganin et al., 2016; Bousmalis et al., 2016). Then according to the theory of domain divergence (Ben-David et al., 2010) shows that the error in the target domain is bounded by the error in the source domain and the divergence. The unsupervised domain adaptation method thus consists of two components: the reduction of the divergence measure and a classifier for the source domain. A new classifier must be learned for every pair of source-target domains, and the method fine-tunes a large number of parameters.

UDAPTER makes unsupervised domain adaptation more parameter efficient (cf. § 2.1, § 2.2) using adapters. We follow the framework proposed by Houlsby et al. (2019) where small bottleneck layers are added to the transformer layers, fine-tuning only the adapter parameters while keeping the other parameters frozen, and propose the following.

2.1 Two-Step Domain and Task Adapters

Domain Adapters. To learn domain-invariant representations, we first train a domain adapter. The adapter architecture follows the work of Pfeiffer et al. (2021), which consists of a simple down-projection followed by an up-projection. In a transformer layer l, let h_l be the hidden representation of the layer **Add & Norm** and let r_l be the representation of the layer **Feed-Forward** (Figure 1a), then the adapter makes the following transformation and calculates a new hidden representation.

$$dom_l = W_{up} \cdot f(W_{down} \cdot h_l) + r_l \tag{1}$$

where f is a nonlinear function such as RELU, $W_{down} \in \mathbb{R}^{h \times d}$ projects the hidden representations down to a lower dimension, $W_{up} \in \mathbb{R}^{d \times h}$ projects them back to a higher dimension, and $d \ll h$. We pass a sample from the source domain $(x_s^{src}) \sim \mathcal{D_S}$ and a sample from the target domain $(x_t^{trg}) \sim \mathcal{D_T}$ through the adapters in layer l and obtain their representations h_l^{src} and h_l^{trg}, respectively. We then reduce the divergence between these representations.

$$\Delta_l = div(dom_l^{src}, dom_l^{trg}) \tag{2}$$

Here $div(\cdot)$ is the divergence function such as the correlation alignment (CORAL) (Sun et al., 2016), the central moment discrepancy (CMD) (Zellinger et al., 2017) or the multi-kernel maximum mean discrepancy (MK-MMD) (Gretton et al., 2012; Bousmalis et al., 2016). In this work, we use MK-MMD for all of our experiments, since it performed the best[1]. Similar ideas are used to adapt representations in computer vision models (Long et al., 2019; Sun and Saenko, 2016). The final divergence loss considers all L layers.

$$\mathcal{L}_{div} = \sum_{l=1}^{L} \Delta_l \tag{3}$$

Task Adapters. Task adapters are stacked with frozen domain adapters. We pass the representations dom_l from the previous step and the supervised data from the source domain $(x_s^{src}, y_s^{src}) \sim \mathcal{D_S}$. Task adapters have the same architecture as domain adapters and perform the following.

$$task_l = W_{up} \cdot f(W_{down} \cdot dom_l^{src}) + r_l \tag{4}$$

The goal of these task adapters is to learn representations that are task-specific. Only task adapters are updated when training on the end task (sentiment classification, natural language inference) and all other parameters, including domain adapters, are frozen. Regular cross-entropy loss is reduced during training of task adapters.

$$\mathcal{L}_{task} = softmax\_ce(W_{task} \cdot h_L) \tag{5}$$

h_L is the hidden representations of the last layer of the transformer, $W_{task} \in \mathbb{R}^{h*|\mathcal{Y}|}$ where $|\mathcal{Y}|$ is the number of classes, and $softmax\_ce$ is the softmax followed by cross-entropy. This two-step process deconstructs UDA methods with a domain adapter and a task adapter. This affords composability, where task adapters can be reused for different pairs of domains (§ 3.4). However, domain and task representations can be learned jointly, as explored in the next section.

Training Process. Given a source-target domain adaptation scenario, we first train the domain adapter and save their weights. We then stack the task adapter with the domain adapter, which is trained using the supervised data from the source domain. When training the task adapter, the domain adapter is frozen. During inference, we stack the domain and task adapter.

2.2 Joint Domain Task Adapters

This method adds a single adapter that performs the reduction of the divergence measure and learns

---

[1] We also tried using CMD and CORAL and our systems performed similarly to MK-MMD

Dataset	Train	Dev	Test
MNLI	69,600	7,730	1,940
AMAZON	1,440	160	400

Table 1: Dataset statistics, showing number of train, dev, and test instances per domain.

task representations jointly. For a given supervised sample from the source domain $(x_s^{src}, y_s^{src}) \sim \mathcal{D}_\mathcal{S}$ and an unsupervised sample $(x_t^{trg}) \sim \mathcal{D}_\mathcal{T}$, let h_l^{src}, h_l^{trg} be the hidden representations of the adapters for x_s^{src} and x_t^{trg} for layer l. We reduce the following joint loss:

$$\mathcal{L} = \lambda \cdot \mathcal{L}_{task} + (1 - \lambda) \cdot \mathcal{L}_{div} \tag{6}$$

Here $\mathcal{L}_{task}$ is the task loss on the source domain supervised samples, λ is the adaptation factor.

Reducing divergence along with cross-entropy loss beyond a certain point makes training unstable and does not contribute to increased performance. Following (Ganin et al., 2016) we suppress the noisy signal from the divergence function as training progresses and gradually change λ from 0 to 1 to reduce the contribution of divergence loss using the following schedule ($\gamma = 10$ for all of our experiments):

$$\lambda = \frac{2}{1 + \exp\left(-\gamma \cdot p\right)} - 1 \tag{7}$$

Similar methods have been proposed to adapt models to other domains by Long et al. (2019) and Wu et al. (2022). Compared to the two-step process introduced earlier (§ 2.2), we need to properly control the losses to obtain optimal results and also this method does not offer composability (§ 3.4).

3 Experiments

3.1 Datasets

We evaluate our approach on two representative datasets with different tasks, both in English. Table 1 shows the details of the datasets. Every dataset has 5 domains, and we consider each domain with every other domain which results in 20 domain adaptation scenarios for every dataset, 120 experiments per method, and 1900+ experiments.

AMAZON: Multi Domain Sentiment Analysis Dataset (Blitzer et al., 2007) that contains Amazon product reviews for five different types of products (domains): Apparel (A), Baby (BA), Books (BO), Camera_Photo (C), and Movie Reviews (MR). Each review is labeled as positive or negative. We follow the setup in (Ramesh Kashyap et al., 2021a)

MNLI: The Multigenre Natural Language Inference (MNLI) corpus (Williams et al., 2018) contains hypothesis–premise pairs covering a variety of genres: Travel (TR), fiction (F), telephone (TE), government (G), and slate (S). Each pair of sentences is labeled Entailment, Neutral, or Contradiction. The train and validation data set are taken from the train set by sampling 90% and 10% samples, respectively. We use the MNLI-matched validation set as our test set.

3.2 Baseline Methods

Fully supervised. *Fine-tune* (🔥): Fine-tunes a language model using labeled data from the target domain. Serves as an upper bound of performance.

Unsupervised Domain Adaptation (UDA). *Domain Adversarial Neural Networks* (DANN): An unsupervised domain adaptation method (Ganin et al., 2016) that learns domain-invariant information by minimizing task loss and maximizing domain confusion loss with the help of gradient reversal layers. *Domain Separation Networks:* (DSN) (Bousmalis et al., 2016) improves DANN, with additional losses to preserve domain-specific information along with the extraction of domain-invariant information. `bert-base-uncased` serves as a feature extractor for both methods.

Adapter Based. DANN *Adapter* (DANN- 🔌): Similar to DANN, but we insert trainable adapter modules into every layer of a PLM. DANN *Adapter with Multiple Classifiers* (DANN- 🔌 -MC): Unlike DANN- 🔌 which involves a single task and domain classifier, here a task and domain classifier are added to each of the last 3 layers of a PLM. The representation of the last layers of a PLM is domain variant (Ramesh Kashyap et al., 2021b), and this model obtains domain-invariant information[2] (vi) Task adapter (TASK- 🔌): Adapter fine-tuning (Pfeiffer et al., 2020a) where adapters are fine-tuned in the labeled source domain and tested in the target domain. (vii) Two-step Domain and Task Adapter (TS-DT- 🔌): This work, where we first train a domain adapter that reduces the probabilistic divergence between two domains and then fine-tunes a task adapter by stacking. (viii) Joint

---

[2] We tried adding classifiers incrementally to the last few layers. Adding it to the last 3 layers performed the best.

Table 2: F1 scores for AMAZON dataset. We report mean and standard deviation of 3 runs. The five domains are Apparel (A), Baby (BA), Books (BO), Camera_Photo (C) and Movie Reviews (MR). On average, our method outperforms all baselines. Our methods are competitive with fully unsupervised domain adaptation methods.

Domain Task Adapter (JOINT-DT-🔌) - We train a single adapter that reduces the domain and task loss jointly. For all adapter-based experiments, the PLM is frozen, and only adapter modules are trained.

Since we use adapters, we only consider other adapter based baselines and omit other methods such as Prefix-tuning (Lester et al., 2021). Also, (Zhang et al., 2021) target multidomain adaptation and use data from all the domains during training unlike our method and is not a fair comparison.

Implementation Details and Evaluation. For our experiments, we use `bert-base-uncased` (Devlin et al., 2019) available in the HuggingFace Transformers library (Wolf et al., 2020) as our backbone. Adapter implementations are from AdapterHub (Pfeiffer et al., 2020a). We follow (Pfeiffer et al., 2021) and add only one bottleneck layer after the feedforward layer.

We use the AdamW optimizer and a learning rate of $1e-4$ for all our adapter-based training and $2e-5$ otherwise. Only for the smaller AMAZON dataset, we used an adapter bottleneck size (reduction factor) of 32. For all other adapter-based experiments and datasets, we use the default adapter bottleneck size of 16. We performed experiments on three different seeds. We report the mean and standard deviation of the F1 scores . For DANN we use 0.04 as our λ and for DSN we use 0.1, 0.1, and 0.3 as our weights for three losses: reconstruction, similarity, and difference respectively. We avoid extensive hyperparameter tuning per domain adaptation scenario for efficiency.

3.3 Results

From Table 2 and Table 3 our methods TS-DT-🔌 and JOINT-DT-🔌 perform well in both AMAZON and MNLI. We find that fine-tuning the task adapter (TASK-🔌) is a strong baseline and, compared to it, we perform well in 17/20 domain adaptation scenarios in AMAZON (largest increase of 8 points for C → BA) and 19/20 domain adaptation scenarios in MNLI (largest increase of 2.2 for F → TE). One possible explanation of scenarios where our method finds the largest increase is the proximity of the two domains. The overlap in vocabularies (Figure 9 in Appendix) between C →BA in AMAZON and F → TE in MNLI is high, and our method takes advantage of learning domain-invariant information that can be used for efficient domain transfer. Our methods for learning domain-invariant information are necessary to achieve good domain adaptation.

UDAPTER is comparable to UDA methods. Compared to UDA methods where all parameters of the backbone model are fine-tuned, we perform close to them on average. JOINT-DT-🔌 performs better than DSN by 0.2% in AMAZON. We are within 0.85% in MNLI compared to DSN. Training DANN is highly unstable and produces varied re-

Table 3: F1 scores for MNLI dataset. We report mean and standard deviation of 3 runs. The five domains are Fiction (F), Slate (S), Government (G), Telephone (TE), and Travel (TR). On average, our method performs better than all baselines.

sults, especially for AMAZON with a small number of examples in each domain. Our adapter method achieves better results compared to DANN with a minimal modification of the hyperparameters.

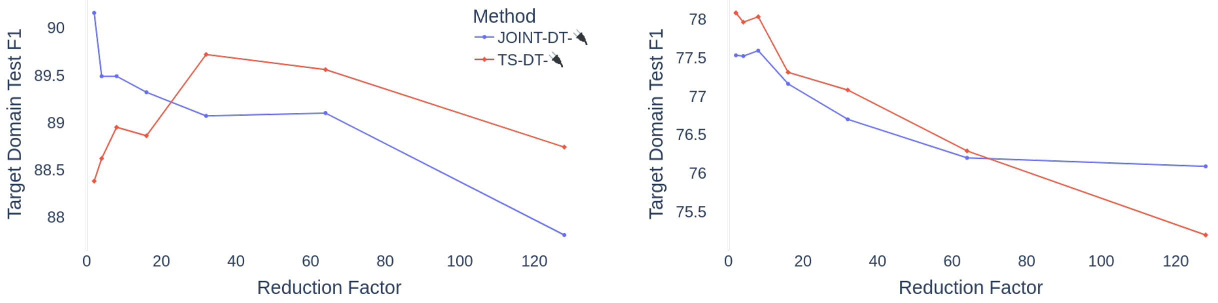
Replacing UDA Feature Extractors with Adapter Versions is insufficient. *Given that fully fine-tuned* UDA *methods perform well, can we freeze the feature extractors* UDA *methods and fine-tune only adapters and perform effective domain adaptation?* We compare our methods with DANN-🔌 and DANN-🔌-MC and outperform them both in AMAZON and MNLI. This is in line with Karouzos et al. (2021) that although domain adversarial training brings domain representations closer, it introduces distortion in the semantic space, reducing model performance. This shows that simply replacing feature extractors with their adapter versions in existing UDA methods is not an effective strategy.

Gap to Full Fine-Tuning. Fine-tuning a PLM with supervised data in the target domain is the upper bound performance for domain adaptation. The gap from full fine-tuning is greater when more data are available (3.15 in AMAZON and 4.13 in MNLI). This is not surprising, as the supervised fine-tuning works better with more data. However, while adapters perform closely to complete fine-tuning in supervised scenarios (He et al., 2021a), there is still a large gap between domain adaptation and complete fine-tuning and would require significant future work.

3.4 Further Analysis

Adapter Reduction Factor. The bottleneck size (d) of the adapters plays an important role in the final performance of the model. We show the performance of the models at various reduction factors in Figure 2. For JOINT-DT-🔌, smaller reduction factors generally perform well in both AMAZON and MNLI, with performance reducing for larger reduction factors. This shows that the JOINT-DT-🔌 method requires a greater number of parameters to reduce divergence and learn task representations together. Since TS-DT-🔌 adds two adapters, this increases the number of parameters added for the same reduction factor compared to JOINT-DT-🔌. As a result, we find that as the data scale up, relatively low reduction factors work well.

The removal of adapters from continuous layer spans. All adapters are not equal. Removing adapters from the first few layers still preserves performance (Figure 3). For JOINT-DT-🔌 and TS-DT-🔌, the F1 slowly decreases as we continually remove the adapters. However, we obtained a comparable performance after removing the adapters from layers 1-6. This suggests that adapters are effective when added to higher layers, where the divergence between domains is greater at higher layers compared to lower layers (Ramesh Kashyap



(a)

(b)

Figure 2: (a) Performance for AMAZON on the C → BA domain adaptation scenario for different reduction factors. (b) Performance for MNLI on the S → TR scenario for different reduction factors.

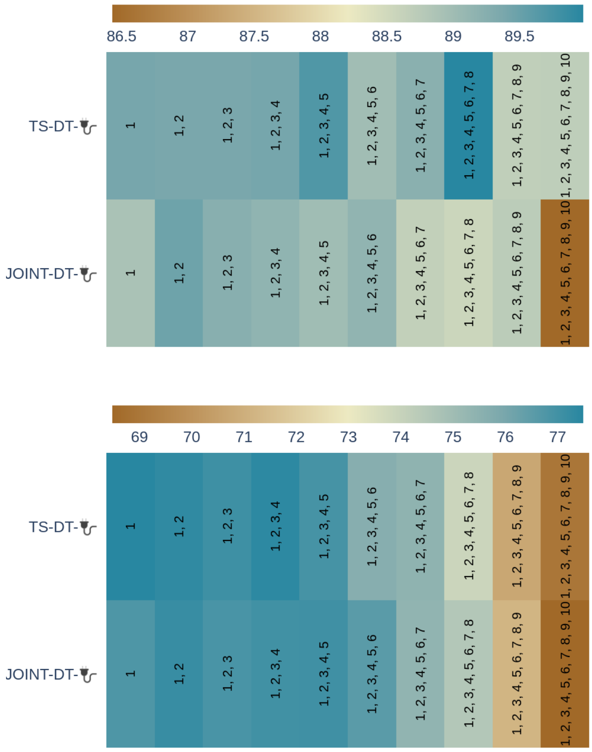


Figure 3: Shows the difference in performance when adapters are removed from certain layers (mentioned inside the cells) for the AMAZON dataset (top) and for MNLI dataset (bottom). The performance reduces if adapters are removed from certain layers

et al., 2021b). Thus we can further reduce the number of parameters for domain adaptation.

t-SNE plots. The t-SNE (van der Maaten and Hinton, 2008) plots from domain adapters are shown in Figure 4 for the data set MNLI. The lower layers have low divergence and the data from the two domains are interspersed, whereas the higher layers have high divergence. Our method effectively reduces the divergence in higher layers.

Composability. We test the composability of our two-step method TS-DT- 🔌 . We reuse the task adapter trained for C → BA and replace the domain adapter with the domain adapter of C → MR and perform inference on C → MR dataset. The initial F1 of the C → MR dataset was 73.22 and after composing it with a different task adapter, the F1 score is 72.66 – a minimal performance loss. This shows the composability of TS-DT- 🔌 .

4 Literature Review

Parameter Efficient Fine-tuning Methods. Adapters (Houlsby et al., 2019) are task-specific modules added to frozen transformer layers, with only the adapter parameters updated. Their plug-and-play characteristics and the avoidance of catastrophic forgetting have resulted in their use for NLP tasks: machine translation (Bapna and Firat, 2019), named entity recognition (Pfeiffer et al., 2020b), etc. Recently, (He et al., 2021b) have shown that they are efficient in scenarios where there is minimal supervised data. However, they neither test their performance under domain shift nor propose methods to improve adapter fine-tuning. Closely related to our method is the work of Ngo Trung et al. (2021), who learns a shared-private representation per layer, similar to DSN (Bousmalis et al., 2016). Their method requires balancing multiple loss functions, compared to our simpler two-step domain adaptation method. The stacking of adapters has been followed before by (Pfeiffer et al., 2020b) for cross-lingual tasks: learning a language adapter first and stacking

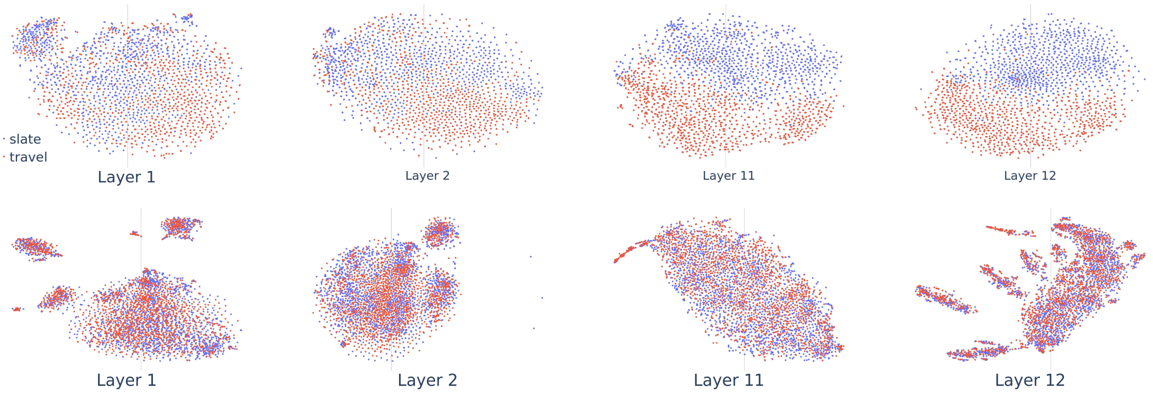

Figure 4: (top)t-SNE plots for the representations from `bert-base-uncased`. The lower layers are domain invariant while the higher layers are domain variant (bottom) tSNE plots from the domain adapter trained on the S → TR domain. We reduce the divergence using domain adapters where even higher layers are domain invariant.

a task adapter. However, one language adapter is learned per language, assumes large amounts of unsupervised data to be available in all the languages, and requires supervised data to be available to learn a task, which is not applicable for domain adaptation. Compared to other methods, we make domain adaptation more efficient using principles of unsupervised domain adaptation.

Unsupervised Domain Adaptation (UDA). Existing UDA approaches can be categorized into model-centric, data-centric, and hybrid. *Model-centric* approaches involve augmenting feature space or altering the loss function, architecture, or model parameters (Blitzer et al., 2006; Pan et al., 2010; Ganin et al., 2016) have been popular. A popular *model-centric* approach is to use adversarial training between the domain and the task classifier (Ganin et al., 2016) to extract domain-invariant information. (Bousmalis et al., 2016) in addition preserves domain-specific information. These works involve training a large number of parameters and require careful balancing of multiple loss functions. Our methods build on top of these works and make it more parameter-efficient.

Large-scale transformers pretrained on domain-specific corpora have been a norm: biomedical (Lee et al., 2019), scientific publications (Beltagy et al., 2019), among others. Another alternative is to continue pretraining generic models on domain-specific data: domain adaptive pretraining (Gururangan et al., 2020). Both solutions are expensive since a huge model has to be stored for every domain while using adapters affords storing a small number of parameters for every domain pair and can be quickly adapted to new domains.

5 Discussion

This work shows that domain adaptation in NLP can be made more efficient using adapters. We use adapters fine-tuning (Houlsby et al., 2019) proposed before and stacking of adapters that have been proposed before for a cross-lingual setting (Pfeiffer et al., 2020b) for the unsupervised domain adaptation. The approach we have discussed will make domain adaptation more practical for real-world use cases, making adaptation faster and cheaper. However, in this work, we have used `bert-base-uncased` for all of our methods. Using other backbone transformer models is part of our future work. We deal only with a classification and natural language inference task. Adapters have previously been used for machine translation (Bapna and Firat, 2019) and other generation tasks (Zhang et al., 2022). We need to explore our domain adaptation methods for other generation tasks.

In this work, we reduce the marginal distribution of the two distributions. Previous works such as Kumar et al. (2018) show that reducing only the marginal distribution is not sufficient and aligning the label distributions is necessary. However, NLP works do not consider this and would require further investigation by the community.

6 Conclusion

In this work, we propose UDApter, to make unsupervised domain adaptation more parameter-efficient. Our methods outperform other strong baselines, and we show that we can perform better than just training a task adapter on supervised data. We perform competitively to other UDA methods at a fraction of the parameters and outperform them when there is limited data – a more practical scenario. Future work should explore other parameter-efficient methods such as prefix-tuning (Li and Liang, 2021) for domain adaptation. NLP should also consider other avenues, such as continuous adaptation to new domains and adaptation to new domains when there are no data available.

7 Acknowledgments

This research is supported by the SRG grant id: T1SRIS19149 and the Ministry of Education, Singapore, under its AcRF Tier-2 grant (Project no. T2MOE2008, and Grantor reference no. MOET2EP20220-0017). Any opinions, findings, conclusions, or recommendations expressed in this material are those of the author(s) and do not reflect the views of the Ministry of Education, Singapore.

8 Limitations

We have several limitations to our work. We have experimented with only one type of parameter-efficient method, which is the adapter fine-tuning method. Several other alternative parameter-efficient methods, such as LoRA (Hu et al., 2021), Bitfit (Ben Zaken et al., 2022), and other unifying paradigms (He et al., 2021a), have been proposed in recent times. These methods are modular and can be easily substituted for adapters.

Another major limitation of our work is that we cannot explore whether we can learn different tasks over a given pair of domains. For example, for a given pair of domains such as NEWS and TWITTER, it would be ideal if we learned a domain adapter and reused it for different applications such as sentiment analysis, named entity recognition, among others. We are limited by the availability of data for such scenarios and this would be a potential future work.

Efficient CTC Regularization via Coarse Labels for End-to-End Speech Translation

Abstract

For end-to-end speech translation, regularizing the encoder with the Connectionist Temporal Classification (CTC) objective using the source transcript or target translation as labels can greatly improve quality metrics. However, CTC demands an extra prediction layer over the vocabulary space, bringing in non-negligible model parameters and computational overheads, although this layer is typically not used for inference. In this paper, we re-examine the need for genuine vocabulary labels for CTC for regularization and explore strategies to reduce the CTC label space, targeting improved efficiency without quality degradation. We propose coarse labeling for CTC (CoLaCTC), which merges vocabulary labels via simple heuristic rules, such as using truncation, division or modulo (MOD) operations. Despite its simplicity, our experiments on 4 source and 8 target languages show that CoLaCTC with MOD particularly can compress the label space aggressively to 256 and even further, gaining training efficiency ($1.18\times \sim 1.77\times$ speedup depending on the original vocabulary size) yet still delivering comparable or better performance than the CTC baseline. We also show that CoLaCTC successfully generalizes to CTC regularization regardless of using transcript or translation for labeling.

1 Introduction

Developing techniques to support the translation from a source-language audio to a target-language text directly, or end-to-end (E2E) speech translation (ST), has attracted increasing attention recently due to its potential of reducing translation latency and avoiding error propagation (Duong et al., 2016; Bérard et al., 2016). However, solving this task is non-trivial because of the speech-text modality gap: one word corresponds to a stochastic sequence of speech signals that vary greatly across speakers and over contexts, which increases the learning difficulty. Recent progress on E2E ST mainly focuses on bridging this gap through the encoder-decoder framework from diverse perspectives (Di Gangi et al., 2019; Salesky et al., 2019; Zhang et al., 2020; Wang et al., 2020b; Han et al., 2021; Zheng et al., 2021).

CTC regularization is such an approach that facilitates the modeling of translation by aligning speech representations from the encoder with discrete labels dynamically via the lens of the Connectionist Temporal Classification (CTC) objective (Graves et al., 2006b). Bahar et al. (2019) first examined the use of the source transcript as discrete labels, improving translation quality consistently across various ST settings; Zhang et al. (2022) further discovered that using the target translation as labels instead can also be surprisingly effective although speech-translation pairs arguably violates CTC's monotonicity prerequisite. Nevertheless, these successes come at the cost of increased computational overheads and model parameters because CTC demands an extra prediction layer over its label space for probability estimation and this space is often huge – traditionally the source or target vocabulary size (Gaido et al., 2020). We thus explore strategies to achieve the best of both worlds, i.e., improving the efficiency of CTC regularization without hurting its performance.

We address this problem by reexamining the need for genuine vocabulary labels for CTC. In contrast to CTC-based generation (Graves et al., 2006b), the prediction layer in CTC regularization of ST is discarded at inference. In other words, sticking to genuine labels is computationally unnecessary. Since the large label space of CTC is a crucial bottleneck hindering training efficiency, we explore ways of reducing it. We propose **Co**arse **La**beling for CTC (CoLaCTC) that manipulates this space by merging vocabulary labels based on simple heuristic rules. Concretely, we map the source or target vocabulary to a pseudo label space subject to some predefined size using simple op-

	Modulo	`f(z) = z % L`	L	`0,1,2,0,1,2,0,1,2`
	Division	`f(z) = ⌊z / (V/L)⌋`	L	`0,0,0,1,1,1,2,2,2`
	Log-Scaling	`f(z) = ⌊log(max(z,1)) * L/log(V)⌋`	L	`0,0,0,1,1,2,2,2,2`

Table 1: Overview of different mappings for CoLaCTC. V and L denote the original vocabulary size and the specified coarse label size, respectively, and $V \gg L$. z is the vocabulary-space token ID starting from 0. The ID sequence is just for a toy example, and we set $V = 9, L = 3$ for illustration. $f(\cdot)$ shows the mapping function. CoLaCTC adopts different operations to reduce the label space from V to L.

erations, such as *truncation*, *modulo*, *division* and *log-scaling* as shown in Table 1.

Despite the label space being transformed, the generated coarse labels still maintain a strong correlation with their vocabulary counterparts, ensuring their informativeness for representation learning. We rigorously examined our method on the MuST-C (Di Gangi et al., 2019) and the Multilingual TEDx (Salesky et al., 2021) benchmarks, covering 4 source languages and 8 target languages. Across diverse settings, CoLaCTC successfully achieves comparable or even better translation performance than the CTC baseline but with significantly improved training efficiency (up to 1.77× speedup depending on the original vocabulary size). Our main contributions are summarized below:[1]

- We propose coarse labeling for CTC regularization which offers a mechanism to decouple the CTC label size from the vocabulary size; with CoLaCTC, a CTC-regularized model can be trained nearly as fast as a non-CTC model.
- We compare two types of CTC regularization for ST, i.e., using transcript or translation for labeling, and show that transcript performs better *when it is available*.
- CoLaCTC delivers promising performance on 4 source and 8 target languages, and also generalizes to both types of CTC regularization.
- Our empirical analysis reveals that CoLaCTC benefits translation similarly to the CTC baseline on different aspects, including homophone translation, and seems to improve the contextualization of speech representations.

2 Related Work

Solving E2E ST requires techniques to mitigate the speech-text modality gap. One way is to develop advanced architectures integrating speech-specific characteristics to the encoder, such as locality modeling for the self-attention (Di Gangi et al., 2019; Gulati et al., 2020) and adaptive speech representation grouping (Salesky et al., 2019; Liu et al., 2020; Zhang et al., 2020). Another way is to leverage knowledge from other languages and/or tasks, including automatic speech recognition (ASR) and machine translation (MT) based multi-task modeling (Anastasopoulos and Chiang, 2018; Dong et al., 2021; Du et al., 2021), cross-lingual transfer learning (Inaguma et al., 2019; Di Gangi et al., 2019; Li et al., 2021), and large-scale weakly, semi- and self-supervised pretraining (Schneider et al., 2019; Ao et al., 2021; Bapna et al., 2022). Our method contributes to E2E ST by accelerating CTC regularization with coarse labels, and is theoretically orthogonal to all the techniques aforementioned. In this study, we mainly focus on bilingual ST using triplet data alone, and leave the exploration of how our method is compatible with other setups to future work.

CTC was first proposed to handle the sequence mismatch problem between acoustic features and transcript tokens, and has been widely applied to ASR (Graves et al., 2006b,a; Chan et al., 2016) and other tasks where the input sequence is longer than the output and their alignment is monotonic (Niu and Mak, 2020; Cai et al., 2022). Recent studies also show promising results when applying CTC to non-monotonic tasks, specifically to non-autoregressive ST and MT (Libovický and Helcl, 2018; Saharia et al., 2020; Gu and Kong, 2021; Chuang et al., 2021). All these methods treat the prediction layer in CTC as a generator, used to predict final outputs. By contrast, Kim et al. (2017) used CTC as an auxiliary objective to improve ASR. In E2E ST, Liu et al. (2020), Gaido et al. (2021), Xu et al. (2021) and Dong et al. (2021) leveraged CTC to compress speech representations to bridge

---

[1] Source code: `https://github.com/bzhangGo/zero`.

the modality gap; Bahar et al. (2019) and Gaido et al. (2022) explored CTC as a regularizer using source transcript as labels, showing encouraging performance although the prediction layer is not used at inference; Zhang et al. (2022) further investigated E2E ST without transcript, and found that CTC regularization with translation as labels also works. Our study follows CTC regularization and extends it with CoLaCTC to address its training inefficiency issue. As far as we know, exploring coarse labels for CTC has never been investigated before, at least on ST.

3 Background: CTC Regularization

CTC regularization improves the encoder-decoder based E2E ST by adding a CTC regularizer to the conventional translation loss (Bahar et al., 2019; Zhang et al., 2022). Formally, given a *(source speech, target translation)* pair denoted as (X, Y) respectively, E2E ST with CTC regularization is optimized via the following interpolated objective:[2]

$$\underbrace{(1-\lambda)\mathcal{L}^{\text{MLE}}(Y|\mathbf{Y})}_{\text{translation loss}} + \underbrace{\lambda\mathcal{L}^{\text{CTC}}(Z|\mathbf{X})}_{\text{regularization}}, \quad (1)$$

where λ is a hyperparameter balancing different sub-objectives. $\mathbf{X} \in \mathbb{R}^{|X|\times d}$ and $\mathbf{Y} \in \mathbb{R}^{|Y|\times d}$ denote the encoder output (or speech representation) and the decoder output, respectively. Z is the label sequence for CTC, which is often either the source transcript or the target translation. $|\cdot|$ indicates the sequence length and d is the model dimension.

The translation loss $\mathcal{L}^{\text{MLE}}$ aims at maximizing the likelihood of observed training instances. Often, we decompose the likelihood token-wise in accordance with the autoregressive generation

$$\mathcal{L}^{\text{MLE}}(Y|\mathbf{Y}) = -\sum_t \log p(y_t|y_{<t}), \quad (2)$$

$$\text{with} \quad p(y_t|y_{<t}) \sim \text{softmax}\left(\mathbf{W}^{\text{MLE}}\mathbf{y}_t\right), \quad (3)$$

where y_t stands for the t-th target token. $\mathbf{y}_t \in \mathbb{R}^d$ is the t-th row of $\mathbf{Y}$, representing the translation prefix $y_{<t} = \{y_1, \ldots, y_{t-1}\}$. $\mathbf{W}^{\text{MLE}} \in \mathbb{R}^{V^{\text{MLE}}\times d}$, also called softmax embedding, is a trainable parameter, and V^{MLE} is the target vocabulary size. E2E ST uses this embedding to estimate the translation probability of each target word as shown in Eq. (3)[3]. At inference, the emitted probability offers direct evidence to search translation candidates.

By contrast, the regularization term $\mathcal{L}^{\text{CTC}}$ encourages the dynamic alignment of speech representations ($\mathbf{X}$) with their corresponding discrete labels (Z) through the CTC algorithm. CTC regularization also maximizes the likelihood. But different from the token-by-token formulation in Eq. (2), CTC estimates the likelihood by marginalizing over all valid mappings between the input and output sequence (Graves et al., 2006b)

$$\mathcal{L}^{\text{CTC}}(Z|\mathbf{X}) = -\log \sum_{A\in\Gamma(Z)} \prod_k p(a_k|\mathbf{x}_k), \quad (4)$$

$$\text{with} \quad p(a_k|\mathbf{x}_k) \sim \text{softmax}\left(\mathbf{W}^{\text{CTC}}\mathbf{x}_k\right), \quad (5)$$

where $\Gamma(Z)$ denotes the set of all valid aligned sequences. The probability of each aligned label a_k in the sequence A is estimated by a prediction layer based on the corresponding speech representation $\mathbf{x}_k$ as shown in Eq. (5). $\mathbf{W}^{\text{CTC}} \in \mathbb{R}^{V^{\text{CTC}}\times d}$ is the prediction parameter, and $V^{\text{CTC}} = V + 1$ denotes the CTC label size. When the source transcript (target translation) is used as labels, V is the source (target) vocabulary size; the extra label is for the special *blank* symbol. We refer readers to Graves et al. (2006b) for more details. Note that this predication layer will be discarded after training when CTC is purely used for regularization.

Previous studies have examined using either source transcript (Bahar et al., 2019; Gaido et al., 2022) or target translation (Zhang et al., 2022) as labels for CTC regularization, but separately. In Section 5.1, we will compare these two types of CTC regularization under the same setup.

4 Coarse Labeling for CTC

Unfortunately, CTC regularization suffers from training inefficiency. Despite CTC being efficiently addressed via dynamic programming, its prediction layer in Eq. (5) is unavoidable. This layer introduces considerable computational overhead due to scaling linearly with the vocabulary size and also brings in large number of model parameters particularly when $V \neq V^{\text{MLE}}$. How to improve the efficiency, and save model parameters while retaining the performance is the focus of our study.

We draw inspiration from the fact that the prediction layer in CTC regularization is not used for inference. Thus, sticking to genuine vocabulary labels is unnecessary technically. If we could design pseudo labels in a reduced label space as alternatives to the genuine ones, that would address the

---

[2] Note we use X, Y to denote the input, and their bold variants to denote the learned hidden representations.

[3] We drop the bias term for clarity.

inefficiency issue. Following this intuition, we propose coarse labeling for CTC (CoLaCTC) which formulates the pseudo label generation process as a vocabulary mapping:

$$f(z) : \mathbb{N}_{[0 \dots V-1]} \mapsto \mathbb{N}_{[0 \dots L-1]}, \quad (6)$$

where z denotes the original vocabulary ID. L is a hyperparameter specifying the label size, and we often set $L \ll V$. This transformation decouples the label size of CTC from the vocabulary size, offering flexibility to optimize the training efficiency. One assumption behind such formulation is that the success of CTC regularization mainly comes from the inductive biases of the CTC algorithm rather than the genuineness of its labels[4], which we verified empirically through experiments.

Eq. (6) merges a set of vocabulary labels into one label according to $f(\cdot)$. Potential mappings are many, such as grouping semantically similar words or considering phonetic similarity. But these linguistically inspired approaches often lack freedom in manipulating the label space (L). Instead, we adopt the following heuristic methods (as shown in Table 1):[5]

Truncation (TRU) Learning speech representations for infrequent items is often difficult, so we merge all vocabulary labels except for the top-$(L-1)$ in TRU

$$f(z) = \min(z, L-1), \quad (7)$$

with the hope that those frequent items could provide informative clues for CTC.

Modulo (MOD) Nevertheless, infrequent items might carry crucial content information. Instead of naively collapsing them, MOD merges diverse labels of varying frequencies based on a fixed interval

$$f(z) = z \pmod{L}. \quad (8)$$

Division (DIV) Different from items with varying frequencies, items of similar frequency often share similar linguistic properties. We explore this in DIV which merges labels of similar ranks uniformly

$$f(z) = \lfloor z * {}^{L}/_{V} \rfloor, \quad (9)$$

where $\lfloor \cdot \rfloor$ denotes the floor function.

Log-Scaling (LOG) One drawback of DIV is that the distribution of its coarse labels becomes badly skewed. To offset this problem, we further study a non-linear, log-scaled transformation, LOG

$$f(z) = \lfloor \log(\max(z, 1)) * {}^{L}/_{\log(V)} \rfloor. \quad (10)$$

Note we intentionally use simple operations to keep the simplicity of CoLaCTC. All the above operations are trivial to implement.

Although labels generated by these operations become linguistically less meaningful, they still keep a strong correlation with their genuine vocabulary counterparts. We expect this correlation could ensure the informativeness of each coarse label and further facilitate the generalization of CoLaCTC to CTC regularization. We compare different operations via experiments.

5 Experiments

Setup We work on two benchmarks, Multilingual TEDx (Salesky et al., 2021) and MuST-C (Di Gangi et al., 2019), covering 4 source and 8 target languages. MuST-C (v1) is an English-audio based multilingual corpus, including translations from English (En) to 8 languages: German (De), Spanish (Es), French (Fr), Italian (It), Dutch (Nl), Portuguese (Pt), Romanian (Ro) and Russian (Ru). The training data for each language pair has ∼452 hours with about 252K utterances on average, and we use the given dev and tst-COMMON splits as the dev and test set, respectively. In contrast, Multilingual TEDx is a multi-source and multi-target ST corpus, containing audios in diverse languages, although its scale is relatively small. We regard this benchmark as a testbed to examine the applicability of our method to audios other than English. We report results on 6 translation directions, i.e., Es-En, Es-Pt, Fr-En, Pt-En, Fr-Es and Fr-Pt. The training data of different language pairs ranges from 25 hours (16K utterances, Fr-Pt) to 69 hours (39K utterances, Es-En), and we use the official dev and test sets for experiments.

---

[4] The inductive biases include the modeling of local structures for speech, word boundary identification and label-guided speech representation learning, etc.

[5] Note that we followed the standard practice and ranked the items in our vocabulary based on their frequency. In this study, the items are (sub)words.

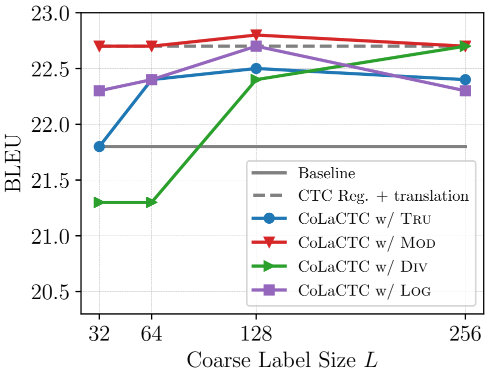

Figure 1: Translation results of different CoLaCTC methods on the MuST-C En-De test set as a function of the coarse label size L. *Reg.*: short for regularization. Here we use **translation** labels for CTC regularization.

We focus on bilingual ST and adopt the E2E ST model following Zhang et al. (2022) which concatenates neighboring frames for downsampling followed by a variant of Transformer for translation. We set $\lambda = 0.3$ for CTC regularization. We evaluate the translation quality using (Sacre)BLEU (Post, 2018).[6] We didn't perform any filtering to the test set. All models are implemented in *Tensorflow*, and trained from scratch without any ASR or MT pretraining. We refer readers to Appendix A for details on data preprocessing and training.

5.1 Analysis on MuST-C En-De

Coarse label size matters, and Mod performs the best. CoLaCTC depends on not only the mapping function selected, but also the coarse label size specified. In general, CoLaCTC with a larger label size produces coarse labels closer to the genuine ones, thus behaving more robustly. We first perform ablations for CoLaCTC with the target translation as labels, where only speech-translation pairs are used at training (Zhang et al., 2022).

We vary L from 32 to 256, and show the results in Figure 1. Different mapping functions have different properties and also show different behaviors, where the label size yields profound impacts. When L is small, Div performs the worst, followed by Log and Tru while Mod performs the best. With the increase of L, the performance difference between different mappings narrows. Label size matters, but the optimal size varies for different mappings. Under different settings, Mod performs the best and is most robust, nearly dominating the others. We next mainly study Mod for CoLaCTC.

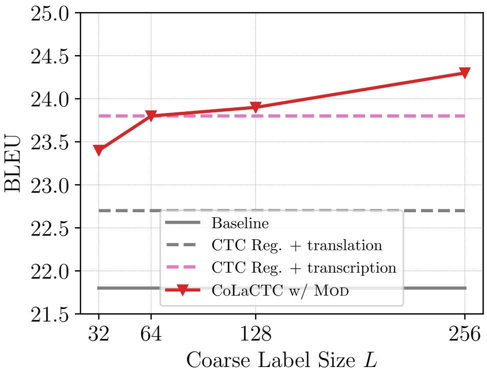

Figure 2: Translation results for CoLaCTC with Mod on the MuST-C En-De test set as a function of L. Here we use **transcription** labels for CTC regularization.

System	#Param	BLEU	Speedup
Baseline	46.1M	21.8	1.39×
CTC Reg. + translation	47.9M	22.7	1.00×
+ CoLaCTC	46.2M	22.7	1.39×
+ share parameters	46.1M	22.4	0.97×
CTC Reg. + transcription	47.5M	23.8	1.00×
+ CoLaCTC	46.2M	24.3	1.31×

Table 2: Test results of different systems on MuST-C En-De. $L = 256$ for CoLaCTC. *#Param*: the number of parameters. *share parameters*: share parameters between $\mathbf{W}^{\text{MLE}}$ and $\mathbf{W}^{\text{CTC}}$. We perform three runs (50 steps each) to evaluate the training speedups on GeForce GTX TITAN X.

CoLaCTC performs comparably to the CTC baseline. Figure 1 also shows that CoLaCTC delivers comparable results to the CTC baseline when proper L is applied; with Mod even across all tested L. Note both methods significantly outperform the vanilla baseline without CTC regularization. This demonstrates that the genuineness of CTC labels matters less for CTC regularization and that our strategy – generating coarse labels in a reduced space – is feasible.

Transcript is more effective than translation as labels for CTC regularization. Despite being effective, using translation as labels for CTC regularization violates the monotonic assumption required by CTC. CTC with transcripts is more established (Bahar et al., 2019; Gaido et al., 2022). We thus compare these two types of CTC regularization and explore how CoLaCTC generalizes.

Figure 2 shows that using transcript instead yields substantial quality improvements (+1.0 BLEU), and that CoLaCTC with Mod generalizes to both settings successfully. Still, the genuineness of CTC labels matters less than their origin does!

---

[6] Signature: *BLEU+c.md+#ref.1+s.exp+tok.13a+v.1.4.14*

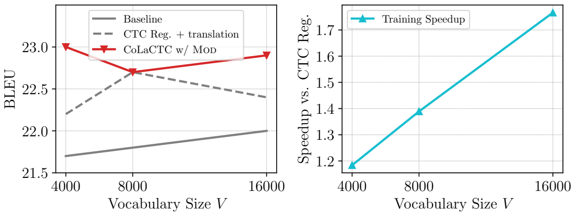

Figure 3: Test results for different methods on MuST-C En-De when varying the target vocabulary size V. We adopt **translation** labels for CTC regularization. $L = 256$ for CoLaCTC.

We observe that using 256 coarse labels works well for CTC regularization under different settings. We set $L = 256$ for the following experiments.

CoLaCTC saves model parameters and greatly improves training efficiency. CTC regularization suffers from inefficiency, which increases model parameters by about 4% and slows the training by 39% as shown in Table 2. We try to solve this problem by sharing parameters between the CTC prediction layer and the softmax output layer when $V = V^{\mathrm{MLE}}$ is the target vocabulary size. Unfortunately, this hurts quality and helps the training efficiency little (+ *share parameters*). By contrast, CoLaCTC nearly recovers the efficiency sacrificed by CTC regularization, running as fast as the vanilla baseline but still retaining quality improvements. Besides, CoLaCTC performs similarly well with different label sequences.

We also note that the degree of inefficiency depends on the computational framework used. We re-tested different methods with PyTorch, where CTC regularization causes a 10% decrease in training speed, much smaller than 39%. However, the conclusion that CTC regularization leads to more trainable parameters and slower running speed, and that CoLaCTC overcomes this issue, still holds.

CoLaCTC performs robustly over different vocabulary sizes; larger V yields higher speedups. Apart from the coarse label size, the target vocabulary size V also affects CTC regularization. Larger vocabulary shortens the target sequence but increases the CTC label space. Figure 3 shows the impact of V on CoLaCTC. Translation performance is highly sensitive to the vocabulary size. Using CTC regularization delivers consistent quality gains against the vanilla baseline, and CoLaCTC shows promising robustness, matching and even outperforming CTC regularization with genuine labels. Regarding training efficiency, the speedup of CoLaCTC should scale linearly with V in theory when L is fixed. Figure 3 confirms this where CoLaCTC achieves higher speedups with larger vocabulary sizes. Particularly, the speedup reaches **1.77×** when V is 16K, a substantial improvement.

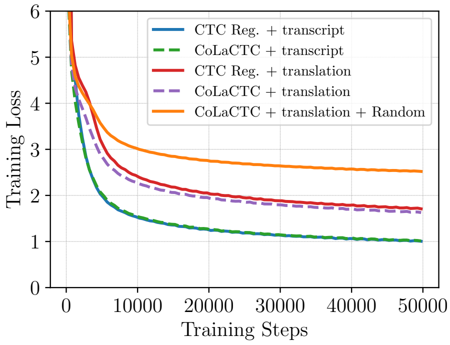

Figure 4: Training loss as a function of training steps for different methods on MuST-C En-De. $L = 256$ for CoLaCTC. *Random* indicates using fully random labels (i.e. `f(z) = randint(0, L)`) with a label size of 256.

CoLaCTC doesn't hurt the trainability of ST models. Would CoLaCTC increase the learning difficulty, which likely reduces performance? Figure 4 shows that 1) CoLaCTC shows similar convergence to the CTC baseline using either transcript or translation for labelling; 2) the model using transcript as labels converges faster and to a better local optima than the counterpart using translation, which also explains the results in Figure 2; 3) random coarse labels result in inferior convergence due to their unpredictable nature.

The vocabulary order of genuine labels has limited impact on CoLaCTC. As shown in Eq. (6), the coarse labeling in CoLaCTC highly relies on the order of original labels in the vocabulary. This ordering encodes word frequency, which might offer crucial clues to CoLaCTC and explain its success. We examine this by randomly shuffling the vocabulary, thus the original vocabulary ID is randomly changed and the ordering information is eliminated. With this shuffled vocabulary, CoLaCTC (Mod) achieves a BLEU score of 23.9 on MuST-C En-De test set, matching the performance of the CTC baseline (23.8) although underperforming the original CoLaCTC (24.3). CoLaCTC benefits from the order information but still achieves promising performance without it.

5.2 Results on Other Languages

CoLaCTC achieves great performance for translation out of English. Table 3 summarizes the results of CoLaCTC on other MuST-C translation

Table 4: BLEU Scores on Multilingual TEDx test sets. $L = 256$ and Mod for CoLaCTC.

directions. The performance of CoLaCTC varies across different languages with both positive and negative gains. But overall, CoLaCTC is on par with its CTC baselines and largely outperforms the vanilla baseline without CTC regularization. On average, CoLaCTC delivers a BLEU score of 25.1 and 26.1 when used with translation and transcription labels, respectively, which also surpasses many strong previous studies (Inaguma et al., 2020; Zhao et al., 2021; Zhang et al., 2021).

Joint training with CTC regularization is preferable to the traditional pretraining-finetuning paradigm for E2E ST. The current *de facto* standard for training an E2E ST model is to firstly initialize it with a pretrained ASR encoder and/or MT decoder and then finetune it on ST data. Despite its effectiveness, this pipeline paradigm often consumes longer training time and inevitably complicates the optimization procedure. In contrast, joint training with CTC regularization is technically simpler and delivers comparable and even better results as shown in Table 3, echoing with Gaido et al. (2022). Note that we also re-implemented the pipeline baseline using our in-house codebase, which achieves 22.9 BLEU on MuST-C En-De, far below the joint training with transcript (23.8).

Since CoLaCTC solves the inefficiency issue for CTC regularization, we would recommend using the joint training as the new standard for E2E ST, especially when only triplet training data is used.

CoLaCTC generalizes to ST settings other than English audios. The above results for CoLaCTC are multilingual, but all use English audio from TED on the source side. To demonstrate generalization across different source languages, we conduct experiments on Multilingual TEDx and work on ST for Es, Fr and Pt. Table 4 shows that CoLaCTC generalizes well to other source languages. In addition, CTC regularization performs much better on this benchmark, substantially outperforming the vanilla baseline by 10.4 BLEU, matching the performance of multilingual ST reported by Salesky et al. (2021). We ascribe this success to the small scale of Multilingual TEDx where regularization techniques, like CTC Reg., often work better.

6 Discussion

The promising performance of CoLaCTC inspires us to further explore why coarse labels could work for CTC regularization. Analyzing the underlying

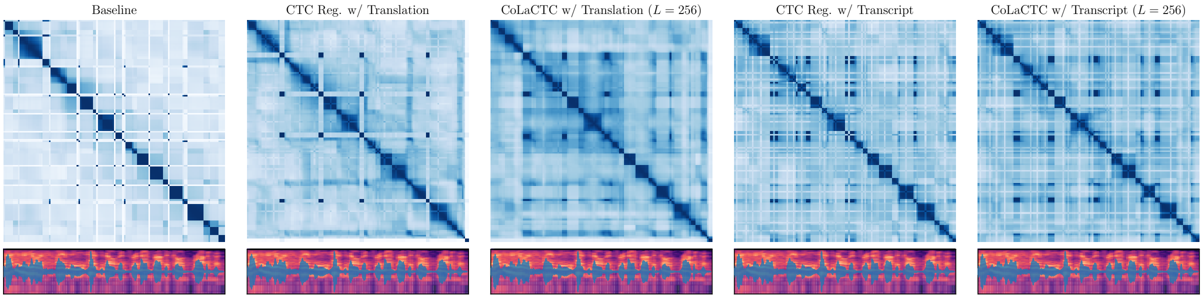

Figure 5: Visualization of the cosine similarity of the final-layer speech encoding for different methods. *Top*: cosine similarity where darker color shows higher similarity; *Bottom*: speech spectrogram. The example is for the first test case in MuST-C En-De.

System	Similarity

System	MT Baseline	CL w/			
		Div	Tru	Log	Mod
BLEU	30.5	10.5	15.1	22.9	25.6

Table 6: BLEU scores for *text-to-text* translation conditioned on coarse labels on the MuST-C En-De test set. *MT Baseline*: En→De translation with the vanilla English input; *CL w/ **: using coarse labels instead as the source input. $L = 256$. We use the standard Transformer base setting for experiments.

mechanism theoretically is non-trivial. Instead, we understand this question through empirical probes, such as inspecting the change of speech representations and examining how CoLaCTC behaves on different translation aspects.

CTC regularization improves the contextualization of speech representations, so does CoLaCTC. The CTC objective is directly stacked onto the encoder, then what happens to the speech representation (the final encoder output)? Figure 5 illustrates an example, where speech representations after applying CTC regularization (and CoLaCTC) become closer to each other as measured by the cosine similarity. This is further supported by the results in Table 5. Still, the local structure of audio, i.e. the diagonal similarity, is kept. Intuitively, the increased cosine similarity is a reflection of contextualization, and CTC regularization (and CoLaCTC) encourages the encoder to consider (distant) contextual clues.

System	Noun	Verb	Adj.	Adv.	H.Phone

Table 7: Translation accuracy of different types of source words on the MuST-C En-De test set. *Adj.*, *Adv.* and *H.Phone* are short for adjective, adverb and homophone.

Coarse labels especially produced by Mod preserve source semantics and are informative for translation. The mappings considered in this study are solely based on heuristic rules. Despite improvements on ST, whether the generated coarse labels themselves are informative is still questionable. We address this concern by performing experiments on text-to-text machine translation and use the coarse label sequence as the source input. Table 6 shows that the coarse labels encode source semantics, achieving non-trivial translation performance. In particular, using Mod achieves a test BLEU score of 25.6. This result still lags far behind the vanilla MT baseline (30.5), but it demonstrates the informativeness of coarse labels, and also partially explains the success of CoLaCTC.

The performance of CoLaCTC is robust on different types of source words. The translation rule for different types of source words often varies greatly. Next, we examine how CoLaCTC generalizes to different words, including nouns, verbs, adjectives, adverbs, and homophones (specific to speech processing). We annotate the part-of-speech tag for each source sentence via Stanford POS tagger (Toutanova et al., 2003), and adopt the homophone list used for contextual evaluation (Zhang

CTC Reg. + translation	56.0	**67.2**	59.9	66.5
+ CoLaCTC	55.9	67.0	59.6	65.4
CTC Reg. + transcript	55.8	66.9	61.6	66.1
+ CoLaCTC	**57.4**	66.9	**62.0**	**66.7**

Table 8: Coverage (*Cov.*) and accuracy (*Acc.*) scores for gender translation on MuST-SHE En-It and En-Fr.

et al., 2021)[7]. We employ translation accuracy as the metric, approximated by the APT framework (Miculicich Werlen and Popescu-Belis, 2017) where *fast_align* is used to get the word alignment (Dyer et al., 2013). Table 7 shows the results.

CTC regularization largely improves the translation of nouns and adjectives; using transcript as labels further benefits the translation for verbs, adverbs and homophones. Regardless of source word and CTC label types, CoLaCTC shows comparable (sometimes even better) performance to the CTC baseline, showing its strong generalization. Note that observations on other languages, e.g. En-Fr and En-It, are similar (see Appendix B). Further analysis shows that the gains by CTC regularization and CoLaCTC mainly come from benefiting rare-word translation, as shown in Figure 6.

CoLaCTC benefits gender translation similarly to the CTC baseline. Languages often differ in gender expression, leading to translation difficulty. We further evaluate how CoLaCTC handles the gender ambiguity using the MuST-SHE benchmark (Bentivogli et al., 2020). Table 8 shows that CoLaCTC achieves comparable performance to the CTC baseline, suggesting that using coarse labels for CTC regularization doesn't hurt its gender disambiguation ability. Besides, we observe that translation and transcript labels show similar positive effects on gender translation.

7 Conclusion and Future Work

In this paper, we have presented coarse labeling for CTC to address the training inefficiency issue of CTC regularization. The key idea behind CoLaCTC is to transform CTC labels from the vocabulary space to a specified and reduced coarse space. We adopt trivial mappings for this transformation, such as using the modulo operation. Despite its simplicity, CoLaCTC successfully achieves the best of both worlds – improving the training efficiency for CTC regularization (up to 1.77× speedup) and retaining its quality benefits – and generalizes to different types of CTC regularization. Note the training speedup scales as the vocabulary size increases. Our analysis further shows that the genuineness of CTC labels matters less than their origin.

In the future, we are interested in examining the complementarity of CoLaCTC with other advanced ST modeling. We will study how our method performs in a multilingual and simultaneous setup as well as ST settings with extra ASR and/or MT data.

Limitations

While the proposed method achieves encouraging performance across diverse languages and translation setups, our understanding of why it performs so well is still limited, particularly considering the simplicity of the adopted mapping function (MOD). Uncovering the underlying reason behind such success might offer valuable insights to further the speech modeling, having a potential broader impact on the speech processing community.

A Experimental Setting

We preprocess texts using Moses scripts (Koehn et al., 2007) and adopt the byte pair encoding algorithm (Sennrich et al., 2016, BPE) to handle rare tokens. In particular, we encode datasets in MuST-C and Multilingual TEDx with a BPE vocabulary size of 8K and 4K, respectively. As for audios, we adopt a sampling rate of 16KHz and filter out segments longer than 3000 frames. We extract 40-dimensional log mel-scale filterbank features for acoustic modeling with a step size of 10ms and window size of 25ms, and further augment them with

	System	Noun	Verb	Adj.	Adv.	H.Phone
En-It	Baseline	48.0	37.5	45.4	44.0	40.9
	CTC Reg. + translation	49.6	38.6	47.2	45.0	41.7
	+ CoLaCTC	49.6	38.7	48.3	45.4	42.0
	CTC Reg. + transcript	50.5	**39.3**	48.0	45.2	42.3
	+ CoLaCTC	**51.2**	39.0	**49.1**	**45.7**	**43.0**
En-Fr	Baseline	57.2	51.0	53.4	53.9	58.1
	CTC Reg. + translation	58.5	52.8	55.4	54.9	58.9
	+ CoLaCTC	58.5	52.3	55.1	54.9	58.2
	CTC Reg. + transcript	59.3	53.0	54.9	55.1	59.7
	+ CoLaCTC	**60.0**	**53.9**	**57.0**	**55.8**	**60.3**

Table 9: Translation accuracy of different types of source words on the MuST-C En-Fr/En-It test set. *Adj.*, *Adv.* and *H.Phone* are short for adjective, adverb and homophone.

their delta and delta-delta features. The final acoustic feature vector is 120-dimensional regularized by mean subtraction and variance normalization.

We focus on bilingual ST and adopt the E2E ST architecture following Zhang et al. (2022): we use Transformer with the post layer normalization structure plus the sinusoidal positional encoding (Vaswani et al., 2017); we set the encoder and decoder depth to 12 and 6, respectively, and adopt the depth-scaled initialization method to stabilize the training (Zhang et al., 2019); we set the model dimension to $d = 256$, the feed-forward layer size to 4096 and the number of attention head to 4; we employ the parameterized distance penalty with $R = 512$ and set $\lambda = 0.3$ for CTC regularization (Zhang et al., 2022).

We train all models via Adam (Kingma and Ba, 2015, $\beta_1 = 0.9, \beta_2 = 0.98$) with a warmup step of 4K and label smoothing rate of 0.1. Samples with around 20K target subwords are scheduled into one batch for training, and we set the maximum training step for MuST-C and Multilingual TEDx to 50K and 20K, respectively. We apply dropout to residual connections and ReLU activations with a rate of 0.2. We perform checkpoint evaluation every 1K training steps on the dev set, and average the best 10 checkpoints for final testing. We use beam search for decoding, and set the beam size to 8. We tune the length penalty for each language pair on its dev set separately.

B Additional Results and Analysis

The performance of CoLaCTC on different types of source words generalizes to other languages. Table 9 shows the translation accuracy of different models on En-Fr and En-It. The observation is similar to Table 7, where transcript labels are more effective than translation labels for CTC regularization, and that CoLaCTC performs comparable to genuine labels. One exception is that CTC regularization also greatly benefits the translation of verbs and adverbs on En-Fr and En-It. These results suggest that our observation is not language-specific or caused by some random effect, but rather CTC regularization and CoLaCTC generalizes to different language pairs.

