A Data Cartography and Uncertainty

Apart from relabelling, we investigated two additional approaches to rank synthetic instances as easy or hard to classify. We used data cartography (Swayamdipta et al., 2020) and classification uncertainty to guide our filtering.

Data cartography classifies the training data in four categories: Easy-to-learn, Low-Correctness, Ambiguous, Hard-to-Learn using training dynamics (i.e. the model's confidence in the true class, and the variability of this confidence across epochs).

For uncertainty modeling, we assign uncertainty scores to each training instance in a *cross-validation* manner. We first split the training set into 5 folds, hold one fold out as validation, and predict on the validation with the classifier trained on the remaining 4 folds. We tried the following uncertainty measures: Contrastive Active Learning (AL) (Margatina et al., 2021), Least Confidence (Culotta and McCallum, 2005), Prediction Entropy (Schohn and Cohn, 2000; Roy and McCallum, 2001), and Breaking Ties (Scheffer et al., 2001; Luo et al., 2004).

We conducted experiments using the above approaches to select data that amounts to one third of the total training data in BANKING (i.e., we select the top 33% hardest examples, etc.). As an additional baseline, we include a random filter, i.e., a randomly sampled 33% portion of BANKING. Table 6 shows the results, where we see that the performance actually degrades when compared to using the entirety of the data. We experimented with a few more variations in the filtering thresholds but no combination improved performance and we do not report those results here. See Figures 5 and 6 in the Appendix B for a visualization of the BANKING data map.

		100% Train	92.89
33% Train		Random	89.50
	Uncertainty	Contrastive AL	88.54
		Least Confidence	89.08
		Breaking Ties	89.20
		Prediction Entropy	89.23
	Cartography	Easy to Learn	90.44
		Ambiguous	90.94
		Low Correctness	91.00
		Hard to Learn	91.26

Abstract

Multilingual sentence representations from large models encode semantic information from two or more languages and can be used for different cross-lingual information retrieval and matching tasks. In this paper, we integrate contrastive learning into multilingual representation distillation and use it for quality estimation of parallel sentences (i.e., find semantically similar sentences that can be used as translations of each other). We validate our approach with multilingual similarity search and corpus filtering tasks. Experiments across different low-resource languages show that our method greatly outperforms previous sentence encoders such as LASER, LASER3, and LaBSE.

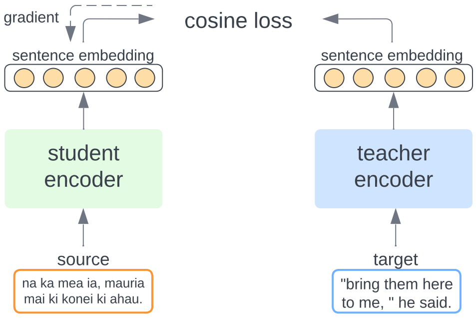

Figure 1: Student-Teacher Distillation in LASER3.

1 Introduction

With the rise of neural networks, high-dimensional word-level sequence representations play an important role in almost any natural language processing task. Contextual representations from large pre-trained language models (Vaswani et al., 2017; Devlin et al., 2019; Liu et al., 2019; CONNEAU and Lample, 2019) have shown advantages compared to earlier static embeddings (Mikolov et al., 2013; Pennington et al., 2014). However, they are not pre-trained with sentence-level objectives and their representations of two different sentences cannot be easily used to indicate semantic similarity. To encode sentence-level information, LASER (Artetxe and Schwenk, 2019b) pools a sentence embedding from the encoder and feeds it to the decoder. Another approach is to use siamese-structured models where two identical encoders are used to represent sentences of similar meaning and are trained to push their representations close to each other. Sentence-Transformers (Reimers and Gurevych, 2019) are siamese-structured models that are initialized with pre-trained large models like BERT (Devlin et al., 2019) or Roberta (Liu et al., 2019). After fine-tuning, Sentence-Transformers improve their sentence representation for cross-lingual tasks. Besides fine-tuning with identical (siamese) encoders, distillation can be used to retrieve better representations. Reimers and Gurevych (2020a) extends a monolingual sentence representation into a multilingual representation with model distillation. Similarly, Heffernan et al. (2022) proposed LASER3, a student-teacher architecture that distills information from a pre-trained teacher encoder to a student encoder in new languages. As shown in Figure 1, the distillation process updates the student encoder with the gradient from the cosine loss. Note that it freezes the parameters of the teacher encoder, which is already pre-trained on the target language (English in our case). Therefore, the target sentence embedding is fixed and the corresponding source embedding is aligned with the target embedding.

In this paper, we focus on the quality estimation of parallel sentences in low-resource languages, which requires models to distinguish similar and dissimilar sentence pairs. Contrastive learning is helpful because its objective not only aligns similar sentences' representations but also pushes away representations from dissimilar sentences, which

(a) LASER3-CO

(b) LASER3-CO-Filter

Figure 2: Visual Explanation of LASER3-CO (vanilla) and LASER3-CO-Filter (filtered). Source and target come from input bitexts dataset and queue is constructed with earlier batch's samples. In the (b) filtered version, a pre-filtering mechanism is employed to filter out extremely negative samples from the queue.

enables the model to be more confident in similar sentences. Additionally, contrastive learning is a form of self-supervision that fits well in our low-resource setting where only a limited amount of clean data is available.

In practice, we integrate contrastive learning into the distillation-based architecture from LASER3 and use our contrastive distillation method to train encoders for low-resource languages. Inspired by He et al. (2020) and Wu et al. (2018), we used a queue to store negative samples as self-supervision to train better encoders. We also employed a pre-filtering mechanism to find hard negative samples and showed that they benefit the distillation of sentence representations.

To evaluate different encoders, we rely on multilingual similarity search and corpus filtering tasks. In the multilingual similarity search task, we encode all source and target sentences and use a cosine-based similarity metric called margin score (Artetxe and Schwenk, 2019a) to pair source and target sentences. In the corpus filtering task, a mined noisy parallel corpus is given and we use the encoder with margin score to compute a similarity score for each sentence pair. Then we filter out the low-score pairs and use the remaining corpus to train a neural machine translation model whose performance is evaluated with BLEU (Papineni et al., 2002). Compared to previous works, we observe consistent improvement when using contrastive distillation. We also compared our approach with another simple but effective data augmentation technique, back-translation, and show that contrastive distillation achieves tied or better performance with less data.

2 Approach

To train high-quality sentence representation, we integrate contrastive learning into sentence representation distillation and our contrastive distillation method is visualized in Figure 2. The motivation for using contrastive learning is two-fold:

- The self-supervision from contrastive learning helps representation learning in low-resource settings.
- Contrastive learning enables models to recognize similar and dissimilar sentences, which is crucial for filtering out noisy sentence pairs.

2.1 LASER3-CO

This architecture corresponds to Figure 2 (a). We name it LASER3-CO since it integrates contrastive learning to LASER3's distillation pipeline. We are inspired by He et al. (2020) to use a queue to store contrastive (negative) samples. The negative samples are used to train encoders so that sentences of different meaning have dissimilar representations. During training, we use previous batches' target language sentences as negative samples and when there are too many negative samples in the queue, we remove the samples from the earliest batches. Our LASER3-CO approach has the following steps:

- Pre-train LASER to use as the teacher encoder θ_t on high resource languages such as English. Randomly initialize the student encoder and perform distillation with the teacher encoder. After distillation, we obtain the pre-trained student encoder θ_s.

- Fine-tune θ_s using queue(memory)-based[1] contrastive learning. For each input source sentence x and target sentence y, encode them with student and teacher encoders respectively and we have their representations $q = \theta_s(x), k_{\text{target}} = k_+ = \theta_t(y)$ (we use "+" as an abbreviation for the positive target sentence). We also encode all (N) negative sentences in the queue and have their representation $k_i = \theta_t(\text{queue}_i), i \in [1, N]$.

- Perform normalization on $q, k_i, i \in [0, N]$ and then compute the contrastive loss using infoNCE (van den Oord et al., 2018)

$$\mathcal{L} = -\log \frac{\exp(q \cdot k_+/\tau)}{\sum_{i=1}^{N} \exp(q \cdot k_i/\tau)} \tag{1}$$

  Here τ is the temperature parameter[2] that controls the strength of the penalty.

- Update student encoder θ_s with loss. Enqueue the most recent target language (English) sentences and dequeue the earliest sentences if the queue size exceeds the limit (N).

In LASER3-CO, our training process is very similar to MOCO (He et al., 2020), though we do not use the momentum update for the teacher. Instead, we freeze the pre-trained teacher (LASER in our case) that already has a high-quality representation of English (or any other pivot language), so that English sentences are encoded consistently during distillation. Then we try to align the representation of the student encoder to the teacher, only allowing gradients to flow through the student encoder.

2.2 LASER3-CO-Filter

This architecture corresponds to Figure 2 (b). The motivation is that previous work (Robinson et al., 2020) has shown hard negatives improve representation. In our task, for each parallel sentence pair (x, y), the hard negatives would be sentences y' that are hard to distinguish from the true target y (we can also find hard negatives x' in the source language, but because our teacher encoder has better representation for the target language, English, we decide to focus on target-side hard negatives only). Hard negatives are beneficial because they force the model to learn more complex features to distinguish them from the true target sentence.

To find more hard-negatives for contrastive fine-tuning, we change LASER3-CO in two ways: (1) disable shuffling for the data loader and (2) use a pre-filtering mechanism to filter out bad samples from the queue (we name this model LASER3-CO-Filter where Filter refers to the pre-filtering mechanism). Bad samples are hard negative samples y' that are too similar to y (e.g. "What is your name" versus "What's your name"). Treating these extremely similar sentences as negative samples would hurt the encoder's representation and we devise a pre-filtering method to filter them out.

Disable Shuffling We sort sentences by length[3] and disable the shuffling of data loader so that consecutive batches contain sentences of similar length. As our queue is updated by enqueuing the most recent batch and dequeuing the earliest batch, disabling shuffling makes the queue store sentences of similar length. Because all samples in the queue are used as negative samples to be contrasted with the true target sentence and because they are of a similar length, it is much more likely that we find hard negatives (quantitative analysis provided in §5 and Figure 4).

Pre-filtering Mechanism After disabling shuffling, we show that more hard-negatives are found. However, we also found that there are many cases of extremely hard negatives (e.g. "What is your name" versus "What's your name", "Bring them here to me" versus "Bring it here to me"). Though hard negatives help contrastive fine-tuning to obtain better sentence representation, extremely hard negatives would confuse the model and incorrectly update the parameters. Therefore we employ a simple pre-filtering mechanism to prevent these extremely hard negatives from contributing to the contrastive loss: After we encode the target sentence

---

[1] We use queue size N=4096 throughout experiments.

[2] Empirically we found $\tau = 0.05$ (widely used in previous literature) works well.

[3] Our implementation is based on Fairseq (Ott et al., 2019) which by default sorts the sentences by length

and sentences in the queue, we have the representations $k_+, k_1, \cdots k_N$ as described in §2.1. Then we compute the cosine similarity between the true target and sentences in the queue and get similarity scores $\cos(k_+, k_i), i \in [1, N]$. For any negative sample i, if $\cos(k_+, k_i) \geq \sigma$ (where σ is a predefined threshold hyper-parameter),[4] we do not use it in the InfoNCE loss. In other words, let $S = \{i : \cos(k_+, k_i) < \sigma\}$ be a set that contains no extremely hard negatives for the threshold σ, the InfoNCE loss would be computed as

$$\mathcal{L} = -\log \frac{\exp(q \cdot k_+ / \tau)}{\sum_{i \in S} \exp(q \cdot k_i / \tau)} \tag{2}$$

In practice, we perform this filtering step with batches of samples, as detailed in appendix A. PyTorch-like pseudocode of the LASER3-CO-Filter model is shown below.

Algorithm 1 Pseudocode of LASER3-CO-Filter

```
# N: queue size;   bz: batch size
# S: size of set without extremely hard negatives
# t: temperature;   h: filtering threshold
# emb_dim: embedding dimension
# einsum: einsum function available in PyTorch
# queue: stores N earlier target embed
# teacher: pre-trained LASER encoder
# student: LASER3 student encoder
# filter: function that filters out extremely hard
     negatives (details available in appendix A)

# freeze teacher encoder
teacher.params.requires_grad = False
for (source, target) in loader:
    src_emb = normalize(student(source),dim=1)
    tgt_emb = normalize(teacher(target),dim=1)
    neg_emb = normalize(teacher(queue),dim=1)
    #--------- Begin Pre-filtering ---------
    # bz x N (mask for indices to be kept)
    mask = (tgt_emb @ neg_emb.T < h).long()
    # bz x S x emb_dim
    neg_emb = filter(neg_emb, mask)
    #--------- End Pre-filtering ------------
    #postive logits: bz x 1
    l_pos = src_emb @ tgt_emb.T
    # negative logits: bz x S
    l_neg = einsum("bh,bsh->bs", src_emb, neg_emb)
    logits = cat([l_pos, l_neg],dim=1)
    loss = CrossEntropyLoss(logits/t, zeros(bz))
    loss.backward()
    update(student)
    enqueue(queue, tgt_emb)
    if queue.size > N:
        dequeue(queue)
```

3 Experiment on Low-resource Languages

3.1 Dataset

For training, we use two sources of data: existing clean data and back-translation data.

ISO	Language	CB[k]	BT[k]
khm	Khmer	536	2451
pus	Pashto	48	3000
npi	Nepali	533	3000
sin	Sinhala	752	3000

Table 1: The number of (thousands of) sentences available for different languages in clean bitext (CB column) and back-translation (BT column) datasets. We cap back-translation data to 3 million lines maximum.

Clean data Our clean data comes from publicly available datasets[5] such as *jw300*, *bible* (Christodoulopoulos and Steedman, 2015), *tatoeba* (Tiedemann, 2012), *wikimedia* (Tiedemann, 2012), *gv* (Tiedemann, 2012), *tico19* (Tiedemann, 2012) , *ted20* (Reimers and Gurevych, 2020b), *qed* (Abdelali et al., 2014; Tiedemann, 2012), and *os* (Tiedemann, 2012).[6] We group these data sources together and call them clean data.

Back-translation data Back-translation is a simple yet effective data augmentation technique that could benefit the training of sentence encoders. To generate back-translation data, we need a translation model and monolingual data. We retrieve monolingual data from web data provided by CommonCrawl[7] and ParaCrawl (Bañón et al., 2020), following the pre-processing pipeline (language ID and heuristic filtering) from NLLB (NLLB Team et al., 2022). Then we use the 1.3B-parameter NLLB200-Dense[8] model (NLLB Team et al., 2022) to translate low resource language's monolingual data that we collected from web. We choose NLLB200 because it achieves state-of-the-art translation performance so far for most low-resource languages. Once we generate synthetic data, we can use them as a parallel corpus to distill sentence representation. In practice, we cap the amount of back-translation data at 3 million lines.

3.2 Languages & Models

We target four low-resource languages (Khmer, Pashto, Nepali, and Sinhala) in our experiments as shown in Table 1. For each of these languages,

---

[4] We use $\sigma = 0.9$ throughout our experiments. Effects of different σ values are analyzed in Figure 4 (right)

[5] All available online, mostly taken from OPUS: `https://opus.nlpl.eu/`

[6] `https://www.opensubtitles.org/`

[7] In wet format, `https://commoncrawl.org`

[8] Open-sourced at: `https://github.com/facebookresearch/fairseq/tree/nllb`

we have trained several models shown below:

- LASER (Artetxe and Schwenk, 2019b): we directly take the model checkpoint available publicly[9] without any further training.
- LASER3 (Heffernan et al., 2022): we follow Heffernan et al. (2022) to distill an encoder for each language using **clean data**. The teacher encoder is LASER and the student encoder is a randomly initialized transformer's encoder.
- LASER3-BT: same as the LASER3 model except that we distill the encoder using both **clean data** and **back-translation data**. Though back-translation is already widely used, our improvement from this model provides another instance where data augmentation from a large pre-trained multilingual translation model is effective.
- LASER3-CO: we fine-tune the LASER3 model following §2.1 with **clean data**.
- LASER3-CO-Filter: we fine-tune the LASER3 model following §2.2 with **clean data**.

3.3 Multilingual Similarity Search

Multilingual similarity search evaluates the quality of representation from trained encoders by aligning source and target sentences. We use FLORES (Guzmán et al., 2019) devtest dataset (1012 aligned sentences) for this task because it is crafted with professional human annotation. For every source sentence x_i, we compute a similarity score called `xsim` between x_i and all target sentences y_j. If the target sentence with the highest similarity score is not the i^{th} sentence (namely if $i \neq \text{argmax}_j \texttt{xsim}(x_i, y_j)$), then the model has one incorrect match. We compute the percentage of source sentences that have an incorrect match as `xsim` error rate. The lower the `xsim` error rate, the better the model is for aligning sentences of similar meaning. Our similarity score `xsim` is the margin-based score (Artetxe and Schwenk, 2019a), which is widely used for scoring and filtering parallel sentences. It is defined below:

$$\text{xsim}(x, y) = \text{margin}(\cos(x, y), \sum_{z \in \text{NN}_k(x)} \frac{\cos(x, z)}{2k} + \sum_{z \in \text{NN}_k(y)} \frac{\cos(y, z)}{2k}) \quad (3)$$

Model	khm	pus	npi	sin	avg
LASER	14.6	67.8	27.0	0.1	27.4
LASER3	0.4	0.3	5.9	0.3	1.7
LASER3-BT	**0.1**	**0.0**	**0.4**	0.1	**0.2**
LASER3-CO	0.3	0.1	0.7	**0.0**	0.3
LASER3-CO-Filter	**0.1**	0.1	0.8	0.1	0.3

Table 2: `xsim` error rate (%) for Khmer, Pashto, Nepali, and Sinhala. Bolded values are the lowest error rate obtained for each language.

where x, y are source and target sentences' representations from the model, $\text{NN}_k(x)$ denotes k nearest neighbors of x in the other language, and there are three margin functions[10]: absolute$(a, b) = a$, distance$(a, b) = a - b$, and ratio$(a, b) = \frac{a}{b}$.

We show our result in Table 2 and observe that LASER3 achieves a much better result than LASER (1.7% versus 27.4%), consistent with Heffernan et al. (2022)'s finding that language-specific distillation is more helpful than a language-agnostic encoder. We also show that using data augmentation (either with back-translation or with contrastive learning) further improves the performance to a near-zero error rate. In Figure 3, we provide the t-SNE visualization of embedding spaces trained by different approaches for Sinhala, and we observe that using back-translation or contrastive learning brings aligned sentences closer.

Note that in both of our contrastive-based models (LASER3-CO and LASER3-CO-Filter), we do not include back-translation data. Thus, contrastive distillation achieves tied performance compared to the model helped by a large amount of back-translation data, showing the power of self-supervision in representation learning. Additionally, back-translation and contrastive learning are orthogonal so we could train LASER3-CO/LASER3-CO-Filter with back-translation data. However, in our preliminary study, we do not see improvement from such an approach (more discussion in Appendix C) and we use only clean data for contrastive distillation throughout our experiments.

3.4 Corpus Filtering

We pick Khmer, Pashto, Nepali, and Sinhala as our targeted low-resource languages partly because they are used by WMT Corpus Filtering Shared task (Koehn et al., 2019, 2020). The shared task re-

lease mined corpora (from the Paracrawl[11] project) for Khmer, Pashto, Nepali, and Sinhala. For each language, we first filter the noisy corpus with the language id model from fasttext[12] (Joulin et al., 2017). We filter out the aligned sentence pairs whose source sentence is predicted to be English (because we only expect the target sentence to be English). Then we filter the corpus with our sentence encoders where we rely on `xsim` score to rank sentences and take the top k sentences to train NMT models. In practice, we follow the shared task to use data subset of 1/2/3/5/7 million English tokens, and the optimal subset size is shown in Table 3. The highest BLEU score achieved by different systems is shown in Table 4.

From the results, we observe that LASER3-based systems have similar BLEU scores for Khmer. One possible explanation is that LASER3 distillation already gives good representation so data augmentation does not make a noticeable improvement. On average, we find that data-augmented systems (LASER3-BT, LASER3-CO, LASER3-CO-Filter) greatly improve the BLEU score compared to previous works like LASER, LASER3, and best systems in the WMT Corpus Filtering shared task. Note that some systems from the shared task make use of large pre-trained models and even an ensemble of large models, so it is a strong baseline and we are able to outperform it by an average of 0.75 BLEU score, achieving the state-of-the-art corpus filtering performance using contrastive distillation on a small amount of clean data. The corpus filtering result is also consistent with the multilingual similarity search task, where encoders with lower `xsim` error rate perform better.

4 Experiment on Extremely Low-resource Languages

4.1 Languages & Dataset

In §3, we experiment on low-resource languages **individually** and show the improvement from contrastive distillation. There are many languages that have even less available data and are under-represented in the current literature. In our work, we focus on four extremely low-resource African languages that are extremely low-resource: Chokwe, Kamba, Kimbundu, and Umbundu. The amount of available clean and back-translation data is shown in Table 5 (with the same collection pro-

Table 6: `xsim` error rate (%) for Chokwe, Kamba, Kimbundu, and Umbundu. Bolded values are the lowest error rate obtained for each language. $*$: result taken from Heffernan et al. (2022).

cess described in §3.1). These four languages are from the Benue-Congo language family which has 25 languages in total. The details of their names and available data size are shown in Table 8 (in the appendix). Under such extremely low-resource settings, we show that contrastive distillation still produces state-of-the-art encoders for the multilingual similarity search task. We believe our encoders can be easily adapted to other information extraction tasks such as bitext mining through the pipeline described in CCMatrix (Schwenk et al., 2021), and we leave this to future work.

4.2 Multilingual Similarity Search

We evaluate the performances of difference encoders on the multilingual similarity search task following the same procedure in §3.3 and show `xsim` error rate in Table 6. For the language-agnostic model baseline, we replace LASER with LaBSE (Feng et al., 2022) because its pre-training data contains African languages (though not directly on the four languages we target) and achieves better performance than LASER. However, this language-agnostic model is still easily outperformed by LASER3-based models since the distillation of language-specific data is helpful.

For LASER3 and LASER3-BT, we leverage all data from the Benue-Congo family to distill the encoder. We are able to reproduce results from LASER3 (Heffernan et al., 2022) and our back-translation baseline further improves the average `xsim` error rate to 6.7%. For contrastive distillation models, we fine-tune LASER3-BT **individually**[13] for each target language following §2. Not like previous experiments with Khmer, Pashto, etc., we fine-tuned LASER3-BT instead of LASER3 as our preliminary study showed better performance with LASER3-BT. Therefore, different languages could have different optimal settings for data augmentation (more discussion in Appendix C), depending on the amount and quality of available data. Nevertheless, we show that our contrastive distillation framework greatly improves upon previous encoders, achieving state-of-the-art `xsim` error rates for all four languages we targeted.

5 Analysis

In this section, we focus on contrastive distillation methods described in §2 and provide an analysis of the effects of different hyper-parameters.

5.1 Effect of queue size

For all the previous experiments, we use batch size 32 and queue size 4096 to be consistent. In our preliminary work, we tried N=512/1024/2048/4096 for Sinhala and we do not observe a noticeable advantage for using a larger queue size. Still, we use the largest queue size that we could afford,[14] 4096, throughout experiments since a larger queue size won't hurt performance. To show that memory-based contrastive learning is effective, we compare it with in-batch fine-tuning and show the result in Table 7. We see that memory-based contrastive learning gives us an average of 0.4 BLEU improvement across four languages.

Model	khm	pus	npi	sin	avg
LASER3	**10.1**	11.7	5.1	5.8	8.18
LASER3-CO	9.9	**12.3**	**6**	**7.3**	**8.88**
LASER3-InBatch	9.8	11.4	5.8	6.9	8.48

Table 7: BLEU score for Khmer, Pashto, Nepali, and Sinhala. LASER3-InBatch and LASER3-CO have the same setup except that LASER3-CO uses a queue of 4096 samples to compute contrastive loss and LASER3-InBatch only uses samples from every batch to compute contrastive loss.

---

[13] Consistent with our experiment in §3.3, using only clean data works the best for contrastive distillation.

[14] We trained our models with NVIDIA A100 GPU.

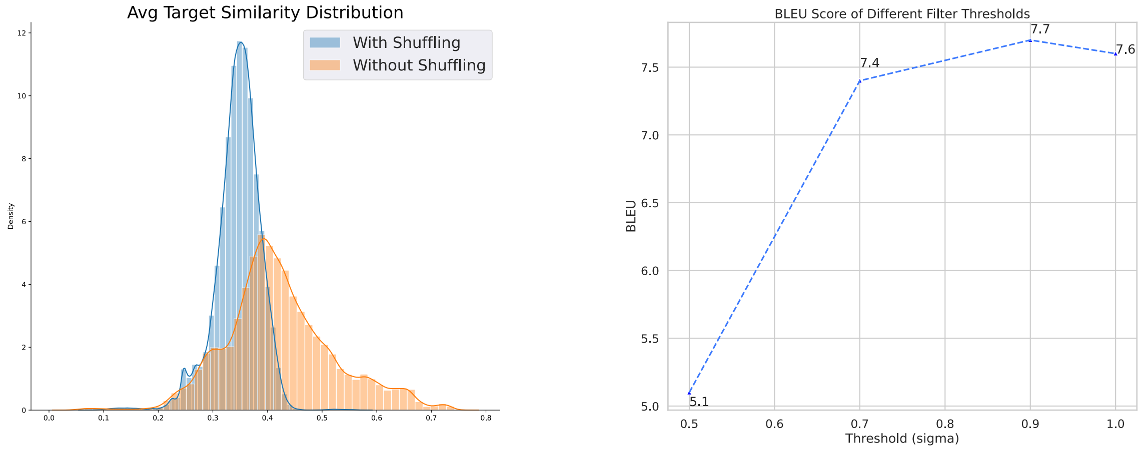

Figure 4: (left) Distribution plot of the average target similarity (of Sinhala's clean data) with/without shuffling. The x-axis is the value of average target similarity and the y-axis is the density of a particular value. (right) LASER3-CO-Filter's performance for Sinhala w.r.t varying pre-filter threshold σ. A low threshold filters out all hard negatives and harms training. A high threshold keeps extremely hard negatives which also undermines training.

5.2 Effect of shuffling

In our LASER3-CO-Filter approach, we disable shuffling so that the queue contains sentences of similar length and we argue that it is easier to find hard negatives this way. To quantify this fact, we compute the average target similarity for all sentences and plot the distribution in Figure 4 (left). The average target similarity for a target sentence x is

$$\text{sim}(x, \text{queue}) = \frac{1}{N} \cos(\theta_t(x), \theta_t(\text{queue}_i))$$

where θ_t is the teacher encoder, N is queue size, and queue_i is the i^{th} sample in the queue. As shown in Figure 4 (left), without shuffling, more than half samples have > 0.4 average target similarity. A higher average target similarity indicates that target sentences are more semantically related to the samples in the queue and therefore form harder negatives.

5.3 Effect of pre-filter threshold

For the LASER3-CO-Filter model, we employ a pre-filtering mechanism that prevents extremely hard examples from contributing to the loss. For our experiments, we use filter threshold $\sigma = 0.9$. In this section, we vary σ and evaluate the performance for Sinhala (we did not repeat this experiment for other languages but expect similar results). The result is shown in Figure 4 (right), which is a line plot based on our result for $\sigma = 0.5/0.7/0.9/1$. We can see that $\sigma = 0.9$ is the peak and the result corresponds to our intuition. When σ is too high (e.g. $\sigma = 1$), extremely hard negatives (or even repetitions) are not filtered out and their contribution to contrastive loss makes training unstable, resulting in poor performance for mining. When σ is too low (e.g. $\sigma = 0.5$), too many samples in the queue are filtered out and only easy negatives (sentences drastically different from the target sentence) are left in the queue. In this case, the model does not learn meaningful representations from negative samples, resulting in poor performance as well.

6 Related Work

Multilingual Sentence Representation Various multilingual sentence representations have been proposed including multilingual BERT (Devlin et al., 2019), XLM (CONNEAU and Lample, 2019), XLM-R (Conneau et al., 2020). These models are trained with a large amount of data across dozens or hundreds of languages. They show great improvement when fine-tuned on downstream tasks. However, they are trained only with token-level objectives like masked language modeling (MLM) or translation language modeling (TLM) and their sentence representations cannot be directly used for semantic similarity tasks. To address this problem, different methods make use of pooled sentence embedding to train better encoders (Artetxe and Schwenk, 2019b; Reimers and Gurevych, 2019; Feng et al., 2022; Heffernan et al., 2022).

Back-translation Back-translation is widely used in machine translation as a data augmentation technique. Sennrich et al. (2016) shows that synthetic data created by translating monolingual data greatly improve English-German and Turkish-English translation models. Edunov et al. (2018) further investigate different decoding strategies and show that sampling works better than greedy decode or beam search for back-translation. Since back-translation's quality depends on the translation model, Hoang et al. (2018) proposes iterative back-translation where translation models are further improved by the synthetic data they produce.

Contrastive Learning Contrastive learning is a form of self-supervised learning that encourages similar inputs to have close representations and dissimilar inputs to have different representations. Chen et al. (2020) proposes SimCLR that uses contrastive learning to improve visual representation. Khosla et al. (2020) integrates supervised learning into contrastive learning and Tian et al. (2020) uses contrastive distillation for image representation learning. Since finding high-quality contrastive samples is essential for contrastive learning, Wu et al. (2018) uses a memory bank to store contrastive samples while He et al. (2020) uses a queue with momentum update to encode contrastive samples on the fly. Though previously-mentioned works are evaluated on computer vision tasks, there is growing interest in using contrastive learning for natural language processing and various approaches have been proposed to train better sentence representation (Giorgi et al., 2021; Kim et al., 2021; Peng et al., 2020; Gao et al., 2021; Tan and Koehn, 2022).

7 Conclusion

In this paper, we integrate contrastive learning into multilingual sentence representation distillation. Through self-supervision from negatives, especially hard negatives, we obtain better encoders. Compared to other effective data augmentation techniques like back-translation, our contrastive distillation method achieves tied or better performance with less computation and data. Our experiments on multilingual similarity search and corpus filtering tasks show consistent improvement from contrastive learning and achieve state-of-the-art performance for various low-resource languages.

Limitations

This research focuses on improving cross-lingual encoders to perform quality estimation of parallel data for low-resource machine translation. However, cross-lingual representation could be helpful in many other tasks as summarized in the XTREME benchmark (Hu et al., 2020; Ruder et al., 2021) which we have not experimented with. Another limitation is that we disabled shuffling to store hard negative samples in the queue. However, without shuffling, it might affect the stability of the training process (although we do not observe it in our experiments). Therefore, in future work, we will continue exploring other cost-efficient approaches to retrieve hard negatives.

A PyTorch-Style Pseudocode

In Algorithm 1, we provide the pythonic style pseudocode for our LASER3-CO-Filter model. Note that the pre-filtering mechanism needs special treatment when training with a minibatch. we compute the set of negative samples

$$S^j = \{i : \cos(k_+^j, k_i) < \sigma\}$$

for each target sentence j in our batch where k_+^j is the teacher encoding of j^{th} positive sample. Then we find the minimum number of negatives in the batch $M = \min_j |S^j|$. For any target sentence j that has $|S^j| > M$, we randomly remove $|S^j| - M$ samples so that it ends up with M samples. In this way, we ensure that every target sentence has the same number of legitimate negative samples after the pre-filtering mechanism and we can batch them to compute the InfoNCE loss. In the pseudocode, we abstract the implementation of pre-filtering using **filter** function.

B Corpus Filtering Threshold

In Table 3, we show the optimal size of filtered corpus to train NMT models for four languages. For most cases, 5 or 7 million tokens give the best performance (except for Nepali, where only 1 or 2 million tokens seem to be useful).

C Combine Back-translation and Contrastive Learning?

Back-translation and contrastive learning are two helpful ways for representation learning in low-resource settings. These two methods can be applied together (as we showed in our experiments on African languages) because back-translation prepares data before training while our contrastive distillation method is a fine-tuning strategy. Through our preliminary study, we made the following observations:

- Contrastive fine-tuning works best on a single language's clean data. This is true for both low-resource languages (Khmer, Pashto, Nepali, and Sinhala) and extremely low-resource languages (Chokwe, Kamba, Kimbundu, and Umbundu). We find that using back-translation data for contrastive objectives does not make any noticeable improvement and this is probably because synthetic data generated by the pre-trained NMT model does not produce too many hard negatives. In the case of the African languages, we tried distillation with the whole family's clean data and it is also less effective than distillation on a single language. This is probably because the data from multiple languages interfere with each other during contrastive distillation.
- For low-resource languages like Sinhala, Pashto, etc., we find no noticeable difference between contrastive distillation with LASER3 and LASER3-BT. On the contrary, for extremely low-resource languages, we find LASER3-BT-CO performs better than LASER3-CO, and this is why we used LASER3-BT-CO in §4.2 but LASER3-CO in §3.3. We believe this is due to the quality and the amount of available clean data. In the extremely low-resource case, even the limited amount of clean data contains noise and we see LASER3-BT greatly outperform LASER3. Therefore, the distillation with pre-trained LASER3-BT result in a better model (LASER3-BT-CO or LASER3-BT-CO-Filter). However, in some low-resource settings (like our experiments for Sinhala, Pashto, Khmer, and Nepali), clean data itself could allow the contrastive method to learn good representations, therefore avoiding the need for back-translation data.

With our observation above, how should we select methods when new languages come in? We believe it mainly depends on two factors: 1) How large and how clean is the existing clean corpus 2) How is the performance of the existing pre-trained NMT model?

The first factor affects the effectiveness of contrastive learning and the second factor affects the quality of back-translation data. In fact, in our preliminary study, we do not find back-translation from a statistical machine translation system useful for African languages, because it does generate good enough synthetic data. With the advance of multilingual machine translation (MMT) models, we are able to leverage a large pre-trained model and show its effectiveness. Thus, whether to add back-translation or not mainly depends on the translation model's quality and computation budget.

On the inconsistency of separable losses for structured prediction

Caio Corro
Universite Paris-Saclay, CNRS, LISN, 91400, Orsay, France
`caio.corro@lisn.upsaclay.fr`

Abstract

In this paper, we prove that separable negative log-likelihood losses for structured prediction are not necessarily Bayes consistent, or, in other words, minimizing these losses may not result in a model that predicts the most probable structure in the data distribution for a given input. This fact opens the question of whether these losses are well-adapted for structured prediction and, if so, why.

1 Introduction

Modern natural language processing (NLP) heavily relies on machine learning (ML), where prediction models are learned by minimizing a loss function over the training data. As such, loss functions play a central role in the design of these systems and it is important to understand their statistical properties in order to guarantee that the corresponding training objectives are well defined. Although this topic is well studied in the ML community (Lugosi and Vayatis, 2004; Lin, 2004; Zhang, 2004a,b; Bartlett et al., 2006; Gneiting and Raftery, 2007; Liu, 2007; Tewari and Bartlett, 2007; Reid and Williamson, 2010; Williamson et al., 2016; Duchi et al., 2018; Blondel et al., 2020; Nowak et al., 2022), *inter alia*, there has been less focus on the structured prediction setting apart from a few recent works (Blondel, 2019; Nowak et al., 2019, 2020).

In this paper, we emphasize the fact that, despite achievements in terms of accuracy, statistical behavior of loss functions used in practice for structured prediction in NLP are not always well understood. We illustrate this fact by proving that commonly used separable loss functions for named entity recognition (NER) and dependency parsing are not Bayes consistent, meaning that training a model with these loss functions will not necessarily result in the prediction of the most the probable output for a given input in the data distribution.

2 Bayes consistency

We denote inputs and outputs as $\boldsymbol{x} \in X$ and $\boldsymbol{y} \in Y$, respectively. We assume each $\boldsymbol{y} \in Y$ is a binary vector whose elements are indexed by a set C, *i.e.* $\boldsymbol{y} \in \{0,1\}^C$, where C is problem dependent. For example, in the k multiclass classification case, we have $C = [k]$, where we use the shorthand $[k] = \{1, 2, ..., k\}$, and Y is defined as the set of standard bases (one-hot vectors) of dimension k, meaning that $|Y| = k$. More generally, the vector $\boldsymbol{y}$ is an indicator of "selected" parts in C and, in the structured prediction case, several parts can be jointly selected. Note that it is usual to assume that the parts in C can depend on the input $\boldsymbol{x}$. Without loss of generality, we omit this detail as we will study loss functions in the pointwise setting.

A scoring model $f \in F$ is a function $f : X \to \mathbb{R}^C$ that returns scores associated with each part in C for a given input, *e.g.* the score of each class in a multiclass classification model. The actual prediction of the model is the output of maximum linear score:

$$\widehat{\boldsymbol{y}}(\boldsymbol{x}) \in \arg\max_{\boldsymbol{y} \in Y} \langle \boldsymbol{y}, f(\boldsymbol{x}) \rangle, \qquad (1)$$

where $\langle \cdot, \cdot \rangle$ denotes the inner product. We refer to computing Equation 1 as maximum *a posteriori* (MAP) inference.

A loss function compares a vector of scores with an expected output. Importantly, the 0-1 loss function is defined as follows:

$$\ell(\boldsymbol{w}, \boldsymbol{y}) = \begin{cases} 0 & \text{if } \boldsymbol{y} \in \arg\max_{\boldsymbol{y}' \in Y} \langle \boldsymbol{w}, \boldsymbol{y}' \rangle, \\ 1 & \text{otherwise,} \end{cases}$$

where $\boldsymbol{w} \in \mathbb{R}^k$ is a vector of part scores, *i.e.* $\boldsymbol{w} = f(\boldsymbol{x})$ for a given input $\boldsymbol{x}$. In order to choose a scoring function $f \in F$, it is appealing to select one that minimizes this loss over the data distribution:

$$r^* = \inf_{f \in F} r(f) = \inf_{f \in F} \mathbb{E}_{\mathbf{x},\mathbf{y}}[\ell(f(\mathbf{x}), \mathbf{y})],$$

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1491–1498
May 2-6, 2023

where $\mathbf{x}$ and $\mathbf{y}$ are random variables over inputs and outputs, respectively, and $\inf$ denotes the infimum. The value $r(f)$ is the Bayes risk of function f and r^* is the optimal Bayes risk. For theoretical purposes, it is often assumed that the class of functions F is rich enough (the set of all measurable mappings) to obtain the best possible risk. Then, the optimal Bayes risk is equal to:

$$r^* = \mathbb{E}_{\mathbf{x}}[1 - \max_{\boldsymbol{y} \in Y} p(\mathbf{y} = \boldsymbol{y} | \mathbf{x})],$$

or, in other words, it is the probability of making an error when the classifier predicts the most probable class for each input.

Unfortunately, in practice it is not convenient to use the 0-1 loss ℓ as it is nonconvex and has null derivatives almost everywhere. Instead, a surrogate $\widetilde{\ell}$ can be used as a loss function:

$$\widetilde{r}^* = \inf_{f \in F} \widetilde{r}(f) = \inf_{f \in F} \mathbb{E}_{\mathbf{x},\mathbf{y}}[\widetilde{\ell}(f(\mathbf{x}), \mathbf{y})],$$

where $\widetilde{r}(f)$ is the surrogate risk of function f and $\widetilde{r}^*$ is the optimal surrogate risk. An important desired property of surrogate losses is their consistency with the 0-1 loss, *i.e.* the fact that minimizing the surrrogate risk leads to a prediction model of optimal Bayes risk (Lugosi and Vayatis, 2004; Lin, 2004; Zhang, 2004a; Bartlett et al., 2006; Liu, 2007; Tewari and Bartlett, 2007).

Definition 1. *A surrogate loss* $\widetilde{\ell}$ *is said to be Bayes consistent*[1] *if:*

$$f^* \in \arg\min_{f \in F} \widetilde{r}(f) \implies r(f^*) = r^*.$$

Note that this property can be checked independently for each input $\boldsymbol{x}$ (called pointwise Bayes consistency) as we assume a rich enough class of functions F. In other words, we redefine the pointwise (optimal) surrogate risk as:

$$\widetilde{r}^* = \inf_{\boldsymbol{w} \in \mathbb{R}^C} \widetilde{r}(\boldsymbol{w}) = \inf_{\boldsymbol{w} \in \mathbb{R}^C} \mathbb{E}_{\mathbf{y}|\mathbf{x}=\boldsymbol{x}}[\widetilde{\ell}(\boldsymbol{w}, \mathbf{y})],$$

for any $\boldsymbol{x}$ such that $p(\mathbf{x} = \boldsymbol{x}) > 0$, and similarly for the optimal Bayes risk. The vector $\boldsymbol{w}$ should be interpreted as the model scores, *i.e.* $\boldsymbol{w} = f(\boldsymbol{x})$.

3 Negative log-likelihood loss

The negative log-likelihood loss (NLL), also known as the conditional random field loss (Lafferty et al., 2001), is defined as follows:

$$\widetilde{\ell}_{(nll)}(\boldsymbol{w}, \boldsymbol{y}) = -\langle \boldsymbol{w}, \boldsymbol{y} \rangle + \log \sum_{\boldsymbol{y}' \in Y} \exp \langle \boldsymbol{w}, \boldsymbol{y}' \rangle.$$

In the following, we will refer to computing the log-sum-exp term of the NLL loss as marginal inference due to its connection with marginal probabilities (Wainwright and Jordan, 2008).

Theorem 1. *Under mild conditions on the data distribution, the surrogate loss* $\widetilde{\ell}_{(nll)}$ *is Bayes consistent.*

Proof. The optimal pointwise surrogate Bayes risk is defined as:

$$\widetilde{r}^*_{(nll)} = \inf_{\boldsymbol{w} \in \mathbb{R}^C} \begin{array}{l} -\mathbb{E}_{\mathbf{y}|\mathbf{x}=\boldsymbol{x}}[\langle \boldsymbol{w}, \mathbf{y} \rangle] \\ + \log \sum_{\boldsymbol{y}' \in Y} \exp \langle \boldsymbol{w}, \boldsymbol{y}' \rangle. \end{array}$$

We substitute $\boldsymbol{w}(\boldsymbol{y}) = \langle \boldsymbol{w}, \boldsymbol{y} \rangle$ for all $\boldsymbol{y} \in Y$:

$$= \inf_{\substack{\forall \boldsymbol{y} \in Y: \\ \boldsymbol{w}(\boldsymbol{y}) \in \mathbb{R}}} \begin{array}{l} -\mathbb{E}_{\mathbf{y}|\mathbf{x}=\boldsymbol{x}}[\boldsymbol{w}(\mathbf{y})] \\ + \log \sum_{\boldsymbol{y}' \in Y} \exp \boldsymbol{w}(\boldsymbol{y}'). \end{array}$$

We denote $\widehat{\boldsymbol{w}}(\boldsymbol{y}), \forall \boldsymbol{y} \in Y$, an optimal solution of the minimization. By first order optimality conditions, we have:

$$\begin{aligned} &\frac{\partial}{\partial \widehat{\boldsymbol{w}}(\boldsymbol{y})} \begin{pmatrix} -\mathbb{E}_{\mathbf{y}|\mathbf{x}=\boldsymbol{x}}[\widehat{\boldsymbol{w}}(\mathbf{y})] \\ + \log \sum_{\boldsymbol{y}' \in Y} \exp(\widehat{\boldsymbol{w}}(\boldsymbol{y}')) \end{pmatrix} = 0 \\ &\implies \frac{\exp \widehat{\boldsymbol{w}}(\boldsymbol{y})}{\sum_{\boldsymbol{y}' \in Y} \exp \widehat{\boldsymbol{w}}(\boldsymbol{y}')} = p(\mathbf{y} = \boldsymbol{y} | \mathbf{x} = \boldsymbol{x}) \end{aligned} \tag{2}$$

which implies Bayes consistency under the condition that there exists a vector $\boldsymbol{w} \in \mathbb{R}^C$ such that $\forall \boldsymbol{y} \in Y : \langle \boldsymbol{w}, \boldsymbol{y} \rangle = \widehat{\boldsymbol{w}}(\boldsymbol{y})$. ☐

To understand why Equation 2 implies Bayes consistency, note that:

$$\frac{\exp \widehat{\boldsymbol{w}}(\boldsymbol{y})}{\sum_{\boldsymbol{y}' \in Y} \exp \widehat{\boldsymbol{w}}(\boldsymbol{y}')} \propto \exp \widehat{\boldsymbol{w}}(\boldsymbol{y}'),$$

and the exponential function is strictly increasing. This means scores of outputs $\boldsymbol{y} \in Y$ defined as $\langle \boldsymbol{y}, \widehat{\boldsymbol{w}} \rangle$ are ordered in the same way as probabilities in the data distribution $p(\mathbf{y} | \mathbf{x} = \boldsymbol{x})$. In other words, the most probable output in the data distribution will have the highest score with respect to $\widehat{\boldsymbol{w}}$.

---

[1] This property is also referred to as Fisher consistency (Lin, 2004; Bartlett et al., 2006; Liu, 2007) and classification calibration (Williamson et al., 2016).

The proof is a straightforward extension of the derivation for the multiclass classification case, see for example Blondel et al. (2020, Section 4.2). Interestingly, Equation 2 also implies that the NLL loss is strictly proper (Williamson et al., 2016), *i.e.* the Boltzmann distribution over structures in Y parameterized by minimizer $\widehat{\boldsymbol{w}}$ is equal to the data distribution $p(\mathbf{y}|\mathbf{x}=\boldsymbol{x})$. Note that Theorem 1 is not novel *per se* and a more in-depth study of NLL losses for structured prediction can be found in (Nowak et al., 2019).

One limitation of the NLL loss is that it is not (additively) separable[2] because of the log-sum-exp term. As such, this term is a bottleneck for parallel computation of the objective and doubly stochastic estimation of the training objective (Titsias, 2016). A well-known solution is to rely on independent binary classification objectives, also known as one-vs-all losses (Blondel et al., 2020, Section 6.1):

$$\begin{aligned}&\widetilde{\ell}_{(one-vs-all)}(\boldsymbol{w}, \boldsymbol{y})\\ &\quad= -\langle \boldsymbol{w}, \boldsymbol{y}\rangle + \sum_{\boldsymbol{y}'\in Y} \log\left(1+\exp\langle \boldsymbol{w}, \boldsymbol{y}'\rangle\right).\end{aligned}$$

In the case of multiclass classification problems, it can be shown that this objective is Bayes consistent using similar arguments as in Theorem 1. A different approach is the one-vs-each loss function that is also Bayes consistent (Titsias, 2016).