Exploring Category Structure with Contextual Language Models and Lexical Semantic Networks

Abstract

Recent work on predicting category structure with distributional models, using either static word embeddings (Heyman and Heyman, 2019) or contextualized language models (CLMs) (Misra et al., 2021), report low correlations with human ratings, thus calling into question their plausibility as models of human semantic memory. In this work, we revisit this question testing a wider array of methods for probing CLMs for predicting typicality scores. Our experiments, using BERT (Devlin et al., 2018), show the importance of using the right type of CLM probes, as our best BERT-based typicality prediction methods substantially improve over previous works. Second, our results highlight the importance of polysemy in this task: our best results are obtained when using a disambiguation mechanism. Finally, additional experiments reveal that Information Content-based WordNet (Miller, 1995), also endowed with disambiguation, matches the performance of the best BERT-based method, and in fact captures complementary information, which can be combined with BERT to achieve enhanced typicality predictions.

1 Introduction

The empirical success of contextual language models (CLMs) (Peters et al., 2018; Devlin et al., 2018; Liu et al., 2019) has led to much research analyzing their functionality (Rogers et al., 2020; Wu et al., 2020; Ethayarajh, 2019) and how they acquire semantic and world knowledge (Petroni et al., 2019). It also raises the question of their plausibility as models of human semantic memory (Chronis and Erk, 2020; Ettinger, 2020; Garí Soler and Apidianaki, 2021). The study of categorical knowledge, in particular *typicality*, provides a window into this question (Murphy, 2004). As initially observed by Rosch (1975), native speakers of English consider that certain exemplars (e.g., `robin`, `crow`) are more representative than others (e.g., `penguin`, `ostrich`) of a conceptual category (`birds`). That is, categorical knowledge is organized along a graded structure. According to prototype theory (Rosch, 1975), the structure follows from the fact that properties frequently shared among category members tend to be integrated into its prototype.

The main question we raise in this paper is whether distributional models, and CLMs in particular, are indeed aware of category structure, as captured in existing human typicality norms for English. The broader question for cognitive science is whether or not this type of knowledge can be learned through text-based exposure alone, thus contributing to the larger debate on the role of language in learning semantic knowledge (Lupyan and Lewis, 2019). But there are also more practical motivations for this work, as many NLP tasks (such as information retrieval, question answering, natural language inference) can arguably benefit from typicality relations by understanding which exemplars are more relevant to particular concepts.

Previous work on this topic provide mostly negative results. Heyman and Heyman (2019) use classical static embeddings and represent typicality scores between categories and their exemplars as the cosine distance between their corresponding word embeddings. They conclude that static embeddings poorly account for human typicality scores, as obtained from Morrow and Duffy (2005). More recently, Misra et al. (2021) use various CLMs to predict typicality. While CLMs have a larger, more expressive parameter space and are tuned over larger corpora with arguably better learning objectives than static word embeddings, Misra et al. (2021) report only slightly better, and still modest, correlations with human typicality judgements (in this case, Rosch (1975)). Their probing approach uses a Cloze test formulation over taxonomic sentences (e.g., *A robin is a bird*).

We revisit this question by first introducing an expanded suite of methods to extract typicality scores

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2277–2290

from CLMs, some of which improve correlations with human norms, showing the importance of using the right probe for typicality. How to reliably and efficiently probe CLMs is still an open question, including supervised and unsupervised approaches (Rogers et al., 2020; Elazar et al., 2021; Wu et al., 2020). The problem is exacerbated by the fact that typicality is a relation between pairs of concepts, abstracted away from contexts, while CLMs produce representations for contextualized word tokens (not types). We consider a wider array of approaches, all unsupervised, for predicting typicality from CLMs, using BERT as representative test case. Our probing approaches fall into two main classes: (i) BERT as a probabilistic language model, and (ii) generating "static" word embeddings from contextual BERT embeddings.

Our second contribution is showing the importance of polysemy (e.g., *orange* can be a fruit, a color, or a company) for typicality, an issue that has been largely overlooked in previous works. When judging category-exemplar pair typicality, humans arguably don’t consider all the senses of the category and exemplar words. Instead they consider the senses of the category and exemplar that are most compatible with one another, in effect performing a joint disambiguation. Polysemy is problematic for static word embeddings as they collapse word senses into a single vector. CLMs, on the other hand, provide some form of sense selection through contextualization (Ethayarajh, 2019; Garí Soler and Apidianaki, 2021), but there are many possible ways to use CLMs and to provide contexts to these models (such as sampled or taxonomic sentences). We find that using a simple disambiguation mechanism, such as the method of deriving multi-prototype embeddings introduced in Chronis and Erk (2020), leads to typicality predictions more closely correlated with human rankings.

Finally, another research question we address in this paper is whether categorical structure is present in lexical semantic networks, such as WordNet (Miller, 1995). The hierarchical concept organization in WordNet was indeed initially inspired by theories of human semantic memory (Beckwith et al., 2021). Note that polysemy is also an issue in using WordNet, as we need to map category and exemplars to specific synsets. However, using the structure of WordNet, a simple disambiguation heuristic, and taking into account word frequency information leads to competitive results. Furthermore, we find that WordNet-based and BERT-based typicality predictions contain complementary information, and creating a simple ensemble method of the two further increases performance.

In summary, our main contributions are:

- We introduce and compare a large array of unsupervised probing approaches for assessing whether BERT capture the internal structure of semantic categories.
- Our experiments reveal BERT can predict human typicality rankings more reliably than previously found in Heyman and Heyman (2019) and Misra et al. (2021), but only when endowed with a disambiguation mechanism.
- Similarly, typicality predictions based on the structure of WordNet (again with a disambiguation mechanism) can achieve similar but complementary performance.
- A simple combination of BERT and WordNet predictions leads to a higher level of correlation (Spearman greater than 0.5) with human typicality rankings.

2 Related Work

Recent years have seen an ever growing body of work on assessing whether distributional models constitute realistic models of human semantic memory, within both NLP (Chronis and Erk, 2020; Ettinger, 2020) and Cognitive Science (Hollis, 2017; Hollis and Westbury, 2016; Mandera et al., 2017; Günther et al., 2019; Lupyan and Lewis, 2019; Kumar, 2021). In this context, the study of categorical knowledge, and specifically graded typicality, plays a crucial role, given it is one of the most reliable findings in the study of human categorical knowledge (Rosch, 1975; Murphy, 2004). The first work on using distributional models to predict typicality scores is Heyman and Heyman (2019), who estimate these scores, in English and Dutch, using cosine distances between the static embeddings of the exemplar and category words. These show that static embeddings, whether trained in a counted- or prediction-based fashion, yield poor correlations with human typicality norms. On the related task of lexical entailment (LE), Vulić et al. (2017) evaluated different unsupervised and supervised methods that use static word embeddings. They also found a significant gap between static word embeddings and human norms. While LE is closely related to typicality, it differs in that LE predicts the relationship between two words, while typicality compares the relationship between two concepts (in which words are used as a proxy, in our case). Also, LE ratings are not restricted to pairs of words belonging to the same category. We differ from these earlier work on typicality by considering more expressive CLMs instead of static embeddings. The most closely related work is Misra et al. (2021) who probe a wide range of CLMs (i.e., different variants of BERT and GPT) for predicting typicality scores: these are extracted using a Cloze task formulation over hand crafted taxonomic sentences (e.g. *A robin is a bird.*). They report better correlation scores with human norms, although still modest, which they take as indication that text exposure is not sufficient to learn category structure. Our focus in this work is different and somewhat broader in that we consider a wider array of probing methods of CLMs, though restricted to unsupervised ones. Supervised probing approaches, based on classifiers taking CLM representations as inputs, are problematic as they provide a less direct probing approach, possibly adding additional confounds (Elazar et al., 2021; Wu et al., 2020). Another distinctive aspect of our work is that we compare CLMs to lexical networks like WordNet (Miller, 1995). Furthermore, we study the impact of polysemy in typicality, which was not controlled in Misra et al. (2021) or in Heyman and Heyman (2019). The work of Apidianaki and Garí Soler (2021) shares some similarities with (Misra et al., 2021): they also use BERT under a Cloze task setting to study typicality, but they focus on identifying whether the model has access to prototypical properties of concepts (e.g., a ball is round).

3 Problem Setting and Framework

This section presents our general framework for assessing whether a lexical representation model (i.e., a CLM or semantic network) is aware of category structure; the specific probing approaches will be described in Sec. 4. Let us assume a generic conceptual space consisting of a set $\mathcal{C}$ of categories as well as a set $\mathcal{E}$ of exemplars of these categories. For each category $\mathtt{c}$ in $\mathcal{C}$, we assume a set of n_c exemplars $\mathtt{e}_i^{\mathtt{c}}$ in $\mathcal{E}$ for $i = 1$ to n_c. Following the findings of Rosch (1975), we posit that this conceptual space has a graded structure, in that certain exemplars (e.g., `robin`, `crow`) are more closely representative of their category (e.g., `birds`) than others (e.g., `penguin`, `ostrich`). This can be expressed through a typicality score $t_i^c \in \mathbb{R}_0^+$, often an ordinal scale, for each $\mathtt{e}_i^{\mathtt{c}}$, where $t_i^c > t_j^c$ indicates that exemplar $\mathtt{e}_i^{\mathtt{c}}$ is more typical of category $\mathtt{c}$ than $\mathtt{e}_j^{\mathtt{c}}$. These typicality scores can be obtained from human subjects through various kinds of stimuli, such as direct scoring of category-exemplar word pairs (e.g., *robin-bird*) and scoring of a taxonomic sentence (e.g., *A robin is a bird.*)(see Sec. 5.1).

To assess whether a lexical representation model is aware of such a structure, three main components are needed. As the conceptual space is latent, we first need a **concept-to-word mapping function** from category and exemplar concepts to words. As is done in human studies and previous work, we assume that categories and exemplars are reliably accessed through their corresponding singular words: the concepts `robin` and `bird` are accessed via the words *robin* and *bird*, respectively. This is a simplification, as the same concept can be realized by plural forms, as well as by different (synonymous) words. Given this functional mapping, we will conflate a category $\mathtt{c}$ with its category word c and an exemplar $\mathtt{e}_i^{\mathtt{c}}$ with its exemplar word e_i^c.

Second, we define a **typicality scoring function** over exemplar-category word pairs, which captures how typical the exemplar is of the category. Each model will assign a typicality score s_i^c to each category c and exemplar e_i^c pair. Some of our methods will make use of a text corpus, denoted S, taking the form of a pre-extracted **set of sentences** containing exemplar and/or category words. This corpus S can be viewed as an extra parameter of the typicality scoring function, as it will directly impact the predicted typicality values s_i^c. Such a corpus is required to be able to fully leverage CLMs, whether they are used as probabilistic language models or to produce word vector representations. It is also through this corpus that one hopes to capture contextual word realizations that approximate the different senses associated with the exemplar and category words. Indeed, we hypothesize that one important aspect of assessing typicality between category and exemplar words is to be able to deal with the **polysemy** of these words, predicting that the best methods should be able to disambiguate these words in such a way that the exemplar word is interpreted in a category-compatible sense and the category word in an exemplar-compatible sense. Using WordNet synsets as a proxy for senses, we find that on average, category words are linked to 4.2 and 4.9 senses, while exemplars are linked to

3.3 and 4.7 senses on the typicality datasets of Morrow and Duffy (2005) and Rosch (1975), respectively[1] (see Sec. 5.1 for dataset details). This shows the depth of the polysemy problem for typicality, as each word on average has multiple meanings.

Finally, we need an **evaluation metric** for measuring how well the predicted typicality scores s_i^c are able to mirror the human judgements t_i^c. The most obvious choice for this metric is to use Spearman rank correlation (Spearman, 1904), as this correlation measure is non-parametric and makes no strong (e.g., linear) assumption on the data distribution or the underlying scoring functions.

4 Methods

We distinguish two classes of methods, depending on whether they use CLMs or WordNet. For CLM-based methods, we use BERT (`bert-base-uncased` specifically) as a prototypical CLM to assess whether CLMs are aware of category structure. The framework and methods easily generalize to other CLMs. While the concept-to-word mapping is the same for these methods, the scoring function and the probing corpus are different. The BERT methods fall into two categories: (i) those that use BERT as a language model (BERT-MLM, BERT-SentEmb, BERT-MLM-Taxo), and (ii) those that extract word vectors from BERT (BERT-Avg, BERT-MPro). Note that these are all unsupervised probing methods: when an additional corpus S is used, it is only used to probe BERT, not to fine-tune it. These methods embody different linguistic hypotheses and adopt different ways of dealing with polysemy. Note that for embedding methods, we test all layers.

Secondly, we consider lexical semantic networks to compute typicality scores, using WordNet (Miller, 1995) specifically. For this, we use the Shortest-Path and the Lin (Lin et al., 1998) similarity measures computed on WordNet (Miller, 1995). We compute the information content (IC) values (Resnik, 1995) used in the Lin measure using the additional corpus S. We deal with polysemy by using the maximum similarity between exemplar and category synset pairs to compute typicality scores.

4.1 Using BERT's Language Model

The first class of methods relies on the language modeling abilities of BERT, using the following hypothesis: the more central (or peripheral) an exemplar is to a category, the more (or less) likely it is to be used in the category context(s). This hypothesis can be turned into two different distributional hypotheses, depending on whether we take a *paradigmatic* perspective (i.e., how likely can the exemplar word be substituted for the category word in the category contexts) or a *syntagmatic* perspective (i.e., how likely can the exemplar be used next to its category). Our first two probing methods take a paradigmatic perspective and are reminiscent of the Distributional Inclusion Hypothesis, first proposed by Geffet and Dagan (2005). They compute typicality scores that reflect how successful the substitution of a category word by an exemplar is, measured by conditional word probability (BERT-MLM) or by cosine distance between sentence embeddings before and after substitution (BERT-SentEmb). In both, the set of sentences is restricted to sentences that contain the category words and is denoted by S_c.

4.1.1 Masked Language Modeling (BERT-MLM)

Under this approach, typicality is computed as the conditional probability of seeing the exemplar word in its category's contexts. Specifically, for each sentence in S_c, the category name is masked using the `[MASK]` token and the resulting sentence is passed through BERT and the MLM classification, yielding MLM logits for each subtoken in the vocabulary, which are softmaxed to probabilities. Typicality scores are obtained by averaging across sentences the MLM probabilities for each exemplar subtoken sequence. Formally, the typicality score s_i^c for an exemplar e_i^c with l_i subtokens and category c, given BERT and masked sentences S_c, is computed by

$$s_i^c = \frac{1}{|S_c|} \sum_{j=1}^{|S_c|} \prod_{k=1}^{l_i} BERT_{MLM}(S_{c_k}^j) \qquad (1)$$

where $S_{c_k}^j$ is the kth subtoken of exemplar e_i^c in the jth sentence of S_c, and $BERT_{MLM}(\cdot)$ gives the probability of this subtoken.

4.1.2 Sentence Embedding Modeling (BERT-SentEmb)

In this method, typicality is taken to be a measure of how well a category word can be substituted by its exemplars in sentences S_c without altering the

---

[1] If restricting synsets to only nouns, the average number of category senses 2.9 and 3.4 for the two respective datasets, and 2.4 and 3.1 for exemplars.

overall sentence meaning, which we approximate as the sentence embedding. Recall that in BERT's NSP objective, the `[CLS]` sentence classification token is input to the NSP classification head. For each category name sentence, we compute layer wise activations of this sentence token. Then, for each exemplar, we replace the category word in each sentence with the exemplar and obtain the same activations. The typicality score is the cosine similarity of the original sentence embedding and that of the replaced sentence, averaged across sentences. The sentence embeddings can be obtained from any layer in the model; we test the method separately for all layers. Formally, given a category c and an examplar e_i^c, a set of sentences S_c containing the category word c, and a $SE(\cdot)$ function which outputs a sentence embedding from a specific layer, the typicality score is computed by

$$s_i^c = \frac{1}{|S_c|} \sum_{j=1}^{|S_c|} cos(SE(S_c), SE(S^j_{c \to e_i^c})) \quad (2)$$

where $S^j_{c \to e_i^c}$ is S^j with c replaced by e_i^c, and $cos(\cdot, \cdot)$ is the cosine similarity operator.

As they rely on paradigmatic substitution, neither BERT-MLM nor BERT-SentEmb explicitly attempt to disambiguate exemplar or category words, but one can argue that some form of sense selection happens through BERT's contextual modeling and the selection of category contexts. This ensures that the word *orange* is used in *fruit* compatible contexts, thus hopefully filtering out contexts compatible with other senses (e.g. color), when predicting typicality within the `fruit` category. But there is no disambiguation of the category word, as all of its contexts are randomly sampled. This might introduce some noise as category examples with another sense (e.g., *fruit of their labor*) or even POS (e.g., *the trees fruit early*) might be sampled.

4.1.3 Masked Language Modeling with Taxonomic Sentences (BERT-MLM-Taxo)

Inspired by Misra et al. (2021)'s Taxonomic Sentence Verification method, our third CLM-based method is similar to BERT-MLM, but different in that it uses *taxonomic* propositions instead of sampled sentences. These propositions are in the form *"A(n) X is a(n) Y"*, where *X* and *Y* are exemplars e_i^c and categories c, respectively. Typicality scores are obtained in the same way as BERT-MLM: exemplar subtokens are masked in the taxonomic proposition, MLM logits are obtained from the model, then the product of the softmaxed logits (probabilities) is the typicality score (same as Eq. 1). While these sentences provide only narrow contexts, and are somewhat artificial and different from the BERT's training data, they are informative in providing implicit mutual disambiguation of *both* the exemplar and category words.

BERT-MLM-Taxo is similar to Misra et al. (2021), but it differs in two ways. First, Misra et al. (2021)'s method uses CLMs to compute the probability of the *category* word in the taxonomic proposition (i.e. $P(c|e_i^c)$), while our method does the opposite ($P(e_i^c|c)$) to more resemble how humans are probed for the task. Second, Misra et al. (2021) calculates conditional probabilities for masked language models such as BERT using the formulation introduced in Wang and Cho (2019): separately masking each subtoken in the word and passing these separately masked variants of the taxonomic sentence through the model, summing the masked subtokens across variants. While this method is more theoretically founded (as BERT is not an incremental language model and cannot compute probabilities through the chain rule), it is subject to skewed MLM logits if used on exemplars[2], as a result of words being broken into subtokens (example from Misra et al. (2021): if the word ostrich is segmented into *ostr* and *ich*, then the probability of *ich* given that it is preceded by *ostr* is anomalously high, skewing the sequence probability). Thus, we mask all subtokens of the exemplar and treat the resulting probabilities as a sequence.

4.2 BERT-Based "Static" Representations

The next CLM-based methods derive static word representations from contextual representations computed over a corpus S which includes sentences containing category words as well as sentences containing exemplar words. We use cosine similarity between category and exemplar embeddings for typicality scores $s_i^c = cos(R(e_i^c), R(c))$, where $R(\cdot)$ provides the static representations of the category and exemplar. We derive static word representations by averaging all hidden state activations of a word over S (BERT-Avg), or clustering these hidden states, allowing for sense modulation (BERT-MPro). For this set of methods, our hypothesis is that the vectorial space induced by BERT captures typicality, as opposed to the language mod-

---

[2] All category words are treated as one subtoken.

eling capabilities used in the methods of Sec. 4.1.

4.2.1 Averaged Contextual Embeddings (BERT-Avg)

The first approach for generating static word *type* vectors from contextualized word *token* embeddings is to simply average them (Bommasani et al., 2020). For each sentence in S, we compute and store the contextual representations of the word at each layer of the BERT model. We then average these representations over sentences for each word, giving a static embedding for each layer, for each category and exemplar. The typicality score of a pair (e_i^c, c) is computed as the cosine similarity between the static embeddings of the representation of e_i^c and of the representation of c. As with BERT-SentEmb, we test the method separately for all layers. Note that this approach inherits the problem found in classical static embeddings that it conflates all possible senses of a word.

4.2.2 Multi-Prototype Contextual Embeddings (BERT-MPro)

To further exploit context, we use multi-prototype BERT embeddings (Chronis and Erk, 2020). For each category name and exemplar, we use k-means to cluster the word's contextual embeddings computed from its sampled sentences, yielding, for a given k, k cluster centroids for each layer, which disambiguate the k different possible meanings of the word. Following Chronis and Erk (2020), we predict scores using the $maxsim(\cdot,\cdot)$ function between the cluster centroids of the category name and exemplar, which yields the maximum similarity value of category-exemplar centroid pairings. Formally, for a given k and layer l, and set of cluster centroids $\tau(w)_1^l ... \tau(w)_k^l$ for category c and exemplar e_i^c, the similarity s_i^c is defined by

$$maxsim(c, e_i^c) = \max_{1 \leq j \leq k, 1 \leq t \leq k} cos(\tau(c)_j^l, \tau(e_i^c)_k^l) \quad (3)$$

where $cos(\cdot,\cdot)$ is the cosine similarity measure. Following Chronis and Erk (2020), we sidestep tuning the number of clusters k and simply take as input to the $maxsim$ operator the union of all clusters from $k \leq 15$. Furthermore, we also test the embeddings from all layers separately.

4.3 WordNet-Based Methods

Our second class of methods uses WordNet (Miller, 1995) to compute typicality scores. Let us suppose that a category word c and exemplar word e_i^c are mapped to synsets $s(c)$ and $s(e_i^c)$, respectively. Only noun synsets are considered for c and e_i^c. The hypothesis here is that the more closely linked $s(c)$ and $s(e_i^c)$ are in the WordNet graph, the more the exemplar is typical of the category. To measure this "linkage" between exemplars and categories, we use two WordNet similarity measures, thus yielding two sets of WordNet-based methods.

4.3.1 Shortest Path (WNSP, WNSP-noWSD)

Our first similarity is the shortest path between $s(c)$ and $s(e_i^c)$ along hypernym/hyponym edges of WordNet. Given that exemplars and category words might be linked to multiple synsets, we need to aggregate the similarities between synsets. A first method, called **WNSP-noWSD**, is to average the similarities between all synsets $s(c)$ and $s(e_i^c)$. The second method (**WNSP**) tries to disambiguate between possible synsets, relying on the $maxsim(\cdot,\cdot)$ operator, but defined over synset similarities (instead of cosine similarity over clusters, as in BERT-MPro). Formally, for a category name c and exemplar e_i^c, the typicality score s_i^c is equated to $maxsim(c, e_i^c)$, which is defined by

$$maxsim(c, e_i^c) = \max_{s(c), s(e_i^c)} sim(s(c), s(e_i^c)) \quad (4)$$

where $sim(\cdot)$ denotes the shortest path similarity.

Note that, irrespectively of the disambiguation process, the shortest path similarity possibly lacks expressivity, as synsets of different exemplars can be at the same distance of the category synset.

4.3.2 Lin Similarity (WNIC, WNIC-noWSD)

For a more expressive method, we use the Lin similarity measure (Lin et al., 1998), which computes similarity using the most specific ancestor node and Information Content (IC) (computed via Wikipedia text dump), a measure of specificity for a concept closely linked to frequency (Resnik, 1995), thus combining frequency with hierarchical semantic knowledge. Pedersen (2010) show that augmenting WordNet with IC results in higher correlation with human judgments on similarity and relatedness tasks. Formally, let $IC(\cdot)$ and $lcs(\cdot,\cdot)$ denote information content and least common subsumer (specific ancestor node), respectively, the similarity between synsets $s(c)$ and $s(e_i^c)$ is defined by

$$lin(s(c), s(e_i^c)) = \frac{2 * IC(lcs(s(c), s(e_i^c)))}{IC(s(c)) + IC(s(e_i^c))} \quad (5)$$

We then can aggregate similarities by averaging, which defines the method **WNIC-noWSD**, or by using Equation 4 where $sim(\cdot)$ is chosen to be the Lin similarity. This latter method is called **WNIC**.

5 Experiments

5.1 Datasets

As ground truth typicality ratings, we use three datasets of human typicality ratings, one from Rosch (1975) (young adult ratings) and two from Morrow and Duffy (2005) (young and older adult ratings). The two dataset sources were produced at different time periods (1975 for Rosch and 2005 for M&D), with different sample sizes (209 participants and 54, respectively) and potential cultural differences (US residents and UK residents, respectively) and with different protocols. Human ratings were obtained by scoring a taxonomic sentence for Rosch and by scoring category-exemplar pairs for M&D. The datasets contain varying number of categories (11 for M&D, 10 for Rosch) and exemplars per category (29-128 for M&D, 42-54 for Rosch), with 7 overlapping categories between the two sources.[3] The human ratings between the two splits of M&D are strongly correlated (average category Spearman correlation: 0.857, see Appendix A.2). However, the correlation between the Rosch rankings and M&D rankings on the category-exemplar intersection of the datasets are much lower, likely because of the differences outlined above (average category Spearman: 0.656 and 0.574 for Rosch vs M&D young and older adults, respectively). We follow the preprocessing procedure of Heyman and Heyman (2019), (see Appendix A.1). Our auxiliary corpus S is extracted by sampling sentences from Wikipedia, described in Appendix A.3.

5.2 Baseline and Competing Methods

Word Frequency The first baseline is typicality scores as the exemplar's number of occurrences in the corpus S. It is natural to think that more typical examples are more popular words, and Heyman and Heyman (2019) show that frequency partly accounts for human ratings in the M&D datasets.

PPMI-SVD, Word2Vec Other baselines are the cosine similarities between the category-exemplar static word embeddings from count-based (singular value decomposition of positive pointwise mutual information matrix: **PPMI-SVD**) and prediction-based (**Word2Vec** skip-gram negative sampling) algorithms. For baseline details, see Appendix A.4.

Taxonomic Sentence Verification We use the Taxonomic Sentence Verification method of Misra et al. (2021), using `bert-base-uncased`. The differences with BERT-MLM-Taxo can be found in Sec. 4.1.3.

5.3 Results and Analysis

5.3.1 Method Performance

Mean Spearman correlations for all methods are reported in Table 1. [4]

BERT-based Methods Our first main result is that the BERT-based methods[5] all improve over baselines on the M&D datasets. For the Rosch dataset, only BERT-MPro and Misra et al. (2021)'s method improve over Word2Vec. BERT-MPro has the highest correlations of the BERT based methods across datasets, with Misra et al. (2021)'s method only slightly edging it on the Rosch dataset.

Comparing the substitution-based methods from Sec. 4.1, BERT-SentEmb and MLM-Taxo have similar performance. BERT-MLM-Taxo performs better than BERT-MLM, showing that taxonomic sentences provide narrow yet more informative contexts than a randomly sampled corpus simply based on the category word, as they allow for mutual disambiguation of category and exemplar words. Misra et al. (2021)'s method performs worse than BERT-MLM-Taxo on the M&D dataset but better on the Rosch dataset.[6] These discrepancies across datasets can be attributed to different protocols for obtaining human ratings: scoring category-exemplar pairs for M&D and scoring a taxonomic sentence for Rosch. They also account for the performance differences of the frequency baseline, which yields higher correlation scores on M&D than on the Rosch dataset. Typicality scores are dissociable from lexical frequency when subjects judge whether a sentence is a good example of their idea of the category. Our results are in line with Mervis et al. (1976), showing that Rosch dataset scores are not correlated with frequency.

Comparing the word embedding methods from Sec. 4.2, the performance increase from BERT-Avg to BERT-MPro shows the importance of disam-

---

[3] See Table 4 in Appendix for category/exemplar statistics.

[4] See Table 7 in Appendix A.6 for results by category.

[5] Recall that we use `bert-base-uncased`.

[6] This was the only dataset used in Misra et al. (2021).

biguation. Layer-wise performance can be found in Appendix A.8. It should be noted that for BERT-MPro, the best performing layer was layer 10, confirming Chronis and Erk (2020)'s claim that similarity-based task performance peaks in layers 8-10,[7]. Later layers show more contextual variation (Ethayarajh, 2019) capturing finer-grained sense differences. Inversely, for BERT-Avg earlier layers perform best as they include less contextual variation, making the mean more stable.

WordNet-based Methods For the WordNet-based methods, WNIC achieves the highest correlations across datasets, and is competitive with the best BERT-based methods. This confirms the findings of Pedersen (2010) on other intrinsic tasks such as similarity. Disambiguation in the WordNet methods seems crucial, as the variants using averaging perform worse than their $maxsim$ versions. WNIC's high performance shows the importance of frequency information.

Conclusion The experimental results confirm the importance of handling polysemy for both BERT- and WordNet-based methods. Note that the best performing method (last row), which combines BERT-MPro and WNIC, is discussed in Sec. 6.

5.3.2 Polysemy Analysis

Experimental results show that disambiguation allows the improvements of BERT-MPro over BERT-Avg and WNIC over WNIC-noWSD. We now study whether the improvement is larger when the number of senses is larger. Our hypothesis is that the more polysemous a word, the more imprecise its representation without disambiguation, and the larger the performance increase from using disambiguation with the $maxsim$ operator. This analysis is difficult to do because: (i) we don't have access to "true" senses, and (ii) both exemplar and category words can be polysemous. One solution is to use WordNet synsets as a proxy for senses.

Looking at the estimated polysemy degree for the category words, we find that 8 of the 11 category words are associated with 2 senses or more, with the maximum ("tools") having 8 senses. Aligning with results for M&D-young-adults, we find that BERT-MPro yields the largest correlation increases over BERT-Avg for the categories associated with polysemous category words: BERT-MPro yields above-average ρ increase for 6 of the 8 polysemous categories, with the largest increase (+0.2) for the most ambiguous category word "tools". However, the same analysis on the same dataset with WNIC and WNIC-noWSD does not yield the same trend: while disambiguation leads to a greater relative increase, some of the category words with the least polysemy (animals, insects) have the largest performance improvement from noWSD to WSD (see Appendix A.9 for more details). Looking at the average number of synsets for exemplars, it is not easy to see a trend in the performance improvements. Further analysis is needed and we leave a detailed study on polysemy and typicality for future work.

6 Combining CLMs and Lexical Networks

Given that WNIC and BERT-MPro rankings achieve the highest correlations, questions arise: how similar are the rankings produced by the two methods? If sufficiently different, how can we combine them? To answer these questions, we perform a series of analyses. We constrict this depth-first analysis to just the younger adults M&D dataset.

6.1 Method Complementarity Study

BERT and WordNet provide different models of lexical meaning: BERT is word-oriented and exploits distributional statistical patterns, while WordNet is sense-oriented and exploits more abstract relations. To test whether this leads to different predictions, we compute category-wise Spearman correlations between BERT-MPro and WNIC rankings. The results are given in the fourth column in Table 2. The values range from 0.274 to 0.570 with six categories below 0.4. This moderate correlation shows some complementarity between the two rankings. Next, we present how different the two methods' rankings of certain exemplars can be in the first four columns of Table 3, showing how complementarity manifests on a granular level. This study raises the question of combining BERT-based methods with WordNet-based methods.

6.2 A Simple Ensemble Method

As an ensemble method, we take the raw scores of BERT-MPro and WNIC, convert them to z-scores (separately for each method and category), then sum them.[8] As shown in the last row of Table 1,

---

[7] They denote this as layers 7-9 in their paper (0-indexed); we index starting at 1 to denote the embedding layer as 0.

[8] As an alternative ensemble method, we present a short study of KnowBERT, a CLM enhanced with WordNet knowledge, in Appendix A.10.

Method Class	Method	M&D-Young	M&D-Old	Rosch
Baselines	Frequency	0.323	0.296	0.059
	PPMI-SVD	0.236	0.227	0.294
	W2V	0.260	0.296	0.338
BERT	BERT-SentEmb	0.381	0.373	0.289
	BERT-MLM	0.354	0.358	0.238
	BERT-MLM-Taxo	0.396	0.393	0.303
	Misra et al	0.338	0.280	**0.396**
	BERT-Avg	0.428	0.405	0.298
	BERT-MPro	**0.473**	**0.451**	0.386
WordNet	WNSP-noWSD	0.114	0.045	0.266
	WNIC-noWSD	0.152	0.128	0.318
	WNSP	0.213	0.136	0.295
	WNIC	**0.467**	**0.456**	**0.448**
Ensemble	BERT-MPro + WNIC	**0.547**	**0.531**	**0.528**

Table 1: Mean across categories (See Table 7 in Appendix A.6 for results by category) of Spearman correlations for each method for the three datasets ($p < .001$). Largest correlations among singular methods for each dataset are bold-faced for BERT-based methods and WordNet-based methods. The last line is the overall best method and scores are also bold-faced. Note that for BERT-AVG, BERT-MPro, and BERT-SentEmb, the best performing layer is shown (layers 1, 10, and 11, respectively; see Appendices A.7 and A.8 for a layer wise analysis).

Category	MPro	WNIC	MPro + WNIC	MPro vs WNIC	Avg. Increase
Animals	0.665	0.522	0.697	0.524	0.125
Birds	0.461	0.391	0.533	0.331	0.100
Clothes	0.498	0.491	0.541	0.570	0.024
Flowers	0.206	0.148	0.224	0.351	0.006
Fruits	0.486	0.365	0.469	0.397	0.076
Furniture	0.657	0.635	0.763	0.369	0.140
Insects	0.366	0.429	0.408	0.476	0.043
Instruments	0.527	0.656	0.620	0.498	0.038
Tools	0.366	0.584	0.607	0.274	0.134
Vegetables	0.579	0.600	0.739	0.346	0.102
Vehicles	0.389	0.314	0.418	0.529	0.053
Mean	0.473	0.467	0.547	0.424	0.077

Table 2: Category wise Spearman correlations between each method and human rankings from (first three columns), Spearman correlations between BERT-MPro and WNIC rankings (fourth column), and the increase of performance of the ensemble method over MPro and WNIC (increases are averaged over the two individual methods). Results are shown for the Morrow and Duffy young adult dataset.

BERT-MPro combined with WNIC achieves the highest correlation (greater than 0.5) with human rankings across all datasets, closing the gap on the human performance given by the inter-dataset correlation between Rosch and M&D older adults. The category Spearman correlations for BERT-MPro, WNIC and the ensemble are shown in Table 2. We find that the lower the correlation between the two methods (second from right column), the larger the improvement by combining: we find a rank correlation of -0.555 between the inter-method correlation and the average correlation increase of the ensemble (the last column of Table 2), showing that the more different the two methods rankings, the more ensembling increases performance. In Table 3 are rankings of certain words within their category, showing how the ensemble improves rankings for exemplars that are badly ranked by one of the methods.

7 Conclusion

We show that BERT and WordNet-based methods are able to outperform previous methods in typicality prediction, but only with a disambiguation mechanism, either implicit through the selection of contexts or explicit via the estimation of distinct word senses. These results emphasize the importance of polysemy in assessing typicality, an issue that had been overlooked in previous work. We also show that BERT and WordNet provide complementary information that are relevant to modeling category structure: a simple ensemble of the two leads to the best correlations with human judgements.

We plan to further analyze the differences between CLMs and WordNet in typicality, and find more sophisticated ways to inject semantic knowledge into CLMs. Also, we want to use datasets in other languages, to find if the results generalize.

Category	Word	WNIC	MPro	WNIC + MPro	Human
Birds	owl	15	5	4	12
Birds	swallow	5	22	11	11
Clothes	shirt	10	4	3	6
Clothes	suit	22	8	13	12
Vegetables	lettuce	7	16	11	11
Vegetables	sprout	17	11	12	12

Table 3: Rankings of certain exemplars within their category, as scored by WNIC, BERT-MPro, WNIC + BERT-MPro, and the human ranking. Examples are from the Morrow and Duffy young adult dataset.

Limitations

The human typicality judgements we use from Morrow and Duffy (2005) is limited to English and uses only participants all from the UK, while the rankings from Rosch (1975) are all from the United States; thus, geographical/cultural biases could affect the typicality judgements (certain bird species or clothing exemplars could be more common in different areas, which could affect how human's judge their typicality).

While we try to analyze exactly why disambiguation increases performance (BERT-MPro, WNIC-WSD) in Sec. 5.3.2 and Appendix 8, we acknowledge this analysis is far from perfect: we don't have access to "gold" senses to measure polysemy (just linked WordNet synsets), and no single trend emerges from the analysis across all the methods.

Lastly, one limitation in our BERT-based methods is that we use the `uncased` pretrained model. In hindsight, we might have avoided some ambiguous word uses by using a `cased` model instead: for example, the model might have been able to more easily distinguish between "Apple", the company, and "apple", the fruit. However, the impact might have been marginal, as the model can still rely on contextual clues of the surrounding text, and such cases of ambiguity are arguably rare in the typicality datasets. Another possible limitation, specific to the BERT-MLM and BERT-SentEmb methods, comes from the current sentence sampling procedure, as it is based on the category word only, thus possibly introducing noise for words that have homonyms with different POS (e.g., noun-verb honomyms).

A Appendix

A.1 Dataset Preprocessing

We follow the preprocessing procedure of Heyman and Heyman (2019), discarding multi-word examples (such as *red cabbage*) and examples containing punctuation. Although these cases could have been handled by BERT-based methods using subtokens, the composition of several terms is non-trivial for word embedding based models (Lenci, 2018), and we are more concerned with comparing category structure than how the different models handle multi-word examples or punctuation. Also following Heyman and Heyman (2019), we discard categories with less than 20 examples leaving 11 categories in the Morrow and Duffy (2005) datasets and 10 in the Rosch (1975) dataset. As some of the baseline models have fixed vocabularies (PPMI-SVD, Word2Vec, WordNet), we remove any out of vocabulary examples from the dataset. While we could have used median or minimum typicality scores for out of vocabulary examples, we wanted to ensure that the comparison of performance was fair across all methods by only evaluating on examples that have a valid typicality score for all methods.

A.2 Dataset Agreement

Tables 5 and 6 show the category-wise agreement between the human rankings of the three datasets. Notice that the agreement between the two Morrow and Duffy datasets are much higher than that of Rosch and the two M&D datasets.

Category	Spearman

Table 6: Spearman correlations between the young adult and older adult rankings of Morrow and Duffy (2005) and Rosch (1975) on the intersection of categories and exemplars between the two datasets. The size of the intersection is shown on the far right column.

A.3 Sentence Sampling

For an auxiliary textual dataset S, we use Wikipedia, specifically searching for sentences that contain the singular form of each category word or exemplar, in order to have comparable contexts. We found text from Wikipedia dumps can be noisy (such as: summarization tables, lists of related topics, other sequences that are not actual sentences), so we remove sentences that are too short or long (number of words must be between 5 and 200). For BERT-AVG and BERT-MPro, we sampled 300 sentences for every exemplar and category word. For BERT-MLM and BERT-SentEmb, we sampled 10000 sentences for each category.

A.4 PPMI-SVD and Word2Vec Details

The PPMI matrix was computed from English Wikipedia using a window size of 2. We experimented with a window size of 5, but found the performance to be worse. We also use off-the-shelf Word2Vec (Mikolov et al., 2013) embeddings (skip-gram with negative sampling, 300 dimensions, GoogleNews training corpus).

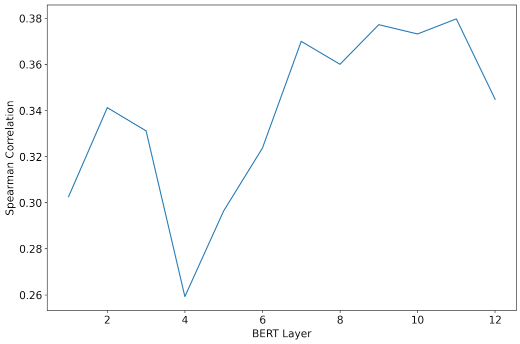
A.5 Runtimes

Frequency, PPMI-SVD, Word2vec, and both WordNet baseline methods take <5 seconds to compute typicality scores on CPU. The Wikipedia word counts used in Frequency and WordNet-IC take 1hr to compute on CPU. The sentence sampling from Wikipedia takes 2hrs to complete. BERT-WordPiece takes 1 min to complete on CPU. BERT-AVG and BERT-MLM take 3hrs to complete on the GPU mentioned in the text; BERT-SentEmb, 5hr; and BERT-MPro, 10hr.

A.6 Results by Category

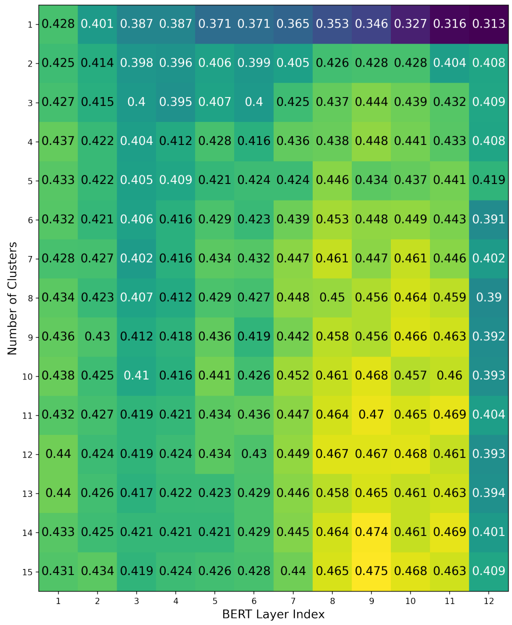
Table 7 shows the Spearman's correlation values for each individual category. Note that just the top performing methods are shown.

A.7 BERT-SentEmb Performance by Layer



The above figure shows the mean Spearman correlations by layer for the BERT NSP method.

A.8 BERT-AVG and MultiPrototype Hyperparameter Performance



The above image shows average Spearman's correlation across all categories for BERT multi-prototype embeddings for each combination of layer index and number of cluster. Note that the top row (number of clusters = 1) is the same as the simple average of contextual representations.

A.9 Detailed Polysemy Analysis

To see whether the $maxsim$ disambiguation mechanism is actually increasing performance more for more polysemous examples, we can compare the performance of the same methods with and without disambiguation when evaluated on words with different number of linked WordNet synsets (a proxy for the degree of polysemy). As shown in Table 8, in general, BERT-MPro's disambiguation increases performance over BERT-Avg more for more polysemous categories (as measured by the synsets linked to the category word). However, this general trend is not seen when comparing WNIC to WNIC-noWSD.

Category	Misra et al			Bert-MLM-Taxo			Bert-Avg			Bert-MPro			WNIC

Table 8: Increase in Spearman's correlation from using BERT-MPro over BERT-Avg (middle left column) and from using WNIC over WNIC-noWSD (middle right column) for each category. The number of linked WordNet synsets for each category and their exemplars are shown in the right columns. Results are shown for the Morrow and Duffy (2005) young adult dataset.

A.10 KnowBERT Results

The combination of CLMs and knowledge graphs is an active research area, mainly the design of knowledge enhanced CLMs (i.e. Wang et al. (2020), Rosset et al. (2020)). We use KnowBERT (Peters et al., 2019), in which knowledge bases are embedded into BERT via an integrated entity linker, which retrieves relevant entity embeddings and updates the hidden states (we leave an in-depth description to the paper). We consider a KnowBERT model with WordNet as the knowledge base[9] with the multi-prototype method for computing typicality scores. We get an average Spearman correlation of 0.446, below that of WNIC and BERT-MPro, showing that a general method for enhancing CLMs with WordNet does not work well for typicality.

---

[9] Candidate WordNet synsets are found for KnowBERT using a similar procedure as we use to find all possible synsets.

An Empirical Study of Clinical Note Generation from Doctor-Patient Encounters

Abstract

Medical doctors spend on average 52 to 102 minutes per day writing clinical notes from their patient encounters (Hripcsak et al., 2011). Reducing this workload calls for relevant and efficient summarization methods. In this paper, we introduce new resources and empirical investigations for the automatic summarization of doctor-patient conversations in a clinical setting. In particular, we introduce the MTS-DIALOG dataset; a new collection of 1,700 doctor-patient dialogues and corresponding clinical notes. We use this new dataset to investigate the feasibility of this task and the relevance of existing language models, data augmentation, and guided summarization techniques. We compare standard evaluation metrics based on n-gram matching, contextual embeddings, and Fact Extraction to assess the accuracy and the factual consistency of the generated summaries. To ground these results, we perform an expert-based evaluation using relevant natural language generation criteria and task-specific criteria such as critical omissions, and study the correlation between the automatic metrics and expert judgments. To the best of our knowledge, this study is the first attempt to introduce an open dataset of doctor-patient conversations and clinical notes, with detailed automated and manual evaluations of clinical note generation.

1 Introduction

The recent progress in automatic summarization has been highly influenced by large transformer-based language models and the availability of large-scale datasets. The summarization of medical conversations is well positioned to benefit from similar approaches, but is facing domain- and task-specific obstacles such as the lack of data and relevant evaluation protocols.

Medical doctors spend on average 52 to 102 minutes per day writing clinical notes from their conversations with the patients (Hripcsak et al., 2011). The time spent with Electronic Health Record systems contributes to work-life imbalance, dissatisfaction, high rates of attrition, and a burnout rate exceeding 50% (Arndt et al., 2017). Summarization models could play a key role in reducing that workload by generating clinical notes from the doctor-patient encounters (Knoll et al., 2022).

Summarizing doctor-patient conversations for a clinical setting brings its own set of challenges and nuances in addition to the typical natural language understanding and generation components. For instance, omission of critical medical facts is likely to alter patient outcomes and should be one of the critical/deciding factors in adopting one summarization system over another. Hallucinations are also likely to impact the clinical outcome if they are not avoided (or detected with a high accuracy).

Designing and improving summarization models that address these challenges can benefit from wider research efforts on the task. However, the lack of publicly available doctor-patient dialogue datasets limits wider research efforts from the NLP community in this summarization task. In this paper, we tackle the lack of data for the task by building a new dataset of doctor-patient conversations and associated clinical notes. We avoid privacy infringement risks, by creating simulated conversations from publicly available clinical notes.

Our main contributions are: **(i)** a new dataset of 1,700 doctor-patient conversations (16k turns and 18k sentences) and their summarized clinical notes (6k sentences). To the best of our knowledge, this is the first publicly-available dataset of medical conversations and associated notes at this scale, **(ii)** an evaluation of several SOTA summarization models, including variants that use existing relevant datasets, augmented training data, and guided summarization for medical conversation summarization, and **(iii)** a study of standard evaluation metrics, domain-specific metrics, and expert judgments for the task, including computing the corre-

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2291–2302

lation between the automatic and manual scores for the evaluation of the generated clinical notes[1].

2 Related Work

Summarization datasets and evaluation methods are often centered around large news articles such as the CNN/DailyMail dataset of 313k newspaper articles (Hermann et al., 2015) and XSum (Narayan et al., 2018) with 227k BBC articles with single-sentence summaries.

Dialogue summarization is relatively less studied in open domain, with a few efforts tackling the summarization of conversations and meetings (Goo and Chen, 2018; Li et al., 2019; Shin et al., 2022) and the creation of meeting summarization datasets (Janin et al., 2003; Carletta, 2007).

Medical conversation summarization is also under-studied, except for a few recent efforts (Liu et al., 2019; Kazi and Kahanda, 2019; Yim and Yetisgen, 2021; Michalopoulos et al., 2022). For instance, (Joshi et al., 2020) applied a pointer generator model to generate summaries from doctor-patient dialogues in telemedicine. Instead of modeling the whole dialogue, they trained the model on snippets taken from the dialogue turns. (Zhang et al., 2021) fined-tuned a pre-trained BART model to automatically generate summaries from doctor-patient conversations. However, they only focused on two specialties (internal medicine and primary care) and the training data only consist of HPI (History of Present Illness) section. (Krishna et al., 2021) proposed an algorithm called Cluster2Sent to generate SOAP notes from doctor-patient conversations. Their summarization model involves both abstractive and extractive methods. (Enarvi et al., 2020) studied both RNN and transformer-based sequence-to-sequence models for generating medical reports. They experimented on Orthopedics data and found that sequence-to-sequence modeling is more promising. The datasets of the studies mentioned above are not made public.

(Song et al., 2020) investigated medical conversation summarization from a Chinese conversational corpus. They applied a hierarchical encoder-tagger model for extractive summarization to generate two types of summaries; one for problem statement and one for the treatment recommendations. Several other medical conversation datasets have been recently created from Chinese online health platform conversation (Liu et al., 2020; Zhang et al., 2020; Lin et al., 2019) but they do not include conversation summaries.

(Moramarco et al., 2022b) studied the task of consultation note generation on a small set of 57 transcript-note pairs (Papadopoulos Korfiatis et al., 2022) and performed a correlation study with several automatic metrics. As their focus was to compare automated metrics with human judgements, they chose models that would "produce different outputs to cover a wider range of errors" instead of attempting to benchmark SOTA summarization models. From the set of metrics they tested, they noted that character-based Levenshtein distance, BERTScore, and METEOR performed best for evaluating the note generation task.

3 MTS-DIALOG

3.1 Data Creation

Our data creation approach consists in generating simulated doctor-patient conversations from publicly available clinical notes. To gather these clinical notes/summaries, we collected notes from the public Mtsamples collection, which provides de-identified clinical notes[2] (South et al., 2014; Moramarco et al., 2022a). The selected clinical notes cover the six most frequent note types and specialties in the collection, including: General Medicine, SOAP (Subjective, Objective, Assessment, Plan), Neurology, Orthopedic, Dermatology, and Allergy/Immunology.

Eight trained annotators, with medical backgrounds, were given all the sections from the clinical notes and asked to create clinical conversations from one section at a time according to detailed guidelines. These guidelines were developed based on an analysis of a large private collection of hundreds of real doctor-patient conversations and associated notes. The annotation guidelines included:

- Conversation creation rules: conversations should be (i) written as it pertains to the day of the visit with the patient and (ii) framed in the context of either an outpatient visit or emergency room visit.
- Medical terms rules: The clinical note may have a more detailed referring expression to the same problem, treatment, or test, than

---

[1] The dataset, source code, and annotations are available at `https://github.com/abachaa/MTS-Dialog`

[2] www.mtsamples.com. Mtsamples categorizes notes to at least one of 40 specialty/note-type labels. Each note explicitly marks section headers as bolded HTML tags.

Dialogue:
Doctor: My chart here says that you're eighty three years old, is that correct, ma'am?
Patient: Yes doctor, that's correct, I just had my birthday.
Doctor: Happy belated birthday! How have you been doing since your last visit?
Patient: Well, my cancer hasn't needed phlebotomies for several months now, which is good.
Doctor: That's great, you have been treated for polycythemia vera, correct?
Patient: Yes, that's the one.
Doctor: I also see you're unassisted today, which is also great.
Patient: Yeah, having some independence is nice.

Section header: History of Present Illness

Section text: The patient is an 83-year-old female with a history of polycythemia vera. She comes in to clinic today for followup. She has not required phlebotomies for several months. The patient comes to clinic unaccompanied.

Table 1: Example of a doctor-patient conversation and associated note/summary from the MTS-DIALOG dataset.

what would be represented in the conversation; for example "Open reduction internal fixation (ORIF)" from the clinical note could be translated to "We will have to do surgery on it" in the conversation.

- Imaginary but plausible rule: if the clinical note is underspecified, it is possible to create a conversation as long as it is plausible. However, the dialogues should be created so that the transcripts are more detailed than the associated clinical notes (except for problems, treatments and tests as mentioned above).
- Formatting rules: annotators should follow standard transcript guidelines such as writing words as they would be pronounced, and capitalization and punctuation rules.
- Conversation characteristics: the goal is to create a dataset with as much variation as possible to mimic real doctor-patient medical visits, including the use of speech disfluencies such as false starts, filler words, interjections, interrupting speech, corrections by the speaker to previous information, using slang and vernacular, and colloquial terms.

We also normalized the 279 original section headers from the notes into 20 types of first-level headers (e.g. *assessment, allergy, diagnosis, exam, medications, past medical history, past surgical*).

The final MTS-DIALOG dataset includes 1,701 pairs of dialogues and associated sections from the clinical notes. Table 1 presents an example from the dataset. The number of pairs from the respective specialties and note types were General Medicine:1,035, SOAP:79, Neurology:296, Orthopedic:208, Dermatology:56, and Allergy/Immunology:27. The dataset was created over a cumulative total of approximately 1,800 hours. Additional statistics are shown in Table 2.

	Dialogue			**Summary**	
	Turns	Sentences	Words	Sentences	Words
count	15,969	18,406	241,685	5,870	81,299
mean	9	11	142	3	48
max	103	136	1,951	57	1,182
25-perc	4	4	48	1	6
50-perc	6	7	88	2	18
75-perc	12	14	176	4	55

Table 2: Statistics of the MTS-DIALOG Dataset.

3.2 Data Quality

The quality of the MTS-DIALOG dataset is ensured by three stages: (1) only candidates with medical training were hired as annotators (e.g. former medical scribes), and (2) the training for this task involved one-on-one periodic feedback during initial stages by an experienced trainer; (3) at the completion of the entire dataset, a separate and independent validation step was conducted to formally evaluate the corpus against a rubric grading system. This independent evaluation graded the conversations according to their adherence with the annotation guidelines and content relevance and coverage w.r.t. the initial clinical note. Table 3 presents the results of this manual validation. The validator was additionally tasked to perform minor corrections (e.g. misspellings or adding back missed information), ensuring that the final data quality would be higher than those reported.

3.3 Comparison with Real Data

The MTS-DIALOG dataset consists of real notes and synthetic conversations that simulate doctor-patient encounters to avoid the public release of private doctor-patient conversations. To study the impact of relying on synthetic data, we investigated the resemblance of the MTS-DIALOG data with real conversations through a blind evaluation of two equal subsets of 52 conversations randomly extracted from (i) the MTS-DIALOG dataset and (ii) a private collection of recorded and tran-

Score	Description	Freq (%)
0.1	Unviable, content is not covered.	25 (1%)
0.3	Content is covered but with logical and medical errors OR Major content is not covered OR At least one major socio-cultural dialogue discrepancy anomaly.	189 (11%)
0.5	Acceptable but some minor content or sociocultural discrepancy issues.	70 (4%)
0.7	Acceptable but with misspellings or transcription rules errors only.	551 (32%)
1.0	Follows guidelines completely, logically and medically sound, no content errors or other issues.	866 (51%)

Table 3: Data validation scoring rubric and frequencies based on manual validation, prior to correction.

scribed doctor-patient conversations. Turns from the real/private subset were selected to match the length of the MTS-DIALOG turns. A medical expert with experience working as a medical scribe in hospitals independently performed this blind annotation by labeling each conversation as real, synthetic, or unknown, together with a written explanation behind each annotation. The annotation criteria included annotating the characteristics of the conversations in terms of disfluency and interruptions.

Label	#Ref	#LabeledAs	TP	FP	FN	P	R	F1
Real	52	34	29	5	23	0.85	0.56	0.67
Synthetic	52	69	47	22	5	0.68	0.90	0.78
Unknown	0	1	0	1	0	0	1	0
Total	104	104	76	28	28	0.73	0.73	0.73

Table 4: Blind Evaluation: #Ref (number of reference samples), #LabeledAs (number of assigned labels), TP (True Positive), FP (False Positive), FN (False Negative), P (Precision), R (Recall), and F1 Score.

The results of this annotation (cf. Table 4) show that 55.77% of real conversations (29/52) were annotated as real, 42.31% of real conversations (22/52) were labeled as synthetic, and 9.61% of synthetic data (5/52) labeled as real. The medical expert's blind labeling was incorrect 26.92% of the time (28/104). If synthetic and real were indistinguishable, the incorrect rate would be 50%.

Dataset	#Turns	MaxTurnLen	#Disfluency	#Interruptions
MTS	7.10 (369)	18.54 (n/a)	0.63 (33)	1.06 (55)
Real	7.10 (369)	34.00 (n/a)	1.77 (92)	1.98 (103)

(a) Statistics on the full annotated datasets

Dataset [#Conversations]	#Turns	MaxTurnLen	#Disfluency	#Interruptions
MTS-mistaken-as-Real [5]	5.0	11.2	0.4	1.0
Real-mistaken-as-MTS [22]	5.9	27.2	1.4	1.5

(b) Statistics on the incorrectly labeled subsets

Table 5: Blind Evaluation: Statistics (Mean (Sum))

A common explanation given by the medical expert for cases where synthetic data was labeled as real is that the content seemed realistic, despite the statistical comparison in Table 5 which shows that the MTS-DIALOG conversations had less disfluencies and interruptions on average. Common explanations for labeling real data as synthetic included the conversation being "to-the-point", clear with low disfluencies, easy to follow, containing abrupt subject changes and containing colloquial speech.

This difficulty in distinguishing synthetic from real indicates that the MTS-DIALOG dataset is a valuable initial dataset, for use in training and benchmarking models for real-world applications, including using the MTS-DIALOG data for data augmentation or as pre-training data for later fine-tuning on (private) real conversations data.

4 Methods

4.1 Summarization Models

To study the specificity of doctor-patient conversation summarization and the relevance of evaluation methods, we generated summaries using several SOTA transformer-based models (e.g. BART (Lewis et al., 2020) and Pegasus (Zhang et al., 2020)), including variants that are pre-finetuned using relevant datasets (e.g. XSum (Narayan et al., 2018) and Samsum (Gliwa et al., 2019)), as well as augmented training data and guided summarization as described in the following sections.

4.2 Data Augmentation via Back-translation

Relevant data augmentation is an effective technique to avoid over-fitting and increase the performance of neural methods. In particular, back-translation augmentation consists in translating the text to another language and then translating it back to the original language. We used two different auxiliary languages to add more variety in the back-translated sentences[3]. To reduce translation errors, we selected French and Spanish for their lexical proximity with English, and high-performing translation models (Tiedemann and Thottingal, 2020).

4.3 Guided Summarization

Several guidance signals can be used to control the output of summarization models. A clinical note

---

[3] We also release the augmented dataset of 3,603 pairs of medical conversations and associated notes.

consists of several sections such as Family History and Assessment, and the simulated conversations from the MTS-DIALOG dataset were generated independently for each section. In the guided summarization trial, we used the section header as a prefix in the training data to guide the summarization of the doctor-patient conversation. This allows the model to learn to generate both the signal (section header) and the following signal-guided summary.

4.4 Evaluation Methods

Despite recurrent efforts in summarization evaluation, automatic evaluation of generated summaries still has several limitations and biases (Hardy et al., 2019; Fabbri et al., 2021; Ben Abacha et al., 2021). These limitations can misinform current and future research efforts and orient neural networks towards optima that do not accurately reflect the relevance and quality of generated summaries. For instance, commonly used evaluation metrics such as ROUGE do not assess whether summaries are factually consistent with source documents, include critical errors, or lack important information (Goodrich et al., 2019). Manual evaluation is another method to assess the quality of the generated summaries, but is time consuming and relies on the availability of domain experts to rate the summaries. Howcroft et al. (2020) examined 165 NLG papers with human evaluations and concluded that the field is in urgent need of standard evaluation methods and terminology.

Taking into account these different factors, we evaluate the generated summaries using a variety of evaluation metrics based on n-gram matching, pre-trained contextualized embeddings (BERTScore), learned metric (BLEURT), automatic fact-based metrics (Fact Scores), and manual evaluation performed by medical experts. BERTScore (Zhang* et al., 2020) uses the pre-trained contextual embeddings from BERT and matches words in candidate and reference texts by cosine similarity. We use two variants: BERTScore-M1 based on the default roberta-large model and BERTScore-M2 based on the deberta-xlarge-mnli model, which was shown to have the best correlation with human evaluation. BLEURT (Sellam et al., 2020) is a learned metric, based on BERT and a pre-training scheme that uses millions of synthetic examples. We use the latest checkpoint BLEURT-20 that correlates better with human judgment and the F1 variants of all the automatic metrics.

For the fact-based evaluation, we utilize a machine learning-based medical fact extraction system to extract medically relevant facts. A medical fact consists of one core attribute with or without one or more other attributes, such as laterality or bodysite. For example, the medical facts identified by the fact extraction system for the input "*the patient has rash on the upper arms*" are *<FINDING_CORE> rash <LATERALITY> upper <BODYSITE> arms*. The Fact Score metric provides F1-score of the extraction of medically relevant facts. The first variant Fact-Core relies on the extraction of seven core fact attributes: *'Procedure_Core', 'Disorder_Core', 'Finding_Core', 'Medication_Core', 'Substance_Use_Core', 'Vital_Sign_Core', and 'Allergy_Core'*. The Fact-Full variant combines these core facts and five additional attributes: *'Negation', 'Hedge', 'Status', 'Laterality', and 'Bodysite'*.

We also investigate the correlation between the automatic metrics and the expert judgments.

5 Experiments

We train the summarization models on 4 Nvidia Tesla K80 GPUs for 4 epochs. We set the learning rate to 3e-05 and regularize the training with an L2 weight decay of 0.1. We use a test set of 100 conversations and notes, randomly selected from the MTS-DIALOG dataset. The remaining pairs are used for training (1,201 pairs) and validation (400 pairs).

5.1 Automatic Evaluation

Table 6 presents the results of different summarization models fine-tuned and evaluated on the MTS-DIALOG dataset. We picked the best performing model from each category (four models in total) for subsequent studies. Table 7 compares the results of these four summarization models using ROUGE-N, Fact Scores, BERTScore, and BLEURT. Examples of generated summaries are shown in Table 9.

These first results highlight the importance of relevant pre-finetuning targets, with XSum yielding substantially better results as a first pre-finetuning stage compared to CNN/DailyMail (40.15 vs. 32.01 ROUGE-1 score). A portion of this differential could be explained by the relatively short length of the MTS-DIALOG summaries (three sentences and 48 words on average) which is likely closer to the length of output for extreme summarization than the longer output summaries in

Table 7: Evaluation of the summarization models using lexical, fact-based, embedding-based, and learned metrics (Macro Average F1 scores over the summaries).

CNN/DailyMail.

Data Augmentation (DA) led to slight improvements across all metrics except ROUGE-2 and BERTScore-M1 as shown in Table 7. Guided Summarization (GS) led to a consistent improvement across all automated metrics except for ROUGE-2 and the Fact-based metrics.

5.2 Expert-based Manual Evaluation

The manual evaluation of the generated summaries is performed using NLG criteria such as Fluency and Non-redundancy, and medical criteria such as Critical Omissions based on fact extraction. For this evaluation, we define a fact as information that cannot be written in more than one sentence. For instance: the sentence "*The father died of stroke at age 89.*" could be written in three sentences: "*The father died*", "*He was 89 yo.*", and "*Stroke was the cause of death.*" and thus contains three facts.

The manual summary evaluation criteria are:

- Fluency: Is the summary fluent to read? (0:"none", 1:"low", 2:"average", 3:"high")
- Non-redundancy: How redundant is the summary? (0-3)
- Critical Omissions: What is the number of medical facts that were omitted?
- Hallucinations: What is the number of hallucinated facts?
- Correct Facts: How many facts in the summary are correct according to the input conversation?
- Incorrect Facts: How many facts are incorrect outside of hallucinations (e.g. wrong age)?

We compute the following scores from the manual counts:

$$FactualPrecision = \frac{\#CorrectFacts}{\#SystemOutputFacts}$$

$$FactualRecall = \frac{\#CorrectFacts}{\#ReferenceFacts}$$

$$HallucinationRate = \frac{\#HallucinatedFacts}{\#SystemOutputFacts}$$

$$OmissionRate = \frac{\#OmittedFacts}{\#ReferenceFacts}$$

- *SystemOutputFacts=Correct+Incorrect+Hallucinated*

	Kappa	F1 (exact)	F1 (tol=1)	F1 (tol=2)	Pearson's correlation
Number of key/reference facts	0.494	0.540	0.780	0.930	0.980
Number of correct facts	0.599	0.710	0.930	1.000	0.841
Number of omitted facts	0.366	0.440	0.740	0.890	0.957
Number of incorrect facts	0.305	0.900	0.990	1.000	0.717
Number of hallucinated facts	0.541	0.920	1.000	1.000	0.695
MACRO-AVG	0.467	0.675	0.875	0.957	0.862

Table 8: Fact count agreements.

	Generated Summary	Reference Summary
1	Family history is significant for coronary artery disease, hypertension, diabetes mellitus, and cerebrovascular disease.	Family history is remarkable for heart disease, cerebrovascular disease, diabetes, and hypertension.
2	The patient denies any history of depression, suicidal ideation, chest pain, shortness of breath, nausea, vomiting, numbness, weakness, or tingling.	Please see history of present illness. Psychiatric: She has had some suicidal thoughts, but no plans. She denies being suicidal at the current time. Cardiopulmonary: She has not had any chest pain or shortness of breath. GI: Denies any nausea or vomiting. Neurological: No numbness, weakness or tingling.
3	Significant for frequent flyer status, anemia, anxiety, bipolar disorder, and iron deficiency anemia. Surgery history is positive for tubal ligation.	1. Bipolar disorder. 2. Iron deficiency anemia. 3. Anxiety disorder. 4. History of tubal ligation.
4	He is a non-cigarette smoker and non-ETOH user. He is single and he has no children. He works as a payroll representative and previously did lot of work in jewelry business, working he states with chemical.	She is a nonsmoker and nondrinker. She is single with no children. Currently works as a payroll representative. Prior to that, she worked in the jewellery business with chemical.
5	The patient was a baby born at 32 weeks' gestation at 4 pounds 11 ounces and placed in an incubator for 3 weeks. He had jaundice, but was not given any treatment.	32 weeks gestation to a G4 mother and weighed 4#11oz. He was placed in an incubator for 3 weeks. He was jaundiced, but there was no report that he required treatment.

Table 9: Examples of generated summaries by Model #4.

To assess the effort level for the end user (clinicians who will use/edit the system generated summary), we compute Levenshtein edit distance (minimum # of character insertion, deletion, substitution or transposition operations) (i) between system summary and reference summary, and (ii) between the initial system summary and a human-corrected version of that summary which fixes all issues. The normalized edit distance is then calculated by dividing the Levenshtein distance by the length of the longest summary between reference and system.

To measure the consistency of these expert evaluations, a common set of 100 reference-system outputs were labeled independently by two trained annotators with medical backgrounds. The remainder of the evaluated data (300 system summaries) was single annotated.

The Pearson correlations between the annotations for the rating-based scores were 0.631 for Fluency and 0.894 for Non-redundancy. We also calculated Cohen's kappa and F1 score for the number of reference facts as well as the correct, omitted, hallucinated, and incorrect system facts. With strict Cohen's kappa and F1, we obtained values 0.467 and 0.675 respectively. As these measures penalize harshly for being off by one or two facts, we also measured a relaxed F1 allowing a count mismatch of one or two facts, which showed an inter-annotator F1 agreement of 0.875 and 0.957 respectively (cf. Table 8). The Pearson correlation between the two annotators' fact counts was also high at a macro-average of 0.862.

The results of the manual evaluation are reported in Table 10. In large part they confirm the automatic evaluation results from Table 7, with Models 2-4 performing better than the baseline Model #1 in terms of Factual Recall and Factual F1. In comparison with Model #3, Data Augmentation (Model #4) led to better fluency, non-redundancy, and factual Recall and F1 with less critical fact omissions, but increased the hallucination rate to 3% from 1% for Model #3.

The model without guided summarization or data augmentation (Model #2) achieved similar results to the best model that employed both (Model #4). Model #2 was also ranked higher according to the automatic fact extraction metrics (cf. Table 7). These results suggest that guided summarization improves the precision of the summary facts (+5.5% improvement) but lowers recall (-5%), with data augmentation reversing the trend. Fact-based performance was thus shown to be more

Evaluation Criteria	Model #1 (BART-large)	Model #2 (BART-PFT)	Model #3 (BART-PFT-GS)	Model #4 (BART-PFT-GS-DA)
Summary Quality Evaluation				
Fluency [0-3] ↑	2.33	**2.44**	2.31	2.37
Non-redundancy [0-3] ↑	**2.97**	2.85	2.90	2.93

BLEURT	0.790	0.429	0.787	0.269	0.247	0.784	0.859	1.000

Table 11: Pearson's correlation coefficients between the automatic evaluation metrics.

sensitive to prefixes in the training data (in the GS experiment we used 20 different section headers as prefixes in the training data). This has likely prevented the models from generalizing factual patterns across different sections, even though the same prefixes helped improve the performance on a token level according to the token-based evaluation measures (ROUGE-1 and BERTScore). On the other hand, guided summarization improved non-redundancy and lowered the factual hallucination rate to only 1% down from 4% for Model #2.

Our four models provided summaries with an average length of 9.76, 24.6, 19.77, and 21.45 tokens, respectively. To evaluate potential performance bias from summary length, we computed the correlation between the summary length and BLEURT as an example of automatic metric and the correlation between the summary length and Factual F1 as an example of manual metric. The Pearson correlation scores between BLEURT and the summary length of Model #1, #2, #3, and #4 are low (-0.200, -0.027, -0.147, and -0.173, respectively). The correlation between Manual Factual F1 an the summary length of the same models are higher with an inverse correlation of -0.511, -0.230, -0.268, and -0.409, respectively, which indicates that the models are prone to more errors in longer summaries.

5.3 Correlation between Evaluation Metrics

Table 11 shows Pearson correlations between the automatic evaluation metrics. BERTScore-M2, based on the DeBERTa model, was the embedding-based metric with the highest correlation with the n-gram metrics ROUGE-1, ROUGE-2, and ROUGE-L, and the embedding-based metrics BERTScore-M1 and BLEURT. However, ROUGE-1 and ROUGE-2 had higher correlation with Fact-Core and Fact-Full.

Table 12 presents the Pearson correlations between the automatic metrics and manual scores. The correlations with the manual scores show a different picture, with BLEURT standing out as the most correlated with manual fact counts and expert-based correctness assessments. BLEURT was also the most correlated metric with the Levenshtein distance, used here as an indicator for the level of effort required to correct the generated summaries.

The manual fact metrics were more correlated with the embedding-based metrics than ROUGE-1, ROUGE-2, and ROUGE-L, in contrast with the automatic fact extraction metrics. This could be explained, in part, by the lower factual coverage of automatic fact extraction vs. manual fact identification. This also highlights an important empirical insight, in that upstream upper bounds, such as the limited coverage of automatic and symbolic fact

Manual / Automatic	**Factual P**	**Factual R**	**Factual F1**	**Hallucination**	**Omission**	**Levenshtein**
	Correctness ↑			**Error Rate** ↓		
ROUGE-1	0.101	0.368	0.402	-0.074	-0.486	-0.326
ROUGE-2	0.086	0.167	0.202	-0.049	-0.237	-0.040
ROUGE-L	0.126	0.393	0.416	-0.073	-0.479	-0.296
Fact-Core	0.039	0.095	0.160	**-0.105**	-0.192	-0.030
Fact-Full	0.056	0.133	0.188	-0.094	-0.214	-0.122
BERTScore-M1	**0.132**	0.445	0.462	-0.078	-0.518	-0.317
BERTScore-M2	0.090	0.437	0.461	-0.080	-0.562	-0.366
BLEURT-20	0.113	**0.477**	**0.480**	-0.082	**-0.591**	**-0.486**

Table 12: Pearson's correlation coefficients between the automatic and manual scores.

extraction, can bias the correlation results against neural embeddings methods which, from their large pre-training, have inherently wider (implicit) coverage than symbolic fact extraction methods.

6 Conclusion

In this paper we conducted an empirical study of clinical note generation from doctor-patient encounters. This included creating a new dataset of 1,700 conversations and notes, evaluating several SOTA summarization models, and using multiple automated metrics and human judgements for the summarization models. Our findings show that pre-finetuning transformer models plays a key role in improving factual accuracy and summary fluency, and in reducing critical fact omissions, with guided summarization improving the precision of the summary facts and reducing hallucinations at the expense of factual recall.

The manual evaluation showed that the generated summaries reached a high fluency score (2.44 on a 0-3 scale) and relatively high factual F1 (0.76), but the best model still had a hallucination rate of 3% and missed 33% of the medical facts. Wider research efforts are needed to design methods and models that can reduce the omission and hallucination rates as well as efficient fact-based evaluation metrics to automatically assess the factual consistency of the generated summaries.

The key bottleneck limiting increased research from the NLP community on medical note generation has been the lack of generally available datasets to train and experiment on. This public release of the MTS-DIALOG dataset will enable wider research and faster research progress on this very important and impactful NLP task. Our comprehensive evaluation of multiple summarization models and evaluation metrics provides valuable baselines and references for comparison, and also shows where these systems and metrics stand on multiple dimensions of human evaluation.

Medical doctors today suffer from heavy documentation burden, which frequently causes physician dissatisfaction and burnout, and distracts doctors from being able to give their undivided attention to their patients. We look forward to a future where NLP research and the NLP community are able to provide doctors with tools for effective automated medical note generation, and enable them to return their focus to what they really love - providing great care for their patients.

Limitations

To address the lack of data and protect patient privacy, we relied on creating simulated doctor-patient conversations from de-identified clinical notes. Although we relied on trained annotators with medical background, those simulated conversations might still not reflect faithfully the actual language or structure of real doctor-patient conversations. For instance, the fraction of disfluencies and speech interruptions may occur at higher frequency than simulated in this dataset. Furthermore, it is often the case that doctor-patient conversations are automatically transcribed from speech to text, and the speech-to-text generation systems can produce errors in the output text. If real conversation benchmarks are made available in the future, they would allow further extrinsic validation of the proposed dataset and the first research insights. Many more summarization models can be tested on the task with the new dataset, and this study explored only some of them. Different, or larger language models could yield different results and lead to new or different insights. Although the introduced dataset is substantially bigger in size compared to other doctor-patient conversation datasets, its size is still limited in comparison with open-domain summarization datasets, which can limit the fine-tuning performance, especially for larger neural models. The dataset is limited in terms of covered diseases. The annotators ensured that the dataset is fully anonymized and balanced the synthetic conversations w.r.t. gender but the notes could still include real-world biases from the original clinical notes. The created dataset is intended for research purposes on automatic clinical note generation and should not be used for medical diagnosis or other health-related applications.

Ethics Statement

No protected health information were used in the creation of this dataset. Annotators were paid a fair hourly wage consistent with the practice of the state of hire.

Instruction Clarification Requests in Multimodal Collaborative Dialogue Games: Tasks, and an Analysis of the CoDraw Dataset

Brielen Madureira[1] and **David Schlangen**[1,2]

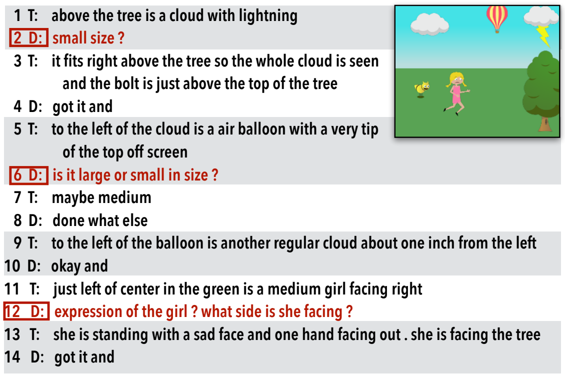
Abstract

In visual instruction-following dialogue games, players can engage in repair mechanisms in face of an ambiguous or underspecified instruction that cannot be fully mapped to actions in the world. In this work, we annotate Instruction Clarification Requests (iCRs) in CoDraw, an existing dataset of interactions in a multimodal collaborative dialogue game. We show that it contains lexically and semantically diverse iCRs being produced self-motivatedly by players deciding to clarify in order to solve the task successfully. With 8.8k iCRs found in 9.9k dialogues, CoDraw-iCR (v1) is a large spontaneous iCR corpus, making it a valuable resource for data-driven research on clarification in dialogue. We then formalise and provide baseline models for two tasks: Determining when to make an iCR and how to recognise them, in order to investigate to what extent these tasks are learnable from data.

1 Introduction

Somewhere in interstellar space are the Voyager Golden Records[1], which left Earth in spacecrafts in 1977 carrying a message about humanity to extraterrestrial civilizations. The committee in charge of designing the message, chaired by Carl Sagan, was careful to include symbolic instructions on how to play the records. But what if these instructions turn out to be incomprehensible to the aliens?

In human dialogue, Clarification Requests (CRs), such as those highlighted in Figure 1, are a common and indispensable mechanism to signal misunderstandings and to negotiate meaning, as recently stressed *e.g.* by Benotti and Blackburn (2017). This utterance-anaphoric conversational move can be realized with various forms, functions/readings and contents (Purver et al., 2003; Ginzburg, 2012) and can trigger responses that may or not be satisfactory (Rodríguez and Schlangen, 2004).



1 T: above the tree is a cloud with lightning
2 D: small size ?
3 T: it fits right above the tree so the whole cloud is seen and the bolt is just above the top of the tree
4 D: got it and
5 T: to the left of the cloud is a air balloon with a very tip of the top off screen
6 D: is it large or small in size ?
7 T: maybe medium
8 D: done what else
9 T: to the left of the balloon is another regular cloud about one inch from the left
10 D: okay and
11 T: just left of center in the green is a medium girl facing right
12 D: expression of the girl ? what side is she facing ?
13 T: she is standing with a sad face and one hand facing out . she is facing the tree
14 D: got it and

Figure 1: Instruction Clarification Requests identified in a portion of a CoDraw dialogue (ID 8906, CC BY-NC 4.0), with a scene from Zitnick and Parikh (2013).

In addition to the scientific motivation to comprehend CRs as a linguistic phenomenon, timely producing and understanding the vast range of CRs is also a desirable property for dialogue systems (Schlangen, 2004). This ability is especially relevant in scenarios where building common ground is necessary to act and collaboratively achieve a goal. Instructional interactions are a particular instance where an instruction follower (*IF*) often needs to ask for clarification in order to execute actions according to an instruction giver's (*IG*) instructions.

Instruction Clarification Requests (iCRs), as we will refer to them, are a type of CRs originating at Clark (1996)'s 4th level of communication, the level of uptake (Schlöder and Fernández, 2014). They are elicited when an instruction utterance is generally understood (*e.g.* acoustically, syntactically, semantically) but some underspecification or ambiguity prevents the *IF* to carry out an action with enough certainty, as shown in Figure 1.

Learning clarification mechanisms from data is still an understudied research problem (Benotti and Blackburn, 2021). We envision the following desiderata for a dataset suitable for data-driven research on iCRs:

---

[1] https://voyager.jpl.nasa.gov/golden-record//

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2303–2319
May 2-6, 2023 ©2023 Association for Computational Linguistics

- ▷ **Naturalness**: iCRs should occur by the spontaneous decision process of the *IF* in real interaction while trying to act and solve a task, ideally not being induced by external incentives in the data collection and also not synthetically generated.
- ▷ **Specificity**: the annotation should pin down iCRs as a single category, not subsumed within other CRs and dialogue acts.
- ▷ **Frequency**: relative and absolute occurrence of iCRs should be large enough for data-driven methods and statistical purposes.
- ▷ **Diversity**: iCRs should occur with various forms and content, being grounded in the game actions and parameters.
- ▷ **Relevance**: iCRs should be pertinent for players to decide on actions and solve the task successfully.
- ▷ **Regularity**: iCRs should emerge from underlying strategies of the players and not be the result of random or idiosyncratic behaviour.

Our research questions are: i) Can *IF* dialogue models trained on data learn to recognise when they would profit from receiving more information in order to execute an action, and thus generate an iCR? ii) Can *IG* dialogue models trained on data learn to recognise when the *IF* is making an iCR and respond to it?

In this work, our contribution to begin addressing these questions is threefold. We (a) perform annotation of naturally occurring iCRs in a collaborative and multimodal dialogue game, namely the CoDraw dataset (Kim et al., 2019), showing that it is a valuable resource for data-driven research on clarification in dialogue; (b) analyse the corpus and provide insights relating iCRs to the game dynamics; and (c) discuss two subtasks and models that can be explored with CoDraw-iCR (v1) and may serve as components of *IF* and *IG* dialogue models capable of handling iCRs.

2 Related Literature

It is a common practice to map CRs to the level of communication (Clark, 1996; Allwood, 2000) where the misunderstanding occurs (Gabsdil, 2003; Schlangen, 2004; Rodríguez and Schlangen, 2004; Rieser and Moore, 2005; Rieser et al., 2005; Bohus and Rudnicky, 2005; Benotti, 2009; Koulouri and Lauria, 2009; Benotti and Blackburn, 2021). When ASR used to be a bottleneck for dialogue processing, several works focused on CRs elicited by problems at levels 2 and 3 – perception and understanding (Healey et al., 2003; Schlangen and Fernández, 2007a,b; Stoyanchev et al., 2013, 2014, *inter alia*). Comparatively less research exists focusing on CRs at level 4, namely intention, uptake or task-level clarifications (Benotti, 2009; Schlöder and Fernández, 2014). We thus contribute to filling this gap, building upon the existing literature we now turn to discuss in more detail.

Schlöder and Fernández (2015) perform a corpus-based study splitting level 4 CRs into two types of intention-related conversational problems: recognition and adoption. Instruction-following dialogues, where utterances are intertwined with actions, is one setting where level 4 CRs play a fundamental role in negotiating meaning. Benotti and Blackburn (2017) discuss the relation between instruction, CRs and contexts in such settings and how conversational implicatures are a rich source of CRs. Task-level reformulations, a clarification strategy where the initiator rephrases an utterance with respect to its effects on the task, are typically used to confirm more complex actions in instruction giving dialogues (Gabsdil, 2003) and happen very frequently (Benotti, 2009). Multimodality, *e.g.* gestures, also play a role in instruction-following CRs (Ginzburg and Luecking, 2021).

Benotti (2009) proposes using planning to infer and generate the task-level clarification potential of instructions and identify level 4 CRs in one dialogue of a corpus of 15 instruction giving dialogues. Benotti and Blackburn (2021) analyse the same corpus and identify six characteristics that may account for the larger proportion of level 4 CRs found in it: task-oriented dialogues, asymmetry in dialogue participant roles (*IF* and *IG*), immediate world validation by the informational or physical actions, shared view and consequent verification of the actions, long dialogues that enable more shared background, and irreversible actions that require more certainty.

Other corpus studies exist in small datasets. Rodríguez and Schlangen (2004) find that 22.17% of the CRs are level 4 CRs in an instruction-following setting. Similarly, Gervits et al. (2021) collect and annotate 22 dialogues with a human-controlled virtual robot that followed high-level or low-level instructions. They propose a very detailed annotation schema for the content of CRs, but there is no clear distinction of level 4 CRs.

A larger dialogue game dataset, the Minecraft Dialogue Corpus (Narayan-Chen et al., 2019) with 509 games, has been annotated with CRs. Lambert et al. (2019) annotate the *IF* utterances with eight dialogue acts, one of which, `clarification questions`, comprises requests for clarification to a given instruction or statement (26.36% of all utterances). Shi et al. (2022) perform a similar annotation with a category `instruction-level questions` to request clarification for a previous instruction that was not clear or ambiguous (18.64%).

The TEACh dataset (Padmakumar et al., 2022) contains 3k dialogues annotated with dialogue acts (Gella et al., 2022), of which the 675 `RequestOtherInfo` spans under the `Instruction` category relate to iCRs.

Kiseleva et al. (2021) extend the Minecraft Dialogue Corpus with 47 games containing 126 CRs for an interactive agent building challenge, but concentrate on the task of modelling a "silent *IF*" that cannot ask questions. The second edition of their challenge, which happened recently (Kiseleva et al., 2022; Mohanty et al., 2022), focuses on when the *IF* should ask for clarification and what it should ask about, similar to Aliannejadi et al. (2021). The dataset for the second challenge is not collected through real, synchronous interaction. Instead, one player builds a structure and generates instructions *a posteriori*, and, in a separate step, another player follows these instructions, deciding whether to make a CR. Similarly, Aliannejadi et al. (2021) collects a large dataset of CRs to user requests, augmented synthetically, in a multiple-step process without interaction. Another large-scale dataset with 53k task-relevant questions and answers about an instruction was constructed Gao et al. (2022). However, the data is created by an annotator that does not have to act, but only watches execution videos, asking a question they think would be helpful and then answering their own question.

Although these strategies facilitate data collection, they abstract away the decision-making and repair processes that emerge when humans collaborate to solve a task jointly, which are present in CoDraw. Our work and the existing literature converge in addressing CRs for ambiguous instructions, but CoDraw-iCR (v1) maintains the interactive aspect of *sequential* rounds and the spontaneous initiative of *IF* to ask. It is large in absolute number of iCRs and dialogues, with short games that have a relatively constrained action space. Moreover, our annotation pins down iCRs among other types of CRs.

A dataset that can be further explored for iCRs is Thomason et al. (2020). It instantiates a navigation task where the *IF* gets an ambiguous or underspecified command about where to navigate to, and can ask questions to an oracle during the trajectory.

In HRI, following commands is a central task. Koulouri and Lauria (2009) investigate miscommunication management mechanisms in robots performing collaborative tasks, in which task-level reformulations is a challenging type of CR that requires identification of the effects of all possible executions of an instruction. Deits et al. (2013) evaluate various clarification question strategies for robots that receive instructions with an ambiguous phrase. Marge and Rudnicky (2015) examine recovery strategies in situated grounding problems, when an agent has to deal with requests containing referential ambiguity or that are impossible to execute. Interestingly, Jackson and Williams (2018) and Jackson and Williams (2019) raise awareness to the fact that merely posing a CR can already imply willingness to follow a command, which is undesirable in morally delicate situations.

Other tangent research areas study clarification edits to solve underspecified phrases in instructional texts (Roth et al., 2022) and clarification responses in community forum questions or search queries (Braslavski et al., 2017; Rao and Daumé III, 2018; Aliannejadi et al., 2019; Kumar and Black, 2020; Hu et al., 2020; Majumder et al., 2021), scenarios with only minimal or no interaction.

Tasks. Deciding when to initiate a CR in various contexts is a task classically discussed in the CR literature (Rieser and Lemon, 2006; Stoyanchev et al., 2012, 2013; Narayan-Chen et al., 2019; Aliannejadi et al., 2021; Shi et al., 2022; Kiseleva et al., 2022, *inter alia*). Fewer works exist specifically about detecting if a CR was made. Identification of CRs in corpora carry out a similar task, although this is not done from the perspective of an agent knowing that it needs to respond to the CR, of which De Boni and Manandhar (2003) is an example. More generally, this task can be subsumed by dialogue act classification, as in, for instance, Gella et al. (2022).

3 Motivation and Problem Statement

CRs occur naturally in human-human interaction and thus also in visual dialogue games. Neural network-based dialogue models trained at such datasets need to properly handle this phenomenon, which comprises various component tasks for identifying, interpreting, generating and responding to CRs. In this section, we formalise the setting and two of these tasks.

3.1 Formalisation: Instruction-Following Dialogue Games

A visual instruction-following dialogue game can be formalised as a tuple $G = (P, S, R, M)$ representing a goal-oriented interaction between players P (an instruction giver *IG* and an instruction follower *IF*). *IG* sees a scene S, hidden to *IF*, and instructs *IF* on how to reconstruct it. They exchange a sequence R of n rounds $r_i = (g_i, a_i, f_i)$ comprised of two utterances (g_i, f_i), from *IG* and *IF*, respectively, and of actions a_i that incrementally create partial reconstructions s_i of S. R is initialised as an empty set and, at each round, it is extended with g_i, a_i and f_i, in that order. The final state of a completed game contains all filled rounds. A scene similarity metric M computes how close the reconstructions are to the original image at each round, and the goal is to maximize similarity of the final reconstruction $M(S, s_n)$.

The dialogue acts by the *IF* include acknowledgements and clarification requests, whereas the dialogue acts by the *IG* include instructions and responses to clarifications. Two variations are possible: the state s_i can be accessible for the *IG* or not. The incremental scenes can be regarded either as the common ground between players (if both can see it) or as what the *IF* considers to be their common ground (when it is private), akin to what is proposed by Mitsuda et al. (2022).

Following Clark (1996), we assume that a pair of equally competent players, committed to the game's goal of maximizing $M(S, s_n)$, seek to minimize joint effort. It is acceptable for the *IG* to produce an underspecified instruction if producing a fully specified instruction would cost more than answering an iCR. Instruction CRs require an extra effort by the *IF*, so they should occur when repair is necessary and the cost of asking is lower than the potential information gain.

3.2 Tasks

We propose to use CoDraw-iCR (v1) to advance research in iCRs by modelling two CRs subtasks in an instruction-following dialogue game grounded in a visual modality. Both subtasks can be regarded as a binary decision step happening right before each player's next utterance generation.

Task 1: Ask iCR? From the *IF*'s perspective as the CR initiator, decide when to initiate a CR. More specifically, after each *IG* utterance, given the dialogue context $D_{0:(i-1)}$ (that is, all previous utterances), the current utterance g_i by IG, and the current state[2] of the scene s_i, the *IF* must decide on the type of their utterance f_i, namely whether to consider the action completed and signal willingness to receive further instructions (*e.g.*, produce something like "OK"), or to ask for clarification on some aspect of a previous instruction. That is, this formulation of the task focuses on the dialogue act to perform, abstracting away from the concrete realisation. It deals with the problem of automatically determining what is a good instruction and what is not, on its context. This task relates to slot filling in the sense that an instruction containing all the needed parameters for the mentioned objects should not require clarification.

Task 2: Was this an iCR? From the *IG*'s perspective as the CR recipient, identify whether an iCR has been made. At each round i, given the dialogue context $D_{0:i}$ (in which the last utterance, f_i, is possibly an iCR) and the original scene S, the *IG* must decide whether to give further instructions or to (also) respond to an iCR.

4 Data and Annotation

CoDraw (Kim et al., 2019) is a collaborative instruction-following dialogue game, in which a "teller" (in our terminology, the *IG*) observes a clipart scene and instructs a "drawer" (*IF*), who has no access to it, on how to reconstruct it, *i.e.* place cliparts in a canvas with the correct size, direction and position. The corresponding crowdsourced dataset contains 9,993 dialogues in English and has been released under a CC BY-NC 4.0 license. This dataset instantiates the formalisation proposed in

---

[2] Under the assumption that the *IF* has manipulated the scene in response to *IG* already. For CoDraw, the exact point when the *IF* types the message has not been preserved.

Section 3, but adds an additional signal: The teller is allowed to peek at the drawer's canvas once during the game whenever they want, *i.e.* the teller can get access to s_i and thus judge how it differs from S. Players exchange messages of up to 140 characters through a chat interface and must alternate turns. We will use round to refer to a pair of consecutive utterances by teller and drawer with the corresponding actions. The drawer's performance is evaluated with a scene similarity score that ranges from 0 to 5, where 5 is a perfect match. Table 1 summarizes quantitative aspects of the dataset.

	train	**val**	**test**
dialogues	7,989	1,002	1,002
with peek	7,315	923	913
avr. final score	4.20	4.19	4.17
before peek	3.97	3.95	3.96
avr. rounds/dialogue	7.76	7.69	7.70
avr. utterance len teller	14.36	14.48	14.31
avr. utterance len drawer	2.58	2.67	2.58
vocab size *IG*		4,506	
vocab size *IF*		2,200	

Table 1: Descriptive statistics: CoDraw dataset.

Each game is about a different abstract scene[3] composed of between 6 and 17 out of a set of 58 clipart types (Zitnick and Parikh, 2013; Zitnick et al., 2013), among which the boy and the girl can have 5 facial expressions and 7 body poses, so the resulting clipart set contains 126 elements and the default background. Multiple types of trees, hats, clouds, glasses and balls can introduce the need for ambiguity resolution in the games. As the individual components can be placed freely, the space of possible resulting scene images is practically unlimited in size.

In the baseline models proposed in the original paper, the authors introduce a simplifying assumption which removes the drawer's utterances from the dialogue history (they call this condition the *silent drawer*). The authors leave the tasks of identifying when a CR is necessary and of generating it for future work. Subsequent works with this dataset have focused on text-to-image generation (El-Nouby et al., 2019; Matsumori et al., 2021; Zhang et al., 2021; Lee et al., 2021; Liu et al., 2020; Fu et al., 2020) but, to the best of our knowledge, no other work has examined CRs in CoDraw. We thus take up this idea to bring back the dialogue modality to this dialogue game.

Identification of Instruction CRs. We observe that a good portion of the drawer's utterances belongs to one of two dialogue act types: *acknowledgements*, signaling that the teller may proceed with the next instruction, and *clarification requests*, initiating repair on aspects necessary to solve the task. We thus consider CoDraw to be a potentially interesting source of iCRs.

The first step we take is identifying instruction-level CRs in this dataset. To achieve that, we perform a binary decision over the drawer's utterances. For our purposes, an utterance is an iCR if the following assertion is likely true:

> "*This utterance indicates that the drawer is requesting further information about one or more instruction(s) previously given by the teller in order to perform an action accordingly, likely because part of the instruction was underspecified, ambiguous or not clear.*"

To reduce the annotation workload, we annotate utterance *types*; forms that occur only once (88.97% of the types) are presented with a one-utterance context window around it. All occurrences of each of the other utterance forms are collapsed into a single datum, presented to the annotators without context.

5 Corpus Analysis

In this section, we present an analysis of iCRs in the CoDraw dataset and their relation to the game dynamics, establishing connections to the items in our desiderata and showing that CoDraw-iCRs (v1) is a promising resource to study the phenomenon and to model dialogue agents that learn what to do in face of unclear instructions, complementing existing initiatives.[4]

5.1 Descriptive Statistics

The 13,727 *IF*'s utterance types have been annotated by two annotators, with a Cohen's κ (Cohen, 1960) of 0.92. Table 2 presents the main descriptive statistics of the annotated corpus.[5] 8,807 (11.36%) of all drawer's utterances in CoDraw are iCRs. 59.45% of the dialogues contain no iCRs. For the purpose of analysis, we also compute numbers relative to the subset of dialogues that contain at least

---

[3] http://optimus.cc.gatech.edu/clipart/

[4] The dataset is available for the community upon request.

[5] In this paper, for the around 3.6% of the utterances with disagreements, we opt for the second annotator's labels, who had more training.

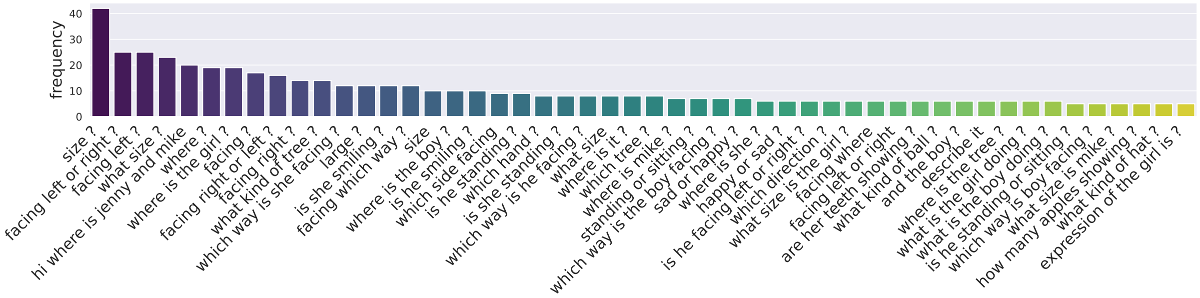


Figure 2: 50 most frequent Instruction CRs in the CoDraw dataset ordered by rank.

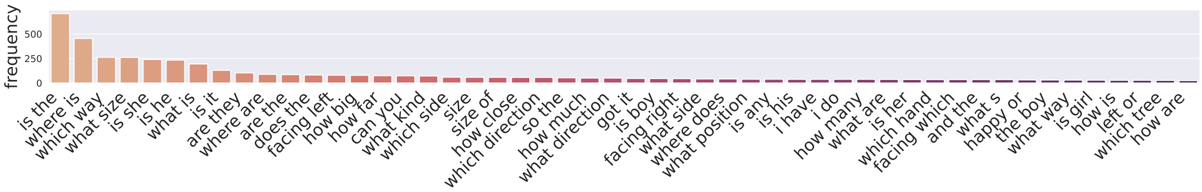

Figure 3: 50 most frequent iCRs initial bigrams in the CoDraw dataset.

one iCR; the idea here is that this excludes players who may not have been willing to use the opportunity to ask iCRs. In this subset, the percentage of iCRs is 24.36%. We also separate out numbers computed from the dialogues up the "peek" action described above, as from that move on, the state of the common ground changes.

	all	w/ iCRs	until peek
dialogues	9,993	4,052	-
rounds	77,502	36,149	61,829
iCR utterances	8,807	8,807	7,803
% iCR utterances	11.36	24.36	12.62
mean iCRs/dialogue	0.88	2.17	0.78
std iCRs/dialogue	1.53	1.73	1.36

Table 2: Descriptive statistics: Annotation.

Figure 2 presents the most frequent iCR utterance types, ordered by rank. 7,260 (94.13% of the types) are *hapax legomena*. Types occupying the highest ranks relate to size, position and orientation, which directly map to the possible actions on cliparts, and to disambiguation of *e.g.* facial expression and body pose. Few types occur more than 5 times, which is evidence that the dataset contains a rich diversity of iCR surface forms. Figure 3 aggregates iCRs by initial bigrams, after removing punctuation and initial *ok* and *okay* tokens (which realise a different dialogue act). Common iCR forms are polar questions and wh-questions also related to the main actions (placement, resize, flip, disambiguation).

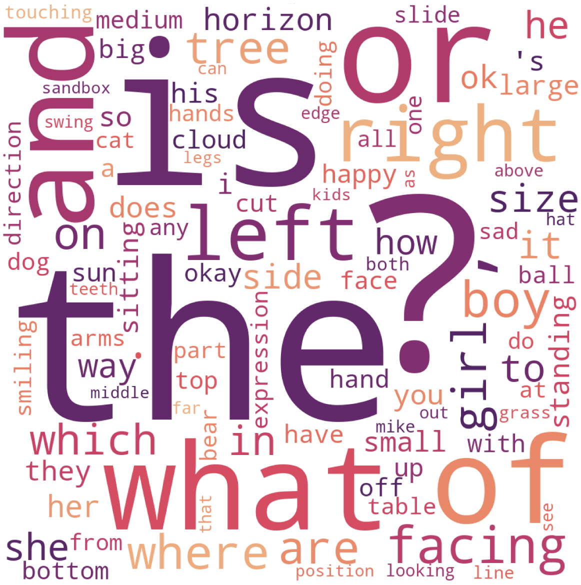
The drawer's vocabulary contains 2,200 token types, out of which 1,468 occur in iCRs. Figure 4 shows an overview of the 100 most common tokens. The frequent iCR vocabulary contains many nouns relating to cliparts (slide, table, bear, dog), in particular those that refer to nouns involving ambiguity (boy, girl, cloud, tree, ball). Question words occur frequently (what, how, where, which) as well as words about object placement (horizon, facing, size, top, touching, edge). Non-iCR utterances commonly contain words related to the task (scenery, picture, image, check, next), greetings and thanks, and acknowledgement words (ok, ready, done).

5.2 Relations to Game Dynamics

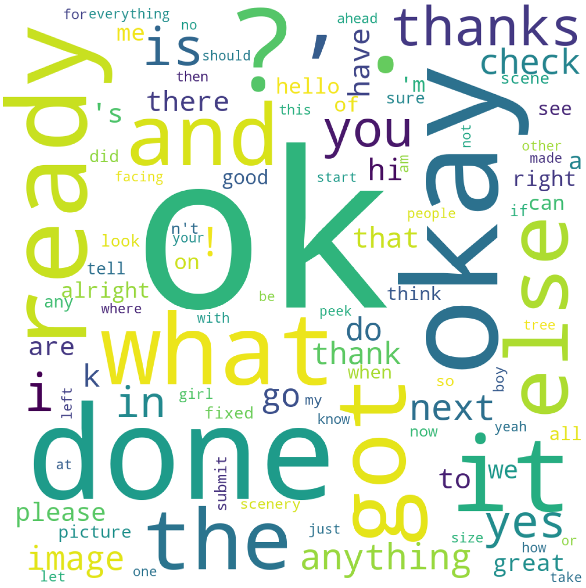
We now turn to examining how the occurrence of iCRs relate to the overall game dynamics.

To analyse CRs, three positions in a dialogue are particularly relevant: the source utterance in which the communication problem occurs, the CR utterance where repair is initiated, and the response utterance where the problem should ideally be dealt with. Since the dialogue is organized into a sequence of rounds with pairs of utterances (g_i, f_i), if an iCR occurs at round i, then f_i is an iCR, g_i is the likely source utterance, and g_{i+1} is possibly the response utterance. In Figure 1, turns 1, 5 and 11 are sources, 2, 6 and 12 are iCRs and 3, 7 and 13 are responses. However, these events do not necessarily occur in immediate sequence.

Here, we investigate how the game dynamics change at two positions: iCR rounds and rounds immediately following an iCR. We look at the mean number of actions per round and the difference in



(a) iCR utterances



(b) other utterances

Figure 4: Most common tokens weighted by frequency.

the score metric with respect to the previous state, as shown in Table 3. On average, more actions occur at iCR rounds than at non-CR rounds. The difference is even larger in post-iCR rounds, where necessary edits can be occurring. iCR rounds also cause an average higher improvement in the metric than other rounds and the same occurs for rounds after iCRs in dialogues containing iCRs.

To conclude this section, we refer back to our desiderata. The **naturalness** of iCRs is a consequence of the data being produced by synchronous human-human interaction in a setting that does not directly induce players to ask for clarification; indeed, almost 60% of the games do not contain iCRs, which we take to be evidence that they are a result of the private decision making of the *IF* and not due to them following instructions on which dialogue acts to produce. **Specificity** is guaranteed by the annotation process which had a definition to distinguish iCRs from other utterances. In terms of **frequency**, iCRs are a common phenomenon in CoDraw-iCR (v1), which contains 8,807 (11.36%) iCR utterances, a sample larger than existing annotated datasets. We have gathered evidence that **diversity** is present, given that iCRs occur in various forms and exhibit lexical and semantic variety on content related to the game. When it comes to **relevance** to the task, we have shown that there are statistically significant differences in number of actions and score differences at turns realising and following iCRs, which is a sign that agents need to process iCRs in order to act accordingly throughout the game. **Regularity** is addressed in the experiments in the next section.

	all	**w/ iCRs**
mean actions per round		
iCR rounds	1.72	1.72
not iCR rounds	1.64*	1.62*
post-iCR rounds	2.11	2.11
not post-iCR rounds	1.59*	1.50*
mean score diff		
iCR rounds	0.59	0.59
not iCR rounds	0.53*	0.43*
post-iCR rounds	0.53	0.53
not post-iCR rounds	0.54	0.44*

Table 3: Round dynamics. * means the difference in relation to the value at the row above is statistically significant at $\alpha = 0.01$ using a permutation test.

6 Models and Experiments

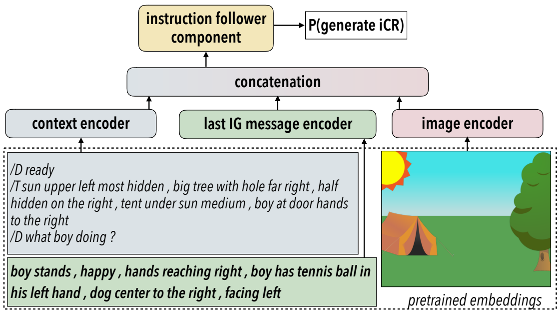
In this section, we present the models for the two tasks discussed in Section 3.2 as well as the evaluation metrics. Both are binary classification tasks using regression to predict the probability of the positive label (iCR) on imbalanced datasets, whose distribution is shown in Table 4.

	train	**val**	**test**
datapoints	62,067	7,714	7,721
% iCR	11.30	11.92	11.28
% not iCR	88.69	88.07	88.71

Table 4: Distribution of labels.

6.1 Models

We model the two prediction subtasks as a function $f : (s, c, u) \mapsto P(l = 1)$ where s is the representation of the scene, c is the representation of the dialogue context, u is the representation of the last utterance and l is the label. This function is approximated with a neural network that takes each input embedding, encodes them, and maps them to a concatenated representation which is fed into a two-layer classifier that outputs the probability of the positive label by applying the sigmoid function to the logit output, as illustrated in Figure 5.[6]



/D ready

6.2 Evaluation

Although the area under the ROC curve is a standard evaluation metric for binary classification, it can be deceptive in imbalanced datasets due to the interpretation of specificity, in which case Precision-Recall curves are more suitable (Saito and Rehmsmeier, 2015). The Average Precision (AP) summarizes this curve into one metric that ranges from 0 to 1, where 1 is the best performance, and the theoretical random is the fraction of positive labels. To facilitate comparison to existing literature, we also report macro-average F1 Score.

As trivial baselines, we perform logistic regression on basic features of the utterances and on the input representation vectors. For Task 1, the features are the length of the last teller's utterance and its boolean bag-of-words representation. For Task 2, we use the length of the last drawer's utterance and a binary variable indicating whether a content word occurs in it. The list of content words was extracted manually from a sample of dialogues.

6.3 Embeddings

The pretrained embeddings for texts are generated with SentenceTransformers (Reimers and Gurevych, 2019) and for images with ResNet101 (He et al., 2016). In order to probe whether the pretrained sentence encoders minimally capture the necessary information for our task, we use the dialogue context representation at the turn before the peek action to predict whether iCRs occurred in the dialogue so far. Using a logistic regression model on dialogues that contain a peek turn, we achieve AP= 0.91 and macro F1 Score= 0.86 in the validation set. This provides evidence that, despite they having been optimized for other tasks, the occurrence of iCRs is, to some extent, encoded in the representations.

7 Results

Table 5 presents the main results of our models on the two tasks. The feature-based baselines provide some gain over the random performance for Task 1, and a considerable improvement for Task 2. The logistic regression baseline is enough to produce good results for Task 2, whereas Task 1 remains very challenging even for the neural network model.

		Task 1: *IF*		**Task 2: *IG***	
		AP	mF1	AP	mF1
random	val	.117	.489	.117	.489
	test	.113	.503	.113	.503

---

[6] Details about the implementation, setup and experiments are in the Appendix and the code is available at https://github.com/briemadu/codraw-icr-v1/.

Ablation. We remove each component of the input to the neural network model in order to understand what information is more relevant for this task. Table 6 shows the differences with respect to the performance in the validation set.

The image representation does not seem to be fully exploited by the model. While in Task 2 the image is expected to be superfluous to detect the dialogue act, it should play a role for Task 1, as it imposes constraints on possible actions. It is possible that the off-the-shelf pretrained model is not adequate to encode cliparts and further investigation with other models and fine-tuning is required.

The last message is the most relevant signal for Task 2, as expected, given that it is the iCR being classified. Without it, the task is almost equivalent to Task 1 and the performance is indeed similar. Interestingly, the most relevant signal for Task 1 is the context and not the last utterance, which is evidence that the model fails to distinguish well which instructions require an iCR. To further investigate this, we remove the teller's utterances and the drawer's utterances from the context embeddings. While removing the teller's utterances causes little change, removing the drawer's utterances is almost as detrimental as removing the whole context. We thus conclude that the model is likely exploring patterns in the drawer's behavior to make decisions.

	Task 1: ***IF***		**Task 2:** ***IG***	
	AP	mF1	AP	mF1
no image	-.032	-.012	.001	.005

8 Discussion

Our findings are aligned with the recent conclusions by Aliannejadi et al. (2021) and Shi et al. (2022) that the task of predicting when a CR should be made is rather difficult with data-driven models. Techniques to deal with the class imbalance (downsampling, upsampling and varying the cost-sensitive loss function) and variations of the models (*e.g.* Transformer-based architectures) so far led us to similar results. On the other hand, the task of identifying iCR utterances is uncomplicated even for a simpler logistic regression model.

The results reached by our model in Task 1 do not quite allow us to see desideratum **regularity** as satisfied at this point, but we are confident that there is much room for interesting further research with this dataset. On their own, these tasks model an overhearer that predicts what the agent should do. What is of interest in reality is having them integrated as subcomponents, implicitly or explicitly, in the models that also make the instruction-giving/following decisions, because these capabilities are not detached in the agents *de facto*. We expect that the decision to ask for clarification should emerge more easily in representations of models that are also making actions.

The fact that the drawer's utterances seem to be informative in the dialogue representations for the task speaks against the "silent drawer assumption" int he original models (Kim et al., 2019). Removing the drawer's utterances from the dialogue likely cause loss of relevant dialogue phenomena that is pertinent to the game.

9 Conclusion

We have shown that CoDraw-iCR (v1), the CoDraw dataset augmented with our iCR annotation, is a valuable resource for investigating instruction-level CRs at scale. Through the corpus analysis, we have also concluded that iCR turns and post-iCR turns imply different game dynamics, which is relevant for models trained to play this game successfully. Therefore, in order to succeed in this type of task, agents need to know how to handle iCRs, as they influence not only the dialogue acts but also the game moves.

Our models perform well on detecting iCRs and lay the groundwork for further research on predicting when an iCR should be made. The research roadmap is to integrate iCRs into the full IF agent, so that the decision to ask for clarification is learnt together with the actions in the game.

The second annotation phase will provide fine-grained categories of iCRs' form and content and ground them to the game objects, opening the possibility to explore other tasks like generation.

10 Limitations

In this section, we discuss some limitations that we inherit from the CoDraw dataset, and then some limitations of our task setup and baseline model.

CoDraw is a simplified but representative instance of instruction giving/following dialogue games and we show that iCRs are frequent and play an important role in it. Since modelling CRs is still an open problem, using abstract scenes is a reasonable strategy to simplify the underlying task while still giving room for iCRs to occur. Limitations are inherent to data collections in controlled environments. We aim for our annotations to add to other recent efforts, which are limited in other ways. CoDraw-iCR (v1) thus aims to move one step forward towards modelling iCRs, but general conclusions depend on various resources and further collaborative efforts in our field.

Actions were not irreversible in CoDraw games. The introduction of the peek action for the teller can be an incentive both for the teller to not give exhaustive instructions and for the drawer to build only an approximation, knowing it could be refined after the peek. We have no access to what the performance would have been if they could not make CRs at all.

Meta-data about crowdworker ID is not available.[7] Because of that, we cannot investigate the effects of individual CR strategies by players. Players that play multiple games get to know what to expect of the game and should both have more practice in identifying underspecified instructions that require repair and be able to make better guesses about the cliparts. Experienced tellers probably anticipate common problems and adapt their instructions to avoid them (*e.g.* they know that multiple cliparts of trees exist and would likely describe it in their instruction, avoiding unnecessary communication problems). Besides, we cannot draw conclusions on whether dialogues without iCRs indeed did not require repair or some players were personally less inclined to make the effort to ask for clarification.

Although CRs annotation should take into account the full context (Benotti and Blackburn, 2021), the decision to annotate utterance types instead of full dialogues, as discussed in Section 4, is due to the limited resources given the size of the dataset and to the nature of the game setting. We avoided the need to go over multiple non-iCR utterances that occur very often. The plan for the second step of the annotation is to provide fine-grained annotation for each identified iCR within its own context.

Our models do not take into account the gallery of cliparts available to the drawer, which is informative (as it limits the choices of cliparts per game) and could be part of the input. Preliminary experiments did not lead to better results. Building a suitable representation of the gallery is left for future research.

Acknowledgements

We are thankful for the anonymous reviewers for their feedback. We thank our student assistants, Sebastiano Gigliobianco and Sophia Rauh, for performing the annotation and Philipp Sadler for generating the step-by-step scenes.

Annotation of Clarification Requests in the CoDraw Dataset

In the next tab you will find **a list of utterances (column B) made by the drawer** in the CoDraw dataset, together with some dialogue context. The preceding teller's utterance is in column A and the subsequent teller's utterance is in column C. Some utterances have no context either because the occur at the beginning/end of the dialogue of because the utterance occurs in different contexts. Your task is:

Step 1. Main annotation: Which utterances are clarification requests?

-> Please **track the time** it takes for you to complete this step. You can use the **third tab** for that.

- Read **each utterance** carefully and decide whether it is/contains a **clarification request**. For our purposes, an utterance is a clarification request if the affirmation in the green cell here is **most likely true**.
- **Type 1 in column D** if it is a clarification request, otherwise **type 0**.
- If it is **impossible to decide without more context**, please **make your best guess** in column D **and also type 1** in **column F**.

"This utterance indicates that the drawer is requesting further information about one or more instruction(s) previously given by the teller in order to perform an action accordingly, likely because part of the instruction was underspecified, ambiguous or not clear."

Please neither change the order of the rows nor edit columns ABC.

Figure 6: Instructions for the first annotator.

A Data Statement

Following Bender and Friedman (2018), in this section we provide information about the extended dataset. Figure 6 shows the instructions given to the first annotator.[8]

Curation Rationale. We annotate iCRs in all dialogues of the CoDraw dataset (Kim et al., 2019), which contains 9,993 dialogues produced by crowdworkers and has been released under a CC BY-NC 4.0 license. Please refer to the original paper for details about their data collection.

Language Variety and Speaker Demographic. The CoDraw dataset comprises written interaction in English, however no information about crowd worker demographic has been released in the dataset repository.

Annotator Demographic. The annotators who identified iCRs in CoDraw are a male and a female Computational Linguistics bachelor students who are non-native fluent English speakers working at colabPotsdam as student assistants. The students were paid according to the German's regulation for student assistants.

Situation. In CoDraw, crowdworkers exchanged written messages of up to 140 characters via a chat interface in a crowdsourcing tool. *IF* and *IG* had to send messages in alternating turns. The interaction was synchronous and task-oriented.

Text Characteristics. The CoDraw authors pre-process all collected utterances using a spell checker and tokenize the text with a natural language toolkit.

B Additional Corpus Analysis

We provide here further descriptive characteristics of the annotated dataset.

Table 7 shows a few negative examples, *i.e.* utterances that are not iCRs. Although utterances like *what do you see in the sky ?* and *anything else to change ?* can indeed be considered task-level CRs, we do not consider them iCRs because they do not directly refer back to a given instruction.

yeah it was a lot but thanks for finishing
i am a patient worker ready to start
check please and tell me what to change
anything else to change ?
what else is in the picture and where ?
i 've made all the changes you 've listed .
ok and look
alright , made changes
please be more specific thanks
ok anything else in the picture ?
yes , please lmk of any corrections
ok i got that :
ready whenever you are . :
what what is the first object and location ?
alright done
what do you see in the sky ?
tell me what we have

Table 7: Negative examples in CoDraw.

Figure 7 depicts in which rounds iCRs occur in the corpus. Given that the average dialogue length is 7.7 rounds, most instruction CRs in this dataset are occurring early in their corresponding dialogue. The distribution of the number of iCRs per dialogue is illustrated in Figure 8, where we see that it is very rare to have dialogues with more than 5 iCRs.

---

[8] The second annotator got more detailed instructions to perform the fine-grained annotation, which is not part of this publication. For the analysis and experiments in this work, we use the labels by the second annotator, who went through a more extensive background reading about CRs. There are few disagreements, as shown in the main text.

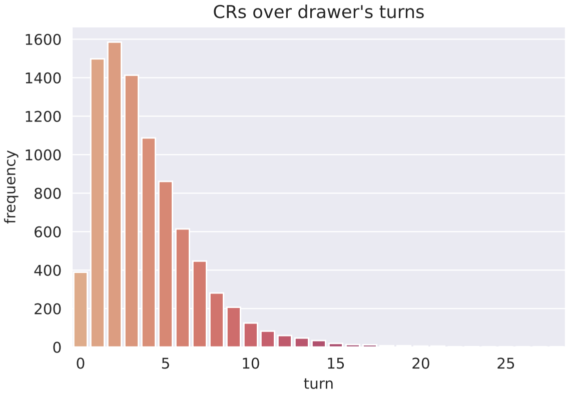

Figure 7: In which round iCRs occur.

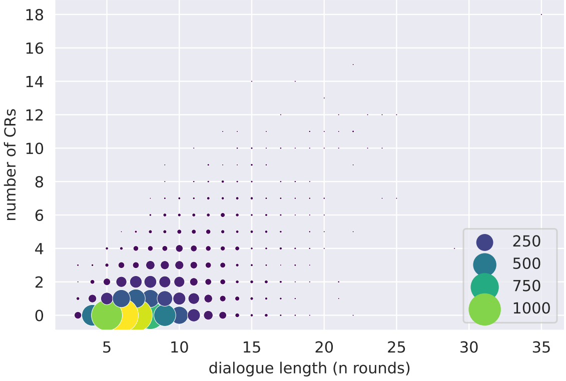

Figure 9: Number of iCRs vs. number of rounds.

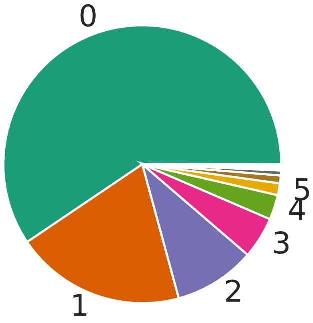

Figure 8: Number of iCRs per dialogue.

Figure 9 breaks down the number of iCRs per number of dialogue rounds. Dialogues with more than 10 iCRs are outliers, which is expected given that most dialogues have no more then 15 rounds.

14.58% of validation and 11.96% of test iCR utterance types also occur in the training set. 17.50% of validation and 14.81% of test iCR utterances also occur in the training set. The overlap is low, which is a desirable characteristic to reduce the memorization shortcuts for models trained on this dataset.

Computing actions and score differences. We group the drawing actions into three main categories: *addition* (when a clipart is added to the scene), *edit* (when some change occurs with an object that existed in the previous round), and *no action* if the drawer did not perform an action in a round. Edits can be deletion, move (position change), flip and resize. We do not track whether newly added cliparts get immediately flipped or resized in relation to the gallery when they are added. We noticed that some actions that visually seem to be only flips or resize happen together with a move. However, our inspection shows that this does not occur consistently with a specific subset of cliparts and there is also a portion of cases where flips and resizes occur without moves. Therefore, each move, resize, flip are counted as one separate action in our analysis. We compute the moves based on the differences over consecutive rounds in sequence of scene strings labeled *abs_d* provided in the original dataset, assuming that they describe the state of the canvas at the moment when the drawer sends their message, *i.e.* at the end of the current round.

Scene similarity is computed with the scripts made available by the CoDraw authors on GitHub.

C Reproducibility

In this section we describe the details of the implementation and datasets for reproducibility purposes. Further information and documentation is available in the code repository.

The random and trivial baselines are trained with scikit-learn (v1.1.2) with class weight set to balanced. A maximum of 1,000 iterations was still not sufficient for convergence is all cases. The hypothesis tests are carried out with SciPy (v1.10.0), using the permutation test for the difference of means, with type set to independent.

Models. Our models are implemented with PyTorch (v1.11.0) and PyTorch Lightning (v1.6.4). Metrics are computed using TorchMetrics (v0.10.0). The experiments were run in Linux 5.4.0-99-generic, machine/processor x86_64 in Python 3.9.12 on an NVIDIA GeForce GTX 1080 Ti GPUs with CUDA v11.6. The architecture of the full neural network model with its corresponding layers and dimensions were:

```
(model): Classifier(
  (img_encoder): ImageEncoder(
    (encoder): Linear(in_features=2048,
                      out_features=128,
                      bias=True)
  )
  (msg_encoder): TextEncoder(
    (encoder): Linear(in_features=768,
                      out_features=128,
                      bias=True)
  )
  (context_encoder): TextEncoder(
    (encoder): Linear(in_features=768,
                      out_features=128,
                      bias=True)
  )
  (classifier): DeeperClassifier(
    (classifier): Sequential(
      (0): LeakyReLU(negative_slope=0.01)
      (1): Dropout(p=0.1, inplace=False)
      (2): Linear(in_features=384,
                  out_features=256,
                  bias=True)
      (3): BatchNorm1d(256,
                       eps=1e-05,
                       momentum=0.1,
                       affine=True,
                      track_running_stats=True)
      (4): LeakyReLU(negative_slope=0.01)
      (5): Linear(in_features=256,
                  out_features=1,
                  bias=True)
    )
  )
)
```

The complete model has 558,465 trainable parameters. For the ablation experiments, the number of dimensions was reduced according to the input, and the number of parameters were 263,425 (no image), 427,265 (no context) and 427,265 (no utterance).

Training is carried out with the Adam optimizer (Kingma and Ba, 2015) to minimize weighted binary cross entropy (the weight is the hyperparameter weight cr) estimated with a sigmoid function applied to the output logits. We use the Bayes algorithm from comet.ml to perform hyperparameter search seeking to maximize Average Precision (and also AUC of the Precision-Recall curve in some preliminary experiments) on the validation set for Task 1. For the final version, we run 111 experiments during hyperparameter search. The optimal hyperparameters used in the experiments are shown in Table 8 together with their corresponding bounds. We use the second best performing configuration, because it is only around 6e-7 below the best one, but has more stable learning curves. All other experiments (ablation and Task 2) use the same configuration, except that the dimensions change according to the input vectors for ablation. We report the results of one run using the best configuration.

We use a decision threshold of 0.5 for the evaluation metrics that require a fixed threshold.

We train the models for up to 20 epochs, which takes around 3-4 minutes, including inference, which requires around 4 seconds. Although it takes more than 20 epochs to achieve a higher performance on the training set, the maximum for the validation set is reached in early epochs. We then use the model checkpoint with the highest Average Precision on the validation set to run evaluation on the test set.