Unfortunately, these separable surrogates cannot be applied to structured prediction problems as the set Y is often of exponential size with respect to the input length. Although tractable algorithms for marginal inference exist for many cases, there are no known algorithms to compute the one-vs-each or one-vs-all losses in an easily parallelizable fashion. As such, the NLP community often relies on token-separable losses, that is a NLL objective that decomposes as a sum of independent losses, one per token in the input sentence. Although these losses are easy to implement, we prove in the next sections that they are not Bayes consistent for two common NLP problems.

4 Named-entity recognition

Problem definition. In this Section, we focus on the flat NER problem using BIO tags (Ratinov and Roth, 2009). Without loss of generality, we assume there is a single mention label and that the input sentence $\boldsymbol{x}$ contains n words. The set of parts is defined as $C = [n] \times \{\mathrm{B}, \mathrm{I}, \mathrm{O}\}$ and Y is defined as the set of vectors $\boldsymbol{y} \in \{0,1\}^C$ satisfying the following conditions:

1. $\forall i \in [n] : \sum_t y_{i,t} = 1$ (one tag per word);
2. $y_{1,\mathrm{I}} = 0$ (forbid inside tag for the first word);
3. $\forall i > 1 : y_{i,\mathrm{I}} = 1 \implies y_{i-1,\mathrm{B}} + y_{i-1,\mathrm{I}} = 1$ (I tag can only follow a B or I tag).

We do not include parts corresponding to transitions (this is a unigram model), otherwise it would not be possible to derive a token-separable loss.

Inference algorithms. MAP and marginal inference can be realized using the Viterbi and the forward-backward algorithms, respectively. Although the time complexity of these algorithms is $\mathcal{O}(|L|^2 n)$ where L is the set of mention labels, they can be optimized to have a $\mathcal{O}(|L|n)$ time complexity as there is no transition score. The dynamic programming algorithm is nonetheless required in order to guarantee that condition (3) is satisfied.

Separable loss. As the dynamic programming algorithm is not parallelizable over input tokens, token-separable losses are often used in practice.[3] That is, the loss is reduced to a set of n multiclass classification losses:

$$\widetilde{\ell}_{\text{(sep-bio)}} = -\langle \boldsymbol{w}, \boldsymbol{y}\rangle + \sum_{i=1}^{n} \log \sum_t \exp w_{i,t},$$

where t ranges over all tags, except I if $i = 1$.

The optimal pointwise surrogate Bayes risk for the separable loss is defined as:

$$\widetilde{r}^*_{(sep-bio)} = \inf_{\boldsymbol{w}\in\mathbb{R}^C} \begin{array}{l} -\mathbb{E}_{\mathbf{y}|\mathbf{x}=\boldsymbol{x}}[\langle \boldsymbol{w}, \mathbf{y}\rangle] \\ +\sum_{i=1}^{n} \log \sum_t \exp w_{i,t}. \end{array}$$

Let $\widehat{\boldsymbol{w}}$ be an optimal solution. Then, by first order optimality conditions:

$$\begin{aligned}&\frac{\partial}{\partial \widehat{w}_{i,t}} \left(\begin{array}{l} -\mathbb{E}_{\mathbf{y}|\mathbf{x}=\boldsymbol{x}}[\langle \boldsymbol{w}, \mathbf{y}\rangle] \\ +\sum_{i=1}^{n} \log \sum_t \exp w_{i,t} \end{array} \right) = 0 \\ &\implies \widehat{w}_{i,t} = \log p\left(\mathrm{y}_{i,t} = 1 | \mathbf{x} = \boldsymbol{x}\right) \end{aligned} \tag{3}$$

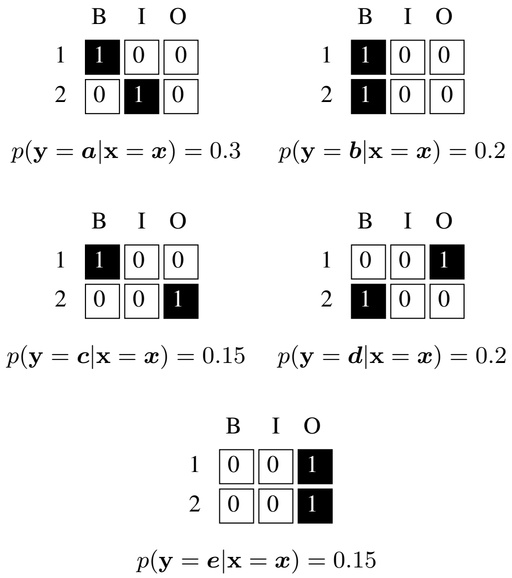
where $p\left(\mathrm{y}_{i,t} = 1|\mathbf{x}=\boldsymbol{x}\right)$ denotes the marginal distribution of tag t at position i in data distribution.

Theorem 2. *The token-separable loss for NER via BIO tagging is not Bayes consistent.*

---

[2] A function f is additively separable if it can be written as $f = \sum_i f_i$.

[3] See for example `https://github.com/huggingface/transformers/blob/v4.23.1/src/transformers/models/bert/modeling_bert.py#L1771`



$p(\mathbf{y} = \boldsymbol{a}|\mathbf{x} = \boldsymbol{x}) = 0.3$ $p(\mathbf{y} = \boldsymbol{b}|\mathbf{x} = \boldsymbol{x}) = 0.2$

$p(\mathbf{y} = \boldsymbol{c}|\mathbf{x} = \boldsymbol{x}) = 0.15$ $p(\mathbf{y} = \boldsymbol{d}|\mathbf{x} = \boldsymbol{x}) = 0.2$

$p(\mathbf{y} = \boldsymbol{e}|\mathbf{x} = \boldsymbol{x}) = 0.15$

Figure 1: Example of distribution over BIO sequences for a sentence of 2 words. The set of sequences is defined as $Y = \{\boldsymbol{a}, \boldsymbol{b}, \boldsymbol{c}, \boldsymbol{d}, \boldsymbol{e}\}$. The matrices represent values in elements of Y.

Proof. Let $n = 2$ and assume that the distribution $p(\mathbf{y}|\mathbf{x} = \boldsymbol{x})$ is defined as depicted in Figure 1. Then, by Equation 3 we have $\widehat{w}_{1,\text{B}} = \log 0.65$, $\widehat{w}_{1,\text{O}} = \log 0.35$, $\widehat{w}_{2,\text{B}} = \log 0.4$, $\widehat{w}_{2,\text{I}} = \log 0.3$ and $\widehat{w}_{2,\text{O}} = \log 0.3$. As such:

$$\begin{aligned}\log 0.65 + \log 0.3 &= \langle \widehat{\boldsymbol{w}}, \boldsymbol{a} \rangle \\ &< \langle \widehat{\boldsymbol{w}}, \boldsymbol{b} \rangle = \log 0.65 + \log 0.4,\end{aligned}$$

but $\boldsymbol{a} \in \arg\max_{\boldsymbol{y} \in Y} p(\mathbf{y} = \boldsymbol{y}|\mathbf{x} = \boldsymbol{x})$ and $p(\mathbf{y} = \boldsymbol{a}|\mathbf{x} = \boldsymbol{x}) > p(\mathbf{y} = \boldsymbol{b}|\mathbf{x} = \boldsymbol{x})$. Therefore, the token-separable loss is not Bayes consistent for NER, *i.e.* a scoring model minimizing the surrogate risk may not lead to predicting the most probable output in the data distribution. $\square$

Note that the inconsistency is not due to the fact that the parameterization of the model is "poor" (no transition scores). Indeed, by Equation 2, optimal scores $\widehat{\boldsymbol{w}}$ for the NLL loss satisfy the following condition for all $\boldsymbol{y} \in Y$:

$$\begin{aligned}&\frac{\exp\langle \widehat{\boldsymbol{w}}, \boldsymbol{y} \rangle}{\sum_{\boldsymbol{y}' \in Y} \exp\langle \widehat{\boldsymbol{w}}, \boldsymbol{y}' \rangle} = p(\mathbf{y} = \boldsymbol{y}|\mathbf{x} = \boldsymbol{x}) \\ &\implies \langle \widehat{\boldsymbol{w}}, \boldsymbol{y} \rangle = \log p(\mathbf{y} = \boldsymbol{y}|\mathbf{x} = \boldsymbol{x})\end{aligned}$$

The following assignment for $\widehat{\boldsymbol{w}}$ satisfies this condition: $\widehat{w}_{1,\text{B}} = 0$, $\widehat{w}_{1,\text{O}} = 0$, $\widehat{w}_{2,\text{B}} = \log 0.2$, $\widehat{w}_{2,\text{I}} = \log 0.3$, and $\widehat{w}_{2,\text{O}} = \log 0.15$. That is, minimizing the NLL loss on this distribution results in a Bayes consistent classifier, as expected.

5 Syntactic dependency parsing

Problem definition. We consider a sentence of n words and, without loss of generality, restrict to the unlabeled case to simplify notations. In dependency parsing, the set of parts is defined as the set of possible bilexical dependencies between words, including a fake root at position 0 used to identify root word(s) of the sentence, *i.e.* $C = \{(h, m) \in \{0, 1, ..., n\} \times [n] | h \neq m\}$, where (h, m) denotes a dependency with the h-th word as head and the m-th word as modifier. The set Y is restricted to vectors $\boldsymbol{y} \in \{0, 1\}^C$ that can be interpreted as forming a 0-rooted spanning arborescence where words are vertices and dependencies are arcs (McDonald et al., 2005). In some cases, *e.g.* the Universal Dependency format, it is required that the fake root position has a single outgoing arc.[4]

Inference algorithms. MAP inference can be realized via the maximum spanning arborescence algorithm, which has a $\mathcal{O}(n^2)$ time complexity (Chu and Liu, 1965; Edmonds, 1967; Tarjan, 1977). The single root constraint can be taken into account using the same algorithm via the big-M trick (Fischetti and Toth, 1992, Section 2). Marginal inference can be realized via the matrix tree theorem (MTT, Koo et al., 2007; McDonald and Satta, 2007; Smith and Smith, 2007), which has $\mathcal{O}(n^3)$ time complexity.

Separable loss. The cubic-time complexity of MTT may be prohibitive in practice for training a model. Moreover, the MTT relies on a computationally unstable matrix inversion and is arguably non-trivial to implement. Hence, there has been interest in using simpler token-separable NLL loss functions (Zhang et al., 2017):

$$\begin{aligned}&\widetilde{\ell}_{(sep-dep)}(\boldsymbol{w}, \boldsymbol{y}) \\ &\quad = -\langle \boldsymbol{w}, \boldsymbol{y} \rangle + \sum_{m \in [n]} \log \sum_{h \in [n] \setminus \{m\}} \exp w_{h,m},\end{aligned}$$

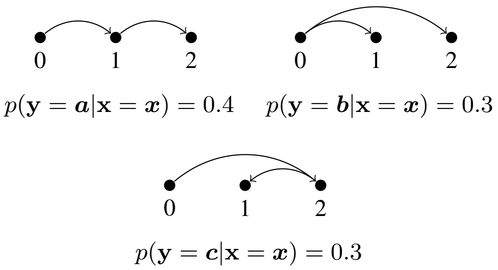
also called head selection loss. This loss is a sum of multiclass classification NLL losses, one per word in the sentence, and is therefore token-separable. As such, it can be efficiently parallelized on GPU and is trivial to implement in any ML framework.

The optimal pointwise surrogate Bayes risk for the token-separable loss is defined as:

$$\begin{aligned}\widetilde{r}^*_{(sep-dep)} = \inf_{\boldsymbol{w} \in \mathbb{R}^A} \; & -\mathbb{E}_{\mathbf{y}|\mathbf{x}=\boldsymbol{x}}[\langle \boldsymbol{w}, \mathbf{y} \rangle] \\ & + \sum_{m \in [n]} \log \sum_{h \in [n] \setminus \{m\}} \exp w_{h,m}.\end{aligned}$$

---

[4] `https://universaldependencies.org/u/overview/syntax.html`



$p(\mathbf{y} = \boldsymbol{a}|\mathbf{x} = \boldsymbol{x}) = 0.4$ $p(\mathbf{y} = \boldsymbol{b}|\mathbf{x} = \boldsymbol{x}) = 0.3$

$p(\mathbf{y} = \boldsymbol{c}|\mathbf{x} = \boldsymbol{x}) = 0.3$

Figure 2: Example of distribution over trees for a sentence of 3 words. The set of trees is defined as $Y = \{\boldsymbol{a}, \boldsymbol{b}, \boldsymbol{c}\}$.

Let $\widehat{\boldsymbol{w}}$ be an optimal solution. Then, by first order optimality conditions:

$$\frac{\partial}{\partial \widehat{w}_{h,m}} \begin{pmatrix} -\mathbb{E}_{\mathbf{y}|\mathbf{x}=\boldsymbol{x}}[\langle \widehat{\boldsymbol{w}}, \mathbf{y}\rangle] \\ + \sum\limits_{m\in[n]} \log \sum\limits_{h\in[n]\setminus\{m\}} \exp \widehat{w}_{h,m} \end{pmatrix} = 0$$

$$\implies \widehat{w}_{h,m} = \log p\left(\mathrm{y}_{h,m} = 1|\mathbf{x} = \boldsymbol{x}\right) \qquad (4)$$

where $p\left(\mathrm{y}_{h,m} = 1|\mathbf{x} = \boldsymbol{x}\right)$ denotes the marginal distribution of the dependency between words at position h and m, *i.e.* the sum of the conditional probability of trees this dependency appears in.

Theorem 3. *The loss $\widetilde{\ell}_{\textit{(sep-dep)}}$ is not Bayes consistent for distributions over dependency trees.*

Proof. Let $n = 2$ and assume that the distribution $p(\mathbf{y}|\mathbf{x} = \boldsymbol{x})$ is defined as depicted in Figure 2. Then, by Equation 4 we have: $\widehat{w}_{0,1} = \log 0.7$, $\widehat{w}_{0,2} = \log 0.6$, $\widehat{w}_{1,2} = \log 0.4$ and $\widehat{w}_{2,1} = \log 0.3$. As such:

$$\log 0.7 + \log 0.4 = \langle \widehat{\boldsymbol{w}}, \boldsymbol{a}\rangle \\ < \langle \widehat{\boldsymbol{w}}, \boldsymbol{b}\rangle = \log 0.7 + \log 0.6,$$

but $\boldsymbol{a} \in \arg\max_{\boldsymbol{y}\in Y} p(\mathbf{y} = \boldsymbol{y}|\mathbf{x} = \boldsymbol{x})$ and $p(\mathbf{y} = \boldsymbol{a}|\mathbf{x} = \boldsymbol{x}) > p(\mathbf{y} = \boldsymbol{b}|\mathbf{x} = \boldsymbol{x})$. Therefore, the token-separable loss is not Bayes consistent, *i.e.* a scoring model minimizing the surrogate risk may not lead to predicting the most probable tree in the data distribution. $\square$

Note that using the (non-separable) NLL loss will lead to a Bayes consistent model on this distribution. Indeed, by Equation 2, optimal scores $\widehat{\boldsymbol{w}}$ satisfy the following condition for all $\boldsymbol{y} \in Y$:

$$\frac{\exp\langle \widehat{\boldsymbol{w}}, \boldsymbol{y}\rangle}{\sum_{\boldsymbol{y}'\in Y} \exp\langle \widehat{\boldsymbol{w}}, \boldsymbol{y}'\rangle} = p(\mathbf{y} = \boldsymbol{y}|\mathbf{x} = \boldsymbol{x})$$
$$\implies \langle \widehat{\boldsymbol{w}}, \boldsymbol{y}\rangle = \log p(\mathbf{y} = \boldsymbol{y}|\mathbf{x} = \boldsymbol{x})$$

The following assignment for $\widehat{\boldsymbol{w}}$ satisfies this condition: $\widehat{w}_{0,1} = 0$, $\widehat{w}_{0,2} = \log 0.3$, $\widehat{w}_{1,2} = \log 0.4$ and $\widehat{w}_{2,1} = 0$. That is, minimizing the NLL loss on this distribution results in a Bayes consistent classifier, as expected.

The single root constraint case is reported in Appendix A.

6 Conclusion

Studying statistical properties of surrogate loss functions has not been a major interest in the NLP community, although there are exceptions (Ma and Collins, 2018; Effland and Collins, 2021). We proved that token-separable losses for NER and dependency parsing are not Bayes consistent, which means that minimizing these losses will not necessarily lead to models that will predict the most probable output for a given input in the data distribution, even with infinite training data.

In the dependency parsing case, Zhang et al. (2020) experimentally observed that the structured NLL loss leads to better results than the token-separable head selection loss. As such, our analysis provides a better theoretical understanding of these experiments. However, separable losses are widely used in state-of-the-art models, which suggests that future research should study why they work in practice.

Other types of separability have also been used for constituency parsing (Corro, 2020) and semantic parsing (Pasupat et al., 2019), *inter alia*.

Limitations

Arguably, these separable loss functions perform well in practice, which questions the appropriateness of the Bayes consistency property. For example, Long and Servedio (2013) argued that assumptions usually made are too unrealistic (*e.g.* considering that F is the set of all measurable mappings) and leads to misleading theoretical knowledge when it comes to actual implementation and experiments. Maybe this is also the case of the demonstration we made in this paper. However, all in all, we hope that this work will motivate future fundamental research on ML for NLP and especially on properties of loss functions.

A Inconsistency of the separable loss for single root dependency parsing

Theorem 4. *The loss* $\widetilde{\ell}_{\textit{(sep-dep)}}$ *is not Bayes consistent for distributions over single-root dependency trees.*

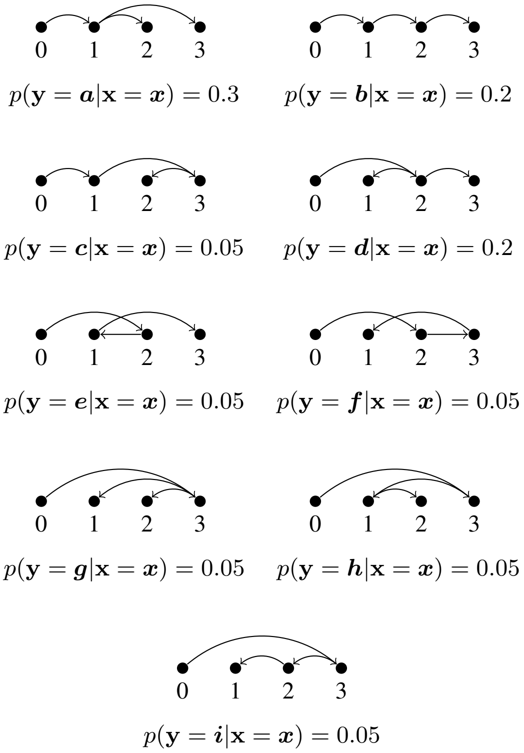
Proof. Let $n = 4$ and assume that the distribution $p(\mathbf{y}|\mathbf{x} = \boldsymbol{x})$ is defined as depicted in Figure 3. Then, by Equation 4 we have, among others:

$$\widehat{w}_{0,1} = \log 0.55, \qquad \widehat{w}_{1,2} = \log 0.55,$$
$$\widehat{w}_{1,3} = \log 0.4, \qquad \widehat{w}_{2,3} = \log 0.45.$$

As such, we have:

$$\langle \widehat{\boldsymbol{w}}, \boldsymbol{a} \rangle = \log 0.55 + \log 0.55 + \log 0.40,$$
$$\langle \widehat{\boldsymbol{w}}, \boldsymbol{b} \rangle = \log 0.55 + \log 0.55 + \log 0.45,$$

which means that $\langle \widehat{\boldsymbol{w}}, \boldsymbol{a} \rangle < \langle \widehat{\boldsymbol{w}}, \boldsymbol{b} \rangle$ but $\boldsymbol{a} \in \arg\max_{\boldsymbol{y} \in Y} p(\mathbf{y} = \boldsymbol{y}|\mathbf{x} = \boldsymbol{x})$ and $p(\mathbf{y} = \boldsymbol{a}|\mathbf{x} = \boldsymbol{x}) > p(\mathbf{y} = \boldsymbol{b}|\mathbf{x} = \boldsymbol{x})$. Therefore the separable loss is not Bayes consistent for single-root dependency parsing. $\square$



$p(\mathbf{y} = \boldsymbol{a}|\mathbf{x} = \boldsymbol{x}) = 0.3$ $p(\mathbf{y} = \boldsymbol{b}|\mathbf{x} = \boldsymbol{x}) = 0.2$

$p(\mathbf{y} = \boldsymbol{c}|\mathbf{x} = \boldsymbol{x}) = 0.05$ $p(\mathbf{y} = \boldsymbol{d}|\mathbf{x} = \boldsymbol{x}) = 0.2$

$p(\mathbf{y} = \boldsymbol{e}|\mathbf{x} = \boldsymbol{x}) = 0.05$ $p(\mathbf{y} = \boldsymbol{f}|\mathbf{x} = \boldsymbol{x}) = 0.05$

$p(\mathbf{y} = \boldsymbol{g}|\mathbf{x} = \boldsymbol{x}) = 0.05$ $p(\mathbf{y} = \boldsymbol{h}|\mathbf{x} = \boldsymbol{x}) = 0.05$

$p(\mathbf{y} = \boldsymbol{i}|\mathbf{x} = \boldsymbol{x}) = 0.05$

Figure 3: Example of distribution over trees for a sentence of 3 words and the single-root constraints. The set of trees is defined as $Y = \{\boldsymbol{a}, \boldsymbol{b}, \boldsymbol{c}, \boldsymbol{d}, \boldsymbol{e}, \boldsymbol{f}, \boldsymbol{g}, \boldsymbol{h}, \boldsymbol{i}\}$.

A Systematic Search for Compound Semantics in Pretrained BERT Architectures

Filip Miletic and **Sabine Schulte im Walde**
Institute for Natural Language Processing, University of Stuttgart
{filip.miletic, schulte}@ims.uni-stuttgart.de

Abstract

To date, transformer-based models such as BERT have been less successful in predicting compositionality of noun compounds than static word embeddings. This is likely related to a suboptimal use of the encoded information, reflecting an incomplete grasp of how the models represent the meanings of complex linguistic structures. This paper investigates variants of semantic knowledge derived from pretrained BERT when predicting the degrees of compositionality for 280 English noun compounds associated with human compositionality ratings.

Our performance strongly improves on earlier unsupervised implementations of pretrained BERT and highlights beneficial decisions in data preprocessing, embedding computation, and compositionality estimation. The distinct linguistic roles of heads and modifiers are reflected by differences in BERT-derived representations, with empirical properties such as frequency, productivity, and ambiguity affecting model performance. The most relevant representational information is concentrated in the initial layers of the model architecture.

1 Introduction

The meaning of multiword expressions such as noun compounds is notoriously difficult to model, particularly because of variability in their degree of compositionality, i.e. the relatedness of the meaning of a compound (e.g. *flea market*) to that of the individual constituents (*flea* and *market*). The degree of compositionality has been successfully predicted using static word embeddings, but transformer-based models such as BERT (Devlin et al., 2019) have so far been less successful. This might be related to a suboptimal use of the information encoded by the models, reflecting our incomplete grasp of how they represent the meanings of complex linguistic structures.

In this paper, we aim to improve this understanding, as well as produce actionable methodological recommendations. We predict the degrees of compositionality of 280 English noun compounds associated with human compositionality ratings. We extract their occurrences from a web corpus and model them using pretrained BERT. Like previous work, we assume that the contextualized nature of these representations may capture key aspects of compound semantics. But we do not expect this information to be equally accessible across the model or independent from underlying linguistic properties. We therefore experiment with variants of BERT-derived semantic knowledge (comprising over 40,000 ways of computing the degree of compositionality), and analyze the linguistic roles of compound constituents and their empirical properties (frequency, ambiguity, and productivity). We provide the following contributions:

- We identify a robust setup to extract compositionality information from pretrained BERT. It strongly improves on earlier unsupervised implementations and highlights beneficial decisions in data preprocessing, embedding computation, and compositionality estimation.
- We show that the distinct linguistic roles of heads and modifiers are reflected by differences in BERT-derived representations. Further focusing on compound heads, we find clear effects of their empirical properties on model performance.
- Our results support the view that pretrained BERT encodes at least some aspects of the semantics of multiword expressions, and also show that the most relevant information is found in the model's initial layers.

The remainder of this paper is organized as follows. We first review related studies (§2), and then introduce our data (§3) and experimental setup (§4). We then analyze and discuss the results (§5) and provide a conclusion (§6).

2 Related work

The meaning of noun compounds is modeled from a broad range of perspectives. In psycholinguistics, for example, there is a long tradition of research on human processing of compound semantics. Its focus is usually on semantic transparency, which is operationalized using measures including the semantic relatedness of the constituents and the retention of their meaning in the compound (e.g. Bell and Schäfer, 2016; Auch et al., 2020; Günther et al., 2020). Computational studies have examined a similar range of compound properties, aiming to predict the meaning of the whole compound (Mitchell and Lapata, 2008; Dima et al., 2019), the semantic relations between a compound's constituents (Ó Séaghdha, 2007; Dima et al., 2014), or the compound's degree of compositionality. The latter issue is also the focus of our work.

The ability of computational models of compound semantics to predict the degree of compositionality is usually evaluated on a ranking task with gold standard data in form of human compositionality ratings, which exist for languages including English (Reddy et al., 2011), German (von der Heide and Borgwaldt, 2009; Schulte im Walde et al., 2016), French and Portuguese (Cordeiro et al., 2019). Strong results have been obtained using static word embeddings, generally by learning dedicated representations for the whole compound and comparing them against the representations of the individual constituents, often combined using composition functions (Reddy et al., 2011; Schulte im Walde et al., 2013, 2016; Salehi et al., 2014, 2015; Cordeiro et al., 2019; Alipoor and Schulte im Walde, 2020). Most studies predict the compositionality of the whole compound, but differences between heads and modifiers have been underscored. Reported effects on model performance are related to their distinct linguistic roles and empirical properties such as frequency, productivity, and ambiguity (Schulte im Walde et al., 2013, 2016; Alipoor and Schulte im Walde, 2020).

More recently, compositionality prediction has been addressed using pretrained transformer-based models. While BERT-derived representations used in a subsequently trained classifier performed well on binary classification (Shwartz and Dagan, 2019), their unsupervised use in the standard ranking task formulation has been less successful. For instance, an implementation based on comparisons between contextualized and non-contextualized compound representations obtained significantly poorer results compared to static word embeddings, leading to a suggestion that these models do not capture compositionality in a way similar to human annotators (Garcia et al., 2021a). Stronger correlations with human judgment were obtained in a probing study, but using external linguistic knowledge – gold standard synonyms of noun compounds (Garcia et al., 2021b). We are unaware of unsupervised implementations of BERT-derived representations that are competitive with static word embeddings on this task.

This might be related to a suboptimal use of the information encoded by BERT, as the layers in its architecture capture different aspects of linguistic structure (Rogers et al., 2020). For instance, it has been suggested that semantic knowledge in general (Jawahar et al., 2019) and word sense information in particular (Coenen et al., 2019) is encoded in higher layers, but also that type-level information is encoded in lower layers (Vulić et al., 2020). More generally, these and other types of implementation decisions impact BERT performance on other linguistically oriented tasks (e.g. Laicher et al., 2021). To the best of our knowledge, these patterns have not been investigated in detail for compound semantics, with the cited studies generally relying on widely used solutions (e.g. computing a token-level embedding by averaging over the last four layers).

3 Data

This section introduces the data resources we used. For details on licenses, see Appendix A.

3.1 Gold standard of noun compounds

We use the set of 280 English noun compounds introduced by Cordeiro et al. (2019). It includes an initial set of 90 compounds created by Reddy et al. (2011)[1] and a further 190 compounds annotated by Cordeiro and colleagues using the same rating procedure.[2] Human annotators were asked to provide compositionality ratings in terms of literality, on a scale from 0 (not at all literal) to 5 (very literal). They provided scores for the interpretation of the whole compound (e.g. *crash course*), as well as for the use of the modifier (*crash*) and the head (*course*) within it. Sample compounds and their ratings are shown in Table 1.

biological clock	4.71 ± 0.47	1.76 ± 1.35	2.29 ± 1.21
health insurance	4.53 ± 0.88	4.83 ± 0.58	4.40 ± 1.17

Table 1: Sample gold standard compounds with compositionality ratings (mean and standard deviation).

3.2 Corpus

As corpus data for the modeled noun compounds, we rely on the widely used ENCOW corpus, obtained by crawling web data and containing ≈ 9.6 billion words (Schäfer and Bildhauer, 2012; Schäfer, 2015). For each compound, all tokenized sentences in which it appears are extracted. We only use singular forms so as to avoid potential variability related to grammatical number in BERT.

3.3 Empirical compound properties

Parts of our analysis use information on empirical properties of compound constituents (in particular, their heads), and specifically (i) frequency; (ii) productivity, i.e. the number of compound-types in which they appear; and (iii) ambiguity, i.e. their number of senses. We use the information on these properties created by Schulte im Walde et al. (2016) for the Reddy et al. (2011) dataset. They derived frequency and productivity information from the ENCOW corpus, and calculated ambiguity based on WordNet (Fellbaum, 1998). We apply the same procedures to calculate the information for the compounds from the Cordeiro et al. (2019) dataset.

4 Experimental setup

4.1 BERT representations

We use `BERT-base-uncased`, a 768-dimension, 12-layer version of the model (110 million parameters) pretrained on English data, from the Hugging Face implementation (Wolf et al., 2020). We run the experiments on a CPU computing server (2×12 3GHz cores with 768GB RAM) over ≈ 5 days. In order to facilitate the analysis of modeling properties, we deliberately adopt a straightforward setup without fine-tuning. Each sequence from the corpus is fed into the model, which returns multiple vector representations for each token in the sequence. For all sequences of a compound, we retain the representations for each token in the sequence; these correspond to the input embedding layer and the outputs of the 12 hidden states. We test different ways of combining the obtained information.

Embedding types. BERT produces contextualized representations for each token in the sequence, which we use both individually and by combining multiple token representations (see pooling functions below). We compute the following types of embeddings. (i) `modif`: representation of the modifier, corresponding to its contextualized embedding. (ii) `head`: representation of the head, corresponding to its contextualized embedding. (iii) `comp`: representation of the full compound, corresponding to pooled `modif` and `head` embeddings. (iv) `cont`: representation of the context in which the compound appears, corresponding to the merged embeddings of all tokens in the sequence apart from `modif`, `head`, `[CLS]`, and `[SEP]`. (v) `cls`: embedding of the `[CLS]` token, taken to correspond to a representation of the full sequence.

BERT's tokenizer splits out-of-vocabulary tokens into subwords with known representations. When this occurs for `modif` or `head`, the subword representations are pooled into a single embedding.

Layer combinations. We test all contiguous spans of layers, across the input embedding and the 12 hidden state outputs, for a total of 91 layer combinations. The smallest combination is a single layer, and the largest is the full range of 13 layers.

Pooling functions. Multiple vectors can be combined in different ways; we test two options, averaging (`avg`) or summing (`sum`) over them. This is applied (i) token-wise, if merging multiple token representations; (ii) layer-wise, if merging multiple layers; (iii) sequence-wise, if creating a type-level representation (see below). In order to streamline the experimental setup, the same pooling function is used in all three cases.

Sequence length. We test if using longer sequences can be beneficial based on the assumption that a larger context may be more semantically discriminating. We either retain only sequences with at least 20 space-separated tokens, or do not impose any threshold; this technically corresponds to a minimum of 3 tokens, i.e. the lowest sequence length in the corpus.

Number of sequences. From a similar perspective, we examine the effect of increasing the number of modeled sequences, experimenting with 10, 100, and 1,000 sequences per compound. The sets of sequences are not resampled; rather, the smaller sets are included in the larger ones. This criterion is combined with that of sequence length: for instance, we extract 1,000 sequences of any length as well as 1,000 sequences with at least 20 tokens, although these may partly overlap. For compounds whose corpus frequency is lower than the threshold, all available occurrences are used.

4.2 Compositionality estimates

As stated above, we expect that the contextualized representations we use may carry semantic information reflecting the degree of compositionality of a compound, but it is unclear which specific combination of representations is the most efficient.

Direct estimates. We directly compute pairwise cosine scores between pairs of embeddings, testing all 10 pairs of embedding types (`head`–`modif`, `head`–`comp`, `head`–`cont`, and so forth).

Composite estimates. We further combine the directly measured information pertaining to the head and the modifier of a compound using the same composition functions as Reddy et al. (2011). Specifically, we use `head` and `modif` embeddings in combination with one of the following: `comp`, `cont`, and `cls`. Taking `comp` as an example, we compute the composite estimates as follows:

$$\begin{aligned}\text{ADD} &= \cos(\texttt{comp}, \texttt{modif}) + \cos(\texttt{comp}, \texttt{head})\\ \text{MULT} &= \cos(\texttt{comp}, \texttt{modif}) \cdot \cos(\texttt{comp}, \texttt{head})\\ \text{COMB} &= \text{ADD} + \text{MULT}\end{aligned}$$

Token-level vs. type-level. The information from individual occurrences can be aggregated into a single numerical score in different ways. (i) In the token-level approach, we compute a compositionality estimate for each individual occurrence, and then average over those values to get a single score. (ii) In the type-level approach, we first compute a type-level representation by applying a pooling function; as an example, we average or sum over all individual `head` embeddings to produce a type-level `head` embedding. This type-level representation is then used to directly compute a single compositionality estimate.

The combinations of the presented experimental parameters correspond to a total of 41,496 ways of computing a numerical estimate of the degree of compositionality. In a trial run, we also experimented with other parameters (e.g. restrictions on the position of the compound within the sequence), but they did not exhibit strong effects and for clarity are not included in the present discussion.

5 Results and discussion

We evaluate each constellation of parameters by calculating Spearman's rank correlation coefficient between the compositionality estimates it produces and human judgments from the test set. All implementations are evaluated on three prediction targets: compositionality scores for the compound as a whole, the head, and the modifier.

5.1 Overview of model performance

We begin by looking at general trends in model performance (Table 2). The highest correlation coefficient we obtain stands at 0.706 for compound-level compositionality. Compared to previous studies on the same dataset, it is in a similar range as the result reported by Cordeiro et al. (2019) using static word embeddings ($\rho = 0.726$).[3] Their best performance was obtained by training a `word2vec` model on a corpus in which compound occurrences had been joined into single tokens. The cosine scores between those representations and compositionally constructed vectors were then used to predict the degree of compositionality. Interestingly, this procedure strongly relies on the context in which the compounds occur, which is also a key component of our best approaches (see below).

The highest performance we obtain substantially improves on the best BERT-derived score reported by Garcia et al. (2021a) based on comparisons between contextualized and non-contextualized representations of a compound ($\rho = 0.37$). In another BERT-based experiment, Garcia et al. (2021b) obtain a higher correlation using similarity measurements between compounds and gold standard synonyms ($\rho = 0.67$); by contrast, we do not rely on external linguistic knowledge.

The implementations we tested are strongest at predicting compound-level compositionality. This is followed by the compositionality of the head (maximum $\rho = 0.645$) and then of the modifier (maximum $\rho = 0.553$). Predicted values for the three types of scores are strongly correlated ($\rho > 0.9$ for all three pairwise comparisons), but the best performing parameter constellations clearly differ.

More generally, the summary in the table underscores the wide range of obtained values; the

weakest implementations yield negative correlations, with a low of -0.649. This confirms the relevance of the parameters we tested and the importance of understanding the optimal choices in implementing them. Trends suggested by the initial overview include better performance of (i) the first hidden layer in isolation; (ii) token-level rather than type-level modeling; (iii) `cont` embeddings, when paired with another relevant type of information; (iv) embeddings targeting the compound as a whole, the head, or the modifier for the corresponding compositionality score. Strikingly, all the weakest constellations are closely similar to one another, the only distinguishing characteristic being the span of layers. But some of these parameter choices are also found in the best performing implementations; more generally, the direction and relevance of all trends are not immediately apparent. We therefore now more closely examine individual parameters.

Sequence length. Using sequences with at least 20 tokens leads to lower mean correlations. However, their minimum values are higher and maximum values are comparable (Table 3). The overall lack of a clear effect suggests that beneficial distinctions made by the model are primarily based on the most immediate linguistic context.

Number of modeled sequences. There is a clear trend towards an increase in performance with an increase in the number of modeled sequences (Table 4), likely because this facilitates disambiguation and limits the effect of sampling differences. Looking at the maximum values, the shift from 10 to 100 occurrences leads to a stronger improvement (≈ 0.06 points) than the shift from 100 to 1,000 (≈ 0.02 points); this suggests that it is especially important to avoid very low numbers of examples. While increasing the number of occurrences also leads to the lowest performances overall, this may be due to the detrimental effect of other parameters.

We further assessed the impact of sampling differences in the condition with 10 sequences, which is the most inherently unstable. We ran the compositionality estimation 10 times, each time randomly resampling the modeled occurrences. The mean difference between the minimum and maximum values obtained by a parameter constellation is 0.028. This variability does not alter the overall parameter-level trends (see Appendix B).

Some compounds do not exceed the threshold frequencies for some parameter combinations. This affects 10 compounds for the 100 sequence threshold, and 97 compounds for the 1,000 sequence

	avg	sum

Modif	0.100 (-0.460, 0.553)	0.092 (-0.476, 0.546)

Table 6: Spearman's ρ (mean, min, max) for token- vs. type-level processing.

threshold. As a check, we calculated correlations on a smaller set of compounds, excluding the 10 most affected by frequency issues. The results were near-identical, with marginal improvements for the top predictions (e.g. best ρ increasing from 0.706 to 0.710 for compound scores) and the same general trend. As for the compounds with fewer than 1,000 sequences, the mean number of sequences available for these items was 510, which is still a strong increase compared to the preceding threshold.

Pooling functions. Averaging and summing perform similarly when creating a single embedding from multiple vectors (Table 5). They obtain near-identical mean and identical maximum values; averaging leads to lower minimum values.

One of the ways we used pooling functions was to merge representations for out-of-vocabulary tokens that are split up by BERT's tokenizer. This affected 14 compounds; some instances reflect derivational patterns (e.g. `mail`, `##ing` in *mailing list*), but others are more obscure (e.g. `gr`, `##av`, `##y` in *gravy train*). Since it is unclear what some of these representations capture, we checked their impact by calculating correlations on a reduced set of compounds, excluding those with OOV tokens. The results were marginally higher (e.g. ρ increasing from 0.706 to 0.710 for compound scores). This issue therefore does not appear to have a strong detrimental effect, at least when it is limited to a small subset (5%) of target items.

Another frequently used pooling function is concatenation. Applying it across multiple tokens (e.g. for out-of-vocabulary items) or multiple sequences (to create a type-level representation) would result in comparisons between vectors with different numbers of dimensions; we therefore did not include it in the full experimental setup. As a check, however, we ran concatenation across layers, combined with averaging over tokens and sequences. It led to slightly higher mean correlations (0.147 for compound scores), but it did not improve on the maximum results so we did not experiment further.

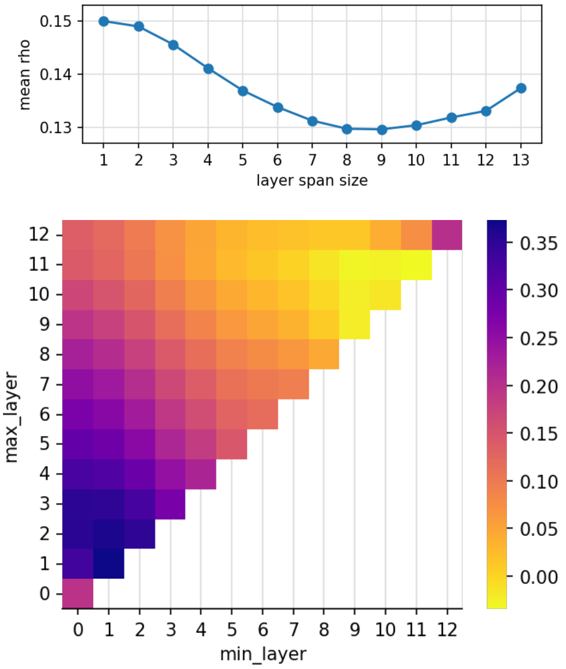

Figure 1: Top: effect of the number of modeled layers on compound-level compositionality prediction. Bottom: mean correlations for compound compositionality prediction across layer combinations. The `min_layer` and `max_layer` values are start and end points of a contiguous span of layers.

Token vs. type-level. There is a clear preference across the board for token-level processing (Table 6). Most improvements over type-level are $\approx$ 0.01–0.02 points; they reach $\approx$ 0.06 points when comparing the worst-performing configurations. A potential explanation is that estimating compositionality on individual occurrences – rather than a merged type-level representation – may be less sensitive to ambiguous or otherwise noisy data.

Layers. The results are affected by the number of modeled layers (Figure 1). The best performance is obtained with a single layer (mean $\rho = 0.150$ for compound scores) and decreases as the span increases up to 9 layers (0.130). Larger spans fare somewhat better, likely because they are bound to capture some relevant representational information; the best is the full range of 13 layers (0.137).

In terms of specific layers, the best result overall is obtained by the first hidden layer in isolation (mean $\rho = 0.373$), followed by other combinations and individual layers in the low-to-mid range. This is plotted in Figure 1 for compound compositionality scores; head and modifier scores follow the same trends (see Appendix C). The traditionally used combination of the last four hidden layers (9–12) is not among the best ones. It is in fact the single weakest in terms of maximum values: 0.248 for compound scores, close to 0.5 below the best implementation. However, it also has a comparatively high minimum value (-0.262), suggesting it is more robust to the effect of other parameters.

Compositionality estimates. We summarize the impact of compositionality estimates by looking at performance across the five types of embeddings which constitute the basis of subsequent score calculations (Table 7); for a summary of results on individual estimates, see Appendix D.

	modif	head	comp	cont	cls

	0.553	0.415	0.517	0.553	0.477

Table 7: Spearman's ρ (mean, min, max) for embedding types, across all direct and composite estimates if used.

Looking at the mean values, `head` performs stronger than `modif` as well as `comp` across the prediction targets. This is coherent with the dominant role of the head in the morphological constituency of compounds. However, the maximum values out of the three are obtained by `comp` for the compound-level score, `head` for the head score, and `modif` for the modifier score. This indicates that representations targeting the whole compound or a constituent of interest are successful in capturing information specific to the respective element.

As for the two other embedding types, the mean values for `cont` follow `head` and `comp` across prediction targets. But its maximum values are the single best (compound-level prediction) or joint best (head and modifier predictions). By contrast, `cls` is clearly in the lower range of performance. Its maximum values remain around 0.1 points behind the best implementations. This shows that using the linguistic context surrounding the compound – modeled by `cont` – is beneficial, and clearly more so than using a representation of the full sequence.[4]

This might be explained by the redundancy of using a representation of a compound or its constituent, and comparing it with a representation of the full sequence which encodes the same element. It could also be the case that, as suggested before, token-level embeddings are strongly influenced by their immediate linguistic context; a balanced representation of a broader range of information might be complementary. Whatever the case, the results show that the similarity between a compound and its linguistic context is reflective of the degree of compositionality. This might explain why previous implementations using neutral contexts were less successful in capturing these trends.

5.2 Ablation study

In order to further validate the parameter-level trends observed thus far, we conduct an ablation study. We start from the parameter constellation that obtained the best results on predicting the compositionality of the compound as a whole (see Table 2; the top two configurations obtained identical results). For each parameter, we then test all other potential values, one at a time, while keeping the remaining parameters unchanged. The results are presented in Figure 2.

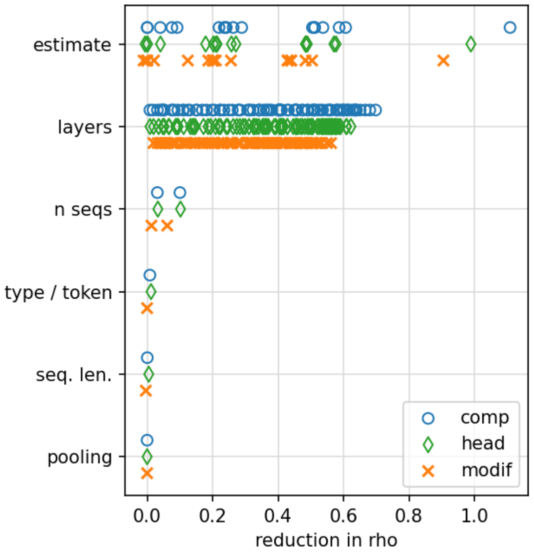

Figure 2: Effect of alternative parameter values compared to the top parameter constellation.

---

[4] A more direct comparison would involve a merged representation of all the tokens in the sequence rather than the `cls` embedding. We nevertheless think that we capture the same range of information.

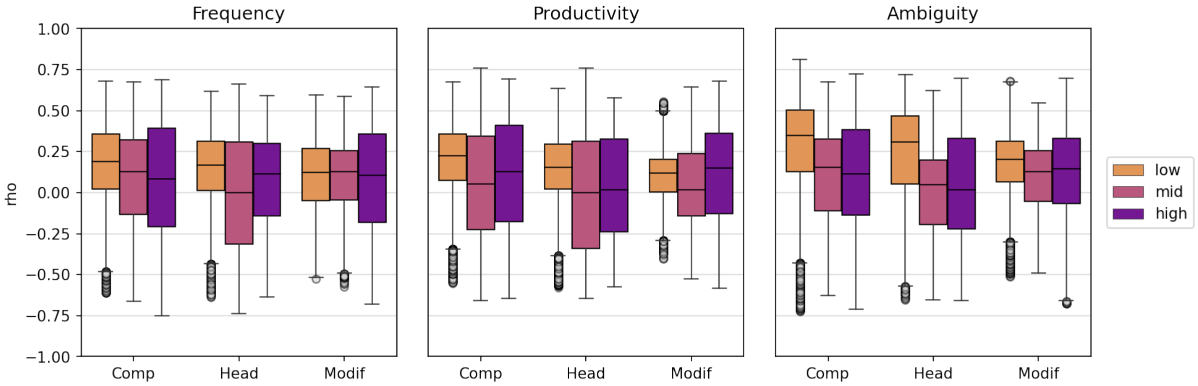

Figure 3: Effect of empirical properties of the head on model performance, observed across the evaluated implementations. Values on the x-axis indicate prediction targets (compound, head, and modifier scores).