We use the `all-mpnet-base-v2` model from SentenceTransformers to encode the texts into a representation with 768 dimensions. The image representation has 2048 dimensions. Images are preprocessed according to PyTorch Vision documentation (without resizing and centering) and features are extracted following recommendation on their forum. We use the pretrained model `resnet101` available from torchvision (v0.12.0).

Datasets. We use the same train/val/test splits as the original CoDraw dataset. The sizes and the distribution of labels in the annotated dataset is in Table 4. For retrieving the context embeddings, we add a /T token before the teller's utterance and a /D token before the drawer's utterances. We also add a /PEEK token before the utterances of the round when a peek action occurs. The context is limited to the last 200 tokens. Utterances are tokenized with blank spaces on the preprocessed published dataset.

D Detailed Results

We present more details about the performance on the validation set.

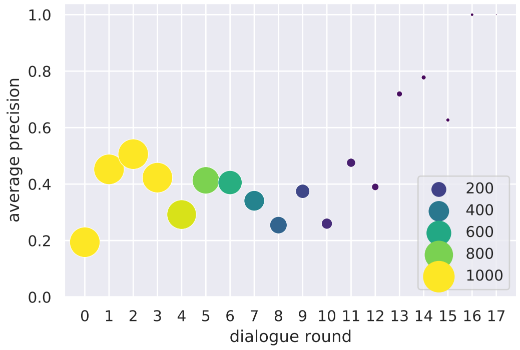

Figure 10: Average precision per round (validation set).

hyperparameter	**type**	**search bounds**	**optimal value**
accumulate gradient	discrete	1, 2, 5, 10, 25	25
batch size	discrete	32, 64, 128, 256, 512, 1024	128
clipping	discrete	0, 0.25, 0.5, 1, 2.5, 5, 10	1
dropout	discrete	0.1, 0.2, 0.3, 0.5	0.1
gamma	discrete	0.1, 0.5, 0.9, 0.99, 1	0.99
hidden dimension	discrete	32, 64, 128, 256, 512, 1024	256
internal embeddings dim	discrete	32, 64, 128, 256, 512, 1024	128
learning rate	discrete	0.1, 0.01, 0.001, 0.0001, 0.003, 0.0003, 0.00001, 0.0005	0.003
lr scheduler	categorical	none, exp, step	exp
lr step	integer	min=1, max=5	2
random seed	integer	min=1, max=54321	35466
weight cr	float	min=1, max=10	2.6125454767515217
weight decay	discrete	1, 0.1, 0.01, 0.001, 0.0001	0.0001

Abstract

In sensitive domains, the sharing of corpora is restricted due to confidentiality, copyrights, or trade secrets. Automatic text generation can help alleviate these issues by producing synthetic texts that mimic the linguistic properties of real documents while preserving confidentiality. In this study, we assess the usability of synthetic corpus as a substitute training corpus for clinical information extraction. Our goal is to automatically produce a clinical case corpus annotated with clinical entities and to evaluate it for a named entity recognition (NER) task. We use two auto-regressive neural models partially or fully trained on generic French texts and fine-tuned on clinical cases to produce a corpus of synthetic clinical cases. We study variants of the generation process: (i) fine-tuning on annotated vs. plain text (in that case, annotations are obtained a posteriori) and (ii) selection of generated texts based on models' parameters and filtering criteria. We then train NER models with the resulting synthetic text and evaluate them on a gold standard clinical corpus. Our experiments suggest that synthetic text is useful for clinical NER.

1 Introduction

The lack of specific resources might be the most common hurdle encountered when working in Natural Language Processing (NLP), whether it be the lack of task-specific resources, domain-specific resources, or both. A major challenge for biomedical NLP in languages other than English is the lack of available clinical corpora that can be shared with the community (Névéol et al., 2018).

One way of addressing this problem is to generate new data automatically. The performance of recent language models based on the transformer architecture (Vaswani et al., 2017) on various tasks that involve generating text (translation, summarization, etc.) makes it possible to use the transformer's power to generate text to address resource sparsity.

More specifically for generation, large generative language models such as GPT-2 (Radford et al., 2019) and GPT-3 (Brown et al., 2020) have the ability to generate well-written text containing a wealth of information. The knowledge gained during the pre-training of those large language models could be helpful in more specialized domains where there is not enough data to train a generative model from scratch.

Dealing with medical data brings one particular issue. The generated data should not contain sensitive information from the data it is inspired by while remaining as close as possible to it. This means that the evaluation of this task is different from the usual evaluation of text generation.

The evaluation of text generation is a difficult problem (Howcroft et al., 2020; Novikova et al., 2017). There is a distinction between intrinsic and extrinsic evaluation (Gehrmann et al., 2022). For intrinsic evaluation in generation tasks such as translation and summarization, the quality is usually first automatically measured using metrics such as BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), or BERTScore (Zhang et al., 2020). Those metrics and many others compare the system's output to one or several human-written references (Frisoni et al., 2022). However, a gold reference does not exist for an open-generation task.

Human evaluation is usually the best way of intrinsically evaluating text generation. Still, there can be several problems. First, human evaluation should be conducted once the system's output can be considered "good enough" to avoid wasting human evaluation costs. This means there is a need to measure if the system is ready to be manually evaluated. Second, it might not be possible for a human to assess the quality of generated data at a larger scale, if the generated data is not considered as a set of independent sentences but as a whole self-sufficient corpus.

This is why extrinsic evaluation of the generated

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2320–2338
May 2-6, 2023 ©2023 Association for Computational Linguistics

data is also important, meaning evaluating the usefulness of the generated data (Stadler et al., 2022). However, to our knowledge, methodologies to extrinsically evaluate open text generation are rare.

In this work, we explore text generation using a pre-trained language model and we focus our evaluation on named entity recognition (NER).

This paper offers the following contributions:

- we generate two sets of clinical cases in French with two variants;
- we introduce an evaluation protocol of the generated texts using ngram overlap and NER models;
- we compare the generated texts with real clinical case corpora.

2 Related Work

Generating data to address resource sparsity is an active field of research. Pre-trained transformer-based models have been used as data augmentation tools, such as in Claveau et al. (2022), where the authors fine-tuned the pre-trained auto-regressive English language model GPT-2 to create labeled examples for training classification models in French and English. In the medical domain, Amin-Nejad et al. (2020) use an encoder-decoder transformer architecture to generate discharge summaries given a context. The context gives a target to the generation that is used to evaluate the generated texts. Melamud and Shivade (2019) train an LSTM-based language model to generate shareable clinical notes using differential privacy (Dwork et al., 2006). Word embeddings are trained on the generated data and compared to word embeddings trained on the original data on two existing benchmarks. Ive et al. (2020) used an entity extraction method to build a generative model with entities as input and the document as output and generated artificial mental health records in English.

Several efforts exploit Generative Adversarial Networks (GANs) (Goodfellow et al., 2014) to seamlessly augment original data. Among them, Abedi et al. (2022) use GANs to generate artificial structured data in the medical domain. Choi et al. (2017) created medGAN, a framework to generate artificial structured electronic health records (EHR) with discrete values. Torfi et al. (2022) rely on a combination of autoencoders (Kingma and Welling, 2014) and GANs to generate artificial structured data with both discrete and continuous values.

3 Method

3.1 Experiment description

The experiment presented in this paper is designed to evaluate open text generation in the clinical domain. The goal is to create an artificial corpus presenting the same *characteristics* as a real clinical corpus. One challenge of this task is that defining and recognizing the *characteristics* of a clinical corpus is an open question.

We envisaged the *characteristics* of clinical corpus along three perspectives:

1. a distributional perspective: we want to create an artificial clinical corpus with a token distribution similar to that of a real corpus. This aspect will be measured using self-BLEU (Zhu et al., 2018) and perplexity;
2. a qualitative perspective: we want to create an artificial corpus that mimics a real clinical corpus in terms of semantic and linguistic content. This aspect will be measured by manual analysis of samples of generated texts;
3. an application perspective: we want to create an artificial clinical corpus that can be used to train NER models to be applied to a real clinical corpus for clinical information extraction. This aspect will be measured through the extrinsic evaluation of Section 4.2.

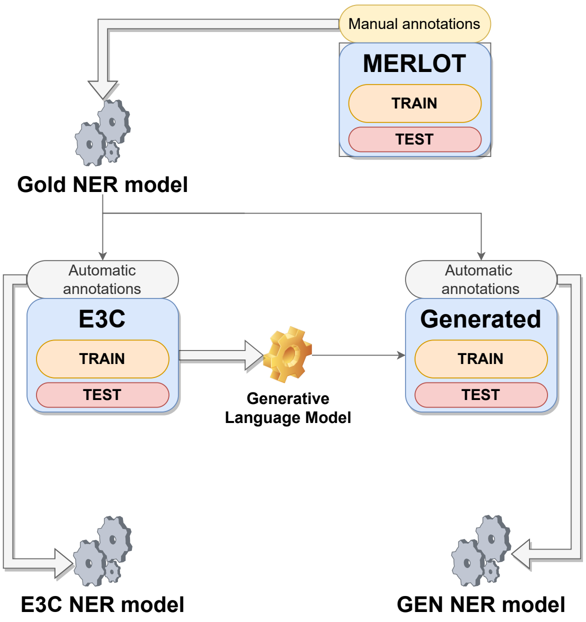

Figure 1: Description of the experiment conducted to evaluate NER on artificial data.

Figure 1 presents the global setup for evaluating generated data for NER. The specific corpora

(MERLOT and E3C) named in the figure will be described in Section 3.2.

Briefly, we leverage a corpus of clinical documents in French containing high-quality entity annotations (MERLOT). This corpus represents the target real data we aim to analyze. It is used in part to train clinical NER models and in part for evaluating clinical NER models. We then use a clinical case corpus (E3C) for fine-tuning generation models, with the option of generating tagged text or plain text that can then be tagged with the Gold NER model.

In the end, each of the newly annotated corpora is split into training and testing sets and is used to train new NER models. These final models are then tested on the test sets of each corpus.

3.2 Corpora

This section presents the corpora used in our experiments. Table 1 presents descriptive statistics.

	E3C$_{FR}$	CAS	MERLOT
Toks	328,645	231,662	148,476
Docs	1,009	717	500
Toks/doc	325.7	323.1	297.0
Sents/doc	15.2	15.8	14.4
Avg sentence length	21.4	20.4	20.6
Self-BLEU	0.68	0.66	0.69

Table 1: Statistics of the real medical corpora.

MERLOT (Campillos et al., 2018) is a corpus of 500 clinical documents in French from the hepato-gastro-enterology and nutrition specialties. It comprises 148,476 tokens with annotations for entities, attributes and relations. This text genre represents the type of clinical narratives contained in electronic health records that we would like to analyze.

CAS (Grabar et al., 2018) is a French medical corpus containing 717 clinical case descriptions published in the literature. Clinical cases contain descriptions of the medical history of patients, treatment received at the hospital, and follow-up care. CAS covers several medical specialties. The corpus has been de-identified and the publication of case descriptions is done with patient consent. The corpus can be obtained from the DEFT 2020 shared task organizers[1].

E3C (Magnini et al., 2020) is a freely available multilingual corpus[2]. It contains biomedical documents extracted from different sources, including journals, abstracts, existing biomedical corpora, patient information leaflets for medicines, and others.

In this work, we focused on the French part of the corpus, selecting only the clinical cases published in the literature, which are the most similar documents to the clinical narratives we are interested in. Clinical cases from E3C cover a variety of medical specialties and are distinct from those in CAS. This part of the corpus contains about 1,000 documents and more than 300,000 tokens.

3.3 Entity annotation for E3C

Entity annotations for E3C are needed for two reasons. First, we integrate the annotations in the form of XML tags into the E3C texts. Fine-tuning the model on this version of the corpus will enable the model to learn to generate tags directly during the generation process. Second, the annotations will be used to train and test NER models. We use the manual annotations of entities made on the MERLOT corpus to train NER models (Bannour et al., 2022) to annotate the E3C corpus. Using an automatic rather than a manual annotation for training our final NER models can lead to error propagation. We use an ensemble strategy to mitigate this issue: five different models are trained and applied to the corpus with a majority vote for the annotation (annotation is kept if more than three models agree on the annotation), which is classically known as a good way to reduce errors. The train and validation sets are shuffled for the training of each NER model and a different seed is used.

3.4 Generation

Pre-trained models such as GPT-2 have been proven to allow for generating complementary textual data in a data augmentation context. In this work, we explore the ability of auto regressive neural models (viz. GPT2 and BLOOM) trained partially or exclusively on French to adapt to the medical domain and generate relevant clinical case descriptions.

We use two existing GPT models. The first model is a one-billion-parameter model pre-trained on generic French texts by Simoulin and Crabbé (2021). The corpus used to pre-train the model was extracted from Wikipedia, Project Gutenberg[3],

[2] `https://github.com/hltfbk/E3C-Corpus`

[3] `www.gutenberg.org`

OpenSubtitle (Lison and Tiedemann, 2016), and CommonCrawl. In this paper, this model will be referred to as LLF.

The second model is a smaller version of the BigScience BLOOM model[4]. BLOOM was trained on 46 different languages, including French[5]. We chose the one-billion-parameter version for a fair comparison between the two models. Both models are available on the HuggingFace platform[6][7].

3.4.1 Fine-tuning the models

We used the freely available `E3C` corpus for fine-tuning our model on medical texts so that the generation process can be replicated[8]. We added special tokens for marking the beginning and end of each document to make the model generate whole documents. Two versions of the corpus were used: one with the annotations described in 3.3 so that the models directly learn to generate annotations, and one without annotations. The corpus was split into training and validation sets, with 90% of the corpus for training and 10% for validation. The model was trained with a maximum of 10 epochs, but training stopped early if the perplexity on the validation set did not decrease significantly during two consecutive epochs. We selected a learning rate of 2e-5, negative likelihood loss with the AdamW optimizer from the torch package[9]. In the end, we have four models, two for each pre-trained model with one version producing plain untagged text and one including annotations to produce tagged text.

3.4.2 Generation process

Clinical documents were generated using the token marking the beginning of a document as input. No additional prompts were supplied to the models. We thought that giving information such as the beginning of a document as a prompt might cause the model to reproduce text seen during fine-tuning.

Many parameters can be used during inference to influence the generative models' output. We decided to focus on three parameters: nucleus sampling (top-p) value, temperature value, and repetition penalty. The rest of the parameters were left with default values. At each step (token) of the generation process, the models output a probability distribution for vocabulary items. For generating diverse outputs, sampling consists in randomly picking the next token to generate, as opposed to greedy decoding, where the most probable token is selected. Nucleus sampling, or top-p sampling, restricts the sampling to the tokens whose summed probabilities exceed a threshold p. It allows for more diversity while remaining consistent. Temperature is a way of decreasing or increasing the disparities in the probabilities of the vocabulary at a generation step. A temperature higher than 1 will bring the probabilities closer and make the model less confident, and bring more diversity in outputs. A temperature lower than 1 will do the opposite. Finally, a repetition penalty will encourage the model to avoid falling into loops. We generated several samples of approximately 10% of the target-generated text to assess the impact of those three parameters on the self-BLEU score of the generated sample and an oracle perplexity with the seven billion parameters version of the BLOOM model. More details can be found in appendix A.2. We noticed expected behaviors: increasing temperature and repetition penalty increases diversity (lower self-BLEU) but also increases perplexity. However, we found that top-p sampling has a low impact on the two metrics. Perhaps because by default, the model also adds top k sampling (selecting amongst the k most probable tokens at each generation step) that lowers the impact of top-p. In the end, since we wanted a high diversity output to match `E3C`'s diversity, we selected high values for temperature (1.2 for models without tags and 1.5 for models with tags). We also kept a very high repetition penalty (10) because we noticed that a lot of generations ended with the model generating the same tokens over and over even with a high value. Finally, we selected a default value of 0.95 for top-p sampling.

We aimed for the models to generate complete documents with length variations similar to `E3C`. We computed the average length of `E3C` documents (for both annotated and non-annotated versions) and combined it with standard deviation, exploiting the ability of the models to close a document with an ending token and start a new one in the same generation process.

3.5 Filtering generated texts

We ensured that the generated corpora had certain characteristics for a fair comparison to the reference corpus `E3C`.

Large auto-regressive language models can generate good-quality texts. However, the generation can present some flaws such as repetitions and incoherence, especially as the generation length gets longer (Pillutla et al., 2021). We established a few criteria that we could handle automatically by observing a few generated samples:

- overly long tokens: the models sometimes generate an incoherent sequence of characters or combine many technical words (e.g., "*céphalo-rachidiencéphalico-mandibulaire*");
- repetition of one to many tokens over and over, especially towards the end of a document;
- the models start a sequence of short tokens often with numbers (e.g., "*classée T4N2 M0 I 2 B 3 C 4 D 5*") or start reciting the alphabet (e.g., "*hépatite A B C D E F*").

We addressed these three cases by excluding documents based on token length, trigram frequency, and regular expressions.

The thresholds used for the three parameters were adjusted by analyzing the excluded documents with different threshold values. In the end, we excluded documents with tokens of thirty characters or more, documents with trigrams appearing more than three times, and repetition of at least three short tokens combined with numbers, or single letters.

We also wanted our generated corpora to have a diversity close to that of `E3C` as computed with the self-BLEU score (0.68 for `E3C`). We generated a significantly bigger amount of text than the targeted 330,000 tokens and selected a subset of diverse documents using the tool developed by Cohen et al. (2013). Then, we computed the self-BLEU score for the selected documents, including the BLEU score of each document. We removed the ten documents with the highest BLEU, that is the documents bringing the least diversity, and repeated the process until obtaining a self-BLEU score and a number of tokens close to the `E3C` corpus.

The characteristics of the generated corpora are shown in Table 2. As we explained, each corpus generated corresponds to a filtered subset of the total amount of text generated. We noticed that text generated with the two configurations using the LLF model needed less filtering compared to their BLOOM counterpart. Configurations with texts generated with tags also needed more filtering. Globally, using both filters, we discarded 0.45% of generated text for $\texttt{Bloom}_{E3C}$, 0.54% for $\texttt{Bloom}_{E3C+T}$, 0.30% for $\texttt{LLF}_{E3C}$, and 0.45% for $\texttt{LLF}_{E3C+T}$. Compared to Table 1, we can see that only $\texttt{Bloom}_{E3C+T}$ presents much shorter documents. However, the sentences of the generated corpora are a lot longer than in `E3C`, especially with $\texttt{Bloom}_{E3C}$ that do not even have two sentences per document. Finally, corpora generated with BLOOM are a little less diverse.

	$\texttt{Bloom}_{E3C}$	$\texttt{Bloom}_{E3C+T}$	$\texttt{LLF}_{E3C}$	$\texttt{LLF}_{E3C+T}$

Perplexity	9.97	9.27	10.03	11.9

Table 2: Statistics of the generated corpora. Oracle perplexity was computed using an oracle pre-trained model of BLOOM with 7 billion parameters. E3C's perplexity using this model was 22.0 (Len Sent=average sentence length).

3.6 Automatic intrinsic evaluation

As a complement to BLEU scores, we measured the overlap between the generated corpus and the original corpus to characterize potential memorization of the original documents processed during fine-tuning.

To this end, we developed a python tool based on overlapping ngrams to compare the generated texts and the original text and to detect the rare ngrams in the original corpus that appear on the generated corpus. For a fair evaluation, we also show results of the same comparison between the corpus used for fine-tuning (`E3C`) and another, non-overlapping, clinical case corpus in French (`CAS`).

4 Results

Table 2 shows global synthetic corpus statistics and Table 3 presents sample texts generated with each model configuration.

Table 4 shows the number of entity annotations for `E3C`, `MERLOT`, and the generated corpora. We can notice that the corpora generated without tags ($\texttt{Bloom}_{E3C}$, $\texttt{LLF}_{E3C}$) contain almost the same number of annotations as the `E3C` corpus (around 9,000

For text generated without entity tags, entity annotations are created post-generation; complete documents are shown in appendix A.4.

annotations each). However, the corpora generated with tags contain a smaller number of annotations with 5,630 annotations for $\texttt{Bloom}_{E3C+T}$ (two-thirds of `E3C`) and 3,893 annotations for $\texttt{LLF}_{E3C+T}$ (around 40% of `E3C`). This suggests that directly generating annotations might not be the optimal way of generating text for a NER task.

4.1 Ngram overlap

To compare the overlap of ngrams between `E3C` and the corpora generated by a model fine-tuned with `E3C`, we compute an overlapping score between the corpora. The overlapping score between two corpora is computed as follows:

$$\frac{\text{Number of unique common ngrams}}{\text{Total number of unique ngrams}} \tag{1}$$

The overlapping score varies between 0 and 1. A high overlapping score means that the two corpora have many tokens in common whereas a low score indicates few common tokens.

Table 5 presents the overlap between `E3C` and the generated corpora. We also added the comparison between `E3C` and `CAS`, another clinical case corpus (see appendix A.1 for the full ngram range). It is interesting to see that the `CAS` corpus has a higher overlapping score with `E3C` than the generated corpora. Amongst the generated corpora, $\texttt{Bloom}_{E3C}$ has the highest overlapping score with `E3C` for unigrams, $\texttt{Bloom}_{E3C+T}$ comes second, and $\texttt{LLF}_{E3C}$ and $\texttt{LLF}_{E3C+T}$ have the lowest scores. However, $\texttt{Bloom}_{E3C}$ has the lowest overlapping score for 8grams than the rest, even less than `CAS`. $\texttt{LLF}_{E3C+T}$ still has a small percentage of tokens in common with E3C, but $\texttt{Bloom}_{E3C+T}$ and $\texttt{LLF}_{E3C}$ have now a higher percentage than the rest. This means that even though they do not have that many unigrams in common with `E3C`, they tend to replicate longer sequences, which indicates more memorization and thus more risks regarding confidentiality. It is surprising to see that there is no regularity between the models and their fine-tuning configurations, and we are not sure how to explain this. In the end, this

table might be in favor of `Bloom`$_{E3C}$, because it appears to be the closest corpus to `E3C` in terms of unigram, while not memorizing too much. However, this is yet to be confirmed.

4.2 Extrinsic evaluation

Tables 6 to 8 present the results of our extrinsic evaluation of the generated corpora through the NER task described in Section 3. More precisely, the three tables report the results of the same set of models on three different types of corpora. All the results were obtained by averaging the scores of five models trained with different seeds and with shuffled documents in the train and validation sets of the corpus.

The first thing to note is that the best performance for the test part of a given corpus is obtained by a model trained on the training part of this corpus. While this is not a surprise from a general viewpoint, it means in our context that the difference in quality between a generated corpus and a natural corpus is not high enough for balancing the advantage brought by the homogeneity between the training and the test corpora. The quality of the generated corpora for our NER task is confirmed by Table 6, which gives the results on the natural corpora and more specifically, on the `MERLOT` corpus. Since it was annotated manually, unlike the other corpora, we consider `MERLOT` as a high-quality reference. While the model trained on `E3C` is significantly outperformed by the model trained on `MERLOT`, we can observe that the models trained on `Bloom`$_{E3C}$ and `LLF`$_{E3C}$ are close to it, with a small advantage for `LLF`$_{E3C}$. Hence, in our context, using a corpus generated from a natural corpus is fairly equivalent to using the natural corpus.

Surprisingly, the performance of all the models on `E3C` strongly decreases compared to their performance on `MERLOT` while all of them, except one, are trained either from `E3C` directly or from a corpus generated from `E3C`. More precisely, it seems that for a NER model, the source of the annotations, `MERLOT` in our case since they are produced by a model trained on this corpus, is more important than the corpus on which the model was trained. Finally, Table 6 shows, through `Bloom`$_{E3C+T}$ and `LLF`$_{E3C+T}$, that generating annotated texts is the worst strategy for both `E3C` and `MERLOT`. This strategy particularly hurts recall, a result which can be certainly explained by the fact that the number of generated annotations (see Table 4) is low compared to the number of annotations produced by the NER model trained on `MERLOT`.

Table 7 reports the results of our models on the generated corpora `Bloom`$_{E3C}$ and `LLF`$_{E3C}$. The first observation is that, with the exception of `Bloom`$_{E3C+T}$ and `LLF`$_{E3C+T}$, the performance of the models is close to the performance obtained on `E3C`, which is not a surprise since the `Bloom`$_{E3C}$ and `LLF`$_{E3C}$ corpora were generated from EC3. However, it confirms that a generated corpus can be used as an interesting substitute for its source corpus. It is true for training a NER model but also for its evaluation. Table 7 also shows that our models obtain better results on `LLF`$_{E3C}$ than on `Bloom`$_{E3C}$, which is not observed with such a magnitude in Table 6 when the corpora are used for training our models: there is no difference between `Bloom`$_{E3C}$ and `LLF`$_{E3C}$ for the evaluation on `E3C` and only a small difference in favor of `LLF`$_{E3C}$ for the evaluation on `MERLOT`. We have observed that the punctuation in the long texts generated by BLOOM tends to be very sparse, which could explain to some extent the difference between the evaluations on `Bloom`$_{E3C}$ and `LLF`$_{E3C}$. Finally, the most noticeable observation is the poor performance of the models trained on `Bloom`$_{E3C+T}$ and `LLF`$_{E3C+T}$, especially recall. In that case, the explanation is once again related to the scarcity of the generated annotations used for training the models. However, the difference with the evaluation on the `E3C` corpus is more difficult to interpret.

The last table of results for the extrinsic evaluation, Table 8, mainly confirms our findings concerning the characteristics of the `Bloom`$_{E3C+T}$ and `LLF`$_{E3C+T}$ corpora. All the models trained on corpora annotated by the NER model trained on `MERLOT` obtain very good recall values since these corpora contain a much larger number of annotations than the `Bloom`$_{E3C+T}$ and `LLF`$_{E3C+T}$ corpora. Moreover, the very good results of the models trained on `Bloom`$_{E3C+T}$ and `LLF`$_{E3C+T}$ tend to show that their generated annotations are fairly easy to learn. Finally, unlike what we have observed in Table 7, the results on the corpus generated by BLOOM, `Bloom`$_{E3C+T}$, are higher than the results on the corpus generated by LLF, `LLF`$_{E3C+T}$. However, further investigations should be done to determine if BLOOM generates better annotations than LLF or if the generation of annotations tends to improve the quality of the text generated by BLOOM.

4.3 Qualitative evaluation

Samples of 15 automatically generated texts per model (for a total of 13,809 tokens for the 60 documents) were annotated using BRAT[10] (Stenetorp et al., 2012) and aimed to assess specific characteristics of the texts including (1) grammaticality; and (2) clinical coherence at the sentence and document level (e.g. in Table 3 one document reports Agpar score, a test performed on newborn infants, for a 50-year-old patient). See appendix A.5 for details.

The manual analysis suggests that clinically incoherent passages are more likely to be found towards the end of the texts, and within text generated without tags. In particular, texts generated with BLOOM tend to exhibit run-on sentences that become increasingly incoherent. However, there are generally more clinical inconsistencies and grammatical errors in the texts generated with the LLF vs. BLOOM models. We also note that the LLF models generate more than one case description inside a single document.

Overall, manual analysis suggests that texts generated with the `Bloom`$_{E3C+T}$ model are the closest

to original clinical case descriptions.

5 Conclusion

We presented four models for generating synthetic clinical cases in French. Our experiments suggest that synthetic text is useful for training NER models in the clinical domain. While text generated with `Bloom`$_{E3C+T}$ seems more natural, text generated with `LLF`$_{E3C}$ and `Bloom`$_{E3C}$ yields promising NER performance.

6 Ethical Considerations

We were able to identify two types of potential ethical issues with our research: i) the carbon footprint generated by the training of the models and ii) the patients' data protection. We detail here how we addressed or measured them.

For our experiments, we had to train a number of models, thus generating a carbon footprint, which we measured using Carbontracker (Anthony et al., 2020), although we acknowledge that this tool can only account for one in four sources of experiment carbon impact (Bannour et al., 2021). The total CO2 emission of our experiments is 11,313g. Carbontracker also measured the energy cost, estimated at 39.2kWh. This includes the fine-tuning of pre-trained language models, the preliminary experiments on evaluation, the generation of artificial corpora, and the training of NER models.

The corpora we used for the experiments are compliant with data privacy regulations: either they do not contain personal information at all (`E3C` and `CAS`) or they were de-identified according to a protocol approved by the CNIL (Commission de l'Informatique et des Libertés), an independent French administrative regulatory body whose mission is to ensure that data privacy law is applied to the collection, storage, and use of personal data (`MERLOT`).

Within the framework of our project, we intend to investigate whether our model contains sensitive data. However, this task needs to be completed by a similar investigation to be led on the language models themselves, as they may contain such data (for example, from blog posts that might have been collected by CommonCrawl).

7 Limitations

One limitation of our study is the scope of the manual evaluation and the fact that it did not involve a clinician. Also, while we tried to explore several parameters and model configurations for text generation, additional exploration could be done, including using larger BLOOM models. Furthermore, these experiments with the generation of clinical cases did not include any constraints regarding the specific content of the documents generated. In future work, we would like to include more control over content to improve clinical coherence and check for privacy leaks of information contained in the training or fine-tuning corpora, to accommodate the use of confidential clinical documents.

Acknowledgements

This work has received funding from the French "Agence Nationale pour la Recherche" under grant agreement CODEINE ANR-20-CE23-0026-01. We thank Ziqian Peng for her contribution to the development of the overlap assessment tool. We thank the institutions and colleagues who made it possible to use the datasets described in this study: the Biomedical Informatics Department at the Rouen University Hospital provided access to the MerLoT corpus and Dr. Grabar (Université de Lille, CNRS, STL) granted permission to use the CAS corpus. This work was granted access to the HPC resources of Saclay-IA through the Lab-IA machine.

A Appendix

A.1 Ngram overlap between E3C and generated corpora

In complement with the overlapping table for unigrams and 8grams in 4.1, Table 9 is a detailed table with ngrams of size between 1 and 8. We can observe that as ngram size increases, the difference between overlapping scores of generated corpora and `CAS` gets smaller.

A.2 Generation parameters selection

We provide here detailed results on the selection of the generation parameters (temperature, nucleus sampling, and repetition penalty). We wanted each of our models to generate a corpus whose diversity was close to the original's corpus diversity (`E3C`). Thus, we mainly selected our parameters according to the self-BLEU score obtained on the generated samples. Results can be seen in Figure 2. We also

Corpus	1gram	2gram	3gram	4gram	5gram	6gram	7gram	8gram
$\texttt{Bloom}_{E3C}$	0.16419	0.03530	0.01072	0.00368	0.00135	0.00055	0.00024	0.00011
$\texttt{Bloom}_{E3C+T}$	0.13887	0.04184	0.01419	0.00531	0.00217	0.00095	0.00043	0.00020
$\texttt{LLF}_{E3C}$	0.11740	0.03479	0.01168	0.00447	0.00196	0.00091	0.00045	0.00023
$\texttt{LLF}_{E3C+T}$	0.11935	0.03807	0.01356	0.00505	0.00203	0.00081	0.00033	0.00013
CAS	0.20373	0.06974	0.02549	0.00899	0.00315	0.00111	0.00041	0.00013

Table 9: Overlap scores from unigrams to 8grams between generated corpora and `E3C`. Each line corresponds to the comparison between the corpus and `E3C`. We added the comparison of `E3C` with `CAS` as a baseline.

computed the perplexity of the generated samples with an oracle model to assess the impact of the parameters' modification on the distribution of the generated texts. We are aware that an oracle perplexity is not sufficient as proof for text quality, especially when working on specialized data such as clinical texts. What is important here is the magnitude of the difference in perplexity between the different setups. Results are reported on Figure 3.

As expected, we notice in Figure 2 that increasing the value of each parameter leads to a lower self-BLEU, meaning higher diversity. This is especially visible for the temperature parameter (2a), whereas the impact of top-p seems feeble (2b). Varying the repetition penalty parameter has a peculiar impact. Going from 1.0 to 3.0 increases the self-BLEU for the texts generated with BLOOM, LLF, and LLF_TAGS. Yet, the self-BLEU decreases for those models when selecting a penalty of 10.0. Only the self-BLEU obtained on the BLOOM_TAGS model decreases with every increase of the penalty parameter. Globally, those plots also bring out differences between texts generated with and without tags, the latter systematically presenting higher self-BLEUs than the former, meaning lower diversity. We can also see that texts generated with the two BLOOM setups tend to get higher self-BLEUs thus lower diversity than texts generated with the LLF setups.

The results for perplexity are presented in Figure 3. Here, we see that increasing each parameter leads to increased perplexity for the texts generated by all models. Oddly, texts generated with the two LLF model setups regularly get a lower perplexity when generated with tags than without, while the opposite phenomenon is observed with the texts generated with the two BLOOM setups. Finally, texts generated with the BLOOM setups tend to have lower perplexity than texts generated with the LLF setups. This could be expected as the oracle model is a bigger version of the BLOOM model.

With the results of the two groups of plots (Figure 2 and Figure 3), we selected a temperature (2a, 3a) of 1.2 for models without tags and 1.5 for models with tags in order to favor diversity. We chose the middle value of 0.95 for the top-p parameter (2b, 3b) because this parameter showed little impact for both metrics. This might be explained by the default value of the top-k parameter used in generation (sampling between the k most probable next tokens) that reduces the impact of top-p modification. Ultimately, we chose the highest value of 10.0 for the repetition penalty parameter (2c, 3c). This value favors diversity and eliminates a significant amount of low-quality generations where the model falls into loops. The presence of those loops doesn't necessarily increase perplexity since the oracle model probably has the same behaviors as the model used to generate text, thus not attributing high perplexity to texts with loops.

A.3 Detailed extrinsic evaluation

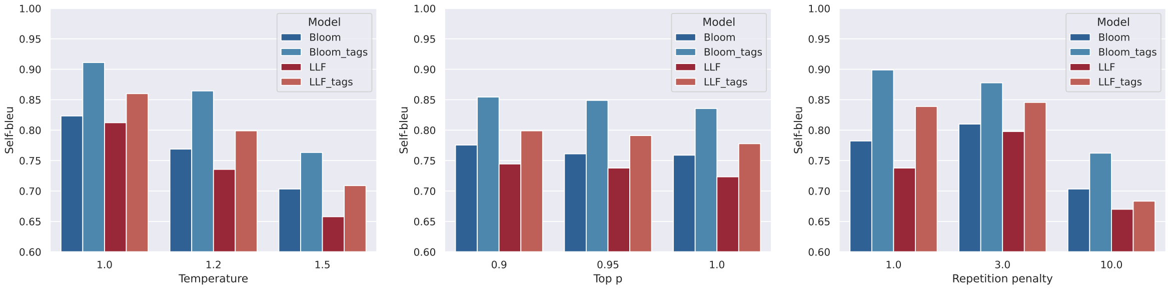
Tables 10 to 12 present the results of our extrinsic evaluation including the standard deviation between the results of the five models used for each configuration.

A.4 Translation of generated examples

Table 13 presents a translation of the sample texts generated with our models, presented in Table 3.

A.5 Manual annotation of generated examples

Tables 14 to 17 present the manual annotations of the full text of the sample excerpts presented in Table 3. These annotations were used for our quality assessment. Grammatical assessment includes sections highlighted in pink (grammatical errors)

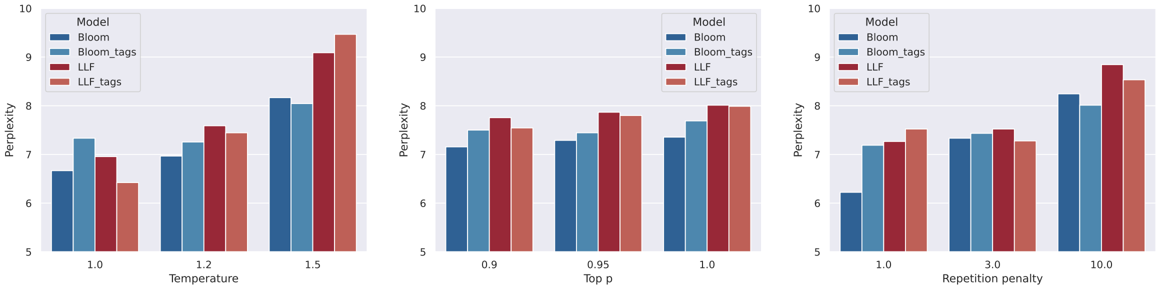


(a) Temperature variation.

(b) Top-p variation

(c) Repetition penalty variation

Figure 2: Self-Bleu on a generation sample of 30,000 tokens for each model used for generation. Self-Bleu for `E3C` : 0.68.



(a) Temperature variation.

(c) Repetition penalty variation

Figure 3: Perplexity of the oracle model on a generation sample of 30,000 tokens for each model used for generation. Oracle perplexity was computed using an oracle pre-trained model of BLOOM with 7 billion parameters. Oracle perplexity on `E3C` : 22.0.

and purple (end of text mid-document). Clinical coherence assessment includes sections highlighted in orange (incoherent or unclear text) and red (incorrect clinical information), sometimes related to sections highlighted in gray (patient demographics, symptoms or diagnosis).

A.6 Computing infrastructure

The computation for training and using generation models was done on a NVIDIA Tesla V100 with 32 GiB of RAM. Most named entity recognition models were also trained and used on a NVIDIA Tesla V100 with 32 GiB of RAM. Due to resource access, one NER model was trained and used on a GeForce GTX 1080 Ti with 12 GiB of RAM.

No	The patient was a 52 years old male with no remarkable previous history. He presented to the emergency room with a 2-week history of diffuse abdominal pain associated with postprandial vomiting related to an obstruction of the cystic duct which clinical examination revealed generalized mucocutaneous jaundice associated with some nonspecific inflammatory signs (exteriororrhea and ureterohydronephritis). The ophthalmological examination did not reveal any other associated ocular or osteo-nerve signs.	The patient was a 55 years old woman with a 10-year history of chronic polyarthritis affecting all the metacarotid joints associated with functional adrenal insufficiency which worsened after the onset of non-insulin-dependent insulin-resistant diabetes requiring her hospitalization six months before her consultation with our ophthalmologist colleague in order to start a drug therapy comprising: imipramine 250 mg/day; dexamethasone 150 mg/day; corticosteroid prednisolone 5mg/kg/24h)
Yes	A 55 year old woman with no remarkable previous history was admitted for a 6-day history of shortness of breath on exertion. Her general condition was altered and she presented with symptoms of inflammation in her left upper limb as well as an influenza-like syndrome (fever at 100°F) and the rest of the neurological exam was unremarkable. Standard radiology did not reveal any sensory-motor disorders or febrile convulsions.	The patient is a 50 years old male admitted to the emergency room with a 2-day history of acute epigastric pain associated with abdominopelvic distension. His past medical history was unremarkable and he was generally in a good state of health (Apgar: 10/10). The preoperative workup showed normal renal function and CRP was at 12 mg/l.

Abstract

The dissemination of false information on the internet has received considerable attention over the last decade. Misinformation often spreads faster than mainstream news, thus making manual fact checking inefficient or, at best, labor-intensive. Therefore, there is an increasing need to develop methods for automatic detection of misinformation. Although resources for creating such methods are available in English, other languages are often underrepresented in this effort. With this contribution, we present IRMA, a corpus containing over 600,000 Italian news articles (335+ million tokens) collected from 56 websites classified as 'untrustworthy' by professional fact-checkers. The corpus is freely available and comprises a rich set of text- and website-level data, representing a turnkey resource to test hypotheses and develop automatic detection algorithms. It contains texts, titles, and dates (from 2004 to 2022), along with three types of semantic measures (i.e., keywords, topics at three different resolutions, and LIWC lexical features). IRMA also includes domain-specific information such as source type (e.g., political, health, conspiracy, etc.), quality, and higher-level metadata, including several metrics of website incoming traffic that allow to investigate user online behavior. IRMA constitutes the largest corpus of misinformation available today in Italian, making it a valid tool for advancing quantitative research on untrustworthy news detection and ultimately helping limit the spread of misinformation.[1]

1 Introduction

Over the last decade, there has been an increase in worry about misinformation, which has led to numerous studies (e.g., Lazer et al. 2018; Pennycook and Rand 2019; Roozenbeek et al. 2020). This level of focus is justified by the threat that misinformation poses to individuals, institutions, and society in an increasingly digitalized world. Helped by social media capillarity and a lack of gatekeeping, misinformation is eroding long-standing institutional barriers, compromising democratic processes, as happened during the last US presidential elections (Allcott and Gentzkow, 2017; Dave et al., 2021), and producing serious sociopolitical uncertainty, as in the examples of global warming and COVID-19 vaccines (van der Linden et al. 2017; Loomba et al. 2021).

Currently, there are two main approaches used to detect misinformation online: manual and automatic. The first relies on human effort, mostly represented by fact-checking services that employ experts to manually verify the accuracy of claims, articles, and entire websites. The second is based on the identification of particular textual content features, usually performed through natural language processing (NLP) tools, e.g., deep learning models. Because misinformation spreads alarmingly faster than reliable news (Vosoughi et al. 2018; Gravino et al. 2022), automatic tools allow to detect and limit the spread of false news quickly and without involving costly human effort. These tools are usually trained on large sets of textual data, which are for the most part in English language (see e.g., Zubiaga et al., 2016; Potthast et al., 2017; Castelo et al., 2019; Miani et al., 2022b).

In a worldwide effort to fight misinformation, resources have been made available for Arabic, Spanish, Portuguese, and German (Alkhair et al., 2019; Posadas-Durán et al., 2019; Monteiro et al., 2018; Vogel and Jiang, 2019). However, to our knowledge, the Italian language has been overlooked. Several attempts have been undertaken to under-

stand misinformation in the Italian context (see e.g., Bessi et al., 2015; Del Vicario et al., 2017), but these works focus on social media, and the data is not made publicly available.

The availability of an open-access dataset would substantially encourage research into the role of misinformation in the Italian context. A recent study conducted in Italy showed how the inability to recognize false information can obstruct public health campaigns (Moro et al., 2021). Misinformation in Italy has also been linked to political parties that have governed in recent years (Monti, 2020), as well as their voters (Cantarella et al., 2020). For example, Caldarelli et al. (2021) showed that right-wing parties were responsible for 96% of COVID-19-related untrustworthy news retweeted by political communities in Italy.

Considering the urgent need to address the societal problems caused by the spread of misinformation in Italy, we created IRMA (the Italian coRpus of MisinformAtion), a corpus containing over 600,000 Italian news articles scraped from websites classified as untrustworthy sources by professional fact-checkers.

2 Method

We decided to use source trustworthiness assessment as a proxy to identify the material of interest (cf. Grinberg et al. 2019; Pennycook et al. 2021). Therefore, we opted for two different misinformation databases, namely NewsGuard (NG, NewsGuard, 2020) and the Misinformation Domains (MD) dataset[2]. NG is a professional fact-checking database that provides indexes of trustworthiness for thousands of news domains. It rates domains in several categories related to news transparency and journalism ethics. The MD dataset is an open-source collection of domains referenced by Gallotti et al. (2020) and extended with other lists curated by fact-checking collectives, individual scholars, and journalists. We decided to use two different databases in order not to be too dependent on one individual source. We chose these two datasets since, differently from other misinformation databases, they comprise a considerable number of Italian sources. We also opted for domain-based rather than article-based fact checking to present a greater variety of data. We recognise that an article-based fact-checking service could have improved the "precision" of the material provided; however, we also think that domain-level fact-checkers represent an optimal balance between quantity and quality of (mis)information. We agree that not all sources deliver only unreliable news. However, having varying degrees of misinformation is an advantage. Future studies could manually annotate documents in IRMA to offer a fine-grained indicator of misinformation, helping the development of classifiers (Mompelat et al., 2022). Finally, the growing number of scholars who have used these two fact-checking databases attests to their reliability (e.g., Edelson et al. 2021; Bhadani et al. 2022; Lasser et al. 2022).

2.1 Corpus construction

We queried both databases (NG and MD) on June 8, 2022. We decided to collect data from a random limited sample of 80 untrustworthy domains in order to keep the database at a manageable size. Once we obtained the list of websites, we started collecting their content using *BeautifulSoup4* (Richardson, 2007), a Python package for parsing HTML documents. Since some of the domains were video-only news sources, paywall-protected websites, or extinct websites, the final number of scraped domains amounted to 56 websites.

Once we obtained the text documents from the websites, we started cleaning the corpus following the pipeline implemented in other works on misinformation (Miani et al., 2022b). In this order, we (1) removed duplicates, (2) selected texts within a word count range between 100 and 10,000 words (counted via white-space tokenization), and (3) removed non-Italian documents by selecting texts in which the percentage of Italian stop words (obtained from Benoit et al., 2021) was above 20% of the whole text (a threshold we chose after visual inspection).

The final corpus, IRMA, is composed of 634,932 documents ($N = 335,021,926$ tokens, $N = 1,137,168$ types) obtained from 56 websites, spanning a date range between 2004 and 2022, with an average document word count of 555 words ($SD = 554$, range: $101 - 9,993$).

2.2 Variables

Although it mostly consists of texts, IRMA also contains metadata such as documents' titles and urls[3], and dates (from 2004 to 2022). Envisioning

---

[2] `https://github.com/JanaLasser/misinformation_domains`

[3] Only valid for domains in MD (N = 22).

the possibility of analyzing IRMA without specific training in NLP, we provide a series of measures related to documents' semantic content such as *keywords*, *topics*, and *lexical features*, so that researchers (e.g., social scientists, psychologists) can download the datasets and start testing their hypotheses.

Documents' dates were obtained automatically via the package *BeautifulSoup4* (accounting for 79.74% of documents' dates). When the script was not able to retrieve webpage's date, we extracted the date from the URL of the document via regular expression. This allowed to obtain dates for 92.8% of IRMA's documents (see distribution in Figure 5 in the Appendix).

2.2.1 Pre-processing

Before extracting keywords and topics from documents, texts were pre-processed. Pre-processing was mostly done by removing stop words and infrequent (e.g., misspellings or extremely rare) words. The text cleaning pipeline was done using the *quanteda* R package (Benoit et al., 2018). The pipeline was as follow: (1) lower casing texts; (2) removing URLs, punctuation, numbers, separators, symbols, and split hyphens; (3) separating contractions; (4) removing stop words (obtained from Benoit et al., 2021); (5) lemmatization.[4] We then built the document-term matrix (DTM) and selected the top 10,000 features, reducing sparsity, i.e., removing rare words, from 99.98 to 98.24%. The DTM was finally composed of 634,932 documents and 10,000 terms, for a total of 167,049,425 types (without trimming, the DTM was composed of 1,137,168 terms accounting for 335,021,926 types).

Note that text pre-processing was done only for extracting keywords and topics from documents. IRMA's domains included in the MD dataset (N = 22) come with raw non-pre-processed texts, so researchers can apply any type of pre-processing depending on the task needed and based on specific theoretical grounding (see e.g., Hills and Miani, Forthcoming). Documents from domains classified by NG (N = 34), on the other hand, do not include raw texts, titles or links, due to policy restrictions. The articles for such domains are attached as DTM, and still retain all other features (see Section A.1).

2.2.2 Keywords

Keywords were extracted from each document by computing the term frequency-inverse document frequency (TF-IDF), a technique that assesses the relevance of a word to a document in a corpus. For each word in a document, TF-IDF is computed by counting how many times a word appears in a document divided by the inverse document frequency of the word in the corpus. TF-IDF was computed using the function `dfm_tfidf` from the R package *quanteda*. Keywords were defined as words with the highest TF-IDF score per document. For all documents in IRMA, we obtained a total of 9,801 unique keywords (see Table 1). In addition, we attach to IRMA the top 10 TF-IDF scores for each document (see top-20 in Table 1).

2.2.3 Topics

Topics were extracted via Latent Dirichlet Allocation, or LDA (Blei et al., 2003), which is an unsupervised probabilistic machine learning model capable of identifying co-occurring word patterns and extracting the underlying topic distribution for each text document. Different from keywords, topics offer a fine-grained indexing of semantic content. Extracting LDA topics from a corpus requires researchers to set a number of topics (k) desired: if a fine-grained resolution is required, then a large number of topics is better; if the number of topics is small, these topics become more general (Colin and Murdock, 2020). Using the *topicmodels* R package (Grün and Hornik, 2011), we extracted three different topic resolutions, setting k at 20, 100, and 200 topics, hence obtaining a total of 320 different topics. Within a set of k topics, for each document in IRMA, topics are expressed as probabilities, hence summing to 1 (note that if all 320 topics are taken, then the sum is 3). The topic for a document with the highest (γ) value is the topic with the highest probability of being represented in such a document, followed by the probabilities of other topics. Note also that we did not provide labels for topics. Instead, we provide the top 10 words per each topic which, taken together, summarize the topic's content (Nguyen et al., 2020).

2.2.4 Lexical features

Lexical features were extracted from the raw texts with the Linguistic Inquiry and Word Count (LIWC, version 2022, Boyd et al., 2022), relying on the most recent Italian translation (Agosti and Rellini, 2007). LIWC is a widely-used standalone

---

[4] `https://raw.githubusercontent.com/michmech/lemmatization-lists/master/lemmatization-it.txt`

application that extracts psychologically meaningful features from texts (Tausczik and Pennebaker, 2010), also in Italian (see e.g., Trevisan et al., 2021). LIWC analyzes texts and checks whether words are included in predefined categories (e.g., negative and positive emotions, social ties, etc.); if so, values associated with the matched categories increases. Different from topic modelling (in which topics' probabilities sum for each document), categories in LIWC are expressed as percentages of words in a document associated with a category and hence, if a word appears in two categories, they overlap. For example, the category `anxiety` (composed of words such as *anxious*, *avoid*, *insecure*) is also a subgroup of the category `negative_emotions`.

2.2.5 Websites metadata

Note that due to proprietary data, all NG's websites are anonymized via a unique website ID (e.g., *website1*, *website2*). Nevertheless, for all websites, we provide a measure of website's quality of information (an aggregated measure of bias, factuality, credibility, and transparency where higher scores correspond to higher quality domains, see Lin et al., 2022). For each website, we also extracted (in October 2022, from SimilarWeb[5]) a set of metadata about websites' incoming traffic such as monthly visits, visit duration, bounce rate (the percentage of visitors who leave after visiting only one page), and pages visited. Incoming traffic is further partitioned into direct traffic (reaching the website by typing the URL on the web browser or recalling it from bookmarks), from a search engines (e.g., using Google), from referrals (when a website is reached through another website), and from social media (e.g., a post on Facebook or Twitter). Traffic from social media was further partitioned across the most popular social media platforms (e.g., Facebook, Twitter, YouTube, etc).

3 Exploring IRMA's features

In this section, we explore some of IRMA's features and provide examples replicating previous works.

We checked whether the type of incoming traffic (i.e., direct and search) was related to websites' credibility, as previous works show (Miani et al., 2022b). We found that credibility of websites was related positively with search traffic ($r = .44, p = .0016$) and negatively with direct traffic ($r = -.30, p = .0341$), suggesting that confirmation bias drives traffic towards towards misinformation websites also in this Italian sample.

We also tested the degree to which credibility was linked to interconnectedness, that is how multiple ideas form a dense and highly interconnected network, a property of conspiracy narratives (Miani et al., 2022a). To this purpose, we created networks for each website from the co-occurrence of the top-fifty most frequent words extracted from the TF-IDF (see variable `tfidf10` in Table 3). We fitted a multilevel regression predicting the degree of connectedness by credibility (nesting observations within keywords). Credibility was negatively related to connectedness ($\beta = -.063, t = -3.193, p = .0014$), meaning that low credible sources are more interconnected. Despite using only misinformation websites, these results replicate previous works on conspiracy theories. In Figure 1, we show two networks built from documents with the highest and lowest credibility scores ($N = 100,000$ in each group): the network in the low (vs high) credibility group is visually more interconnected.

Finally, we explored to what extent lexical features were linked to websites' credibility. To this goal, we fitted a series of linear models predicting credibility by the lexical features extracted with LIWC. In Figure 2, we show the 20 highest and 20 lowest beta coefficients from regression (all $ps < .001$, Bonferroni corrected). Results parallel previous works (Miani et al., 2022b; Fong et al., 2021; Klein et al., 2019; Oswald, 2016) showing that low quality sources tend to endorse a language characterized by anger (category `Rabbia`), negative emotions (`Emo_Neg`), causality (`Causa`), and negations (e.g., "do not", `Negazio`) along with use of longer words (indexing sophisticated lexicon, `BigWords`), swear words (`parolac`), and longer texts overall (i.e., word count `WC`).

4 Conclusions

We introduced IRMA, our publicly available corpus of 'untrustworthy' news in Italian. This is, as far as we know, the first Italian corpus of its kind. It consists of over 600,000 texts (335+ million words) and a number of variables to help scholars find the material that meets their needs. It can be used to develop deep learning classifiers as well as conduct different types of qualitative/quantitative research.

IRMA allows for a vast range of textual analyses thanks to the variety and quantity of data and

Low credibility sources

Figure 1: Co-occurrence of the top-fifty most frequent words extracted from the TF-IDF.

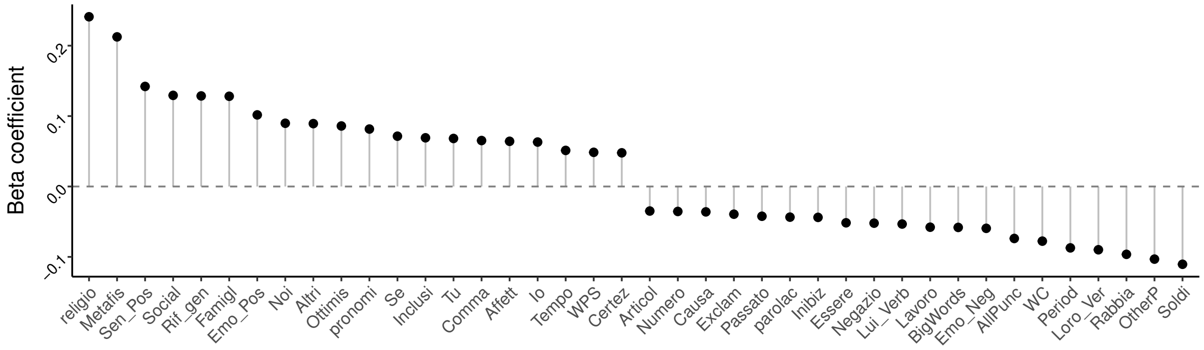

Figure 2: Coefficients (β, Y axis) from regressions predicting LIWC lexical features (on the X axis) by websites credibility scores. Positive values indicate the feature being positively correlated with credibility.

metadata included. For example, time-based data associated with textual data allows for the identification of specific periods for historical analysis (e.g., Hills and Miani, Forthcoming). A set of different semantic indexes in the form of keywords and topics help researchers find data relating to specific topics. Lexical features (specifically, LIWC scores) allow a variety of sociological and psychological studies (e.g., Fong et al., 2021). Topics and lexical features can be traced along a time series to explore their evolution through time (see e.g., Figure 3 in Appendix for topics) exploring cultural and societal trends (e.g., Lansdall-Welfare et al., 2017). IRMA also contains domain-specific features such as the type(s) of news typically shared by a specific source, as well as data on the incoming traffic for a domain, which can be used to study digital community behaviour (e.g., conspiracy websites' incoming traffic in Miani et al., 2022b).

Concluding, IRMA represents a fresh resource in an underrepresented context, such as the Italian one. This corpus was created under PRODEMINFO, an ERC-funded project that also involves other languages (e.g., German, Spanish, Hungarian). This means that the same pipeline employed to generate IRMA can be applied to other languages in the future. As a result, we hope our effort will encourage the creation of new similar corpora and stimulate future research into misinformation.

5 Limitations

Our dataset contains material classified as 'untrustworthy' by two different datasets, which relied on different classification criteria. NG ranks websites based on nine weighted criteria. Each site is assigned a trust score ranging from 0 (very poor) to

100 (exemplary). Domains with less than 60 points are labelled as "not trustworthy". On the other hand, the MD dataset is a curated collection of domain-level fact-checking databases, where the different proprietary rates are mapped onto two unifying labels, namely “accuracy” and “transparency”. Although potentially leading to a different alignment of source reliability, depending on the dataset that classified the source, Lasser et al. (2022) found a high degree of agreement between the MD dataset and the NG database scores (Krippendorff’s α = 0.84), as well as other collections (Lin et al., 2022).

Despite the fact that the two datasets label the websites in IRMA as "untrustworthy", this does not necessarily imply that they are all actively spreading fake news. This is due to the fact that domains could be rated not just on news quality and reliability, but also on other complimentary factors such as company policies (e.g., whether and how websites disclose information about ownership and financing). However, we are unable to provide the classification standards for the domains in our database, as well as the domains themselves due to restrictions of NG proprietary data policies. Therefore, we suggest prospective users to judge the quality of news for themselves perhaps via data-driven approaches.

Finally, it is important to note that both the NG and the MD datasets can vary over time, thus websites previously deemed untrustworthy may no longer be so in the future (and vice-versa).

6 Acknowledgements

This project has received funding from the European Research Council (ERC) under Advanced Grant PRODEMINFO (101020961). SL was also supported by funding from the Humboldt Foundation in Germany. FC was supported by the Templeton Foundation through a grant awarded to Wake Forest University.

A Appendix

A.1 Data availability

IRMA is freely available[6] and include the files:

1. **corpus.csv.zip**. A compressed file (.zip) containing the csv file of the corpus itself: 634,932 rows (documents) x 7 columns. Documents are identified by a hexadecimal unique ID stored in the variable `doc_id`. See dataset's variables in Table 3.
2. **website_description.csv**. A csv file containing detailed descriptions of websites. 56 rows (websites) x 25 columns. Note that due to proprietary data, NG's websites are anonymized via a unique website ID (e.g., *website1*, *website2*). See dataset's variables in Table 4.
3. **IRMA.dfm.rdata**. The IRMA's DTM. No preprocessing has been applied prior to conversion: the file contains punctuation and cased words (634,932 documents; 1,531,576 features). Note that the file was too large to be converted into a matrix, therefore we exported it as a quanteda DFM object, hence it requires the *quanteda* R package (Benoit et al., 2018).
4. **LDA_over_time.pdf**. A PDF file containing each topic's gamma values plotted over time. It contains 320 pages (i.e., the number of topics: k20 + k100 + k200). See Figure 3 for an example (at page 182 of the pdf file). Terms can be searched within the pdf.
5. **corpus_LF.csv**. The Lexical features obtained from LIWC. A csv file of 634,932 rows (documents) x 95 columns (94 LIWC lexical features and 1 documents' ID [`doc_id`]). See dataset's variables in Table 2.
6. **LDA_topic_gamma.csv.zip**. A compressed file (.zip) containing the csv file of 634,932 rows (documents) x 320 columns (LDA gamma values for k20, k100, and k200 topics). Each cell contains gamma value, that is the probability a topic is part of a document.
7. **topic_description.csv**. A file containing detailed descriptions of topics. 320 rows (topics) x 6 columns. See dataset's variables in Table 5.

Table 2: List of columns for the dataset **corpus_LF.rdata**

Variable	Description
`doc_id`	Hexadecimal sequence of document unique identification number (e.g., `D1d049`)
`date`	The date the webpage was uploaded (format: `YYYY-MM-DD`, $N_{empty} = 45,185$)
`website`	The identification number for websites from which the document was extracted (e.g., *website15*, *ilprimatonazionale*; see also Table 4, below)
`title`	Title of the document ($N_{empty} = 359,526$)
`txt`	Document text ($N_{empty} = 358,851$)
`URL`	URL associated with the document ($N_{empty} = 360,137$)
`WC`	Word count
`KW`	Keyword associated with the document (see Table 1)
`tfidf10`	Top-10 words ordered by TF-IDF scores

Table 3: Names and variable descriptions for the dataset **corpus.csv.zip**

Variable	Description
`website`	Website's identification (e.g., *grandeinganno*, *website21*)
`Ndoc`	Number of documents for each website
`WC_{type}`	Word count statistics. Type includes: mean, SD, min, and max
`DATE_{type}`	Date range. Type includes: min and max ($N_{empty} = 8$)
`type_of_news`	Website type of content (e.g., conspiracy, political, health-related, religious, general, and/or viral)
`Monthly_Visits`	Count of visits in the past month (i.e., September 2022). Note that for websites with less than 5,000 monthly visits, SimilarWeb does not collect further traffic data. To those websites, ($N = 7$), we assigned the value 5,000
`Visit_Duration`	Average of visit duration (in seconds)
`Bounce_Rate`	The percentage of visitors who enter a site and leave after visiting only one page
`Pages_per_Visit`	Average of pages visited in each visit
`Traffic_{type}`	Proportion of incoming traffic. Type includes: Direct, Referrals, Search, and Social
`Social_{type}`	Proportion of incoming traffic from social media. Type includes: Linkedin, Vkontakte, Others, Telegram_Webapp, Youtube, Twitter, and Facebook
`credibility`	Websites' credibility scores (obtained from Lin et al., 2022).