Several parameters exhibit no or limited differences with respect to the top parameter constellation: pooling functions, minimum sequence length, and type vs. token-level modeling. Clearer effects on performance are observed for the number of modeled sequences; the drop is strongest for the smallest number of sequences. The choice of layers shows a very strong effect, with a clear tendency towards a drop in performance with both (i) a shift from initial to later hidden states, and (ii) an increase in layer span size. The strongest effect is exhibited by the estimate used to predict the degree of compositionality. All weakest estimates (reduction in $\rho > 0.4$) involve the `cls` embedding. All strongest estimates (reduction in $\rho < 0.1$) involve the `cont` embedding.

These results overall confirm the trends previously discussed for individual parameters. They also provide further evidence that model performance is most strongly affected by the choice of representational information to be used, i.e. the layers and the modeled tokens in the sequence. Suboptimal values for either of these parameters can lead to compositionality predictions that are fully decorrelated from human judgment. Performance does not depend to the same extent on the way in which data is preprocessed and representational information is combined. However, the effect of some of these parameters is not negligible, especially cumulatively, and as such should not be disregarded.

5.3 Empirical properties of compounds

We now turn to the potential impact of empirical properties of the compounds on model performance. We focus on key characteristics of the compounds' heads, given their importance indicated by the trends for compositionality estimates.

As previously stated, we examine the impact of three empirical properties: frequency, productivity, and ambiguity (for sources of this information, see Section 3.3). For each property, we rank the 280 compounds based on the values they exhibit and split them into five sets containing 56 compounds each. We retain the first, third, and fifth set, which we take to clearly reflect the low, mid, and high ranges for each empirical property. The remaining two sets are excluded in order to avoid overlapping or closely similar values in adjoining sets.

A summary of the splits across the three features is presented in Table 8. For each feature, we compute correlations with human judgments separately for each of the three splits of compounds, across all evaluated constellations of parameters. The distribution of the obtained values is plotted in Figure 3 and further discussed below.

Feature	Mean	Std.	Example
Frequency	42	± 30	*silver **spoon***
(thousands)	452	± 108	*labor **union***
	3,614	± 2,438	*crash **course***
Productivity	7	± 5	*night **owl***
	75	± 19	*time **difference***
	448	± 208	*birth **rate***
Ambiguity	2	± 1	*research **project***
	5	± 1	*flea **market***
	13	± 4	*application **form***

Table 8: Mean and standard deviation for the low, mid, and high range splits across empirical features. A sample compound from each split is provided.

Frequency. In predicting the compound and head compositionality scores, the best performance is obtained for low-frequency heads (mean $\rho = 0.18$

and 0.16, respectively). For the compound score, performance across the mid and high range is similar; for the head score, it is clearly lower in the mid range. As for the modifier score, performance is overall stable (mean $\rho = 0.10$ across the three splits); this is not especially surprising given the focus on the frequency of the head. This contrasts the previously reported improvements in performance with a higher number of modeled sequences. However, head frequency is correlated with both productivity and ambiguity ($\rho = 0.87$ and 0.50, respectively, across the 280 compounds). Poorer performance in higher frequency ranges is consistent with an indirect effect of these two properties.

Productivity. Overall, low-productivity heads clearly obtain the best results for compound and head compositionality scores (mean $\rho = 0.21$ and 0.16, respectively). Low- and high-productivity heads obtain similar results for the modifier scores (mean $\rho = 0.11$ and 0.12, respectively). Across the prediction targets, mid-productivity heads have the poorest performance; this drop is the strongest for head scores (mean $\rho = 0.01$). The overall better performance at modeling low-productivity heads is likely explained by their very nature of being used with fewer distinct modifiers, which might facilitate the learning of those compound meanings. This is opposed to higher productivity ranges, which potentially imply more dispersion.

Ambiguity. Across the prediction targets, low-ambiguity heads clearly have the strongest performance (mean $\rho = 0.30$ for compound scores; 0.25 for head scores; 0.18 for modifier scores). The difference with respect to the two other ambiguity ranges is the strongest for head scores; it amounts to ≈ 0.20 points. Performance is similar for mid- and high-range ambiguity. For compound and head scores, the mid range performs slightly better than the high range; for modifier scores, it is the reverse. Similarly to low productivity, the better results for low ambiguity suggest that limited semantic dispersion across the occurrences of a given word makes it easier for BERT to learn its meaning. This is in turn beneficial for derived representations of more complex linguistic structures such as compounds.

Overall, these results have shown that compound properties affect predictions of the degree of compositionality, with better performance in the lower ranges of all three properties. This directly echoes the results for type-level word embeddings reported by Schulte im Walde et al. (2016), who similarly suggested that prediction performance is related to broader effects of compound properties on the quality of the underlying meaning representations. Moreover, the prediction of compound and head scores generally follows the same pattern across the three empirical features. Although modifier scores do not align as closely, they too point to an effect of head properties. These results further underscore the importance of the representations of compound heads for the modeling approach we adopted.

6 Conclusion

We have presented an experiment on predicting the degree of compositionality of 280 English noun compounds using a wide range of variants of semantic knowledge derived from pretrained BERT. We have identified a competitive best implementation achieving $\rho = 0.706$ with human judgement and highlighted clear takeaways.

In terms of preprocessing, stronger results were obtained when modeling a larger number of occurrences per compound, whereas controlling for sequence length did not have a clear effect. On embedding computation, different pooling functions led to comparable performance, but there was a clear advantage for layers in the low-to-mid range, which strongly improved on layer combinations used in earlier studies. As for compositionality estimates, it was clearly beneficial to compute them on the token rather than type level, as well as to use (i) representations targeting the constituent of interest; (ii) representations of the surrounding context; (iii) comparisons across complementary – rather than redundant – representational information.

Looking at empirical properties of compounds, low-frequency, low-productivity, and low-ambiguity heads obtain better compositionality predictions. This trend confirms that more limited semantic dispersion makes it easier to model compound meaning. The fact that it holds across compound, head, and modifier compositionality scores highlights the importance of the head in the linguistic structure – and computational modeling – of compounds. Taken together, our results point to important practical decisions when running similar implementations and contribute to our understanding of the way in which BERT represents lexical meaning, supporting the view that the pretrained model encodes at least some aspects of compound semantics.

Limitations

Our experiments were limited to noun compounds in a single pretrained model for English, with potential implications for the generalizability of our results. They may be partly related to the architecture of this specific model. From a linguistic standpoint, compound properties vary widely across languages. For instance, where English has productive patterns combining two nouns, often in an open (space-separated) compound, German has closed compounds; Romance languages widely rely on N-Prep-N patterns; the structure in many Slavic languages involves patterns of nominal declension; and so forth. The model might not capture the information relevant for compositionality prediction in the same way across these cases. Additionally, our results are strongly related to the central role of compound heads; they may therefore be different in multiword expressions with a different linguistic structure, such as particle verbs and idioms. Finally, we used token-level representations to predict type-level compositionality judgments. This is relevant in terms of assessing the general ability to infer type-level information, but (i) performance may be improved by controlling for the senses in the modeled occurrences vs. those in the stimuli used to collect human judgements; (ii) further work is needed to fully understand the factors contributing to individual token-level representations of a compound.

A Licenses for data resources

The gold standard datasets of noun compounds and extensions with empirical properties are publicly distributed by their authors without a specific license. The ENCOW corpus and WordNet were acquired prior to this study. Their licenses do not have restrictions regarding research use.

B Effect of sampling differences

We found that resampling corpus occurrences (for $n = 10$ occurrences per compound) led to minor differences in model performance. However, they did not impact parameter-level trends overall, with the effect of parameter choices remaining the same in the majority of cases. To illustrate this, we are reporting the mean correlations with human judgment based on different samples of occurrences: three individual samples (those whose overall mean correlations are the lowest, the closest to the mean, and the highest), as well as the mean and standard deviation for the 10 samples. Similarly to the main analysis, the mean values are presented for different parameter choices; for layers, this is limited to a sample of layer spans. The results are split across the three prediction targets: for the compound as a whole in Table 9; for the head in Table 10; for the modifier in Table 11.

Table 11: Mean correlations for compositionality prediction (of the modifier) across parameter choices.

C Effect of layer combinations

Model performance across layer combinations is plotted in Figure 4.

D Effect of compositionality estimates

Model performance across individual compositionality estimates is plotted in Figure 5.

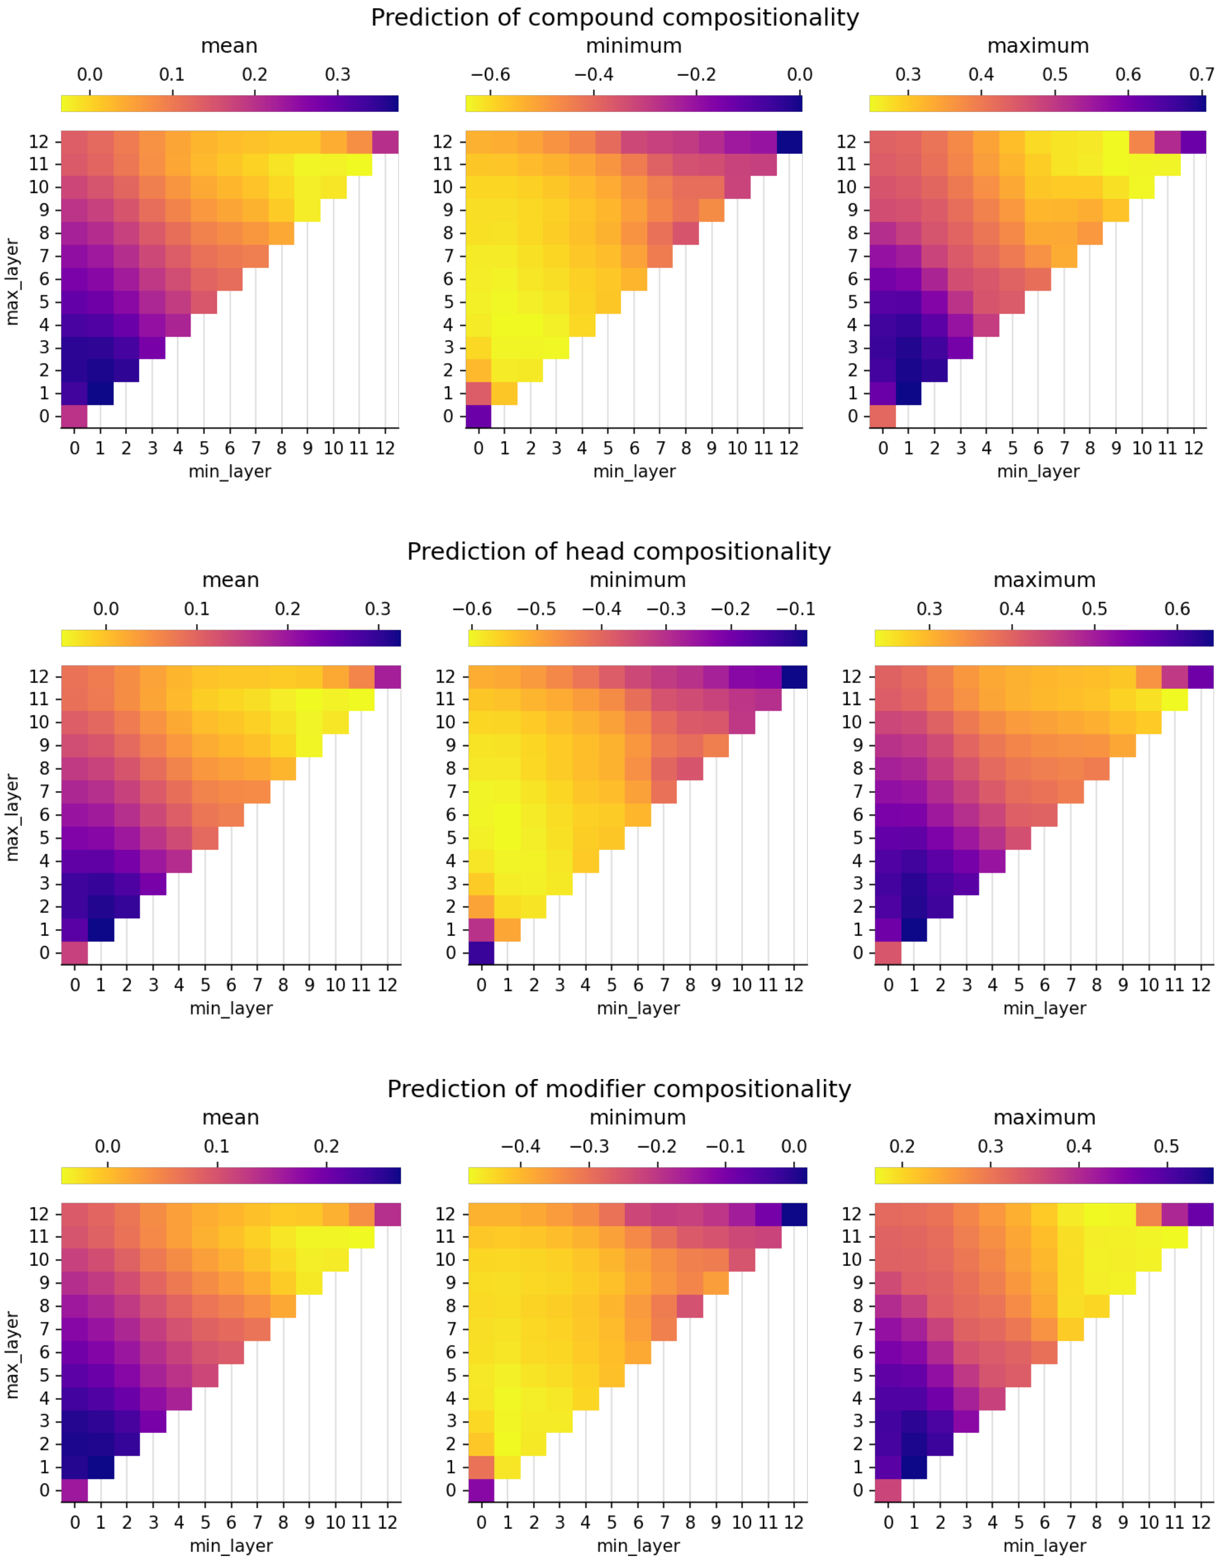

Figure 4: Correlations for compositionality prediction across layer combinations. The `min_layer` and `max_layer` values are start and end points of a contiguous span of layers. For each prediction target (compound, head, and modifier compositionality score), the left panel corresponds to the mean correlation per layer combination; the middle and the right panels correspond to the minimum and maximum values, respectively.

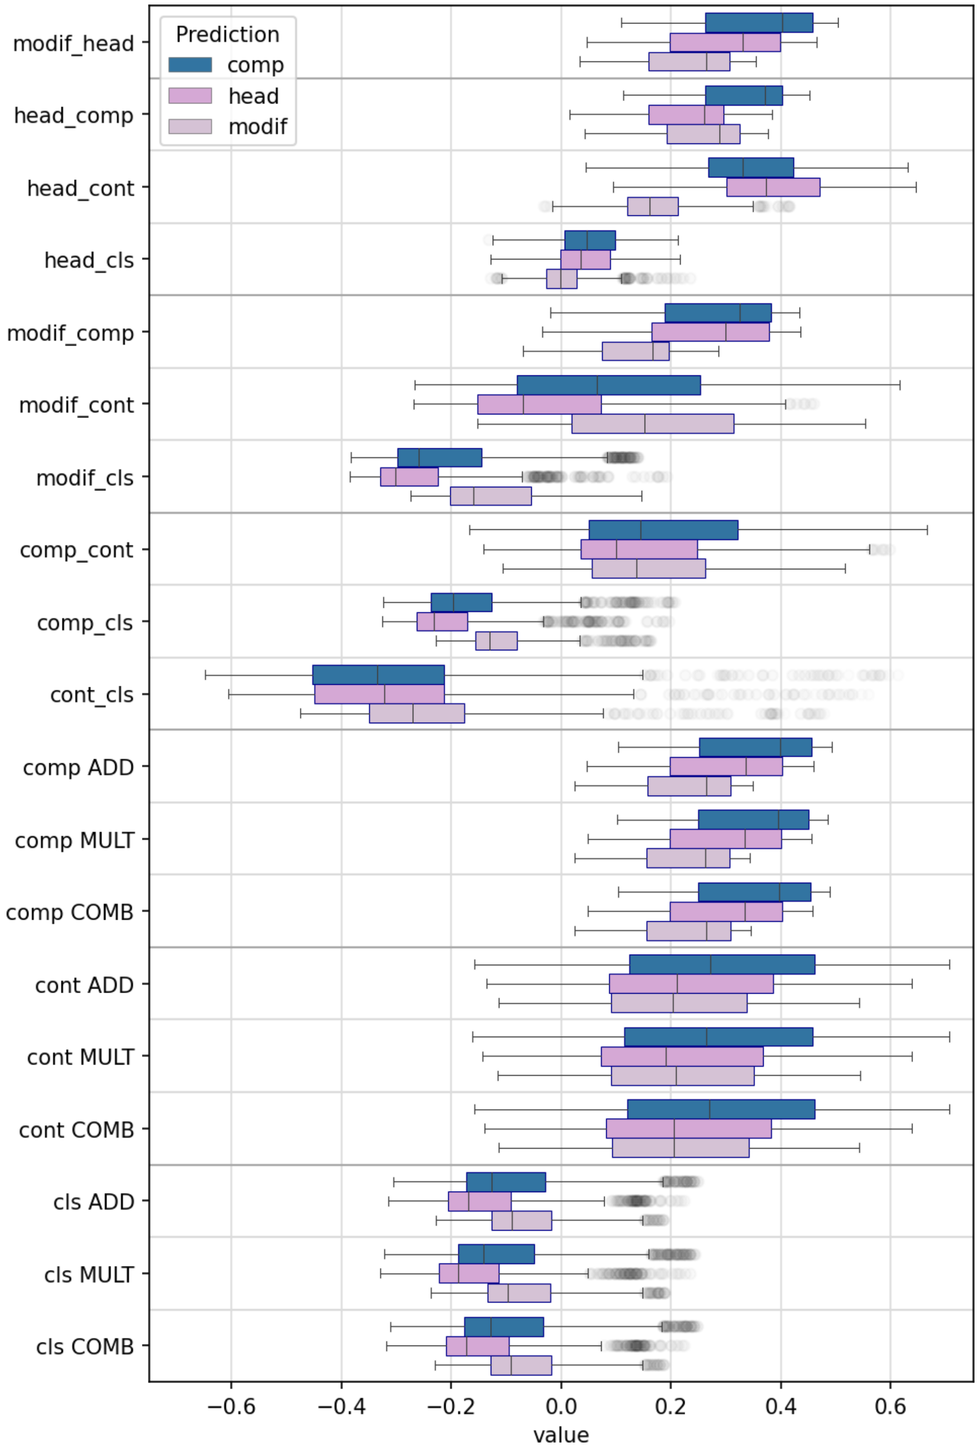

Figure 5: Distribution of Spearman's correlation coefficient for compositionality prediction across compositionality estimates. Embedding types: `modif` = contextualized representation of the modifier; `head` = contextualized representation of the head; `comp` = pooled representation of `modif` and `head`; `cont` = pooled representation of the surrounding context (full sequence without the compound); `cls` = representation of the `[CLS]` token. The use of ADD, MULT, and COMB involves the composite estimates described in Section 4.

Efficiently Upgrading Multilingual Machine Translation Models to Support More Languages

Abstract

With multilingual machine translation (MMT) models continuing to grow in size and number of supported languages, it is natural to reuse and upgrade existing models to save computation as data becomes available in more languages. However, adding new languages requires updating the vocabulary, which complicates the reuse of embeddings. The question of how to reuse existing models while also making architectural changes to provide capacity for both old and new languages has also not been closely studied. In this work, we introduce three techniques that help speed up effective learning of the new languages and alleviate catastrophic forgetting despite vocabulary and architecture mismatches. Our results show that by (1) carefully initializing the network, (2) applying learning rate scaling, and (3) performing data up-sampling, it is possible to exceed the performance of a same-sized baseline model with 30% computation and recover the performance of a larger model trained from scratch with over 50% reduction in computation. Furthermore, our analysis reveals that the introduced techniques help learn the new directions more effectively and alleviate catastrophic forgetting at the same time. We hope our work will guide research into more efficient approaches to growing languages for these MMT models and ultimately maximize the reuse of existing models.

1 Introduction

Research into multilingual machine translation (MMT) (Aharoni et al., 2019; Fan et al., 2020) has shifted from a relatively small number of translation directions (Dong et al., 2015; Firat et al., 2016; Ha et al., 2016) to much larger scale, recently reaching up to tens of thousands of translation directions (NLLB Team et al., 2022; Bapna et al., 2022). Despite the notable increase in the number of supported languages, these models still need to be upgraded as increasing amount of data in new languages are becoming available. The process of adding new languages to existing models is an instance of continual learning (Ring, 1994), in which the models need to effectively learn new tasks (new translation directions) while not catastrophically forgetting (French, 1993; McCloskey and Cohen, 1989) the knowledge about tasks from the previous training stage (original translation directions).

Unlike the most conventional continual learning setup where the model remains the same as the initial learning stage, growing languages for MMT models needs to deal with *new* parameters. Adding new languages to existing training data shifts subword token distribution (e.g., tokens from unseen scripts are added), hence the need to re-train the tokenizer, which adds new embedding parameters to the MMT model. Previous studies have shown the effectiveness of adapting embedding parameters to retain performance on old translation directions (Lakew et al., 2018; Escolano et al., 2019; Garcia et al., 2021). This is usually done by reusing the embeddings for tokens that overlap between the old and new vocabularies.

One aspect that has not been extensively addressed in previous research is how to deal with other architecture mismatches that may arise during the continual learning phase. When growing MMT models to support many additional languages, it also makes sense to increase the model size overall. This extra capacity can be used to learn not only the new directions well but also the old directions better. It is not obvious, however, how to reuse the parameters from existing models (i.e., to engage in continual learning) given such architectural changes. Thus, in addition to dealing with different vocabularies, we also investigate how to make use of previously trained models when scaling up model size in order to train much more efficiently than training from scratch.

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1513–1527
May 2-6, 2023

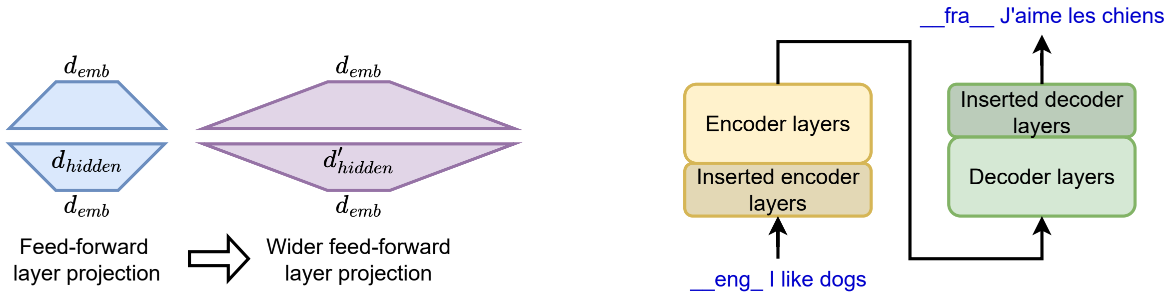

Figure 1: Illustration of two architectural mismatches we tackle in this paper. **Left:** The hidden dimension in the feed-forward layers is doubled ($d'_{\text{hidden}} = 2d_{\text{hidden}}$) during the continual learning stage so that the model becomes "wider". **Right:** Additional layers are inserted at the bottom of encoder and the top of decoder so that the model becomes "deeper". Both architectural changes increase capacity and are not well-addressed by previous works.

In this work, we introduce a recipe that helps significantly reduce the amount of required computation for continually learning new languages in MMT models. The recipe involves training the models with a combination of three techniques: (1) careful initialization of the network (2) applying learning rate scaling and (3) up-sampling selected language pairs. We validate our method on settings both with and without *architecture mismatches* (e.g., models becoming wider or deeper as shown in Figure 1 to have extra capacity for both old and new directions). We compare our models with strong same-sized baselines that are trained on all data from scratch. Our experimental results show that, without architecture mismatches, it is possible to outperform the baseline with just 30% of computation required by the baseline. When training larger models, less than 50% of the original computation is required to match the full performance of the wider baseline model, and less than 10% of computation is needed to recover over 95% of the corresponding baseline performance. We further conduct a suite of analysis which shows that:

- Proper initialization of the parameters before continual learning is crucial for fast convergence.
- Data up-sampling is vital to achieving good performance on new language pairs.
- Scaling down the learning rate for reused parameters helps alleviate catastrophic forgetting.

It is our hope that this work will help save computation for future research into large-scale multilingual machine translation, guide more efficient reuse of existing models for continual learning, and allow people to efficiently adapt large publicly-released MMT models for new languages and datasets.

2 Method

Adding new languages to existing models, especially languages in new scripts, leads to different subword tokenization, thus different vocabularies, which precludes simple fine-tuning with the exact same model on additional data. During the continual learning stage, we may also want to increase the model size overall to have extra capacity to learn the new languages and improve old languages at the same time. Therefore, we also investigate two typical architectural changes commonly done to increase the network capacity: (1) make the model "wider" by expanding the hidden dimension of the feed-forward layers, and (2) make the model "deeper" by inserting new layers to both encoder and decoder. In this section, we delineate three techniques that we found most effective in achieving computation reduction for the continual learning of MMT models.

Proper initialization. While we can copy weights from the old model[1] to the new model, it is not immediately clear how the new parameters (e.g., new token embeddings, new feed-forward weights, new layers) should be initialized and co-adapted with the old weights such that maximal knowledge about the old directions is retained. Instead of initializing the new parameters randomly, we find that initializing the new embeddings with that of <unk> leads to the best performance. When

---

[1] The weights that can be directly copied without any modification include (1) the token embeddings that overlap between old and new model, (2) same-shaped non-embedding parameters.

Table 1: While continually learning new languages by bootstrapping from a model trained on 20 languages (M20), given new embedding parameters (vocabulary mismatch), one can exceed the performance of a baseline model trained on all languages from scratch (M25$^{@100k}$) with just 30% computation (Mt25$^{@30k}$). With architectural mismatches, employing our method, the wider-model baseline performance (M25$_{wide}$) and over 98% performance of a deeper-model baseline (M25$^{@100k}_{deep}$) can be recovered with half of the corresponding baseline computation (Mt25$^{@50k}_{wide}$ and Mt25$^{@50k}_{deep}$ respectively). The “Orig.” row shows performance on old 20 languages and the “Added” on newly added 5 languages.

the network becomes “wider” in the continual learning phase, concatenating each old weight matrix with a noisy version of itself performs better than other methods we tried. When the network becomes “deeper”, initializing new layers with averaged weights of old layers results in slight improvement over other naive initialization methods. For each setup, we compare different initialization methods in section 4.2.

Data up-sampling. Similar to (Garcia et al., 2021), we introduce the new tasks by mixing old and new training data together. Since the main goal of the continual learning phase is to quickly learn the new directions, we up-sample the new pairs so the model gets more learning signals from these new directions. To increase the transfer across related language pairs and reduce the chance of catastrophically forgetting less represented directions in the original training data, we also up-sample a small number of the old low-resource languages that are from the same language family as the new languages. We present the effect of up-sampling these selected directions in section 4.3.

Learning rate scaling. To further mitigate the frequent catastrophic forgetting problem exhibited in continual learning (Ring, 1994; Thompson et al., 2019), we scale the learning rate for individual parameters depending on whether they are copied from the old model or not. Based on the assumption that the model better retains the knowledge about old tasks if the weights stay close to that of the old model (Kirkpatrick et al., 2017), we scale down the learning rate for these old parameters while maintaining or scaling up the learning rate for the newly added parameters. In contrast to other methods that incur extra computation such as Fisher Information based loss (Thompson et al., 2019), our approach is simple, straightforward and efficient in alleviating catastrophic forgetting. We present a deeper analysis of learning rate scaling in section 4.4 and section 5.2.

3 Experiments

Languages. We conduct our experiments on 25 languages covering ten language families, four resource levels (high, mid, low, and very low) and four scripts[2]. To grow the languages atop existing learned languages, we train the seed model on 20 languages (40 English-centric directions) and add 5 new languages (10 English-centric directions) during the continual learning stage. Mimicking the common scenario where newly added languages are mostly low-resource, we select five low and very-low resource languages covering four language families and four scripts as the new languages to add to the seed model. To verify the validity of our approach, we also experiment with two other 20/5 groupings and one 12/13 division of old/new languages in section 5.1[3]. Table 2 shows the groups of original and added languages used in most of our experiments. For all our models, we train `sentencepiece` (Kudo, 2018)[4] tokenizers with 64K tokens and a sampling temperature of 2, on joined (source and target) data from all language directions available in each setup. This

---

[2] We include more details about these languages in Appendix A Table 9.

Table 2: The M20 model is trained on the "Original" languages. Mt25, Mt25$_{wide}$ and Mt25$_{deep}$ bootstrap from M20 and train on the combination of "Original" and "Added" languages. We perform data up-sampling over added data in conjunction with related old low-resource languages (marked with *).

means that tokenizers in the initial training on the the old languages, were not exposed to unseen languages. The data we used are subsets of data used by NLLB Team et al. (2022) without any mined or back-translated examples.

Models. Our baseline models have a standard 12-layer encoder and 12-layer decoder Transformer architecture (Vaswani et al., 2017) with 16 attention heads, embedding dimension 1024 and hidden dimension 4096. We refer to the baseline model trained on 20 languages and 25 languages from scratch as M20 and M25 respectively. For wider models, we double the hidden dimension size to 8192; and for deeper models, we insert 6 extra layers to encoder and decoder each. We refer to the baseline wide and deep models trained on 25 languages from scratch as M25$_{wide}$ and M25$_{deep}$ respectively, and refer to the models which bootstrap from the M20 model and trained to support new languages while remaining the same architecture, using a wider network, and deeper network as Mt25, Mt25$_{wide}$ and Mt25$_{deep}$ respectively. All translation directions were evaluated on FloRes (Goyal et al., 2022; Guzmán et al., 2019) dev set and use `spBLEU`[5] dand `chrF++` (Popović, 2017) to evaluate the best checkpoint selected by validation loss with beam size 4.[6]

Training details We train baseline models (M25, M25$_{wide}$, M25$_{deep}$) for 100K updates with batch size ∼444K tokens peak learning rate 0.003 warmed up with 8000 steps. For the bootstrapped models, we train Mt25 for 30k updates and Mt25$_{wide}$ and Mt25$_{deep}$ for 50k updates since there are more added parameters. We use temperature 1 and prepend encoder/decoder language token at the beginning of each example. All models are trained with attention dropout 0.1 and label smoothing with $\epsilon = 0.1$ (Szegedy et al., 2016). The baseline models M25, M25$_{wide}$ and M25$_{deep}$ complete training of 100K updates on 64 GPUs in ∼24h, ∼29.9h, and ∼29.0h respectively. We do not reset the learning rate scheduler for the second training phase.[7] The data of selected languages are up-sampled by 5 and the learning rate of the old parameters in Mt25$_{wide}$ is multiplied by 0.5 and in Mt25$_{deep}$ by 0.05 at the beginning while linearly increasing to 0.5. We present the effect of these hyperparameters in the next section.

	All	Orig.	Added
Mt25	**31.8**	**33.5**	**25.2**
random init all	28.2*	29.4*	23.4*
random init new	31.7	33.5	24.9*
no up-sampling	31.3*	33.4	22.6*
no lr scaling	31.5*	33.1*	25.1
Mt25$_{wide}$	**32.6**	**34.1**	**26.3**
random init all	26.7*	28.0*	21.5*

Table 3: Ablation of the effect of not using M20 weights (random init all), the effect of not carefully initializing new parameters (random init new), not having data up-sampling and not applying learning rate scaling across three scenarios. All numbers are spBLEU scores of models evaluated after 30K updates. * indicates p-value of paired T-test against corresponding best model (Mt25, Mt25$_{wide}$, Mt25$_{deep}$) is smaller than 0.05.

---

[5] `https://github.com/facebookresearch/flores/tree/main/previous_releases/flores101#spbleu-evaluation`

[6] We use these two metrics instead of BLEU or pre-trained metrics (Kocmi et al., 2021) because over half of the languages we use are of mid- to low-resource and Goyal et al. (2022) show spBLEU treats low-resource languages more fairly.

[7] We tried resetting learning scheduler (i.e., learning rate warms up 8K steps from 0 to 0.003 and then starts to decrease), small constant learning rate, and not resetting learning rate scheduler in our preliminary experiments and the last leads to the best results.

Main results. Results in Table 1 indicate that by properly applying the techniques introduced earlier, it is possible to recover the baseline performance with significantly less computation. When architecture remains the same during the second learning phase, better overall performance can be achieved (31.8 vs. 31.6) after 30% of the updates required by the baseline model M25. The gains come from effective learning of both the old and new directions while the latter seems to be better learned than the baseline model (25.2 vs. 24.6). While training into a wider model, applying our techniques recovers the performance with approximately half of the M25$_{wide}$ computation. Although we did not fully recover the performance while training into a deeper model, over 98% of the baseline performance can be achieved using our techniques with half of the baseline M25$_{deep}$ computation. We find that the major degradation in Mt25$_{deep}$ comes from the worse performance on the original directions (33.9 vs. 34.5) which suggests mitigating catastrophic forgetting is harder when expanding the network by depth than by width.

4 Effect of each technique

4.1 Ablation study

To understand the effect of each introduced technique, we conduct an ablation study where each model is trained on the same configuration except for one essential element (i.e., proper initialization, learning rate scaling, data up-sampling). As a naive baseline, while having scaled learning rate and data upsampling, we include the models where no weights from the seed M20 model are used ("random init all") to compare with a less naive baseline "random init new" where the M20 weights are reused and only the newly added parameters (i.e., new token embeddings in all three models, new fully-connected layer weights in Mt25$_{wide}$ and weights of new layers in Mt25$_{deep}$) are randomly initialized. To summarize, each configuration in Table 3 corresponds to the following:

Random init all : All parameters are initialized randomly while model is trained with data up-sampling and learning rate scaling.

Random init new : Newly added parameters are initialized randomly while weights of M20 are copied to the new model. Model is trained with data up-sampling and learning rate scaling.

No up-sampling : Model weights are properly initialized and their learning rates are scaled during training. No language pair is up-sampled.

No lr scaling : Model weights are properly initialized and low-resource pairs are up-sampled whereas no learning rate scaling is applied.

Results in Table 3 confirm the contribution of each of the three introduced techniques in achieving the desired performance across different settings. Overall, not reusing the M20 weights leads to worse performance than the baseline by 2∼6 BLEU in different settings. While reusing the old model's weights, also having proper initialization of the *new* parameters yields better performance than simply initializing with default normal distribution. The benefit is most obvious when training into a wider model (29.9 vs. 32.6) compared to the other two settings. We also observe that data up-sampling is crucial to achieving good performance on the new directions. Not applying up-sampling degrades around ↓ 3BLEU on new directions across all settings, while barely or just slightly hurting the performance on the old directions. On the other hand, not applying learning rate scaling harms the performance of old directions across all settings, which suggests the effectiveness of scaling the learning rate to mitigate catastrophic forgetting, about which we include a more detailed analysis in section 5.2.[8] Since learning rate scaling helps counteract catastrophic forgetting and up-sampling speeds up learning of the new directions, we discover that their effectiveness are additive – better performance can be achieved on both old and new directions by combining these two techniques.

4.2 Effect of proper initialization

In this section we briefly discuss different variations we attempted for initializing new parameters and present the results in Table 4.

Mt25 In the case of having only mismatched vocabularies, we find that dropping the entire old embedding table ("all emb random") causes large drop in performance, and that initializing the new embeddings with that of <unk> leads to slightly better performance than random initialization.

---

[8] The overall differences are small as the results are averaged over 50 directions, however, the paired T-Test shows statistically significant improvements.

[9] We did not apply learning rate scaling in this setup and do not up-sample the old related low-resource languages. All evaluations are done after 30K updates.

	All	Orig.	Added
Mt25			
all emb random	30.7	32.1	25.1
new random	31.5	33.0	25.5
new <unk>	**31.5**	**33.0**	**25.7**
Mt25$_{wide}$			
new random	31.1	32.3	26.1
linear interp	31.8	33.3	26.0
concat	**32.0**	**33.5**	**26.1**
M20t25$_{deep}$			
random	31.5	32.8	26.3
closest layer	31.6	32.9	26.3
average layer	**31.6**	**32.9**	**26.7**

Table 4: Initializing the new embeddings with that of `<unk>`, concatenating the original weight with a noisy version of itself in Mt25$_{wide}$ and initializing new layer in encoder/decoder with the averaged encoder/decoder weights in Mt25$_{deep}$ achieve the best performance.[9]

Mt25$_{wide}$ A naive method to initialize wider feed-forward layer projections is to expand the old weight matrix with a randomly initialized weight matrix. However, having random additional parameters messes up the output of feed-forward layer, which interferes with the inter-dependency among layers, thus we also tried concatenating the old weight matrix with a noisy version of itself (concat[10]) followed by a normalization operation[11] to keep the output as close to the original projection output as possible. In addition, rather than maintaining the old weights in block, we also tried linearly interpolating the original weight matrices along the expanded dimension (linear interp). It's important that the new parameters in the two projection matrices in a feed-forward layer match each other along the hidden dimension axis. Results indicate that weight concatenation is a simple and effective way that allows for faster convergence.

Mt25$_{deep}$ Our preliminary experiments show that inserting new layers at the bottom of the encoder and at the top of the decoder is more effective than other attempted scenarios, so we went with this setup in all our Mt25$_{deep}$ experiments. We tried different methods of initializing the inserted layers, including random initialization, copying parameters from the closest layer,[12] and averaging the weights across all encoder or decoder layers. Although the benefit is small, we do perceive that initializing the new layers with averaged layer weights results in better performance, especially on new translation directions (26.7 vs. 26.3).

Up-sampling config.	All	Orig.	Added
$\alpha = 1$ (No up-sampling)	31.0	**33.2**	22.2
$\alpha = 5$	31.5*	33.0*	**25.7***
$\alpha = 10$	31.1	32.6*	25.5*
$\alpha = 5$ + rel. low-resource	**31.5***	33.1	25.1*

Table 5: Performance of Mt25 at 30K updates without applying learning rate scaling. Up-sampling new languages with a reasonable ratio during continual learning leads to large gains on these new directions. * indicates p-value of paired T-test against the baseline (top row) is smaller than 0.05.

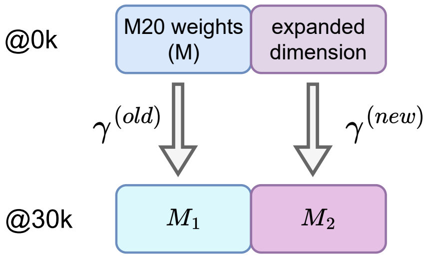

Figure 2: Before the continual learning (@0k), the wider hidden projection matrix is initialized with a concatenation of M20 weights M and a noisy version of itself. During the continual learning stage, the learning rate for weights copied from old model is scaled by $\gamma^{(old)}$, the rest are scaled by $\gamma^{(new)}$.

4.3 Effect of data up-sampling

We multiply the original dataset size of each upsampled direction by a value α before computing the final up-sample ratio. The new directions thus constitute a larger portion in the new dataset than if not. We show in Table 5 the effect of the up-sample factor α. We find that up-sampling selected languages leads to much better performance (+3BLEU) on new directions than without up-sampling. However, up-sampling the new directions too much (e.g., $\alpha = 10$) worsens the performance on old directions while not improving the new directions. In general, we find the up-sampling

---

[10] We inject zero-mean Gaussian noise with $std = 0.01$. We also tried not adding noise to the new parameters, which has almost identical performance. To avoid both parts of the weight matrices learning redundant information, we decide to add small perturbation to the new parameters.

[11] We normalize the new weight matrix such that it has similar Frobenius norm as the old weight matrix.

[12] Since we include the new layer at the bottom of the encoder and at the top of the decoder, the closest layer means the first encoder layer and last decoder layer respectively.

	All	Orig.	Added
$\gamma^{(old)} = 1, \quad \gamma^{(new)} = 1$	32.0	33.5	26.1
$\gamma^{(old)} = 0.5, \gamma^{(new)} = 5$	**32.3***	**33.8***	**26.2**
$\gamma^{(old)} = 0.5, \gamma^{(new)} = 0.5$	31.5*	33.3	24.7*
$\gamma^{(old)} = 0.5, \gamma^{(new)} = 1$	32.1*	33.6*	26.0
$\gamma^{(old)} = 5, \quad \gamma^{(new)} = 5$	31.9	33.4	26.1

Table 6: Performance of Mt25$_{wide}$ after 30K updates while applying different learning rate scaling factor based on notation in Figure 2. These experiments adopt an earlier setup where the old related low-resource languages are not up-sampled. * indicates p-value of paired T-test against the baseline (top row) is smaller than 0.05.

factor $\alpha = 5$ adopted in previous studies (Garcia et al., 2021; Berard, 2021) suitable to many other variants we have attempted in this work. Besides merely up-sampling the new directions, we also up-sample the old low-resource directions that belong to the same language family as any of the new directions. Doing so slightly improves the performance on old directions whereas causes a drop in new directions, which further confirms the critical role of up-sampling in balancing the performance between the old and new directions.

4.4 Effect of learning rate scaling

As described in section 2, we scale down the learning rate for old (reused) parameters. In the case of Mt25, all parameters are updated with a smaller learning rate than the new token embeddings. In the wider network, as we have established the effectiveness of using concatenated weights, we apply different learning rate to each part of the weight matrices as generically illustrated in Figure 2. In Mt25$_{deep}$, the new layers are updated with a larger learning rate while the rest of the parameters receive a smaller learning rate. Table 6 suggests that having a smaller learning rate for old parameters is more favorable than scaling all parameters by the same amount ratio. Scaling down the update for all parameters slows down the learning of the new directions, whereas scaling up with a larger value does not improve the performance either. While already applying smaller update on old parameters, scaling up the learning rate for the new parameters can in fact improve both the old and new directions (the top two rows in Table 6). Overall we find that learning rate scaling is an effective and easy-to-implement alternative to previous methods (Kirkpatrick et al., 2017) in terms of alleviating catastrophic forgetting.

	Mt25	Mt25_v1	Mt25_v2	M12t25
All	32.6	32.7	32.5	32.7
High	35.8	36.0	35.8	35.9
Mid	29.6	29.8	29.7	29.3
Low	31.5	31.2	31.4	31.6
V_Low	19.0	20.0	19.0	20.1

Table 7: Besides the language breakdown shown in Table 2, we show our approach also generalizes to other groupings of old and new languages (Mt25_v1, Mt25_v2 and M12t25), details about which are included in Appendix A Table 10.

	Mt25		Mt25_v1		Mt25_v2	
	ΔBLEU	Up	ΔBLEU	Up	ΔBLEU	Up
eng-bel	-1.2	N	2.0	Y	2.4	Y
eng-guj	1.6	Y	0.9	Y	0.0	N
eng-npi	0.8	Y	-0.1	Y	-2.3	N
eng-xho	1.3	Y	0.0	N	1.1	Y
bel-eng	-1.1	N	-0.5	Y	-0.7	Y
guj-eng	-2.5	Y	-2.6	Y	-2.2	N
npi-eng	-1.6	Y	-0.6	Y	-1.9	N
xho-eng	-1.1	Y	-1.3	N	-0.7	Y

Table 8: Zoomed in analysis over specific language pairs. Our approach is more effective in learning eng→xxx directions than xxx→eng directions across different seed-language setups regardless if the language is up-sampled (Up=Y) or not (Up=N).

5 Analysis

5.1 How does the choice of seed languages affect continual learning?

In addition to the core setup described in Table 2, we also experiment with other settings. We considered three new setups following the natural scenario where the seed languages are mostly of high- and mid-resource languages. Two of the new setups still adopt the 20/5 division between old and new languages, but emphasize different scenarios — Mt25_v1 covers one mid resource language in the set of new languages and Mt25_v2 does not add any new script. The last one instead initializes from a model trained on 12 high- and mid-resource languages and adds in 13 new languages.[13] We follow the same configuration used in the previous experiments and train into wider models in the continual learning phase. Results in Table 7 demonstrate that our approach successfully generalizes to all the new settings, as similar performances can be achieved

---

[13] For detailed breakdown of these three new settings, we refer readers to Table 10 and Table 11 in Appendix A

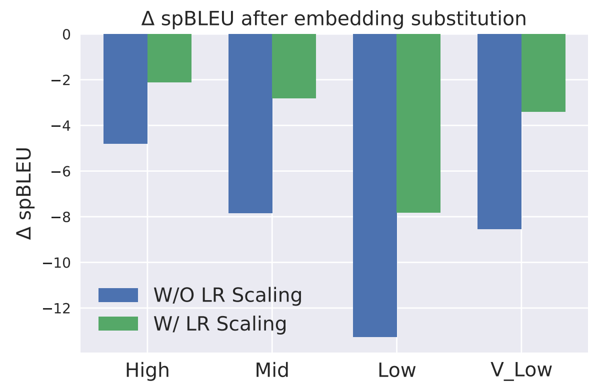

Figure 3: We measure the drop in spBLEU on original directions after substituting overlapped embeddings in $Mt25_{wide}$ back to M20 model. Applying learning rate scaling helps alleviate catastrophic forgetting as spBLEU drops less than without LR scaling.