Table 4: Names and variable descriptions for the dataset **website_description.csv**

Variable	Description
`topic_name`	Topic unique ID. It is composed by the topic resolution plus a three-character serial number (e.g., `k100_032` is the 32th topic at 100k resolution)
`top_words`	Top-ten words ordered by importance (for the topic)
`topic`	Name of the topic with the highest correlation (within the same topic resolution)
`topic_cor`	Pearson r correlation estimate for the highest correlated topic
`LF`	Name of the LIWC's lexical feature with the highest correlation
`LF_cor`	Pearson r correlation estimate

Table 5: Names and variable descriptions for the dataset **topic_description.csv**. Note that correlation are computed on the document level ($N = 634,932$)

Parameter-Efficient Korean Character-Level Language Modeling

Abstract

Character-level language modeling has been shown empirically to perform well on highly agglutinative or morphologically rich languages while using only a small fraction of the parameters required by (sub)word models. Korean fits nicely into this framework, except that, like other CJK languages, it has a very large character vocabulary of 11,172 unique *syllables*. However, unlike Japanese Kanji and Chinese Hanzi, each Korean syllable can be uniquely factored into a small set of subcharacters, called *jamo*.

We explore a "three-hot" scheme, where we exploit the decomposability of Korean characters to model at the syllable level but using only jamo-level representations. We find that our three-hot embedding and decoding scheme alleviates the two major issues with prior syllable- and jamo-level models. Namely, it requires fewer than 1% of the embedding parameters of a syllable model, and it does not require tripling the sequence length, as with jamo models. In addition, it addresses a theoretical flaw in a prior three-hot modeling scheme.

Our experiments show that, even when reducing the number of embedding parameters by $> 99.6\%$ (from 11.4M to just 36k), our model suffers no loss in translation quality compared to the baseline syllable model.

1 Introduction

Subword modeling has been used for Korean to reduce the required vocabulary size due to its agglutinative nature and morphological richness. Several works have characterized the many subword tokenization strategies for Korean (Park et al., 2020; Moon and Okazaki, 2020).

(Sub)character modeling has been employed for translation in Asian languages (Nguyen et al., 2017; Ngo et al., 2019; Yu et al., 2017). Likewise, it has found use in generic Korean NLP tasks (Cho et al., 2019; Choi et al., 2017). Further, Stratos (2017) investigated exploiting the hierarchical nature of Korean characters for modeling. However, nearly all of these works are restricted to the input side only, either because the downstream task is a classification task or it is a translation task where Korean is the *source* language, and so syllable generation is unnecessary. An exception is Song et al. (2018), where the authors propose a "multi-hot" scheme that appears on both the embedding and decoding sides of a sequence-to-sequence denoising autoencoder applied to Korean spelling correction.

The baseline approaches of syllable- and jamo-level modeling each have downsides. Syllable models must have embeddings for all 11,172 syllables to provide full coverage, which requires an enormous number of parameters. On the other hand, jamo-level modeling requires fewer than 70 embeddings, but the sequence lengths become 3x longer, which greatly slows inference in attention-based models. Here, we propose a three-hot model[1] that addresses both of these issues, as well as an issue in the architecture from Song et al. (2018).

We emphasize that our goal is specifically to investigate parameter-efficient character-level modeling, and not to compare with (sub)word models.

1.1 Korean Syllabary

$\mathcal{V}_i$	ㄱ ㄲ ㄴ ㄷ ㄸ ㄹ ㅁ ㅂ ㅃ ㅅ ㅆ ㅇ ㅈ ㅉ ㅊ ㅋ ㅌ ㅍ ㅎ
$\mathcal{V}_v$	ㅏ ㅐ ㅑ ㅒ ㅓ ㅔ ㅕ ㅖ ㅗ ㅘ ㅙ ㅚ ㅛ ㅜ ㅝ ㅞ ㅟ ㅠ ㅡ ㅢ ㅣ
$\mathcal{V}_f$	ㄱ ㄲ ㄳ ㄴ ㄵ ㄶ ㄷ ㄹ ㄺ ㄻ ㄼ ㄽ ㄾ ㄿ ㅀ ㅁ ㅂ ㅄ ㅅ ㅆ ㅇ ㅈ ㅊ ㅋ ㅌ ㅍ ㅎ $\oslash$

Table 1: The three jamo classes. $\oslash \in \mathcal{V}_f$ represents the *absence* of a final consonant.

---

[1] Our three-hot implementation has been packaged as a library alongside code to reproduce our experiments: `https://github.com/mcognetta/ThreeHotKoreanModeling`.

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2350–2356
May 2-6, 2023

a) 기계번→역

b) ㄱㅣ∅ㄱㅖ∅ㅂㅓㄴ→ㅇ→ㅕ→ㄱ

c) (ㄱ, ㅣ, ∅)(ㄱ, ㅖ, ∅)(ㅂ, ㅓ, ㄴ)→(ㅇ, ㅕ, ㄱ)

Figure 1: Modeling scenarios for predicting the syllable 역 (*yeok*:'decode'), from the context "기계번"(*gigyebeon*:'machine translate') using a) syllable, b) jamo, and c) three-hot modeling. Notice that in jamo modeling, the prediction is spread over three time-steps.

Korean syllables are made up of three subcharacters: an initial consonant, a vowel, and an optional final consonant, collectively known as jamo. There are 19, 21, and 28 initial consonants, vowels, and final consonants (including the lack of a final consonant, represented by $\oslash$), denoted $\mathcal{V}_i$, $\mathcal{V}_v$, and $\mathcal{V}_f$, respectively, shown in Table 1. These classes are disjoint, and even visually similar jamo in $\mathcal{V}_i$ and $\mathcal{V}_f$ (e.g., ㄱ) are distinct subcharacters.

Any Korean syllable can be uniquely decomposed into three jamo, and any choice $(i, v, f) \in \mathcal{V}_i \times \mathcal{V}_v \times \mathcal{V}_f$ corresponds to a unique syllable. For example, 한: (ㅎ, ㅏ, ㄴ) and 무: (ㅁ, ㅜ, $\oslash$).

Specific details about Korean jamo and their Unicode representations are in Appendix A.

2 Three-hot Modeling

Naïve syllable-level and jamo-level modeling use one-hot encodings to represent each token. We propose a three-hot scheme, where jamo triplets representing syllables are consumed and generated at each step. Figure 1 gives examples of each of the considered modeling schemes.

2.1 Embedding

In three-hot modeling, we learn embeddings for jamo and combine them to produce a syllable embedding as:

$$emb_s = emb_i + emb_v + emb_f,$$

where $+$ is vector addition. We also experimented with combining $emb_{i,v,f}$ via concatenation, but this method requires more parameters and we observed no performance difference.

Similar factored embeddings have been considered before in language-agnostic settings (Svenstrup et al., 2017) and for Korean specifically (Stratos, 2017).

2.2 Independent Three-hot Decoding

Song et al. (2018) proposed a three-hot decoder for a sequence-to-sequence autoencoder which produces syllables by predicting three jamo subcharacters as a three-hot vector. In their scheme, they predict the individual jamo *independently*, as:

$$\mathcal{P}(s \mid h) \approx \mathcal{P}(i \mid h) \times \mathcal{P}(v \mid h) \times \mathcal{P}(f \mid h).$$

However, a syllable's jamo are *not* independent, and thus this method does not capture the true joint probability distribution:

$$\mathcal{P}(s \mid h) = \mathcal{P}(i, v, f \mid h).$$

2.3 Conditional Three-hot Decoding

To properly model the true joint distribution, we factor it as:

$$\mathcal{P}(s \mid h) = \mathcal{P}(i \mid h) \times \mathcal{P}(v \mid i, h) \times \mathcal{P}(f \mid i, v, h).$$

Given a context embedding h from a base language model, we first predict the initial consonant, π_i, from $\texttt{softmax}(I(h_i))$, where $I : \mathbb{R}^d \to \mathbb{R}^{|\mathcal{V}_i|}$ and h_i is a vector generated from h and an initial vector h_0. Then, we generate a continuous embedding for π_i via $\texttt{embedding}_i : \mathbb{R}^{|\mathcal{V}_i|} \to \mathbb{R}^d$. The continuous embedding is combined with h_i and used to predict the vowel jamo, π_v. Likewise, π_v is re-embedded and used to predict the final consonant, π_f. As such, a triplet (π_i, π_v, π_f) is generated similarly to a three-step, unrolled RNN:

$$\begin{aligned}
h_i &= \texttt{tanh}(W_e h + W_h h_0) \\
\pi_i &\sim \texttt{softmax}(I(h_i)) \\
emb_i &= \texttt{embedding}_i(\pi_i) \\
h_v &= \texttt{tanh}(W_e emb_i + W_h h_i) \\
\pi_v &\sim \texttt{softmax}(V(h_v)) \\
emb_v &= \texttt{embedding}_v(\pi_v) \\
h_f &= \texttt{tanh}(W_e emb_v + W_h h_v) \\
\pi_f &\sim \texttt{softmax}(F(h_f))
\end{aligned} \tag{1}$$

In the decoding layer, we define $\texttt{embedding}_{i,v}$, but not $\texttt{embedding}_f$. This is because once the prediction π_f has been made, decoding for that time-step is done, and so an embedding emb_f is not needed to generate any more jamo.

2.3.1 Parameter Reduction via Weight Sharing and Diagonal RNNs

A common way to reduce parameter counts is to share weights between the embedding and decoding layers. For jamo and syllable models, this is

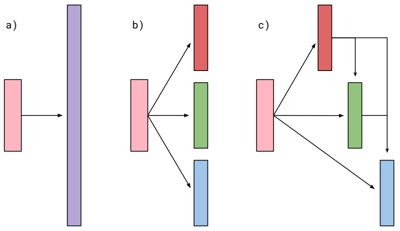

Figure 2: The three decoding types: `a)` one-hot decoding (jamo or syllable), `b)` independent three-hot decoding (Song et al., 2018), and `c)` conditional three-hot decoding (ours). The light pink box is a contextual embedding h, while red, green, and blue are $\mathcal{V}_i$, $\mathcal{V}_v$, and $\mathcal{V}_f$, respectively.

straightforward, as the one-hot embedding table can be reused for the final linear output layer.

For independent three-hot models, the embedding weights from Section 2.1 can also be reused in the final output layers. For conditional three-hot models, the embedding weights can be used for both $\texttt{embedding}_{i,v}$ and I, V, F in Equation 1, so that only the matrices W_e and W_h are unshared. Additionally, we hypothesize that, due to the strictly bounded context length Equation 1, a fully dense RNN transition matrix may be excessive, and so we experiment with replacing W_e and W_h with diagonal matrices (Sübakan and Smaragdis, 2017).

2.4 Prediction Order

In multi-label classification, it has been observed that the order in which labels are generated can impact a model's accuracy (Read et al., 2021). For three-hot decoding, we experiment with the six triplet-generation permutations to see if there is any significant difference. This does not require any modification of the training data or architecture, as we need only permute the order of Equation 1.

2.5 Triplet Representation

Three-hot decoding models output jamo triplets representing a full syllable. However, the model may need to process non-Korean characters, which do not have a three-hot jamo decomposition. To unify the representations of Korean and non-Korean tokens, we add all non-Korean tokens to $\mathcal{V}_i$ and introduce a padding character $\mathbf{x} \in \mathcal{V}_{v,f}$. Then, a non-Korean token c is represented by $(c, \mathbf{x}, \mathbf{x})$.

To ensure a fair comparison between the three-hot decoding schemes and the jamo model, no logic is used to prohibit the generation of degenerate triplets, such as a non-Korean symbol followed by jamo subcharacter. Syllable and jamo models do not generate $\mathbf{x}$ when predicting non-Korean tokens, but jamo models are trained to predict $\oslash$ if a syllable does not have a final consonant.

3 Parameter Counts

Table 2 shows the parameter counts for each of the architectures. Since the three-hot models use jamo embeddings, they have the same number of embedding parameters as the jamo-level models. The conditional three-hot models have additional parameters for the three-stage decoding step: two internal transition matrices W_e and W_h (Equation 1), which dominate the decoding layer's parameter count. But, when the transition matrices are diagonalized and weight sharing is used, the total number of parameters is only 1k more than the shared-weight jamo and independent three-hot models.

The syllable models contain several orders of magnitude more parameters than any other architecture. In the most extreme case, unshared syllable vs. shared, diagonal three-hot, the latter has only $\frac{36k}{11.4M} \approx 0.32\%$ as many embedding parameters.

Our underlying LM is a transformer model with 15.7M parameters on the target side[2], not counting those for embedding or generation. Thus, the unshared syllable-level embedding/decoding layers increase the target-side parameter count by 73%, while the unshared jamo, independent, and diagonal conditional three-hot increase it by less than 2%, and non-diagonal conditional three-hot by less than 6%.

4 Evaluation Metrics

Since we are modeling at two different granularities, perplexity is not immediately comparable between the different architectures. To unify them, we use bits-per-jamo (BPJ) as our granularity-agnostic metric.

We use BLEU and chrF to evaluate the quality of the translations produced by our models. Since our models work on different granularities, we canonicalize their outputs for comparison.

For syllable-level modeling, we split all syllables into their jamo subcharacters and leave all non-Korean-syllable tokens as is. For three-hot models, triplets are flattened to a string of three characters. We remove the **x** pad from non-Korean tokens and replace degenerate triplets with a special `BAD` token. For all models, all jamo are converted to a

---

[2] See Appendix B for architecture details.

	Embedding	Decoding	Total	BPJ	BLEU	chrF
Syllable (unshared)	5.7M	5.7M	11.4M	33.9	14.1	38.1
Syllable (shared)	5.7M	-	5.7M	0.342	14.0	38.1
Jamo (unshared)	35k	35k	70k	0.355	13.7	37.8
Jamo (shared)	35k	-	35k	0.356	14.1	38.0
Three-hot (Ind., unshared)	35k	35k	70k	0.555	7.9	28.9
Three-hot (Ind., shared)	35k	-	35k	0.556	8.3	29.4

	Embedding	Decoding	Total	BPJ	BLEU	chrF
Three-hot (IVF, unshared)	35k	579k	614k	0.287	14.3	38.1
Three-hot (IVF, shared)	35k	524k	559k	0.292	14.1	38.1

Three-hot (FIV, diag., shared)	35k	1k	36k	0.304	13.8	37.8

Table 2: Parameter counts (when $d = 512$, as in our experiments) and metrics (BPJ, BLEU, and chrF) for each of the architectures. For brevity, only some decoding orders are listed here. The decoding column lists only parameters that are not shared with the embedding layer. A complete set of metrics is given in Appendix C.

canonical *compatibility jamo* format (see Appendix A). Finally, we remove all punctuation.

For BLEU, we use the standard n-gram order of 4, since this operates on the word-level (in our experiments, contiguous token sequences surrounded by whitespace). The default chrF character n-gram order is 6, which we interpret as meaning 6 *syllables* for Korean. Since we measure our metrics on decomposed jamo sequences, we use a jamo n-gram order of 18.

5 Experiments

We use an English-Korean news translation dataset from AI Hub[3] with 400k sentences. We remove all sentence pairs that have more than 100 syllables on the Korean side, leaving 365k , from which we select 5k and 5k for testing and validation.

As our only goal is to evaluate the effectiveness of three-hot modeling compared to naïve syllable- and jamo-level modeling, we use the same base transformer model architecture and hyperparameters in all experiments and only change the target-side embedding and decoding layers. The complete hyperparameter list is given in Appendix B.

In total, we train 30 models: unshared and shared weights for syllable, jamo, and three-hot independent modeling (6 total) and $\{\text{unshared, shared}\} \times \{\text{dense, diagonal}\}$ for each of the 6 conditional three-hot prediction orders (24 total). Each model is trained for 50 epochs, and the epoch with the lowest bits-per-jamo on the validation set is used.

For inference, we use a beam size of 15 for syllable models and 8 for jamo models. Three-hot decoding is two-staged: an internal beam search constructs triplets jamo-by-jamo, and the highest probability triplets are added to the outer beam as syllables. For the independent three-hot models, we use beam size of 5 and an internal beam size of 3. For the conditional three-hot models, we use a beam size of 15 and an internal beam size of 4. These hyperparameters were determined by a sweep search on the validation set.

6 Results and Analysis

Table 2 lists the metrics for each model type.

Independent three-hot modeling performs the worst across all metrics. On translation in particular, we suspect that it is because the model can generate high probability but meaningless triplets, especially in scenarios where several reasonable syllable continuations exist. The highest probability triplet may contain individual jamo that come from each of the true high probability syllable continuations, but which are combined in a way that forms a meaningless character. Such triplets quickly saturate the beam with gibberish contexts and degrade the translation quality.

For bits-per-jamo, conditional three-hot models vastly outperform all other architectures. However, this has some caveats. Since the syllable model must predict all three jamo simultaneously, the bits-per-jamo is spread evenly throughout the component jamo. On the other hand, conditional three-hot modeling has a relatively difficult time predicting the first jamo, but the subsequent elements are increasingly easy due to the additional conditioning (Appendix C lists BPJ-per-jamo-class for each model). Jamo models must deal with a longer context (and thus less focused attention) and the output layer can output any class of jamo or non-Korean tokens at any time step, which makes modeling less structured and more difficult than conditional three-hot and syllable-level models.

We observed that the independent three-hot models had the highest perplexity on $\mathcal{V}_v$, followed by $\mathcal{V}_i$, then $\mathcal{V}_f$. Since this family generates jamo independently, it approximates the true entropy of the marginal subcharacter distributions. Thus, we conjectured that (f, i, v) order would be the best and (v, i, f) the worst for model accuracy, but found that no prediction order consistently outperformed

---

[3] `https://aihub.or.kr/`

the others.

For translation, the BLEU and chrF scores for jamo, syllable, and conditional three-hot models are extremely close. We found that, as we moved from unshared, dense three-hot models to shared, diagonal models, there was a slight loss in BPJ performance, but even in the diagonal, shared case, all three-hot models perform on-par with syllable models on translation (± 0.3 BLEU and ± 0.3 chrF), supporting our claims that the syllable models are massively overparameterized, and using fully dense W_e and W_h matrices in Equation 1 is unnecessary.

7 Conclusion

We presented a conditional three-hot decoder for Korean character-level language models. Our model addresses several issues with other Korean (sub)character-level modeling schemes. Compared to syllable-level models, it uses only a small fraction of the number of parameters, and, unlike jamo-level models, it does not triple the sequence length, avoiding the resulting inference time increase with attention mechanisms. It also addresses a theoretical flaw in a prior three-hot decoding scheme, where a syllable's subcharacters were generated independently. Finally, we proposed several variants of our model to further reduce parameters.

On a character-level translation task, we found that all of our conditional three-hot models perform on-par with jamo and syllable models, even when using as little as ~0.3% of the embedding parameters of a syllable model. They also outperform the prior independent three-hot model in every metric.

These results suggest that conditional three-hot modeling is an efficient and principled method of character-level Korean language modeling.

9 Limitations

One limitation of this work is that it is specific to the writing system typically used in Korean, Hangul. A similar idea could be used for subword modeling in other scripts, but the idea presented here draws specifically on the hierarchical and compositional nature of Hangul syllables that is unique to the script itself. A second is that we did not compare to state-of-the-art non-character-level Korean translation models. However, this was on purpose, as the point of this paper is specifically to investigate efficient character-level modeling.

A Hangul and Jamo

Korean is divided into three Unicode blocks: syllables[4], jamo[5], and *compatability* jamo[6].

The syllable block contains a codepoint for each of the 11,172 unique syllables and the jamo block contains one codepoint for each of the initial, vowel, and final jamos, separated by class. Table 1 shows all of the jamo. Note that some visually identical jamo exist in both the initial and final consonant classes (e.g., ㄱ). These are technically distinct jamo, hence the need for two unique codepoints. The compatibility jamo block contains a codepoint for each consonant and vowel, but merges visually identical ones from across different classes. In total there are 51 compatibility jamo. Conversion from syllables to jamo and compatibility jamo is deterministic using basic modular arithmetic on the codepoints[7]. Likewise, it is trivial to recompose jamo into syllables. Since compatibility jamo has ambiguities about which class a specific jamo belongs to, it must be composed greedily from left to right using a state machine. However, in all cases, assuming that that jamo sequence is valid, both jamo and compatibility sequences can be unambiguously recomposed into syllables.

In our experiments, we always convert from syllables/triplets/jamo to compatibility jamo, and never from compatibility jamo, so all ambiguities are avoided even in the case of invalid jamo sequences.

B Baseline Transformer LM

A single baseline transformer model configuration was used across all experiments, with only the target side embedding and decoding layers swapped out. Table 3 lists the relevant hyperparameters. All models were trained on an NVIDIA RTX A6000 GPU using PyTorch 1.12.

Hyperparameter	**Value**
English Vocabulary	30k BPE
Embedding Dimension	512
Feed Forward Dimension	512
Encoder Layers	6
Decoder Layers	6
Heads	8
Optimizer	ADAM
Learning Rate	1e-4
Betas	(0.9, 0.98)
Batch Size (tokens)	4k (10k for Jamo)
Epochs	50

Table 3: Hyperparameters for the base transformer language model.

C Full Metrics

The full metrics for all experients are listed in Table 4. This is the complete version of Table 2.

Abstract

Designing dialog tutors has been challenging as it involves modeling the diverse and complex pedagogical strategies employed by human tutors. Although there have been significant recent advances in neural conversational systems using large language models (LLMs) and growth in available dialog corpora, dialog tutoring has largely remained unaffected by these advances. In this paper, we rigorously analyze various generative language models on two dialog tutoring datasets for language learning using automatic and human evaluations to understand the new opportunities brought by these advances as well as the challenges we must overcome to build models that would be usable in real educational settings. We find that although current approaches can model tutoring in constrained learning scenarios when the number of concepts to be taught and possible teacher strategies are small, they perform poorly in less constrained scenarios. Our human quality evaluation shows that both models and ground-truth annotations exhibit low performance in terms of equitable tutoring, which measures learning opportunities for students and how engaging the dialog is. To understand the behavior of our models in a real tutoring setting, we conduct a user study using expert annotators and find a significantly large number of model reasoning errors in 45% of conversations. Finally, we connect our findings to outline future work.

`https://github.com/eth-nlped/dialog-tutoring`

1 Introduction

The goal of dialog tutoring research is to build systems that can tutor students using natural language conversation (Wollny et al., 2021). For several decades, learning scientists have been studying the features of domain-specific dialog tutoring systems that engender learning in students (Chi et al., 1994; Graesser et al., 1995; Moore et al., 2004; Litman et al., 2006; Graesser, 2016; Ruan et al., 2019) and have established strong learning gains that are even comparable to human tutoring in specific domains (Nye et al., 2014). However, these systems require extensive authoring of materials by teachers (MacLellan and Koedinger, 2020) and therefore cannot fully utilize the scalability of online learning.

Building dialog tutors is technically challenging as tutoring dialogs typically exhibit properties that are absent in other forms of dialog. Tutoring dialogs are often *long*, enabling students to be exposed to the concepts in a way that they can use them in future (Chi and Wylie, 2014), and *grounded* in the learning scenarios (Graesser et al., 2009). Finally, good dialog tutors are engaging and create opportunities to learn, providing students space to seek and provide explanations, and self-reflect (Chi and Wylie, 2014; Reiser, 2004).

The growing success of deep neural network based language generators in other dialog settings (Adiwardana et al., 2020; Roller et al., 2021) suggests new possibilities in dialog tutoring that could scale beyond domain-specific approaches. However, despite their promise, advances in neural generative models have seen little adoption in dialog tutoring.

In this paper, we contribute a comprehensive study of the applicability of neural generative models in tutoring. We formally introduce the dialog tutoring task and analyze existing tutoring datasets (§2). Then, we describe several generative and retrieval-based models for dialog tutoring (§3) and benchmark them on two open-access dialog tutoring datasets for language learning: *CIMA* (Stasaski et al., 2020, a crowdsourced role-played dataset for learning prepositional phrases in Italian) and

Teacher-Student Chatroom Corpus (TSCC) (Caines et al., 2020, a one-to-one English tutoring dataset from an online chatroom) (§5.1). We evaluate our models on various automatic metrics (§4.2) as well as two human evaluation studies: an evaluation of the quality of the generated response with respect to various measures of goodness (§6.1), as well as a more realistic user study with a learning interface (§6.2).

Overall, while we find that pretrained models improve over simpler baselines in terms of automatic metrics, our consequent human evaluation reveals several shortcomings that ought to be addressed before these models can be adopted in the real world. We find that while neural generative models can model more constrained learning settings well, they struggle when the learning goal is more open-ended. Specifically, these models are unable to understand and reason about student solutions and misconceptions, and thus, are unable to use effective pedagogical strategies.

We find that the field of dialog tutoring is significantly limited by the quantity and quality of available datasets. The available datasets are both too small and not rich enough to capture the nuances of the dialog tutoring problem. Our analysis also reveals the inadequacy of automatic evaluation metrics for capturing tutoring quality. Not only are the existing metrics unable to capture faithfulness to the learning material and the student dialog history, but they also cannot capture moves of good human tutors that allow learners the space for reflection, explanation, follow-ups, and real engagement in the process of learning.

Based on our findings, we end with an outline of potential avenues of future research (§7). We hope that our paper will bring attention to this underexplored natural language processing application with the potential for significant social good.

2 The Dialog Tutoring Task

Dialog tutoring can be described as a multi-turn interaction between two interlocutors, where one performs the role of a *teacher* seeking to teach the other interlocutor who acts in the role of a *student*. We then can describe a dialog tutoring session formally as a sequence of turns $\mathcal{H} = (u_1, \ldots, u_{|\mathcal{H}|})$ that are taken by either of the interlocutors. Each turn $u_t \in \mathcal{V}^*$ is a finite sequence of tokens from a vocabulary $\mathcal{V}$.

Further, each turn u_t can be associated with a sequence of dialog acts $\mathbf{a}_t \in \mathcal{A}$ that indicate the action taken by the interlocutor in the corresponding turn. The dialog act is a key aspect of dialog tutoring as it can refer to the teaching strategy employed by the tutor. These may include strategies such as *providing a hint* or *seeking a clarification* (see Appendix A for more details). The set of dialog acts $\mathcal{A}$ is usually fixed according to a predefined taxonomy and may be split into two subsets $\mathcal{A} = \mathcal{A}_{\text{teacher}} \cup \mathcal{A}_{\text{student}}$, each corresponding to the teacher and student role. Each dialog session $\mathcal{H}$ may also be accompanied with some *grounding* information K, which grounds the response in relevant information and may refer to the teaching material that needs to be taught to the student. This information K may come in various formats, including images and videos. However, we restrict ourselves to using only text-based grounding in this work such that $K \in \mathcal{K} \subseteq \mathcal{V}^*$ is again a sequence of tokens from the common vocabulary $\mathcal{V}$ and $\mathcal{K}$ is used to describe the set of possible groundings (e.g., a textbook with a set of chapters). In Section 3 we derive different methods to model the role of the teacher, to which we restrict this work.

CIMA (Stasaski et al., 2020)	*TSCC (Caines et al., 2020)*
 **K:** “blue” is “blu“ [...] **Grammar Rules:** Adjectives (such as color words) follow the noun they modify in Italian [...]	**N/A**
Teacher: (N/A) “Blue" is "blu" in Italian. **Student:** But what are the other words? **Teacher:** (N/A) Can you give me your best guess? **Student:** es en front de blu tree. **Teacher:** *(Correction)* Getting there. Remember that the adjective always follows the noun in modifies.	**Teacher:** *(eliciting)* So in fact fractions (half/third/quarter etc) are good to use for variety in language OK? and what about e.g. 23%? **Student:** just less than a quarter **Teacher:** *(eliciting)* so if you say 'less' you need to say 'less than' ....so just use one word ok? beginning with 'u'! **Student:** I am not sure of the word. **Teacher:** (scaffolding) just under a quarter

Figure 1: Examples of tutoring conversations from both datasets. The (image) grounding is shown in the second row and dialog acts in brackets indicate the pedagogical strategy.

2.1 Existing tutoring datasets

To our knowledge, only three conversational tutoring datasets are openly available: *CIMA* (Stasaski et al., 2020) is a crowd-sourced dataset, where annotators were asked to role-play students and teachers by working through an exercise on translating a prepositional phrase from English to Italian, given an image and a shared set of concepts. *TSCC* (Caines et al., 2020) uses real teachers leading one-on-one language tutoring sessions in English language learning, thus creating a more open-ended scenario. Finally, *TalkMoves* (Suresh et al., 2022a).

is a collection of scraped classroom transcripts of K-12 mathematics lesson videos that contain challenging, multi-party interactions.

The scarcity of tutoring datasets stands in contrast to other dialog scenarios, where plenty of datasets have been proposed and studied. For example, task-oriented dialog has been studied in domains like reservations (Wen et al., 2017; Budzianowski et al., 2018; Kim et al., 2020) or public service information (Feng et al., 2020). On the other hand, chit-chat or open-domain dialog has been studied on movies (Zhou et al., 2018), Wikipedia knowledge (Dinan et al., 2019), agent persona (Dinan et al., 2020), knowledge graphs (Moon et al., 2019), and open-ended settings (Komeili et al., 2022).

Furthermore, we note the following limitations and characteristics of tutoring datasets, also in comparison to other dialog domains: 1) Low pedagogical quality (CIMA), 2) Limited teaching strategies (all), 3) Exclusive focus on classroom settings (TalkMoves), 4) Small dataset size (all). 5) Significantly larger context sizes (TSCC) 6) Harder readability according to the Flesch score (TSCC). We provide more evidence in Table 1 which shows a comparison of dialog tutoring datasets with widely-used task-oriented and open-domain datasets.

2.2 Related work on generative dialog models

Similarly, while the advent of large pretrained models has sparked ample research on generative models for dialog (Bao et al., 2021; Peng et al., 2021; Roller et al., 2021; Shuster et al., 2022; Cohen et al., 2022), this has not carried over to research on tutoring systems, where existing solutions are predominantly rule-based and do not generate open-ended responses. For example, the authors on CIMA define heuristics to select responses (Stasaski et al., 2020). Pretrained transformers in general have only very recently been studied in this setting, however only for dialog act classification (Suresh et al., 2022b) and to study the pedagogical ability of existing large pretrained models (Tack and Piech, 2022).

3 Dialog Tutoring Models

After introducing the dialog tutoring task, this section highlights the models we evaluate on the task. We note that our aim is an analysis of existing models.

We explore turn-level models that can generate a teacher response $\mathbf{y} := u_{t+1}$ given a tutoring session $\mathcal{H} = (u_1, \ldots, u_{|\mathcal{H}|})$. During training, we obtain the dialog history by teacher forcing, i.e., we take the ground-truth dialog history. Furthermore, we do not model the problem of retrieving grounding information but rather assume it as given.

Generative Model In order to study if generative models can capture a *given* teaching strategy, we first derive a model that assumes the ground-truth dialog act sequence $\mathbf{a} = \{\mathbf{a}_1, \ldots, \mathbf{a}_{|\mathcal{H}|}\}$ to be given as an input. Then, given dialog history $\mathcal{H}_{<t} = \{u_1, \ldots, u_t\}$, grounding information K and $\mathbf{a}_{t+1} \subseteq \mathcal{A}_{\text{teacher}}$, the set of dialog acts relevant at timestep $t + 1$, the teacher response $\mathbf{y}$ is generated according to a locally-normalized language generation model. In the case that no grounding information K is given, the dependency on K may be dropped.

$$\begin{aligned} \mathbf{y}^{\star} &= \operatorname*{argmax}_{\mathbf{y} \in \mathcal{V}^*} \{p\left(\mathbf{y} \mid \mathbf{a}_{t+1}, \mathcal{H}_{<t}, K\right)\} \qquad (1) \\ &= \operatorname*{argmax}_{\mathbf{y} \in \mathcal{V}^*} \prod_{i=1}^{|\mathbf{y}|} \{p\left(y_i \mid \mathbf{y}_{<i}, \mathbf{a}_{t+1}, \mathcal{H}_{<t}, K\right)\} \end{aligned}$$

We separate the turns in the dialog by special ⟨teacher⟩ and ⟨student⟩ tags and prepend the dialog act as a special token, followed by a special ⟨knowledge⟩ token and the grounding information K as the input to the encoder. In CIMA we encode the triples defining the grounding information in a simple natural language format, where we separate the English and Italian words for an object, color, and preposition as well as the whole phrase by the word "is", for example as "blue is blu" in Figure 1. Further, we add the grammar rules separated by a special token. We study different models to parametrize p that are described in Section 4.

Finally, we use the version of **CTRL** (Keskar et al., 2019) presented by Rashkin et al. (2021). The aim of the model is to improve the faithfulness of grounded response generation models, a significant problem in neural language generation (Roller et al., 2021) which holds high importance in the field of tutoring, where one trusts a teacher to present correct information. The model is augmented by a sequence of control tokens that are intended to steer the generations to desirable properties. We use the *lexical overlap* and *entailment tokens*, which we obtain as follows. In training, the lexical overlap is measured on a token-level between ground-truth response and grounding. Then, three equally sized buckets are created indicating

Dataset	Train samples	#DA	Tgt. length	Src. length	#prev. turns	corpus-div.	Flesch score	F1($\hat{\mathbf{y}}, K$)

Table 1: Statistics of dialogue datasets with lines separating groups by task - tutoring, task-oriented, open-domain dialog tasks. Target length and source length in average number of tokens (Bart tokenizer), # prev. turns is averaged for each teacher response, corpus-div is ngram entropy averaged for uni to four-grams. * We only count system dialog acts.

low, medium, and high overlap which is indicated by a control token. Entailment is determined by an MNLI model and again a corresponding token is added. At test time, we always use the token that encourages the desirable property, in this case high lexical overlap and entailment. Finally, using a sequence of control tokens $\mathbf{c}$, the model from equation 1 becomes:

$$p\left(\mathbf{y} \mid \mathbf{a}_{t+1}, \mathbf{c}, \mathcal{H}_{<t}, K\right) \tag{2}$$

Joint Model In order to study how well current neural models can decide on a reasonable teaching strategy and perform in real case scenarios, we also implement a model that first decides the dialog act $a_{t+1} \in \mathcal{A}_{\text{teacher}}$ (instead of assuming the ground-truth dialog act) and then uses it to generate a response $\mathbf{y} = u_{t+1}$. We use a simple model that again takes the grounding and dialog context as input but now generates the concatenation of dialog act and response in one utterance, akin to SOLOIST (Peng et al., 2021). Thus, for a given $\tilde{\mathbf{y}} := \mathbf{a}_{t+1} \circ \mathbf{y}$ with act sequence $\mathbf{a}_{t+1}$ of length N and response $\mathbf{y}$ of length T, the model is

$$p\left(\tilde{\mathbf{y}} \mid K, \mathcal{H}_{<t}\right) = \prod_{i=1}^{m+N} p\left(\tilde{y}_i \mid \tilde{\mathbf{y}}_{<i}, K, \mathcal{H}_{<t}\right) \tag{3}$$

In training, we use teacher forcing and prepend $\mathbf{a}_{t+1}$ to $\mathbf{y}$ to obtain the label sequence. At test time, the model performs a beam search over the dialog act sequence and response jointly.

Retrieval-based model Since generative models are known to produce erroneous outputs that are factually incorrect and potentially inappropriate (Ji et al., 2022), we also experiment with using a retrieval-based model that selects responses from the training corpus at test time. As opposed to previous work on the topic (e.g., Stasaski et al. (2020)), we do not employ a rule-based model but rather a learned retrieval model that does not require handcrafting elaborate and possibly brittle rules. Therefore, we use the **Bi-Encoder** architecture (Mazaré et al., 2018; Dinan et al., 2019) where a dialog context encoder $\text{enc}_{\mathcal{H}_{<t};\theta}$ and a response encoder $\text{enc}_{\mathbf{y};\theta}$ encode context $\mathcal{H}_{<t}$ and possible responses $\mathbf{y}$ into a fixed size vector of same dimension n. In our experiments, the weights θ of both encoders are shared.

The model is trained using contrastive learning. Suppose we are given a training pair $\mathcal{H}, \hat{\mathbf{y}}$ from a training dataset $\mathcal{D}$ that we use for teacher forcing. We then train the model by sampling a negative response $\bar{\mathbf{y}}$ from the set of responses in $\mathcal{D}$ and using the Triplet Loss criterion, which for a metric function $d : \mathbb{R}^n \times \mathbb{R}^n \to \mathbb{R}$ is defined as:

$$\begin{aligned}\mathcal{L}(\theta; \mathcal{H}, \hat{\mathbf{y}}, \bar{\mathbf{y}}) = [m + d(\text{enc}_{\mathcal{H};\theta}(\mathcal{H}), \text{enc}_{\mathbf{y};\theta}(\hat{\mathbf{y}}))\\ - d(\text{enc}_{\mathcal{H};\theta}(\mathcal{H}), \text{enc}_{\mathbf{y};\theta}(\bar{\mathbf{y}}))]_+,\end{aligned} \tag{4}$$

where m is a margin hyperparameter, and d is the euclidean norm in our experiments. Further, we do stratified sampling on CIMA to not select negatives from the same preposition, color, or object that might be false negatives. At test time, given a dialog context $\mathcal{H}_{<t}$, we choose a response $\mathbf{y}^\star$ from the training set $\mathcal{D}$ by maximum inner product search using the decision rule

$$\mathbf{y}^\star = \underset{\mathbf{y} \in \mathcal{D}}{\operatorname{argmax}} \{\text{enc}_{\mathcal{H};\theta}(\mathcal{H}_{<t})^T \text{enc}_{\mathbf{y};\theta}(\mathbf{y})\}. \tag{5}$$

4 Experiments

We use the following models for parameterizing p in Equation 2: A **sequence-to-sequence** model (Sutskever et al., 2014) with a copy mechanism (Gu et al., 2016) trained from scratch. A wide range of pretrained Transformers, namely **BART** (Lewis et al., 2020), **DialoGPT** (Zhang et al., 2020), **T5** (Raffel et al., 2020) and its multilingual version **mT5** (Xue et al., 2021).

Table 2: Comparison of models on CIMA and TSCC. We note that the strong sacrebleu differences are caused by the brevity penalty (all generative models generate too short sequences), †: use predicted dialog act label, others use ground-truth. * numbers taken from (Stasaski et al., 2020) which may not be comparable as there is no standard split of CIMA dataset.

BART and T5 are pretrained encoder-decoder models that were trained on denoising and text-to-text tasks, respectively. mT5 bases on T5 but is multilingual which might help with the code-switched utterances in CIMA. Lastly, DialoGPT is an autoregressive language model based on GPT-2 (Radford et al., 2019) that was pretrained on a large dialog dataset obtained from Reddit. With this, we intend to study whether large-scale dialog-specific pretraining can aid in training educational tutors, as well.

Implementation Details We implement our experiments using the Huggingface transformers library and finetune the checkpoints provided as part of it for all Transformer-based models. For these models, we use an initial learning rate of 3.25×10^{-5}, 500 warmup steps and linear learning rate decay. We train the models using a batch size of 8 and evaluate on the validation sets after each epoch. In the end, we select the best model to be the one that has a minimal loss on the validation set. The sequence-to-sequence baseline is trained from scratch using an initial learning rate of 0.001 for 25,000 steps using the Adam optimizer and a dropout rate of 0.1 We use beam search with a beam size of 10 to generate model responses.

4.1 Dataset splits

Since there are no official dataset splits for CIMA and TSCC, we split both datasets randomly into training, validation and test sets. We provide the exact split of the dataset in an accompanying code repository. For CIMA, we use all such samples with less than three annotated tutor responses for training. The other conversations are split randomly into equally-sized validation and test sets which results in 2715/300/300 samples each.

For TSCC, we split randomly along the conversations to obtain 82/10/11 training, validation, and test conversations each.

4.2 Evaluation metrics

To evaluate our models, we use the BLEU implementation provided by the sacrebleu package (sBLEU) (Post, 2018) to measure lexical overlap between generated and ground-truth response. Furthermore, we use BERT F1 (BERTScore) to measure their semantic similarity. Lastly, for CIMA we also calculate Q^2 (Honovich et al., 2021) which measures the factual consistency of the response $\mathbf{y}$ with the grounding information K by employing a question-answering based matching. Both BERTScore and Q^2 have shown strong correlation with human judgements on factual consistency Honovich et al. (2022).

5 Results

In this section, we summarize our main findings in terms of automatic evaluation. First, we give an overview of the performance of different models that we train on CIMA and TSCC in Section 5.1. Then, we assess their ability to stay faithful to teaching strategies (Section 5.2) and study how grounding annotations can influence the faithfulness of neural dialog tutors (Section 5.3), before studying their scaling behavior with dataset size and complexity (Section 5.4) and their generalization capabilities (Section 5.5). We then finish with an assessment of using education-specific data for pretraining (Section 5.6).

	Method				
	GT	BART$_{\text{base}}$	BART$_{\text{large}}$	CTRL	Retrieval
DA F1	78.3	**81.0**	70.1	63.0	43.1

Table 3: F1 score of the dialog act classification based on the generated responses of our models.

5.1 Comparison of different models

Table 2 shows the key results from our experiments. First, all automatic metrics are *significantly higher* on CIMA, which indicates that the models can fit CIMA much better than TSCC, with which current approaches still struggle. We further analyse this finding in Section 5.2 and show that this is because TSCC has *richer teaching strategies which are harder to model*. Our comparison also suggests that finetuning large pretrained *Transformer models generally gives better results than the rule-based and LSTM model* reported in (Stasaski et al., 2020), and our implemented retrieval and sequence-to-sequence baselines. This illustrates the potential of LLMs for dialog tutoring.

We also see a significant difference among different LLMs. Dialog-specific pretraining of DialoGPT does not help and gives worse results than BART and T5, primarily because the model tends to generate short and generic responses more often. Multilingual pretraining in mT5 improves over T5 only in some metrics, notably in BLEU and BERT F1 on CIMA but not in terms of Q^2. Similarly, adding control tokens to BART does not improve Q^2 or other automatic metrics. Surprisingly, using very large models actually degrades performance in our experiments. Finally, the last two rows show results obtained with our joint model that does not use the ground-truth dialog act but predicts it together with the response sequence and still provides reasonable performance.

5.2 How well can generative models capture teaching strategies?

We study this question first by evaluating the dialog act prediction accuracy of our joint model. We find that it is *significantly low* on TSCC with 21.8 compared to 71.2 on CIMA for BART-base which indicates significant room for improvement. Notably, the joint model tends to predict more frequently occuring dialog acts, which results in fewer follow-up questions and "Other" never being predicted in CIMA, the least frequent act in the data. The distribution of dialog acts in the ground-truth annotations and model predictions with a BART-base joint model is in Figure 2.

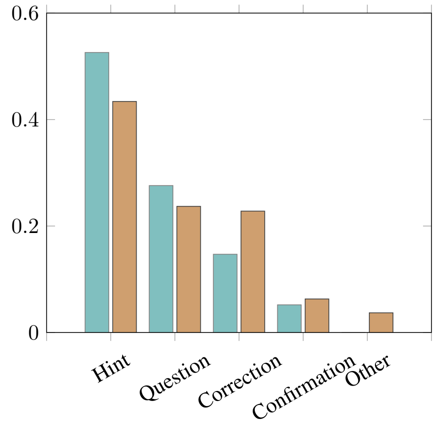

Figure 2: Distribution of predicted and ground-truth dialog acts on CIMA.

Model	sBLEU (↑)	BERT F1 (↑)	Q^2 (↑)
BART-base	6.69 / 38.6	0.718	0.571
+ triples	9.20 / **45.3**	**0.730**	0.642
+ grammar rules	**9.58** / 42.5	0.726	**0.680**

Table 4: Comparison of models with different inputs on CIMA. Triples are made up of preposition, object, and color translations. Grammar rules are a textual description of a learning concept.

Then, we evaluate how well different models can stick to a given ground-truth dialog act by predicting the dialog act of the *generated response* with a BART-base model trained to predict the ground-truth dialog act sequence based on the ground-truth response. The results are shown in Table 3. Notably, *BART-base performs better than the ground-truth annotations*. The CTRL model, on the other hand, has worse performance since the control tokens do not respect tutoring principles (e.g., lexical overlap to grounding discourages follow-up questions in favor of just giving hints).

5.3 Does grounding in learning concepts help?

Prior work has shown that grounding responses in relevant data can improve their quality, especially in terms of faithfulness (Shuster et al., 2021). We intend to validate this for dialog tutoring by studying three models with different inputs on CIMA. The first model is not provided grounding information, whereas the second and third are grounded in learning concepts (cf. Equation 1) with one using only the (preposition, object, color) triples and the other making use of additional grammar rules. The results with these models are shown in Table 4 and suggest that *grounding responses in relevant knowledge helps the model to produce better and*

Table 6: Influence of pretraining on educational and non-educational data. Please note that no grounding information is used in this setting.

more faithful responses.

5.4 How do models scale with more data?

Due to the limited availability of high-quality pedagogical datasets and the time-consuming process of authoring new materials (MacLellan and Koedinger, 2020), it is important to understand how quickly generative models can generalize to new settings. Thus, we assess how well the model can model tutoring in low-resource scenarios. We construct a study, where we randomly sample subsets of the CIMA training set and test the performance of the various models. We can see from Figure 3(a) that with more training data, the faithfulness of responses appears to improve and is not saturated before we reach the full training set. This supports the intuition that *additional training data might improve the performance further*.

Similarly, we study how well our model can deal with an increase in complexity with respect to learning concepts at similar training data sizes. Therefore, we construct different training datasets with 735 samples and a varying number of concepts each time. We begin by taking samples concerned with the concept “in front of the” and evaluate exclusively on it, gradually adding new concepts. Figure 3(b) suggests that Q^2 drops sharply at four concepts. BLEU on the other hand increases, and this might be due to the metric encouraging generic utterances that, for example, repeat a grammar rule.

5.5 Can models generalize to new concepts?

As the students progress and gain new knowledge, it might be a desirable property of dialog tutoring models to be able to handle new concepts that suit this increase in prior knowledge. Hence, we study how well our CIMA model can generalize to new concepts that it has not seen in training, for example, a new preposition. For this analysis, we create a set-up where we first train the model on all of the training data and evaluate on the subset of samples for each preposition separately. We then compare this number to a model that is not trained on the corresponding concept it is evaluated on, creating a zero-shot set-up which we carry out for a grounded and ungrounded response generation model. As measured by Q^2 (cf. Table 5), this model can indeed *generalize to new concepts well, albeit with performance degradation*. Furthermore, *grounding information improves generalization* as these define the learning concept (in this case the preposition) and how it is used. Without this information, we observe that the model generates generic responses more often.

5.6 Does education-specific pre-training help?

As educational data are widely available on the internet, next we study how education-specific pretraining effect results. In Table 6, we show results obtained with finetuning a BART-base model directly on CIMA and pretraining it on tutoring dialogs from TSCC or non-tutoring dialogs from MultiWoZ 2.1 (Eric et al., 2020), Personachat (Zhang et al., 2018), CMU DoG (Zhou et al., 2018), DSTC9 (Kim et al., 2020) and Topicalchat (Gopalakrishnan et al., 2019). In both cases, we only see *minor improvements*, which may be explained by the different dataset settings and the lack of a unified dialog act taxonomy.

6 Human Evaluation

We further evaluate previously assessed models with human judgments firstly by obtaining quality estimates according to different criteria and secondly by conducting a simulation study, where expert annotators are asked to provide novel rewritings of existing conversations and to categorize errors made by the model.

6.1 Quality of the generated responses

We perform a human quality evaluation of the generated response for four models - retrieval (Bi-Encoder), BART-base, BART-base$_{\mathrm{CTRL}}$ and the joint model (BART-base). A randomly chosen subset of the CIMA test set conversations were annotated by 4 annotators (with one annotator speaking C1 level Italian). All annotators labeled 60 examples in total, of which 20 overlapped. To further distinguish the quality of training data for the models, we annotated ground-truth responses on a small sample of 20 examples. We evaluate the following criteria on a 3-point Likert scale (disagree to completely agree) and outline our findings in the following, as shown in Figure 4.

Fluency *"The response is grammatically correct and fluent."* We find that all models have very high fluency scores.

Coherence *"The response naturally follows up on previous utterance and context and has no logical conflicts with the context or DA label."* We find that all generative models are able to produce coherent responses but not the retrieval model.

Correctness *"The response is factually correct and respects learning concepts being taught."* All models score comparable to ground-truth responses on the constrained CIMA dataset. It is noteworthy, however, that a response may be correct in itself but not coherent with the context or the grounding (often the case in the retrieval model), and this could explain the discrepancy between correctness and our automatic Q^2 scores.

Equitable tutoring *"The response gives a learning opportunity for the student by providing space for reflection, explanation, pointing to follow-up challenge, or engaging student in other ways."* Here we find significant deficiencies not only for our evaluated models but notably also for the annotated ground-truth responses (gt). This might explain the insufficiencies in the responses as they reflect this distributional behavior of the training data. We think that future dataset collections should take better care of this property and resort to more expert annotators as opposed to crowdsourcing.

Quality Attribute	sBLEU	BERTScore
Fluency	0.14	0.12
Coherence	0.17	0.26
Correctness	0.06	0.15
Equitable Tutoring	0.08	0.16

Table 7: Pearson correlation coefficients between the human judgements on our quality criteria and automatic metrics.

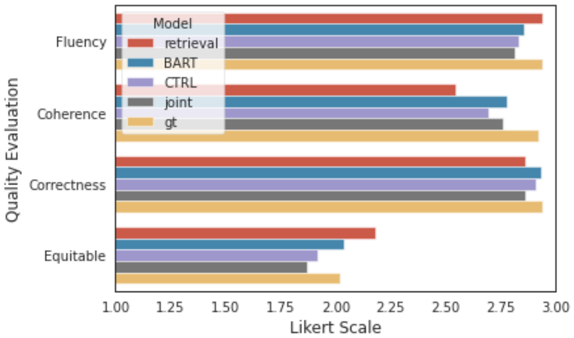

Figure 4: Comparison of models on four criteria (reporting M) in the human quality evaluation. We observed high SD for coherence and equitable metrics.

Furthermore, Table 7 shows that our automatic metrics correlate poorly with human judgements.

6.2 User study with a learning interface

Lastly, we seek to study how well dialog tutoring models can perform in a realistic setting with questions obtained from real users (containing out-of-distribution samples) and not the fixed dataset. Therefore, we randomly sampled conversations from the CIMA test set. We asked two C1-level expert Italian speakers to 1) rephrase these conversations using a conversational dialogue interface and 2) assign erroneous model responses to predefined error categories. The interface used in the qualitative evaluation is shown in Figure 6. We obtain all model responses from the BART-base model that first predicts the dialog act and then the response. Error categories adopted from previous work (Bommasani et al., 2021) describe the ideal behavior of tutoring models as simulating the behavior of good human teachers along two dimensions:

Understanding *"Being able to understand and reason about student solutions, misconceptions, and learning concepts."* We find that of the 20 modified conversations, 45% exhibit *Understanding errors*, such as an incorrect solution assessment or incorrect translations.

Pedagogy *"Being able to use effective pedagogy to instruct students."* We find that 10% of the responses exhibit *Pedagogical errors*, for example telling the correct solution directly without offering any engagement point to the student.

50% of the conversations were labeled good by the annotators. Examples of the conversations are available in Table 8.

7 Discussion: Towards More Equitable and Faithful Tutoring Systems

In this section, we outline directions of research that we think can be important steps towards more equitable and faithful tutoring models. Namely, we first address the small scale and quality of current tutoring datasets and cast doubt on the crowdsourcing data quality checks. Then, we suggest ways of improving the underperformance of both equitable tutoring and teaching strategy prediction identified in current generative models under these constraints by drawing from learning sciences literature. Finally, we outline desiderata for more reliable dialog evaluation of neural tutoring models.

Datasets Based on the analysis in §2.1 and Table 1, we think that the community will benefit from a dataset that lies between CIMA and TSCC in terms of its difficulty. Moreover, the low equitable tutoring scores of CIMA's ground-truth responses indicate that crowdsourcing with untrained annotators can lead to low pedagogical quality. A similar observation has been found by human evaluation for the TSCC dataset (Tack and Piech, 2022). Finally, we encourage the establishment of better dialog act taxonomies that are backed by learning sciences research. As outlined in §5.6 and in He et al. (2022), a unified taxonomy may also strongly aid in transfer learning.

Models So far, dialog tutoring models have only covered limited domain-specific settings linked to a particular activity, such as learning Italian prepositions or solving math word problems. We argue that the community could benefit from working on problems common to learning in general, for example tracking problem-solving states and modeling pedagogies used by teachers. Here, knowledge tracing (Corbett and Anderson, 1994) (the problem of estimating students' skill mastery level) could be used for tracking problem-solving states and increasing the coherence of dialog tutoring conversations and dialog act selection performance which would contribute to better modeling of global teaching strategies. Furthermore, validated instruction quality coding schemes (Michaels et al., 2010; Hennessy et al., 2016) used by classroom teachers can be computationally modeled (Demszky et al., 2021; Ganesh et al., 2021) and incorporated into models.

We also think that recently proposed constrained decoding approaches that can balance between multiple criteria (Qin et al., 2022) hold great promise in improving faithfulness in complex tutoring dialogs. Finally, as data collection is labor-intensive in expert domains, we see great potential in few-shot learning methods, such as prompt-based methods (Schick and Schütze, 2022).

Evaluation Our experiments highlight the insufficiencies of current automatic dialog evaluation metrics, as both BLEU and BertScore show comparatively low correlation with our collected human judgements from §6.1. This is in line with previous research (Mehri and Eskenazi, 2020; Mehri et al., 2022) and shows the necessity not only for better automatic evaluation metrics but also for verification based on human judgements or user studies that should incorporate criteria relevant to tutoring (e.g., equitable tutoring outcomes). Metrics that incorporate task success, which have been used in task-oriented dialog systems (Budzianowski et al., 2018), are a promising direction of future research for automatic evaluation.

8 Conclusion

In this work, we reflected on the state of research in dialog tutoring and explored the potential of neural generative models in this domain. We found some promising initial results with these models in comparison to rule- or retrieval-based methods. However, we also established limitations of currently available benchmarks and evaluation criteria. Furthermore, we showed that there are a number of challenges that need to be addressed before neural generative models of text can be deployed as intelligent tutoring systems on a larger scale, such as controllability and being able to model a sound pedagogical strategy. Based on these findings, we outline potential avenues for future research.

Limitations

A key limitation of our work is the use of only two available tutoring datasets. Despite a limited number of datasets available in this domain, using the TalkMoves dataset (Suresh et al., 2022a) could help further generalize our findings. This remains an avenue for future work.

Based on the prior work, we focused on the specific conversational goal of dialog tutors which is providing learning aid for students' skill development and more opportunities to learn. While this is the most widespread type (Wollny et al., 2021), it is not covering all the goals of human tutors, and other aspects could be important, for example, rapport-building or mentoring on the meta-cognitive level. We acknowledge this both as a prerequisite for our work and at the same time as a limitation. For further discussion we refer the reader to Appendix B and C.

Finally, our user study could be further extended with more participants. In the future, we plan a more comprehensive study with real language learners using an end-to-end dialog tutoring system.

Ethics Statement

We do not foresee any significant harm directly as a result of our work. Having said that, we must understand that automatic tutoring is a high-stake setting that can pose significant harm if appropriate care is not taken before the deployment of these systems. Issues of biases and lack of trust, and other ethical issues such as privacy concerns must be considered. Considering learners only as data points within a neural dialog tutoring context may prevent us from seeing the societal and socioeconomic barriers that they may be up against, thereby running the risk of not only failing to help relevant learner subgroups but also sometimes giving additional privileges to those who use these systems.

9 Acknowledgements

This project was made possible by an ETH AI Center Doctoral Fellowship to Jakub Macina with partial support by the Asuera Stiftung and the ETH Zurich Foundation and has received funding by the German Federal Ministry of Education and Research and the Hessian Ministry of Higher Education, Research, Science and the Arts within their joint support of the National Research Center for Applied Cybersecurity ATHENE. We thank the group members and our reviewers for their valuable feedback.

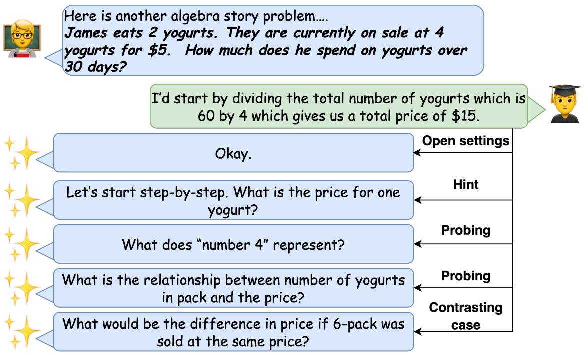
A Pedagogical strategy and dialog acts in dialog tutoring



Here is another algebra story problem....

James eats 2 yogurts. They are currently on sale at 4 yogurts for $5. How much does he spend on yogurts over 30 days?

I'd start by dividing the total number of yogurts which is 60 by 4 which gives us a total price of $15.

Okay.

Let's start step-by-step. What is the price for one yogurt?

What does "number 4" represent?

What is the relationship between number of yogurts in pack and the price?

What would be the difference in price if 6-pack was sold at the same price?

Figure 5: Example dialogue between a tutor and a student solving an algebra story problem. Key questions are: What teacher pedagogical strategies are the best in terms of learning gains of students? How to adapt language models to generate pedagogically valid responses?

In the context of this paper, we assume that the pedagogical strategy is represented using dialog act annotations. An example of the teacher strategy is providing hints (cf. example in Figure 5), where a teacher provides helpful support or clarifies goals to the student. Another example is Probing (cf. example in Figure 5), which prompts students to explain better or reflect on the current solution. CIMA contains five teacher dialog acts - *hint, open-ended question, correction, confirmation, other*. TSCC contains more fine-grained dialog acts such as *eliciting, scaffolding, enquiry, or recap*.

From a learning science standpoint, pedagogical strategy could be viewed as a global strategy (knowing how to effectively guide students e.g. using questioning or providing contrasting cases) and dialog acts as a specific decision on how this strategy is implemented on the local turn-based level.

B Equitable tutoring

Although tutoring is typically conceived as a scenario where a subject matter expert works synchronously with one or multiple students and takes interpretive authority, there is increasing empirical evidence supporting the case for incorporating active learning approaches in the classroom (Freeman et al., 2014; Sinha and Kapur, 2021). With collaborative creation of knowledge where teachers position themselves as co-learners and students also take interpretive authority, such approaches are better poised to build classroom equity than monologic educational practices where only one voice (primarily the teacher's) tends to be heard, legitimized and sometimes imposed. Therefore, if we rethink of the goals of education as providing opportunities for students to enter into the workforce with a positive identity about themselves and the subject matter, equitable tutoring via increased student chances to pose ideas, construct knowledge and as a result feel welcomed into the intellectual discussion, holds tremendous promise.

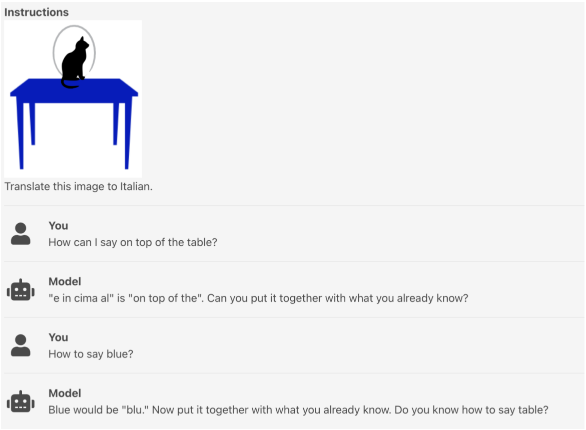
C Conversational Goals

In this work, we studied only 1:1 dialog tutoring settings with a specific focus on the role of a teacher/tutor. We focused on the most commonly used goal of dialog tutoring which is a learning aid to support students' skill development and provide opportunities to learn (Wollny et al., 2021).