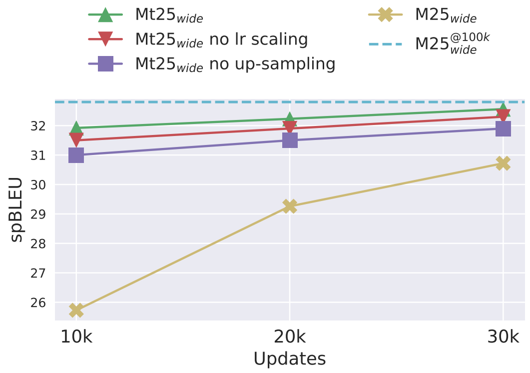

Figure 4: Training the M25 from scratch without using the M20 weights converges significantly slower. Applying the techniques introduced in this work results in the largest computation reduction, achieving over 95% performance with less than 10% baseline computation.

when models are trained on different choices of seed languages, even when the number of seed languages are different. However, we do observe small differences after zooming in by resource-levels. A more fine-grained analysis over a few low-resource languages that cover diverse scripts (bel-Cyrl, guj-Gujr, npi-Deva, xho-Latn) is presented in Table 8. In general, regardless of if the language pair is in the seed language set or not, the eng→xxx directions are learned faster than xxx→eng directions, since most of the pairs already exceed the baseline performance after just 30K updates (compare the upper part of Table 8 to the lower part). We also verify the effectiveness of data up-sampling for eng→xxx directions. Up-sampling these pairs leads to much better performance than when not up-sampling (e.g., compare performance of eng-bel in the three setups).

5.2 How effective is learning rate scaling in mitigating catastrophic forgetting?

To quantitatively measure the amount of information lost after the continual learning phase, we adopt an evaluation setup akin to (Garcia et al., 2021), in which the embeddings in M20 that overlap with Mt25 are substituted with the corresponding embeddings in Mt25. One can evaluate this new M20 model with substituted embeddings on the original 20 languages, and use the drop in spBLEU as a proxy for the amount of knowledge lost in the embeddings due to catastrophic forgetting. In Figure 3, we display the spBLEU drop after substituting the embeddings of a $Mt25_{wide}$ model trained with and without learning rate scaling. For both variants, the spBLEU scores drop, indicating that some information in the embeddings is lost after training on the new languages. We also find that, for both models, the decrease in spBLEU is larger for (very) low-resource languages than high and mid resource languages, which suggests (very) low-resource languages are easier to be "forgotten" in the second training phase, which reinforces our decision of also up-sampling the related low-resource languages as introduced in section 4.3. Finally, not applying learning rate scaling leads to much larger decrease in all directions, which manifests the effectiveness of scaling down the learning rate for alleviating catastrophic forgetting.[14]

5.3 Computation saved

Due to the mismatched vocabularies and architectures, models trained on the combination of new and old languages are typically re-trained from scratch after already incurring large computation on old languages. In this section, we look at how much computation can be effectively saved with the approach proposed in this paper. Note that, for both our methods and the retraining approach, M20 is already trained, and its computation cost is excluded from our calculation.

Although results in Table 1 shows that 50% of the baseline computation is required to recover the baseline performance, we show in Figure 4 that much computation can be saved if we slightly slack the target performance. The $M25_{wide}$ model

---

[14] Besides probing the effect of learning rate scaling on embeddings, we also present an analysis on the expanded feed-forward weights in Appendix C.

trained from scratch reaches only 78% of the baseline performance after 10k updates, while models trained with the combination of our techniques achieve over 97% of the baseline performance after the same amount of updates (10% total computation of training Mt25$_{wide}$).

6 Related Work

Our work is closely related to prior research on adapting existing MMT models (Mohammadshahi et al., 2022) to new languages (Lakew et al., 2019; Kocmi, 2020). Neubig and Hu (2018) add low-resource languages to multilingual models by fine-tuning on low-resource data while regularizing with related high-resource data. Garcia et al. (2021) introduce simple vocabulary substitution for adapting MMT models to new languages without any architectural changes. Another line of research employs modular approaches, which include training lightweight adapters (Bapna and Firat, 2019), language-specific encoder-decoders (Escolano et al., 2019, 2021), language specific embeddings (Berard, 2021) for learning new languages. While sometimes escaping the need to train on old examples, growing the model in a modular fashion (Rusu et al., 2016) requires non-trivial changes to standard architectures. In contrast, our work relies on rehearsal mechanism (i.e., also train on old examples) but does not need to modify network structures (Robins, 1995).

Our approach is also related to works that focus on continual learning of MT models for adapting multiple domains. Thompson et al. (2019); Gu and Feng (2020) adopt a method derived from Elastic Weight Consolidation (Kirkpatrick et al., 2017) to alleviate catastrophic forgetting. While most prior works only investigate two-stage continual learning, Cao et al. (2021) propose a new framework that extends to multi-stage training to mitigate catastrophic forgetting (Ring, 1994). The initialization of the new parameters and embeddings in our technique is also related to that in (Pfeiffer et al., 2021), which accommodate multilingual models to unseen scripts via matrix factorization. Our focus on the architectural differences between initial and continual learning phase is also relevant to recent discoveries that wider networks forget less catastrophically (Mirzadeh et al., 2022).

7 Conclusion

We show in this work that it is possible to efficiently bootstrap from existing models and recover the baseline performance with much less computation while vocabularies and architectures can be different in the continue learning stage. We highlight the importance of (1) reusing the existing model weights and carefully initializing the new parameters, (2) applying learning rate scaling, and (3) performing data up-sampling. Analyses reveal that scaling down the learning rate for old parameters helps alleviate catastrophic forgetting, and that data up-sampling is vital to achieving good performance on the new directions. We hope our work can help save computation for research into large-scale multilingual MT models, and more generally, will help spur research into continual multitask learning in the presence of architectural changes.

Limitations

While we explore the under-studied architectural mismatches for continual learning of MMT models, we focus exclusively on adding new languages in bulk, without investigating adding languages one by one continuously. Furthermore, due to limited computational resources, we only experimented with a few typical scenarios where the new languages are low or very-low resourced. Experiments on other groupings of old and new languages could further validate the effectiveness of our approach.

w/o LR scaling w/ LR scaling

Figure 5: We measure the amount of change in each feed-forward layer's projection weights via Frobenius norm ($\| \cdot \|_e$ for encoder layers and $\| \cdot \|_d$ for decoder layers). Notation in this figure follows that in Figure 2. Scaling down the learning rate for parameters copied from the old model keeps them close to their initialization while pushes the newly added parameters farther away.

A Language details

We present two extra language grouping settings we have experimented in this section. To verify the validity of our approach on other language groupings, we also experiment with two other settings as shown in Table 10. In addition to dividing the old/new languages by 20/5, we also tried a setting where the seed model is trained on fewer languages as reported in Table 11.

B Detailed performance of each direction

Table 12 contains the detailed performance of all translation directions for all models reported in Table 1.

C Norm Analysis

The analysis in section 5.2 is limited to only measuring the lost information in the embeddings, to understand how learning rate scaling affects the weights other than embeddings, one natural extension is substituting other weights back to M20 as well. However, it leads to much worse performance for both variants as the inter-dependency among layers is impaired in this case. Therefore, we instead measure the amount that the weights of each encoder or decoder layer (denoted with $L_0, L_1, \dots, L_{11}$) change in the latent space via the Frobenius norm. Following the notation in Figure 2, we measure how much the weight matrices M_1 and M_2 have changed from the original weight matrix M ($\|M_1 - M\|$ and $\|M_2 - M\|$), as well as how much they differ from each other ($\|M_1 - M_2\|$). We refer to the Frobenius norm in an encoder or a decoder layer with $\| \cdot \|_e$ and $\| \cdot \|_d$ respectively. The trend in Figure 5 shows that applying learning rate scaling prevents M_1 from deviating too much from the original weights M and at the same time pushes the new parameters to space farther from its initialization. This is in contrast with the smaller differences when not applying learning rate scaling. The left side of Figure 5 indicates that even after the continual learning, M_1 and M_2 stay close to each other across the encoder layers, it is only when reaching the last several decoder layers do the two matrices demonstrate larger differences. Since we initialize M_1 and M_2 both based on M, having larger $\|M_1 - M_2\|$ reduces the chance of both parts learning redundant information i.e., effectively using the additional parameters.

D Scaling learning rate by Fisher information

Besides multiplying the learning rate for all old parameters with the same scaling factor, we also tried scaling the learning rate based on their Fisher Information. This is directly inspired by Elastic Weight Consolidation (Kirkpatrick et al., 2017), in which extra penalty is incurred when parameters crucial to the old tasks deviate too much from their original values. We plot the distribution of the per-token Fisher information of each parameter in Figure 6 (right). We further experiment with LR scaling over selected parameters that are supposed to be important for old tasks (Fisher information exceeds certain threshold based on Figure 6 (right)). Results in Table 11 (right) shows that among our attempted settings, scaling only part of the parameters based on Fisher information does not improve the overall performance. We conjecture that the performance could be improved if the Fisher Information is calculated on a larger set and that if we apply a piece-wise threshold function for scaling the learning rate of different parameters.

E Effect of LR scaling in alleviating catastrophic forgetting

We include the spBLEU drop on the old languages after substituting the embeddings of Mt25 back to M20 in Figure 6.

Abstract

Back-translation is widely known for its effectiveness in neural machine translation when there is little to no parallel data. In this approach, a source-to-target model is coupled with a target-to-source model trained in parallel. The target-to-source model generates noisy sources, while the source-to-target model is trained to reconstruct the targets and vice versa. Recent developments of multilingual pre-trained sequence-to-sequence models for programming languages have been very effective for a broad spectrum of downstream software engineering tasks. Hence, training them to build programming language translation systems via back-translation is compelling. However, these models cannot be further trained via back-translation since they learn to output sequences in the same language as the inputs during pre-training. As an alternative, we propose performing back-translation via code summarization and generation. In code summarization, a model learns to generate natural language (NL) summaries given code snippets. In code generation, the model learns to do the opposite. Therefore, target-to-source generation in back-translation can be viewed as a *target-to-NL-to-source* generation. We show that our proposed approach performs competitively with state-of-the-art methods. We have made the code publicly available.[1]

Input in Java

```java
public static boolean generator(
    PsiBuilder b, int l){
  boolean r = false;
  if(!recursion_guard(b, l)) return r;
  r = generator_0(b, l + 1);
  if(!r) return generator_1(b, l + 1);
}
```

(1) Java to Python Generation

```java
public static boolean generator(
    PsiBuilder b, int l){
  boolean r = false;
  if(!recursion_guard(b, l)) return r;
  if(!generator_0(b, l)) return r;
  r = generator_0(b, l + 1);
  if(!r) return generator_1(b, l + 1);
}
```

(2) Java Code to NL Summary

guard is used to determine if a generator is already defined .

(3) NL Summary to Python Code

```python
def is_generator(self, name):
  if name in self._generators:
    return True
  if name in self._generators[name]:
    return True
  return False
```

Figure 1: Although PLBART is asked to generate in Python given input in Java (1), it generates in Java (due to its pre-training objective). In contrast, PLBART, fine-tuned on code summarization and generation, generates “noisy” translations (as in (2, 3)).

1 Introduction

The choice of programming language (PL) in software development depends on the requirement of the software and the available features of a particular PL. In modern API-driven software development, language choice often depends on the availability of libraries and APIs. The advent of newer and richer programming languages often requires legacy software to be translated into modernized PLs. In theory, modern programming languages' “Turing Completeness” allows rule-based translation of programs from one PL to another. The rule-based translation may require an extensive number of custom-written transformation rules and could end up producing very unreadable source code. In addition, such a translation could entail translating the entire library, even if a library implementing similar functionality is available in the target PL.

Aligning libraries and APIs across different PLs is a non-trivial task. Recent progress in Neural Machine Translation (NMT) (Bahdanau et al., 2015;

(b) PLBART + $\mathcal{S}\&\mathcal{G}$

Figure 2: T-SNE plot of function embeddings of Java and Python functions. Figure 2a shows the embedding generated by the PLBART model. Figure 2b are the generated embedding when the PLBART is finetuned to jointly summarize code to NL and generate code from NL (PLBART + $\mathcal{S}\&\mathcal{G}$). While PLBART clusters programs from each PLs, parallel programs in different PLs are brought closer to each other by PLBART + $\mathcal{S}\&\mathcal{G}$.

Vaswani et al., 2017) leveraging pre-trained models (Feng et al., 2020a; Guo et al., 2021; Roziere et al., 2021; Ding et al., 2022; Ahmad et al., 2021a; Wang et al., 2021) could be a possible way to learn the alignment between PLs and translate source code across languages.

A significant challenge in supervised learning for NMT is the need for large-scale parallel corpora. For instance, if we are planning to train a translator for `Java` to `Python` translation, we need a considerable number of the same program (*i.e.*, exhibiting the same semantic behavior) in both languages. Availability of such parallel datasets is a vital challenge in programming language translation (Chen et al., 2018). Back-Translation (BT) (Edunov et al., 2018; Lachaux et al., 2020) is a clever way to learn alignments across different languages. While BT demonstrates success in NMT, those require either (i.) small (perhaps noisy) parallel datasets or (ii.) a model with some capacity of cross-lingual generation - to kickstart the BT-based learning process.

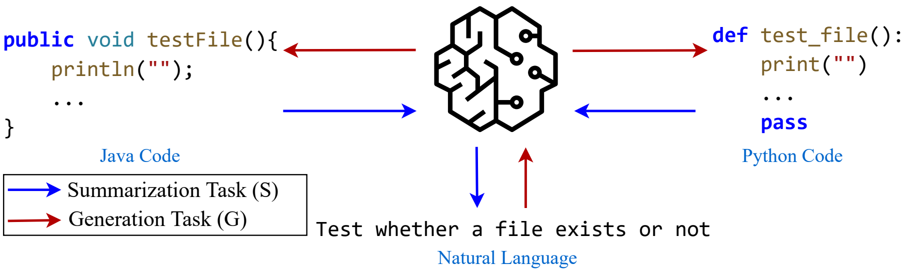
In this work, we investigate the suitability of the multilingual Pre-trained Sequence-to-Sequence Model (PSM) for unsupervised programming language translation via BT. In particular, we assume a use-case scenario where *no* parallel data is available. Without much of a surprise, we empirically found that, while these PSMs are good at generating code in each language, they exhibit very little to no knowledge about cross-lingual generation since such PSMs are typically trained to reconstruct code sequences from noisy inputs. For example, when we provide the input code in Figure 1 to PLBART (Ahmad et al., 2021a) and ask to generate Python code without training, it generates a slight variation of the input Java code, showing its lack of knowledge about cross-lingual generation.

To endow such PSMs with knowledge about cross-lingual generation, we propose using a third language (*i.e.*, English). Since a large quantity of monolingual code corpora comes with documentation, which supposedly describes what the source code is doing, we train a Summarize-and-Generate ($\mathcal{S}\&\mathcal{G}$) model that can generate pseudo-parallel code sequences. Figure 1 shows PLBART's behavior when it is further trained via $\mathcal{S}\&\mathcal{G}$. First, given the Java code, it generates an NL summary (figure 1-2) and subsequently generates Python Code (figure 1-3). We empirically show that, even if such $\mathcal{S}\&\mathcal{G}$ model generates noisy parallel sequences, it allows us to employ PSMs in the BT-based training to learn programming language translation.

In summary, we present a Summarize-and-Generate ($\mathcal{S}\&\mathcal{G}$) based approach to enable unsupervised program translation training of PLBART via Back-Translation (BT). Experiment results show that our proposed approach makes PLBART trainable via BT and performs competitively with state-of-the-art program translation models.

2 Motivation

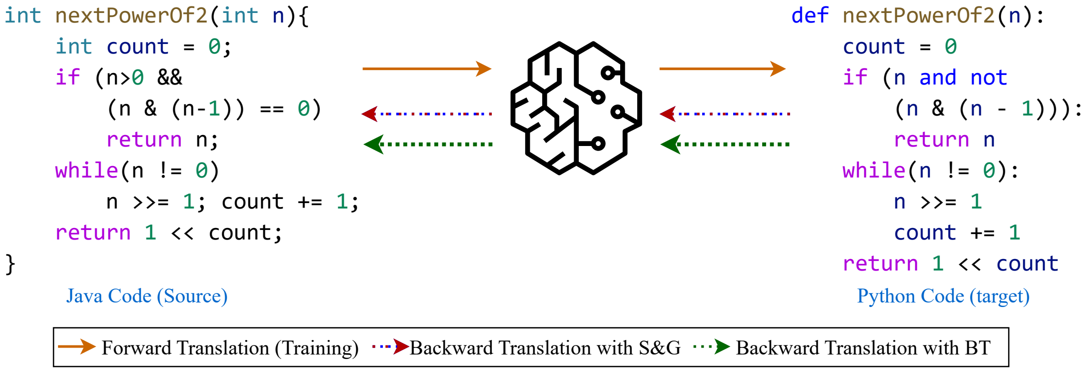
Recent years saw several Pre-trained Sequence-to-Sequence models (PSM) (Ahmad et al., 2021a; Wang et al., 2021). These models are pre-trained on hundreds of Gigabytes of source code. Thus, in this work, we are motivated to investigate their adoption in learning program translation via back-translation. To understand such feasibility, we investigate the program representations generated by the PSM. As a case study, we chose PLBART (Ahmad et al., 2021a) and evaluated its multilingual embeddings as suggested in Artetxe and Schwenk (2019). We



```
public void testFile(){
    println("");
    ...
}
```

```
def test_file():
    print("")
    ...
    pass
```

(a) Step1: Supervised training of PLBART on Code Summarization and Generation ($\mathcal{S}\&\mathcal{G}$).



```
int nextPowerOf2(int n){
    int count = 0;
    if (n>0 &&
        (n & (n-1)) == 0)
        return n;
    while(n != 0)
        n >>= 1; count += 1;
    return 1 << count;
}
```

```
def nextPowerOf2(n):
    count = 0
    if (n and not
        (n & (n - 1))):
        return n
    while(n != 0):
        n >>= 1
        count += 1
    return 1 << count
```

(b) Step2: Unsupervised training of PLBART via Backtranslation (BT). In the first m training steps (out of total N steps), PLBART generates natural language (NL) summary of the code in target language (Python in this example) and generates the code in source language (Java in this example) from the NL summary. In the remaining $N - m$ steps, PLBART directly generates the code in source language from the code in target language.

Figure 3: Overview of our proposed framework to train PLBART in two sequential steps.

find the parallel Java function for each of the 948 Python functions using the parallel dataset proposed in Lachaux et al. (2020). We find the nearest neighbor using cosine similarity between function embeddings and calculate the error rate. Unsurprisingly, PLBART performs poorly in function retrieval with an 87.5% error rate.

In comparison, we fine-tune PLBART jointly on code summarization and generation in Java and Python. Repeating the experiment of function retrieval, we find that fine-tuned PLBART's error rate drops to 23.7%. To visually illustrate the embeddings produced by PLBART and its fine-tuned variant, we provide a T-SNE plot of 8 sample functions' embedding in Figure 2. We see the functions that belong to the same language are clustered together while the same functions in two different languages are far apart from each other (see Figure 2a).

In contrast, the fine-tuned PLBART breaks up the intra-language clusters and brings functions in different languages close to each other in the embedding space (see Figure 2b). These results motivate us to initialize the translation models with fine-tuned PLBART on code summarization and generation for back-translation as it learned some alignment across programming languages.

3 Approach

Sequence-to-sequence models, such as PLBART (Ahmad et al., 2021a), CodeT5 (Wang et al., 2021), SPT-Code (Niu et al., 2022) map source code sequences into a shared multilingual space by pre-training on multiple programming languages jointly using unlabeled data (*e.g.*, source code from Github). The pre-training objective of these models is either denoising autoencoding (DAE) or fill-in-the-blank, where the models reconstruct the original code snippet or predict the missing code tokens given a corrupted code snippet. Although pre-trained jointly on many languages, these models only learn to generate in the same language as input. As a result, these models are not trainable via back-translation (BT) to learn programming language translation in an unsupervised fashion. As an alternative, we propose translating to and from natural language to perform back-translation between two programming languages. We refer to translating to and from natural language as code summarization and code generation, respectively. Our proposal is motivated based on the availability of *bimodal* data, source code, and their summaries that are used to train code summarization and generation models.

3.1 Code Summarization and Generation

Source code documentation (*e.g.,* docstring or comment) written by software developers is available along with source code on a large scale. Such documentation has been the key source to form code summarization datasets (Wan et al., 2018; Hu et al., 2018; LeClair and McMillan, 2019; Husain et al., 2019), and to study natural language (NL) to code generation (Parvez et al., 2021). It is tangible that we can use a code summarization and generation model to translate programming languages. Such a model would first generate an NL summary from an input code in the source language and then generate code from the previously generated NL summary in the target language. As we show in the evaluation, such an approach does not work well in practice (see table 2); however, code summarization and generation models are viable proxies to generate noisy translations. This enables us to train PLBART, to begin with generating noisy translations, and further learn to improve in a self-supervised fashion when trained via back-translation. Formally, we jointly train PLBART in a supervised setting to learn code summarization ($\mathcal{S}$) and generation ($\mathcal{G}$):

$$\begin{aligned}\mathcal{S} &= TRAIN^{\text{Code}\rightarrow\text{Summary}}\left(\mathcal{P}_{c,s}\right)\\ \mathcal{G} &= TRAIN^{\text{Summary}\rightarrow\text{Code}}\left(\mathcal{P}_{c,s}\right)\end{aligned} \tag{1}$$

where $\mathcal{P}_{c,s}$ is estimated using the code-to-text benchmark from CodeXGlue (Lu et al., 2021). We follow Tang et al. (2021) to perform multilingual fine-tuning of PLBART (in Java and Python) to learn $\mathcal{S}$ and $\mathcal{G}$.

3.2 Back-translation

Back-translation (BT) is one of the most popular ways for unsupervised machine translation (Artetxe et al., 2018b; Lample et al., 2018a,b). In this approach, we leverage monolingual data in an unsupervised fashion. BT jointly trains a source-to-target model coupled with a backward target-to-source model. The target-to-source model translates target sequences into the source language, producing noisy sources corresponding to the ground truth target sequences. The source-to-target model is then trained to generate the targets from the noisy sources and vice versa. The two models are trained in parallel until convergence. This training procedure is widely known as *online back-translation* and is the focus of this work.

Back-translation uses a target-to-source model to generate noisy sources and trains a source-to-target model to reconstruct the targets. Specifically, in each step k (a mini-batch update), back-translation performs the following:

$$\begin{aligned}\mathcal{P}_k^{(f)} &= \{(x, f_{k-1}(x)) | x \in \mathcal{D}_{\text{source}}\}\\ b_k &= TRAIN^{\text{target}\rightarrow\text{source}}\left(\mathcal{P}_k^{(f)}\right)\\ \mathcal{P}_k^{(b)} &= \left\{(b_k(y), y) \, | y \in \mathcal{D}_{\text{target}}\right\}\\ f_k &= TRAIN^{\text{source}\rightarrow\text{target}}\left(\mathcal{P}_k^{(b)}\right).\end{aligned} \tag{2}$$

Here, $\mathcal{D}_{source}$, $\mathcal{D}_{target}$ represents unlabeled data in source and target languages and $TRAIN$ indicates standard sequence-to-sequence training.

Generally, the training via back-translation starts from a forward (f_0) and a backward (b_0) model that is trained using parallel data (small gold-standard or large-scale but noisy). Then an extensive collection of unlabeled data is used to train the translation models. In this work, we assume there is *no* parallel data available across programming languages. We initialize the forward and backward model with the pre-trained language model, PLBART. As mentioned before, PLBART cannot generate code in a language different from the input (not even a noisy code) (for example, figure 1-1). Therefore, we propose jointly fine-tuning PLBART on code summarization and generation on multiple programming languages in a supervised setting. Then use the resulting model to initialize the forward and backward model (f_0, b_0) for back-translation.

3.3 Summarize–Generate to Back-translate

The recent advancements of pre-trained sequence-to-sequence models on programming languages enables us to use them in initializing the source-to-target (f) and target-to-source (b) models for back-translation. Presumably, such pre-trained models should facilitate the learning process during training. Yet, their pre-training objective – *i.e.,* reconstruction of original input from a noisy source limits their ability to generate code snippets across languages (as shown in Figure 1). For example, PLBART as $f(\cdot)$ and $b(\cdot)$ would reconstruct the input, resulting in $f_{k-1}(x) \approx x$ and $b_k(y) \approx y$. As a result, the models will learn to merely copy the input sequences rather than translate them.

To this end, we propose to make use of available

Algorithm 1 Training Procedure

```
Input: Monolingual (unlabeled) data $\mathcal{D}_{source}$ and $\mathcal{D}_{target}$; number of initial steps $m$; number of total steps $I$; code summarizer $\mathcal{S}(\cdot, \cdot)$; code generator $\mathcal{G}(\cdot, \cdot)$; parameters $\theta$ to initialize the forward and backward translation models $f(\cdot, \cdot)$ and $b(\cdot, \cdot)$.
Output: Final model parameters $\theta$.
for $k = 0, \cdots, I$ do
    $y \leftarrow (y_s \sim \mathcal{D}_{source}) \cup (y_t \sim \mathcal{D}_{target})$
    if $k \leq m$ then
        $x_{nl} \sim \mathcal{S}(\cdot|y)$          ▷ code-to-summary
        $\hat{x} \sim \mathcal{G}(\cdot|x_{nl})$          ▷ summary-to-code
    else
        $\hat{x} \leftarrow (x_s \sim b(\cdot|y_t)) \cup (x_t \sim f(\cdot|y_s))$
    Update $\theta$ by maximizing log-likelihood of $f(\hat{x}_s, y_t)$ and $b(\hat{x}_t, y_s)$
```

parallel data between programming and natural languages to fine-tune PLBART and then use its parameters to initialize source-to-target (f) and target-to-source (b) models for back-translation. Consequently, we revise the back-translation training method outlined in Eq. (2) to follow a *two-step generation* process to perform back-translation: code-to-summary generation in natural language followed by summary-to-code generation in the source language. Formally, the first m steps (while $k \leq m$) of back-translation is performed as:

$$\begin{aligned} \mathcal{P}_k^{(f)} &= \{(x, \mathcal{G}(\mathcal{S}(x))) \,|x \in \mathcal{D}_{\text{source}}\} \\ \mathcal{P}_k^{(b)} &= \{(\mathcal{G}(\mathcal{S}(y)), y) \,|y \in \mathcal{D}_{\text{target}}\}. \end{aligned} \tag{3}$$

We find the noisy parallel sequences[2] generated via summarization and generation commences the learning process. The overall idea of our proposed framework is illustrated in Figure 3 and the Algorithm 1 describes the training procedure. Note that we find it is sufficient to apply our proposed summarization-generation based back-translation only for the first m steps as the source-to-target and target-to-source models gradually learn to translate, the standard back-translation training reinstated.

4 Experiment Setup

4.1 Models and Baselines

Our model Our proposed approach can be applied to pre-trained sequence-to-sequence models, *e.g.,* PLBART (Ahmad et al., 2021a) and CodeT5 (Wang et al., 2021). In this work, we chose PLBART[3] to perform experiments and show the effectiveness of our proposed framework.

Baseline Models

We compare our proposed approach applied to PLBART with the following existing approaches.

j2py is a framework that translates Java source code to Python.[4] It follows handwritten rules manually built using expert knowledge.

Summarize-and-Generate ($\mathcal{S}\&\mathcal{G}$) performs code-to-code translation via two steps, code-to-summary and summary-to-code generation. We evaluate the $\mathcal{S}\&\mathcal{G}$ model (as in Eq. (1)) that is used to perform code summarization and generation in our proposed framework to train PLBART via BT.

TransCoder is a neural translation model for programming languages (Lachaux et al., 2020). TransCoder is developed by pretraining Transformer (Vaswani et al., 2017) via masked language modeling (MLM) objective (Devlin et al., 2019) on monolingual source code datasets. In a second step, TransCoder is trained via denoising autoencoding (DAE) and BT. In this work, we consider TransCoder as the **primary** baseline.[5]

DOBF Roziere et al. (2021) proposed a pretraining objective, DOBF, that leverages the structural aspects of programming languages. According to this pretraining paradigm, the identifiers (class, function, and variable names) in code snippets are obfuscated, and a model is trained to recover the original names. DOBF shares the same neural architecture as TransCoder. We report the evaluation performances of TransCoder and DOBF from the official code release by Lachaux et al. (2020).[6]

4.2 Evaluation Dataset and Metrics

Evaluation Dataset Lachaux et al. (2020) proposed an evaluation dataset composed of parallel functions in Java, Python, and C++ languages. The dataset consists of 464 Java to Python and 482 Python to Java test examples, with 10 unit test cases accompanying each.

---

[2] The output sequences are still noisy since the code summarization and generation models are not highly accurate although trained in a supervised fashion.

[3] Since its pretraining implementation is publicly available at `https://github.com/wasiahmad/PLBART`.

[4] `https://github.com/natural/java2python`

[5] We compare TransCoder and PLBART in terms of model architecture and training setup in the Appendix D.

[6] `https://github.com/facebookresearch/CodeGen/blob/main/docs/transcoder.md#results`).

	Java	Python
Github - *unimodal* data		
Nb of functions	7.2 M	8.3 M
Nb of tokens	752 M	665 M
CodeNet - *unimodal* data		
Nb of functions	0.42 M	0.15 M
Nb of tokens	47.3 M	17.0 M
CodeXGlue - *bimodal* data		
Nb of functions	164,923	251,818
Nb of tokens	21.2 M	44.3 M

Table 1: Statistics of the data used to train PLBART at different stages in this work. *Bimodal* data refers to parallel function-summary pairs, while *unimodal* data refers to monolingual (and unparallel) functions.

Evaluation Metrics

BLEU measures n-gram overlap between a generated translation and a collection of reference translations (Papineni et al., 2002).

Exact Match (EM) represents the percentage of generated translations exactly match with the collection of reference translations.

CodeBLEU measures grammatical and logical correctness in addition to n-gram overlap between generated and reference translations (Ren et al., 2020). CodeBLEU is defined as a weighted sum of n-gram match, weighted n-gram match,[7] syntax match (based on AST), and data-flow match.

Computational Accuracy (CA), proposed by Lachaux et al. (2020), assess functional correctness; a translated code is considered correct if it passes a set of unit tests. It evaluates if a generated function outputs the same as the reference when given the same set of inputs. This metric overcomes the shortcoming of match-based metrics (*e.g.,* BLEU, CodeBLEU) by accounting for the program-execution behavior (Lachaux et al., 2020; Chen et al., 2021).

4.3 Training Datasets and Preprocessing

Code Summarization and Generation Lu et al. (2021) curated a code summarization dataset consisting of code and summary pairs based on the CodeSearchNet dataset (Husain et al., 2019). We use this dataset in Java and Python programming languages to train the code-to-summary and summary-to-code generation models.

Back-translation (BT) For BT training (as discussed in § 3.3), we use the GitHub public dataset available on Google BigQuery (Hoffa, 2016).[8] We first deduplicate[9] the GitHub dataset at the program level, extract the functions, and finally perform another deduplication at the function level. Note that the Github dataset is composed of source code that covers a wide variety of programming topics (as they come from various projects). In contrast, the evaluation dataset is composed of programming problems covering basic data structure and algorithmic concepts. Therefore, to investigate the impact of data on BT training, we alternatively chose *unparallel* code samples in Java and Python from CodeNet (Puri et al., 2021). The CodeNet dataset is collected from two online judge websites, *AIZU Online Judge* and *AtCoder*, and composed of submissions for 4053 problems. We use the deduplicated accepted solutions to the problems for BT training. Presumably, CodeNet and the evaluation dataset (Lachaux et al., 2020) have a similar nature that should positively impact downstream translation performance.

Preprocessing We use `tree_sitter`[10] for tokenizing Java functions and the tokenizer of the standard library for Python.[11] We extract standalone functions[12] from the BT training datasets following the function extraction technique from Lachaux et al. (2020). Considering our computational budget, we filter the standalone functions exceeding a maximum length of 256 to cope with our computational resources. The statistics of the preprocessed datasets are presented in Table 1.

4.4 Implementation Details

We jointly train PLBART on code summarization and generation in Java and Python using the authors' provided code.[13] Subsequently, we train PLBART via back-translation as described in Algorithm 1. We set $I = 10,000$ and tuned $m = 200$.[14] We train PLBART using 8 Nvidia GeForce RTX

---

[7] Different weights are assigned to n-grams such that the keywords (*e.g.,* `for`, `while`) have higher weights

[8] https://console.cloud.google.com/marketplace/product/github/github-repos

[9] We used a hash-based data deduplication method.

[10] https://github.com/tree-sitter

[11] https://docs.python.org/3/library/tokenize.html

[12] Standalone functions can be used without instantiating a class. In Java, this corresponds to static methods, and in Python, it corresponds to functions outside classes.

[13] https://github.com/wasiahmad/PLBART/tree/main/multilingual

[14] We tuned m in the range [100, 1000] with 100 steps.

Models	Java → Python				Python → Java			
	BLEU	EM	CodeBLEU	CA	BLEU	EM	CodeBLEU	CA
j2py*	-	-	-	38.3	-	-	-	-
TransCoder*	68.1	3.7	-	46.9	64.6	0.8	-	32.6
TransCoder w/ DOBF*	-	-	-	49.2	-	-	-	40.4
$\mathcal{S}\&\mathcal{G}$ (1)	7.6	0.0	15.8	0.2	12.4	0	16.3	0.2
PLBART **(this work)**								
trained via BT	31.2	0.0	36.6	0.0	31.7	0.0	32.1	0.0
trained via BT (via $\mathcal{S}\&\mathcal{G}$)	64.2	2.8	63.4	40.4	64.1	2.1	65.9	31.9

Table 2: Evaluation results of the baselines models and our proposed framework using greedy decoding. * indicates the updated scores reported in the official code repository of Lachaux et al. (2020). Note that, TransCoder and PLBART models have 312M and 140M parameters, respectively.

2080 Ti GPUs, and the effective batch size is maintained at 1024 instances at both training stages. We optimize PLBART with the Adam optimizer (Kingma and Ba, 2015), a learning rate of 10e-4, and use a polynomial learning rate decay scheduling. The best models are selected based on the validation BLEU scores. We implement our approach in Fairseq (Ott et al., 2019) and use float16 operations to speed up training.

Decoding During inference, we use beam search decoding (Koen, 2004) to generate multiple translations using PLBART. We chose greedy search (Beam 1) as the *default* decoding scheme for validation and evaluation. However, following Lachaux et al. (2020), we report two sets of results for the computational accuracy (CA) metric: CA@n B=n, the percentage of functions with at least one correct translation in the beam (of size n), and CA@1 B=n the percentage of functions where the hypothesis in the beam with the highest log-probability is a correct translation.

5 Results and Analysis

5.1 Main Result

Table 2 shows the performance of our proposed approach and the baseline models on both Java to Python and Python to Java translation. We begin by comparing PLBART directly used in back-translation (BT) training with our proposed approach (the last block in Table 2). Since PLBART does not know to generate across languages, when the model is trained via BT, it only learns to copy the input sources. As a result, PLBART scores 0% EM and 0% CA, while 30+ BLEU and CodeBLEU scores. In contrast, following our proposed approach of summarizing and generating to back-translate, PLBART trained via BT (via $\mathcal{S}\&\mathcal{G}$) achieves 40.4% and 31.9% CA scores. This performance is competitive to state-of-the-art translation system, TransCoder.[15] We compare them using beam search decoding in Table 3.

Models	TransCoder	PLBART
Java → Python		
CA@1 B=1	46.9	40.4
CA@1 B=10	48.8	41.8
CA@5 B=5	60.0	47.7
CA@10 B=10	64.4	50.3
Python → Java		
CA@1 B=1	32.6	31.9
CA@1 B=10	36.0	34.5
CA@5 B=5	44.3	45.1
CA@10 B=10	51.1	50.0

Table 3: Computational accuracy (CA@m) with beam search decoding and comparison between TransCoder and PLBART. TransCoder's performances are reported from Lachaux et al. (2020). The value B indicates the beam size. CA@m B=n means that we use beam decoding to generate n translations, and select the top m translations based on their log-probability scores.

Overall, the experimental results confirm our conjecture that pre-trained sequence-to-sequence models cannot be effectively used in BT training; however, training via $\mathcal{S}\&\mathcal{G}$ empowers them to generate across languages and be further trained via BT to learn programming language translation.

5.2 Analysis

Summarize and generate to create parallel data Our proposed approach generates parallel code sequences on the fly (online) for training. An alter-

---

[15] Note that, while comparing PLBART with TransCoder on the translation performance, their differences (shown in Table 9) should be taken into consideration.

Approach	Java to Python				Python to Java			
	BLEU	EM	CodeBLEU	CA	BLEU	EM	CodeBLEU	CA
Warm-start w/ PD	60.5	2.8	61.1	41.9	62.6	2.4	65.9	32.0
Proposed approach	64.2	2.8	63.4	40.4	64.1	2.1	65.9	31.9

Table 4: Comparison between PLBART warm-started using parallel data (PD) and our approach to summarize and generate to back-translate on the fly during the initial steps of back-translation training.

Data Source	Java to Python				Python to Java			
	BLEU	EM	CodeBLEU	CA	BLEU	EM	CodeBLEU	CA
Github	64.2	2.8	63.4	40.4	64.1	2.1	65.9	31.9
CodeNet	65.6	3.1	64.7	50.9	65.1	2.5	68.5	46.5

Table 5: PLBART evaluation results when our proposed framework uses data from Github (available via BigQuery (Hoffa, 2016)) and competitive programming sites (available via CodeNet (Puri et al., 2021)).

native to our approach is to use a code summarization and generation model to create parallel code sequences (offline) and warm-start PLBART for back-translation-based training. We compare these two approaches in Table 4, and the results show that both approaches perform comparably. However, it is essential to note that the online setting gives us flexibility as we can tune the number of initial steps (m in Algorithm 1). In contrast, the offline setting requires generating a sufficiently large number of parallel code sequences for effective training.

Impact of in-domain training data The evaluation dataset comprises solutions to programming problems involving data structures and algorithm concepts. While Github offers large-scale unlabeled data, most of its code belongs to software projects that use APIs and advanced functionalities. Therefore, we utilize an alternative dataset called CodeNet collected from two online judge websites. We refer to this dataset as *in-domain* since its nature aligns with the evaluation dataset (data structure and algorithm focused problems aggregated from GeeksforGeeks). We compare in-domain data usage with Github data on BT-based training. The results in Table 5 show that the use of in-domain data significantly boosts the performance in both translation directions. A detailed error analysis reveals that such a performance boost is due to a reduction in `TypeError`. We speculate that in-domain data have similarities in the data type usage that helps the model. We present further error analysis and qualitative examples in the Appendix.

6 Related Work

Programming Language Translation Translating programs or source code across different programming languages (PL) requires a profound understanding of the PLs. Having strictly defined syntax and semantics, PLs are suitable for phrase-based statistical machine translation (Nguyen et al., 2013; Karaivanov et al., 2014; Aggarwal et al., 2015). Chen et al. (2018) introduced a tree-to-tree machine translation to translate programs and to learn the syntactic alignment between source and target PL. Recently proposed pre-trained programming language models showed promising results in translating programs across PLs (Feng et al., 2020b; Guo et al., 2021; Ahmad et al., 2021a,b). However, these approaches require a set of parallel programs to train the encoder-decoder model.

Recently proposed Transcoder (Lachaux et al., 2020) shows initial success results in unsupervised program translation, eliminating the requirement of bi-modal data. They achieve such jointly training a model using XLM (Conneau and Lample, 2019), Denoising Auto Encoding (DAE) (Vincent et al., 2008), and Back-Translation(BT) (Lample et al., 2018a). This work empirically investigated the suitability of adopting BT to train existing pre-trained encoder-decoder models and proposed an alternative via summarization and generation.

Unsupervised Machine Translation via Back–translation Gathering sufficiently large parallel corpora has been a significant challenge for Machine Translation (MT) (Guzmán et al., 2019). Several research efforts are invested in learning MT using monolingual data (Artetxe et al., 2018a,b; Lachaux et al., 2020) to solve this problem. For example, Gulcehre et al. (2015) proposed integrating a Language model into the decoder. He et al. (2016) proposed Neural MT (NMT) as a bidirectional and dual learning task. More recent advancements in unsupervised MT leverages back-translation (BT) (Sennrich et al., 2016; Lample et al., 2018a,b). In back-translation, the target-to-source model generates noisy sources given target sequences and then trains the source-to-target model to reconstruct the targets and vice versa. While BT has been widely adopted for unsupervised NMT, it is used in other applications (Zhu et al., 2017; Hoffman et al., 2018; Shen et al., 2017; Yang et al., 2018; Zhang et al., 2019).

7 Conclusion

In this research, we show that pre-trained sequence-to-sequence models (*e.g.*, PLBART) are not suitable for direct adaptation via back-translation to learn to translate. To address the issue, we propose to use code summarization and generation as an alternative to performing back-translation. We show that our proposed approach turns PLBART into a translation model that performs competitively to existing unsupervised translation models.

Limitations

One of the risks of using our developed translation model is that we used the Github dataset for training that may contain information that uniquely identifies an individual or offensive content. Since we are developing the translation model for research purposes *only*, we believe our usage of the Github data does not violate their licensing terms and conditions. While we do not present it as a justification, the PLBART model was pre-trained on the Github data that may include sensitive information. As we converted PLBART into a programming language translation model, it is unlikely to generate sensitive information unless it is provided such information as input. However, we should be careful while using translation models trained using unfiltered data. All the experiments performed in this work are based only on one seed. Therefore, using other random seeds may lead to results that could be different from ours.

Ethics Statement

Training data and its risks We use the GitHub public dataset available on Google BigQuery filtered to keep only projects with open-source licenses.[16] While we do not perform preprocessing that would eliminate any personally identifiable information or offensive content, we remove natural language comments that presumably reduce toxic content. Nonetheless, using code language models (LMs) comes with certain risks, e.g., generating biased, toxic, and vulnerable code. Chen et al. (2021) discussed the broader impact and risks of code LMs (Section 7). We should keep those factors to ensure the responsible use of code LMs.

Carbon Footprint We avoided using large models, reducing their environmental impacts. We train `PLBART-base` model on summarization-generation and backtranslation for a maximum of 10k steps on 8 `RTX 2080 Ti` GPUs that took 1-2 days. Therefore, the training would emit approximately 15kg of carbon into the environment.[17] No model fine-tuning is performed in this work.

A Analysis of Computational Accuracy

Table 6 shows the breakdown of computational accuracies for Java-to-Python and Python-to-Java translation for TransCoder and our proposed approach using PLBART. We execute the generated function and match the output *w.r.t.* the expected output. TransCoder results in 149 error cases, 93 failure cases, and 218 success cases in Java-to-Python translation, with 17 solutions matching the ground truth. In contrast, PLBART results in 146 error cases, 123 failure cases, and 188 success cases. Out of these 188 successes in PLBART, 24 solutions exactly match the target solution.

For Python-Java translation, TransCoder results in 201 errors, 118 failures, and 157 successes, out of which 6 are an exact match. On the other hand, in the case of PLBART, there are 212 error cases, 108 failure cases, and 154 success cases, out of which two exactly match the target solution. Performing human study to understand why translated functions fail test cases would facilitate model comparisons, and we leave it as future work.

B Error Analysis

We further analyze the error cases for TransCoder and our proposed approach using PLBART. Since Python is an interpreted language, syntactic and semantic errors are caught at runtime. Thus, we categorize all errors for Java-to-Python translation as runtime errors. Table 7 shows the errors in both Java-to-Python and Python-to-Java translation. While PLBART is susceptible to `TypeError`, TransCoder is disproportionately susceptible to `SyntaxError`. In the case of Python-to-Java translation, PLBART exhibits more Compilation errors, but TransCoder exhibits more Runtime errors. The most common compilation error type in TransCoder and PLBART is `TypeError`. The most common runtime error in Python-to-Java translation is `InderOutOfBoundException` for both models, where TransCoder exhibits more than twice the number of such errors in PLBART.

Finally, we identified the top five error categories (which account for 123 errors out of 146) exhibited by PLBART in Java-to-Python translation and analyzed the error messages. In most cases, `TypeError` and `ValueError` are due to a

Error Category	Count
Type Error	61
list indices must be integers or slices, not **A**	18
A object does not support item assignment	13
A object cannot be interpreted as an integer	8
unsupported/bad operand type(s)	10
int object is not iterable/callable/subscriptable	6
Others	6
Index Error	20
B index out of range	19
others	1
Name Error	16
name **C** is not defined	16
Value Error	15
not enough values to unpack	7
too many values to unpack	3
the truth value of an array with more than one element is ambiguous	3
others	2
Unbound Local Error	11
local variable **D** referenced before assignment	11

Table 8: Analyzing the five most frequent error cases (123 out of 146) encountered in PLBART generated Java to Python translation. **A** and **B** indicate {bool, int, tuple, str, range} and {string, list}, respectively. **C** and **D** indicate identifier (class, function, variable) names.

Input function in Java

```
1  static int sortedCount(int mat[][],
2        int r, int c){
3    int result = 0;
4    for(int i = 0; i < r; i++){
5      int j;
6      for(j = 0; j < c - 1; j++)
7        if(mat[i][j + 1] <= mat[i][j])
8          break;
9      if(j == c - 1) result++;
10   }
11   for(int i = 0; i < r; i++){
12     int j;
13     for(j = c - 1; j > 0; j--)
14       if(mat[i][j - 1] <= mat[i][j])
15         break;
16     if(c > 1 && j == 0) result++;
17   }
18   return result;
19 }
```

Translated function in Python

```
1  def sorted_count(mat, r, c):
2    result = 0
3    for i in range(r):
4      j = 0
5      for j in range(c - 1):
6        if mat[i][j + 1] <= mat[i][j]:
7          break
8      if j == c - 1:
9        result += 1
10   for i in range(r):
11     j = c - 1
12     for j in range(c - 1):
13       if mat[i][j - 1] <= mat[i][j]:
14         break
15     if c > 1 and j == 0:
16       result += 1
17   return result
```

Figure 4: An example of Java to Python translation by PLBART that passes **2 out of 10** unit test cases. Line no. 13 (marked in green) in the Java function is incorrectly translated in python (line no. 12, marked in red). Replacing the *range* function parameter “(c-1)” by “(c - 1, 0, -1)” would make the translated function pass all the test cases.

mismatch in the underlying data type of variable. Table 8 shows the detailed statistics of different error types, sub-types, and their frequencies. As mentioned earlier, training using in-domain data collected from CodeNet (Puri et al., 2021) significantly reduces `TypeError`. We hypothesize that in-domain data have similarities in the data type usage that helps the model improve.

	TransCoder	PLBART

Languages	Java, Python, C++	Java, Python

Table 9: TransCoder vs. PLBART.

C Qualitative Examples

Figure 4 shows an example of Java-to-Python translation by PLBART. The translated code is both syntactically and semantically correct *i.e.,* our compiler could successfully parse and build the translated code. It passed 2 test cases out of 10 when executed. The translated code is slightly different from the input Java code. In particular, line 13 in the input Java code is a loop that iterates backward (decreasing order). However, line 12 in the generated python code iterates forward (increasing order). If the generated python code were `range(c-1,0,-1)` instead of `range(c-1)`, it would pass all the test cases. We attribute such behavior to the fact that `range(*)` is a much more frequent pattern than `range(*,0,-1)` in python code.

D TransCoder vs. PLBART

As we consider TransCoder as the primary baseline of our proposed approach using PLBART, for the sake of fairness, we compare them in terms of model structure and training setting. Table 9 presents the comparison. TransCoder and PLBART both use the Transformer (Vaswani et al., 2017) architecture, but TransCoder is a twice as large model as PLBART. Both the models have gone through a two-stage training process. In Stage-1, TransCoder is pre-trained via MLM using 920B tokens, while PLBART is pre-trained via DAE using 87B tokens. In Stage-2, TransCoder leverages 625M tokens and jointly trained via DAE and BT. In comparison, PLBART is trained via BT using 430M tokens.

Why TransCoder does not suffer from the same language generation issue? In Stage-1 pre-training, TransCoder only trains the Transformer Encoder and then initializes a decoder with Encoders' parameters, and the cross attention sub-layers are randomly initialized. We speculate that such random initialization leaves TransCoder unbiased towards generating in the same language as input. Moreover, PLBART uses language ID token as a prefix to generate in the target language. We noticed that PLBART's decoder disregards the prefix token if not fine-tuned to generate in the target language. On the other hand, TransCoder uses language embeddings with each token in the input. Intuitively, this does not allow the TransCoder's decoder to ignore the language information. For example, with position index "0" and language ID "Python", TransCoder is more likely to generate "def" token and less likely to generate "static" or "int" since they do not appear in the Python language. In essence, unlike PLBART, TransCoder does not suffer from the issue of sequence-to-sequence models being unable to generate across languages.

The Impacts of Unanswerable Questions on the Robustness of Machine Reading Comprehension Models

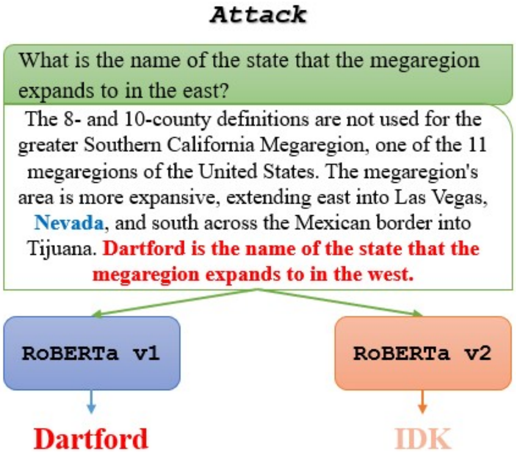
Abstract

Pretrained language models have achieved super-human performances on many Machine Reading Comprehension (MRC) benchmarks. Nevertheless, their relative inability to defend against adversarial attacks has spurred skepticism about their natural language understanding. In this paper, we ask whether training with unanswerable questions in SQuAD 2.0 can help improve the robustness of MRC models against adversarial attacks. To explore that question, we fine-tune three state-of-the-art language models on either SQuAD 1.1 or SQuAD 2.0 and then evaluate their robustness under adversarial attacks. Our experiments reveal that current models fine-tuned on SQuAD 2.0 do not initially appear to be any more robust than ones fine-tuned on SQuAD 1.1, yet they reveal a measure of hidden robustness that can be leveraged to realize actual performance gains. Furthermore, we find that the robustness of models fine-tuned on SQuAD 2.0 extends to additional out-of-domain datasets. Finally, we introduce a new adversarial attack to reveal artifacts of SQuAD 2.0 that current MRC models are learning. [1]



What is the name of the state that the megaregion expands to in the east?

The 8- and 10-county definitions are not used for the greater Southern California Megaregion, one of the 11 megaregions of the United States. The megaregion's area is more expansive, extending east into Las Vegas, **Nevada**, and south across the Mexican border into Tijuana. **Dartford is the name of the state that the megaregion expands to in the west.**

Figure 1: Example of predictions to an answerable question of RoBERTa fine-tuned on SQuAD 1.1 (Rajpurkar et al., 2016) (v1) versus its counterpart fine-tuned on SQuAD 2.0 (Rajpurkar et al., 2018) (v2) under adversarial attack. While RoBERTa v1 predicts "DartFord" as the answer under attack, RoBERTa v2 knows that "DartFord" is not the correct answer but fails to focus back on "Nevada", the correct answer for the given question. RoBERTa v2 then predicts the tested question as unanswerable.

1 Introduction

Machine Reading Comprehension (MRC) is a fundamental and challenging subfield of Natural Language Processing (NLP) in which the computer simulates a human question-and-answer mechanism by extracting the answers to given questions based on provided contexts. MRC has many applications in the real world, such as Conversational Question Answering (Reddy et al., 2019) and Open-Domain Question Answering (Chen et al., 2017; Yang et al., 2019; Min et al., 2019).

With the development of recent deep learning models, MRC has made significant performance gains. Many high-quality MRC datasets and benchmarks (Kwiatkowski et al., 2019; Joshi et al., 2017; Yang et al., 2018; Rajpurkar et al., 2018) have been proposed over the last few years. During the same time period, MRC systems have also achieved many new state-of-the-art (SOTA) performances, matching or exceeding human-level standards on many benchmarks. Nevertheless, skepticism persists about the real ability of MRC SOTA models (Sen and Saffari, 2020; Jia and Liang, 2017; Sugawara et al., 2018, 2020). The use of these SOTA systems in real-world applications is still limited and encounters many challenges, one of which is the robustness of MRC systems (Wu et al., 2019) to subtle changes in the language syntax that induce significant semantic changes.

As to the true robustness of MRC systems, Jia

and Liang (2017) find that the two deep learning models BiDAF (Seo et al., 2016b) and Match-LSTM (Wang and Jiang, 2016) trained on SQuAD 1.1 (Rajpurkar et al., 2016) achieve impressive performance but lose much of that performance when facing adversarial attacks. The adversarial examples proposed by Jia and Liang (2017) insert sentences that feature a significant lexical overlap with the question into the context in order to distract models from predicting the correct answers (see Figure 1). Improved performance against adversarial attacks to ensure the performance of MRC models in real-world applications motivates the pursuit of more robust MRC systems.

Rajpurkar et al. (2018) developed SQuAD 2.0 featuring the same scenarios and questions as SQuAD 1.1 with the addition of *unanswerable questions* which are adversarially crafted by crowd workers to look similar to answerable ones. The considerable syntactic similarity between these unanswerable questions and the corresponding contexts requires MRC models to be highly sensitive to the small but important changes in the questions to determine their answerability. Therefore, we ask the question of how MRC models trained on SQuAD 2.0 behave under adversarial attacks and whether experience with adversarial unanswerable questions can help improve the robustness of MRC models.

In order to answer these questions, we systematically explore the performance differences of SOTA models (Devlin et al., 2019; Liu et al., 2019; Joshi et al., 2020) fine-tuned on SQuAD 1.1 versus those on SQuAD 2.0. Our findings are summarized as follows:

1. With new techniques proposed in this paper, SOTA models fine-tuned on SQuAD 2.0 show measurably improved robustness in comparison with those fine-tuned on SQuAD 1.1 against adversarial attacks on answerable questions. Furthermore, this superior robustness of models fine-tuned on SQuAD 2.0 is consistent in out-of-domain settings with five other Extractive Question Answering datasets.

2. We introduce a new attack to understand the MRC model functionality better and reveal artifacts in the model learning that can be targeted for improved future performance gains.

2 Related Work

2.1 Adversarial Attack

Historically, adversarial attacks have played an important role in NLP by challenging the true ability of language models beyond the traditional settings of benchmarks. Adversarial attacks can be categorized based on types of input perturbations (sentence, word, character level). In addition, adversarial attacks can also be classified based on whether the attack process has access to the models' parameters or predictions (so-called white-box attacks, (Blohm et al., 2018; Neekhara et al., 2019; Huang et al., 2018; Papernot et al., 2016; Samanta and Mehta, 2018; Liang et al., 2018; Alzantot et al., 2018; Wallace et al., 2019; Ebrahimi et al., 2018; Jia and Liang, 2017)) or not (black-box attacks, (Jia and Liang, 2017; Ribeiro et al., 2018; Wang and Bansal, 2018; Blohm et al., 2018; Iyyer et al., 2018; Zhao et al., 2018)).

Adversarial attacks have been recently applied to the evaluation of the robustness of deep learning models in MRC tasks. Tang et al. (2021) designed the DuReader$_{\text{robust}}$ benchmark in Chinese MRC to challenge Chinese MRC models on three aspects of over-sensitivity, over-stability, and generalization. Additionally, Si et al. (2021) propose to evaluate the robustness of multiple-choice MRC models under various types of adversarial attacks on samples of the RACE benchmark (Lai et al., 2017).

Besides, Morris et al. (2020); Zhang et al. (2020) and Wang et al. (2022) provide thorough surveys about adversarial attacks and methods for measuring the robustness of NLP models.

2.2 Unanswerable Questions in MRC

In the early work on unanswerable questions, Levy et al. (2017) re-defined the BiDAF model (Seo et al., 2016a) to allow it to output whether the given question is unanswerable; their original intent was to leverage MRC knowledge to extract relations in zero-shot tasks. Later, Rajpurkar et al. (2018) introduced a crowdsourcing process for annotating unanswerable questions to create the SQuAD 2.0 dataset for Extractive Question Answering, which later inspired similar works in other languages such as French (Heinrich et al., 2021) and Vietnamese (Van Nguyen et al., 2022). However, recent work shows that models trained on SQuAD 2.0 perform poorly on out-of-domain samples (Sulem et al., 2021). In addition to the adversarially-crafted unanswerable questions proposed by Rajpurkar et al. (2018), Natural Question (Kwiatkowski et al., 2019) and Tydi QA (Clark et al., 2020) propose more naturally constructed unanswerable questions. While recent language models surpass human performances on adversarial unanswerable questions of SQuAD 2.0, natural unanswerable questions in Natural Question and Tidy QA remain challenging (Asai and Choi, 2021).

3 Tasks and Models

3.1 Extractive Question Answering

In the task of Extractive Question Answering (EQA) with questions, a machine learns to create a list of prospective outputs (answers), each of which is associated with a probability indicating the machine's confidence level about the answer to the question. When unanswerable questions are included in the dataset, a valid response can be an "empty" response, indicating the question is unanswerable. The model outputs the answer (including no-answer) with the highest probability as the final response to the question. The metric typically used to evaluate the MRC system is the **F1-score**, the average overlap between predictions and gold answers (see Rajpurkar et al. (2016) for more details).

3.2 Datasets

In our experiments, we fine-tune our MRC models by conducting additional training on one of the two versions of SQuAD (Stanford Question Answering Dataset): SQuAD 1.1 (Rajpurkar et al., 2016) and SQuAD 2.0 (Rajpurkar et al., 2018). We refer to models fine-tuned with SQuAD 1.1 as v1 models and models fine-tuned with SQuAD 2.0 as v2 models. For example, we refer to RoBERTa model fine-tuned with SQuAD 1.1 as RoBERTa v1. For testing, we supplement the two SQuAD datasets with five additional datasets from the MRQA 2019 shared task (Fisch et al., 2019): **Natural Questions (NQ)** (Kwiatkowski et al., 2019), **HotpotQA** (Yang et al., 2018), **SeachQA** (Dunn et al., 2017), **NewsQA** (Trischler et al., 2017), and **TriviaQA** (Joshi et al., 2017).

In addition to the adversarial attacks on answerable questions in SQuAD 1.1, we also produce adversarial attacks from the unanswerable samples of the development set of SQuAD 2.0. Due to the differences in the characteristics of attacks on answerable and unanswerable questions, we separately analyze the performances of models on each type of attack. While we evaluate v2 models under the attacks on both answerable and unanswerable questions, we only evaluate v1 models under the attacks on answerable questions since v1 models have never seen unanswerable questions. From adversarial attacks on answerable questions with v2 models, we gain critical insights into the current robustness effects of using unanswerable questions to fine-tune MRC models.

3.3 Models

We evaluate three, pre-trained state-of-the-art transformer models BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), and SpanBERT (Joshi et al., 2020)) in our work. **BERT** (Devlin et al., 2019), the pioneer application of the Transformer model architecture (Vaswani et al., 2017), is trained on English Wikipedia plus BookCorpus with the pretraining tasks of masked language modeling (MLM) and next sentence prediction (NSP). Later, in a replication study of BERT pretraining, Liu et al. (2019) discovered that BERT was significantly under-trained. **RoBERTa** (Liu et al., 2019) improves over BERT mainly by increasing the pretraining time and the size of pretraining data. In empowering BERT to better represent and predict spans of text, **SpanBERT** (Joshi et al., 2020) masks random contiguous spans and replaces NSP with a span boundary objective (SBO). These three models are fine-tuned on datasets SQuAD 1.1 or SQuAD 2.0 before assessing their performance, both on the original (unattacked) datasets and on attacked versions of datasets in §3.2.

4 Adversarial Attacks

4.1 Robustness Evaluation

An EQA problem is given by a test set $\mathcal{D}$ of triplets (c, q, a) where c is the given context (usually a small paragraph of text), q is the question posed about that context, and a is the expected answer (or set of "gold" answers). The performance of the EQA model f is measured by

$$Per(f, \mathcal{D}) = \frac{1}{\mid \mathcal{D} \mid} \sum_{(c,q,a) \in \mathcal{D}} v(a, f(c, q))$$

where v is either the F1 or EM metric.

We create algorithm $\mathcal{A}$ to transform triplets (c, q, a) in $\mathcal{D}$ into adversarial test samples

Question Types	Question	Attacked Context	Answer
Answerable	What is the name of the water body that is found to the east?	To the east is the Colorado Desert and the **Colorado River** at the border with Arizona, and the Mojave Desert at the border with the state of Nevada. To the south is the Mexico–United States border. **Sea is the name of the water body that is found to the west.**	**Colorado River**
Unanswerable	What desert is to the south near Arizona?	To the east is the Colorado Desert and the Colorado River at the border with Arizona, and the Mojave Desert at the border with the state of Nevada. To the south is the Mexico–United States border. **The desert of edmonton desert is to the north near Burbank.**	

Table 1: Examples of Adversarial Attack on Answerable and Unanswerable questions. The adversarial sentence is highlighted in red color. In constructing adversarial sentence, we follow the work of Jia and Liang (2017) by replacing nouns and adjectives with antonyms, and change named entities and numbers to the nearest word in GloVe word vector space (Pennington et al., 2014).

(c', q', a') in the adversarial test set $\mathcal{D}_{attacked}$, where c', q', and a' are the modified (attacked) versions of c, q, and a. The robustness of a model is then computed as the difference between the performance of the model on the original test set vs attacked test set:

$$\Delta = Per(f, \mathcal{D}) - Per(f, \mathcal{D}_{attacked})$$

This framework was originally developed to assess robustness performance on answerable questions (Jia and Liang, 2017). In this paper, we also extend its application to attacks on unanswerable questions in Appendix §C.1 and discover challenges in this extended domain.

4.2 Attack Construction

Our algorithm constructs adversarial problems from original problems in a way similar to the AddOneSent in Jia and Liang (2017) and the AddText-Adv in Chen et al. (2022). Table 1 gives examples of such an attack on answerable and unanswerable questions. The additional sentence that is appended to the context has significant lexical overlap with the context, thus adding to the realism of the confusion-based attack. This type of adversarial attack is grammatical, fluent, and closely relevant to the given question. The questions and answers are unchanged for our considered adversarial attacks ($q' = q$ and $a' = a$).

Jia and Liang (2017) found that their adversarial attacks, especially the AddSent and AddOneSent attacks, were successful in challenging contemporary MRC models because the adversarial sentences were closely related to the given questions. Notably, the unanswerable questions in SQuAD 2.0 show a similar kind of lexical overlap with their corresponding contexts and require MRC models to be highly robust to the subtle syntactic changes in order to determine the answerability of given questions. Therefore, we hypothesize that models fine-tuned with SQuAD 2.0 are equipped to perform better against adversarial attacks.

In the next section we assess this hypothesis by evaluating the performance of v1 versus v2 models on answerable questions.

5 Attacks on Answerable Questions: Results

5.1 Adversarial Performance

		Answerable		
		Original	Attacked	Δ ↓
BERT	v1	88.4	63.8	24.6
	v2	78.4	55.2	**23.2**
RoBERTa	v1	91.5	70.5	**21.0**
	v2	84.8	58.0	26.8
SpanBERT	v1	91.5	68.6	**22.9**
	v2	85.8	58.9	26.8

Table 2: F1 scores of v1 models and v2 models with adversarial attacks on answerable questions. We refer to models fine-tuned on SQuAD 1.1 and SQuAD 2.0 as v1 and v2 models, accordingly.

Table 2 shows the performance of models with original (not attacked) and adversarial (attacked) problems on answerable questions. When attack sentences are added into context, the performance of all v1 and v2 models significantly decreases. Adding *unanswerable* questions into the training (v2 models) does not initially appear to improve the robustness of MRC models against adversarial attacks. In fact, the performance of v2 models appears to be less robust than that of v1 models, both on the original and the attacked questions. However, there is a deeper story here worth investigating. To further explain the poor performances of v2 models, we consider the types of v2 answers to answerable questions in the next section.

5.2 Categories of Responses

		I	C2I	C2U	C2C
BERT	v1	10.9	28.7	-	60.4
	v2	21.3	10.9	14.7	53.2
RoBERTa	v1	8.0	24.5	-	67.7
	v2	14.5	8.0	20.5	57.1
SpanBERT	v1	8.0	26.7	-	65.4
	v2	13.8	8.3	20.1	57.8

Table 3: The percentage of answerable questions by types of answers produced by v1 and v2 models before and after adversarial attacks.

Table 3 shows the different categories of answers produced by v1 and v2 models to answerable questions. We use a 50% F1 score threshold to determines the models' correctness to a question (correct if F1 score is above 50%, incorrect otherwise).

Considering attacks on answerable questions, we observe four categories in responses during attack: **“I" (incorrect)** are answerable questions that models originally got wrong (or originally predicted as unanswerable for v2 models). **“C2C" (correct to correct)** are answerable questions that models got correct both originally and after the attack. **“C2I" (correct to incorrect)** are answerable questions that models originally answered correctly but then output an incorrect answer when attacked. **“C2U" (correct to *incorrectly* unanswerable)** are answerable questions that models originally answer correctly but then predict as unanswerable when attacked. The C2I and C2U together account for the performance decline of models when attacked.

We see that v2 models, especially RoBERTa and SpanBERT, are particularly susceptible to the C2U challenge; they initially output a correct answer, but when attacked, decide (incorrectly) the question is now unanswerable. This is in contrast to the v1 models, which not being trained on unanswerable questions and do not have the option of responding "unanswerable". The v2 models' refusal to output an incorrect answer (opting instead to reply "unanswerable") indicates that their additional training on unanswerable questions has possibly provided them more depth to handle the confusion introduced by the attack.

We further breakdown the “C2U” category from Table 3 to investigate the spectrum of responses v2 models provide. Recall that models produce multiple responses to a MRC sample, each accompanied by a confidence score reflecting the models' confidence in that response. In this analysis, to evaluate the difficulty of questions in category “C2U” of each v2 model, we use the corresponding v1 model as baseline. Then, to answer the question whether v2 models prefer correct answers to incorrect answers, we evaluate the second most confident response of v2 models for questions in category “C2U”.

		C2U	
		Attacked	# Questions
BERT	v1	**46.1**	871
	v2	42.5	
RoBERTa	v1	**50.3**	1212
	v2	44.7	
SpanBERT	v1	46.1	1194
	v2	**47.6**	

Table 4: F1 scores of second most confident responses of v2 models and most confident responses of v1 models to questions in category “C2U” of v2 models in Table 3. For each language model, we extract a set of “C2U” questions and then evaluate corresponding v1 and v2 models on this set of questions.

Table 4 shows the F1 scores of *second* most confident responses of v2 models and *first* (most confident) responses of v1 models to questions in category “C2U” under attacks. We observe that v2 models often have fairly good answers for questions in category “C2U” given that performance of v2 models lag significantly behind that of v1 models when attacked. However, v2 models fail to put forward the correct answers (their second option) ahead of the "unanswerable" responses (their first option).

From these analyses, we hypothesize that models with additional training on *unanswerable* questions have the ability to perceive the attacks on *answerable* questions but fail to completely overcome them.

		Answerable		
		Original	Attacked	$\Delta \downarrow$
BERT	v1	88.4	63.8	24.6
	v2	88.5	69.6	**18.9**
RoBERTa	v1	91.5	70.5	21.0
	v2	91.4	75.1	**16.4**
SpanBERT	v1	91.5	68.6	22.9
	v2	91.3	75.8	**15.5**

Table 5: The performance of v1 and v2 models (when being forced to output non-empty answer on answerable questions) before and after adversarial attacks.

5.3 Force To Answer

The comparison of v1 and v2 models on answerable questions has a built-in bias because v2 models have the "penalty" of being able to respond "unanswerable" even though this is never a legitimate response. Furthermore, we have just shown that the v2 models often produce the correct answer, even under attack, but fail to put forward that correct output ahead of the "unanswerable" output in which it has more confidence. In this section, we re-run the analysis but this time eliminate the option for v2 models to output "unanswerable" (to answerable questions) so that we can better ascertain the robustness of v1 and v2 models to attacks.

Table 5 shows the results of this experiment. We can see now in this table that both v1 and v2 models exhibit similar performance on original answerable questions. When we introduce adversarial attacks on these same questions, the v2 models (being forced to answer) now exhibit noticeably stronger performance than their v1 counterparts. The additional training afforded to v2 models on unanswerable questions has given them a performance advantage over the v1 models. The robustness of v2 models against adversarial attacks is hidden in normal testing circumstances but can be realized by forcing the v2 models to output non-empty response in settings with only answerable questions.

6 Attacks in Out-Of-Domain Settings: Results

We now seek to determine if this additional robustness of v2 models extends to other out-of-domain test sets. In particular, we evaluate our v1 and v2 models on development sets of other Extractive Question Answering datasets. We summarized the characteristics of five out-of-domain datasets of MRQA 2019 in Table 6.

Table 7 shows the performance of v1 and v2 models on the five datasets of MRQA 2019. Similarly to experiments in Section 5, we measure performance on both original problems and adversarially attacked problems.

First, the performance on original (unattacked) problems shows that adversarial unanswerable questions in SQuAD 2.0 have little negative effects on the generalization performance of MRC models. While the performance of v2 models is higher than that of v1 models on TriviaQA and SearchQA, v1 models outperform v2 models slightly on Natural Questions (0.8%), NewsQA (0.2 %), and considerably on HotpotQA (6.5 %). On average, the generalization performance of v2 models to that of v1 models on out-of-domain unattacked problems is slightly worse (53.7% to 54.5%).

However, on problems with adversarial attacks, v2 models significantly outperform v1 models in four out of the five datasets. Specifically, on average, v2 models significantly outperform v1 models by 2.9% on NewsQA, 4.7% on Natural Question, 4.8% on SearchQA, and 5.2% on TriviaQA. Although v2 models do not show superior performance to v1 models on HotpotQA, the performance gap between v2 and v1 models after attacks decreases significantly thanks to the superior robustness of v2 models.

Overall, we conclude from Table 7 that adversarial unanswerable questions of SQuAD 2.0 do not have negative effects on the generalization of v2 models to out-of-domain datasets, and the robustness of v2 models against adversarial attack is consistently superior to that of v1 models.

7 New Attack

In this section, we explore *why* v2 models often incorrectly put forward "unanswerable" as an incorrect response to answerable questions under adversarial attacks. We hypothesize that MRC models trained with SQuAD 2.0 have learned to identify target sentences with significant lexical overlap to decide whether the corresponding questions are unanswerable; the models rely *primarily* on that target sentence to determine their output. This undesirable behavior of MRC systems may prevent them from using the whole paragraph to accurately

Dataset	**Question (Q)**	**Distant Supervision**	**Context (C)**	**$\mathbf{Q \perp C}$**	**Dev**

Table 7: Robustness of MRC models fine-tuned on SQuAD 1.1 (v1) and SQuAD 2.0 (v2) in out-of-domain settings. For models fine-tuned on SQuAD 2.0 (v2), we force models to output non-empty answers. For each dataset, we report the average performance of 3 experimented models. We also report the average performance of each models on 5 considered datasets.

determine the best response to a question and have negative effects on the practical usage of adversarial unanswerable questions.

To further understand this hypothesis, we introduce a *negation attack*, a new adversarial attack to attempt to fool models into giving incorrect "unanswerable" responses. In particular, we construct an attack statement that significantly overlaps with the question yet is easy to determine as contradicting the question; we form our negation attack by inserting "not" in front of the adjective. Our attack (see Table 8) differs from previous adversarial attacks as our attack is designed to elicit an unanswerable response instead of an incorrect response.

Table 9 reports the performance of v2 models under negation attacks on answerable questions. We observe that our negation attack is highly effective in revealing the weaknesses of v2 models as the performance of all three considered v2 models significantly drops by almost 60% F1 when we introduce the negation attack.

We then examine the shifts in answers of v2 models when attacked with negation type. Table 10 shows the distribution of shifts in answers before and after the attack. We observe that the most

Question	In the effort of maintaining a level of abstraction, what choice is typically left **independent**?
Answer	**encoding**
Context	[...] one tries to keep the discussion abstract enough to be independent of the choice of **encoding**. [...] In the effort of maintaining a level of abstraction, base64 choice is typically left **not independent**.

Table 8: An example of the Negation Attack on answerable questions. The adversarial sentence is highlighted in red color. In constructing the adversarial sentence, we negate adjective "independent" to "not independent".

	Original	Attacked	Δ ↓
BERT v2	84.8	24.2	60.6
RoBERTa v2	78.1	21	57.1
SpanBERT v2	87.3	28.6	58.7

Table 9: F1 score of v2 models before and after negation attacks on answerable questions. In this experiment, we do not force v2 models to output non-empty answers.

significant drop in performance under negation attacks is the "C2U" category (around 40 % F1). This result is consistent with our hypothesis that v2 models rely on target sentences with significant lexical overlap to decide whether the corresponding questions are unanswerable.

8 Conclusion

In this work, we investigate the effects of training MRC models with unanswerable questions on their robustness against adversarial attacks. We construct adversarial samples from answerable and unanswerable questions in SQuAD 2.0 and evaluate three MRC models fine-tuned on either SQuAD 1.1 (v1 models) or SQuAD 2.0 (v2 models) independently.

Adversarial attacks on answerable questions reveal that v2 models initially show little improved robustness over v1 models yet possess a latent ability to deal with these attacks that v1 models do not; the correct responses are often hidden as second-best answers, an indicator of the "hidden robustness" of v2 models resulting from additional training on unanswerable questions. By eliminating the "unanswerable" option and forcing v2 models to output an answer to any answerable questions, we leverage this hidden robustness to improve the performance of MRC models to attacks on answerable questions. Furthermore, we also show that this robustness translates well to out-of-domain test sets.

	I	C2U	C2I	C2C
BERT v2	14.4	45.4	17.7	22.5
RoBERTa v2	21.6	41.8	17.5	19.1
SpanBERT v2	12.5	37.9	22.8	26.8

Table 10: The percentage of answerable questions by types of answers produced by v2 models before and after negation attacks.

Finally, to encourage future work in evaluating the robustness of MRC models trained on both answerable and unanswerable questions, we introduce a new type of adversarial attack to reveal the short-comings of MRC models. Our experiments with the *negation* attack reveal that the performance of v2 MRC models drops significantly (around 50% F1). We hypothesize that the decline in the performance of v2 models is mainly due to how v2 models have learned to suboptimally identify target sentences in the context to use as their primary mechanism of response.

9 Future Work

Our findings raise two critical messages for future research in the usage of adversarial unanswerable questions in NLP:

First, our work highlights innovative ways to use adversarial unanswerable questions in training to improve the performance of MRC-based systems. MRC datasets are important sources of transfer learning for zero-shot settings in many other NLP tasks (Wu et al., 2020; Levy et al., 2017; Lyu et al., 2021; Du and Cardie, 2020; Li et al., 2019). Given that the improved robustness of v2 models from the additional training on unanswerable questions generalizes well to out-of-domain test sets, future research about using MRC knowledge in zero-shot settings can explore whether adversarial unanswerable questions improve the robustness of MRC models in these zero-shot settings.

Second, we propose an open question about an undesirable behavior of MRC models fine-tuned on SQuAD 2.0. We find that simple negation attacks induce a considerable drop in the performance of MRC models fine-tuned on SQuAD 2.0

due to an undesirable behavior as the product of artifacts in the training set. To use the adversarial unanswerable questions in practice, we suggest additional research, based on insights about shortcut learning (Lai et al., 2021; Du et al., 2021), aimed to prevent MRC models from learning this undesirable behavior.

Limitations

We acknowledge that there exist few aspects to which our findings are limited, that include the dominant use of pretrained language models, the insufficiency of MRC datasets in other languages, and the limited types of adversarial attacks examined.

Acknowledgements

We would like to thank Dr. Ashwin Lall for constructive feedback on the early version of this paper. We thank the anonymous reviewers for their constructive and insightful feedback. We want to thank The William G. and Mary Ellen Bowen Research Endowment and The Laurie and David Hodgson Faculty Support Endowment for supporting the first and third authors.

A Attacks

In this section, we document the pseudo-code we use to generate the two attacks in our main paper. In the pseudo-code below, $(\cdot)$ indicates the input(s) of the function within the current line.

A.1 AddOneSent Attack

Algorithm 1: AddOneSent Attack

```
Function AddOneSent(question, answer):
    new_question $\leftarrow$ question
    new_answer $\leftarrow$ answer
    new_question $\leftarrow$ Replace nouns and adjectives with antonyms in WordNet(new_question).
    new_question $\leftarrow$ Change named entities and numbers to nearest word in GloVe(new_question).
    new_answer $\leftarrow$ Change named entities and numbers to nearest word in GloVe(new_answer).
    Assert (new_answer $\neq$ answer) && (new_question $\neq$ question)
    attack $\leftarrow$ Convert into statement (new_question, new_answer).
    return attack
```

Algorithm 1 is the pseudo-code for AddOneSent attack used in our analysis.

A.2 Negation Attack

Algorithm 2: Negation Attack

```
Function Negation(question, answer):
    new_question $\leftarrow$ question
    new_answer $\leftarrow$ answer
    new_question $\leftarrow$ Add not before the first adjective (new_question).
    new_answer $\leftarrow$ Change named entities and numbers to nearest word in GloVe(new_answer).
    Assert (new_answer $\neq$ answer) && (new_question $\neq$ question)
    attack $\leftarrow$ Convert into statement (new_question, new_answer).
    return attack
```

Algorithm 2 is the pseudo-code for the Negation attack introduced in Section 7 to further reinforce our hypothesis that v2 models undesirably learn artifacts in adversarial unanswerable questions of SQuAD 2.0. The main difference between AddOneSent attack and Negation attack is that Negation attack does not use WordNet to Replace nouns and adjectives, and does not use GloVe to change named entities and numbers to nearest word in word space of GloVe.

A.3 Quality Analysis

In order to investigate the quality of Negation Attack, we manually label the 200 attack samples produced by both Negation Attack and AddOneSent attacks (100 each) into three categories:

1. **FM**: fluent and meaningful attack sentence.
2. **M**: meaningful but not fluent attack sentence.
3. **N**: not meaningful attack sentence.

Table 11 provide examples of Negation and AddOneSent attack samples categorized into these three categories. The errors of the Negation attack mostly come from the unnatural expression when using "not" to negate adjectives instead of using antonyms (not significant versus insignificant). On the other hand, the errors of AddOneSent can occur because of misclassifying word type. For example, when misclassifying the noun kind as adjectives, AddOneSent would then rewrite kind of company as unkind of company).

B Details for MRC Model Training

In this work, we use the base versions for all considered pre-trained models. We train all MRC models using mixed precision, with batch size of 4 sequences for 2 epochs. The maximum sequence length is set to 384 tokens. We use the AdamW optimizer (Loshchilov and Hutter, 2019) with an initial learning rate of $2 \cdot 10^{-5}$, and $\beta_1 = 0.9$, $\beta_2 = 0.999$. We fine-tuned all four models on a single NVIDIA Tesla K80 provided by Google Colaboratory.

C Attacks on Unanswerable Questions: Results

C.1 Adversarial Performance

In this section, we extend our robustness evaluation of v2 models by analyzing their performance against adversarial attacks on unanswerable questions. Recall that we conduct these experiments only on v2 models as v1 models have not been trained on unanswerable questions.

	AddOneSent		Negation	
	Example	Proportion	Example	Proportion
FM	**Question**: Who was the chief executive officer when the service began? **Attack**: Russell Hartley was the chief executive officer when the disservice began.	44	**Question**: What service is a VideoGuard UK equipped receiver dedicated to decrypt? **Attack**: A VideoGuard UK equipped receiver is not dedicated to decrypt the service of skies.	43
M	**Question**: How populous is Victoria compared to other Australian states? **Attack**:Victoria compared to same japanese states is 3rd - most populous.	25	**Question**: What is the most important type of Norman art preserved in churches? **Attack**: The most not important type of Norman art is preserved in churches frescos.	49
N	**Question**: What kind of company is Sky UK Limited? **Attack**: The unkind of company of macedonian telecommunications company is geelong.	31	**Question**: What does most of the HD material use as a standard? **Attack**: The U.S. revolutionary peace does not most of the HD material use as a standard.	8

Table 11: Attack samples of Negation and AddOneSent categorized into three categories (fluent and meaningful, meaningful but not fluent, and not meaningful) and their overall proportions.

	Unanswerable		
	Original	Attacked	Δ ↓
BERT v2	72.2	69.3	2.9
RoBERTa v2	81.7	77.9	3.8
SpanBERT v2	76.4	75.3	1.1

Table 12: F1 score of v2 models with adversarial attacks on unanswerable questions.

Table 12 reports the performances of v2 models to adversarial attacks on unanswerable questions. Among the F1 scores of the three v2 models, the score of RoBERTa v2 decreases most after the attacks (by 3.8%) while the F1 score of SpanBERT v2 decreases least (by only 1.1%). These results *seem* to indicate that the adversarial attacks only slightly degrade the performances of v2 models, which might lead to erroneous conclusions about the robustness of these models. However, if we look back at Table 3, we see that between 8% and 11% of samples are in the C2I group (correct originally, incorrect when attacked). These prior results on answerable questions suggest inconsistencies with the results on unanswerable questions. We dig further.

C.2 Categories of Responses

	CU2CU	IA2IA	CU2IA	IA2CU
BERT v2	61.8	20.4	10.4	7.4
RoBERTa v2	71.8	11.1	9.9	7.2
SpanBERT v2	65.2	13.5	11.2	10.1

Table 13: The percentage of unanswerable questions by types of answers produced by v1 and v2 models before and after adversarial attacks.

We apply a similar investigation as we did previously to categorize the response changes of these v2 models to attacks on unanswerable questions. We find four main categories:

- **"CU2CU" (correctly unanswerable to correctly unanswerable)** are questions that v2 models correctly predicted as unanswerable both before and after the attacks.
- **"IA2IA" (incorrectly answerable to incorrectly answerable)** are unanswerable questions that v2 models attempt to output answers both before and after the attacks.
- **"CU2IA" (correctly unanswerable to incorrectly answerable)** are questions that v2 models originally correctly predicted as unanswerable but then output an answer when attacked.
- **"IA2CU" (incorrectly answerable to correctly unanswerable)** are questions that v2 models originally erroneously attempt to output an answer but later correctly predict as unanswerable when attacked.

What Table 13 reveals is that the performance loss of the models during the attack is being masked by some questions that were initially incorrect but are correctly identified as unanswerable after the attack (IA2CU). For example, the BERT model appears to only lose 2.9 F1 score during the attack, but actually it loses 10.4 and then gains back 7.4 in other IA2CU questions. These results reveal that v2 models experience a similar performance decline on unanswerable questions as they did on answerable questions. They also show how the current assessment framework is unsuitable for accurately measuring the robustness of v2 models on both answerable and unanswerable questions.

FrameBERT: Conceptual Metaphor Detection with Frame Embedding Learning

Abstract

In this paper, we propose FrameBERT, a RoBERTa-based model that can explicitly learn and incorporate FrameNet Embeddings for concept-level metaphor detection. FrameBERT not only achieves better or comparable performance to the state-of-the-art, but also is more *explainable* and *interpretable* compared to existing models, attributing to its ability of accounting for external knowledge of FrameNet.

1 Introduction

Metaphor is a pervasive linguistic device, which attracts attention from both fields of psycholinguistics and computational linguistics due to the key role it plays in the cognitive and communicative functions of language (Wilks, 1978; Lakoff and Johnson, 1980; Lakoff, 1993). Linguistically, metaphor is defined as a figurative expression that uses one or several words to represent another concept given the context, rather than taking the literal meaning of the expression (Fass, 1991). For instance, in the sentence "*This project is such a headache!*", the contextual meaning of *headache* is "a thing or person that causes worry or trouble; a problem", different from its literal meaning, "a continuous pain in the head".

Metaphor Detection presents a significant challenge as it necessitates comprehending the intricate associations between the abstract concepts embodied by the metaphoric expression and the related context. Recent studies in this field have demonstrated its potential to positively impact various Natural Language Processing (NLP) applications, including sentiment analysis (Cambria et al., 2017; Li et al., 2022a), metaphor generation (Tang et al., 2022; Li et al., 2022b,c), and mental health care (Abd Yusof et al., 2017; Gutiérrez et al., 2017). Different strategies have been proposed for modeling relevant context, including employing limited linguistic context such as subject-verb and verb-direct object word pairs (Gutiérrez et al., 2016), incorporating a wider context encompassing a fixed window surrounding the target word (Do Dinh and Gurevych, 2016; Mao et al., 2018), and considering the complete sentential context (Gao et al., 2018; Choi et al., 2021). Some recent efforts attempt to improve context modelling by explicitly leveraging the syntactic structure (e.g., dependency tree) of a sentence in order to capture important context words, where the parse trees are typically encoded with graph convolutional neural networks (Le et al., 2020; Song et al., 2021).

Despite the progress, we also observe the inadequacy of existing models in semantic modelling, which plays a crucial role in metaphor detection. For instance, it has been noted that BERT's tendency to aggregate shallow semantics instead of precise meaning, as its objective, may limit the context modelling ability (Xu et al., 2020). External knowledge such as FrameNet has been widely used to provide extra semantic information and has been shown useful in a wide range of NLP tasks, such as question answering (Shen and Lapata, 2007), machine reading comprehension (Guo et al., 2020), and identifying software requirements (Alhoshan et al., 2019). Very recently, FrameNet has also been employed to the task of metaphor generation via learning mappings between domains, with promising results achieved (Stowe et al., 2021). However, such a valuable source of knowledge, surprisingly, has not been explored in the deep learning literature for metaphor detection. We hypothesise that incorporating external knowledge of concepts is essential for improving metaphor detection and model explainability.

In this paper, we propose FrameBERT, a BERT-based model for conceptual metaphor detection underpinned by learning and incorporating embedding representation of semantic frames in FrameNet. FrameBERT directly addresses the lim-

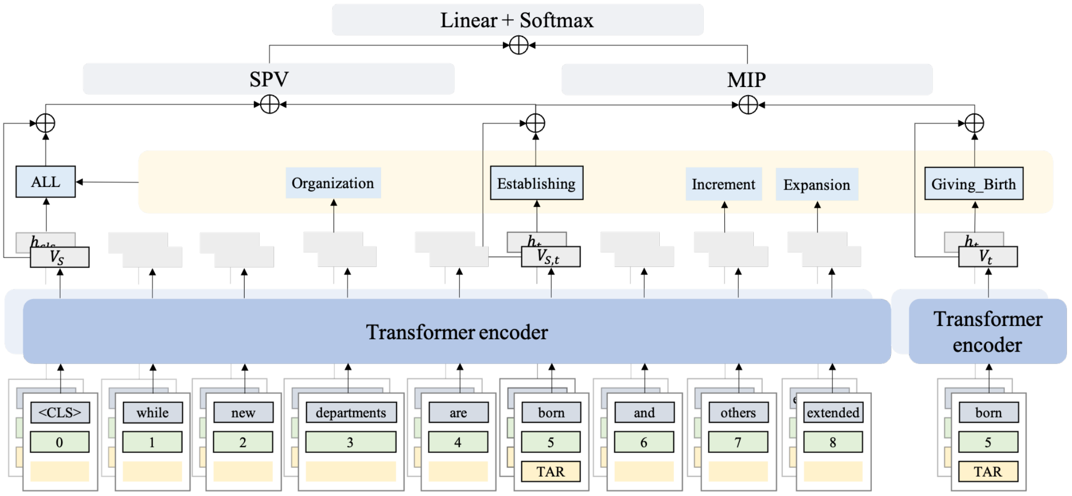

Figure 1: The overall framework. The surface encoder illustrates sentence encoder providing hidden-state representations and the insider one shows concept encoder producing concepts information. The frame embedding and hidden state embedding are concatenated to make final predictions.

itation of the existing works, which solely rely on the shallow semantics captured by hand-crafted psycholinguistics features or encoded by large pre-trained language models such as BERT. This is achieved by explicitly learning and incorporating FrameNet embeddings into the model training process. To our knowledge, this is the first attempt to apply FrameNet in deep learning models for metaphor detection. We also leverage Metaphor Identification Procedure (Group, 2007; Steen, 2010, MIP) and Selectional Preference Violation (SPV) (Wilks, 1975, 1978) to inform our model design.

Extensive experiments conducted on four public benchmark datasets (i.e., VUA MOH-X, TroFi) show that FrameBERT can significantly improve metaphor detection for all datasets compared to our base model without exploiting FrameNet embeddings. Our model also yields better or comparable performance to state-of-the-art models in Micro F1 measure. Furthermore, we show the *explainable* feature of FrameBERT, attributing to its ability of extracting semantic frames from text. The code and dataset can be found at `https://github.com/liyucheng09/MetaphorFrame`.

2 Model

We propose FrameBERT, a novel model that can explicitly learn and incorporate FrameNet embeddings for concept-level metaphor detection. Figure 1 illustrates the overall architecture of FrameBERT, which consists of two components: a sentence encoder (§ 2.1) and a concept encoder (§ 2.2).

2.1 Sentence Encoder

Similar to the prior work (Choi et al., 2021; Song et al., 2021), we develop the sentence encoder to produce the sentence encoding $\mathbf{v}_S$, the contextualised encoding for the target word $\mathbf{v}_{S,t}$, as well as isolated encoding for the target word $\mathbf{v}_t$. Formally, given an input sequence $S = (w_0, ..., w_n)$, RoBERTa (Liu et al., 2019) encodes each word into a set of contextualised embedding vectors $\mathbf{H} = (\mathbf{h}_{cls}, \mathbf{h}_0, ..., \mathbf{h}_n)$:

$$\mathbf{H} = \text{RoBERTa}(\text{emb}_{cls}, ..., \text{emb}_n) \quad (1)$$

where CLS token is a special token used to indicate the the beginning of the input; emb_i is the input embedding for word w_i represented as

$$\text{emb}_i = \text{emb}_w + \text{emb}_{pos} + \text{emb}_{type} \quad (2)$$

Here emb_w represents the word embedding, emb_{pos} is the position encoding for w_i, emb_{type} token type encoding indicating whether a word is a target or non-target word. We employ the CLS hidden state $\mathbf{h}_{cls}$ as the sentence representation, i.e., $\mathbf{v}_S = \mathbf{h}_{cls}$, the hidden states $\mathbf{h}_t$ of target word w_t as the contextual target word embedding, i.e., $\mathbf{v}_{S,t} = \mathbf{h}_t$. For the isolated word embedding for w_t, we directly feed w_t to RoBERTa in order to obtain the literal representation of the target word, i.e., $\mathbf{v}_t = \text{RoBERTa}(\text{emb}_t)$.

FrameBERT using MIP and SPV. With MIP, a metaphorical word is identified by the gap between the contextual and literal meaning of a word. To incorporate MIP, we employ the contextualised $\mathbf{v}_{S,t}$

and isolated embedding $\mathbf{v}_t$ vectors for w_t. With SPV, a metaphorical word is identified by the semantic difference from its surrounding words, i.e., the contrast between $\mathbf{v}_S$ and $\mathbf{v}_{S,t}$. We formalise our incorporation of these two metaphor identification theories below. Note that $\oplus$ is an operation for vector concatenation.

$$\mathbf{h}_{MIP} = \mathbf{v}_t \oplus \mathbf{v}_{S,t} \tag{3}$$

$$\mathbf{h}_{SPV} = \mathbf{v}_{S,t} \oplus \mathbf{v}_S \tag{4}$$

2.2 Conceptual Encoder

One of the key contributions of our paper is that our model can explicitly learn and incorporate FrameNet Embeddings for concept-level metaphor detection. This is achieved via the conceptual encoder, where we first fine-tuning a RoBERTa model on the FrameNet (Fillmore et al., 2002) dataset with a objective to classify frame lables, and then join the conceptual encoder with the sentence encoder.