However, teacher-student interactions may entail multiple conversational goals that can serve interactional functions (e.g., turn-taking) and interpersonal functions (e.g., rapport-building moves such as self-disclosure, praise, social norm violation). Research in human tutoring and collaborative learning, more generally, has shown that how students manage the task space (consisting of the problem to be solved, e.g., do I agree with the interlocutor's reasoning?) and the relational space (consisting of the interactional challenges and opportunities, e.g., can I disagree without threatening the interlocutor's face?) is critical to learning outcomes (Roschelle and Teasley, 1995; Zhao et al., 2016). Neural dialog tutoring, which can account for this crucial, but fundamental distinction among conversational goals is challenging.

D Qualitative user evaluation

The interface used in the qualitative evaluation is shown in Figure 6.



Instructions

Translate this image to Italian.

You
How can I say on top of the table?

Model
"e in cima al" is "on top of the". Can you put it together with what you already know?

You
How to say blue?

Model
Blue would be "blu." Now put it together with what you already know. Do you know how to say table?

Abstract

Discrete prompts have been used for fine-tuning Pre-trained Language Models for diverse NLP tasks. In particular, automatic methods that generate discrete prompts from a small set of training instances have reported superior performance. However, a closer look at the learnt prompts reveals that they contain noisy and counter-intuitive lexical constructs that would not be encountered in manually-written prompts. This raises an important yet understudied question regarding the *robustness* of automatically learnt discrete prompts when used in downstream tasks. To address this question, we conduct a systematic study of the robustness of discrete prompts by applying carefully designed perturbations into an application using AutoPrompt and then measure their performance in two Natural Language Inference (NLI) datasets. Our experimental results show that although the discrete prompt-based method remains relatively robust against perturbations to NLI inputs, they are highly sensitive to other types of perturbations such as shuffling and deletion of prompt tokens. Moreover, they generalize poorly across different NLI datasets. We hope our findings will inspire future work on robust discrete prompt learning.[1]

1 Introduction

Pre-trained Language Models (PLMs) have been successfully adapted to a wide range of Natural Language Processing (NLP) tasks using *prompt-based* learning (Radford et al., 2018, 2019; Brown et al., 2020; Petroni et al., 2019) such as sentiment classification (Gao et al., 2021), natural language inference (NLI) (Schick and Schütze, 2021, 2022), relation extraction (Shin et al., 2020), cross-lingual inference (Qi et al., 2022). However, manually writing prompts that generalize well is very challenging for several reasons such as (a) it might not always be possible to recruit domain-expert human annotators, (b) human annotators might not be able to cover all corner cases by writing prompts, and (c) there can be disagreements between human annotators regarding the coverage of a particular prompt. To address these challenges, automatic learning of discrete prompts has been proposed such as AdvTrigger (Wallace et al., 2019), AutoPrompt (**AP**; Shin et al., 2020), WARP (Hambardzumyan et al., 2021), and RLPrompt (Deng et al., 2022).

Although discrete prompt learning methods have achieved good performance in numerous downstream tasks by automatically learnt prompts, such automatic prompts seem to be significantly different from the manually-written ones. For example, Table 1 shows manually-written and AP-learnt prompts for fact retrieval (Petroni et al., 2019). We see that the AP-learnt prompts for BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) outperform the manual prompts in precision1 (P@1) scores. However, the AP-learnt prompts contain various counter-intuitive language constructs such as punctuation (e.g. '(', '?', '!', ')'), spelling errors (e.g. *commuenrug*) etc., which seem unrelated to the target relation. Similar cases can be observed for AP-learnt prompts for other tasks as well (see Appendix in Shin et al. (2020)). It is unrealistic that a human annotator would be able to write such prompts even if they were able to see the same training instances as used by automatic methods.

Considering the fact that discrete prompt learning methods are trained in a few-shot setting where they use only a small number of training instances, the seemingly counter-intuitive nature of the discrete prompts learnt by automatic methods raises concerns about their robustness. For example, *How will the performance of a target task change if we add small random perturbations to the prompts learnt by AP?* and *Whether the prompts learnt by AP generalize to out-of-domain data?*. To study these issues, in this paper we evaluate the robust-

ness of discrete prompts learnt by automatic prompt learning methods and compare that with manually-written prompts and direct fine-tuning of PLMs.

An evaluation of the robustness of discrete prompts is important for two main reasons. First, given that discrete prompt learning methods are learning those prompts from a small set of training instances, it is important that they cover the core patterns that generalize to the target task and not simply capture some random artefacts in the training samples. Second, unlike embedding-based continuous prompts (Li and Liang, 2021; Lester et al., 2021), discrete prompts (Wallace et al., 2019; Shin et al., 2020; Deng et al., 2022) are represented in natural language and supposed to be interpretable. However, if a discrete prompt learning method is less robust, a seemingly harmless perturbation such as removing a punctuation character can significantly alter the performance of a downstream task.

In contrast to the numerous work that has used prompts for fine-tuning PLMs, to the best of our knowledge, the robustness of discrete prompts to random or adversarial perturbations has not been systematically studied. To address this gap, we use AP as a concrete example of a widely-used method and evaluate its robustness under different types of carefully designed perturbations. However, we note that our perturbation techniques are not limited to AP and can be used for any discrete prompt learning method. We compare the performance of AP-learnt prompts against fine-tuning using Manually-written Prompts (MP), and Head-based Fine-Tuning (HFT), where we fine-tune both the classifier head and the PLM parameters.

From our evaluation, we find several interesting facts about the robustness of discrete prompts as summarized below.

- Overall, when the number of training instances is increased, MP outperforms both AP and HFT on CB (De Marneffe et al., 2019) and MNLI (Williams et al., 2018), two independent benchmark datasets for NLI (§ 3.1). In particular, the performance of AP on MNLI is much worse than that on CB. This is in contrast to the superior performance of AP on SICK-E (Marelli et al., 2014), another NLI dataset, as reported by Shin et al. (2020).

- Moreover, we see a performance drop when we use discrete prompts learnt from CB for MNLI and vice-versa (§ 3.4). These results indicate that the performance of discrete prompts learnt by AP is highly dataset-dependent and such discrete prompts do not generalize well across datasets.

- Compared to MP, AP-learnt discrete prompts turn out to be highly sensitive to the ordering of prompt tokens (§ 3.2).

- Random deletion of prompt tokens decreases performance in both AP and MP (§ 3.3).

- We create an adversarial NLI dataset from randomly-sampled test instances from MNLI and CB, and manually modify the hypothesis sentences with keeping the corresponding premise sentences unchanged, such that (a) the target label would not change, and (b) would reverse an entailment label to a contradiction (or vice-versa). Both AP and MP remain relatively robust against the perturbations that do not change the target label, but the performance of MP drops significantly in the label-changing setting (§ 3.5). This shows that AP is relatively more robust against adversarial perturbations than MP, which explains AP's superior performance in various tasks.

2 Related Work

Prompting Methods: Prompting or *in-context-learning* has received wide attention as an efficient method to extract knowledge from PLMs (Brown et al., 2020; Petroni et al., 2019; Cui et al., 2021). However, to manually write prompts one must possess task-specific domain knowledge. As an alternative, methods that can automatically learn prompts from training data have been proposed. Two distinct types of prompts have been learnt in prior work: discrete prompts (learns lexical sequences), and continuous prompts (learns embeddings). Continuous prompts (Li and Liang, 2021; Lester et al., 2021) are parameter efficient because they learn generalizable task-specific embeddings, with performance comparable to PLM fine-tuning. However, continuous prompts cannot be learnt when a PLM is publicly unavailable and the only access to it is via an API (Brown et al., 2020). Moreover, compared to discrete prompts, continuous prompts are difficult to interpret. Learning discrete prompts (Wallace et al., 2019; Shin et al., 2020; Deng et al., 2022) does not suffer from these limitations of continuous prompts and can be used with diverse NLP tasks. Especially, fine-tuning massive PLMs has become computationally costly, which has made discrete prompt learning an attractive alternative.

Analysis of Prompting Methods: Prior work has analyzed prompts from various viewpoints. Scao and Rush (2021) studied the effect of training dataset size on fixed-prompt PLM fine-tuning and head-based fine-tuning and found that prompting is often worth 100s of instances on average across classification tasks. Kavumba et al. (2022) showed that the performance of prompt-based models varies significantly depending on the surface cues in the sentence. Lu et al. (2022) found that ordering of task input significantly affects the performance. Utama et al. (2021) focused on the reliance on lexical overlap in sentence pair classification and showed that prompt-based models fail to make predictions dependent on the lexical overlap. To the best of our knowledge, the robustness of discrete prompts under different types of perturbations has not been studied in prior work, which is the main focus of this paper.

3 Experiments

Let us first describe experimental settings common to all experiments.

Prompting and Fine-Tuning Methods: We compared the following methods.

- **AutoPrompt** (**AP**; Shin et al., 2020) is a representative method of discrete prompt learning. The learning strategy is based on fill-in-the-blank task (Devlin et al., 2019). First, a manually created prompt template (e.g., `[X] <MASK> <T> ... <T> [Y]`) is given, and a prompt token (called a trigger token) is learnt by replacing `<T>`, which is a special token representing a trigger token. In the search for trigger tokens, the probability of `<MASK>` is converted into class probability by using label tokens (e.g., {'*nobody*', '*nor*'} for contradiction (Shin et al., 2020)), and trigger tokens are searched by gradient-guided search (Wallace et al., 2019) to find a candidate set consisting of trigger tokens from a vocabulary of the language model. As a template for NLI, we used the one given by Shin et al. (2020), and the prompt tokens were learnt from the training dataset. In our experiments, we used the official implementation.[2]

- **Manually-written Prompts** (**MP**; Schick and Schütze, 2021) is a method for fine-tuning the entire masked language model with training data using manually-written prompts as the input and predicting the `<MASK>` tokens for the labels (e.g., '*yes*' for entailment). We used the template `{hypothesis}? | <MASK>, {premise}` and verbalizer ('*yes*' for entailment, '*no*' for contradiction, '*maybe*' for neutral) following prior work (Schick and Schütze, 2021; Scao and Rush, 2021). Schick and Schütze (2021) proposed an ensemble-based method with multiple rounds of fine-tuning using different templates. However, because a single template is used in AP, for a fair comparison in our experiments, we fine-tuned a PLM using one MP template.

- **Head-based Fine-Tuning** (**HFT**; Devlin et al., 2019) fine-tunes the PLM with a classifier head. We report the head-based results trained by Scao and Rush (2021). They

---

[2] https://github.com/ucinlp/autoprompt

trained HFT with a low learning rate (10^{-5}) and always with a large number of steps (at least 250), following the recommendations in prior work (Mosbach et al., 2021; Zhang et al., 2021). Note that HFT is not a prompt-based method, so it was excluded from some experiments on the robustness of discrete prompts.

Datasets: We used NLI as an evaluation task to compare the robustness of discrete prompting methods. The NLI task has been used in multiple previous studies to evaluate and/or propose novel prompt learning methods because it is a fundamental task related to many NLP applications (Shin et al., 2020; Scao and Rush, 2021; Webson and Pavlick, 2022). It is important to use the same NLI task and datasets in our experiments to facilitate fair comparisons and reach reproducible conclusions. We used the two datasets: CommitmentBank (**CB**; De Marneffe et al., 2019)[3] (a corpus of short texts), and Multi-Genre Natural Language Inference Corpus (**MNLI**; Williams et al., 2018)[4] (a crowdsourced collection of sentence pairs for NLI). Each sentence pair is labelled with *entailment*, *neutral*, or *contradiction*.

PLM: In our experiments, we used the same pre-trained language model to evaluate AP, MP, and HFT equally. Specifically, we used RoBERTa-large (355M parameters) [5] (Liu et al., 2019), which has been used in much prior work in prompt learning (Shin et al., 2020; Scao and Rush, 2021). The PLM was trained on five datasets, including BookCorpus[6], English Wikipedia[7], CC-News[8], OpenWebText[9], and Stories[10]. The texts were tokenised using a byte-level Byte-Pair Encoding (BPE; Sennrich et al., 2016) vocabulary of size 50,000.

Evaluating the Robustness of Prompts: We used *rate of degradation* (**RoD**) (Meyers et al., 2020) to evaluate robustness, which is defined as the decrease in accuracy of the target task due to the perturbations added to the prompt. If the RoD of a model is small after the inclusion of a perturbation, the model is considered to be robust against that perturbation. Specifically, we first calculate the respective accuracies acc_x and acc_{x^*} on the same evaluation set for both prompt x and its perturbated version x^*. Using the average accuracies avg-acc_x and avg-acc_{x^*} over M prompts $x_1, ..., x_M$, we calculate the RoD as $(\text{avg-acc}_x - \text{avg-acc}_{x^*})/\text{avg-acc}_x = 1 - \text{avg-acc}_{x^*}/\text{avg-acc}_x$.

3.1 Effect of the Training Dataset Size

Before moving on to robustness experiments, we first investigate the number of training instances on which AP and MP perform best, and used the best-performing AP and MP to evaluate their robustness in the subsequent experiments.

Experimental Settings: We gradually increased the size of the training dataset following the experimental setup of Scao and Rush (2021). Specifically, we experimented with randomly sampled subsets of the training dataset having varying numbers of instances in $\{10, 15, 20, 30, 50, 70, 100, 150, 200\}$. Because the performance of few-shot learning methods often varies due to the high feature variance in the training data, we randomly sampled four subsets per each dataset size and used them independently for training the models[11] (i.e. trigger tokens and label tokens for AP, or fine-tuned language model for MP and HFT) for each subset and report the average accuracy on the validation data for the four models ($M = 4$). We used the matched (example from the same source as the training set) validation set for MNLI. For CB, we held out 50 training instances for development as in Scao and Rush (2021) and evaluated the original validation set as test data.

We searched for the optimal values for the following hyperparameters: the number of trigger tokens in {3, 5, 10}, the number of label tokens in {3, 5, 10}, and the number of tokens in a candidate set in {10, 50}. We evaluated the test accuracy using the hyperparameters that had the highest accuracy on the validation data for each dataset size. In the training of MP, we used AdamW optimizer (Loshchilov and Hutter, 2019) with an initial learning rate of 10^{-5} and a learning step of 1,000 following Mosbach et al. (2021).

Main Results: Figure 1 shows the performance[12] against the training dataset size. We see that in both CB and MNLI **MP is always superior to AP**. For example, with a dataset of size 200, AP and MP

Method	#Train	Template	#Prompt tokens	#Label tokens per class	Avg. accuracy	
					CB	MNLI
AP	200	p <MASK> <T> ... <T> h	10	3	68.3	37.7
MP	200	h ? | <MASK> , p	3	1	95.1	65.5
HFT	-	<CLS> p <SEP> h	0	-	-	-

Table 2: The average accuracy of the experiment with four training subsets of 200 instances. Red represents the task inputs, h represents the hypothesis, p represents the premise, blue represents the prompt tokens, and <T> represents a trigger token. Unreported values were marked with '-'.

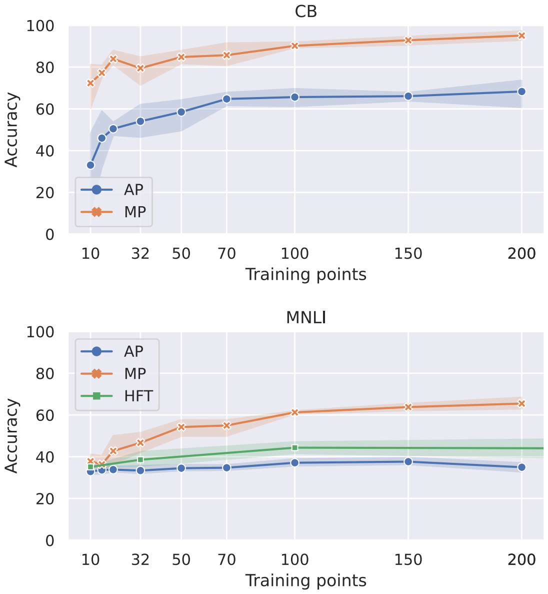

Figure 1: Performance of AutoPrompt (AP), Manually-written Prompt (MP), and Head-based Fine-Tuning (HFT) on the scale of dataset size for CB and MNLI. Means and their 95% confidence intervals are plotted. The accuracy of HFT for dataset size for CB was not plotted because the accuracy was not reported.

achieved the best accuracy in CB, MP's accuracy was 92.7%, while that of AP was lower at 54.2%.

Our results also suggest that **the performance of discrete prompts learnt by AP is highly dataset dependent.** Shin et al. (2020) reported results for AP and HFT on SICK-E (Marelli et al., 2014), which is another NLI dataset. They concluded that AP was always superior to HFT up to training dataset sizes of 1,000 for the same RoBERTa-large PLM that we use. However, our experiments show the opposite trend (i.e. HFT is superior to AP). This suggests that even if AP is superior to HFT on a given dataset, it is not guaranteed to be superior in a different dataset for the same task. This may be due to the differences in the domain and annotation guidelines for each dataset. For example, the accuracy of MNLI was quite low on AP, which contrasts with that of CB. This result suggests that the discrepancies in domains and annotation guidelines make it difficult for AP to perform consistently.

Best Prompts: Table 2 shows the average accuracy of models trained on 200 instances that performed well in both CB and MNLI. Note that there are four training subsets for each dataset size, resulting in corresponding four trained AP prompts and four PLMs fine-tuned by MP.[13] In the robustness evaluations in § 3.2 through § 3.5, we used these learnt APs and MPs. In this paper, (a) trigger tokens learnt by AP, and (b) manually-written prompts excluding the task inputs and mask tokens are collectively referred to as the *prompt tokens*.

3.2 Token Reordering

As seen from Table 1, compared to MPs where the ordering of tokens in a prompt is manually determined, discrete prompts learnt by AP appear to have no obvious ordering among their tokens. To empirically investigate the importance of the token order in a discrete prompt, we conduct an experiment where we randomly shuffle the prompt tokens and measure the effect on the downstream task performance.

Experimental Procedure: Given a discrete prompt, we first randomly reordered its prompt tokens (e.g. shaded in blue in Table 2). Next, we used the reordered prompt with the PLM to make entailment predictions for the test instances in the CB and MNLI datasets. Finally, the entailment prediction accuracy (Acc) obtained with the reordered prompts was computed. We repeated this evaluation 10 times for each prompt and report the averaged values and the corresponding RoD values.

Main Results: From Table 3 we see that the accuracy drops for both AP and MP when the prompt

---

[13] We show the four best prompts learnt by AP in Appendix A.

Method	Metrics	CB	MNLI
AP	Acc	**54.2**	**34.3**
	RoD	**0.21**	**0.10**
MP	Acc	<u>92.7</u>	<u>59.3</u>
	RoD	<u>0.03</u>	<u>0.09</u>

Table 3: Performance of reordered prompts. Acc denotes accuracy; RoD denotes the RoD from before the reordering (Table 2). The largest drops in accuracy are **bolded** and the smallest drops are <u>underlined</u> for each method and dataset. AP relies more strongly on word order than MP.

tokens are randomly reordered. In particular, the accuracy of AP drops significantly compared to that of MP. For example, the accuracy of AP on CB drops by ca. 14% due to token reordering, while that for MP drops only by ca. 2%. Intuitively, one would expect that changing the order of prompt tokens in MP would result in a significant drop in accuracy because the meaning of the prompts would change. However, we see that this is not the case. This result shows that **the discrete prompts learnt by AP strongly rely on the token order**.

Additional Analysis: To further analyze the relationship between the level of perturbation introduced by reordering prompt tokens in AP and its effect on the performance, we computed the token-level edit distance (Levenshtein distance; Levenshtein et al., 1966) between each prompt and its token-shuffled version as shown in Figure 2. For all four AP prompts, we see that the accuracy drops when the perturbation noise (i.e. measured by edit distance) increases. This reconfirms the lack of robustness in discrete prompts learnt by AP to the random shuffling of prompt tokens.

3.3 Token Deletion

As seen from Table 1, the discrete prompts learnt by AP perform better than MP. However, it is often difficult to determine the importance of prompt tokens to the target task due to their lack of interpretability (e.g. prompt token '*neau*' in Table 1). To understand the significance of individual prompt tokens to the overall discrete prompt, we conducted an experiment where we systematically deleted one or more prompt tokens at various positions from a given discrete prompt and measure the drop (if any) in the performance of the NLI task.

Experimental Procedure: We evaluated two settings of prompt deletion: *single* and *multiple* token deletion. In the single token deletion setting, we deleted one token at different positions in a given prompt. For AP, we repeated this with each of the four discrete prompts (shown in Table 2) and report the average accuracy. In the multiple token deletion setting, we delete $n \in \{1, 3, 5, 7\}$ prompt tokens following three strategies: *Random-deletion* deletes n prompt tokens randomly, *Front-deletion* deletes n consecutive prompt tokens from the beginning of the prompt, and *Back-deletion* deletes n tokens counted backwards from the end of the prompt. In random-deletion, we ran 100 trials and report the average accuracy. As in the previous experiments, we used four prompts for AP and report the averaged results.

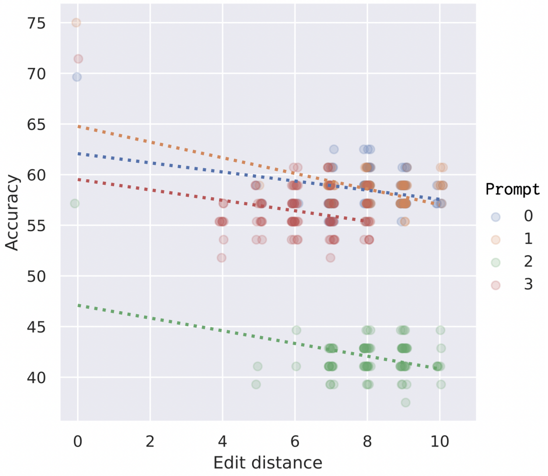

Figure 2: Edit distance and accuracy of the reordered trigger tokens. We evaluated them on the validation data of CB. The prompts numbered 0 through 3 each represent the four prompts learnt by AP (shown in Table 9). Note that a point with an edit distance of zero indicates accuracy with the original trigger token.

Results: From Table 4 we see that the **accuracy of both AP and MP drops even when a single token is deleted** at specific positions. However, the observed trends differ in CB and MNLI. For example, AP resulted in higher RoD values in CB compared to MNLI. This shows that the robustness of AP under single token deletion heavily depends on the dataset. Table 5 shows the results for the multiple token deletion setting. We see that **the performance of both AP and MP degrades when more tokens are deleted.** Interestingly, the accuracy drop in CB is very small for MP even when all prompt tokens are deleted (i.e., only the task inputs and `<MASK>` were used as the input). This suggests that the performance on CB is less reliant on the

Task	Method	Metrics	Position of the deleted prompt token 1	2	3	4	5	6	7	8	9	10	Orig.
CB	AP	Acc	62.1	**61.6**	63.4	59.4	65.6	65.6	62.1	63.8	62.1	62.9	68.3

Table 4: Average accuracy was obtained after deleting a single token at different positions of a given prompt. The largest drops in accuracy over the deletion positions are **bolded** and the smallest drops are underlined for each method and dataset. Column 'Orig.' shows the performance of the original prompt.

prompt tokens in MP.

3.4 Cross-Dataset Evaluation

Given that discrete prompt learning methods such as AP learn prompts from a small set of training instances, it is important that the learnt prompts encode generalizable task-specific features and not random artefacts in the training sample used. To study the transferability of the learnt discrete prompts from one dataset to another, we conduct a cross-dataset evaluation as described next.

Experimental Procedure: We used one NLI dataset (e.g. CB) to learn the prompts and then use them to make entailment predictions in another NLI dataset (e.g. MNLI). We then measured the drop in accuracy using RoD for this cross-dataset transferability task with respect to the accuracy of test data from the same dataset.

Results: As seen from Table 6, **AP-based prompts do not generalize well across datasets.** For both AP and MP, RoD is larger in the transfer from CB to MNLI than in the opposite direction. This implies that MNLI is a better dataset for fine-tuning a PLM for NLI using discrete prompts.

3.5 Adversarial Perturbations

Introducing carefully designed adversarial perturbations to the test instances such as modifications to sentences that might or might not alter the original target labels have been used as a technique for probing the robustness of models (Goodfellow et al., 2015). Previous studies (Samanta and Mehta, 2017; Jin et al., 2020) have shown that pre-trained models can be easily fooled to make incorrect predictions with seemingly innocuous perturbations to the test instances. Therefore, we evaluate discrete prompt-based NLI models for their robustness against adversarially perturbated test instances.

Strategy	Method	Metrics	#Deleted Tokens 1	3	5	7	Orig.

Table 5: Average accuracy was obtained after deleting multiple tokens from a given prompt. The largest drops in accuracy over the deleted tokens are **bolded** and the smallest drops are underlined for each strategy and method.

Method	Test Dataset CB	Test Dataset MNLI	RoD
AP trained on CB	68.3	36.1	0.47
AP trained on MNLI	42.9	37.7	0.12
MP trained on CB	95.1	43.4	**0.54**
MP trained on MNLI	43.8	65.5	**0.33**

Table 6: Accuracy and RoD for the cross-dataset evaluation where a method (AP/MP) is trained on one NLI dataset (CB/MNLI) and the learnt prompts are used to make entailment predictions in a different NLI dataset.

	Hypothesis	Label
Original	The Wither's only had daughters.	contradiction
Perturbation		
w/o label changes	The Wither's did not have sons.	contradiction
w/ label changes	The Wither's had a boy.	entailment

Table 7: Examples of our evaluation set consisting of task inputs with perturbations. The premise sentence is '*The Wither's eldest boy, one of the four of the town militia, saluted in the old style with his stick sword.*'

Evaluation Dataset: For this purpose, we asked two annotators to manually edit hypothesis sentences in NLI test data considering two types of perturbations: (1) perturbations that do not change reference labels, and (2) perturbations that change reference labels. An example is shown in Table 7.

For the first type of perturbation, we edited a hypothesis sentence such that its relationship with the corresponding premise remains unchanged. For the second type, we edited a hypothesis sentence such that its relationship (e.g., from *entailment* to *contradiction*) will be reversed. The premise and hypothesis pairs were sampled from CB (validation set) and MNLI (test set). Because there are ca. 10,000 test instances in MNLI and it is costly to manually edit sentences, we used 100 randomly-chosen sentence pairs covering MNLI and CB.

Experimental Procedure: We computed the RoD of average accuracies obtained with original and adversarial test instances. Specifically, we used the AP prompts in Table 2 under three settings: (a) original (without perturbations), (b) perturbations without label changes, and (c) perturbations with label changes. Then, we calculate RoD from (a) to (b) and (a) to (c) as shown in Table 8.

Results: Overall, we see that the RoD of AP is consistently smaller than that of MP in both CB and MNLI under both types of perturbations. However, it is also clear that the accuracy obtained with AP is much smaller than that with MP. For the perturbations without label changes, both AP and MP show small RoD values, compared to those with label changes.[14] This shows that both AP and MP are relatively robust against modifications to the hypotheses that do not significantly alter the meaning. However, when stronger perturbations are introduced that would result in label changes, the accuracy of both AP and MP drops significantly. [15] This is a concern because it shows that **neither AP nor MP is sufficiently robust to correctly predict the target labels when the hypothesis sentences in test data are adversarially modified.**

Perturbation	Method	Metrics	CB	MNLI
Original	AP	Acc	54.5	40.5
		RoD	-	-
	MP	Acc	95.5	71.0
		RoD	-	-
Perturbation w/o label changes	AP	Acc	55.5	43.2
		RoD	-0.02	-0.07
	MP	Acc	93.0	66.7
		RoD	**0.03**	**0.06**
Perturbation w/ label changes	AP	Acc	42.3	39.4
		RoD	0.22	0.03
	MP	Acc	41.8	61.2
		RoD	**0.56**	**0.14**

Table 8: Accuracy and RoD in prompts for task inputs that include perturbations. The RoD here is the rate of degradation in the average accuracy from the original without perturbations to perturbations without label changes or perturbations with label changes. The largest drops in accuracy are **bolded** and the smallest drops are underlined for each perturbation and method.

4 Conclusion

We investigated the robustness of discrete prompts under different perturbations. We found that although discrete prompts remain relatively robust against token deletion, it is highly sensitive to other types of perturbations such as token shuffling. For adversarial perturbations to the input, discrete prompts were robust to weak perturbations without

---

[14] w/o label change modifications slightly increase the average length of a hypothesis and AP seems to better exploit this extra information for inference resulting in a slight improvement in accuracy (negative RoD).

[15] MP is less robust compared to AP, likely as a result of overfitting to strongly perturbed training data during finetuning the PLM.

label changes, but AP was more robust than MP for perturbations with label changes. Moreover, they generalize poorly across different datasets annotated for NLI. We hope our analysis will inspire future work to develop methods that learn both accurate as well as robust discrete prompts.

5 Limitations

Possible limitations of this work are:

- We chose popular discrete prompt methods of AP and MP and did not investigate other methods in this work. Our analysis procedure can still be applied to other discrete prompts such as AvgTrigger (Wallace et al., 2019).

- We chose RoBERTa-large following previous studies of HFT (Scao and Rush, 2021) and AP (Shin et al., 2020) for reproducible and identical comparisons with them. Other PLMs would lead to different results, but they can also be investigated in the same way as in this work.

- This work focuses on NLI because it is a fundamental natural language understanding task and still difficult even with PLMs (Brown et al., 2020). Other complex downstream tasks are worth investigating for a deeper understanding of prompt-based approaches in future work.

- The results and conclusions are from the English datasets and would differ in other languages. However, our methodologies do not depend on English and can be applied to other languages as important future studies.

- Since there was a performance gap between MP/HFT and AP, the accuracies by the perturbations could be affected. However, this work does not aim to find the best prompt learning method but to analyze the robustness of discrete prompts for a deeper understanding of them.

6 Ethical Considerations

Our adversarial dataset came from existing datasets of CB and MNLI. We visually checked the instances in the data development and found no instances with ethical concerns.

One should also be aware of social biases (e.g. gender stereotypes) in PLM. RoBERTa, the PLM we used in our experiments, is known to have gender biases (Sharma et al., 2021). Since we used it as-is in order to follow the experimental conditions of previous studies using RoBERTa, our current results are possibly influenced by such biases. However, the consideration of the prompt robustness of this work would not pose or magnify such ethical concerns.

Assessing Out-of-Domain Language Model Performance from Few Examples

Abstract

While pretrained language models have exhibited impressive generalization capabilities, they still behave unpredictably under certain domain shifts. In particular, a model may learn a reasoning process on in-domain training data that does not hold for out-of-domain test data. We address the task of predicting out-of-domain (OOD) performance in a few-shot fashion: given a few target-domain examples and a set of models with similar training performance, can we understand how these models will perform on OOD test data? We start from the baseline of looking at model accuracy on the few-shot examples, then investigate how to incorporate analysis of the models' behavior using feature attributions to improve our understanding of generalization. Specifically, we explore a set of "factors" designed to reveal model agreement with certain pathological heuristics that may indicate worse generalization capabilities. On textual entailment, paraphrase recognition, and a synthetic classification task, we show that attribution-based factors can help rank relative model OOD performance. However, accuracy on a few-shot test set is a surprisingly strong baseline, particularly when the system designer does not have in-depth prior knowledge about the domain shift.

1 Introduction

The question of whether models have learned the right behavior on a training set is crucial for generalization. Deep models have a propensity to learn shallow reasoning shortcuts (Geirhos et al., 2020) like single-word correlations (Gardner et al., 2021) or predictions based on partial inputs (Poliak et al., 2018), particularly for problems like natural language inference (Gururangan et al., 2018; McCoy et al., 2019) and question answering (Jia and Liang, 2017; Chen and Durrett, 2019). Unless we use evaluation sets tailored to these spurious signals, accurately understanding if a model is learning them remains a hard problem (Bastings et al., 2021; Kim et al., 2021; Hupkes et al., 2022).

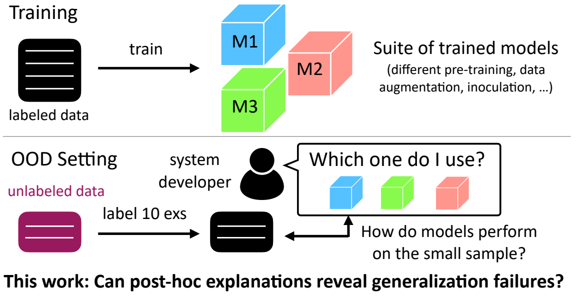

Figure 1: Our setting: a system developer is trying to evaluate a collection of trained models on a small amount of hand-labeled data to assess which one may work best in this new domain. Can baselines / attributions help?

This paper addresses the problem of *predicting* whether a model will work well in a target domain *given only a few examples from that domain.* This setting is realistic: a system designer can typically hand-label a few examples to serve as a test set, but labeling more may be burdensome. Computing accuracy on this small set and using that as a proxy for full-test set performance is a simple baseline for our task, but has high variance, which may cause us to incorrectly rank two models that achieve somewhat similar performance. We hypothesize that we can do better if we can interpret the model's behavior beyond accuracy. With the rise of techniques to analyze post-hoc feature importance in machine-learned models (Lundberg and Lee, 2017; Ribeiro et al., 2016; Sundararajan et al., 2017), we have seen not just better interpretation of models, but improvements such as constraining them to avoid using certain features (Ross et al., 2017) like those associated with biases (Liu and Avci, 2019; Kennedy et al., 2020), or trying to more generally teach the right reasoning process for a problem (Yao et al., 2021; Tang et al., 2021; Pruthi et al.,

2022). If post-hoc interpretation can strengthen a models' ability to generalize, can they also help us understand it?

Figure 1 illustrates the role this understanding can play. We have three trained models and are trying to rank them for suitability on a new domain. The small labeled dataset is a useful (albeit noisy) indicator of success. However, by checking model attributions on our few OOD samples, we can more deeply understand model behavior and analyze if they use certain pathological heuristics. Unlike past work (Adebayo et al., 2022), we seek to automate this process as much as possible, provided the unwanted behaviors are characterizable by describable heuristics. We use scalar factors, which are simple functions of model attributions, to estimate proximity to these heuristics, similar to characterizing behavior in past work (Ye et al., 2021a). We then evaluate whether these factors allow us to correctly rank the models' performance on OOD data.

Both on synthetic (Warstadt et al., 2020), and real datasets (McCoy et al., 2019; Zhang et al., 2019), we find that, between models with similar architectures but different training processes, both our accuracy baseline and attribution-based factors are good at distinguishing relative model performance on OOD data. However, on models with different base architectures, we discovering interesting patterns, where factors can very strongly distinguish between different types of models, but cannot always map these differences to correct predictions of OOD performance. In practice, we find probe set accuracy to be a quick and reliable tool for understanding OOD performance, whereas factors are capable of more fine-grained distinctions in certain situations.

Our Contributions: (1) We benchmark, in several settings, methods for predicting and understanding relative OOD performance with few-shot OOD samples. (2) We establish a ranking-based evaluation framework for systems in our problem setting. (3) We analyze patterns in how accuracy on a few-shot set and factors derived from token attributions distinguish models.

2 Motivating Example

To expand on Figure 1, Figure 2 shows an in-depth motivating example of our process. We show three feature attributions from three different models on an example from the HANS dataset (McCoy et al., 2019). These models have (unknown) varied OOD performance but similar performance on the in-domain MNLI data (Williams et al., 2018). Our task is then to correctly rank these models' performance on the out-of-domain HANS dataset in a few-shot manner.

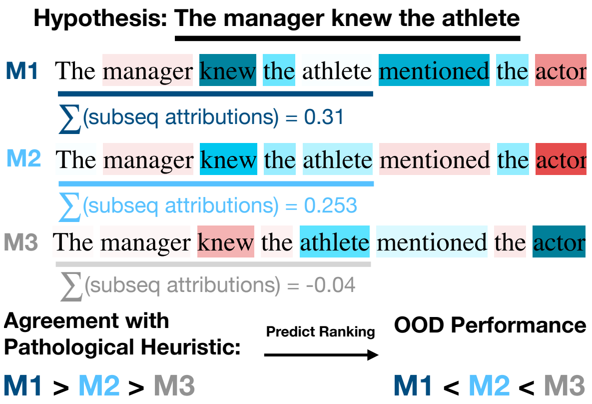

Figure 2: Explanations generated on the same sample for HANS subsequence data models M1, M2, M3 (have ascending OOD performance). The factor (shaded underlines) from knowledge of the OOD allows us to in this example predict the model ranking.

We can consider ranking these models via simple metrics like accuracy on the small few-shot dataset, where higher-scoring models are higher-ranked. However, such estimates can be high variance on small datasets. In Figure 2, only M3 predicts non-entailment correctly, and we cannot distinguish the OOD performance of M1 and M2 without additional information.

Thus, we turn to explanations to gain more insight into the models' underlying behavior. With faithful attributions, we should be able to determine if the model is following simple inaccurate rules called *heuristics* (McCoy et al., 2019). Figure 2 shows the heuristic where a model predicts that the sentence A entails B if B is a subsequence of A. Crucially, we can use model attributions to assess model use of this heuristic :we can sum the attribution mass the model places on subsequence tokens. We use the term *factors* to refer to such functions over model attributions.

The use of factors potentially allows for the automation of detection of spurious signals or shortcut learning (Geirhos et al., 2020). While prior work has shown that spurious correlations are hard for a human user to detect from explanations (Adebayo et al., 2022), well-designed factors could automatically analyze model behavior across a number of tasks and detect such failures.

3 Attributions to Predict Performance

In this section, we formalize the ideas presented thus far. Token-level attribution methods (a subset of post-hoc explanations) are methods which, given an input sequence of tokens $\mathbf{x} \overset{\text{def}}{=} x_1, x_2, ..., x_n$ and a model prediction $\hat{y} \overset{\text{def}}{=} M(\mathbf{x})$ for some task, assign an explanation $\phi(\mathbf{x}, \hat{y}) \overset{\text{def}}{=} a_1, \ldots, a_n$ where a_i corresponds to an attribution or importance score for a corresponding x_i towards the final prediction. For cases where the model, prediction, and inputs are unambiguous, we abbreviate this simply $\phi_i \equiv \phi(\mathbf{x}) \overset{\text{def}}{=} \phi(\mathbf{x}, M_i(\mathbf{x}))$.

We assume that the model is trained on an in-domain training dataset D_T and will be evaluated on some unknown OOD set D_O. Given two models M_0 and M_1, with a small amount of data $D_{(O,t)} \subset D_O$ ($t = 10$ examples or fewer in our settings), our task is to predict which model will generalize better. We break the process into 2 steps (see Figure 2):

1. Hypothesize a heuristic. First we must identify an underlying heuristic H that reflects pathological model behavior in the OOD dataset. For example, the subsequence heuristic in Figure 2 corresponds to a heuristic which always predicts entailed if the hypothesis is contained within the premise. Let $h(M_i)$ abstractly reflect how closely the ith model's behavior aligns with H. Let $s(M_i)$ be the true OOD performance of model M_i. If we then assume that $h(M_i)$ faithfully models some pathological heuristic H, we should have that $h(M_0) > h(M_1) > \ldots > h(M_m)$ implies $s(M_0) < s(M_1) < \ldots < s(M_m)$. In other words, the more a model M_i agrees with a pathological heuristic H, the worse it performs.

2. Measure alignment. We now want to predict the ranking of $s(M_i)$; however, with few labeled examples there may be high variance in directly evaluating these metrics. We instead use factors $f(\mathbf{x}, \phi_i)$ which map tokens and their attributions for model M_i to scalar scores that should correlate with the heuristic H. Factors can be designed to align with known pathological heuristics, where higher scores indicate strong model agreement with the associated heuristic. We then estimate the ranking of $s(M_i)$ using the relative ranking of the corresponding $h(M_i)$ approximated through factors.

Concretely, to measure the alignment, we first compute for each input $\mathbf{x}_j \in D_{(O,t)}$ the prediction $M_i(\mathbf{x}_j)$ and the explanation $\phi(\mathbf{x}_j)$ for that prediction. These $\phi(\mathbf{x}_j)$ are used to compute the score $f(\mathbf{x}_j, \phi(\mathbf{x}_j))$ for model M. We take the overall score of the model to be $F(i) = \frac{1}{t}\sum_{j=1}^{t} f(\mathbf{x}_j, \phi(\mathbf{x}_k, M_i(\mathbf{x}_k)))$, the mean over the t examples in $D_{(O,t)}$. We then directly rank models on the basis of the $F(i)$ values: the higher the average factor value (the more it follows the heuristic), the lower the relative ranking: $F(0) > F(1) \implies s(M_0) < s(M_1)$. Therefore we can sort the models by these values and arrive at a predicted ranking. We later also consider factors which to not intuitively map to specific heuristics.

Baselines We also consider three principle explanation-agnostic baselines. A natural baseline given $D_{(O,t)}$ is to simply use the accuracy (`ACC`) on this dataset: $\frac{1}{n}\sum_{i=1}^{n} \mathbb{1}[y_i = M(\mathbf{x_i})]$, however this may be noisy on only a few examples, and frequently leads to ties.[1]

We also assess model confidence (`CONF`), the softmax probability of the predicted label, as well as looking at `CONF-GT`, the softmax probability of only the ground-truth label.

4 Experimental Setup

4.1 Models Compared

In this work, we compare various models across different axes yielding different D_O performance. The first approach we use is **inoculation** (Liu et al., 2019a), which involves fine-tuning models on small amounts or batches of D_O data alongside in-domain data to increase model performance on OOD data. The second approach we use is varying the model architecture and pre-training (e.g., using a stronger pre-trained Transformer model).

In Section 5, we use inoculation to create 5 RoBERTa-base (Liu et al., 2019b) models of varying D_O performance for each of the three MSGS sets. In Section 6 where we consider the HANS and PAWS datasets, we inoculate a variety of models. For HANS, we inoculate 5 RoBERTa-large models. We additionally examine DeBERTa-v3-base (He et al., 2021b,a) and ELECTRA-base (Clark et al., 2020) models fine-tuned on in-domain MNLI data. For PAWS, we inoculate 4 RoBERTa-base models on the in-domain D_T set. We also inoculate ELECTRA-base and DEBERTA-base models. We include complete details for these models in Ap-

---

[1] Most considered datasets are constructed to mislead models following the heuristic, so this baseline directly measures agreement with a heuristic h.

pendix A. The generated models represent a realistic problem scenario: a practitioner may have many different models with similar D_T performance, but different D_O performance. We specifically crafted suites of models which have both near pairs (models with similar D_O performance) and far pairs.

4.2 Attribution Methods

We experiment using several token-level attributions methods: **LIME** (Ribeiro et al., 2016) computes attribution scores using the weights of a linear model approximating model behavior near a datapoint. **SHAP** (Lundberg and Lee, 2017) is similar to LIME, but uses a procedure using Shapley values. Finally, **Integrated Gradients (TOKIG)** (Sundararajan et al., 2017) compute ϕ_i by performing a line integral over the gradients with respect to token embeddings on a path from a baseline token to the ground truth token; commonly, this baseline token is chosen to be `<MASK>`. While intuitively sensible, Harbecke (2021) has voiced concerns regarding the use of TOKIG in NLP.

4.3 Evaluation Setup

Because model ranking using a small $D_{(O,t)}$ may be unstable, we conduct all experiments over a number of different sampled $D_{(O,t)}$ sets. We first sample M examples from each set (in the range of 200-600), then generate explanations for all models on each example. We then take 400-500 bootstrap samples of size n (we report results for $n = 10$, as experimental results were similar for sizes 5 and 20), simulating many few-shot evaluations. For each bootstrap sample, we analyse $\binom{m}{2}$ model pairs. Details can be found in Appendix B.

We define a "success" as a technique correctly ranking a model pair, when measured by D_O performance (on the full set); otherwise is a "failure". We define *pairwise accuracy* as the accuracy for a method ranking a particular model pair across all bootstrap samples. We define *few-shot accuracy* (or just *accuracy*) as the average of the pairwise accuracies over the $\binom{m}{2}$ model pairs. By reporting ranking accuracy across a diverse set of models, we ensure a comprehensive evaluation.

5 MSGS: A Proof of Concept

We first show experiments on the Mixed Signals Generalization Set (MSGS) dataset presented in Warstadt et al. (2020) as a proof of concept for our methodology. MSGS is a synthetic classification dataset. The training (in-domain) set is composed of sentences where both some linguistic feature (e.g., the presence of an adjective) and a spurious surface feature (e.g., the word "*the*" being in the sentence) are always associated with a positive label $y = 1$. This data is ambiguous, which means the model could rely on either the linguistic or surface feature completely yet still get 100% accuracy on in-domain data. Warstadt et al. (2020) then create sets of OOD data where the linguistic feature becomes associated with the $y = 1$ positive label, and the surface feature with a $y = 0$ label. The resulting test accuracy reflects model reliance on one feature or the other. Warstadt et al. (2020) use this to investigate what generalizations are learned at which stages of model pre-training; we investigate whether information from small probe sets can help assess model reliance on the surface feature.

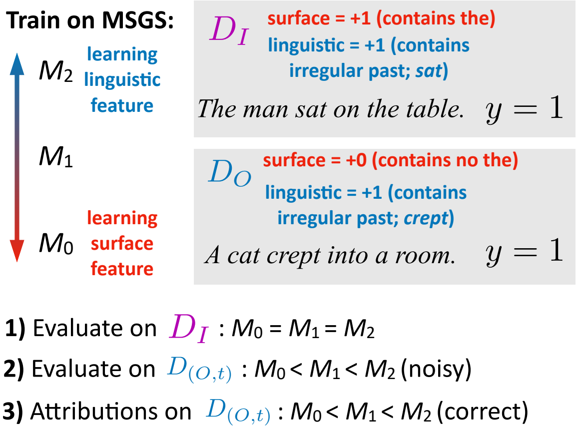

Figure 3: Example from the MSGS train and OOD test sets. The training data conflates a surface and linguistic generalization as described in Warstadt et al. (2020), resulting in models that learn a range of behaviors. Direct evaluation OOD on small data can tell us this, but explanations can also differentiate which of the two patterns is learned and how strongly they are learned.

We consider three linguistic features: MORPH (presence of an irregular past verb like "*drew*"), ADJECT (presence of an adjective), and VERB (if the main verb is an -ing verb), each paired with the surface feature of "*the*" being in the sentence.

We design factors which look at attributions on the tokens corresponding to these linguistic features, including the tokens surrounding these features as well to account for feature dependence on surrounding words. Our factor $f(\mathbf{x}, \phi) = -\sum_{i=(m-2)}^{m+2} \phi(x_i)$, where m is the index of the feature-critical word for that dataset (e.g., "*slept*" for `IRREG`) and $\phi(x_i)$ is the attribution at an in-

Feature	Method	Accuracy		
MORPH	`ACC`	90.9		
	`CONF`	50.9		
	`CONF-GT`	90.1		
		TOKIG	SHAP	LIME
	`IRREG`	89.2	90.6	**92.8**†
VERB	`ACC`	94.5		
	`CONF`	58.0		
	`CONF-GT`	93.3		
		TOKIG	SHAP	LIME
	`VERB`	92.1	94.0	**94.9**
ADJECT	`ACC`	89.9		
	`CONF`	50.5		
	`CONF-GT`	91.3		
		TOKIG	SHAP	LIME
	`ADJ`	87.4	92.1	**93.5**†

Table 1: Few-shot ranking accuracy metric results on $D_{(O,t)}$ for MSGS. `IRREG`, `VERB`, and `ADJ` are detailed in Section 5. † indicates statistically significant improvement over accuracy (paired bootstrap test: $p < 0.05$)

dex. This factor corresponds closely to the heuristic that the dataset was designed for, or alternately, we can see this factor as inversely proportional to what *other* information the model is using (that is, information outside of this window). We name the factors `IRREG`, `VERG`, and `ADJ` for the MORPH, VERB, ADJECT sets respectively.

Note that this approach assumes that a system designer has prior knowledge of the relevant linguistic and surface feature. This is a generous assumption, and for this dataset is almost sufficient to formulate the rule used to construct it, hence why we call this a proof of concept. We will show more realistic conditions in Section 6.

Models To create a suite of models with varying D_O performance, we inoculate following the steps outlined in Section 4.1. We evaluate our factors via accuracy as described in Section 4.3. More details about the inoculation is present in Section A of the appendix.

Results Table 1 shows the results on this dataset. Our `ACC` baseline performs well: when models differ greatly in performance (e.g., one gets 50% and another gets 90% on the D_O), accuracy on the small $D_{(O,t)}$ ranks these correctly even despite the small subset size. The high regularity of the dataset also means that a model's behavior does not vary greatly from example to example, further reducing variance. However, this ranking is nevertheless still not perfect. We see that `CONF` performs very poorly, by contrast, showing that confidence is not helpful for measuring model behavior.

Overall, we see that methods using explanations are able to beat the `ACC` baseline, with the exception of TOKIG. We additionally found trends within the explanation techniques themselves, with LIME reliably performing the best, and TOKIG being the worst. But generally, all techniques can offer relevant information, and in the best case, the attributions can tell us more reliably what a model is learning than evaluation on a small set of $D_{(O,t)}$ data can. In Section 6, we investigate if these results generalize to real-world datasets.

6 Realistic OOD Settings

We now consider two datasets corresponding to realistic OOD settings treated in past work.

First, **HANS** (McCoy et al., 2019) targets spurious heuristics within MNLI (Williams et al., 2018), such as the hypothesis being a subsequence of the premise, with balanced test sets that can be used to detect model reliance on these heuristics. Models following these heuristics always predict *entailed* for the hypotheses, and will perform at random chance accuracy on the dataset. We use MNLI as our in-domain training set in this setting.

Second, **PAWS** (Zhang et al., 2019) is a paraphrase identification task. PAWS-QQP is an OOD dataset for Quora Question Pairs (QQP) (Iyer et al., 2017) that is composed of pairs with swapped content words/phrases (e.g., *I ran from the Grand Canyon to California* to *I ran from California to the Grand Canyon*). A paraphrase model that relies heavily on lexical overlap will not be sensitive to these changes, and will always predict the label of $y = 1$ to indicate paraphrase. We use QQP as our in-domain training set in this setting.

Details regarding models used in this section are presented in Section 4.1. From the test sets of the corresponding datasets, we randomly sample 400 examples from PAWS and 600 from HANS-CON and HANS-SUB each for use in bootstrap sampling, as detailed in Section 4.3. Table 9 provides additional dataset information.

6.1 Factors

General Factors Both HANS and PAWS involve comparing two sequences $\mathbf{a}, \mathbf{b}$ of tokens, unlike MSGS which is classification over a single sequence. We can define our input $\mathbf{x} = a_1, a_2, ...a_n, b_1, b_2, ..., b_m$ as composed of these two sequences $\mathbf{a}$ and $\mathbf{b}$ with respective attributions

ϕ_a, ϕ_b. We evaluate a number of factors that generally target sensitivity to both sequences and their differences, which represent a broad class of potential heuristics.

`MAX-DIFF`: The difference between maximum attribution in $\mathbf{a}$ and $\mathbf{b}$, i.e. $\max(\phi_a) - \max(\phi_b)$.

`SUM-DIFF`: the difference of the sum of attributions, i.e. $\sum_{i=1}^{n} \phi_{a,i} - \sum_{i=1}^{m} \phi_{b,i}$.

`INDEX-DIFF`: The difference of attributions between shared words in $\mathbf{a}$ and $\mathbf{b}$.

`FIRST-TOK`: The attribution at the the first `<SEP>` token.

We explicitly note that this is the exhaustive set of factors we experimented with, not a cherry-picked set, in order to provide a comprehensive view of what does and doesn't work. We crafted these by manually examining attribution patterns on various datasets rather than trying a large number and keeping the best ones.

HANS Factors We look at the "subsequence" heuristic discussed in Section 2 and the constituent heuristic, which assumes that the premise entails all complete subtrees in its parse-tree. For the subsequence OOD set (HANS-SUB) we note that the `INDEX-DIFF` factor, which specifically examines tokens in the shared subsequence, captures the setting's pathological heuristic.

On the constituent OOD set (HANS-CON) we evaluate a factor that examines the attribution on the control words of the premise. For example, for the premise "*Unless the doctors ran, the lawyers encouraged the scientists*" and the hypothesis "*The doctors ran*", we would consider the attributions on the word "*Unless*".

PAWS Factors We further investigate two intuitive heuristics that are based on the construction of the OOD set. `SWAP-AVG` uses the average attribution across all swapped tokens and `SWAP-MAX-DIFF` subtracts the highest magnitude attribution of swapped tokens in the first sentence and the highest magnitude attribution of swapped tokens in the second sentence. For example, for the pair ("*What factors cause a good person to become bad ?*", "*What factors cause a bad person to become good ?*"), `SWAP-AVG` would consider the attributions on "*good*" and "*bad*". `SWAP-MAX-DIFF` is analogous.

6.2 Inoculated Results

We first evaluate models that differ primarily through inoculation, as described in Section 4.1.

	$D_{(O,t)}$		
Ranking Method	PAWS	HANS-SUB	HANS-CON
Baselines			
`ACC`	88.7	90.6	81.6
`CONF`	9.2	40.4	52.8
`CONF-GT`	34.9	20.2	38.9
`RANDOM`	50.7	51.4	49.6
Factors			
`CONST`	–	–	**87.1**
`SWAP-MAX-DIFF`	76.2	–	–
`SWAP-AVG`	**91.4**	–	–
`INDEX-DIFF`	60.5	**91.3**	68.6
`MAX-DIFF`	65.9	69.2	50.6
`SUM-DIFF`	56.6	60.0	75.2
`FIRST-TOK`	74.3	50.4	55.6

Table 2: Few-shot heuristic ranking performance on OOD samples for HANS/MNLI and QQP/PAWS, specifically when comparing **inoculated models** (SHAP explanations). We divide rows by baselines, dataset-specific factors, and general factors.

Results are shown using SHAP in Table 2 which we selected through experiments in this setting as being the best performing. The conclusions here differ somewhat from those on MSGS. We note that the `ACC` baseline remains strong, while `CONF` is near random. We find that *certain* attribution factors are able to outperform the `ACC` baseline, with `SWAP-AVG` the best on PAWS (91.4%), `INDEX-DIFF` the best on HANS-SUB (91.3%), and `CONST` on HANS-CON (87.1%).

This shows that even in settings more realistic than MSGS, **the right choice of factor reveals meaningful information about model generalization**. Moreover, the heuristics that work well are those hand-designed for these datasets, confirming that measuring association with a heuristic via a factor may reveal something about performance.

We qualify these results by noting that in a true few-shot setting, there is some uncertainty regarding whether a chosen factor is truly the best one. As a coarse option, we find `ACC` to be reliable. However, these high-performing factors would still be useful in conjunction with accuracy, or if we had previously validated a factor as ranking models well and we wanted to apply it to rank new models in this domain; the factors will generalize to new models even if they do not generalize to new datasets necessarily.

6.3 Architectural Change Results

We further examine our approach when ranking the performance of different pre-trained models

Ranking Method	$D_{(O,t)}$ HANS/PAWS POOLED
Baseline	
ACCURACY	61.0
GUESS	72.0
Factors	
SET-DEPENDENT	75.5
MAX-DIFF	72.6
INDEX-DIFF	83.0
SUM-DIFF	83.1
FIRST-TOK	69.4

Table 3: Few-shot heuristic ranking performance on OOD samples for HANS/MNLI and QQP/PAWS, specifically when comparing **non-inoculated models** (SHAP explanations), where we take the mean of pairwise accuracies for 3 pairs (for 3 models) on each set.

(RoBERTa, ELECTRA, and DeBERTa).

Table 3 shows that a heuristic `GUESS` based on the expectation across choosing a *best* model and then randomly guessing consistently with that, gives a strong baseline of 72%. Factors also seem to do well in this setting, with all of the general heuristics outperforming the very low `ACC` baseline.

This suggests that in few-shot factors are able to capture distributional information that baselines can't. However, to qualify this, given that each set only compares between 3 pairs of models, it's easier for factors to happen upon strong accuracy patterns by chance.

Thus, in Table 4, we analyze this further by showing resuts on some individual model pairs. (R1, R2 are RoBERTa; E is Electra; D is DeBERTa) R1-E and D-R2, have different architectures, but similar OOD accuracy (see Table 6 in the Appendix). R1-D, E-D and E-R2 are different model types with more distant accuracy. Accuracy values for a single pair on this single dataset therefore only reflect differences across bootstrap samples. What we find in common across these types of pairings is that while some values are close to 50%, including the `ACCURACY` baseline, each column has several factors achieving very distinct (0%, 100%) accuracy values, consistently differentiating these models. As we note in Figure 4 (Appendix), this pattern of strong distinctions is quite common when different types of models are compared. We further discuss this in Section 7.

7 Analysis / Discussion

Accuracy is reliable, but factors can provide more fine-grained distinctions. On MSGS, where factors beat strong accuracy baselines, we notice that these pairwise accuracies are consistently high. For example, on the MORPH setting, for two models with 95% and 98% accuracy, our factors `IRREG` is 100% accurate, while the accuracy baseline here is only 58%, as test accuracy on $D_{(O,t)}$ does not discriminate well between two models with such close overall accuracy.

	Model Pair (M_1-M_2)				
Ranking Method	R1-E	R1-D	E-R2	D-R2	E-D
Baseline					
ACCURACY	77.4	54.6	55.2	67.2	64.4
Factors					
SWAP-MAX-DIFF	57.6	57.6	70.6	65.6	42.6
SWAP-AVG	93.4	93.4	65.0	47.6	17.0
MAX-DIFF	63.2	63.2	39.2	4.8	0.2
INDEX-DIFF	0	0	99.6	99.6	15.0
SUM-DIFF	99.8	100	0	0	88.0
FIRST-TOK	1.2	100	99.6	0	0

Table 4: SHAP pairwise accuracies, different types of models, PAWS. Model R1 (69.7%), R2 (82.9%), Model E (80.5%), and Model D (71.8%)

This holds at the fine-grained pairwise level as well. Figure 5 (also see Figure 6 in appendix) shows the baseline $D_{(O,t)}$ accuracy against a specific factor's accuracy for each model pair in MSGS. Each datapoint in the scatterplot represents a model pair and a point's vertical distance from the red line represents how much better or worse a given factor does compared to the baseline on a specific pair. We see a regular trend: explanations seem to systematically outperform the baseline across various pairs, with a few significant deviations for low-performing pairs.

These results suggest that explanations can be useful and do add information otherwise missing from accuracy probing alone, especially when the underlying model architecture is held constant. With differing architectures (Figure 6), the problem is made more difficult, and selecting the right factor is less obvious; few-shot accuracy may be more reliable in this setting. Note, however, that these successes from any technique are in spite of us only inspecting 10 examples from the target domain.

Factors differentiate models strongly, though not always in a way aligned with OOD performance. Figure 4 and Table 4 both show that factors will often consistently decide in favor of a certain model regardless of the choice of $D_{(O,t)}$, especially when dealing with models with different

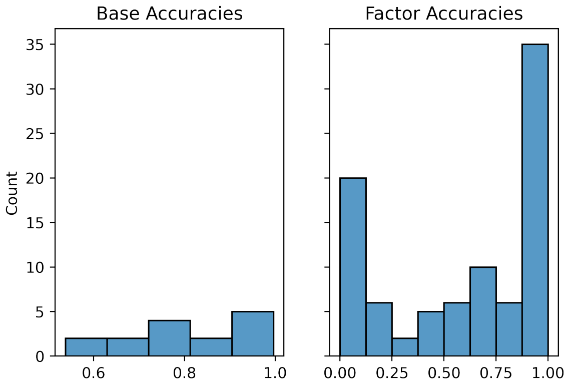

Figure 4: Distributions of pairwise accuracies on PAWS SHAP non-inoculated, all model pairs (left for accuracy baseline, right for all factors).

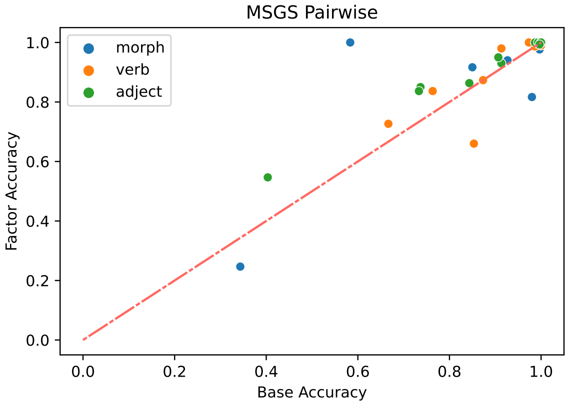

Figure 5: LIME pairwise factor against baseline accuracies for MSGS. Additionally see Figure 6.

base architectures. Since ranking accuracy correlates with whether these strong alignments are consistent across a spectrum of models and choose the models with higher OOD performance, the tendency for factors to strongly favor a specific model doesn't necessarily correlate with strong overall performance, but does heavily imply that these factors extract meaningful information about the model from the attributions. Looking close at Table 4, we can see that that even between different model architectures, certain factors are more (`INDEX-DIFF`) or less (`SWAP-MAX-DIFF`) capable of making these distinctions.

Factors as projections of model feature space. Based on these results, we have evidence that the distributions of attributions are unique to models: in other words, a factor is like a scalar *signature* for a model's feature space with respect to some relevant features. Methods like inoculation, that change a model's behavior in direct ways lead to regular changes in that signature. In these cases, factors align with OOD performance, which explains why factors are so strong in our inoculated experiments. For our non-inoculated experiments (i.g. ELECTRA vs DeBERTa), the feature spaces are fundamentally different, so factor signatures will still capture these differences, but in a way less aligned with ranking on OOD performance. Future work may be able to expand on these differences and what they tell us beyond OOD performance.

8 Related Work

This paper relates to a long line of work on understanding explanations, including explanations' human interpretability (Miller, 2019; Jacovi and Goldberg, 2020; Alqaraawi et al., 2020; Nguyen et al., 2021), explanations' faithfulness and ability to detect shortcuts (Geirhos et al., 2020) or spurious features (Bastings et al., 2021; Madsen et al., 2021; Zhou et al., 2021), and applications to OOD data (Ye and Durrett, 2022; Choi et al., 2022), including papers in the intersection of multiple directions (Adebayo et al., 2022; Kim et al., 2021).

Past work has also investigated performance prediction (Xia et al., 2020; Ye et al., 2021b; Varshney et al., 2022), and using explanations to detect spurious correlations (Kim et al., 2021; Bastings et al., 2021; Adebayo et al., 2022). We are different in that we focus on ranking an array of models which exhibit different levels of generalization abilities, as opposed to giving a binary judgment of whether a model is relying on some shortcuts (Kim et al., 2021; Bastings et al., 2021; Adebayo et al., 2022). In addition, we experiment with tasks having nuanced shortcuts 'in the wild', contrary to synthetically constructed datasets in Bastings et al. (2021). In particular, Adebayo et al. (2022) study the usefulness of explanations in detecting unknown spurious features in an image classification task involving (realistic) possible shortcuts, but find that attributions are ineffective for detecting unknown shortcuts in practice.

9 Conclusion

We establish a robust framework for evaluation of fine-grained few-shot prediction of OOD performance, benchmarking approaches in this setting on a range of models. We find that accuracy is a reliable baseline, but intuitive attribution-based factors derived from explanations can sometimes better predict how models will perform in OOD settings, even when they have similar in-domain performance. We further analyze patterns of our approaches, discovering the potential for factors to represent views of model feature space, leaving further exploration to future work.

10 Limitations

There are a large number of explanation techniques and many domains these have been applied to. We focus here on a set of textual reasoning tasks like entailment where spurious correlations have been frequently identified. However, correlations in other settings like medical imaging (Adebayo et al., 2022) could yield different results. We also note that these datasets are all English-language and use English pre-trained models, so different settings may yield different results; additionally, our factors depend on how explanations are normalized between different examples.

Our paper and analysis themselves comment on the limitations of our methodology as well as explanations as a whole: we find that while explanations often can clearly distinguish different models, knowing which factors will do so, or guaranteeing that explanations align with OOD performance, remains difficult.

Table 5: MSGS accuracies of various inoculated models.

A Details of Inoculation

One of the methods we used to obtain models with different performances on the OOD sets was inoculation (Liu et al., 2019a), which involves fine-tuning or further fine-tuning models on small amounts or batches of OOD data alongside in-domain data to bring model performance on OOD sets up.

MSGS We borrow notation from Warstadt et al. (2020). Most of the fine-tuning data is ambiguous data that doesn't test the spurious correlation, but we add in small percentages of non-ambiguous data where the label favors either the surface or linguistic generalization, tilting the model in that direction. Here, for each set (VERB, MORPH, ADJECT), we used the following inoculation splits. Linguistic (L) and surface(S) are the features that the inoculation data would favor: 2% L, 2% S, mixed (2% L, 1% S), (1% L 2% S), (2% L, 2% S), in addition to no inoculation. The results on D_O are present in Table 5.

HANS Specific innoculation results for RoBERTa-large are present in Table 6. We additionally use MNLI pre-trained ELECTRA and DeBERTa models from huggingface. These performance details are also located in Table 6.

PAWS We used several inoculation techniques to get a variable number of models here. For our RoBERTA-base model, we start with the base model (35% OOD accuracy) and fine-tune it with D_T data with 2% of the data having D_O data mixed in. We trained this over several epochs to get models with 82.8% and 90.8% accuracy on D_O. We also tried fine-tuning our 35% model on batches of pure D_O data to get a model with 69% accuracy. For our ELECTRA and DeBERTA models, we use similar batch-only inoculation (fine-tuning on batches of only OOD data). More details are present in Table 6.

Tables 7-8 contain the same information as Table 2, but for the other 2 studied explanation technique.

B Bootstrapping Details

We now describe our process for bootstrapping and evaluating the capability of explanations in our setting.

For a sampled population of examples from the D_O set, for the m models that we're examining at a time, we generate explanations for each of the m models on all of the sampled population. We then repeatedly take a sample with replacement (500 times) of 10 examples $D_{O,t}$ each, where we have $500 \times 10 \times m$ total explanations we want to examine. We calculate factors for each of the 10 explanations in each $D_{O,t}$ sample and pool them to get a list of factor metrics for the $D_{O,t}$, one for each model.

For each pair, we then look at the ground-truth D_O ranking for models and their respective factor metrics, getting *successes* where these match, and *failures* otherwise. When we average these accuracies across our 500 bootstrap samples, we get pairwise distributions (the distribution of successes vs failures on a sample for a given pair), which we can further aggregate to get few-shot accuracies.

Note, in practice, to prevent variance from run-to-run, we fix the population of 500 $D_{O,t}$s, but we validated that re-running on new sampled populations didn't impact any numbers greatly. Though we tried using several (5, 10, 20) $D_{O,t}$ sizes, we decided to use the probe size of 10 as a realistic probe size for our setting, which wouldn't be burdensome to hand-craft in practice.

Our methodology can be run quickly in a post-hoc manner as many times as needed on top of a population of the necessary explanations.

C Additional Plots

Figure 4 shows additional information about the distrbution of pairwise accuracies between different model architectures.

D Reproducibility

D.1 Computing Infrastructure

All experiments were conducted on a desktop with 2 NVIDIA 1080 Ti (11 GB) and 1 NVIDIA Titan Xp (12 GB).

D.2 Runtimes

For PAWS and MSGS fine-tuned models, we fine-tuned for roughly 1 GPU hour per model. Since HANS models were trained for very few steps, their training time is inconsequential. Generating attributions required for numerical evaluation took less than 6 GPU hours.

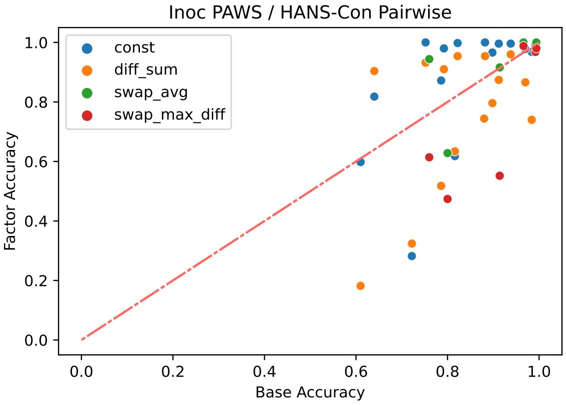

Figure 6: SHAP pairwise factor compared to `ACC` for HANS-CON and PAWS. Each point represents a factor accuracy (y-axis) for a pair of models in comparison to `ACC` (x-axis) for the same pair. Points above the red $y = x$ line represent factors outperforming the accuracy baseline. `CONST` and `DIFF-SUM` are for HANS-CON, `SWAP-AVG` and `SWAP-MAX-DIFF` are for PAWS

D.3 Dataset Details

We used datasets in the JSONL format. We simplified all our dataset settings to binary classification for simplicity, and used data directly from the downloads made available in the original papers.

Mind the Labels: Describing Relations in Knowledge Graphs With Pretrained Models

Zdeněk Kasner,[1] **Ioannis Konstas**[2] and **Ondřej Dušek**[1]
[1]Charles University, Faculty of Mathematics and Physics, Prague, Czechia

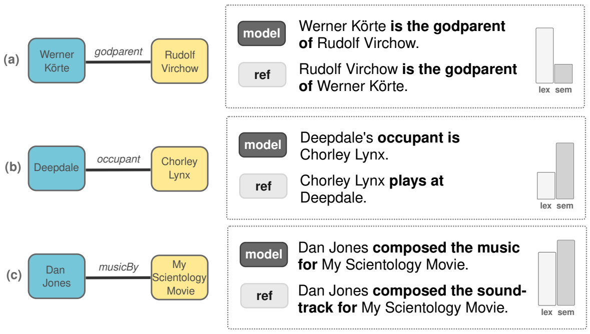
Abstract

Pretrained language models (PLMs) for data-to-text (D2T) generation can use *human-readable data labels* such as column headings, keys, or relation names to generalize to out-of-domain examples. However, the models are well-known in producing semantically inaccurate outputs if these labels are ambiguous or incomplete, which is often the case in D2T datasets. In this paper, we expose this issue on the task of descibing a relation between two entities. For our experiments, we collect a novel dataset for verbalizing a diverse set of 1,522 unique relations from three large-scale knowledge graphs (Wikidata, DBPedia, YAGO). We find that although PLMs for D2T generation expectedly fail on unclear cases, models trained with a large variety of relation labels are surprisingly robust in verbalizing novel, unseen relations. We argue that using data with a diverse set of clear and meaningful labels is key to training D2T generation systems capable of generalizing to novel domains.[1]

1 Introduction

D2T generation systems need to accurately capture the semantics of relations between values in the data. However, the data labels such as relation names (Färber et al., 2018; Haller et al., 2022), table headings (Parikh et al., 2020), or meaning representation keys (Dušek et al., 2020) may provide only superficial or—if the labels are abbreviations, such as in the Rotowire dataset (Wiseman et al., 2017)—no usable hints about the data semantics. Learning how to properly describe the data is thus a challenge for D2T systems, typically requiring in-domain training data of sufficient quality and quantity (Dušek et al., 2019).

PLMs such as BART (Lewis et al., 2020) or T5 (Raffel et al., 2020) can quickly adapt to new domains and exhibit robustness to out-of-domain inputs. However, the PLMs for D2T generation are still limited by the expressivity of the data labels. Consider Figure 1 (a): the model can use its representation of *“godparent”* to understand there is a *“is-a-godparent-of”* relation between the entities, but it has to infer (or guess) who is the godparent of whom. Even in the less ambiguous cases (b) and (c), the model still has to correctly capture the intended semantics of the relation (e.g. *“occupant”* meaning *“home team”*).



model Werner Körte **is the godparent of** Rudolf Virchow.

ref Rudolf Virchow **is the godparent of** Werner Körte.

model Deepdale's **occupant is** Chorley Lynx.

ref Chorley Lynx **plays at** Deepdale.

model Dan Jones **composed the music for** My Scientology Movie.

ref Dan Jones **composed the soundtrack for** My Scientology Movie.

Figure 1: Data-to-text generation models use relation labels (such as *godparent*, *occupant*, and *musicBy*) to describe relations between entities. However, unclear labels can lead to various lexical or semantic incoherencies in the output descriptions, such as swapping the relation direction (a) or using too literal expressions (b).

In this paper, we investigate to what extent PLMs are able to use arbitrary labels describing relations between entities. A suitable testing ground is the task of describing (i.e., *verbalizing*) individual triples in a knowledge graph (KG), which can be considered a trivial case of graph-to-text (G2T) generation (Ribeiro et al., 2021; Koncel-Kedziorski et al., 2019). In this task, there is a wide range of lexical choices for the *relation label* (see Table 1), while the *entities* can be copied verbatim or with only minor morphological changes.

Current human-annotated datasets for D2T generation contain only a small number of relations and rarely contain any unseen relations in the test

---

[1] We release the code and data for our experiments: `https://github.com/kasnerz/rel2text`.

relation	possible verbalization
is part of	X is part of Y.
duration	X lasted for Y.
platform	X is available on Y.
	X runs on Y.
country	X was born in Y.
	X is located in Y.
parent	X is the parent of Y.
	Y is the parent of X.
ChEMBL	X has an id Y in the ChEMBL database.

Table 1: Examples of relation labels and their possible verbalizations, with placeholders for head (X) and tail (Y) entities. Relations can be copied verbatim (*is part of*), have a unique verbalization (*duration*), or multiple equivalent lexical choices (*platform*). There is also ambiguity stemming from the semantics of the entities (*country*) or the relation itself (*parent*, *ChEMBL*).

set (Mille et al., 2021). We collect a novel dataset Rel2Text (Re-writing edge labels to Text),[2] acting as a test bench for our experiments. It contains 4,097 single triples from three large-scale KGs (Wikidata, DBPedia, and YAGO) and their crowd-sourced verbalizations, covering 1,522 unique relations (§3). Each relation is equipped with a label, a textual description, and up to five triples in which the relation occurs in the KG.

Using the Rel2Text dataset, we evalute the ability of PLMs to verbalize relations which were not present in the training set. We consider both models finetuned on other relations in our dataset and models finetuned on datasets from a related domain. We also experiment with scenarios involving few-shot finetuning, training on masked labels, and extending the labels with descriptions (§4, 5).

We find that the PLMs are quite robust in verbalizing a diverse set of relations based on their label (achieving ~90% of overall entailment probability). We show that semantically unfaithful model outputs are often caused by incomplete, ambiguous, or noisy input data. Somewhat suprisingly, we also show that longer relation descriptions do not provide substantial improvements over using short labels. However, even for data using short relation labels, the model trained on verbalizing relations can achieve results comparable to verbalizing relations using manual templates in two downstream tasks (§6).

The contributions of our work are as follows:

- We examine the ability of PLMs to describe graph relations, showing that *clear and meaningful labels* are the basis for successful generalization to unseen relations.
- We present Rel2Text—a human-annotated dataset with 4,097 examples verbalizing 1,522 relations from three large-scale open KGs.
- We show that a model trained on Rel2Text can serve as a drop-in replacement for manual templates, preserving or improving performance on downstream tasks.

2 Related Work

Earlier works in natural language generation from KGs exploited domain-specific ontologies for rule-based systems (Cimiano et al., 2013; Bouayad-Agha et al., 2012; Sun and Mellish, 2007, 2006). With the advance of PLMs, structure-aware modeling and task-specific pretraining has lead to remarkable progress on **D2T benchmarks** such as WebNLG (Gardent et al., 2017b; Ferreira et al., 2020), AGENDA (Koncel-Kedziorski et al., 2019), or E2E (Dušek et al., 2020), indicated via both automatic and human evaluation metrics (Ke et al., 2021; Guo et al., 2020; Ribeiro et al., 2020; Harkous et al., 2020).

Agarwal et al. (2021) used a multi-step approach with semantic filtering and distant supervision for verbalizing the English Wikidata, **covering the wide range of relations** present in the KG. The authors use the approach to generate the KeLM corpus – an automatically cleaned corpus with *synthetic* (model-generated) verbalizations of Wikidata triplesets. We use the KeLM corpus to investigate how models trained on large-scale synthetic data differ from models trained on a small-scale human-annotated dataset (cf. §4).

Other works have tried **incorporating descriptions of data labels** in the model inputs. In one of the experiments, Wang et al. (2021) use descriptions of relations from Wikidata instead of their labels for relation embeddings, concluding that it results in worse performance on downstream tasks. Conversely, Kale and Rastogi (2020) and Lee et al. (2021) improve the performance of their systems by including schema descriptions on the input for the dialogue state tracking and dialogue response generation systems.

There has also been a research interest in **verbalizing single triples** as a stand-alone preprocessing step for NLP tasks. The step has been shown to improve the generalization ability of downstream

---

[2] Or simply "Relations-to-Text".

models for data-to-text generation (Laha et al., 2019; Kasner and Dušek, 2020, 2022; Xiang et al., 2022) and response generation in dialogue systems (Kale and Rastogi, 2020). This step can also serve for making the input similar to the format used during pretraining, e.g. for natural language inference (NLI) models (Gupta et al., 2020; Neeraja et al., 2021; Dušek and Kasner, 2020). The above works employ a variety of methods to convert triples to text, ranging from simple templates and rule-based systems to prompting large PLMs. However, none of these works investigate how PLMs behave when presented with novel relations.

In a work concurrent to ours, Keymanesh et al. (2022) investigate the aspects of **generalization performance of PLMs** on the DART dataset[3] (Nan et al., 2021). They compare prompt-based and finetuning-based approaches to D2T generation, focusing on the ability of models to perform on difficult examples. In contrast, we focus on finetuned encoder-decoder models, which were shown in Keymanesh et al. (2022) to be more efficient for D2T generation, and we evaluate the models on clean and manually curated data.

3 Data

For our experiments, we need data with diverse labels and their human verbalizations. In this section, we describe how we gather RDF[4] triples from large-scale KGs (§3.1) and collect their verbalization through crowdsourcing (§3.2, 3.3).

3.1 Input Data

An RDF triple is a tuple $t = (e_h, r, e_t)$, where r denotes the relation between the head entity e_h and the tail entity e_t. We retrieve triples from three open large-scale KGs encoding factual knowledge:

- **Wikidata** (Vrandečić and Krötzsch, 2014) is a large-scale Wikipedia-based KG created using collaborative editing. With approximately 10,000 human-created relations equipped with descriptions,[5] it is by far the largest source of variety in relation labels.
- **YAGO** (Tanon et al., 2020) is a KG which builds upon factual knowledge from Wikidata, but uses a limited set of 116 pre-defined relations from `schema.org` (Guha et al., 2016) mapped to a subset of Wikidata relations.
- **DBPedia** (Lehmann et al., 2015) is a KG that maps Wikipedia infotables to a predefined ontology containing 1,355 relations, about 350 of which are accompanied by a description.

We query all KGs using their openly available endpoints to retrieve a list of relations in each KG. For each relation, we retrieve up to five *triples* that use this relation, and the relation *description*, i.e. a short explanatory text. If present, we also retrieve descriptions for the head and tail entities.

We apply a set of filtering heuristics, leaving out e.g. relations describing KG metadata or identification numbers.[6] In this way, we collect 7,334 triples with 1,716 relations in total. For the full description regarding the data retrieval, please refer to Appendix A.

3.2 Annotation Process

We collect human-written verbalizations for all input triples using Prolific.[7] We built a web interface in which the human annotators are shown a single triple t and asked to describe it in a single sentence. The annotators are encouraged to re-use the entities in their original form, but they are able to change the form if necessary. The annotators can also report noisy inputs. We employed 420 annotators in total, each of which annotated 20 examples. We set the average reward per hour according to the platform recommendations to £7.29 per hour and we accepted all the inputs which passed our built-in checks. See Appendix B for more details on the annotation process.

3.3 Postprocessing the Data

A considerable portion of the collected verbalizations contain typos and grammatical errors, misunderstood meaning of the relation, or extra information in the input. To ensure high quality of our data, we manually examined all crowdsourced examples and annotated them as *OK*, *noisy*, *corrupted* or *containing extra information*. Appendix C includes postprocessing details. In the rest of the paper, we only use the subset of our dataset

---

[3] We did not use DART (which is a compilation of several datasets including WebNLG) for our experiments since it contains many noisy relations.

[4] `https://www.w3.org/TR/PR-rdf-syntax/`

[5] `https://www.wikidata.org/wiki/Wikidata:Database_reports/List_of_properties/all`

[6] Relations describing various IDs make up a suprisingly large portion of relations in Wikidata. Since we focus on diversity instead of coverage, we decided not to include these relations in our dataset.

[7] `https://www.prolific.co/`

with *OK* annotations, one per input triple (4,097 examples, 1,522 distinct relations), although we also make the remaining noisy instances available for future research.

4 Analysis and Evaluation

In our analysis, we are interested in the following research questions:

- **RQ1:** Are the PLMs finetuned for D2T generation able to describe relations *not present in the finetuning corpus*?
- **RQ2:** How many *training examples* do the PLMs need to generate satisfactory outputs?
- **RQ3:** How do the PLMs behave when provided *limited lexical cues* about the relation?
- **RQ4:** Can relation *descriptions* help to clarify ambiguous cases and improve semantic accuracy of the outputs?

To answer these questions, we divide our REL2TEXT dataset into a training and test splits (see §4.1 for details). We then use the **REL2TEXT test set** to evaluate a finetuned BART model (Lewis et al., 2020), a pretrained encoder-decoder transformer, which is used as a backbone of many recent data-to-text models (Ke et al., 2021; Xing and Wan, 2021; Ribeiro et al., 2021; Liu et al., 2021).[8]

To answer *RQ1*, we compare the performance of BART finetuned on the REL2TEXT training set with BART finetuned on two qualitatively different D2T datasets – WEBNLG and KELM. Using REL2TEXT only, we then prepare various setups for answering *RQ2*, *RQ3*, and *RQ4* (details in §4.2). We analyze the outputs of the models both automatically (§4.3) and manually (§4.4).

4.1 Experimental Setup

Datasets We experiment with the following datasets, all of which focus on verbalizing factual information from KGs and use the same triple-based input data format:

- REL2TEXT. Our dataset (cf. §3.2) with single triples from three KGs with 4,097 examples, 1,522 relations and *human-annotated* outputs.
- WEBNLG (Ferreira et al., 2020; Gardent et al., 2017b). A DBPedia-based triple-to-text dataset with 38k examples, 411 relations, up to 7 triples per example, and *human-annotated* outputs. We use the English part of version 3.0 from HuggingFace.[9]
- KELM (Agarwal et al., 2021). A Wikidata-based dataset with 11M examples, 1,519 relations, up to 13 triples per example, and *model-generated* outputs. We use the dataset released by the authors, splitting it in a 1:100 ratio into validation and training data.

Rel2Text Data Split We use approximately 15% of the REL2TEXT examples for the **test set**. To ensure maximum fairness and focus on model generalization to unseen relations, we do not include in the REL2TEXT test set any relations which have an exact string match with a relation in KELM, WEBNLG, or the REL2TEXT training set. We also exclude any relations for which the maximum semantic similarity[10] to any KELM/WEBNLG/REL2TEXT training relation exceeds a threshold of 0.9. We set this threshold empirically in order to exclude relations which are almost synonymous, but slightly lexically different. We use 90% of the remaining examples for the training set and 10% for the validation set.

Data Preprocessing We split the camel case in the relation labels. For finetuning the models, we linearize the input triples by marking the triple constituents with special tokens <*head*>, <*rel*> and <*tail*>, which we add to the model vocabulary.

Training and Decoding Setup In a default scenario, we finetune BART-BASE for 10 epochs and select the best checkpoint using validation BLEU score, then use greedy decoding to produce outputs. We repeat each experiment with five random seeds, averaging the results. See Appendix D for details.

4.2 Compared Systems

Copy Baseline We introduce a simple baseline by outputting the triple constituents separated by space: "$e_h\ r\ e_t$".

Full Training Data We use the default setup (§4.1) on full REL2TEXT and WEBNLG training sets. For KELM (which is about 300× larger than WebNLG), we finetune the model for 1 epoch only. We denote the trained models *full-rel2text*, *full-webnlg*, and *full-kelm*, respectively.

---

[8] We believe that our findings also apply to similar models such as T5 (Raffel et al., 2020), which have shown comparable performance on related tasks.

[9] `https://huggingface.co/datasets/web_nlg`

[10] Computed as cosine similarity between embeddings of the labels, which are encoded using `all-distilroberta-v1` from SBERT (Reimers and Gurevych, 2019).

Limited Training Data For the limited training data setup, we prepare few-shot splits from REL2TEXT as subsets containing $N = \{25, 50, 100, 200\}$ relations with a single example per relation. We select examples at random, ensuring that each few-shot split is a subset of the larger splits. We finetune the *fewshot-N* models for 10 epochs without validation, using the last checkpoint.

Limited Lexical Cues In D2T datasets (with certain exceptions, cf. Gardent et al. (2017a)), unclear labels are kept in original form, implicitly assuming that the models will learn the verbalizations from the training data. We investigate how the models behave if we take this issue to the extreme, i.e. if the relation labels are not available at all. We consider three scenarios:

- *mask-test* – We train the model on REL2TEXT in the standard training setup. For testing, we replace the relation labels in REL2TEXT with the <*mask*> token.
- *mask-train* – For training, we replace the relation labels in REL2TEXT with the <*mask*> token. We test the model on REL2TEXT in the standard evaluation setup.
- *mask-all* – We replace the relation labels in REL2TEXT with the <*mask*> token for both training and testing.

Incorporating Descriptions Our dataset contains short textual descriptions of the relations, which may be useful to disambiguate its meaning and provide additional cues to the model. We consider two scenarios:

- *desc-repl* – We replace the relation label with its description.
- *desc-cat* – We concatenate the relation description with the input, separated using the special token <*rel_desc*>.

4.3 Automatic Evaluation

To get a high-level overview of model behavior, we evaluate generated outputs using the GEM-metrics[11] package (Gehrmann et al., 2021), which provides an extensive set of automatic metrics for text generation.

Lexical Similarity We first measure lexical similarity between the model outputs and human references using **BLEU** (Papineni et al., 2002), **METEOR** (Banerjee and Lavie, 2005), and **BLEURT** (Sellam et al., 2020). The first two metrics focus on n-gram overlap; the latter is a trained metric that also captures semantic similarity between the output and the reference. Although these metrics should not be used in isolation (Gehrmann et al., 2022), they give us a better overview of the output quality in combination with other metrics.

Semantic Similarity and Legibility Lexical similarity metrics focus on the surface form, which may not be telling the whole story. For example, if the relation *parent* denotes that e_t *is the parent of* e_h, but the entities are swapped in the generated text, the output will be incorrect, although lexical similarity metrics will be high. To get deeper insights into semantic and lexical properties of the outputs, we use NUBIA (Kane et al., 2020), which is a trained metric combining several features to measure "interchangeability" (equivalence) of two texts. The metric outputs a single score (**NB**) with a value between 0 and 1. We also report its individual underlying features: the semantic similarity score (**SS**) on a 0-5 scale, predicted by RoBERTa (Liu et al., 2019) finetuned on the STS-B benchmark (Cer et al., 2017); the contradiction (**C**), neutral (**N**), and entailment (**E**) probabilities from RoBERTa finetuned on the MNLI challenge from the GLUE benchmark (Wang et al., 2018); and the perplexity score (**PPL**) from vanilla GPT-2 (Radford et al., 2019), computed as a geometric mean of probabilities of the tokens in each step (this score is referenceless).

Lexical Diversity To assess lexical diversity of the generated texts, we use several metrics used in previous work (Dušek et al., 2020; van Miltenburg et al., 2018). We measure the number of unique n-grams (**U-1**), conditional entropy of bi-grams (**CE-2**), and the mean segmental type-token ratio over segment lengths of 100 (**MSTTR**; Johnson, 1944). We also measure the average output length in tokens (**len**).

4.4 Manual Error Analysis

To examine the sources of errors, we perform an in-house annotation of the model outputs. We identify four model error types based on preliminary observations: semantic errors (SEM), with a swap of the relation direction (DIR) as a special case, too

---

Table 2: The summary of evaluation using automatic metrics on REL2TEXT test set. See §4.1 for the descriptions of the models, §4.3 for the descriptions of the metrics, and Table 6 for standard deviations.

	Label	**Example input**	**Model**	**Example outputs (✗ incorrect, ✓ correct)**
model	SEM	(Yousra Matine, *sport country*, Morocco)	*mask-mask* *full-rel2text*	✗ Yousra Matine was born in Morocco. ✓ Yousra Matine plays for Morocco.
	DIR	(Kentucky Channel, *former broadcast network*, KET ED)	*fewshot-100* *full-rel2text*	✗ KET ED was broadcast on Kentucky Channel ED. ✓ The Kentucky Channel was broadcast on KET ED.
	LIT	(Vietnam Television, *first air date*, 1970-09-07)	*full-kelm* *full-rel2text*	✗ The first air date of Vietnam Television was 1970-09-07. ✓ Vietnam Television first aired on 1970-09-07.
	LEX	(RPG-43, *used in war*, The Troubles)	*full-rel2text* *full-kelm*	✗ RPG-43 was used in the The Troubles. ✓ The RPG-43 was used in the Troubles.
data	ENT	(The Age of Entitlement, *by artist*, The Basics)	*full-kelm* *full-rel2text*	✗ The Age of Entitlement was written by The Basics. ✓ The Age of Entitlement was recorded by The Basics.
	LBL	(General Motors Epsilon platform, *vehicle*, Cadillac XTS)	*full-webnlg* *desc-cat*	✗ General Motors Epsilon is a vehicle similar to the Cadillac XTS. ✓ General Motors Epsilon platform is used in the Cadillac XTS.

Table 3: Error categories used in manual analysis, with examples of errors found and corresponding correct verbalizations. Model error types (top): SEM – The output is semantically incorrect, DIR – The direction of the relation is swapped, LIT – The verbalization is too literal, LEX – There is a lexical error in the output. Input data error types (bottom): ENT – The verbalization may depend on the entities, LBL – The relation label is not clear.

literal (LIT), i.e. containing awkward or misleading phrasing, and grammar/lexical errors (LEX). We further annotate two types of input data errors: ambiguous relations (ENT) and relations with unclear labels (LBL). Examples are shown in Table 3. We select 100 random examples together with their corresponding outputs from the *full-rel2text*, *full-webnlg*, *full-kelm*, *fewshot-100*, *mask-all* and *desc-cat* models. Without revealing the output sources, we ask three expert annotators to mark all error categories that apply.

5 Results

5.1 Automatic Evaluation Results

Table 2 shows automatic scores for all our models. *full-rel2text* is the best among the fully trained models in terms of lexical overlap metrics (which is expected, as it is trained on the most similar reference distribution), but the *full-webnlg* and *full-kelm* models are almost equal in terms of semantic consistency, achieving around 90% average entailment probability, which is on par with the copy baseline.

Semantic consistency is much lower for the few-shot models (e.g. the average entailment probability is between 65% and 85%), showing that there is a certain minimum amount of data needed to achieve consistent outputs. Using more examples for training the model generally helps to decrease variance and increase performance across various metrics (cf. Figure 2).

Interestingly, the models which do not see the relations during test time (*mask-test* and *mask-all*) still achieve around 60% average entailment probability, similarly to the worst few-shot model. Although their rate of contradictions is higher than for other models, the results suggest that in many cases, the guessed relation is compatible with the correct relation.

Another interesting observation is that the *mask-train* model (trained not to use the labels) is able to use the labels provided at test time to improve the outputs considerably (contradiction rate drops from 17% to 5% compared to *mask-all*). The fact that the short labels are both sufficient and necessary for the successful verbalization is emphasized by the fact that the *desc-repl* model is worse than *full-rel2text* (although the descriptions are longer and supposedly explain the relation semantics), and the benefits of concatenating the descriptions alongside the relation labels (*desc-cat*) are negligible, only slightly improving lexical similarity metrics (0.5 BLEU point gain over *full-rel2text*).

In terms of lexical diversity, human references use more unique n-grams, but the model outputs are very similar in other aspects. It remains to be seen if the model outputs can stay semantically consistent with diversity-focused decoding techniques such as nucleus sampling (Holtzman et al., 2020).

5.2 Error Analysis Results

Results are summarized in Figure 3; complete results are presented in Appendix F. Examples of model outputs for each error type are shown in Table 3; more examples are given in Appendix G.

The *full-kelm* and *full-webnlg* models use expressions that are too literal (LIT) in 23 and 29 cases, respectively, while the *full-rel2text* and *desc-cat* models do the same only in 11 cases (5 out of which are marked as LBL, i.e., with an unclear label). This suggests that the variability of our dataset helps models to apply more natural expressions, especially if the relation is understandable from its label.

There is a near-constant portion of examples where the models make a semantic error (SEM) *and* the input is marked as needing an extra description (LBL). The models also make relatively many semantic errors on their own, most prominently in the case of the *fewshot-100* and the *mask-all* models. The *mask-all* model made a semantic error in 78 cases, suggesting that guessing the exact relation just from the entities is difficult (although still possible in 22 cases). Morevover, the outcomes from this model are fluent (only 4 LEX errors), making it hard to detect faulty cases.

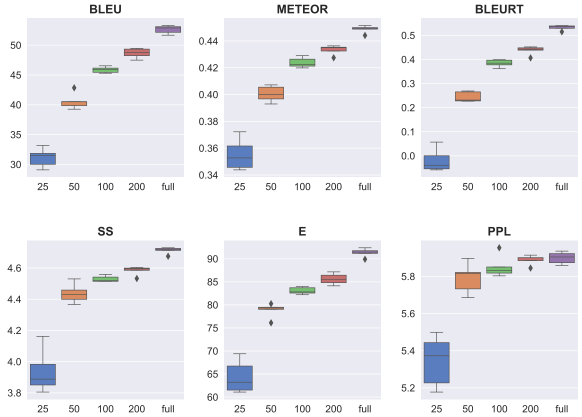

Figure 2: Boxplots for selected metrics from Table 2 w.r.t. the number of examples (displayed on the x-axis, *full* $= 1522$), taking into account variance from individual random seeds (cf. Table 6).

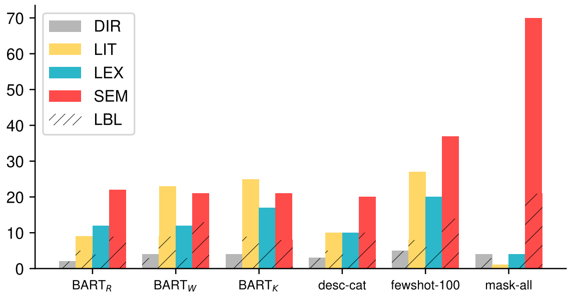

Figure 3: Number of annotated errors per model (see §4.4 and Table 3 for the description of error categories and §4.2 for the models). The striped part signifies that the label of the input was marked as unclear. See Appendix F for details.

The case of swapping the relation direction (DIR) is surprisingly not that common. This is probably down to having only a few examples in our dataset prone to this kind of error. Notably, the results for *full-rel2text* and *desc-cat* are very similar, rendering the impact of extra descriptions negligible.

Finally, there were only 12 out of 100 examples annotated as ENT, which suggests that the verbalization of the relation can be mostly decided irrespective of the entities in the triple.

6 Downstream Tasks

Given that the *full-rel2text* model can describe relations from their labels with high accuracy, we investigate if we can use the model to replace manually created templates in downstream tasks. We select two qualitatively different tasks, both using the idea of transforming individual input triples to

premise repr.	dev	α_1	α_2	α_3
OPR (Gupta et al., 2020)	76.78	75.30	68.46	64.63
BPR (Neeraja et al., 2021)	77.04	74.44	67.46	63.17
full-rel2text (ours)	74.44	74.31	64.59	63.46

Table 4: Accuracy for the dev set and test sets $\alpha_{1,2,3}$ from the INFOTABS dataset. The results are averaged over 3 random seeds.

simple sentences as a preprocessing step: tabular reasoning (§6.1) and zero-shot data-to-text generation (§6.2).

6.1 Tabular Reasoning

Gupta et al. (2020) presented the INFOTABS dataset as an NLI benchmark on tabular data. Each example is a structured table with a set of premises, i.e. natural language claims about the table; the task is to determine whether each premise is entailed by the table, contradicted by it, or neither.

They represent the table as *a paragraph* where each table cell is represented as a short sentence, mostly using a simple template "The *key* of *title* are *value*." Neeraja et al. (2021) extend Gupta et al.'s approach, including a *better paragraph representation* for which they prepare a fine-grained set of rules for individual entity categories. The rules[12] aim to minimize the number of ungrammatical sentences and improve the reasoning abilities of the NLI model.

We replicate the setup of Neeraja et al. (2021) for the original (OPR) and better (BPR) paragraph representation using their public codebase. We then replace their templates with our *full-rel2text* model, verbalizing the triple (*title*, *key*, *value*). The results are summarized in Table 4.

Our preliminary manual evaluation suggests that the sentences from our model are indeed more grammatical (even compared to BPR). However, we observe that the performance is comparable across all three test sets. In line with McCoy et al. (2019), we conclude that for classification tasks such as NLI, the input content appears to be more important than the input form.

6.2 Zero-shot Data-to-Text Generation

Kasner and Dušek (2022) proposed a setup for zero-shot D2T generation in which pretrained models are used to gradually transform text into the final description. The first step of the pipeline requires transforming individual triples into text. We focus on the WebNLG dataset, for which the authors manually created 354 templates.[13] We replicate the authors' setup using their public code, applying *full-rel2text* instead of the templates. The results are summarized in Table 5.

dataset	model	BLEU	METEOR	O	H
filtered	orig	43.19	39.13	0.152	0.073
	full-rel2text	45.39	38.97	0.056	0.161
full	orig	42.92	39.07	0.051	0.148
	full-rel2text	44.63	38.93	0.058	0.166

Table 5: Lexical similarity metrics (BLEU, METEOR) and ommission (O) and hallucinaton (H) rate; following the setup in Kasner and Dušek (2022).

We note that the pipeline using our model for preprocessing is able to achieve improvements of ~2 BLEU points, at the cost of a slightly higher omission and hallucination rate, but crucially without needing the manual effort to create templates. Cursory examination shows that sentences produced by our model are qualitatively similar to the manual templates, but more varied. Unlike the templates, our model may verbalize a relation differently depending on the context. Overall, we argue that training a PLM on verbalizing individual relations can potentially replace the manual effort of creating simple templates, which will have a notable impact for scaling similar approaches to larger datasets.

7 Discussion

Based on our experiments, we can conclude that PLMs are indeed able to verbalize novel relations (**RQ1**). However, there is a caveat: if the relation label is ambiguous or when the cues about the relation are limited (**RQ3**), the model will resolve to guessing and the semantic accuracy of the output descriptions may drop. A takeaway for datasets which do not follow standard naming conventions, such as the Rotowire dataset with basketball summaries (Wiseman et al., 2017) which uses abbreviations for column headers (e.g. FG3A stands for *"the number of shots the player attempted beyond the arc"*), is that rephrasing the labels to natural language may increase the robustness of D2T systems applied on these datasets.

We have focused on finetuned PLMs, which

---

[12] Formalized using more than 250 lines of Python code: `https://github.com/utahnlp/knowledge_infotabs/blob/main/scripts/preprocess/bpr.py#L120`

[13] Available at `https://github.com/kasnerz/zeroshot-d2t-pipeline/blob/main/templates/templates-webnlg.json`

in our case require at least several hundreds of examples to produce satisfactory results (**RQ2**). However, recent research suggests prompting large PLMs capable of in-context learning (Brown et al., 2020) may help to bring down the number of examples required close to zero (Li and Liang, 2021; Reynolds and McDonell, 2021; Schucher et al., 2022; Chia et al., 2022; Xiang et al., 2022). In this case, the models do not have a possibility to learn the correct verbalizations from the training data, which will probably make using clear and unambiguous labels even more important: an issue to investigate in future work.

We showed that improving the outputs using longer relation descriptions is not straightforward (**RQ4**). To achieve more notable improvements, it may be necessary to combine a more detailed specification regarding the relation direction, type, acceptable values, etc., together with a model able to reason about this specification. A promising research in this direction could be using chain-of-thought reasoning, so far applied for tasks such as open-domain question answering or solving math word problems (Gao et al., 2022; Wei et al., 2022; Yao et al., 2022; Nye et al., 2021).

The remaining open question is how to handle input data with noisy labels. We suggest that detecting these cases and fixing them prior to generation (for example with knowledge-augmented systems or a human-in-the-loop setup) could help to improve the robustness of D2T systems in real-world scenarios.

8 Conclusion

We analyzed the abilities of PLMs to verbalize unseen relations in KGs using the relation labels. Based on our findings, we believe that having expressive and unambiguous data labels is a good starting point for adapting D2T systems to new domains. For the analysis, we collected the REL2TEXT dataset, which can help to replace the hand-crafted templates on downstream tasks. Future work may investigate how our findings generalize to prompt-based few-shot or zero-shot D2T generation with large PLMs.

Limitations

Our analysis is limited to verbalizing single triples, which is only a stepping stone towards full-fledged G2T generation. To generate data for entire subgraphs, other issues need to be solved first, including compositional generalization and structure-aware modeling. Nevertheless, we believe that this simplified setting allows us to distill insights which are still applicable to G2T generation in general.

The factuality of the REL2TEXT dataset is tightly related to the data in the input KGs, which may contain outdated or incorrect information, and may be influenced by our processing methods (see Appendix A for details). Using the models trained on our dataset should be done with caution, since it can lead in producing harmful, imprecise, or factually incorrect statements.

We focus only on the English part of the KGs and English datasets. In the future, our approach could be extended to multilingual setting using multilingual PLMs and non-English parts of KGs. For more morphologically rich languages, an extra effort would have to be put into correctly inflecting the entities in the generated text.

Ethics Statement

As we are aiming to develop D2T systems which can robustly generate text for multiple domains, we are building upon PLMs which are known to reflect or amplify biases found in their pretraining corpus (Bender et al., 2021). Although the purpose of our study is to minimize these biases, the outputs of our models can still contain statements which are not aligned with the input data and user needs.

We collected our training and evaluation data through the Prolific crowdsourcing platform. We ensured that all the annotators were given an average reward per hour according to the platform recommendations and we put extra attention into informing the participants about the content and purpose of our study. We also manually filtered the output to minimize the amount of noisy references in our dataset. See 3.2 and Appendix B for more details on the annotation process.

A Data Retrieval

DBPedia We query DBPedia through its SPARQL access point: `http://dbpedia.org/sparql`. We retrive relations as objects of type `rdf:Property` which have a property `rdfs:comment` (i.e., the relation description) and language `'en'`.

YAGO We download the English Wikipedia subset of YAGO 4 database dump from `https://yago-knowledge.org/downloads/yago-4`. We retrieve all objects of type `rdf:Property` which have a property `rdfs:comment`. For the entity descriptions, we parse the entity page at YAGO website `http://yago-knowledge.org/resource/`.

Wikidata We first use the Wikidata SPARQL access point: `https://query.wikidata.org/sparql` to retrieve the list of relations as objects of type `wikibase:Property` with `wikibase:language="en"`, together with their English descriptions (`lang(?altLabel) = "en"`). Second, we query Wikidata through the LDF endpoint `https://query.wikidata.org/bigdata/ldf`, which is better able to handle heavy requests, to retrieve the list of triples involved in the relation. Finally, for retrieving the entity descriptions, we use the API at `https://www.wikidata.org/w/api.php`.

Filtering We apply a comprehensive set of filters for filtering out noisy triples, including triples with entities containing meta-information (*"Category:"*, *"XMLSchema#"*), URLs, entites longer than 64 characters, relations having the string *"id"*, *"number"*, or *"code"* in the label, or having *"Reserved for DBpedia"* in the description. As a consequence, we lose some relations, most notably about 2/3 of the relations from Wikidata describing various identifiers (we opted for this step in order to maintain data diversity). If KGs contain relations with identical labels, we prefer the relations from DBPedia and YAGO (which have a substantially lower amount of relations) to Wikidata relations.

Missing Units Our dataset mostly does not contain units for quantities. Although the units are usually present in the KGs, they are not part of the quantity itself – they may be either connected to the quantity with another property, or described informally in the relation label. Since our focus was on the relation labels, we decided to not put additional effort in retrieving and processing the units. In effect, we consider verbalizations not using the units (e.g., (Bommersheim substation, *voltage*, 20000) → "Bommersheim substation has a voltage of 20000.") as correct.

Factual Correctness A certain part of the data is factually incorrect, either because there was an error in the knowledge graph (e.g., (Catalans, *population place*, **Italy**)) or because there was a processing error (e.g., (Child Language Teaching and Therapy, *final publication year*, **-1985**). Since our focus was not on judging the factuality of the inputs (which is a difficult problem on its own right), we decided to keep the examples in the dataset and consider the examples semantically consistent with the input triple as correct.

Other Notes

- All the data was retrieved in February 2022, except for YAGO where we used the newest available dump *2020-02-24*.

- Although we retrieved the entity descriptions wherever possible and we include them in our dataset, we decided not to use them in our experiments.
- The Python code for retriving the data is available in the paper repository.

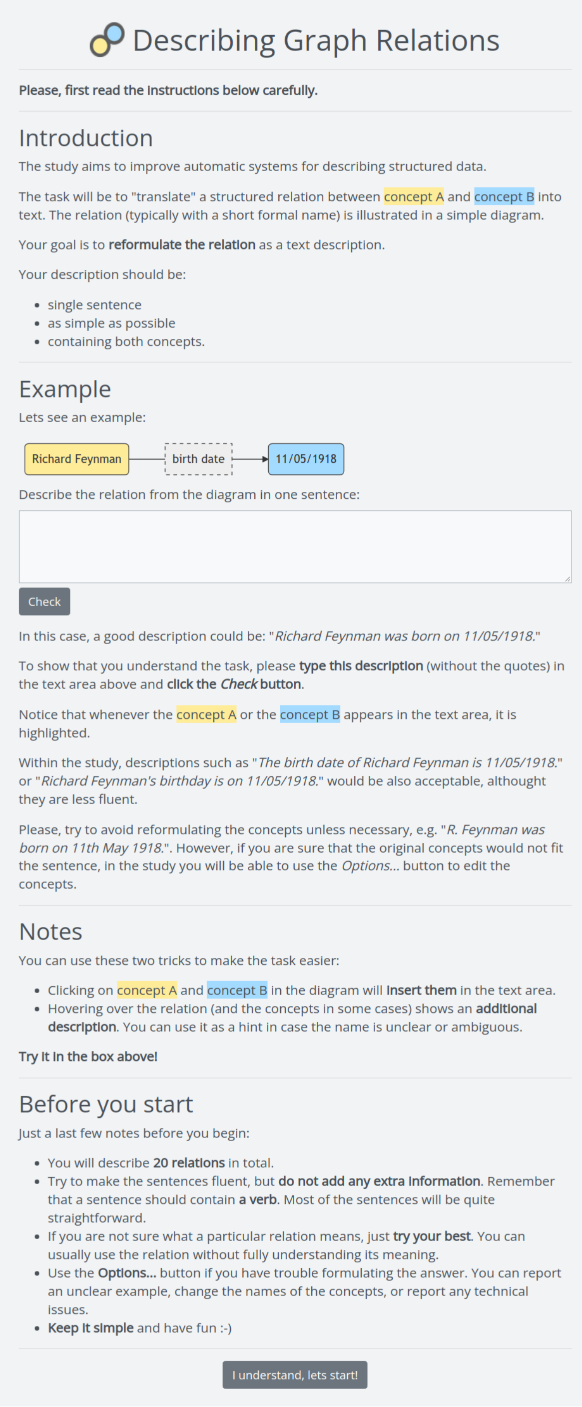
B Crowdsourcing Details

We built a web interface for collecting verbalizations for the triples. Figure 4 shows the introductory instructions displayed for the participants and Figure 5 shows the annotation interface.

We hired annotators on the Prolific crowdsourcing platform `https://app.prolific.co/`. We required that the annotators are native speakers of English. After completing an introductory example, the annotators were given 20 randomly selected triples presented in a sequential order. The annotators were asked to write a short, single-sentence description of the triple. For making the annotation easier, hovering the mouse over the relation revealed its description (this applied also for the entities, if the description was present).

The annotators could also click on the entity to insert it in the text. This motivated the users to insert the entities in the original form. Once the entity appeared in the text (either typed or inserted), it was highlighted. We required that both entities (and at least two extra characters) are present in the text before proceeding to the next step. Because of this requirement, approximately 98.6% sentences in our dataset can be delexicalized using exact string matching. The users also had an option to modify the entity name, which would be recorded as a new ground-truth input (e.g., to make its form more natural). However, this option was used only sparingly.

In total, we collected 8,265 responses for 7,334 examples. Multiple responses for some examples are a consequence of random selection combined with sessions running in parallel. In the final dataset used in our experiments, we selected at most one correct answer for each example (see Appendix C).



Describing Graph Relations

Please, first read the instructions below carefully.

Introduction

The study aims to improve automatic systems for describing structured data.

The task will be to "translate" a structured relation between concept A and concept B into text. The relation (typically with a short formal name) is illustrated in a simple diagram.

Your goal is to **reformulate the relation** as a text description.

Your description should be:

- single sentence
- as simple as possible
- containing both concepts.

Example

Lets see an example:

Describe the relation from the diagram in one sentence:

In this case, a good description could be: "*Richard Feynman was born on 11/05/1918.*"

To show that you understand the task, please **type this description** (without the quotes) in the text area above and **click the *Check* button**.

Notice that whenever the concept A or the concept B appears in the text area, it is highlighted.

Within the study, descriptions such as "*The birth date of Richard Feynman is 11/05/1918.*" or "*Richard Feynman's birthday is on 11/05/1918.*" would be also acceptable, althought they are less fluent.

Please, try to avoid reformulating the concepts unless necessary, e.g. "*R. Feynman was born on 11th May 1918.*". However, if you are sure that the original concepts would not fit the sentence, in the study you will be able to use the *Options...* button to edit the concepts.

Notes

You can use these two tricks to make the task easier:

- Clicking on concept A and concept B in the diagram will **insert them** in the text area.
- Hovering over the relation (and the concepts in some cases) shows an **additional description**. You can use it as a hint in case the name is unclear or ambiguous.

Try it in the box above!

Before you start

Just a last few notes before you begin:

- You will describe **20 relations** in total.
- Try to make the sentences fluent, but **do not add any extra information**. Remember that a sentence should contain **a verb**. Most of the sentences will be quite straightforward.
- If you are not sure what a particular relation means, just **try your best**. You can usually use the relation without fully understanding its meaning.
- Use the **Options...** button if you have trouble formulating the answer. You can report an unclear example, change the names of the concepts, or report any technical issues.
- **Keep it simple** and have fun :-)

- You can *click* on the concepts to insert them in the text field.
- You can *hover* your mouse over the diagram to see additional description(s).
- Click *Options...* if you have troubles formulating the answer.

Describe the relation from the diagram in one sentence:

The home port of Balmoral Castle is in London.

Figure 5: The annotation inteface.

C Postprocessing the Dataset

Two of the paper authors manually postprocessed the dataset. We used the following criteria for marking the responses:

- **OK** – The sentence is fluent and semantically consistent with the input.
- **Noisy** – The sentence contains a minor typographical or grammatical error, or the sentence sounds "awkward" (e.g., the relation label is used too literally).
- **Corrupted** – The sentence is semantically incorrect, contains a major typographical or grammatical error, or generally does not make sense.
- **Extra information** – The sentence is correct, but contains extra information about the entities which cannot be derived from the triple itself (e.g., the country of origin of the person found in the entity description).

Figure 6 shows the distribution of responses in our dataset. We marked 4,469 (54.1%) responses as *OK*, 1,314 (15.9%) responses as *Noisy*, 2,246 (27.2%) responses as *Corrupted* and 235 (2.8%) responses as *Extra information*.

Because our priority was to have clean data for evaluation, we decided to use only the *OK* part of our dataset in our experiments. We only use one example for each input triple in our experiments, which gives 4,097 instances. However, since we believe that the human outputs can also be an interesting research target, e.g. for investigating the feasibility of verbalizing the input data, we release all the annotations for future investigations.

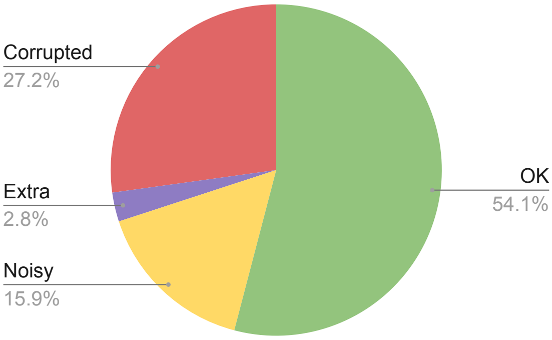

Figure 6: The distribution of crowdsourced responses in our dataset.

Sidenote: Entity Overlap The overlap between entities in test set of Rel2Text and train sets of Rel2Text and WebNLG is around 1%, only 0.5% being named entities (the rest are numerical values). On the contrary, around half of the entities in Rel2Text test set are included in the KeLM train set since KeLM covers a large portion of Wikidata with ca. 6M unique entities. In general, we believe that entity overlap does *not* have a notable influence on the results since all the pretrained models already have a representation of the entities from the pretraining stage.

Table 6: Standard deviations for the model experiments in Table 2. Results were computed for 5 random seeds.

D Experimental Setup

Framework We implemented the models in PyTorch Lightning (Paszke et al., 2019). We used the PyTorch (et al., 2019) version of BART-BASE from the Huggingface library (Wolf et al., 2020), with 140M parameters as a basis for all our models.

Hyperparameters We use the Adam (Kingma and Ba, 2015) optimizer ($\beta_1 = 0.9, \beta_2 = 0.98, \varepsilon = 1^{-6}$) with learning rate 2^{-5} and polynomial scheduling with 10% warmup steps. We train the models with batches of size 8 and accumulating gradients with factor 4 (an effective batch size of 32).

Training We train the models for 10 epochs on a single GeForce RTX 3090 GPU with 24 GB RAM, except for *full-kelm* model which we train for 1 epoch. Training times were around 15 minutes for the datasets based on REL2TEXT, 2 hours for *full-webnlg* and 3 days for *full-kelm*. We use greedy decoding in all our experiments.

E Automatic Evaluation

The standard deviations for each experiment from Table 2 are listed in Table 6.

F Manual Evaluation

Table 7 shows full results of our manual evaluation.

In total, there were 7 examples annotated as ENT only, 24 examples annotated as LBL only, and 5 examples annotated as ENT+DESC.

Shapley Head Pruning:
Identifying and Removing Interference in Multilingual Transformers

William Held
`wheld3@gatech.edu`

Diyi Yang
`diyiy@stanford.edu`

Abstract

Multilingual transformer-based models demonstrate remarkable zero and few-shot transfer across languages by learning and reusing language-agnostic features. However, as a fixed-size model acquires more languages, its performance across all languages degrades. Those who attribute this interference phenomenon to limited model capacity address the problem by adding additional parameters, despite evidence that transformer-based models are overparameterized. In this work, we show that it is possible to reduce interference by instead identifying and pruning language-specific attention heads. First, we use Shapley Values, a credit allocation metric from coalitional game theory, to identify attention heads that introduce interference. Then, we show that pruning such heads from a fixed model improves performance for a target language on both sentence classification and structural prediction. Finally, we provide insights on language-agnostic and language-specific attention heads using attention visualization.[1]

1 Introduction

Cross-lingual transfer learning aims to utilize a natural language processing system trained on a source language to improve results for the same task in a different target language. The core goal is to maintain relevant learned patterns from the source while disregarding those which are inapplicable to the target. Multilingual pretraining of transformer language models has recently become a widespread method for cross-lingual transfer; demonstrating remarkable zero and few shot performance across languages when finetuned on monolingual data (Pires et al., 2019; Conneau et al., 2019; Xue et al., 2021).

However, adding languages beyond a threshold begins to harm cross-lingual transfer in a fixed-size model as shown in prior work (Conneau et al., 2019; Xue et al., 2021). This phenomenon, termed interference, has been addressed with additional parameters, both language-specific (Pfeiffer et al., 2020) and broadly (Conneau et al., 2019; Xue et al., 2021). Wang et al. (2020) justifies this by showing that competition over limited capacity drives interference. This seems to contradict the lottery ticket hypothesis, which has shown that pretrained language models are highly overparameterized (Frankle and Carbin, 2019; Chen et al., 2020).

We offer an alternate hypothesis that interference is caused by components that are specialized to language-specific patterns and introduce noise when applied to other languages. To test this hypothesis, we introduce a methodology that selectively removes noisy components to improve language-specific performance without updating or adding additional language-specific parameters. Our work builds on prior research studying monolingual models that shows they can be pruned aggressively (Michel et al., 2019; Voita et al., 2019).

We leverage Shapley Values, the mean marginal contribution of a player to a collaborative reward, to identify attention heads that cause interference. Unlike prior methods, Shapley Values map each head to positive and negative values in a way that abides by all axioms of fair attribution (Ali et al., 2022). Therefore, negative values soundly mark interfering heads where removal will improve performance. We approximate Shapley Values in a computationally tractable but functionally accurate manner using truncation and multi-armed bandit sampling following prior work in computer vision (Ghorbani and Zou, 2020). We contribute the following:

1. **Attention Head Language Affinity:** Even when computed from aligned sentences, Attention Head Shapley Values vary based on the language of input. This highlights that a subset of attention heads has language-specific importance, while others are language-agnostic as shown in Figure 1.

---

[1] We release code to compute Shapley Values on GitHub

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2416–2427

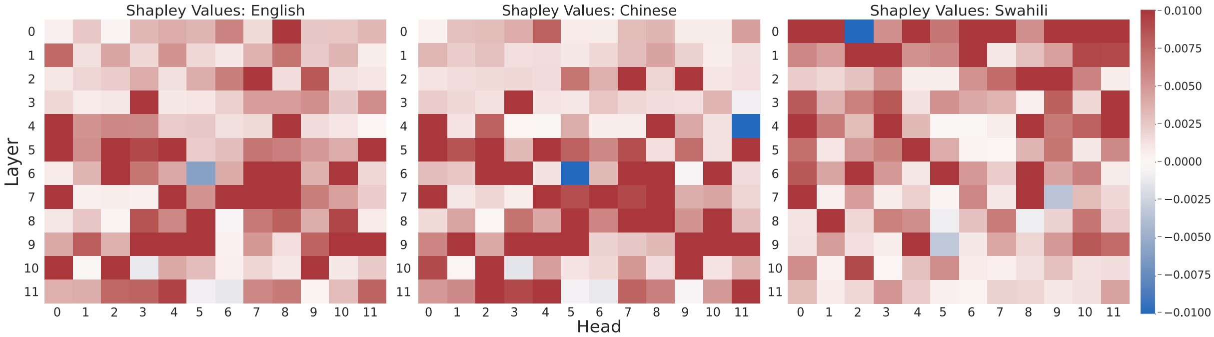

Figure 1: Attention Head Shapley Values for 3 Languages computed from 512 aligned examples for XLM-R finetuned on English XNLI. Each value represents the mean marginal effect an attention head has on accuracy for the test set in that language. The set of harmful heads changes for language, with the most distinct set for Swahili.

2. **Improving through Pruning:** Model pruning according to Shapley Values improves performance without updating parameters on the Cross-Lingual Natural Language Inference corpus (Conneau et al., 2018) and the Universal Dependencies Part-of-Speech corpus (Nivre et al., 2020). This opens a path of work to reduce interference through pruning rather than scaling.

3. **Interpreting Multilingual Heads:** In a qualitative study, we find that the most language-agnostic heads identified have a visible language-agnostic function, while language differences can be measured meaningfully for language-specific heads.

2 Related Work

2.1 Multilingual Learning

A large amount of work has studied both the theoretical underpinnings of learning common structures for language and their applications to cross-lingual transfer. Early works exploited commonality through the use of pivot representations, created either by translation (Mann and Yarowsky, 2001; Tiedemann et al., 2014; Mayhew et al., 2017) or language-agnostic task formulations (Zeman, 2008; McDonald et al., 2011).

As NLP has increasingly used representation learning, dense embedding spaces replaced explicit pivots. This led to methods that identified the commonalities of embedding spaces and ways to align them (Joulin et al., 2018; Artetxe et al., 2018; Artetxe and Schwenk, 2019). Recently, many works (Pires et al., 2019; Conneau et al., 2019; Liu et al., 2020; Xue et al., 2021; Hu et al., 2021) have trained multilingual transformer models as the basis for cross-lingual transfer. These models both implicitly and explicitly align the embedding space across languages, although they empirically achieve stronger alignment between closely related languages (Artetxe et al., 2020; Conneau et al., 2020).