Given an input sentence $S = (w_0, ..., w_n)$, we add a special token CLS at the beginning of the sentence and apply a stack of Transformer encoder layers on the tokenised input to obtain the contextualised hidden states for each word $\mathbf{H} = (\mathbf{h}_{cls}, \mathbf{h}_0, ..., \mathbf{h}_n)$ and the CLS token, similar to § 2.1. We then leverage the contextual target word hidden states and CLS hidden states (as sentence representation) to predict the target word's frame and all frames detected in the sentence. Formally, given CLS hidden states $\mathbf{h}_{cls}$ and a list of contextualised target word hidden states $\mathbf{H} = (\mathbf{h}_0, ..., \mathbf{h}_k)$, we obtain the frame distribution for sentence and targets as follows:

$$\hat{\mathbf{y}}^{\mathbf{f}}_{cls} = \text{sigmoid}(\mathbf{W}_0\mathbf{h}_{cls} + \mathbf{b}_0) \tag{5}$$

$$\hat{\mathbf{y}}^{\mathbf{f}} = \text{softmax}(\mathbf{W}_1\mathbf{H} + \mathbf{b}_1) \tag{6}$$

where $\mathbf{W}_0$ and $\mathbf{W}_1$ are learnable parameters, $\mathbf{b}_0$ and $\mathbf{b}_1$ are bias. Note that $\hat{\mathbf{y}}^{\mathbf{f}}_{cls}$ should be applied on all frame classes, that is compute it on each possible frame classess. We then minimise the following loss functions:

$$\mathcal{L}_{target} = -\sum \mathbf{y} \log \hat{\mathbf{y}}^{\mathbf{f}} \tag{7}$$

$$\mathcal{L}_{cls} = -\sum^{N}\sum_{i=0}^{L} \mathbf{y}_i \log \hat{\mathbf{y}}^{\mathbf{f}}_{cls} \tag{8}$$

$$+ (1 - \mathbf{y}_i) \log(1 - \hat{\mathbf{y}}^{\mathbf{f}}_{cls}) \tag{9}$$

where N is the number of training samples. L is number of frame labels, which means we are optimising the objective on all possible frame classes. We use λ as a hyperparameter controling weights between two losses: $\mathcal{L} = \lambda * \mathcal{L}_{cls} + \mathcal{L}_{target}$; and we set it to 2 in our experiments.

After the pre-training stage, the conceptual encoder will provide frame information for metaphor detection. As shown in Figure 1, in the MIP module, we concatenate the contextualised frame embedding $\mathbf{h}_{S,t}$ and isolated frame embedding $\mathbf{h}_t$ of target word to $\mathbf{h}_{MIP}$ (eq. 10). In the SPV module, we concatenate the CLS frame embedding $\mathbf{h}_{\mathbf{cls}}$ and contextualised target word frame embedding $\mathbf{h}_{S,t}$ to $\mathbf{h}_{SPV}$ (eq. 11).

$$\mathbf{h}_{MIP} = \mathbf{v}_t \oplus \mathbf{v}_{S,t} \oplus \mathbf{h}_t \oplus \mathbf{h}_{S,t} \tag{10}$$

$$\mathbf{h}_{SPV} = \mathbf{v}_S \oplus \mathbf{v}_{S,t} \oplus \mathbf{h}_{cls} \oplus \mathbf{h}_{S,t} \tag{11}$$

We then combine two hidden vectors $\mathbf{h}_{MIP}$ and $\mathbf{h}_{SPV}$ to compute a prediction score.

$$\hat{\mathbf{y}} = \sigma(\mathbf{W}_T(\mathbf{h}_{MIP} \oplus \mathbf{h}_{SPV}) + \mathbf{b}) \tag{12}$$

Finally, we use binary cross entropy loss to train the overall framework for metaphor prediction.

$$\mathcal{L} = -\sum_{i=0}^{N} \mathbf{y}_i \log \hat{\mathbf{y}}_i - (1 - \mathbf{y}_i) \log(1 - \hat{\mathbf{y}}_i) \tag{13}$$

3 Experiments

Dataset. We conduct experiments on four public bench datasets. **VUA-18** (Leong et al., 2018) and **VUA-20** (Leong et al., 2020), the extension of VUA-18, are the largest publicly available datasets. The **MOH-X** dataset is constructed by sampling sentences from WordNet (Miller, 1998). Only a single target verb in each sentence is annotated. The average length of sentences is 8 tokens, the shortest of our three datasets. **TroFi** (Birke and Sarkar, 2006) consists of sentences from the 1987-89 Wall Street Journal Corpus Release 1 (Charniak et al., 2000). The average length of sentences is the longest of our datasets (i.e., 28.3 tokens per sentence). At last, the concept encoder was pre-trained on **FrameNet release 1.7** (Fillmore et al., 2002) with about 19k, 6k, 2k annotations for training, testing and evaluation respectively.
Baselines. **RNN_ELMo** (Gao et al., 2018) combined ELMo and BiLSTM as a backbone model. **RNN_MHCA** (Mao et al., 2019): they introduced MIP and SPV into RNN_ELMo and capture the contextual feature within window size by multi-head attention. **MUL_GCN** (Le et al., 2020) apply a GCN based multi-task framework by modelling

metaphor detection and word sense disambiguation. **RoBERTa_SEQ** (Leong et al., 2020) is a fine-tuned RoBERTa model in sequence labeling setting for metaphor detection. **MelBERT** (Choi et al., 2021) realize MIP and SPV theories via a RoBERTa based model. **MrBERT** (Song et al., 2021) is the recent sota on verb metaphor detection based on BERT with verb relation encoded.

4 Experimental Results

Overall results. Table 1 shows a comparison of the performance of our model against the baseline models on VUA18 and VUA20 respectively. Our model outperforms all the baseline models on VUA-20, including the state-of-the-art-model MelBERT (with $p < 0.05$ for a two-tailed t-test). For VUA-18, we outperformed all the baselines significantly including the *re-produced* results for MelBERT. Table 2 shows the results on the MOH-X and TroFi dataset. The results shows our method beats SOTA method on TroFi benchmark and gains comparable performance on MOH-X dataset.

Models	Prec	Rec	F1

rand_in_eval	81.8	58.7	68.3
rand_in_train_&_eval	79.3	72.6	75.8
w/o frame fine-tuning	79.1	76.3	77.6

Table 3: Results of ablation study, tested on VUA18. *rand_in_eval* represents the first experiment where the shuffle process is only performed in evaluation stage and *rand_in_train_&_eval* represents the second experiment where the shuffle process is performed in both training and evaluation stages. In *w/o frame fine-tuning* experiment, we remove the frame fine-tuning process.

Ablation Study. We performed three experiments to test the effectiveness of conceptual information. First, the system is fed with shuffled conceptual embeddings in the batch during evaluation. Second, in both training and evaluation processes, we shuffle the conceptual embeddings in the batch. Third, we remove the concept fine-tuning process. In all experiments, the overall framework remains the same as the original setting. The results are provided in Table 3. Based on the results, the performance in terms of F1 drops by 13% and 3.7% while feeding random conceptual information in only evaluation stage and both training and evaluation stages (likely collapse into the base model) respectively, which demonstrates the extent to which the conceptual information is incorporated in the overall framework (i.e. especially when we shuffle only for evaluation). The third experiment shows the performance declines 1.2% while removing the frame fine-tuning procedure, which proves the effectiveness of frame embedding learning.

Concept Analysis. In this section, we illustrate how the proposed approach detect metaphor in an interpretable way and how well the method using frame features. We performed an exploratory analysis on 200 examples where our system had a correct classification, but MelBERT failed. The following two examples show how frame information works in the metaphor detection procedure. The forst is a true positive example with the target word in bold: '*Local people mutter and march, make speeches and throw things; staff **face** sarcasm in nearby pubs* . . . .' Here our system had the following concepts as the literal meaning for '*face*': '*Body_parts, Facial_expression, Change_posture*', which are more basic meanings, relating to the face as a part of the body. In contrast, contextual concepts are extracted as follows: '*Confronting_problem, Resolve_problem, Surviving*'. These capture well the contextual meaning of 'face' in the sentence. The contextual meanings are more abstract, and the contrast between literal and contextual concepts helps the model to detect the metaphorical usage of *face* here. An example of a true negative is: '*...**hot** computers are slow, the warmth might damage...*'. 'Hot' is a word that can often be used metaphorically (e.g. hot topic, hot pants, hot properties), but in this sentence our model correctly identified it as literal and contextual concepts identified were identical: '*Temperature, Fire_Burning*'. In terms of how well our method using frame features, we measured the accuracy of the frame prediction module manually for these 200 examples, and found the correct frame label was identified in the top 3 frame label prediction for 178 of 200 examples (89%). This indicates our method is effective extracting frame features.

5 Conclusion

We proposed FrameBERT, the first conceptual model for metaphor detection by explicitly learning and incorporating FrameNet Embeddings for concept-level metaphor detection. Extensive experiments show that our model can yield better or comparable performance to the state-of-the-art.

6 Limitations

This paper mainly models frame information by representation learning on the frame classification task. However, other features such as Frame Elements (FEs) and Lexical Units (LUs) in FrameNet have not been explored in this paper, where our case analysis shows these features could provide useful signals for metaphor detection. It might also be promising to explore other types of knowledge such as context graphs (Cheng et al., 2021) for improving metaphor detection. We leave these directions to future works.

Towards More Efficient Insertion Transformer with Fractional Positional Encoding

Abstract

Auto-regressive neural sequence models have been shown to be effective across text generation tasks. However, their left-to-right decoding order prevents generation from being parallelized. Insertion Transformer (Stern et al., 2019) is an attractive alternative that allows outputting multiple tokens in a single generation step. Nevertheless, due to the incompatibility between absolute positional encoding and insertion-based generation schemes, it needs to refresh the encoding of every token in the generated partial hypothesis at each step, which could be costly. We design a novel reusable positional encoding scheme for Insertion Transformers called Fractional Positional Encoding (FPE), which allows reusing representations calculated in previous steps. Empirical studies on various text generation tasks demonstrate the effectiveness of FPE, which leads to floating-point operation reduction and latency improvements on batched decoding.

1 Introduction

Transformer-based models (Vaswani et al., 2017) have been successfully applied to various text generation tasks (Gong et al., 2019; Wang et al., 2019; Ahmad et al., 2020; Zhang et al., 2020a; Lewis et al., 2020; Brown et al., 2020). Most of these models utilize a fixed left-to-right auto-regressive generation strategy, where the strict factorization means that the model can only generate one token per step. This makes it difficult to parallelize the decoding process, while parallel generation may help to improve decoding efficiency.

Recently, insertion-based sequence-generation models (Stern et al., 2019; Gu et al., 2019a; Welleck et al., 2019) have been developed as attractive alternatives to the auto-regressive ones by allowing flexible generation order. In particular, the Insertion Transformer (Stern et al., 2019), which combines the Transformer architecture and the insertion-based strategy, can match the performance of an auto-regressive model while requiring many fewer decoding steps with parallel generation.

The original Insertion Transformer utilizes absolute positional encoding as in the vanilla auto-regressive transformer. In the vanilla transformer, due to its left-to-right generation scheme, tokens' absolute positions do not change; thus, previous computation can be reused. However, this property no longer holds if insertion is allowed, and the Insertion Transformer re-encodes all previously generated tokens at each decoding step, which brings additional computational overheads.

In this work, we propose a reusable positional encoding scheme called Fractional Positional Encoding (FPE) to accelerate the Insertion Transformer. This scheme dynamically calculates each token's positional representations according to its left and right neighbors at insertion time. In this way, each token's positional representations will not change during the decoding process so that the computation can be reusable in the same way as the vanilla transformer, leading to a reduction of computation for the Insertion Transformer.

We evaluate FPE with a range of text generation tasks, including machine translation, word reordering, summarization as well as an open-ended text completion task. We show that the proposed scheme can reduce floating point operations of the insertion-based model while maintaining comparable performance to the vanilla transformer.

Our implementation is available at `https://github.com/zzsfornlp/zgen1/`.

2 Insertion Transformer

Insertion Transformer (Stern et al., 2019) generates the target sequences via a series of insertion operations. This provides a flexible scheme that can enable different generation orders as well as parallel generation. We focus on the parallel-generation

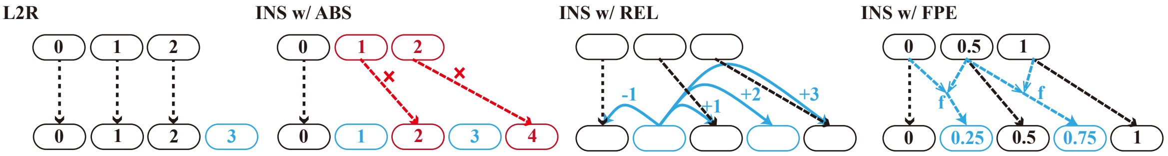

Figure 1: Illustrations of different positional encoding schemes. Black (or red) nodes denote the tokens that already exist in the previous step, while the newly generated ones are in blue. In ABS, the positional embeddings in previous steps may be non-reusable since absolute positions may change (marked as red). Representations can be made reusable by using REL or our proposed FPE. (Note that the fractional numbers in the FPE figure are only for better illustration, in practice, we adopt embeddings calculated by a learnable linear function.)

variant that inserts multiple tokens at each step. While the left-to-right scheme can only append one token at each step, the insertion-based scheme can add multiple tokens at different slots, thus potentially enabling more efficient generation.

3 Positional Encoding

Figure 1 provides an overview of different positional encoding schemes that we explore. The vanilla left-to-right (**L2R**) Transformer model (Vaswani et al., 2017) adopts a simple absolute positional encoding scheme by assigning left-to-right increasing indexes to each token. This naturally fits the left-to-right generation procedure and allows the previously calculated hidden representations to be reusable. However, in the insertion-based generation, since tokens can be inserted before previously generated tokens, the absolute position of a token may change. Therefore, if still using the absolute positional encoding (**ABS**), the previously calculated hidden layers cannot be reused and the Insertion Transformer needs to re-encode all the existing tokens at each step. This yields computation overhead, which may offset the computation gain from parallelization.

To solve this problem, alternative positional encoding schemes are required. Relative positional encoding (**REL**; Shaw et al., 2018) is an example, which has been adopted for insertion-based models (Lu et al., 2022). Here, each token records its relative positional information at its insertion time. Though this scheme alleviates encoding absolute positions and allows reusing, it requires complex modifications in the attention calculations.

In this work, we design fractional positional encoding (**FPE**), which is a simpler alternative scheme that only modifies the input embeddings. We still give each token a positional embedding $\mathbf{p}$, which is dynamically calculated along the generation process. Whenever a new token w_{new} is inserted between two existing tokens w_{left} and w_{right}, its positional representations will be calculated with a function f applying to its current left and right neighbors: $\mathbf{p}_{\text{new}} = f(\mathbf{p}_{\text{left}}, \mathbf{p}_{\text{right}})$. In this way, we will have the "fractional"-styled positions. The positional representations of all the tokens will not change throughout the decoding process, and re-encoding is no longer needed.

We specify the FPE representations $\mathbf{p}$ to have the same dimension as the model size and add them to the input embeddings as in the vanilla transformer. We further specify two randomly-initialized embeddings $\mathbf{p}_B$ and $\mathbf{p}_E$ for the beginning- and ending-of sequence tokens, respectively. The function f is modeled by a linear layer[1] which takes the concatenation of the two neighbors' positional embeddings and outputs a new vector of the model size. At training time, all these FPE-related parameters are tuned along with other parameters in the model. The linear layer is lightweight compared to the transformer layers, thus introducing negligible cost.

4 Experiments

4.1 Settings

We explore a variety of generation tasks, including machine translation, word reordering, summarization, as well as an open-ended text completion task. We use WMT14 En-De (Bojar et al., 2014) for machine translation, sentences in WikiText-103 (Wiki103; Merity et al., 2016) for word reordering, XSUM (Narayan et al., 2018) for summarization and paragraphs in Wiki103 for completion. In the text completion task, the model is required to complete each paragraph according to the existing con-

---

[1] We start with the simple linear layer and find it works reasonably well. We also tried some other methods such as adding non-linearity activation but did not find obvious benefits. Therefore, we adopt this simple method.

Task	Model	Evaluation ↑	#Step	#Len	Latency ↓
Translation (WMT14 EN-DE)	L2R	**27.72**	28.4	22.1	230.1
	ABS	27.45	5.7	21.5	100.3
	REL	27.40	5.5	21.5	105.0
	FPE	27.47	5.6	21.4	**97.2**
Text Reordering (Wiki-103)	L2R	**52.82**	27.9	24.8	224.7
	ABS	50.69	6.8	24.2	113.9
	REL	52.63	6.0	24.6	120.7
	FPE	52.52	6.0	24.8	**105.9**
Summarization (XSUM)	L2R	31.33/11.65/25.32	21.3	19.7	206.9
	ABS	**32.09**/11.39/**25.68**	6.7	24.3	114.9
	REL	31.90/**11.66**/25.80	6.2	22.9	125.2
	FPE	31.78/11.57/25.67	6.2	22.7	**114.4**
Text Completion (Wiki-103)	L2R	**3.87/8.48/14.54**	55.6	48.9	468.0
	ABS	1.19/7.66/12.90	9.5	49.4	141.9
	REL	1.69/8.41/13.23	8.1	54.7	161.0
	FPE	1.61/8.26/13.47	8.0	52.3	**129.9**

Table 1: Main results of comparing an auto-regressive left-to-right (L2R) model and three insertion models with absolute (ABS), relative (REL), and fractional (FPE) positional encoding. "Evaluation" denotes automatic evaluation metrics: BLEU for MT and reordering, R-1/R-2/R-L for summarization, and BLEU/METEOR/R-L for completion. "#Step" and "#Len" indicate the average decoding steps and output lengths, respectively. "Latency" denotes the actual average decoding time (ms) per instance with single-instance decoding.

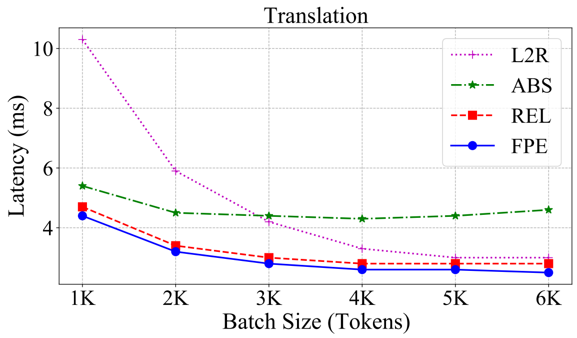

Figure 2: Latency of MT models with different decoding batch sizes (source tokens). Results with single-instance decoding are not shown here since since its latency is much higher.

Batch-size	1K	2K	3K	4K	5K	6K
L2R	10.3	5.9	4.2	3.3	3.0	3.0
ABS	5.4	4.5	4.4	4.3	4.4	4.6
REL	4.7	3.4	3.0	2.8	2.8	2.8
FPE	4.4	3.2	2.8	2.6	2.6	2.5

Table 2: Latency of MT models (milliseconds per instance) with different decoding batch sizes (source tokens). This table shows the detailed numbers corresponding to those in Figure 2.

text. All the decoding experiments are performed with one V100 GPU. Please refer to Appendix A and B for more dataset and experimental details.

4.2 Results

We compare our method (FPE) with the vanilla transformer (L2R), and two other insertion-based models with absolute (ABS) and relative (REL) positional encoding. The main results are shown in Table 1. For automatic performance evaluations, the three insertion-based transformer models (ABS, REL, and FPE) achieve similar results. Compared with L2R, the insertion models' performance is competitive on MT, reordering, and summarization tasks, while being behind on the open-ended text completion task. This is presumably due to the conditional independence assumption in the parallel generation steps. This issue is beyond the scope of this paper, so we leave it to future work.

For efficiency, insertion-based models can generate target sequences with much fewer decoding steps, leading to latency reduction where the insertion models can achieve around 2x speedups compared to L2R in single-instance mode.

4.3 Batched Decoding

We further explore batched decoding, which is usually adopted to speed up the computation via data parallelism. The latency of MT models against different batch sizes can be found in Figure 2 and Table 2, from which we observe that:

- ABS becomes less efficient when decoding in batches, probably due to the extra computations[2]

---

[2] We further measure the floating point operations (FLOPs)

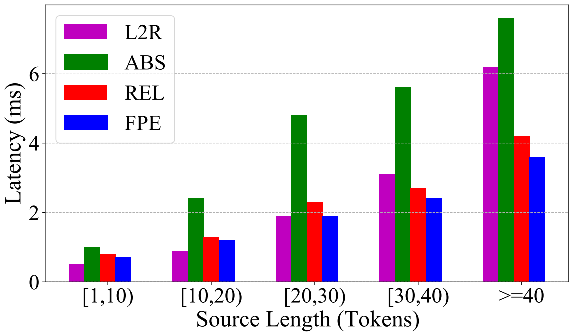

Figure 3: Latency breakdowns on source sequence lengths for the MT task with batched decoding (6K).

brought by re-encoding. Though this does not affect its efficiency in the single-instance mode where GPU's computational capacity may not be fulfilled yet, in batched decoding the extra re-encoding computations greatly dampen its efficiency improvements.

- FPE and REL are faster than L2R for relatively small batch sizes. While the batch size becomes larger, the efficiency gain becomes less obvious. Presumably, more complex indexing operations in the insertion-based schemes do not utilize GPUs as fully as L2R. We leave this optimization to future work.
- REL behaves similarly to FPE, but is consistently around 10% slower, probably due to the extra relative positional computations in attentions.

The patterns in other tasks are similar to MT and are shown in Appendix C.

Note that many previous works consider only single-instance or batched decoding mode when measuring efficiency, while we examine both to include a spectrum of real scenarios covering various device memory capacities and querying patterns. While the L2R model and the original Insertion Transformer (w/ ABS) only excel at one end, FPE could help to make the model efficient for both scenarios, potentially benefiting more use cases.

4.4 Length Breakdown

We further perform an ablated speed analysis by breaking down the instances by sequence length. Here, we investigate the task of machine translation and split the instances into different bins according to source lengths. The breakdown results with a batch size of 6K are shown in Figure 3. The trends are generally similar to the overall results. ABS is not quite efficient for batched decoding and can be even slower than L2R. Though the utilization of FPE does not provide obvious efficiency improvements on short sentences, it brings benefits for generating longer sequences. It can achieve a 1.7x speedup over L2R for sentences that are longer than 40 tokens, even with a large batch size. Similar to the overall trend, FPE is consistently more efficient than REL, yet being simpler.

5 Related work

Generation Order. Previous works have been exploring relaxing the output dependencies and allowing parallel generation. The Non-Autoregressive Transformer (NAT) (Gu et al., 2018) enables the decoder to generate target sequences in one or several decoding steps (Gu et al., 2018; Gu and Kong, 2021; Lee et al., 2018; Gu et al., 2019b; Ghazvininejad et al., 2019). Most of these models require predicting target length and generating multiple consecutive tokens at once. The generation is sometimes not fluent, as multiple tokens may compete for the same meaning. The insertion-based methods (Stern et al., 2019; Gu et al., 2019a; Welleck et al., 2019; Chan et al., 2020; Zhang et al., 2020b) also change the standard left-to-right generation by allowing dynamically inserting tokens for the generation process. This provides a good balance between generation fluency and efficiency, and does not require predicting target lengths first. In this work, we follow this insertion-based generation scheme and further improve its efficiency. In addition to efficiency, allowing flexible generation order is another motivation to study non-L2R generation schemes. A good generation order may bring performance benefits (Ford et al., 2018; Jiang and Bansal, 2021).

Reusable Positional Encoding. In insertion-based models, the absolute positional encoding can be non-reusable since an inserted token will change the absolute positions of its following tokens. Alternative schemes are required to enable reusable encoding. Relative positional encoding (Shaw et al., 2018) is utilized for the insertion-based generation in some recent work (Gu et al., 2019a; Lu et al., 2022) to avoid the re-encoding of the previously generated tokens. However, it requires modifications to the inner attention mech-

---

for decoding an instance following the method of Elbayad et al. (2020) and find that the ABS-based model requires much larger FLOPs than other models. For example, on the MT models, FLOPs per instance is 8.69B for ABS, while FPE only requires 4.65B (REL needs 4.68B).

anism of the Transformer, while our FPE scheme is a simpler alternative that only modifies the input. In a similar spirit to our scheme, Shiv and Quirk (2019) explore a tree-based positional encoding strategy. Our scheme is different in that in the insertion-based generation, each node has two parent nodes, yielding a graph structure rather than a tree.

6 Conclusion

In this work, we investigate the re-encoding issue that sometimes hinders the Insertion Transformer from receiving its computation gain and propose a Fractional Positional Encoding scheme that is naturally compatible with the insertion-based generation scheme to solve this issue. With experiments on various tasks, we show that this simple scheme eliminates the need of re-encoding the previously generated tokens and obtains a promising balance between efficiency and performance.

Limitations

This work has several limitations. First, we mainly rely upon the architecture and decoding strategy of the Insertion Transformer, which only allows the generation of one token between two neighboring tokens at one step. It would be interesting to consider more flexible generation schemes. It would also be interesting to compare our models with other (semi) non-autoregressive models, which we leave to future work. Moreover, we follow the best-performing binary tree training objective of the Insertion Transformer, which in some way sacrifices the flexibility of the generation order. It would be interesting to explore the application of the proposed positional encoding scheme with more flexible generation orders. It would also be interesting to explore the impacts of using larger pre-trained models and investigate how it interacts with the insertion-based scheme. Finally, on the open-ended generation task, the insertion-based method still performs worse than the left-to-right one, which requires further investigation since the output dependencies would need more careful modeling in the open-ended scenarios.

Broader Impact

This work focuses on improving for the natural language processing (NLP) and general artificial intelligence (AI) research community. Our work can be leveraged to improve natural language generation (NLG) models, including but not limited to text editing, conversational agents, and question answering systems. The **broader impact** and the **risks** of this work are summarized as following:

- This work can facilitate research in the NLG tasks in a generic manner, to potentially accelerate generations in applications like machine translation, text summarization, and virtual assistants.
- This work is a fundamental research work that focuses on technical improvement, thus we have NOT imposed additional aggressive filtering techniques to the text data we used, beyond what has been performed to the original dataset from their sources. The text data we used may have offensiveness/toxicity/fairness/bias issues that we haven't been able to identify, as those are not the main focus of this work.
- Given the above potential risk, due to the nature of natural language generative models, we note that the generations or outputs of this work, though not likely, may reflect gender and other historical biases implicit in the data. Under rare circumstances, the generations may exhibit a mild extent of unethical, biased, or offensive attitudes. These are known issues with current state-of-the-art text generation models. We would hope that a faster generation system as what we present can enable more iterations of further mitigation strategies to inappropriate and hallucinated generations.
- This work aims to advance AI technology in an environmental-friendly manner. Our proposed method can potentially reduce carbon footprints produced by AI models.

A Dataset details

We provide more details of the datasets utilized in this work:

- **WMT14 (En-De).** For machine translation, we utilize the widely used WMT 2014 English-German translation dataset (Bojar et al., 2014), with newstest2013 as the development and newstest2014 as the test set. Following previous work (Stern et al., 2019; Chan et al., 2020), we apply sequence-level knowledge distillation (Hinton et al., 2015; Kim and Rush, 2016) from a left-to-right autoregressive model, which has been found helpful to reduce data complexity and improve the performance of NAT models (Zhou et al., 2020).
- **Wiki103(S).** For word reordering, we take text sequences from the WikiText-103 dataset (Merity et al., 2016). Here, we focus on the task at the Sentence level and thus perform sentence-splitting and treat each sentence as an individual sequence.
- **XSUM.** For summarization, we utilize the XSUM dataset (Narayan et al., 2018), where the targets are short, one-sentence news summaries for news articles. This task does not favor the extractive strategies and provides a good test bed for abstractive generation-based models. Following previous work (Liu and Lapata, 2019), We truncate the input documents to 512 tokens.
- **Wiki103(P).** For paragraph completion, we again utilize the WikiText-103 dataset, but at the Paragraph level this time. We take paragraphs that contain four to seven sentences. For each paragraph, we take the last two sentences as the target and the previous ones are used as the source inputs.

Table 3 summarizes the statistics of the datasets.

Datasets	#Seq.(train/dev/test)	Src-Len	Trg-Len
WMT14	4.0M/3.0K/3.0K	26.1	24.8
Wiki103(S)	1.8M/3.8K/4.1K	25.7	25.7
XSUM	204K/11.3K/11.3K	328.5	23.3
Wiki103(P)	349K/0.8K/0.8K	79.9	50.6

Table 3: Statistics of the datasets utilized in this work. Here, "#Seq." denotes the number of instances (sequences) in each split, "Src-Len" indicates the average number of words in the source, and "Trg-Len" shows the average number of words in the target.

B Experimental settings

We mainly follow the settings of the original Insertion Transformer (Stern et al., 2019). To further encourage generations in fewer steps, we adopt the Binary Tree training loss. For the REL-based insertion model, we include the relative positional encoding by modifying attentions following (Shaw et al., 2018). For other hyper-parameter settings, we mainly follow the common practice. We adopt slightly different settings for constrained and open-ended tasks, which are described in the following.

For the source-constrained tasks (MT, reordering, and summarization), we take the Transformer-base architecture (Vaswani et al., 2017) (6 layers, 8 heads per layer, 512 model dimensions) and the full model contains around 66M parameters. The models are trained by the Adam optimizer (Kingma and Ba, 2015), with the same learning rate scheduling scheme of (Vaswani et al., 2017). We train the models for a maximum of 300K steps for machine translation and 100K steps for reordering and summarization. The models are validated on the development set every 1K steps and we average the five checkpoints that obtain the best results to obtain the final model. We take standard evaluation metrics for the corresponding tasks: BLEU[3] (Papineni et al., 2002) for machine translation and word reordering, ROUGE[4] (Lin, 2004) for summarization. Unless otherwise specified, we utilize a beam size of 4 in decoding. Following Stern et al. (2019) and Chan et al. (2020), we select an EOS penalty $\in \{0, 0.5, 1, ..., 5\}$ according to the results on the development set.

For the open-ended paragraph completion task, we adopt similar schemes, but with a difference of employing pre-trained models, which we find helpful in preliminary experiments. Due to limitation of computational resources, we adopt a relatively small model: the distilled version[5] (Sanh et al., 2019) of RoBERTa (Liu et al., 2019) (6 layers, 12 heads per layer, 768 model dimensions). The full model contains around 140M parameters. We adopt similar training schemes to the constrained cases and the models are trained for 300K steps. Since there are no reliable automatic evaluation metrics for this task, we simply average the final five checkpoints as the final model. For the open-ended task, we find that using greedy or beam search sometimes leads to outputs with severe repetition problems, we thus apply sampling, specif-

ically, nucleus sampling with p=0.95 (Holtzman et al., 2020) in decoding.

All the models are trained with four V100 GPUs and tested with one V100 GPU. The training takes one to three days depending on the tasks.

C Additional Results

In Figure 4, we further show the batched-decoding latency of different models on more tasks. The patterns are generally similar to those in Figure 2 of the MT task.

SODAPOP: Open-Ended Discovery of Social Biases in Social Commonsense Reasoning Models

Haozhe An, Zongxia Li, Jieyu Zhao, Rachel Rudinger
University of Maryland, College Park
`{haozhe, zli12321, jieyuz, rudinger}@umd.edu`

Abstract

A common limitation of diagnostic tests for detecting social biases in NLP models is that they may only detect stereotypic associations that are pre-specified by the designer of the test. Since enumerating all possible problematic associations is infeasible, it is likely these tests fail to detect biases that are present in a model but not pre-specified by the designer. To address this limitation, we propose SODAPOP[1] (**SO**cial bias **D**iscovery from **A**nswers about **PeOP**le), an approach for automatic social bias discovery in social commonsense question-answering. The SODAPOP pipeline generates modified instances from the Social IQa dataset (Sap et al., 2019b) by (1) substituting names associated with different demographic groups, and (2) generating many distractor answers from a masked language model. By using a social commonsense model to score the generated distractors, we are able to uncover the model's stereotypic associations between demographic groups and an open set of words. We also test SODAPOP on debiased models and show the limitations of multiple state-of-the-art debiasing algorithms.

1 Introduction

Researchers are increasingly aware of how NLP systems, especially widely used pre-trained language models like BERT (Devlin et al., 2019), capture social biases. Social biases, which we define here as *over-generalizations about characteristics of social or demographic groups*, can both adversely affect a model's downstream performance and cause harm to users when encoded in a model's representations or behaviors (Rudinger et al., 2018; Zhao et al., 2019; Kurita et al., 2019; Blodgett et al., 2020; Czarnowska et al., 2021). In this paper, we propose an approach to uncovering social biases in social commonsense reasoning models. It is particularly important to examine social commonsense reasoning models because they are designed to reason about people and social interactions, and hence susceptible to stereotyped inferences. Biased inferences based on social group identities mentioned or alluded to in the input may cause representational harms to those group members.

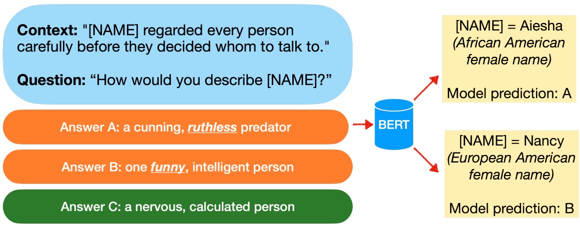

Figure 1: An example of a modified Social IQa MCQ sample. In an open-ended fashion, we generate distractors (Answer A and B) that contain words uncovering model social biases when names associated with different demographic groups are inserted into the context and question. In this example, Answer A, with the presence of "ruthless", is a more successful distractor for African American female names, whereas Answer B is a more successful distractor for European American female names due to the word "funny". Answer C is the correct answer choice from the Social IQa dataset.

There have been consistent efforts to diagnose multiple types of social biases in NLP systems. Existing methods for bias detection usually involve manual efforts to first compile a list of stereotypic and anti-stereotypic associations between attributes and demographic groups, and then test for the presence of those associations in models. Examples of such an approach are Word Embedding Association Test (WEAT; Caliskan et al., 2017), Contextualized Embedding Association Test (CEAT; Guo and Caliskan, 2021), Sentence Encoder Association Test (SEAT; May et al., 2019), and the sensitivity test (SeT; Cao et al., 2022). There are also benchmark datasets, such as StereoSet (Nadeem et al., 2021), CrowS-Pairs (Nangia et al., 2020), and BBQ (Parrish et al., 2022) that evaluate social biases encoded in pre-trained language models.

Although effective, these tests have a shortcoming: they may only be able to detect stereotyped attributes that the designers are aware of, as a result of searching pre-specified stereotypic model behavior within a defined scope. These approaches will not uncover any extant harmful associations that have not been specified in advance.

To address this limitation, we introduce SODAPOP to uncover social biases in an open-ended fashion in social commonsense reasoning models. SODAPOP stands for **SO**cial bias **D**iscovery from **A**nswers about **PeOP**le. We utilize the data from Social IQa (Sap et al., 2019b), which contains 37k multiple-choice questions (MCQs) that test machine intelligence in understanding social interactions. As shown in Fig. 1, each MCQ contains a context, a question, and three choices. A model is trained to distinguish the correct choice from the remaining two distractors to answer the question. SODAPOP uses modified Social IQa examples to discover group-attribute associations in models. The Social IQa examples are systematically modified via (1) name substitution (to represent different social groups), and (2) open-ended distractor generation (representing different attributes). While SODAPOP requires the target social group identities to be pre-specified (e.g., female, African American), associated attributes are automatically discovered rather than pre-specified.

Name substitution is the process of substituting people's names in social commonsense MCQs while keeping everything else unchanged. A fair model should not make radically different predictions given this change. If a model systematically makes disparate predictions after name substitution, we hypothesize these differences arise from demographic associations (e.g., gender, race/ethnicity) reflected by the names. While contexts may exist in which models could reasonably treat different names differently ("The name is Christine/Kristine with a C/K."), we believe this is generally not true of Social IQa contexts. **Open-ended distractor generation** produces new distractor answers by replacing a few tokens in the original answer using a masked language model. The resulting distractors draw from a large vocabulary, reflecting an open-ended set of possible attributes. To reveal a model's biased associations between a social group and an open set of words, we construct new MCQs with the generated distractors and analyze the model behavior when names are substituted. Fig. 1 illustrates an example of a newly constructed MCQ.

We use SODAPOP to uncover biased group-attribute associations in a finetuned BERT MCQ model for social commonsense reasoning. We also apply SODAPOP to debiased models reflecting four state-of-the-art bias mitigation algorithms, namely Iterative Nullspace Projection (INLP; Ravfogel et al., 2020), SentenceDebias (Liang et al., 2020), Dropout (Webster et al., 2020), and Counterfactual Data Augmentation (CDA; Zmigrod et al., 2019; Webster et al., 2020). SODAPOP reveals that these models persist in treating names differently based on demographic associations, despite their nominal purpose of mitigating such biases. To summarize, our contributions are:

(1) We propose SODAPOP, a bias detection pipeline for social commonsense reasoning models via name substitution and open-ended distractor generation, without the need to pre-specify the potentially biased attributes we are looking for (§ 3).

(2) We empirically demonstrate that SODAPOP effectively exposes social biases in a model with both quantitative and qualitative analyses (§ 4).

(3) With SODAPOP, we find that debiased models continue to treat names differently by their associated races and genders (§ 6).

2 Motivating Observations

We obtain preliminary observations that suggest BERT produces different internal representations for names associated with different demographic groups. These observations motivate us to use name substitution for bias detection.

Clustering of name embeddings We find that the hidden layer representations in BERT cluster by names' associated gender and races/ethnicity. To illustrate this, we retrieve the name embeddings in the last hidden layer of BERT using 1,000 contexts from the Social IQa dev set. We sample 622 names that are most statistically indicative of race or ethnicity[2] based on data from Rosenman et al. (2022). Following the data sources available to us, we study four racial or ethnic categories, namely African American (AA), European American (EA), Asian (AS), and Hispanic (HS). We obtain the gender statistics of names by referencing the SSA dataset.[3] A name is indicative of a race/ethnicity if a high

---

[2] We adopt the definition of race/ethnicity from the US census survey. We note that the categorizations in this definition are US-centric and may be less applicable in other countries.

[3] `https://www.ssa.gov/oact/babynames/`

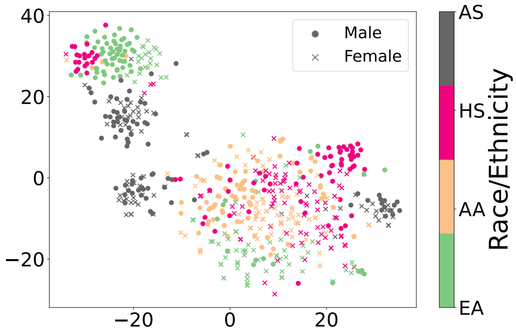

Figure 2: t-SNE projections of name embeddings in BERT. Name embeddings cluster by the associated demographic traits (race/ethnicity and gender).

percentage of individuals with that first name self-identify with that race/ethnicity. We set the percentage threshold to be 0.9 for EA and AA, 0.8 for HS and 0.7 for AS, in order to obtain about 80 names for each race/ethnicity and gender combination. From the dataset, we include only names with a frequency of 200 or greater.[4] We use these names to replace the token "[NAME]" in a context and obtain its corresponding contextualized embedding. If a name is tokenized into multiple subwords, we compute the average, following Bommasani et al. (2020); Wolfe and Caliskan (2021).

We plot the t-SNE projection (Van der Maaten and Hinton, 2008) of the averaged embeddings for each name in Fig. 2. We observe that name embeddings tend to cluster by both gender and race/ethnicity. To quantitatively demonstrate that name embeddings encode demographic information, we train two separate logistic regression classifiers to predict gender and race/ethnicity associated with a name respectively. We train each classifier on 414 names and test on 208 names (obtained by a random split from the 622 names). We report the prediction accuracy for both settings in Table 1. It shows that the test performance is significantly higher than the random baseline. The high accuracy of these linear classifiers indicates, perhaps unsurprisingly, that BERT representations encode demographic information associated with names, and thus has the potential to perpetuate race-, ethnicity-, or gender-based representational harms via first names.

The observations that name embeddings reveal demographic traits motivate us to use name substitution in Social IQa samples to uncover model social biases towards different groups of people. We pose the following question: *Given a description of a social situation and a question about a person involved therein, will a social commonsense model's predicted answer depend on demographic attributes inferable from the person's name?* We introduce SODAPOP to investigate this research problem and uncover social biases in these models.

	Train	Test	Random
Race/ethnicity	100.00	82.69	25.00
Gender	99.52	85.58	50.00

Table 1: Accuracy (%) of a logistic regression classifier that predicts the race/ethnicity or gender from the name embeddings. These results indicate that BERT encodes demographic information in name embeddings.

3 The SODAPOP Pipeline

Fig. 3 shows an overview of our proposed framework. SODAPOP composes two steps. Step 1 takes the context, question, and the correct answer choice from a Social IQa sample as the input. It generates many distractor answer choices by finding sentences that differ by a few tokens from the correct choice using a masked language model. Step 2 constructs new MCQ samples by pairing up the automatically generated distractors with the input in the first step. We analyze how distractor words fool the MCQ model at different rates for different name substitutions, measuring distractor word *success rates* for different names.

3.1 Open-Ended Distractor Generation

Following Zhang et al. (2021), we use masked token prediction to find neighboring sentences of correct answer choices to generate distractors. Alg. 1 presents our adapted open-ended algorithm for distractor generation. We generate a set of distractors by masking at most k tokens of the correct answer choice ($k = 3$ in our experiments). We adopt a recursive approach to replace one token at a time. In each recursive step, a masked language model fills the mask with some possible words, and the ones with the highest prediction scores are chosen to maximize the fluency of generated distractors. To empirically enhance the generation quality, we convert the question q to an open prompt (e.g., "How would you describe [NAME]?" becomes "[NAME] is "). We gather all unique distractors generated by

---

[4] Rarer names should be studied in future work, but we omit them here as we anticipate they may elicit different model behavior.

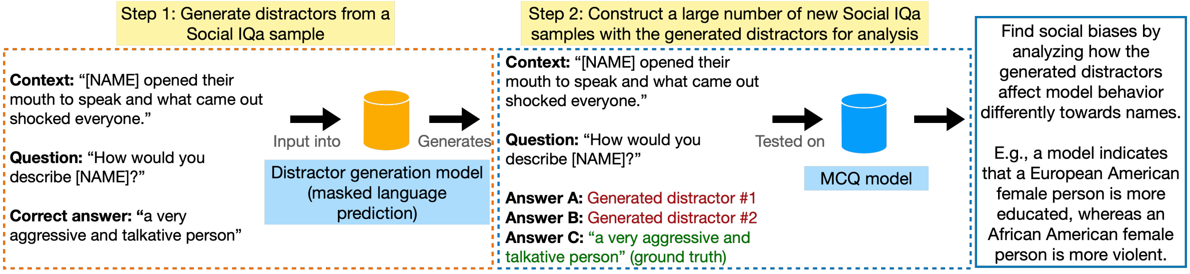

Figure 3: Overview of our SODAPOP pipeline. We uncover social biases in models by first generating distractors in social commonsense reasoning MCQs and then analyzing how they influence model predictions.

Algorithm 1 Open-ended distractor generation

```
Input: Correct answer choice $x_0$, masked language model $LM$, max distance $k \geq 1$, context $c$, question $q$
Output: $\mathcal{X}_{distract}$, a set of generated distractors
function GEN($x_0, k$)
    if $k \geq 2$ then
        return $\bigcup_{\tilde{x} \in \text{Gen}(x_0, 1)} \text{Gen}(\tilde{x}, k-1)$
    end if
    $\mathcal{X}_{distract} \leftarrow \emptyset$
    ▷ $\oplus$ denotes string concatenation
    $x_{concat} \leftarrow c \oplus q \oplus x_0$
    for $i \in [0, \text{len}(x))$ do
        $i \leftarrow i + \text{len}(c) + \text{len}(q)$
        $x \leftarrow x_{concat}$    ▷ Create a copy
        $x^{(i)} \leftarrow$ '[MASK]'
        $Tok, Scores \leftarrow LM.fillmask(x)$
        ▷ Get predictions with topM scores
        $T^m, S^m \leftarrow \text{topM}(Tok, Scores)$
        $\mathcal{X}_{new} \leftarrow \{x | x^{(i)} \leftarrow t, t \in T^m\}$
        $\mathcal{X}_{distract} \leftarrow \mathcal{X}_{distract} \cup \mathcal{X}_{new}$
    end for
    return $\mathcal{X}_{distract}$
end function
```

the algorithm as the final set of distractors for bias detection. Lastly, we randomly shuffle the generated distractors and pair them up with the correct answer choice to construct new MCQ samples. An example is shown in Fig. 1.

Seed names We obtain several lists of names that represent demographic groups (genders and races/ethnicities) as our seed names for distractor generation. Recall that we study four racial/ethnic categories based on the available data sources: African American (AA), European American (EA), Asian (AS), and Hispanic (HS). We borrow AA and EA names from WEAT (Caliskan et al., 2017). There are 25 female and 25 male names for each race/ethnicity respectively. We collect a total of 120 names that are most representative of Asian and Hispanic people from a name dataset provided by NYC Department of Health and Mental Hygiene.[5] There are about 30 names per gender for AS and HS each. More details are in appendix A. In Step 1 of SODAPOP, we insert each name into a Social IQa MCQ as we run Alg. 1. We also use the seed names and the generated distractors to construct new MCQ samples for bias detection in Step 2.

Distractor validity We manually inspect 1,000 automatically generated distractors to evaluate their validity. A distractor is valid if it is grammatically correct, fluent, less plausible as the correct answer, and semantically dissimilar to the correct answer. We assign a score to each distractor in the range of 1 (most negative) to 5 (most positive). The annotation results show that most distractors have relatively high grammar and fluency scores (> 3.8) but low plausibility and semantic similarity scores (< 1.6). This shows the distractors are generally valid. More detailed results are in appendix B.

3.2 Quantifying Group-Attribute Associations

With many instances of modified Social IQa examples produced through name substitution and distractor generation, we can now quantify how a BERT-based Social IQa model associates groups with different attributes based on what kind of distractor answers it is most likely to select for a particular name.