With language-specific data, further work has studied how to reduce interference by adding a small number of language-specific parameters. These works adapt a model for the target language by training only Adapters (Wang et al., 2020; Pfeiffer et al., 2020; Ansell et al., 2021), prompts (Zhao and Schütze, 2021), or subsets of model parameters (Ansell et al., 2022).

Ma et al. (2021) previously investigated pruning in multilingual models using gradient-based importance metrics to study variability across attention heads. However, they used a process of iterative pruning and language-specific finetuning. This iterative process is not consistent since there are many trainable subnetworks within large models (Prasanna et al., 2020). Our method is the first to address interference and improve cross-lingual performance purely by pruning, without updating or adding additional language-specific parameters.

2.2 Model Pruning

Model pruning has largely been focused on reducing the onerous memory and computation requirements of large models. These techniques are broken into two approaches: structured and unstructured pruning. *Unstructured pruning* aims to remove individual parameters, which allows for more fine-grained removal. This process often has minimal effects even at extremely high degrees of sparsity. To efficiently prune a large number of parameters, many techniques propose using gradients or parameter magnitude (Sundararajan et al., 2017; Lee et al., 2019; Frankle and Carbin, 2019; Chen et al., 2020) as importance metrics.

Structured pruning, or removing entire structural components, is motivated by computational benefits from hardware optimizations. In the case of Transformers, most of this pruning work targets removal of attention heads, either through static ranking (Michel et al., 2019) or through iterative training (Voita et al., 2019; Prasanna et al., 2020; Xia et al., 2022). These pruning methods have also been used to study model behavior, but methods with iterative finetuning are not consistent as many sub-networks can deliver the same level of performance once trained (Prasanna et al., 2020).

Our work studies pruning without updating model parameters, which aligns with Michel et al. (2019) which was able to remove up to 40% of total attention heads without impacting accuracy on English Natural Language Inference. However, their gradient-based importance metric does not meet key criteria of efficiency in fair allocation, which states that the sum of the metric across all heads should sum to the model's total performance (Ali et al., 2022). Furthermore, Kovaleva et al. (2019) found that pruning attention heads could sometimes improve model performance without further finetuning. We build on this to develop a methodology for consistently identifying pruned models which improve performance.

3 Methods

To identify and remove interference, we need a metric that can separate harmful, unimportant, and beneficial attention heads. Prior work (Michel et al., 2019; Ma et al., 2021) utilized the magnitude of gradients as an importance metric. However, this metric measures the sensitivity of the loss function to the masking of a particular head. Defined in this way, importance will spike indiscriminately for both harmful and beneficial heads. Therefore, we develop a simple yet effective method to separate these classes.

Shapley Values (Shapley, 1953) have often been applied in model interpretability since they are the only attribution method to abide by the theoretical properties of local accuracy, missingness, and consistency laid out by Lundberg and Lee (2017). In our setting, Shapley Values have two advantages over gradient-based importance metrics. Firstly, gradient-based approaches require differentiable relaxations of evaluation functions and masking, but Shapley Values do not. Therefore, we can instead use the evaluation functions and binary masks directly. Secondly, Shapley Values are meaningfully signed which allows them to distinguish beneficial, unimportant, and harmful heads rather than just important and unimportant heads. This latter property is essential for our goal of identifying interference.

We apply Shapley Values to the task of structural pruning. In order to compute Shapley Values for each head, we first formalize the forward pass of a Transformer as a coalitional game between attention heads. Then, we describe a methodology to efficiently approximate Shapley Values using Monte Carlo simulation combined with truncation and multi-armed bandit search. Finally, we propose a pruning algorithm using the resulting values to evaluate the practical utility of this theoretically grounded importance metric.

3.1 Attention Head Shapley Values

We formalize a Transformer performing a task as a coalitional game. Our set of players A are attention heads of the model. In order to remove self-attention heads from the game without retraining, we follow Michel et al. (2019) which augments multi-headed attention with an added gate $G_h = \{0, 1\}$ for each head Att_h in a layer with N_h heads as follows:

$$\mathrm{MHAtt}(x, q) = \sum_{h=1}^{N_h} G_h \underset{h}{\mathrm{Att}}(x, q) \qquad (1)$$

With $G_h = 0$, that attention head does not contribute to the output of the transformer and is therefore considered removed from the active coalition.

Our characteristic function $V(A)$ is the task evaluation metric $M_v(A)$ over a set of validation data within a target language, adjusted by the evaluation metric with all heads removed to abide by the $V(\emptyset) = 0$ property of coalitional games:

$$V(A) = M_v(A) - M_v(\emptyset) \qquad (2)$$

With these established, the Shapley Value φ_h for an attention head Att_h is the mean performance improvement from switching gate G_h from 0 to 1 across all P permutations of other gates:

$$\varphi_h = \frac{1}{|P|} \sum_{A \in P} V(A \cup h) - V(A) \qquad (3)$$

3.2 Approximating Shapley Values

The exact computation of Shapley Values for N attention heads requires 2^N evaluations of our validation metric, which is intractable for the number of heads used in most architectures. The computation becomes more tractable with Monte Carlo simulation as an approximation (Castro et al., 2009). This replaces the full permutation set P in Equation 3 a randomly sampled subset of permutations.

Computing low-variance Shapley Value estimates with Monte Carlo simulation alone is computationally expensive and provides no clear metric for convergence. Therefore, we follow Ghorbani and Zou (2020) to accelerate our computations. We add a truncation heuristic using priors about the behavior of neural networks and formulate estimation as a multi-armed bandit problem of separating harmful heads from all others. We show in Section 4.3 that this approximation not only reduces the number of samples but explicitly converges to a consistent set of harmful heads across runs, showing consistency even across languages.

Truncation Heuristics Truncation stops sampling the marginal contributions from the rest of a permutation of features once a stopping criterion is reached for that permutation of the Monte Carlo simulation. Prior work selects stopping criterion based on either total performance (Ghorbani and Zou, 2020) or marginal improvements (Ghorbani and Zou, 2019). To avoid tailoring a threshold to each dataset, we instead choose to truncate based on the percentage of remaining attention heads. For all experiments, we truncate when less than 50% of attention heads remain in the coalition. This biases our estimations towards the effect of heads when the majority of the full network is present.

Multi-Armed Bandit Sampling The multi-armed bandit optimization stops sampling the marginal contributions of a particular player once a stopping criterion has been reached according to the variance of that player. Our stopping criterion is based on Empirical Bernstein Bounds (Maurer and Pontil, 2009), a confidence interval based on variance estimation. For t samples with observed variance σ_t and a maximum variance range of R, there is a probability of $1 - \delta$ that the difference between the observed mean $\hat{\mu}$ and true mean μ abides by the following inequality formulated by Mnih et al. (2008):

$$|\hat{\mu} - \mu| \leq \sigma_t \sqrt{\frac{2\log(3/\delta)}{t}} + \frac{3R\log(3/\delta)}{t} \quad (4)$$

We stop sampling for a particular head once this bound is less than $|\mu - 0|$, meaning that we have identified the Shapley Value as positive or negative with probability $1 - \delta$. This saves us significant computation while confidently separating heads into helpful and harmful buckets. For all experiments, we use $R = 1$ since the model's worst-case performance is zero and $\delta = 0.1$ to give a 95% confidence lower and upper bound.

3.3 Importance-Based Structured Pruning

Our pruning procedure works with any signed importance metric. Specifically, we test the utility of the Shapley Values metric for removing interference and helping multilingual models generalize to unseen test data.

Our hypothesis is that attention heads with negative Shapley Values introduce interference. Our pruning method reflects this by using the sign of our approximation directly. We remove all attention heads whose Shapley Value is negative with probability $1 - \delta$ by the Empirical Bernstein inequality from Equation 4. This is a parameter-free approach for deciding the number of heads to preserve. This approach is consistent, with the same set of negative heads identified for pruning across 3 separate runs.

Alternatively, once Shapley Values are computed the model could be pruned to any sparsity level. Unlike prior pruning approaches besides Michel et al. (2019), we do not perform any weight updates following or during pruning and leave all parameters fixed. This provides constant time pruning to the desired size. We evaluate performance in this configurable pruning setting in 4.6.

4 Experiments

4.1 Datasets

We evaluate our methodology on the Cross Lingual Natural Language Inference (XNLI) and Universal Dependencies Part-Of-Speech (UDPOS) tasks. These allow us to analyze the applicability of Attention Head Shapley Values to both sequence classification and structured prediction. We provide a description of dataset sizes in Table 1.

Cross-Lingual Natural Language Inference (XNLI) We use the Cross Lingual Natural Language Inference (XNLI) Benchmark (Conneau et al., 2018). This dataset is aligned which allows us to control for possible confounding semantic variation in the content. Given a premise and a hypothesis and tasks, XNLI is the task of classifying

Dataset	EN	AR	BG	DE	EL	ES	FR	HI	RU	SW	TH	TR	UR	VI	ZH

Figure 2: Spearman ρ of Attention Head Shapley Values across languages in XNLI using XLM-R finetuned on the English training split.

Universal Dependencies Part-of-Speech (UDPOS) For structured prediction, we evaluate on the Part-of-Speech (POS) tags from the Universal Dependencies (UD) v2 corpus (Nivre et al., 2020), which has the largest cross-lingual gap in the XTREME benchmark (Hu et al., 2020). The authors suspect that structured prediction requires more language-specific knowledge than many classification tasks.

For direct comparison with our experiments on XNLI, we only retain the 13 languages from UDPOS which have a development and test split, which also exist in XNLI. Unlike XNLI, each language in UDPOS hasa different number of examples which are not aligned across languages.

4.2 Experimental Setup

As the basis for our experiments, we finetune XLM-R Base (Conneau et al., 2019) using the Transformers library (Wolf et al., 2020) on only English data. Evaluation is done using the Datasets library (Lhoest et al., 2021) implementation of the accuracy metrics. Finetuning and Shapley Value computation were both done on a single NVIDIA GeForce 12GB RTX 2080 Ti. We finetune the following hyper-parameter tuning procedures from prior work: using Hu et al. (2020) for XNLI and de Vries et al. (2022) for UDPOS.

For all tasks and languages, we use the accuracy on 512 examples of the development set as the characteristic function for our coalitional game. Our pruning baselines include the gradient-based importance metric of Michel et al. (2019) and the average of 10 randomly pruned networks. We prune the same number of heads pruned by our method for all strategies since our baselines require selecting the number of heads to prune.

4.3 Language Affinity

First, we analyze the Attention Head Shapley values for XNLI. We focus only on the role of the source language by using an aligned sample from XNLI to control our results for differences independent from language variation. In Figure 1, we visualize the results across English, Chinese, and Swahili. As expected from prior work (Michel et al., 2019; Voita et al., 2019), many heads have low magnitude Shapley Values indicating that they play no significant role in the final network. We compare the similarity of Shapley Values learned across languages using Spearman's ρ in Figure 2 and find that Shapley Values are heavily correlated between all languages but Swahili, which is a major outlier. This cross-lingual consistency across languages is juxtaposed with inconsistency of methods that utilize finetuning as shown by Prasanna et al. (2020).

Despite this consistency, we find some attention heads demonstrate high language-specificity. Most notably, the fifth attention head in layer six is positive for Swahili but strongly negative for all other 14 languages. This indicates that this head serves a function specific to Swahili within the model. We investigate the behavior of language-specific and language-agnostic heads further in Section 5.

It is worth noting that the outlier, Swahili, is the language with the fewest number of examples in the

For all metrics, we remove the Bottom-K heads ($K = |\{H_i \mid \varphi_i < 0\}|$) according to that metric. $^{+}$ and $^{-}$ indicate significant ($P < 0.05$) improvement and harm by a pairwise bootstrap test. Model parameters remain fixed for all methods.

data used in the pretraining of XLM-R. Whether the large variation between Swahili and all other languages is induced by linguistic features or the training dynamics of low-resource languages within multilingual models is unclear. We leave this to be explored further in future work.

4.4 Targeted Pruning

To understand the practical applicability of the resulting Shapley Values, we evaluate models before and after pruning all attention heads with negative Shapley Values as described in Section 3.3.

Each resulting language-specific model can be represented with only the 144 mask parameters which indicate whether each attention head is removed or kept. Therefore, this pruning can be seen alternatively as a parameter-efficient learning method, using $1 \cdot 10^{-6}\%$ of the parameters it would require to finetune the model for each language[2].

XNLI In Table 2, we report the accuracy of models after targeted pruning across all languages for both XNLI and UDPOS. For XNLI, we see that targeted pruning improves performance by an average of +1.59 across all 15 languages with the maximum improvement being in Chinese (+3.78) and the minimum improvement in Swahili (+0.37). We might expect that languages closely related to our finetuning language of English would benefit less from pruning, even closely related languages such as French (+1.97) and German (+1.53) are improved significantly.

UDPOS Improvements in UDPOS vary to a higher degree. Only 6 out of 13 languages improve after pruning, with the rest identical with no negative Shapley Values. Surprisingly, this indicates that attention heads do not introduce interference for these languages. We hypothesize that interference for these languages may instead lie largely within the Transformer feed-forward layers, which we do not study in this work. The largest improvement is again in Chinese (+12.4) and the smallest in French (+1.3). In the case of Chinese, this is a 24.7% improvement purely by removing attention heads. Across the languages which were pruned, the average improvement is 3.4 – reducing the cross-lingual gap (Hu et al., 2020) by 0.7.

Comparison to Baselines Randomly pruning is ineffectual or harms performance in both tasks, indicating that pruning alone is not the source of our improvement. Pruning according to the gradient-based metric proposed by Michel et al. (2019) maintains rather than improves performance. This supports our hypothesis that methods that use the magnitude of gradients largely identify non-impactful heads as opposed to harmful heads.

4.5 Zero-Shot Pruning

Given the high rank correlation between many of the languages, we evaluate transferability by using the Shapley Values for English to prune the model for all languages. We report results in Table 3.

XNLI On XNLI, surprisingly, this transferred pruning across languages has similar benefits to our targeted pruning results despite only being learned

---

[2] 144 parameters compared to $1.25 \cdot 10^8$ for full finetuning.

Table 3: Accuracy for XNLI after pruning using importance metrics from English. For all metrics, we remove the Bottom-K heads ($K = |\{H_i \mid \varphi_i < 0\}|$) according to that metric. $^{+}$ and $^{-}$ indicate significant ($P < 0.05$) improvement and harm by a pairwise bootstrap test.

for English. Two languages (Urdu and German) achieve better results in the zero-shot pruning than they did in the targeted pruning, five achieve worse results, and the remaining eight are equivalent.

It is likely that the strength of zero-shot transfer is largely due to the removal of the fifth head of layer six, which is one of the top 2 most negative heads for all languages barring Swahili. Interestingly, the Attention Head Shapley Values for Swahili also have the lowest rank correlation with English of any language.

UDPOS However, UDPOS highlights the major shortcoming of zero-shot pruning: all attention heads receive a positive Shapley Value for English for UDPOS. This means that no zero-shot pruning is performed despite targeted pruning finding benefits for languages shown in Table 2.

4.6 Iterative Pruning of Attention Heads

Finally, we evaluate the effectiveness of Shapley Values as a ranking methodology for the iterative pruning evaluation performed by Michel et al. (2019). Iterative pruning evaluates how well each importance ranking captures the combinatorial effects of removing attention heads at different compute budgets. We compare random pruning, the gradient-based approach from Michel et al. (2019), and Shapley Values computed through plain Monte Carlo simulation and Shapley Values using Truncation and Multi-Armed Bandit optimization (TMAB). We plot results in Figure 3.

Averaged across all levels of sparsity, our method outperforms the Random baseline (+5.8), Monte Carlo Shapley Values (+1.6), and the Gradient baseline (+0.6). At different stages. Depending on the target sparsity of interest however, Shapley Values and Gradient-based pruning have different levels of sparsity. Our method is the only method that identifies strongly harmful heads, with performance improving compared to the unpruned model for the first 6 heads removed. Our method achieves the largest performance gap at 44% of model capacity outperforming the Gradient baseline, Monte Carlo Shapley Values, and the Random Baseline by +12.2, +15.1, and +20.9 respectively. However, the gradient baseline outperforms our method when more than 80% of heads are pruned, although neither method performs well above chance at this sparsity.

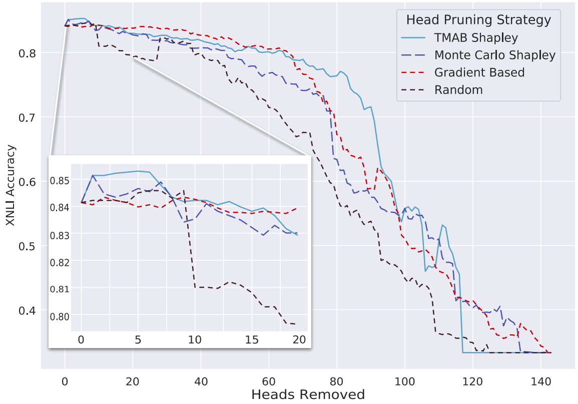

Figure 3: Evolution of XNLI Accuracy as Heads are removed according to different pruning strategies.

5 Qualitative Attention Analysis

In order to provide intuition into the function of attention heads, prior work has turned to attention visualization as the basis for qualitative analysis of the inner workings of transformer models. Clark et al. (2019) and Hoover et al. (2020) both explore patterns within attention heads.

We visualize the attention patterns of outlier attention heads using BertViz (Vig, 2019) from our model to give a qualitative understanding of the attention head patterns associated with language-agnostic and language-specific heads.

5.1 Language-Agnostic Heads

We define the set of language-agnostic heads as the intersection of the the top 20 attention heads for each language. In Figure 4, we visualize the

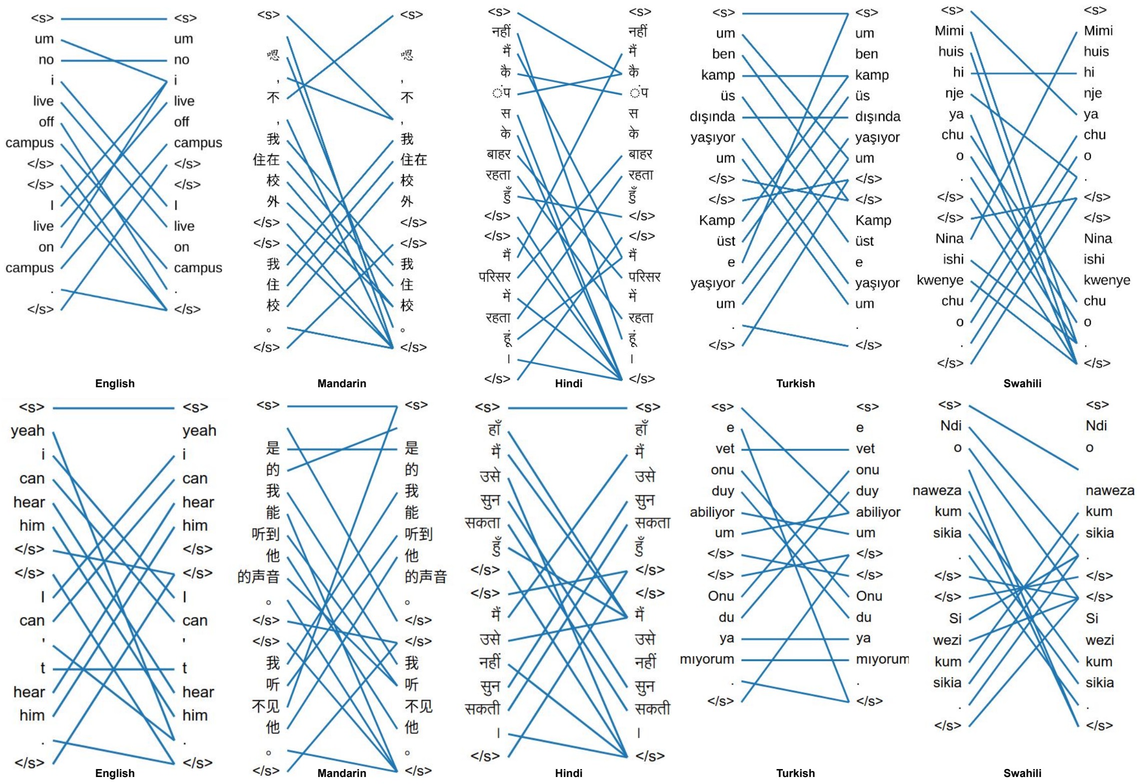

Figure 4: Attention of Layer 2, Head 9 of our XNLI model which is identified as language-agnostic. The attention pattern links synonyms in the premise and hypothesis for all languages. For clarity, we connect the left token to the token on the right which receives the largest attention weight.

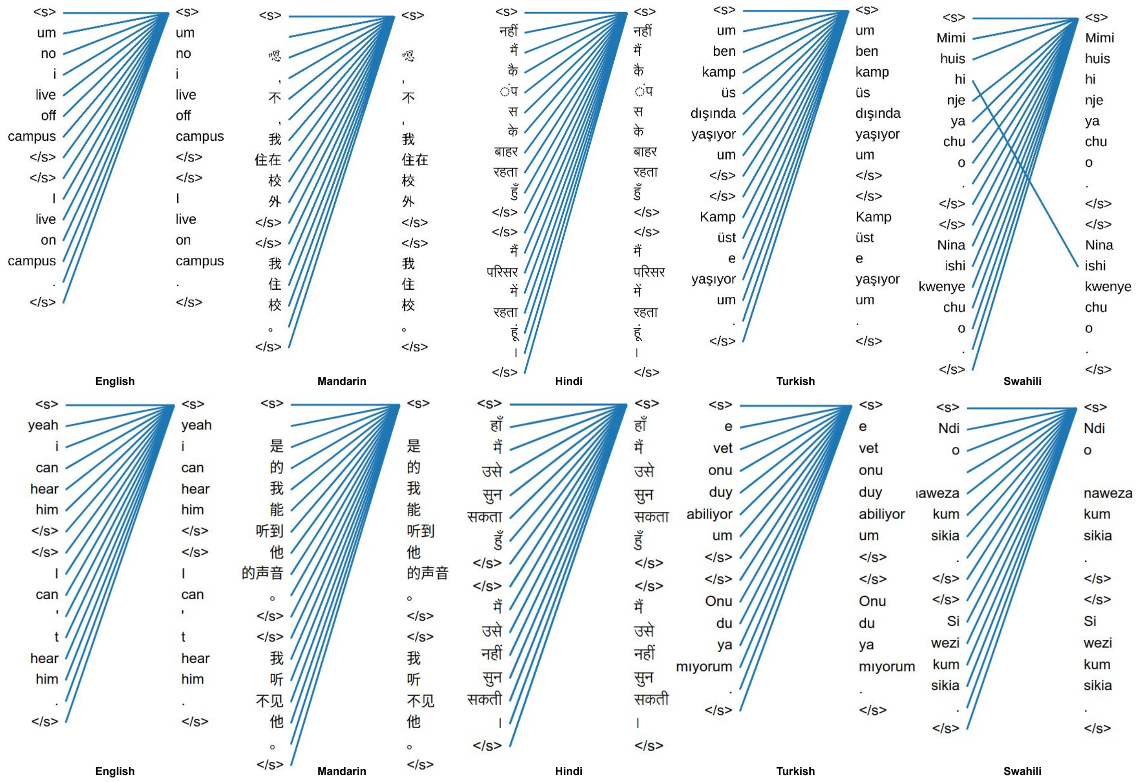

Figure 5: Attention of Layer 6, Head 5 of our XNLI model which is identified as language-specific to Swahili. Unlike the language-agnostic head, there is no obvious pattern in visualisation. However, in Section 5.2 we measure a significant difference in Swahili's attention to separator tokens compared to other languages.

attention pattern of the highest-ranked of the 4 heads which meet this criterion. The visualization highlights the same attention pattern across all languages: words from the premise are matched to near-synonyms in the hypothesis and vice versa.

The synonym-matching pattern clearly applies to NLI, where synonyms critically participate in commonalities and contradictions between the premise and hypothesis. Synonym linking is possible via token semantics and the separator tokens, so this pattern does not require any knowledge of language-specific syntax or morphology.

The visualization reveals a meaningful language-agnostic pattern which may explain why the positive Shapley Value across all languages. This usage highlights that while we utilize Shapley Values to remove harmful learned patterns, they also can direct mechanistic interpretability work to understand the effectiveness of transformers for a particular task (Wang et al., 2022).

5.2 Language-Specific Heads

As highlighted in Section 4.3, the fifth head of layer six has a positive Shapley Value only for Swahili. In Figure 5, we see that this head sometimes exhibits unique behavior for Swahili, connecting the incorrectly tokenized "ishi" suffix of "*Mimi Huishi*" and "*Ninaishi*" meaning "*I live*" in the Habitual and Present tense respectively. However, this use is not found frequently in our Swahili examples, as shown in the second example.

Therefore, we aim to understand whether the head functions in a measurably different fashion for Swahili across our entire dataset rather than on specific examples. Using the hypothesis from Clark et al. (2019) that attention to separator tokens indicates an inapplicable learned pattern, we look at the percentage of sentences where all tokens attend primarily to separators. This criterion is true in 56% Swahili XNLI inputs, but only 41% of non-Swahili inputs on average ($\sigma = 4.3\%$).

The frequency of separator attention combined with the minimal negative performance impact from removing this head for Swahili in Section 4.5 supports the idea that this head supports a rare pattern, perhaps stemming from poor tokenization. However, the relatively low rate of separator attention indicates that this head does impact other languages often, introducing noise.

6 Conclusions & Future Work

In this work, we developed a simple yet effective approach to measure the impact of individual attention heads on task performance by leveraging Shapley Values. We used this to identify language-specific and language-agnostic structural components of multilingual transformer language models. We demonstrated that the resulting values exhibit language affinity, varying across languages. We then applied these Attention Head Shapley Values to improve cross-lingual performance through pruning for both sequence classification and structured prediction. Finally, we performed provided insights on language-agnostic and language-specific attention heads using attention visualization.

We believe that attention head Shapley Values have strong potential to systematically inform future studies of multilingual models and transformers broadly. Future work should explore the relationship between linguistic features, training data volume, and the language-specificity of attention heads. Additionally, the benefits of removing heads motivates work that reduces cross-lingual interference introduced by language-specific components during pre-training, such as pruning during pre-training or utilizing sparsely activated networks.

7 Limitations

Even with our optimizations, using Shapley Values as an importance metric requires a significant computational cost compared to gradient-based methods: gradient-based methods take approximately 3.33e14 FLOPs and our optimized Shapley Values take approximately 3.27e16 FLOPs to converge. While the computation is parallelizable, it took several days on a single GPU to compute accurate estimates. This expense is reasonable for understanding the behavior of base models more deeply but limits the use of this method as a rapid iteration tool. For those looking to reduce this computational cost further, we recommend first using gradient-based methods to identify a set of heads to which the output is sensitive and then using Shapley Values to interpret the direction of the effect. While this may miss some harmful heads, it is likely to find the most harmful heads for a reduced cost.

Additionally, we rely on analysis of attention patterns to help ground our findings. However, there is debate as to whether analysis of attention patterns is a sound analytical tool (Jain and Wallace, 2019; Wiegreffe and Pinter, 2019).

Why Don't You Do It Right?
Analysing Annotators' Disagreement in Subjective Tasks

Abstract

Annotators' disagreement in linguistic data has been recently the focus of multiple initiatives aimed at raising awareness on issues related to 'majority voting' when aggregating diverging annotations. Disagreement can indeed reflect different aspects of linguistic annotation, from annotators' subjectivity to sloppiness or lack of enough context to interpret a text.

In this work we first propose a taxonomy of possible reasons leading to annotators' disagreement in subjective tasks. Then, we manually label part of a Twitter dataset for offensive language detection in English following this taxonomy, identifying how the different categories are distributed. Finally we run a set of experiments aimed at assessing the impact of the different types of disagreement on classification performance. In particular, we investigate how accurately tweets belonging to different categories of disagreement can be classified as offensive or not, and how injecting data with different types of disagreement in the training set affects performance. We also perform offensive language detection as a multi-task framework, using disagreement classification as an auxiliary task.

Warning: *This paper contains examples that may be offensive or upsetting.*

1 Introduction

The development of benchmark datasets based on the reconciliation of annotators' disagreement has been a standard practice within the NLP community for decades. However, in the last few years this paradigm has been questioned (Basile, 2020; Abercrombie et al., 2022), since aggregating discording labels is based upon the assumption that texts have a single interpretation and that annotators' disagreement is something that should be corrected. On the contrary, it may convey useful information on the task, the data and the annotators themselves (Aroyo and Welty, 2015). For example, annotators may disagree because of poorly described guidelines, or because they interpret in different ways a text based on their background and beliefs. The text may be ambiguous because of a lack of context, or annotators may simply be working poorly, without paying much attention to the task they should perform on the text (Uma et al., 2021).

Having a better understanding of the reasons behind annotators' disagreement could lead to better annotation guidelines and provide insights into the advantages and limits of developing NLP systems able to deal with disagreement (Davani et al., 2022). It would also contribute to a better understanding of how disagreement interferes with systems' performance. Finally, automatically detecting instances that are likely to obtain discording labels could help researchers in creating linguistic datasets with more or less challenging examples (Lehmann et al., 1996).

In this work, we contribute to the research line on annotators' disagreement by first presenting a taxonomy, where we classify possible reasons behind discording annotations in subjective tasks, i.e. tasks admitting diverse valid beliefs about what the correct data labels should be (Rottger et al., 2022). We also annotate part of an existing dataset for offensive language detection (Leonardelli et al., 2021) in order to assess the validity of our categorisation. We further perform several experiments aimed at addressing the following research questions: *i)* What are the most challenging categories of disagreement to classify in a task of abusive language detection? *ii)* What is the effect of including specific categories of disagreement in the training set? *iii)* Can multi-task learning be effectively used for offensive language detection using disagreement classification as auxiliary task? Are these

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2428–2441

results consistent across disagreement categories?

Evaluation results can contribute to ongoing studies investigating the negative impact of disagreement on systems performance (Schwartz et al., 2011; Beigman Klebanov and Beigman, 2014; Leonardelli et al., 2021; Uma et al., 2021) by providing a more fine-grained view on disagreement types.

The annotated data used in our experiments can be obtained as an extension of Leonardelli et al. (2021)'s dataset, at this link: `https://github.com/dhfbk/annotators-agreement-dataset`.

2 Related work

Despite all the efforts to minimize inter-annotator disagreement, every large-scale project involving linguistic annotation has to deal with cases of diverging perceptions among human workers, especially in tasks where human sensibility is at play. However, disagreement due to interpretation divergences is also found in text annotation tasks usually perceived as objective, such as Part-of-Speech tagging (Plank et al., 2014), semantic role labeling (Dumitrache, 2019) or word sense disambiguation (Martínez Alonso et al., 2015).

In subjective tasks, the hypothesis that a single truth exists for all instances has been debated in several past works (Basile et al., 2021; Uma et al., 2021; Basile et al., 2022). Indeed, many researchers suggested that disagreement has to be treated as a signal, and not as noise (Aroyo and Welty, 2015; Plank et al., 2014; Basile et al., 2019). For this reason, Plank (2022) has recently proposed to use *human label variation* rather than the term *disagreement* to capture the fact that two or more views may sometimes be plausible in text annotation. Along the same line, different approaches have been proposed with the primary aim of amending the traditional way in which disagreement is dealt with (i.e., to treat it as noise and discard it from the training set), thus demonstrating that disagreement provides insights into human perception, linguistic data as well as classification systems.

Concerning the integration of disagreement in NLP classifiers, few approaches have been proposed so far (for an overview, see Uma et al. (2021)). Beside aggregating judgments based on majority voting, which has the clear shortcoming of reducing different voices and points of view in favour of the dominant one, some approaches consider disagreement as an indicator of the difficulty of the instances to be annotated (Reidsma and op den Akker, 2008). Past works have proposed to train separate classifiers, one for each annotator, and build an ensemble classifier that makes a prediction when all classifiers agree on the class label (Basile, 2020) or to adopt a multi-task architecture using a shared representation to model annotator disagreements (Davani et al., 2022). Similarly, Fornaciari et al. (2021) use soft-labels (i.e., probability distributions over the annotator labels) as an auxiliary task in a multi-task neural model. As an alternative, disagreement can also be excluded from the data by training the model only on items that show high agreement (Reidsma and op den Akker, 2008) or, conversely, models can be trained and evaluated only on disagreement-raising items (Beigman Klebanov and Beigman, 2014).

Concerning the analysis of annotators' behaviour on subjective tasks, past works showed that disagreement is to be expected (Basile, 2020; Davani et al., 2022). This is confirmed by Kenyon-Dean et al. (2018), showing that around 30% of the instances in a Twitter corpus for sentiment analysis are controversial, thus likely to lead to disagreement. They also propose to merge them in a new class of sentiment called "complicated", so that they are not excluded from the data. Sang and Stanton (2022) show that age and personality are factors that greatly influence annotators' perception of offensive content. Kocoń et al. (2021) show that disagreement can be reduced and annotation quality increased by combining text representations of labeled annotators' opinions with their demographic traits. Akhtar et al. (2019) deal with disagreement in hate speech annotation by partitioning the annotators into clusters reflecting more uniform subjective judgments.

As regards the categorisation of disagreement in subjective tasks, one of the first studies on this topic was presented in Beigman Klebanov et al. (2008), where in a metaphor annotation task a distinction is made between annotators' attentions slips and genuine disagreement. Basile et al. (2021) identify three main sources of disagreement: individual differences related to annotators' background and beliefs, stimulus characteristics, i.e. inherent ambiguity of texts, and context. Uma et al. (2021) further extend this categorisation by listing the following reasons behind disagreement: annotation errors, imprecise or vague annotation scheme, context-dependent text ambiguity, introduced in

Poesio et al. (2019), item difficulty and annotators' subjectivity. In our proposed taxonomy, we rely on previous works in the choice of categories, keeping the distinction between inherent text ambiguity and context-dependent one, as well as annotators' subjectivity. We further specify these categories by proposing subtypes that take into account different linguistic phenomena.

A recent work introducing a taxonomy of disagreement has also been presented in Jiang and de Marneffe (2022), which focuses on the task of natural language inference. Interestingly, the authors propose a three-layered taxonomy which has some high-level overlaps with ours, for example our *Ambiguity* class can be roughly mapped onto *Uncertainty in sentence meaning*, and *Subjectivity* onto *Annotator behavior*. The lower categories, however, are in some cases very task-specific. The analysis of task-specific and task-independent categories of disagreement may be an interesting research direction to explore in the future.

3 A Taxonomy of Disagreement

As a first step towards a better understanding of the reasons behind annotators' disagreement, we propose a taxonomy of disagreement for subjective tasks, which is built starting from past categorisations presented in the literature and iteratively adding subtypes based on the analysis of examples in existing datasets. An overview of the taxonomy is reported in Figure 1. The taxonomy includes four macro-categories, which are further specified through more fine-grained subtypes. For each category we report also selected examples, all taken from the dataset of disagreement presented in Leonardelli et al. (2021) (see a more detailed description of the dataset in Section 4). In the following, we illustrate each category in detail.

3.1 Sloppy Annotation

This category covers errors in the annotation due to annotators' carelessness. This can happen in particular with crowd-sourcing platforms, when annotators are recruited without a proper training and their annotation quality is not monitored. In general, this type of disagreement can be minimised by adopting tools that identify which annotators are not trustworthy (Hovy et al., 2013).

The only specification for this category is *Noise* (Figure 1), corresponding to messages clearly labeled with the wrong category, see for instance the tweet below annotated as "offensive":

(1) *In a singular voice, art across the world..*

3.2 Ambiguity

The second source of disagreement we include in the taxonomy is *Ambiguity*, that is a much debated topic in linguistics. It is generally referred to as a property of words or phrases to allow more than one interpretation (Tuggy, 1993; Cruse, 2004). This category comprises mainly cases of figurative language, a phenomenon related to the use of words with a diverging meaning from their literal use in order to express colorful images and emotions (Dancygier and Sweetser, 2014). This category includes six subtypes:

Analogy. This label includes comparison mechanisms, such as simile and metaphor, along with the figure of speech of analogy. Both these phenomena involve the cognitive concept of mapping between two conceptual domains (Dancygier and Sweetser, 2014). Below we report an example of metaphor:

(2) *Trump is a walking petri dish. His goal is to spread the virus to as many people as possible.*

False Assertion. Under this label we group all the cases that are characterized by an assertion that is false if compared to the reality of facts and that can therefore trigger irony (Cignarella et al., 2018). In other words, users express the opposite of what they think or something false and exaggerated in relation to the context. This figure of speech needs knowledge of the world to be understood and this is the main reason behind disagreement. An example is reported below:

(3) *Another attempt backfired on them, George Floyd cured Covid-19 and opened up the economy!*

Rhetorical Question. We group under this label all the instances containing a question asked not to obtain an answer but with the purpose of rhetorically pointing out a concept (Stivers and Enfield, 2010), see example below:

(4) *why do we treat our prisoners like this? Is it really because we decided once you commit a crime you're worthless non-human?*

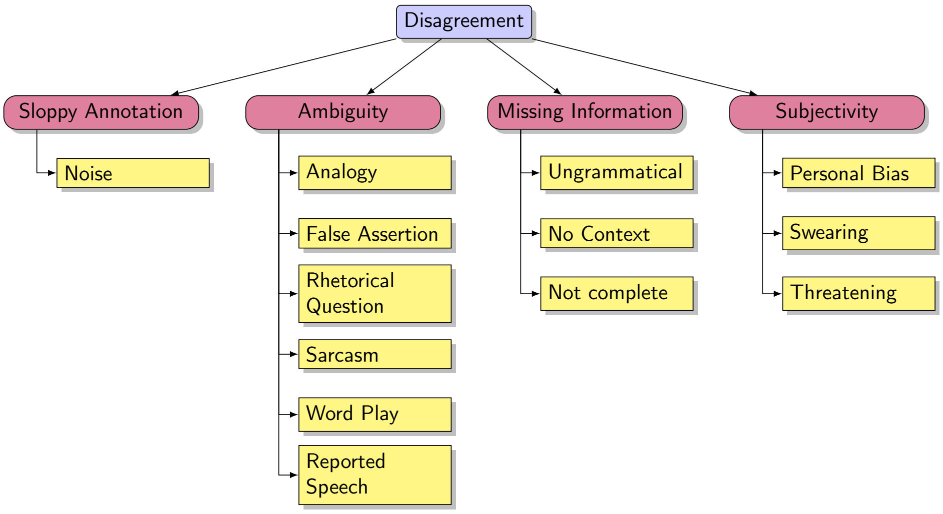

Figure 1: Taxonomy of annotators' disagreement in subjective tasks. Pink boxes represent coarse-grained categories, while yellow boxes correspond to subtypes.

Sarcasm. Sarcasm is characterized by words employed to express the opposite of their literal meaning, mainly used to make fun of a specific topic or person. Sarcasm needs context and other extra-linguistic expressions like pauses and intonation to be understood and it features a disproportion of emphasis regarding the real situation, giving a caustic effect (Gibbs, 1986). However, in writing, these extra-linguistic hints are not possible, thus we must rely on our knowledge of the world or of the addressee to understand sarcasm.

(5) *Who knew a side effect of COVID would be gross incompetence.*

Word Play. Word Play is a figure of speech that involves literary devices to alter some words, with the purpose of giving proof of someone's wit. Among the literary techniques used to convey word play are acronyms, alliterations, i.e. repeating the same sounds in a sentence, and puns, i.e. using words with multiple meanings to obtain a humorous result.

(6) *The only people ripping this country apart are your fellow liberal #DemocRATS and your militant concubines.*

Reported Speech. It is commonly defined as the presentation of discourse that purports to be from a prior occasion, and may originate from another author (Holt, 2009). It can be ambiguous because it can be mistaken as something written by the same author of the text to be annotated.

(7) *White Bystanders With Rifles Stare Down George Floyd Protesters: 'You Ain't Got No Guns'*

3.3 Context sensitivity: Missing Information

In this category we group all cases in which annotators' disagreement may be caused by a lack of information or of context to unambiguously interpret a text (Donaldson and Lepore, 2012). It includes the three following subtypes.

Ungrammatical and Non Standard Language. We assign this label to all the texts that could cause disagreement due to marked uses of the language (e.g. non-standard varieties), use of slang, code-switching or mere typing errors. Intuitively, annotators who do not speak a specific language variety are more likely to misunderstand or misinterpret it (Sap et al., 2019), leading to disagreement. See the example below:

(8) *mane it's hard for some of da blaxk people out dere when dey go into a store they got everybody looking at them "what they doing"*

No Context. This class covers well-known linguistic phenomena which need context to be unequivocally interpreted such as anaphora and deixis (Poesio and Artstein, 2005). We include in this category also messages containing links, typically used in online communication. Deictic expressions include devices such as demonstratives (*this, that*, etc.), personal pronouns (*I, you, he, she*, etc.), possessives (*his, her, their*, etc.) (Levinson, 2004). As regards anaphoric expressions, instead, the interpretation of the textual content is determined by that of the antecedent (Levinson, 1987), therefore, if there is not enough context, crucial information may be missing. We report below an example containing both a deictic expression (*this*) and an anaphoric pronoun (*them*):

(9) *Dude this guy is serious? And trump retweeted this?????? Please anonymous take them out*

Not Complete. In the last subclass of *Missing Information*, we group all cases that do not convey complete information and do not fall into any other subcategory. A typical example is social media threads written by a user. If just one message is extracted from a thread and annotated, it may be very difficult to understand what its tone and meaning is. As an example, see below:

(10) *Wtaf, a farce in three parts:*

3.4 Bias and Desemanticization: Subjectivity

We group in this category cases of disagreement due to the annotators' identity, beliefs and background, which have been recognised as leading to biased judgments (Sap et al., 2022). This is a major source of disagreement in subjective tasks such as hate speech detection, sentiment analysis or political stance detection. The category includes three subtypes.

Personal Bias. Although it is not easy to identify cases of disagreement due to personal biases, in particular when annotators are unknown, this category can be inferred because it is very likely to occur when the text to be labeled belongs to a divisive topic, such as politics, covid-19, social movements, etc. (Wich et al., 2020). See for example the sentence below:

(11) *#DemocratsAreDestroyingAmerica #BlackLivesMatter is a terrorist organization*

Swearing. Another cause of disagreement related to annotators' subjectivity is how they interpret swear words. Indeed, some annotators perceive specific swear words as offensive and hurtful, while for others they appear to be desemanticized (Ljung, 2011). A typical example in English is the use of the word *bitch*:

(12) *2nd wave about to be a bitch*

Threatening. Disagreement may arise from texts containing linguistically violent expressions or threats and depend on annotators' sensitivity to verbal violence and menaces (Storey, 1995), see for instance, the following text:

(13) *U r going to jail.*

4 Data Annotation and Analysis

We apply the taxonomy illustrated above to the dataset of disagreement in abusive language presented in Leonardelli et al. (2021), which contains more than 10k English tweets labeled as offensive or not offensive by five crowd-workers, and covers three topics: covid-19, US Presidential elections and Black Lives Matter movement. The dataset has been designed so as to include a balanced set of tweets with full agreement (A^{++}), with partial agreement (A^{+} class, 4 matching labels versus 1) and with disagreement (A^{0} class, 2 vs. 3 labels) and has been released divided into a balanced training and test split.

We manually annotate all A^{+} and A^{0} tweets in the test set (1,756 in total), plus a portion of tweets from the training set (809 tweets). A total of 2,574 tweets is annotated, divided in 1,518 for the A^{0} agreement level and 1,056 for the A^{+} agreement level. Annotation was performed by a trained linguist, and during the process the initial taxonomy was adjusted by refining the category definitions or introducing new ones when needed. A second linguist annotated a sample of 200 tweets divided equally into A^{0} and A^{+} following the annotation guidelines (see Appendix B). Cohen's Kappa is 0.591, which corresponds to a moderate agreement. After computing agreement, a discussion and adjudication phase was conducted.

Based on the annotator's feedback, we foresaw the possibility to assign multiple labels to the same tweet when the source of disagreement could refer to two or more categories in the taxonomy, considering however the first label as the most probable interpretation. A multi-category annotation scheme was adopted for the same reason also in Jiang and de Marneffe (2022).

In Table 1 we report the distribution of annotated tweets by category and by agreement level.

In case of multiple labels, we include the first one in the statistics. However, tweets annotated as belonging to more than one category are around 40%, showing that disagreement is often due to a mix of different linguistic phenomena. The category with the most multiple annotations is *Subjectivity*, labeled together with *Missing Information* in most of the cases.

	A^0	A^+
Subjectivity	996	703
Ambiguity	302	201
Missing Information	218	142
Sloppy Annotation	2	10
Total	**1,518**	**1,056**

Table 1: Number of annotated tweets by category and agreement level. A^0 is 3 vs. 2 judgments; A^+ is 4 vs. 1 judgment.

Table 1 shows that the cases leading to disagreement because of annotators' subjectivity cover most of the tweets in the dataset, and that the ranking of the four categories is the same for the two agreement levels. As expected, clear annotation mistakes (i.e. *Sloppy Annotation* category) are more frequent for A^+, but in general they have a minimal impact on the cases of disagreement. This is probably due to the fact that the dataset in Leonardelli et al. (2021) was created adopting a strict quality control protocol aimed at excluding low-quality crowd-workers.

In Figure 2 we report how the subtypes are distributed in the annotated dataset. As shown in previous studies, swear words are often a signal for a hateful attitude, but they are also used in casual contexts with positive social functions (Pamungkas et al., 2020). This double interpretation is likely the main reason why the *Swearing* subtype is very frequent in our dataset of disagreement. Concerning *Personal Bias*, its relevance is probably related to the fact that the annotated tweets deal with controversial topics such as US American elections, Black Lives Matter and covid-19. For instance, few tweets targeting Trump were labeled as not offensive by annotators, who were likely to be Biden supporters, and vice versa.

If we compare the above statistics with the analysis reported in Jiang and de Marneffe (2022) on disagreement in natural language inference (NLI), we observe that the most frequent causes of disagreement are task-specific: in our dataset, they are mostly due to annotators' subjectivity and their perception of what is offensive, while in NLI they often stem from the underspecified meaning of lexical items in the sentence pairs to be labeled, or in the probabilistic nature of the inferred content.

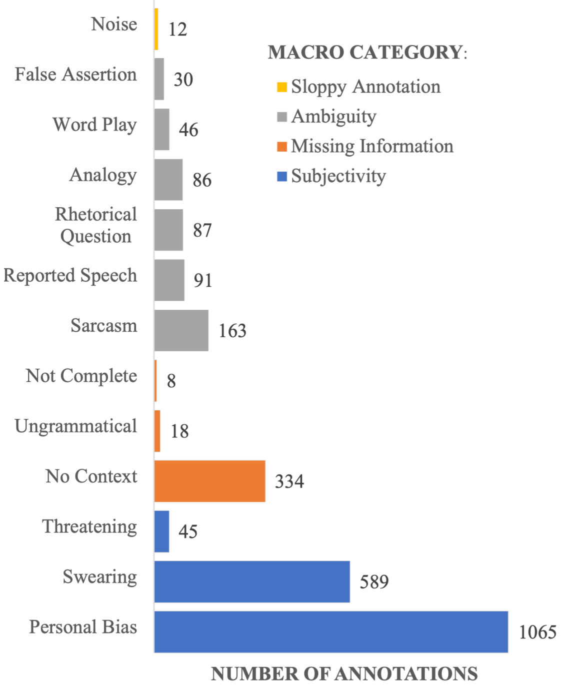

Figure 2: Summary of annotated data by main category and subtype.

5 Experiments

In the next subsections we describe a series of experiments conducted on the annotated dataset, aimed at analysing the relationship between annotators' disagreement and various aspects of automatic offensive language detection. For all the experiments described below, we use the MaChAmp v0.2 toolkit (van der Goot et al., 2021), a classification tool that allows easy implementation of transformers-based classification tasks and supports single-task and multi-task learning. For all the experiments we employ BERT-base uncased (Devlin et al., 2019) (110M parameters) and perform 20 restarts. We keep the default hyperparameter setting of MaChAmp, i.e. max seq length 128, batch size 32, 0.3 dropout, 10 epochs. All the results reported in the following subsections are the average values of 20 runs. All experiments are run on a NVIDIA Quadro RTX 5000 GPU.

Subtype	Main category	Test size	micro F1		
			All	Offensive	Not offensive
Swearing	*Subjectivity*	427	$75.74_{\pm 0.64}$	89.45	39.83
Rhetorical Question	*Ambiguity*	60	$71.75_{\pm 4.00}$	65.79	74.51
Not complete	*Missing Info*	7	$71.43_{\pm 12.78}$	-	-
No context	*Missing Info*	183	$71.26_{\pm 2.35}$	43.75	77.09
Reported Speech	*Ambiguity*	82	$70.37_{\pm 2.62}$	60.24	73.85
Threatening	*Subjectivity*	41	$68.78_{\pm 4.12}$	74.12	65.00
Word Play	*Ambiguity*	33	$65.61_{\pm 3.22}$	65.31	65.88
Personal Bias	*Subjectivity*	729	$64.98_{\pm 2.05}$	63.35	65.89
Ungrammatical	*Missing Info*	14	$64.29_{\pm 5.05}$	53.12	79.17
Sarcasm	*Ambiguity*	97	$63.71_{\pm 3.49}$	58.75	65.34
Analogy	*Ambiguity*	62	$60.56_{\pm 2.91}$	70.52	51.82
False Assertion	*Ambiguity*	20	$53.00_{\pm 6.20}$	37.22	65.91

Table 2: Classification performance of the best system from Leonardelli et al. (2021) for each category and subtype of disagreement. We report the average F1 obtained from 20 restarts and, for the overall results, also the standard deviation.

5.1 Classification performance on disagreement categories

Our first experiment aims at analysing differences in classification performance among disagreement categories and subtypes. To this end, we use the best model for offensive language classification previously described in Leonardelli et al. (2021), which was trained using only tweets with perfect (A^{++}) and high (A^{+}) agreement. We run this model on the tweets in our dataset that belong to the test set of the original work, and calculate separated performance scores for each category and subtype. We report the results in Table 2.

The best performance is obtained on the *Swearing* subtype (75.74 micro-F1). However, the results on the two classes, i.e. Offensive and Not offensive, show that this high F1 mainly depends on the good performance yielded on the offensive class. Indeed, swear words tend to be very predictive of offensive content, and have already been recognised in previous studies as so-called *authentic artifacts*, i.e. highly-discriminating and informative tokens in conveying hatefulness (Ramponi and Tonelli, 2022). On the contrary, swear words in non-offensive tweets are both controversial for human annotators and difficult to detect for classifiers (Pamungkas et al., 2020).

For the most numerous subtype, *Personal Bias*, performance is rather low compared to the other types. However, the classifier yields a comparable performance on the offensive and not offensive class, showing that the two classes are equally challenging when annotators' beliefs and background come into play. In general, classification performance on offensive tweets is lower than on not offensive ones, except for *Swearing*, *Threatening* and *Analogy*. Offensive language detection systems tend to perform better on the not offensive class, because it is usually represented by more examples in the training set. Our experiment confirms this trend with few exceptions.

As a further analysis, in Figure 3 we report the classification results (average of 20 runs) on the different subtypes for A^0 and A^+ tweets. For all the categories except for *Analogy*, the classification performance is better on A^+ cases (low disagreement) compared to A^0 (high disagreement). This is probably because assigning a label to A^0 cases through majority voting is rather arbitrary, leading to cases that a system can poorly classify.

5.2 Training with disagreement

Several works showed that training a classifier using data with a low level of agreement is detrimental to the system performance (Reidsma and op den Akker, 2008; Jamison and Gurevych, 2015). We delve further into this issue by evaluating whether this negative effect depends on the presence of a specific class of disagreement in the training set. To this end, we retrain a classification model for offensive language detection using the original training split used in Leonardelli et al. (2021), and we compare it with the performance obtained including in the same training set only the subset of A^0 tweets belonging to a specific category, i.e. either *Subjectivity* or *Missing Information* or *Ambiguity*. The performance of the models is evaluated on the same three categories in the test set. Results are reported in Table 3.

To reliably compare differences between models' performances, we use Almost Stochastic Order (Dror et al., 2019; Del Barrio et al., 2018) in its

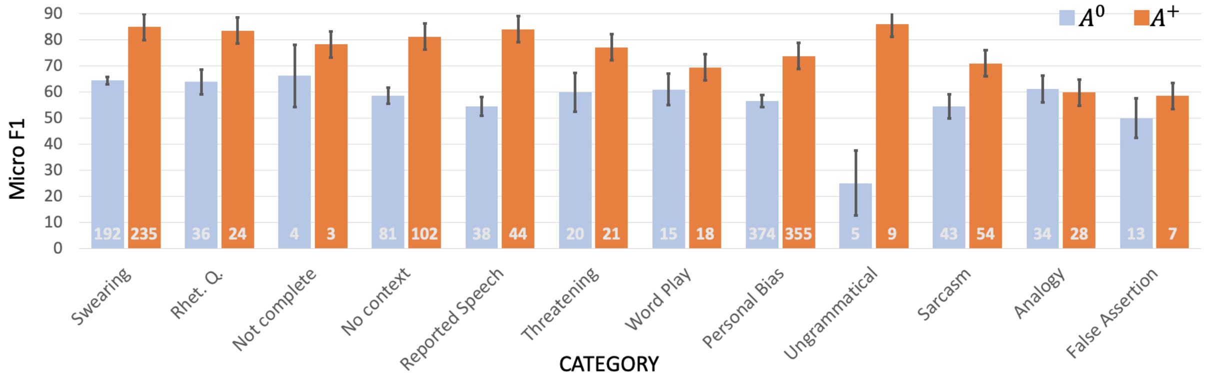

Figure 3: Performance of the classifier for the different agreement levels and categories. Error bars represent standard deviation obtained from 20 restarts.

Training split	**Train. size**	**Testing on**		
		Subj.	*Missing*	*Amb.*
$A^{++/+}$	1,800	68.95	70.78	65.64
$A^{++/+/0}$	2,700	68.79	69.71	**66.31***
$A^{++/+/0(SUBJ)}$	2,206	68.55	69.29	65.48
$A^{++/+/0(MISS)}$	1,927	68.93	**70.84***	65.79
$A^{++/+/0(AMB)}$	1,923	**69.07**	69.48	64.58

Table 3: Classifier performance (F1) with different versions of the training set, with and without specific classes of disagreement. Statistically significant results (compared to the lowest F1) are marked with (*).

implementation by Ulmer et al. (2022). For each of the three test sets, we compare the models scores across the 20 restarts. For statistical significance a threshold of $\tau = 0.2$ is considered.[1]

As shown in Table 3, while the differences in performance when testing on the *Subjectivity* category are not statistically significant, the best scores obtained on *Ambiguity* and on *Missing Information* show a statistically significant improvement over the lowest F1 and, in the case of *Missing Information*, also over training with $A^{++/+/0(AMB)}$.

For the classification of examples from *Missing Information*, adding only the A^0 examples belonging to the same category of disagreement yields to the best performance among all models. On the contrary, when classifying tweets in the *Ambiguity* class, the best performance is obtained when all A^0 are added to the training set regardless of the tweet category or disagreement level. The lowest performance, instead, is the obtained when adding only A^0 examples from the *Ambiguity* class. This may be due to the fact that this class is the most heterogeneous one, with different subtypes all represented in the data with few examples, covering very different linguistic phenomena. Overall, these results suggest that removing A^0 instances from training is not always the best solution, contrary to what was suggested in previous works (Leonardelli et al., 2021). Instead, distinctions should be made among different types of disagreement when deciding whether to remove training instances or not.

5.3 Multi-task learning with disagreement

Finally, we investigate whether using information about disagreement can improve offensive language detection. We employ a multi-task framework, which has already been used to include disagreement information in classification tasks (Fornaciari et al., 2021; Davani et al., 2022; Ramponi and Leonardelli, 2022). In a multi-task setting, the encoder component is unique and shared between both tasks that during training are jointly fine-tuned. In our case, we consider offensive language detection as the primary task, and disagreement detection as the secondary one, to test whether the latter can provide useful signals to potentially improve the performance on the main task. We test two variants in this respect: *i)* we cast the auxiliary task as a three-way classification aimed at recognising tweets labeled as A^{++}, A^{+} and A^0, and *ii)* we implement a more fine-grained version of the previous task, aimed at assigning tweets to one of six classes: A^{++} offensive and not offensive, A^{+} offensive and not offensive and A^0 offensive and not offensive. All these labels were already provided in the dataset by Leonardelli et al. (2021), so no additional annotation was required. The classifier for offensive language detection is tested separately on the three classes of disagreement *Subjectivity*, *Missing Information* and *Ambiguity*, like in the ex-

---

[1] Based on Ulmer et al. (2022), this threshold is comparable to a Type I error rate of p-value .05

periments in Section 5.2.

Results are shown in Table 4. The first row presents the single-task setting, i.e. offensive language detection, compared with the multi-task ones, i.e. three-class and six-class classification.

Multitask		**Testing on**		
Task 1	**Task 2**	*Subj.*	*Missing*	*Amb.*
Offensive language	-	68.79	69.61	**66.31**
Offensive language	Agr. level $A^{++,+,0}$	69.15	**69.84**	66.26
Offensive language	Agr. level $N/O^{++,+,0}$	**69.24**	69.34	65.82

Table 4: Classification performance (F1) with multi-task learning. N=Not offensive; O=Offensive.

Although the differences across settings are slight, the best result for the *Subjectivity* category is obtained within the multitask framework with 6-way classification as an auxiliary task. For *Missing Information*, instead, the multitask setting with three-way classification is the best one, while for *Ambiguity* providing auxiliary information on disagreement levels does not seem to yield any improvement. These differences support our intuition that we should distinguish among the different types of disagreement, since different strategies would be necessary to deal with them during classification. However, a statistical analysis similar to the one presented in previous section failed to reveal any significant difference between the models' performances.

6 Conclusions

In this work, we first introduced a two-layered taxonomy for the classification of annotators' disagreement in subjective tasks, consisting in four main categories and a number of subtypes aimed at covering different linguistic phenomena. We then annotated part of an existing dataset developed to study disagreement with the above classes and subtypes. A first analysis shows that the *Subjectivity* class is the prevalent one in the dataset, and that *Personal Bias* and *Swearing* are two major reasons leading to frequent cases of disagreement among annotators for the task of offensive language detection. Secondly, we run several experiments to gain novel insights into disagreement phenomena. In particular, we investigate whether a system for offensive language detection is more prone to wrong classification on specific classes of disagreement. Our results show that the presence of *Sarcasm*, *Analogy* and *False Assertions* negatively affects classifier performance, while *Swearing* obtains the best classification results, despite showing a bias in favour of offensive tweets. Furthermore, cases with high disagreement are generally more difficult to classify than those with mild disagreement for all categories except for *Analogy*. In a second experiment, we show that adding instances of *Missing Information* to the training set, even if they belong to the A^0 class, has a positive effect on the classification of this specific class, while this is not true for *Ambiguity*, probably because it contains more heterogeneous data. Finally, we show that adding disagreement information as an auxiliary task in a multi-task setting, having offensive language detection as the main task, is not generally better, and has different effects on the three above classes.

As regards tweets annotated with multiple labels, we observe that it is rather frequent to find more than one cause of disagreement (around 40% of the tweets in our dataset). We performed a preliminary experiment (not reported in this paper) comparing the performance of the best system configuration on single-label and multi-label examples, and we observed no significant difference. We will further investigate this aspect and compare single- and multi-label items in detail in the future.

In general, we hope that this work can contribute to the ongoing debate on the importance of considering, and not removing, disagreement when creating datasets and when developing classifiers. Furthermore, we advocate for a differentiation of the types of disagreement, showing that their presence in training and test data can have different effects on classification.

Limitations

While the taxonomy of disagreement is designed to be language-independent and to cover the annotation of subjective tasks, we have applied it only to a dataset for offensive language detection in English. Its applicability to other tasks will be investigated in the near future, together with its portability across languages. Also, the small size of the annotated dataset may limit the generalisability of our findings. In particular, the differences in performance across settings in our experiments are not always statistically significant.

Ethics Statement

We do not foresee specific ethical risks related to the current work. On the contrary, the analysis of different types of disagreement is aimed also at making the role of subjective annotations accepted within the NLP research community, making sure that the voices of minorities are included. Indeed, this work contributes to providing methodologies to distinguish subjective annotations from mistakes and poor-quality judgments.