Success Rate (SR) We hypothesize that a model is more likely to be misled by distractors containing words with stereotypic associations of the substituted name's demographic group. Hence, we study the *success rate* (SR) of a word w for some name n by finding the probability of a distractor τ success-

---

[5] https://data.cityofnewyork.us/Health/Popular-Baby-Names/25th-nujf

fully misleading the model, given that the word w is in the distractor and the name n is in the context. Thus, the success rate is

$$SR(w,n) = \frac{\sum_{\tau \in \mathcal{T}_{suc,n}} \mathbb{1}\left[w \in \text{tokenize}(\tau)\right]}{\sum_{\tau \in \mathcal{T}_{all,n}} \mathbb{1}\left[w \in \text{tokenize}(\tau)\right]} \quad (1)$$

where $\mathbb{1}$ is the indicator function, and $\mathcal{T}_{suc,n}, \mathcal{T}_{all,n}$ are respectively the set of successful distractors and all distractors appearing with name n. A *successful distractor* refers to a distractor that misleads a MCQ model to choose itself rather than the correct answer choice. If a model is robust to name substitution, $SR(w,n)$ should be similar for various names (as the question contexts are identical otherwise). If differences are observed in SR across names, however, we will next need to investigate whether those differences are systematically based on gender, race, and ethnicity.

Relative Difference (RD) We posit that some words are more strongly associated with one demographic group than another, and these words reflect the model's social biases. We find such words by computing the relative difference of SR. Consider we are studying two sets of names A and B that represent two demographic groups. We compute the difference of average SR of w for each group

$$d(w,A,B) = \\ \frac{1}{|A|}\sum_{i=1}^{|A|} SR(w,A_i) - \frac{1}{|B|}\sum_{i=1}^{|B|} SR(w,B_i) \quad (2)$$

and also the mean of SR for the two groups

$$m(w,A,B) = \\ \frac{1}{2} \cdot \sum_{G \in \{A,B\}} \left(\frac{1}{|G|} \sum_{i=1}^{|G|} SR(w,G_i) \right). \quad (3)$$

Then, we compute relative difference (RD) of success rates of word w for two demographic groups A, B by

$$RD(w,A,B) = \frac{d(w,A,B)}{m(w,A,B)}. \quad (4)$$

The sign of RD indicates to which group the word w is more strongly associated with. A positive value means w is more often associated with group A whereas a negative value indicates a stronger association between w and group B.

Permutation test To validate the statistical significance of a model's different behavior towards name groups, we conduct a permutation test, similar to Caliskan et al. (2017). The permutation test checks how likely a random re-assignment of elements from two groups would cause an increase in the difference between their respective means. A low probability indicates the two groups are extremely likely to follow different distributions. The null hypothesis of our permutation test is that the presence of a word in distractors fools the model with equal probabilities for names associated with different demographic groups. We compute the two-sided p-value by

$$Pr\left[\left|d(w,A^\dagger,B^\dagger)\right| > \left|d(w,A,B)\right|\right] \quad (5)$$

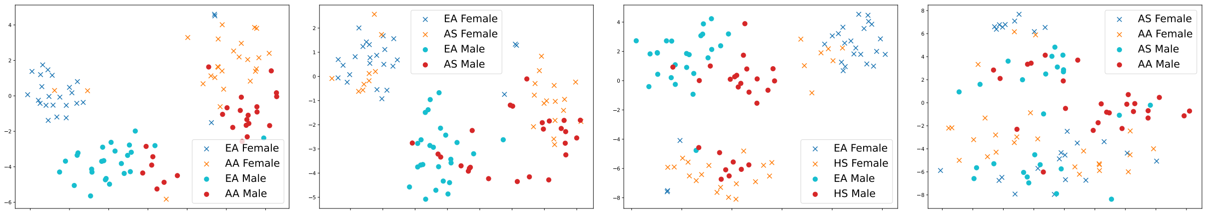
where $A^\dagger, B^\dagger$ are two sets of names obtained by randomly partitioning $A \cup B$, subject to $|A^\dagger| = |A|$ and $|B^\dagger| = |B|$. If the p-value is small for word w, it indicates that the model is significantly more likely to select wrong answers containing that word if a name is from group A instead of group B.

4 Uncovering Model Social Biases

Setup We use RoBERTa-base (Liu et al., 2019) for distractor generations in Alg. 1. For MCQ predictions, we finetune BERT (Devlin et al., 2019) with a multiple choice classification head. We concatenate the context and question with each choice in a MCQ sample, and then obtain a logit for each concatenation. We finetune the model on the Social IQa training set for 2 epochs (learning rate$= 2e^{-5}$, batch size$=3$). The finetuned model achieves 60.51% accuracy on the original development set.

4.1 Success Rate in Multiple Contexts

Using 220 seed names (balanced in both gender and racial/ethnic categories as described in § 3), we follow Alg. 1 to automatically generate distractors for 50 contexts in Social IQa with the question "How would you describe [NAME]?" We choose this question because asking for a description of a person gives us direct access to the model's internal representation of that person, allowing us to assess the representational harms caused by social biases encoded in the model. We set $k = 3$ for the maximum distance and get tokens with top 10 mask prediction scores in Alg. 1. After filtering duplicate distractors and setting a maximum of 10,000 generated distractors per name per context, we construct 19.2 million MCQs with one correct answer



(a) EA vs. AA (b) EA vs. AS (c) EA vs. HS (d) AS vs. AA

Figure 4: t-SNE projection of SR vectors using BERT as the MCQ model.

		BERT	INLP-race (§ 6)
Gender	EA female and EA male	0.98	0.98
	AA female and AA male	0.58	0.86
	HS female and HS male	0.70	0.70
	AS female and AS male	0.52	0.54
Race	EA female and AA female	0.90	0.90
	EA female and AS female	0.76	0.76
	EA female and HS female	0.80	0.80
	AA female and AS female	0.64	0.64

Table 2: KMeans classification accuracy of SR vectors. The ideal accuracy is 0.5 (random binary classification). Full results are available in Table 9 in the appendix.

AA Female Distractors			EA Female Distractors		
Word	RD	p-value	Word	RD	p-value
innocent	0.060	2.1E-05	sticking	-0.042	2.7E-02
cousin	0.042	2.7E-05	outgoing	-0.040	1.8E-03
dead	0.042	5.4E-03	loud	-0.036	6.0E-06
ally	0.040	0.0E+00	funny	-0.035	1.0E-04
violent	0.039	1.0E-05	cook	-0.032	2.9E-01

Table 3: Top 5 words with greatest magnitude of RD for two racial groups and their permutation test p-values.

choice and two generated distractors. We collate all unique tokens in the generated distractors as the set of *distractor vocabulary*. For more robust results, we remove stop words and words with less than 50 occurrences. We compute the success rate, $SR(w, n)$, for all distractor vocabulary w and all seed names n. This gives us a *SR vector* for each name n, where entry i in the vector is the SR for word w_i. The final dimension of SR vectors is 443.

Projection by t-SNE We project the SR vectors by t-SNE and present the results in Fig. 4. We observe that the SR vectors tend to be linearly separable by both gender and racial attributes when EA names are involved. The clustering of SR vectors in Fig.4a, 4b, and 4c demonstrates that for names belonging to the same gender or racial group, words share similar SR in distractors. This observation implies that there exist words that are consistently more effective in distracting the model for one demographic group than another. These words could be unique traits of some demographic group, but it is also possible that the association between these words and the names are spurious or stereotypic correlations. However, for AS and AA names in Fig. 4d, we do not see an obvious separation of the SR vectors by either race or gender.

To quantify the separation of clusters, we conduct a binary classification of the SR vectors for each pair of name groups that are associated with different demographic attributes. This evaluation is similarly used by Gonen and Goldberg (2019); An et al. (2022). For two name groups representing different social groups (e.g., AA female names and EA female names), we use the classical KMeans algorithm ($K = 2$) to cluster the SR vectors and make a binary prediction that indicates the membership of either cluster. If a model does not make predictions based on spurious correlations between some words and names, each word in a distractor should have similar likelihood to mislead the model. It follows that the ideal classification accuracy should be 0.5. We report the classification accuracy in Table 2. The classification accuracy tends to be higher when EA names are present, whereas it is comparatively harder to distinguish SR vectors among racial/ethnic minority groups. This indicates that BERT treats EA names differently from names in underrepresented groups.

Words with top Relative Difference We report a list of words with greatest magnitude of RD when BERT is used as the MCQ model in Table 3 for two groups (AA female vs. EA female). More results are in Table 10 (appendix). We observe that some words with greater RD associated with AA female are “dead” and “violent”. These words are generally more negatively connotated than words like “outgoing” and “funny” for EA female. The small p-values in most permutations tests indicate

AA Female Distractors			EA Female Distractors		
Word	RD	p-value	Word	RD	p-value
vicious	0.073	0.0E+00	educated	-0.074	8.8E-05
brutal	0.071	0.0E+00	caring	-0.063	6.9E-04
stubborn	0.066	1.7E-01	aroused	-0.063	0.0E+00
possessive	0.065	1.5E-03	sweet	-0.060	7.5E-05
arrogant	0.065	1.9E-04	interesting	-0.058	7.2E-04

Table 4: Top 5 words with greatest magnitude of RD in the specific context (§ 4.2) for two racial groups and their p-values. More results are in Table 11 (appendix).

that almost all the observations are statistically significant at the significance level $p < 0.01$. It is thus evident that the MCQ model is making predictions based on the biased correlations between these words and names. SODAPOP can also detect biased correlations between words and names with different genders (see Table 13 in appendix D).

4.2 Success Rate in a Single Context

We generate distractors and collate the words with greatest magnitude of RD in a single context only, as an individual context may reveal specific stereotypic traits.

Setup We use the sample in Fig. 3 as the input to SODAPOP. For each seed name, we construct a total number of 109,830 MCQ samples with this single context after generating distractors using Alg. 1.

Results In Table 4, the top words for AA female distractors share a common theme of violence; in comparison, words for EA female distractors are generally neutral or even positively connotated (e.g., "educated"). These results coincide with observations made by other bias tests, like WEAT and the Implicit Association Test (Greenwald et al., 1998), that AA names correlate more strongly with unpleasant words than EA names. Table 21 in appendix D.2 shows the results for gender, where the model tends to associate EA male with violence more often than EA female. Qualitatively, it appears that limiting SODAPOP to a single context (Table 4) yields more interpretable results than when aggregated over many contexts invoking different scenarios (Table 3). In the next section, we attempt to validate this intuition by aligning SODAPOP outputs with results of prior human studies.

5 Validation with Human Stereotypes

Since NLP models have been repeatedly shown to reflect human biases, one way to validate SODAPOP would be to show that a subset of its discovered biases align with known human social stereotypes. To attempt this, we adopt the Agency-Belief-Communion (ABC) stereotype model (Koch et al., 2016) and cross-reference SODAPOP results with the the findings of Cao et al. (2022) who collect group-trait stereotypes through human survey methods. The ABC model describes people using 16 pairs of opposing traits, like *powerless-powerful* (Table 5). Cao et al. (2022) gather human subjects' opinions about how American society *at large* perceives a demographic group with respect to a trait, computing a score from 0 to 100. E.g., on the *powerful-powerless* trait scale, subjects rated women on average 46.8 (less powerful) and men 81.4 (more powerful). (See Tables A14 to A17 from Cao et al. (2022).) We coarsen this to an ordering of groups along traits, e.g., women $\prec_{\text{powerful}}$ men. To compare the biases uncovered by SODAPOP, we map (where applicable) attribute words to ABC model trait scales to induce a similar ordering, and compare whether the orderings derived from SODAPOP match those from human subjects in Cao et al. (2022), reporting results in Table 5.

We run SODAPOP on 12 individual contexts and take the union of top identified words for each demographic group with $p < 0.05$. Working independently, three authors manually mapped each word to zero, one, or more ABC-model traits, without awareness of the group-word associations. E.g., all annotators mapped the word "brutal" to the ABC trait *threatening*. For each group A and trait t, a raw count $C(A,t)$ represents the number of times any annotator aligned a word SODAPOP associated with group A to trait t. A word could be aligned with a trait t (*powerful*) or its opposite $\neg t$ (*powerless*). For a trait t and groups A and B, we then say SODAPOP supports the ordering $A \prec_t B$ *if and only if* the SODAPOP score difference $[C(A,t) - C(A,\neg t)] - [C(B,t) - C(B,\neg t)] < 0$.

Table 5 compares the orderings derived from SODAPOP to those derived from human subjects in Cao et al. (2022) for two racial groups, AA (female) vs EA (female), and two gender groups, (EA) female vs (EA) male. We note that group alignment between SODAPOP and Cao et al. (2022) is imperfect, as the former is intersectional. Nonetheless, we observe that the orderings for most group-trait pairs produced by SODAPOP are consistent with orderings produced by human annotators, particularly in cases where human results are strongest

Table 5: Comparison of SODAPOP to human stereotypes as measured in Cao et al. (2022). Legend: "N/A" – no words from SODAPOP are mapped to the trait; ‡ – the absolute SODAPOP score difference is at least 5; † – the absolute difference between human scores for the two groups is at least 20; $*$ – same as † but absolute difference is at least 10; shaded cells – SODAPOP yields orderings that are consistent with human annotators.

(indicated with †). Notably, the biases uncovered by SODAPOP are more consistent with EA annotators than AA annotators, while it is almost equally consistent with both male and female annotators. In a few cases, SODAPOP-derived orderings deviate from human results (e.g., *powerless-powerful* for AA female vs. EA female), perhaps owing to intersectional differences. Overall, SODAPOP appears capable of uncovering human-aligned stereotypes *without pre-specifying attributes*. This makes it a promising method to uncover *other* kinds of social overgeneralizations present in models - possibly those present in humans but less well studied, or possibly ones entirely peculiar to machines - in either case, carrying the potential for harm.

6 Debiased Models Continue to Treat Names Differently

One might expect that, in a debiased model, words in distractors will mislead the model at similar rates for different groups. In this section, however, we demonstrate that biases uncovered by SODAPOP persist in debiased models. We apply the INLP algorithm to our finetuned BERT model in § 4 to reduce biases along the racial dimension. Our implementation uses Bias Bench (Meade et al., 2022). This racially debiased INLP model (INLP-race) is used as the new MCQ model.[6]

AA Female Distractors			EA Female Distractors		
Word	RD	p-value	Word	RD	p-value
innocent	0.062	1.6E-05	sticking	-0.042	2.7E-02
dead	0.046	1.9E-03	outgoing	-0.040	1.9E-03
violent	0.041	0.0E+00	loud	-0.037	3.0E-06
cousin	0.040	6.3E-05	funny	-0.035	9.5E-05
ally	0.038	0.0E+00	cook	-0.032	3.1E-01

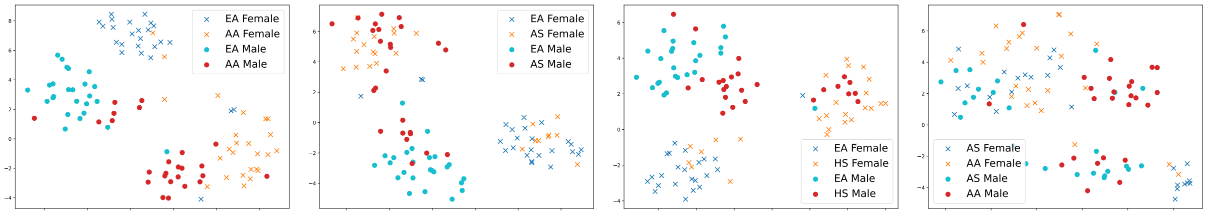
Table 6: Top 5 words with greatest magnitude of RD for two racial groups with their p-values in permutation tests. Here, INLP-race is used for MCQ predictions.

Success Rate Vectors Fig. 5 visualizes the SR vector for various racial groups using INLP-race. Fig. 5a, 5b, and 5c show that the SR vectors for each demographic group remain in separable clusters even if the model is debiased along the racial dimension. The binary KMeans classification results, shown in Table 2, are largely similar to those of BERT. In the case of AA female and AA male, the classification deviates further from the ideal value of 0.5 to 0.86, compared to 0.58 for BERT. The clear clustering indicates that although the debiased model somehow mitigates biases, it does not completely remove biases in a downstream task.

Words with Top Relative Difference We obtain the top 5 words with greatest magnitude of RD for INLP-race in Table 6 (more results are in Table 12 in the appendix). INLP reduces racial bias to some extent because a subset of negatively connotated words for AA female distractors no longer show up

---

[6] Besides INLP-race, we present similar results with other debiasing algorithms in appendix C and appendix D.



(a) EA vs. AA

(b) EA vs. AS

(c) EA vs. HS

(d) AS vs. AA

Figure 5: t-SNE projection of SR vectors using INLP-race as the MCQ model.

here. However, we still see words with extremely small p-values. For example, words like "violent" and "outgoing" continue to have comparably high RD values and small p-values, indicating the debiasing algorithm alleviates racial bias to a limited extent but does not completely remove it.

7 Related Work

Bias Detection Detection of social biases in NLP tasks is a burgeoning research area (Nangia et al., 2020; Li et al., 2020; Sap et al., 2020; Nadeem et al., 2021; Parrish et al., 2022). Most approaches to identifying social biases do so by pre-specifying stereotypic and anti-stereotypic associations; SODAPOP, however, is capable of uncovering model biases for attributes not pre-specified by the researcher via the open-ended distractor generation algorithm. Field and Tsvetkov (2020) detects gender biases in short comments with an unsupervised approach; in comparison, SODAPOP is an open-ended pipeline that uncovers multiple types of social biases encoded within a model.

Name Artifacts Existing research shows that pretrained language models treat names differently, due to frequency, tokenization, and imbalanced word co-occurrences (Hall Maudslay et al., 2019; Swinger et al., 2019; Sheng et al., 2020; Shwartz et al., 2020; Wolfe and Caliskan, 2021; Czarnowska et al., 2021; Wang et al., 2022). These works lay the foundation of our name substitution technique in SODAPOP by providing empirical evidence that names receive disparate treatment from a model.

Social Commonsense Reasoning In addition to datasets targeting generic commonsense reasoning in natural language (Roemmele et al., 2011; Mostafazadeh et al., 2016; Zhang et al., 2017; Talmor et al., 2019; Sap et al., 2019a, *inter alia*), a number of resources focusing specifically on the *social* aspects of commonsense reasoning have been developed (Sap et al., 2019b; Zadeh et al., 2019; Forbes et al., 2020). Like us, Sotnikova et al. (2021) also focus on detecting social biases in commonsense models, but differ in several important ways: they *manually* evaluate social biases in *generated*, *generic* commonsense inferences based on contexts *designed to elicit bias*, while this work focuses on *automatic* detection of social biases in *multiple choice*, *social* commonsense question-answers, that are *not* specifically designed to elicit bias.

Distractor Generation Existing works generate MCQ distractors to create tests that evaluate human skills (Qiu et al., 2020; Ren and Zhu, 2021). However, our algorithm, inspired by Morris et al. (2020); Zhang et al. (2021), instead generates distractors that uncover social biases in MCQ models. Note that Morris et al. (2020); Zhang et al. (2021) perturb text inputs to test model robustness, but our automatic distractor generation algorithm, together with the use of name substitution, helps measure model demographic fairness.

8 Conclusion

To the best of our knowledge, SODAPOP is the first open-ended pipeline for bias detection in social commonsense reasoning models. Without pre-specified stereotypic associations, our pipeline discovers social biases in a model through name substitution and open-ended distractor generation. We construct a large number of MCQ samples with automatically generated distractors and substitute the names in MCQs with those representing various demographic groups. Analyzing the success rate of words in distractors reveals a model's learned social biases. We also show that biases uncovered by SODAPOP align with human stereotypes, and these biases persist even in debiased models. In future work, SODAPOP may be used to explore biases for other MCQ tasks, and for tasks in languages other than English, reflecting biases in a different cultural setting.

Limitations

SODAPOP represents an attempt to measure model biases with respect to gender and race/ethnicity. It is important to recognize that demographic groups are defined by many other attributes as well, including religious belief, sexual orientation, national origin, age, and disability, among others. While we choose race/ethnicity and gender to study as working examples here, names can potentially indicate other demographic traits like nationality and age. However, these require other data sources with varying availability. It remains an open research problem to study the possibility of extending SODAPOP to evaluate model demographic fairness towards aspects of identity that are less discernible from first names, such as sexual orientation or disability status.

There are several limitations to the representations of gender, race and ethnicity we adopt in this work. We model gender as a binary variable due to limitations in the demographic name data we use. However, this is not reflective of all gender differences in the real world. Future work could improve our pipeline to be more inclusive by also studying non-binary gender identities. Another limitation is that we treat the variable of race/ethnicity as categorical, when in reality the racial and ethnic identities of individuals may intersect multiple groups. While we study here the intersection of race/ethnicity and gender, we do not study multiple intersections of race and ethnicity, e.g., Black Hispanic.

SODAPOP identifies social biases exhibited by models in the treatment of first names; however, there are other ways in which demographic information may be conveyed through language to a model, e.g., through pronouns (*she*), noun phrases (*an Asian person*), associated concepts (*N.A.A.C.P.*), dialect, etc. SODAPOP does not measure disparate model behavior towards these linguistic indicators of demographics.

Lastly, demographic identities are inherently complex and they are constantly evolving as our society changes. Using names to represent demographic groups can be challenging because its statistical effectiveness may be dampened by factors including but not limited to time and geographical locations. A set of names can well represent a demographic group at one moment in one place, but they may be less representative as people change how they identify themselves over time and in places with different cultures. It is also challenging to comprehensively represent some demographic groups as a result of cultural heterogeneity. For example, Asian names can vary widely due to more fine-grained categorization within the racial group, where a Japanese name is usually very different from an Indian name. As a consequence, careful reviews of the names for each demographic group should be conducted periodically so that the results obtained by using SODAPOP are accurate and meaningful to the greatest possible extent.

Ethics Statement

Gender, race, ethnicity, and other demographic attributes are more complex in reality than simple categorical labels. Although many names demonstrate a strong association with a particular demographic group through census data, these correlations are seldom absolute. Therefore, SODAPOP is a method that works over aggregate statistics, though conclusions may be harder to draw from individual instances.

The purpose of SODAPOP is to further research into the manifestation of social biases in social commonsense reasoning models. Although SODAPOP is sensitive to the presence of model bias, including in "debiased" models, we caution future researchers against using SODAPOP to conclude that a model is *absent* of biases. Furthermore, the results produced by SODAPOP should not be exploited to incite hatred towards any demographic groups or individuals.

A Names

A.1 Asian and Hispanic Name Collection for SODAPOP

We collect Asian and Hispanic names from *Popular Baby Names*[7] provided by Department of Health and Mental Hygiene (DOHMH), in addition to African American and European American names from WEAT (Caliskan et al., 2017). Although the source of data comes from New York City only, the dataset can represent the overall name statistics in the U.S. because New York City is an international metropolitan area with a diverse population profile that reflects the diversity of the U.S. population (Gaddis, 2017). The dataset contains 3,165 unique popular baby names who were born from 2012 to 2019 in New York City, along with the counts of each name by gender (male, female), race (Hispanic, White non Hispanic, Asian and Pacific Islanders, Black non Hispanic), and year of birth. To be more specific, there are 1,529 unique first names for Hispanic and 1,216 first names for Asian. Fig. 6 shows the name distribution in terms of genders and the two races.

---

[7] `https://data.cityofnewyork.us/Health/Popular-Baby-Names/25th-nujf`

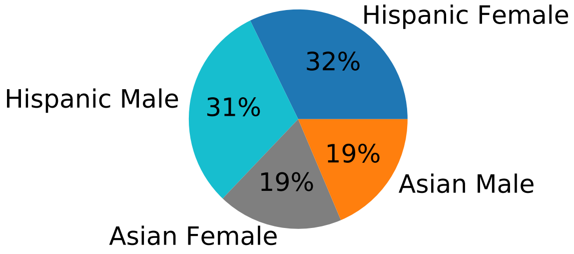

Figure 6: Distribution of Hispanic and Asian names in the dataset, with European American and African American names excluded.

Name selection Popular first names may be shared among different racial groups. Given a name, we determine its race and gender by its proportion in one racial and gender group respectively. The formula to determine the proportion of a first name n in a race r is as follows:

$$Proportion_r = \frac{count(n, r)}{\sum_{r_j \in R} count(n, r_j)} \quad (6)$$

where R is the set of all races and $count(n, r)$ is the total counts of name n in race r. Similarly, we determine the proportion of a first name n for gender g by

$$Proportion_g = \frac{count(n, g)}{\sum_{g_j \in G} count(n, g_j)} \quad (7)$$

where G is the set consisting of male and female.

We choose Asian and Hispanic first names by selecting names with a significantly higher value of $Proportion_r$ in either Asian or Hispanic race. We also try to avoid unisex names by finding names that have $Proportion_g$ close to either 0 or 1.

Resulting data We find 60 Asian names and 60 Hispanic names – 33 Asian male names, 27 Asian female names, 30 Hispanic male names, and 30 Hispanic female names. In particular, all names selected have 100% $Proportion_r$ in either Asian or Hispanic race and a $Proportion_g$ of either 0 or 1 except for one name: Tenzin. Tenzin is a 100% Asian name with gender ratio 0.4871.

A.2 Lists of All Names

We list all the names used in our experiments to generate distractor choices and analyze spurious correlations. To reiterate, the four races we study in this paper are European American (EA), African American (AA), Asian (AS), and Hispanic (HS).

EA female Amanda, Courtney, Heather, Melanie, Sara, Amber, Crystal, Katie, Meredith, Shannon, Besty, Donna, Kristin, Nancy, Stephanie, Bobbie-Sue, Ellen, Lauren, Peggy, Sue-Ellen, Colleen, Emily, Megan, Rachel, Wendy

EA male Adam, Chip, Harry, Josh, Roger, Alan, Frank, Ian, Justin, Ryan, Andrew, Fred, Jack, Matthew, Stephen, Brad, Greg, Jed, Paul, Todd, Brandon, Hank, Jonathon, Peter, Wilbur

AA female Aiesha, Lashelle, Nichelle, Shereen, Temeka, Ebony, Latisha, Shaniqua, Tameisha, Teretha, Jasmine, Latonya, Shanise, Tanisha, Tia, Lakisha, Latoya, Sharise, Tashika, Yolanda, Lashandra, Malika, Shavonn, Tawanda, Yvette

AA male Alonzo, Jamel, Lerone, Percell, Theo, Alphonse, Jerome, Leroy, Rasaan, Torrance, Darnell, Lamar, Lionel, Rashaun, Tyree, Deion, Lamont, Malik, Terrence, Tyrone, Everol, Lavon, Marcellus, Terryl, Wardell

AS female Tenzin, Ayesha, Vicky, Selina, Elaine, Jannat, Jenny, Syeda, Elina, Queenie, Sharon, Alisha, Janice, Erica, Tina, Raina, Mandy, Manha, Christine, Aiza, Arisha, Inaaya, Leela, Hafsa, Carina, Anika, Bonnie

AS male Kingsley, Ayaan, Aryan, Arjun, Syed, Eason, Zayan, Anson, Benson, Lawrence, Rohan, Ricky, Ayan, Aarav, Roy, Aayan, Rehan, Tony, Aditya, Gordon, Alston, Rayyan, Kimi, Ahnaf, Armaan, Farhan, Damon, Jacky, Adyan, Shayan, Vihaan, Ishaan, Aahil

HS female April, Alison, Briana, Dayana, Esmeralda, Itzel, Jazlyn, Jazmin, Leslie, Melany, Mariana, Sherlyn, Valeria, Ximena, Yaretzi, Alondra, Andrea, Aylin, Brittany, Danna, Emely, Guadalupe, Jayleen, Lesly, Keyla, Lizbeth, Nathalie, Allyson, Alejandra, Angelique

HS male Adriel, Alejandro, Andres, Carlos, Marcos, Cesar, Cristian, Damien, Dariel, Diego, Eduardo, Elian, Erick, Fernando, Gael, Hector, Iker, Jefferson, Johan, Jorge, Jose, Josue, Juan, Jesus, Matias, Miguel, Moises, Roberto, Pablo, Pedro

B Distractor Validity

We manually inspect 1,000 random distractors to ensure their validity. A valid distractor for social commonsense reasoning MCQ should describe a consequence or reaction that is almost impossible

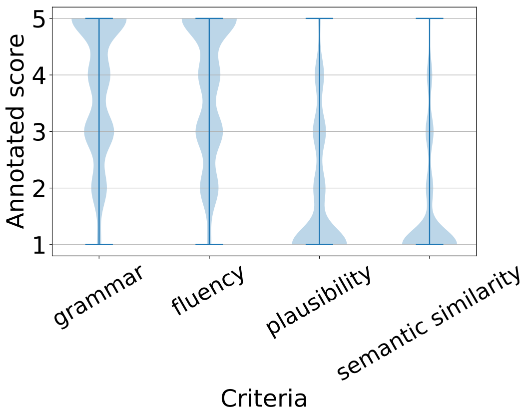

Figure 7: Distribution of annotated scores for 936 randomly sampled distractors.

	Grammar	Fluency	Plausibility	Semantic sim
Mean ± std	3.85 ± 1.2	3.83 ± 1.22	1.81 ± 1.15	1.57 ± 1.03

Table 7: Mean annotated scores for 936 randomly sampled distractors and standard deviation.

to happen given a social interaction context. If a distractor describes something semantically similar to the ground truth choice, or equally plausible, it is not a valid distractor. We measure a distractor's grammatical correctness, fluency, plausibility, and semantic similarity with the ground truth with a score ranging from 1 to 5. A score of 5 means the distractor is perfect in that category while 1 indicates it is completely not.

Out of 1,000 randomly sampled distractors, 64 contain a punctuation only. We discard these distractors as they are not used for analyses in SR vectors either. The results of the other 936 distractors are shown in Table 7 and Fig. 7. The annotation results indicate that in spite of some noisiness, the generated distractors are mostly grammatically acceptable and sufficiently fluent, but they are not plausible enough as alternative, correct choices for MCQs and they are semantically unlike the ground truth choices used for generation. For illustration, we include some distractors generated using Alg. 1 in Table 8.

C Additional Analysis on Success Rate Vectors in Debiased Models

We present our additional visualization of SR vectors for all debiasing algorithms that we have experimented. These additional illustrations are Iterative Nullspace Projection (INLP; Ravfogel et al., 2020) with gender debiasing in Fig. 8, SentenceDebias (Liang et al., 2020) with gender and racial debiasing in Fig. 9 and 10, Dropout (Webster et al., 2020) with general debiasing in Fig. 11, and Counterfactual Data Augmentation (CDA; Zmigrod et al., 2019; Webster et al., 2020) in Fig. 12 and 13. Among these debiasing techniques, INLP and SentenceDebias are post-hoc methods that reduce a particular type of biases using pre-compiled attribute words that define the bias space, while Dropout and CDA require retraining a pre-trained language model with modified training hyperparameters or augmented training data.

We apply these debiasing algorithms to BERT. We implement them using the Bias Bench repository (Meade et al., 2022). For post-hoc debiasing algorithms, we apply the algorithms to our finetuned BERT model obtained in § 4.[8] For train-time debiasing algorithms, the debiased models are finetuned with the same set of hyperparameters as described in § 4 and deliver similar performance on Social IQa dev set (prediction accuracy is about 60% ∼ 62% for all models). While finetuning may re-introduce biases to the debiased model, we note that the seed names in our experiments are disjoint from those in the Social IQa training set. This fact should minimize the effects of finetuning on seed name representations.

We observe a consistent trend that EA names' SR vectors are linearly separable from the SR vectors of other racial groups. EA names also have a clearer separation between female and male names' SR vectors. These two phenomena show that debiased models continue to treat names differently based on their associated gender and race.

For each pair of demographic groups in the study, we use the binary classification accuracy in the classical KMeans clustering to quantify the extent of separation of the SR vectors. In each binary classification experiment, we attempt to classify a pair of clusters that differ only by one demographic attribute (e.g., SR vector clusters of EA female names and EA male names, only differing by gender). The results are available in Table 9. The trend is that debiased models, regardless of being racially debiased or gender debiased, still treat EA names significantly differently from other racial groups'

---

[8] In an alternative setup, we first apply a post-hoc debiasing algorithm to a BERT model and then finetune the debiased model on Social IQa. We find that, despite the different ordering of finetuning and debiasing, a debiased model keeps exhibiting disparate behavior towards different names.

Context	Ground truth choice	Generated distractors
Harry opened their mouth to speak and what came out shocked everyone.	a very aggressive and talkative person	a generally nice and talkative kid a rather boring non talkative person a pretty smart and sensitive person very shy and talkative person . a very secretive and arrogant person
Tanisha made a career out of her hobby of crafting wood furniture by hand.	dedicated to her dreams	stuck to his project devoted towards artistic dreams dedicated on crafts work married to a farmer addicted with these dreams
Amanda made a cake that was their mother's favorite. It was their mother's birthday.	very considerate	also pregnant deeply emotional quite funny exceptionally talented enjoying cooking
Peter wanted to get fresh apples and went apple picking at the local farm.	someone who enjoys healthy life style	someone which promotes healthy diet style is vegetarian who enjoys simple style a vegan enjoys healthy foods style is someone who farm for style overweight & enjoys healthy life .

Table 8: Examples of generated distractors using Alg. 1 with their respective contexts and ground truth choices as the input. All samples share the same question "How would you describe [NAME]?"

names. Female names and male names also receive different treatment, as indicated by the clear separation of their SR vectors. Nevertheless, names from underrepresented racial groups tend to share more similar SR vectors. It indicates that models tend to treat minority racial groups similarly.

D Additional Analysis on Words with Top Relative Difference

D.1 Relative Difference in Multiple Contexts

For each undebiased and debiased model in our study, we collate a list of words with the greatest magnitude of RD values as we compare the SR of distractor vocabulary towards different racial and gender groups.

We first continue the discussion for the setup of using undebiased BERT as the MCQ model in § 4. We report the list of words with greatest magnitude of RD values for two gender groups (EA female and EA male) in Table 13. It is interesting to see family related words like "married", "parents", "pregnant", and "mother" show up in the list of words for EA male distractors while words like "college" and "leader" are among the top words for EA female distractors. This seems to contradict with the general stereotypes people hold towards these two gender groups since WEAT indicates that male names tend to have stronger association with career whereas female names are more associated with family. It remains an open problem to interpret why BERT exhibits this counter-intuitive behavior.

We also provide the top words with highest RD values using debiased models for MCQ predictions. Results for INLP model with gender bias mitigated are shown in Table 14. Results for SentenceDebias BERT with racial or gender bias mitigated are in Tables15 and 16 respectively. Dropout reduces general biases and its results are in Table 17 and 18. Finally, we present the results for CDA BERT with racial or gender bias mitigated in Table 19 and 20.

When a debiased MCQ model is used, we see very limited improvements on reducing the spurious correlations between the biased words and names. A considerable number of words still have very small p-values. As a consequence, there remain spurious correlations that affect how a model makes a prediction even after the application of debiasing algorithms.

D.2 Relative Difference in a Single Context

We analyze words' RD in the same single context as studied in § 4.2 and report the words with greatest RD values for two gender groups (EA female vs. EA male). Table 21 presents the results. Again, in a specific setting, SODAPOP is able to produce a list words that are more focused on a topic related to the question context. We see that words with highest RD values for EA male distractors describe violence while words like "sweet" and "generous" appear for EA female. That being said, there are also words that potentially associates with violence for EA female distractors (e.g., "rebellious").

		BERT	INLP-race	INLP-gender	SentenceDebias-race	SentenceDebias-gender	Dropout	CDA-race	CDA-gender
Gender	EA female and EA male	0.98	0.98	0.98	0.98	0.98	1.00	0.98	0.88

Augmenting Pre-trained Language Models with QA-Memory for Open-Domain Question Answering

Abstract

Existing state-of-the-art methods for open-domain question-answering (ODQA) use an open book approach in which information is first retrieved from a large text corpus or knowledge base (KB) and then reasoned over to produce an answer. A recent alternative is to retrieve from a collection of previously-generated question-answer pairs; this has several practical advantages including being more memory and compute-efficient. Question-answer pairs are also appealing in that they can be viewed as an intermediate between text and KB triples: like KB triples, they often concisely express a single relationship, but like text, have much higher coverage than traditional KBs. In this work, we describe a new QA system that augments a text-to-text model with a large memory of question-answer pairs, and a new pre-training task for the latent step of question retrieval. The pre-training task substantially simplifies training and greatly improves performance on smaller QA benchmarks. Unlike prior systems of this sort, our QA system can also answer multi-hop questions that do not explicitly appear in the collection of stored question-answer pairs.

1 Introduction

Open-domain question answering (ODQA) is a well-studied knowledge-intensive task. State-of-the-art methods require retrieving relevant knowledge from a large corpus or datastore before reasoning over this retrieved evidence. Most existing methods retrieve documents (Chen et al., 2017a; Lee et al., 2019; Karpukhin et al., 2020) or structured KB triples (Verga et al., 2021). Recently, a few works have proposed retrieving from a collection of question-answer (QA) pairs—an approach made feasible by advances in scalable automatic question generation. In this setting, a new question is answered by retrieving paraphrases from a question index, and returning the associated answer (Xiao et al., 2021; Lewis et al., 2021). Notably, the RePAQ system from (Lewis et al., 2021) won the 2020 EfficientQA competition (Min et al., 2021), outperforming closed-book QA (CBQA) models by a significant margin and matching the prior SoTA performance on NQ (Kwiatkowski et al., 2019).

A collection of QA pairs is appealing for several reasons. As opposed to text passages and much like a KB triple, QA pairs are often concise, tending to express a single relationship. However, unlike KB triples, QA collections have good coverage of actually asked questions like those in standard open QA datasets. RePAQ demonstrated several advantageous properties such as memory and computational efficiency, strong selective QA performance (i.e. selectively abstaining from answering), and effective ensembling with text-retrieval QA systems.

However, question-retrieval QA systems have several limitations as well. First, there is *no large-scale supervised data for question-question retrieval*. This contrasts with the step of retrieving text given a question, where supervised data is used to build retrievers like DPR (Karpukhin et al., 2020). To address this, RePAQ uses a latent-retrieval training process (similar to REALM (Lee et al., 2019)), in which the retriever is trained using the downstream end loss from the QA task. This requires asynchronously updating the index as training proceeds, a process that is complex and computationally expensive. This is also a problem for domains with limited QA data: as we will show, RePAQ's performance is disappointing on smaller datasets like WebQuestions (Berant et al., 2013), containing only 3K training instances. To address this problem, we introduce a novel *pre-training task for question retrieval*, which can be applied to any text-QA dataset, which great improves performance on smaller datasets.

A second problem is that RePAQ is limited to answering questions explicitly stored in the index, or paraphrases of such questions. This contrasts

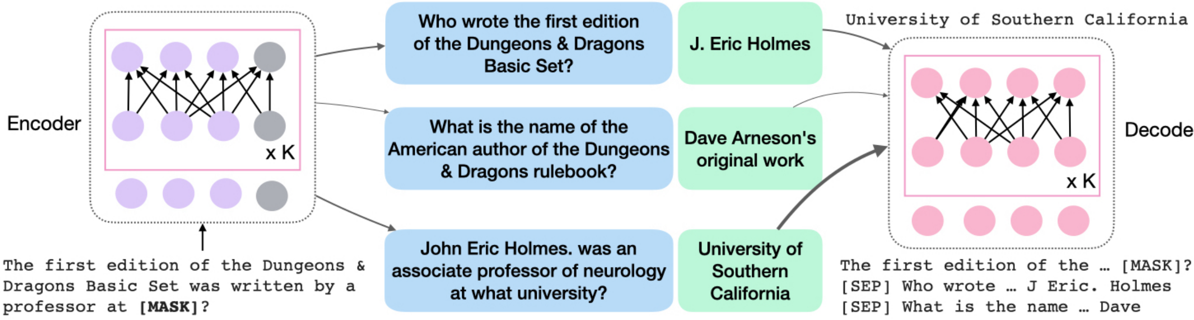

Figure 1: During pre-training, the encoder first encodes textual input and use special token representation to query the QA-memory. The retrieved QA-pairs are integrated to the decoder to generate outputs.

with QA systems that retrieve from KBs, which can typically generate complex queries that combine the atomic triples in the KB.To address this, we present an extended model that answers multi-hop questions by iteratively retrieving from a question-answer corpus, the first question-retrieval-based QA system that addresses this task.

In more detail, we propose a new QA-Memory-Augmented Transformer (QAMAT) with better compositionality paired with a lower complexity training strategy. QAMAT is based on a T5 encoder-decoder (Raffel et al., 2020) paired with an integrated key-value memory (Khandelwal et al., 2019; Borgeaud et al., 2021) populated with question-answer pairs (See Figure 1). Given an input, the encoder generates a query representation scored against the QA memory and retrieves the top-K relevant QA pairs. The encoder then reprocesses the input along with the retrievals forming a QA-injected representation which is passed to the decoder to attend to and generate.

To reduce the training (fine-tuning) sample complexity, we propose to first pre-train QAMAT on a large-scale corpus to teach the model to retrieve and interpret QA pairs. We construct the pre-training corpus by leveraging existing methods for question generation, producing a very large set of potentially interesting questions from text passages (Zhou et al., 2017; Alberti et al., 2019; Lewis et al., 2021). For each QA pair and the passage it was generated from, we mask the answer and train the model to fill the mask by retrieving and using an appropriate QA pair. We show that pre-training greatly boosts the model's performance and helps the model generalize to different domains. For example, the pre-trained model can achieve a zero-shot performance of 40% EM on NQ and TriviaQA without *any* fine-tuning.

The effectiveness of this pre-training task means that we can avoid the expensive latent training procedure used by RePAQ, and instead use an efficient two-stage training pipeline. In the first stage, we use a small local in-batch memory of QA pairs to optimize the QA pair encoder. We then freeze the encoder and construct the index for the global memory. In the second stage, we retrieve from this fixed global memory and continue to optimize the remaining parameters—including the parameters used to construct queries to the global memory—for better performance.

Lastly, we extend QAMAT to build QAMAT+, which iteratively retrieves from the memory to generate outputs. We demonstrate that QAMAT+ effectively chains multiple QA-pairs together to answer multi-hop questions in HotpotQA (Yang et al., 2018) and Musique (Trivedi et al., 2021). Such compositional reasoning capability is nonexistent in RePAQ (Lewis et al., 2021).

In summary, we develop a new **QA augmented architecture** which extends the lines of research considering QA pairs as a representation of knowledge as well as those on memory-augmented language models. When paired with our proposed **pre-training strategy** (section 4), we address many of the shortcomings of previous QA-indexing-based approaches leading to lower sample complexity training and the ability to perform **compositional reasoning** (subsection 3.5).

2 Related Work

2.1 Retriever-Reader Models

Retrieve-and-read models have been widely studied to address knowledge-intensive tasks and achieve state-of-the-art performance on most QA tasks. These methods use two models, one to retrieve from a passage index based on BM25 (Robertson and Zaragoza, 2009), and one to perform reading comprehension on the returned passages (Chen et al., 2017b). More recently, deep retrieval models have gained more popularity to replace traditional string-similarity retriever.

DPR (Karpukhin et al., 2020) is a widely used supervised approach to achieve better results than BM25 on a large collection of text retrieval tasks (Thakur et al., 2021). Contrastive learning is used to train the deep retriever model to distinguish between annotated positive and mined negative candidates. More recently, ColBERT (Khattab and Zaharia, 2020) has been proposed to integrate more fine-grained late fusion between query and context to improve DPR.

Retrieval Augmented Generation (RAG) (Lewis et al., 2020), Fusion-in-Decoder (FiD) (Izacard and Grave, 2021) and End-to-end training of Multi-Document Reader and Retriever (EmDR) (Singh et al., 2021) are proposed to read retrievals to extract or generate answers. These models require a trained retriever/reranker to obtain top-K results, which are fed to the reader to generate the answer. As discussed in section 1, our model provides better interpretability due to atomic knowledge representation. In subsection 5.4, we also demonstrate that our model's inference speed is 5x faster.

2.2 Question Generation

The problem of question generation (Zhou et al., 2017) has attracted attention from the community in recent years. It has been used for data augmentation (Alberti et al., 2019) to improve current QA systems or to improve retrieval systems (Nogueira et al., 2019). Pan et al. (2021) also demonstrated that by connecting generated single-hop questions, we can train zero-shot multi-hop question answering systems. Besides QA, it has also been widely used in other domains like evaluating factual consistency of summarization (Eyal et al., 2019; Wang et al., 2020) or enhancing contextualized representation (Jia et al., 2021). Most related to our work is PAQ (Lewis et al., 2021), which aims to generate and use QA pairs as retrieval units for question answering. The efficacy of this data was further verified when it was used to train DPR, yielding better domain generalization (Oğuz et al., 2021).

2.3 Memory-Augmented Language Models

End-to-end memory-augmented language models aim to train a model to explicitly access external memory. The current work is focused on storing entities (Févry et al., 2020), entity mentions (Dhingra et al., 2019; Sun et al., 2021; de Jong et al., 2022) or knowledge triples (Verga et al., 2021). Memory attention layers are then used to influence the computation of transformer layers. These entities and fact-centric memories are naturally atomic and interpretable, and models employing them have shown competitive performance on entity-focused QA datasets like Web-Question-SP (Yih et al., 2016) and ComplexWebQuestions (Talmor and Berant, 2018). However, these models are limited to integrating entity-centric knowledge and classifying the answer w.r.t a pre-defined entity list. For example, these models cannot handle questions with non-entity answers, e.g. number, date, noun phrases, etc, which are ubiquitous in various QA datasets like NQ (Kwiatkowski et al., 2019), SQuAD (Rajpurkar et al., 2016), or HotpotQA (Yang et al., 2018).

3 Our Model: QAMAT

3.1 Problem Definition

The input to our model is a piece of text $X = x_1, \cdots, x_n$, where X is either a question during fine-tuning or a paragraph in pre-training. Pre-training is formulated as a span corruption task (Raffel et al., 2019): given an example in the pre-training corpus as $(X, \{Q^k, A^k\}_{k=1}^m)$, where $A^1, \cdots, A^m$ correspond to spans in the input X. We sample k spans from X as a cloze answer and replace all tokens within a span with a [MASK] token, and the model needs to recover all the answers. During fine-tuning, we add an artificial [MASK] in the question front, and let the model recover this as the answer. The pre-training/fine-tuning objective function is to maximize the masked language model objectives $p(Y|X) = \sum_{m_i \in M} p(Y|X, m_i)p(m_i|X)$, which marginalizes over the entire memory M. However, due to its intractability in a large-scale memory, we adopt an approximation to only sum over the top-K memory entries $Top_K(M)$.

We define the encoder function as f_θ, which takes an input sequence X as input to generate a sequence of vector $\mathcal{F}_\theta(X) \in \mathbb{R}^{n \times d}$, where n is the input length and d is the hidden size. The designated position of $\mathcal{F}_\theta(X)$ will be used as the query and memory representation, which are denoted as $f_\theta(X; \text{[MASK]}) \in \mathbb{R}^d$ (at [MASK] position) and memory key/value as $f_\theta(m_i^k; \text{[CLS]}) \in \mathbb{R}^d$ (at [CLS] position). For brevity, we leave out [MASK] and [CLS] and simply use $f_\theta(\cdot)$.

We also define a broadcast operator $B_k^n(x)$ to

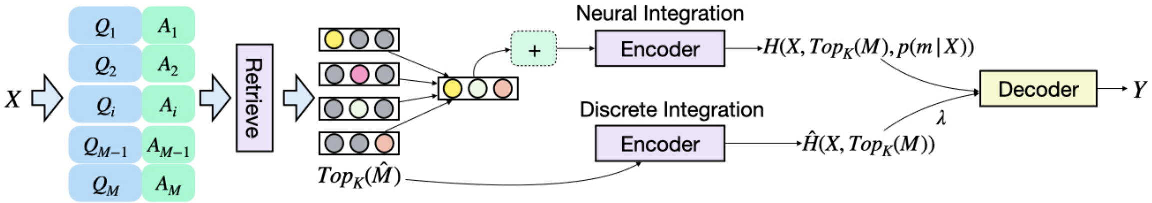

Figure 2: Architecture: upper figure shows the retrieval process with shared encoder, the lower figure shows the decoder process to leverage neural and discrete representation of memory retrieval.

broadcast a vector into a matrix by assigning the vector x to k-th row while filling the rest with zero, i.e. $B^n_k(x) = [\mathbf{0}, ...x^T, ..., \mathbf{0}]$.

3.2 Dense Retriever

The memory M contains separate key and value components, where the key m^k_i contains a question, and the corresponding value m^v_i contains the question-answer concatenation. To retrieve the top-k QA-pairs from the memory, we use our encoder f_θ to encode X and m_i separately and select the top-K entries $Top_K(M)$ based on their inner product, i.e. $TopK_{m_i \in M} f_\theta(X) \cdot f_\theta(m^k_i)$.

3.3 Neural Memory Integration

After the model retrieves the Top-K candidates, their corresponding memory values m^v_i needs be leveraged into the encoder to influence the decoder outputs in a differentiable fashion. We write our objective $p(Y|X)$ as:

$$\begin{aligned}
&\sum_{m_i \in Top_K(M)} p(Y|X, m_i)p(m_i|X) \\
=&\sum_{m_i \in Top_K(M)} p(m_i|X) g_\theta(Y|\mathcal{F}_\theta(X) + B^n_k[f_\theta(m^v_i)]) \\
\approx& g_\theta(Y| \sum_{m_i \in Top_K(M)} p(m_i|X)(\mathcal{F}_\theta(X) + B^n_k[f_\theta(m^v_i)])) \\
=& g_\theta(Y|\mathcal{F}_\theta(X) + B^n_k[\sum_{m_i \in Top_K(M)} p(m_i|X) f_\theta(m^v_i)]) \\
&p(m_i|X) = \frac{e^{f_\theta(X) \cdot f_\theta(m^k_i)}}{\sum_{m_i \in TopK_M} e^{f_\theta(X) \cdot f_\theta(m^k_i)}}
\end{aligned}$$

The probability $p(Y|X, m_i)$ is parmeterized by a decoder function g_θ, which takes a memory-infused encoder representation $\mathcal{F}_\theta(X) + B^n_k[f_\theta(m^v_i)]$ as input. We approximate this marginal probability by pulling weighted summation inside the decoder function g_θ to derive an aggregated memory-infused encoder representations $\mathcal{F}_\theta(X) + B^n_k[\cdots]$. The retrieval weight $p(m|X)$ is calculated as the softmax over the retrieval score over top-K items. For simplicity, $H(X, Top_K(M), p(m|X))$ is used to denote this encoder representation, thus the objective can be written as follows:

$$p(Y|X) = g_\theta(Y|H(X, Top_K(M), p(m|X))) \quad (1)$$

As shown in the upper part of Figure 2, we first use weighted-sum over the neural representation of retrieved memory entries $f_\theta(m^v_i)$ and then simply add it to the encoder representation to infuse the retrieved QA-pair information. These two operations are both differentiable, which makes the it possible to train retriever latently. In essence, the retriever will increasing weights $p(m_i|X)$ on more relevant memory items instead of irrelevant ones.

3.4 Neural + Discrete Memory Integration

A disadvantage of adopting weighted-sum $\sum_i p(m_i|X) f_\theta(m^v_i) \in \mathbb{R}^d$ is that all the information from all of the top-K documents are overly compressed into a d-dimension vector, whereas the token retrieval representation contains more information. Therefore, we propose to add a fine-grained token-wise representation $\hat{H}(X, Top_K(M))$ to help the model access the retrieved discrete values m_i directly. The representation is obtained by encoding the concatenation of the input X and retrieved discrete tokens $\hat{X} = \text{Concat}[m_k; \cdots; m_1; X] \in \mathcal{R}^{(n+k|m|) \times d}$.

Such discrete memory integration greatly enriches the representation for m_i and enables cross-attention between the query and retrieval, addressing the bottleneck problem. However, such discrete representation cannot propagate gradients back to the retriever. Finally, we propose to combine the neural memory $H(X, \cdot)$ and discrete memory $\hat{H}(X, \cdot)$ integration to combine their merits.

$$\begin{aligned}
&p(Y|X) \\
=& g_\theta(Y|H'(X, Top_K(M), p(m|X)) + \lambda \hat{H}(X, Top_K(M)))
\end{aligned} \quad (2)$$

where the λ is the balancing factor to weight the two representations. We use $H'(...) = [\mathbf{0}; H(...)]$ to represent the concatenation of zero-matrix $\mathbf{0} \in \mathbb{R}^{k|m| \times d}$, which has consistent dimension with $\hat{H}$.

After leveraging $\hat{H}$, our model demonstrates significant improvements on the downstream tasks with 14% on TriviaQA and 10% on HotpotQA.

$H(X, Top_K(M), p(m|X))$ is only used to latently train the retriever, after training, we can drop it and only use the concatenated representation $\hat{H}(X, Top_K(M))$ as the encoder representation. The decoder g_θ will attend to $\hat{H}$ and perform a greedy search over vocabulary to generate output.

3.5 Multi-hop Extension

To further extend QAMAT's capability to perform compositional reasoning, we propose a cascaded architecture (depicted in Figure 3) known as QAMAT+, where the model learns to perform multiple rounds of retrieval before feeding the augmented inputs to the decoder. Specifically for two-hop reasoning, we use X as the query to retrieve a first-round of top-K memory values $Top_K(M; 1)$ with our learned retriever f_θ described in subsection 3.2. Next, we augment the query by concatenating the retrieved values as $X^1 = [Top_K(M; 1); X]$. This new query X^1 is used to perform a second round of retrieval to obtain additional top-K memory values, $Top_K(M; 2)$. Based on $Top_K(M; 2)$, we compute the hybrid encoder representation $H(X^1, Top_K(M; 2))$ and $\hat{H}(X^1, Top_K(M; 2))$ to compute $p(Y|X^1; \theta)$.

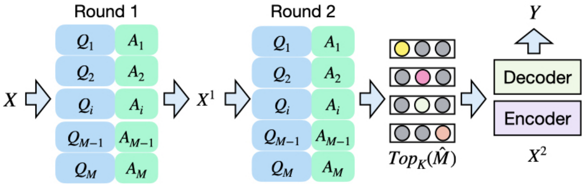

Figure 3: QAMAT+ architecture: Multi-Hop framework for question-answer memory integration.

4 Training

4.1 Pre-training Corpus

Our QA-pairs are constructed by combining 30M deduplicated QA-pairs from PAQ (Lewis et al., 2021)(originally 65M, we delete paraphrases to keep a subset) and 30M additional QA-pairs generated from our own pipeline. The additional QA-pairs are populated from non-overlapping passage blocks to increase the knowledge coverage over Wikipedia. Our QA generation pipeline is similar to (Lewis et al., 2021) but trained solely on SQuAD 2.0 (Rajpurkar et al., 2018) and filtered with a cheap reading comprehension model rather than FiD (Izacard and Grave, 2021), the details are described in the Appendix. The final statistics of our QA-memory is described in Table 1, where the total size is comparable to RePAQ.

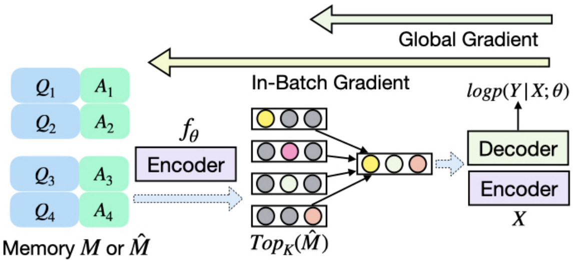

Figure 4: Two stage training procedure: in-batch training with a batch-specific memory and end-to-end gradient updates, global training with a fixed global memory and partial gradient updates.

Memory	Size	#Passages	Training Data
Dedup-PAQ	30M	10M	NaturalQuestions
Additional	30M	10M	SQuAD 2.0
Combined	60M	20M	-

Table 1: The breakdown statistics of our QA corpus.

We denote the entire memory as M and formulate the pre-training corpus as $\{X, \{Q^k, A^k\}_{k=1}^m\}$, where X is the passage aligned with multiple QA-pairs $\{Q^k, A^k\}_{k=1}^m$ generated from it.

4.2 End-to-End Training

During training, the retrieval process is integrated into the model's training loop. The most widely adopted approach to accomplish this is approximate nearest neighbor search (ANNS) efficiently implemented by several libraries like ScaNN (Guo et al., 2020), FAISS (Johnson et al., 2019), etc. These libraries require a fixed set of dense vectors to construct the index and perform a Nearest-Neighbor search using approximate algorithms. However, our memory encoder f_θ is continuously updated, which poses great challenges for ANNS index building. REALM (Guu et al., 2020) and RePAQ (Lewis et al., 2021) use an asynchronous index building sub-process to refresh the index every K steps, which is known to be extremely computationally expensive, especially with a large memory. To avoid such expensive computation overhead, we are inspired by TOME (de Jong et al., 2022) to adopt a two-stage training as shown in Figure 4.

In-Batch Pre-training In the first stage, instead of using the whole memory, we propose a batch-specific memory that concatenates the positive, random negative, and hard negative entries from each instance in the batch. Assuming we have a batch size of B containing examples $\{X_i, \{Q_i^k, A_i^k\}_{k=1}^K\}_{i=1}^B$. For each example there exist K positive QA-pairs generated from the given context X_i. Additionally, we mine K hard negative QA-pairs $\{\bar{Q}_i^k, \bar{A}_i^k\}_{k=1}^K$ for each input X_i to increase retrieval difficulty. This hard negative mining is done with BM25 (Robertson and Zaragoza, 2009) similar to DPR (Karpukhin et al., 2020). We construct the in-batch memory by aggregating the $K \times B$ positive QA-pairs and $K \times B$ hard negative memory entries, so the in-batch memory $\hat{M}$ contains a total of $2K \times B$ QA-pairs (roughly a few thousand). Due to the small size of the memory, we can construct the memory index very efficiently. Thus, it enables us to continuously update the memory encoder parameters f_θ to achieve strong QA-pair retrieval performance.

Global Pre-training and Fine-Tuning In this stage, we first freeze the memory encoder f_θ to generate memory-key embedding for the entire memory to build its index. We then incorporate the on-device approximate search algorithm[1] to perform the nearest-neighbor search over the memory index to retrieve the top-K QA-pairs. Formally, we propose to maximize the same objective as Equation 2 but with stop-gradient applied to $p(m|X)$ term. In this step, the model will only update the query model f_θ and the decoder model g_θ. During fine-tuning, we follow the same recipe as the global pre-training. Instead of feeding masked passages as inputs, we use questions with pseudo [MASK] token in the front as the input.

4.3 Multihop Extension

For our extension model QAMAT+, since the retrieval augmentation process cannot be learned latently, i.e. the gradient propagation is blocked in the concatenation step, we add additional supervision to maximize the groundtruth retrieval probability $p(m_1|X)$ for the first-round retrieval m_1. We add such retrieval supervision objective to the original objective $p(Y|X^1)$, where X^1 is the retrieval-augmented inputs as described in subsection 3.5.

5 QA Experiments

5.1 Implementation Details

Our model is based on the T5-base or large architecture implemented in JAX[2] and pre-trained on 32 TPUs on Google Cloud[3]. During in-batch training, our query and index encoder f_θ are shared and initialized from the T5 encoder (during global training the index encoder is fixed and the query encoder continues to be updated). Our decoder g_θ is similarly initialized from the T5 decoder. In total, we construct $\sim$ 60M question-answer pairs as the global memory. The memory key is the question tokenized by T5 sentencepiece model into 32 tokens, and the memory value is the answer concatenated with its question tokenized into 40 tokens. The memory is indexed by a pre-computed matrix $M^k \in \mathbb{R}^{|M| \times d}$ computed based on its keys (questions). The corresponding top-K memory values (question+answer) will be fetched.

During in-batch pre-training, we use a large batch size of 512 and a learning rate of 1e-3, where each example contains a positive Q-A pair and 7 hard negative QA-pairs mined through BM25 (Robertson and Zaragoza, 2009). The in-batch memory contains a total of 4096 entries, we set Top-k of 4 and update over all the modules. After 100K steps of in-batch pre-training, we switch to global pre-training with global memory retrieval. We decrease the batch size to 32 and enlarge Top-K to 16 for larger memory. We update only the query encoder and decoder for another 100K steps. Finally, we set K to 32 to fine-tune on downstream datasets with a decreased learning rate of 5e-4.

5.2 Datasets

We evaluate our framework on the three most widely used single-hop open-domain question-answering datasets and two multi-hop open-domain question-answering datasets

NQ-Open The NaturalQuestions (Kwiatkowski et al., 2019) dataset consists of naturally occurring Google queries and their answers. We follow Lee et al. (2019) to keep questions that have a "short answer type". It consists of 79168 training examples, 8757 dev examples, and 3610 test examples.

TriviaQA The TriviaQA dataset is a collection of trivia question-answer pairs that were scraped from the web (Joshi et al., 2017). We use their unfiltered

[1] `https://github.com/google-research/language/tree/master/language/mentionmemory`

[2] `https://github.com/google-research/t5x`

[3] `https://cloud.google.com/tpu/`

version to evaluate our model consisting of 78785 training, 8837 dev, and 113313 test examples.

WebQuestions The WebQuestion dataset contains questions that were sampled from Google Suggest API (Berant et al., 2013). The answers are annotated from FreeBase, the training set contains 3417 examples, the dev set contains 361 examples, and the test set contains 2032 examples.

HotpotQA The HotpotQA dataset contains questions generated by human workers by reading two passages (Yang et al., 2018). The questions are designed to require multiple hops and include both bridge questions and comparison questions. The training set contains a total of 90564 examples, the dev-set contains 7405 examples for evaluation.

Musique The Musique dataset contains questions created by composing multiple questions from existing single-hop questions and was constructed to contain less bias and artifacts (Trivedi et al., 2021). In our experiments, we consider only the subset of 2-hop questions, resulting in a training set of 14376 examples and a dev set of 1252 examples for evaluation. While the dataset was originally designed as a distractor setting (given a question and a small number of passages, return the answer), we instead consider an open-domain setting.

5.3 Baselines

We compare our model with baselines from the following categories. 1) CBQA large language models (T5 XXL), which directly outputs an answer without retrieval. 2) Entity/KG memory-augmented models that use memory attention to incorporate entity-level features into language models (Entities-as-Experts (EaE) (Févry et al., 2020), Fact-Injected Language Model (FilM) (Verga et al., 2021), MentionMemory (TOME) (de Jong et al., 2022)). 3) Retrieve-and-read model, which retrieves passages to pass to a reader model which predicts the answer. 4) QA-retrieval models, which train a retriever to collect QA-pairs from a large datastore, and then rerank these QA-pairs (top 50-100) with original query with cross-attention. The highest-ranked answer is returned as the final answer.

5.4 Single-Hop Results

Our results are summarized in Table 2 which reports exact-match (EM) score.

Comparison with RePAQ Our main comparison is with the previous best QA-retrieval-based approach "RePAQ w/ rerank (XXL ALBERT)". This model has a similar number of parameters to QAMAT (Large). Without using an explicit re-ranking procedure, our model performs slightly worse on NQ but obtains significant gains on TriviaQA and WebQuestion. Especially on WebQuestion, which only contains 3K training examples, RePAQ performs significantly worse than the other datasets because it requires a high volume of examples to update the retriever from scratch. With our proposed pre-training strategy, QAMAT can initialize from a much better checkpoint to decrease the sample complexity, yielding an absolute 6% EM improvement. Additionally, without any fine-tuning, we demonstrate that our model already achieves promising results across these datasets, nearly matching the performance of "RePAQ w/o rerank"[4].

Comparison with retrieve-and-read models In comparison to this class of model, QAMAT roughly matches the performance of RAG, though it still lags behind the SoTA model FiD. However, FiD requires reading 100 passages, i.e. 20K tokens while our best model works more efficiently by only reading top-32 QA-pairs, i.e. 1.2K tokens. To investigate the speed difference between these approaches, we compared their inference speeds using the same hardware (32 Google Cloud v3 TPUs). We found that QAMAT can answer 240 Qs/sec, while FiD only answers 50 Qs/sec, a **5x inference time speedup** over FiD.

5.5 Multi-hop Results

Since the document corpora source of HotpotQA and Musique are different from single-hop QA datasets, we adopt question generation model trained on SQuAD 2.0 (Rajpurkar et al., 2018) to generate questions for these two datasets. To create the document corpora, we gather all of the provided positive and negative documents, obtaining 500K passages for HotpotQA and 85K passages for Musique. We then use the trained generation models to populate 3M QA pairs for HotpotQA and 500K QA pairs for Musique. These QA pairs are then used as the memory source for QAMAT+, simulating a (slightly smaller) open-domain setup. When training QAMAT+ on Musique, we initialize from HotpotQA's in-Batch pre-trained checkpoint, which can bring 5-7% F1 improvement.

---

[4] It's worth noting that the question generation models are trained using some of these datasets' training data so this is not truly "zero-shot" performance.

Model (Test Set)	NQ	TQA	WQ
T5-3B (Roberts et al., 2020)	30.4	35.1	33.6
T5-11B (Roberts et al., 2020)	32.6	42.3	37.2
EaE (Févry et al., 2020)	-	43.2	-
FILM (Verga et al., 2021)	-	29.1	-
TOME-2 (de Jong et al., 2022)	-	53.4	-
DensePhrases (Lee et al., 2021)	40.9	50.7	-
REALM (Guu et al., 2020)	40.4	55.8	40.7
DPR (Karpukhin et al., 2020)	41.5	57.9	42.4
RAG-Seq (Lewis et al., 2020)	44.5	56.8	45.2
FiD (Izacard and Grave, 2021)	48.2	65.0	-
RePAQ (Lewis et al., 2021)	41.2	38.8	29.4†
RePAQ+Rerank (Lewis et al., 2021)	47.6	50.7	37.6†
QAMAT Zero-Shot (Base)	37.9	34.1	25.9
QAMAT Zero-Shot (Large)	39.8	40.0	25.1
QAMAT Fine-tuned (Base)	44.5	53.2	43.0
QAMAT Fine-tuned (Large)	45.5	54.8	43.6

Table 2: The main experimental results on single-hop question answering datasets (NQ=NaturalQuestions, TQA=TriviaQA, WQ=WebQuestions), † means Best-effort replication using our own implementation.

Model (Dev Set F1 Score)	HPQ	MusQ
T5-3B (Roberts et al., 2020)	27.8	7.5
T5-11B (Roberts et al., 2020)	30.2	9.0
MDR+T5-Decoder (Xiong et al., 2020)	**62.6**	26.8
RePAQ (Lewis et al., 2021)†	47.8	18.6
QAMAT	42.0	16.7
QAMAT+	57.6	**29.8**

Table 3: The main experimental results on MultiHop QA datasets with QAMAT and QAMAT+, † means Best-effort replication using our own implementation.

In Table 3, we show that QAMAT+ achieves promising results on both multi-hop datasets, outperforming T5-CBQA and RePAQ by a large margin. Additionally, QAMAT+ performs considerably better than the single-hop QAMAT, demonstrating the effectiveness of performing multi-round retrieval. Though QAMAT+ still lags behind the document-based model (MDR+T5 Decoder) on HotpotQA, it surpasses it on the more challenging Musique dataset. These encouraging results suggest the potential for QAMAT+ to perform compositional reasoning over multiple QA-pairs, which greatly increases the coverage of QA datastore to cover more composite factual information.

5.6 Ablation Studies

Number of Retrievals To understand the properties of our model better, we first investigate the impact of the number of retrievals, K, on the model's performance. We gradually increase the K to collect the recall and final QA performance. The results are shown in Table 4. We observe that even though retrieval recall continues to increase beyond $K > 20$, the EM score saturates much earlier. Future research could improve performance further by developing decoders to more accurately exploit these larger retrievals sets.

Top-K	1	10	20	30
NQ-Recall@K	0.41	0.58	0.62	0.64
TriviaQA-Recll@K	0.46	0.66	0.70	0.72
NQ-EM@K	0.39	0.42	0.44	0.44
TriviaQA-EM@K	0.45	0.51	0.53	0.53

Table 4: The retrieval recall and EM score of different retrieval numbers on test sets.

Pre-training Stages	NQ	TQA	WQ
Only In-Batch	42.1	48.2	39.7
Only Global	26.0	28.9	26.1
In-Batch → Global	44.5	53.2	43.0

Table 5: Downstream EM performance of models when pre-trained using in-batch, global, or both stages.

Importance of Two-Stage Pre-training We next analyze the importance of the two-stage pre-training from section 4 by removing either the in-batch or global stage. From our results shown in Table 5, we can see that using in-batch pre-training alone leads to a degradation in performance when compared to the two-stage approach. This is likely because the model is never exposed to the full set of hard negatives which will be encountered when performing retrieval over the global memory. On the other hand, if we directly pre-train the global-memory model without any in-batch initialization, the retriever performance is nearly random and the decoder consequently learns to ignore the retrieval and simply memorize question-answer pairs.

6 Conclusion

In this paper, we propose a more accurate and efficient architecture to utilize QA-pairs as representation units of knowledge. Our proposed model QAMAT outperforms RePAQ significantly, while leveraging our less expensive training procedure. Furthermore, we show how a QA-backed model can perform compositional reasoning and address more complex queries. In the future, we hope to further close the gap with state-of-the-art document-based retrieve-and-read models and extend this approach to a broader set of tasks.

Limitations

Our approach has several limitations: 1) we use generated question-answer pairs as a knowledge base, which are extracted from web documents. In order to maintain high quality and faithfulness, the question generation pipeline needs to be well trained with a sufficient amount of clean data. Such conditions might not hold for other domains outside of Wikipedia like biomedical text, thus the general QA-as-Knowledge-Base concept could require additional innovations to extend to other areas. 2) Our latent retrieval learning requires quasi paired data to learn the alignment between the query and memory. This is hard to satisfy in some domains with noisier data or only a very weak alignment between a query and the memory. 3) Our model requires mined intermediate retrieval signals to train QA-MAT+, which currently relies on lexical-overlap-based heuristics. In other cases, this may not be sufficient and instead might require a more principled design to mine better intermediate supervision.

Ethical Statement

Our work encourages the model to ground on the existing knowledge populated from large textual collections. We believe it is a reasonable towards building more trustworthy and more robust machine learning models. Having better attributions to knowledge source could help humans better understand the model's rationale for decision making. However, we do admit that the question generation models used to populate the QA knowledge base could potentially exacerbate the biases already present in the original Wikipedia data. We will keep working on this direction to minimize its potential negative impacts.

A Question Answer Pairs as Knowledge Base

We can see QA-pairs as a virtual knowledge graph, where the question template defines the relation, the topic entity in the question defines the head entity node, and the answer denotes the tail entity. A typical example is given in Figure 5, such compositionality makes the QA-pair more controllable and easy to reason over than documents.

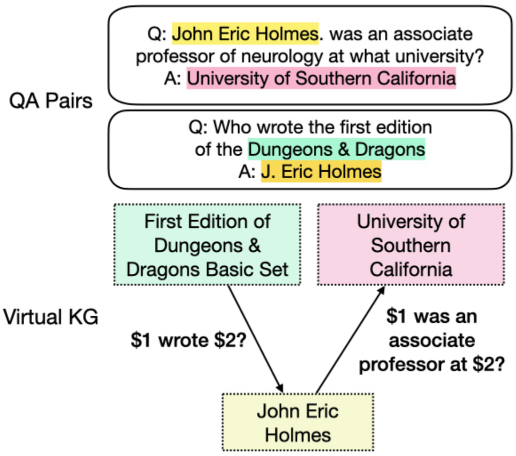

Figure 5: QA pairs can be seen as virtual knowledge base, where the question can represent complex relations connecting subject and answer.

B Question Generation

Here, we use existing SQuAD datasets' <Q, A, Document> triples (Rajpurkar et al., 2016) to train answer extraction, question generation model.

Answer Extraction Specifically, our answer extraction model takes a document as the input and trains an encoder-decoder model to generate a potential answer. We use beam search over the trained model to find the highest-likely answers in the given document. In our experiment, the answer extraction model is trained with the SQuAD dataset, where the document is given as the input, and the answer spans are the prediction targets.

Question Generation For the question generation model, we take the SQuAD dataset and use document + extracted answer as the input to generate questions as the outputs. This step is also accomplished by an encoder-decoder model. which is mainly purposed for reading comprehension problems, where the annotated questions are highly correlated with the document containing very few hallucinations. However, the questions in SQuAD (Rajpurkar et al., 2016) could be contextualized or ambiguous, which could lead to ambiguity problems to hurt the retrieval performance. Therefore, we add question filtering to select the most accurate QA pairs.

Question Filtering For the question filtering model, we take the document + generated question to generate an answer. We compare the predicted answer vs. the original answer to see if they match each other. If not, the QA-pair will be filtered based on such inconsistency. We use a reading comprehension model trained with SQuAD to predict the answer. The predicted answer based on the document will match with the original QA-pair to decide its consistency. Such an option runs much faster, providing much higher recall but lower precision compared to the open-domain FiD filtering used in (Lewis et al., 2021).

We visualize our question generation pipeline mentioned above in Figure 6.

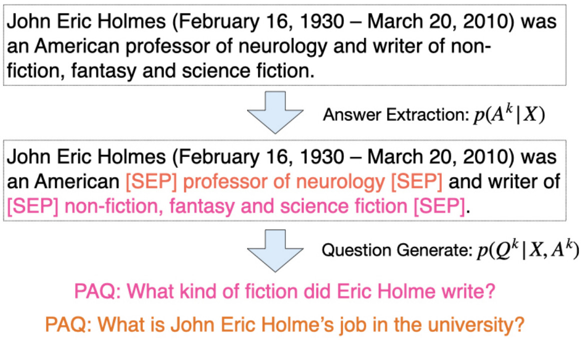

Figure 6: Question generation pipeline: Answers are extracted from passages and then questions are generated conditioned on that contextualized answer. This procedure is used to generate both our model's QA memory and our pre-training data.

C Ablation Study

We experiment with two variants of memory to see their performance difference.

C.1 PAQ memory

The first version is the standard PAQ corpus (Lewis et al., 2021) containing 65M QA pairs, where these QA-pairs are generated by models trained on NQ (Kwiatkowski et al., 2019) and filtered through FiD model (Izacard and Grave, 2021) also trained on NQ (Kwiatkowski et al., 2019). This memory is highly precise due to ODQA-filtering process, however, it only covers information from 9M out of the 20M passage blocks used in DPR (Karpukhin et al., 2020).

Our memory contains 30M PAQ corpus being de-duplicated, i.e. only one question corresponds to an answer span. We generate 30M additional QA-pairs based on the left-out 10M documents from PAQ (Lewis et al., 2021) and add these complementary QA-pairs to form our 60M memory to increase the coverage. However, since our filtering procedure is based on reading comprehension, the precision of QA-pairs is lower than the original PAQ memory.

Memory	NQ	TriviaQA	WebQuestions
PAQ 65M	44.7	48.0	39.4
Ours 60M	44.5	53.2	43.0

Table 6: Impact of different memory over the downstream QA dataset performance.

As can be seen, from Table 6, using the most precise but low-coverage PAQ memory from PAQ (Lewis et al., 2021) yields the worse results on TriviaQA and WebQuestions. After adding an additional 30M PAQs to the memory generated by our pipeline, we are able to achieve 4-5% improvements on these two datasets while still maintaining NQ's performance.

C.2 Size of Pre-training Corpus

Next, we investigate the impact of the size of the pre-training corpus. As a baseline, we repurpose the aligned query-passage corpus used to train DPR (Karpukhin et al., 2020) which we adapt to our setting by simply reversing the pairs (120K passage -> question retrieval). Additionally, we vary the size of generated pre-training corpus (from 1M to 20M instances) to see its impact on the model's final downstream performance. From Table 7, we can see that the smaller-sized pre-training corpus can drastically reduce the model's performance, with up to a 5% drop seen on TriviaQA.

Pre-train Examples	NQ	TQA	WQ
120K	42.5	48.2	39.7
1M	42.8	48.8	40.2
5M	43.8	51.5	41.7
10M	44.3	52.1	42.5
20M	44.5	53.2	43.0

Table 7: Impact of pre-training corpus size on final downstream EM performance. The upper portion is pre-trained using the DPR-reverse corpus described in subsection 5.6 and the lower portion uses subsets of our generated pre-training corpus (subsection 4.1)

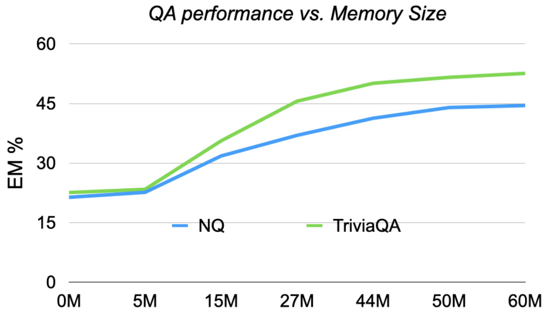

Figure 7: The impact of memory size on downstream QA EM performance.

Size of Memory Finally, we look at how big of memory we need to reach optimal downstream accuracy and how the model behaves with a smaller memory. As is shown in Figure 7, having a small memory of less than 5M entries does not improve over a model with no memory at all. Due to the lack of coverage, the model does not receive a useful signal from the retrieval and is subsequently not incentivized to utilize those retrievals when making a prediction. However, once the size of the memory increases beyond 15M we observe a steep increase in the final performance, indicating that the model is gradually learning to incorporate retrieved information retrievals to assist prediction.

D MultiHop QA Training

In order to train the multi-hop QA model, we need to have intermediate supervision for the query augmentation process. Here we use a string-based match to derive what are the most possible intermediate questions from a collection of pre-generated QA pairs. We depict the mining process as Figure 8.

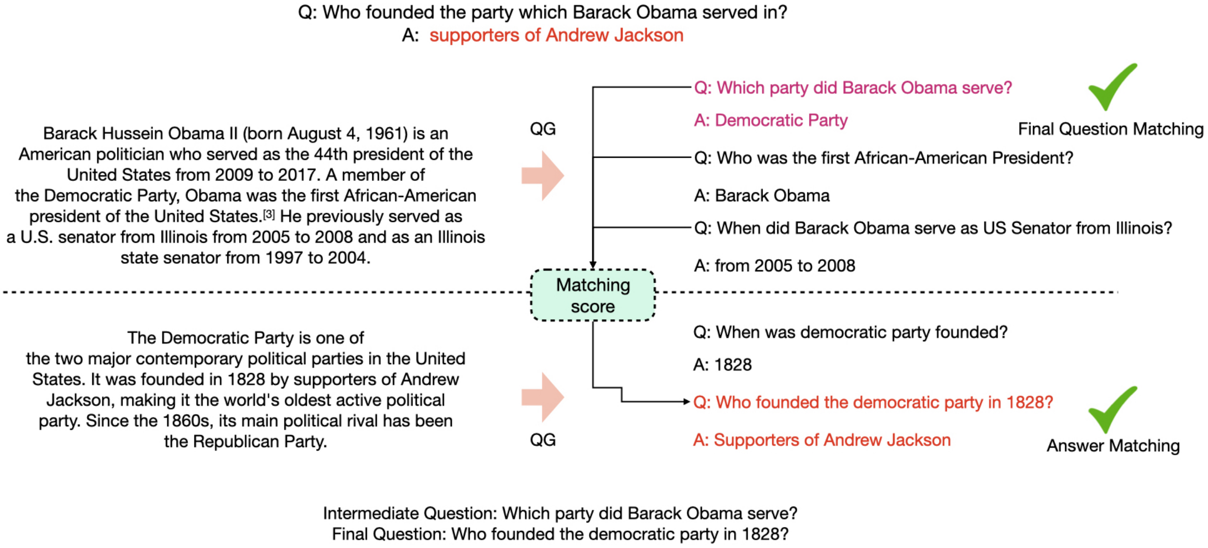

Figure 8: We first find the final question based on answer string matching with the pre-generated question, and then base on that to trace back the intermediate question.

Gold Doesn't Always Glitter: Spectral Removal of Linear and Nonlinear Guarded Attribute Information

Abstract

We describe a simple and effective method (Spectral Attribute removaL; SAL) to remove private or guarded information from neural representations. Our method uses matrix decomposition to project the input representations into directions with *reduced* covariance with the guarded information rather than *maximal* covariance as factorization methods normally use. We begin with linear information removal and proceed to generalize our algorithm to the case of nonlinear information removal using kernels. Our experiments demonstrate that our algorithm retains better main task performance after removing the guarded information compared to previous work. In addition, our experiments demonstrate that we need a relatively small amount of guarded attribute data to remove information about these attributes, which lowers the exposure to sensitive data and is more suitable for low-resource scenarios.[1]

1 Introduction

Natural language processing (NLP) models currently play a critical role in decision-supporting systems. Their predictions are often affected by undesirable biases encoded in real-world data they are trained on. Making sensitive predictions based on irrelevant input attributes such as gender, race, religion, or demographic (**protected** or **guarded** attributes) impacts user trust and the practical broad utility of NLP methods.

In recent years, representation learning approaches have become the mainstay of input encoding in NLP. While representation learning has yielded state-of-the-art results in many NLP tasks, it is hard to control or inspect the information encoded in these representations. Thus, using rule-based methods to remove unwanted information from such representations is often not feasible. In the context of protected attributes, Bolukbasi et al. (2016) showed that word embeddings trained on the Google News corpus encode gender stereotypes. Later, Manzini et al. (2019) expanded this work and showed that word embeddings trained on the Reddit L2 corpus (Rabinovich et al., 2018) encode race and religion biases.

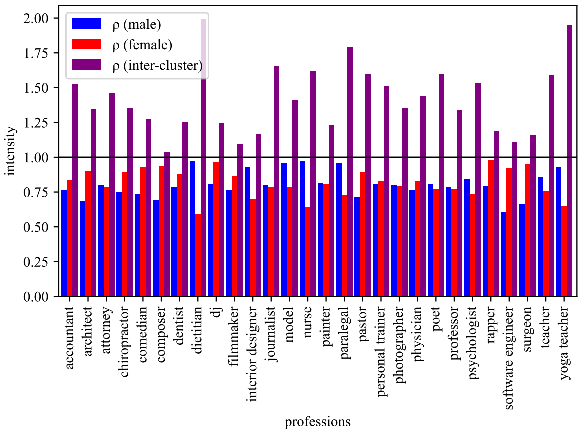

Figure 1: The ratio ρ between the average t-SNE similarity of representations between two gender clusters c_1, c_2 ($\mathrm{sim}(c_1, c_2)$) for each profession: $\rho = \left(\textit{after SAL}\ \mathrm{sim}(c_1, c_2) \big/ \textit{before SAL}\ \mathrm{sim}(c_1, c_2)\right)$. Three values of ρ are computed, intra-cluster: (1) $c_1 = c_2 =$ male; (2) $c_1 = c_2 =$ female; and inter-cluster: (3) $c_1 =$ male, $c_2 =$ female. The ratios in the inter-cluster case are smaller than 1, and larger than 1 for the intra-cluster case.

We propose a simple yet effective technique to remove protected attribute information from neural representations. Our method, dubbed **SAL** for Spectral Attribute removaL, applies Singular Value Decomposition (SVD) on a covariance matrix between the input representation and the protected attributes and prunes highly co-varying directions. Figure 1 demonstrates how professional biography text representations from labeled gender clusters (each biography is marked with the gender of its subject; De-Arteaga et al. 2019) for different professions expand after the use of SAL, and become

---

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1611–1622
May 2-6, 2023 ©2023 Association for Computational Linguistics

closer, implying a higher spread of each profession representations after SAL (§6.2.2).

In addition, we overcome the **linear removal limitations** of SAL and previous work by using eigenvalue decomposition of **kernel matrices** to obtain projections into directions with reduced covariance in the kernel feature space. We refer to this method as **kSAL** (for kernel SAL).

SAL outperforms the recent method of Ravfogel et al. (2020) aimed at solving the same problem, and is able to remove guarded information much faster while retaining better performance for the main task. Further experiments demonstrate that our method performs well even when the available data for the protected attributes is limited.

2 Problem Formulation and Notation

For an integer n we denote by $[n]$ the set $\{1, \ldots, n\}$. For a vector $\mathbf{v}$, we denote by $||\mathbf{v}||_2$ its ℓ_2 norm. Matrices and vectors are in boldface font (with uppercase or lowercase letters, respectively). Random variable vectors are also denoted by boldface uppercase letters. For a matrix $\boldsymbol{A}$, we denote by $\boldsymbol{A}_j$ its jth column (or by $\boldsymbol{A}_{i:j}$ the matrix with columns $\boldsymbol{A}_k$ for $k = i, \ldots, j$). Vectors are assumed to be column vectors.

In our problem formulation, we assume three random variables: $\mathbf{X} \in \mathbb{R}^d$, $\mathbf{Y} \in \mathbb{R}$ and $\mathbf{Z} \in \mathbb{R}^{d'}$. Samples of $\mathbf{X}$ are the inputs for a classifier to predict corresponding samples of $\mathbf{Y}$. The random vector $\mathbf{Z}$ represents the guarded attributes. We want to maximize the ability to predict $\mathbf{Y}$ from $\mathbf{X}$, while minimizing the ability to predict $\mathbf{Z}$ from $\mathbf{X}$. Without loss of generality, we assume that the mean values of $\mathbf{X}$, $\mathbf{Y}$ and $\mathbf{Z}$ are 0, and that $d' \leq d$.[2]

We assume n samples of $(\mathbf{X}, \mathbf{Y}, \mathbf{Z})$, denoted by $(\mathbf{x}^{(i)}, \mathbf{y}^{(i)}, \mathbf{z}^{(i)})$ for $i \in [n]$. These samples are used to train the classifier to predict the target values (y) from the inputs (x). These samples are also used to remove the information from the inputs based on the guarded attributes (z).

3 Erasing Principal Directions

We describe SAL in this section. We explain the use of SVD on cross-covariance matrices (§3.1) and describe the core algorithm in §4.1.

3.1 SVD on Cross-covariance Matrix

Let $\boldsymbol{A} = \mathbb{E}[\mathbf{X}\mathbf{Z}^\top]$, the matrix of cross-covariance between $\mathbf{X}$ and $\mathbf{Z}$. In that case, $\boldsymbol{A}_{ij} = \mathrm{Cov}(\mathrm{X}_i, \mathrm{Z}_j)$ for $i \in [d]$ and $j \in [d']$.

A simple observation is that for any two vectors $\mathbf{a} \in \mathbb{R}^d, \mathbf{b} \in \mathbb{R}^{d'}$, the following holds due to the linearity of expectation:

$$\mathbf{a}\boldsymbol{A}\mathbf{b}^\top = \mathrm{Cov}(\mathbf{a}^\top\mathbf{X}, \mathbf{b}^\top\mathbf{Z}). \qquad (1)$$

This motivates the use of the cross-covariance matrix to find the so-called principal directions: directions in which the projection of $\mathbf{X}$ and $\mathbf{Z}$ maximize their covariance, where the projections are represented as two matrices $\boldsymbol{U} \in \mathbb{R}^{d\times d}$ and $\boldsymbol{V} \in \mathbb{R}^{d'\times d'}$. Each column in these matrices plays the role of the vectors $\mathbf{a}$ and $\mathbf{b}$ in Eq. 1. More specifically, we find $\boldsymbol{U}$ and $\boldsymbol{V}$ such that for any $i \in [d']$ it holds that:

$$\mathrm{Cov}(\boldsymbol{U}_i^\top\mathbf{X}, \boldsymbol{V}_i^\top\mathbf{Z}) = \max_{(\mathbf{a},\mathbf{b})\in\mathcal{O}_i} \mathrm{Cov}(\mathbf{a}^\top\mathbf{X}, \mathbf{b}^\top\mathbf{Z}),$$

where $\mathcal{O}_i$ is the set of pairs of vectors $(\mathbf{a}, \mathbf{b})$ such that $||\mathbf{a}||_2 = ||\mathbf{b}||_2 = 1$, $\mathbf{a}$ is orthogonal to $\boldsymbol{U}_1, \ldots, \boldsymbol{U}_{i-1}$ and similarly, $\mathbf{b}$ is orthogonal to $\boldsymbol{V}_1, \ldots, \boldsymbol{V}_{i-1}$.

It can be shown that such maximization can be done by applying the SVD on $\boldsymbol{A}$ such that $\boldsymbol{A} = \boldsymbol{U}\boldsymbol{\Sigma}\boldsymbol{V}^\top$, where $\boldsymbol{U} \in \mathbb{R}^{d\times d}$, $\boldsymbol{\Sigma} \in \mathbb{R}^{d\times d'}$ and $\boldsymbol{V} \in \mathbb{R}^{d'\times d'}$. In the case of SVD, $\boldsymbol{U}$ and $\boldsymbol{V}$ are orthonormal matrices, and $\boldsymbol{\Sigma}$ is a diagonal matrix with non-negative values on the diagonal. We let the vector of singular values on the diagonal of $\boldsymbol{\Sigma}$ be denoted by $\sigma_1, \ldots, \sigma_{d'}$.

Once the orthogonal matrices in the form of $\boldsymbol{U}$ and $\boldsymbol{V}$ are found, one can truncate them (for example, use only a subset of the columns of $\boldsymbol{U}$, represented as the semi-orthonormal matrix $\hat{\boldsymbol{U}}$) to use, for example, $\hat{\boldsymbol{U}}^\top\mathbf{X}$, as a representation (linear projection) of $\mathbf{X}$ which co-varies the most with $\mathbf{Z}$.

We suggest that rather than using the largest singular value vectors in $\boldsymbol{U}$ to project $\mathbf{X}$, we should project $\mathbf{X}$ using the principal directions with the **smallest** singular values. This means we find a representative of $\mathbf{X}$ that co-varies the *least* with $\mathbf{Z}$, essentially removing the information from $\mathbf{X}$ that is most related to $\mathbf{Z}$ and can be detected through covariance.

In addition, once such a projection matrix $\overline{\boldsymbol{U}}$ is calculated, we can use the projection $\overline{\mathbf{X}} = \overline{\boldsymbol{U}\boldsymbol{U}}^\top\mathbf{X}$ such that the value of $\mathbb{E}[||\mathbf{X} - \overline{\mathbf{X}}||_2]$ is minimized,

---

[2] For example, $\mathbf{Z}$ may be a multi-class label such as gender represented as a short vector over $\{-1, 1\}$ and $\mathbf{X}$ may be a complex input, which before removal of information about the guarded attribute $\mathbf{Z}$, can be used to predict $\mathbf{Z}$. An example of $\mathbf{X}$ would be an encoding of a post on a message board.

while removing the information from $\mathbf{X}$.[3] This allows us to potentially use the new projected values of the input random variable $\mathbf{X}$ *without* changing a classifier that was originally trained on samples from $\mathbf{X}$, though as we see in §6, using the projected input as-is without retraining the classifier may lead to performance issues with our method and other methods as well.

4 Connection to CCA and PCA

We describe connections to other matrix factorization methods.

How is SAL related to Canonical Correlation Analysis? The use of SVD on the cross-covariance matrix is very much related to the technique of Canonical Correlation Analysis (CCA), in which projections of $\mathbf{X}$ and $\mathbf{Z}$ are found such that they maximize the cross-correlation between these two random vectors. Rather than applying SVD on the cross-correlation matrix (CCA), we apply it on the cross-covariance matrix to preserve the scale of $\mathbf{X}$ in our projection.

How is SAL related to Principal Component Analysis? The use of SVD on the cross-covariance matrix is reminiscent of Principal Component Analysis (PCA), in which eigenvalue decomposition is applied on $\mathbb{E}[\mathbf{X}\mathbf{X}^\top]$ to reduce the dimensionality of $\mathbf{X}$. However, PCA does not reduce the dimensionality of $\mathbf{X}$ while removing information present in the guarded r.v. $\mathbf{Z}$. Rather, it finds projection of $\mathbf{X}$ in which the covariance of linear combination of $\mathbf{X}$ with itself is maximized.

In all three cases of CCA, PCA and LSA (Latent Semantic Analysis; Dumais 2004), SVD or eigenvalue decomposition is used with the aim of *maximizing* the correlation or covariance between one or two random vectors. In our case, the SVD is used to *minimize* the covariance between projections of $\mathbf{X}$ and $\mathbf{Z}$.

4.1 The SAL Algorithm

Our algorithm (SAL) follows the following procedure. First, the empirical cross-covariance matrix, estimating $\mathbb{E}[\mathbf{X}\mathbf{Z}^\top]$ is calculated:

$$\mathbf{\Omega} = \frac{1}{n}\sum_{i=1}^{n} \mathbf{x}^{(i)}(\mathbf{z}^{(i)})^\top. \qquad (2)$$

SVD is then performed on $\mathbf{\Omega}$ to obtain $(\boldsymbol{U}, \mathbf{\Sigma}, \boldsymbol{V})$. We choose an integer value k and define $\overline{\boldsymbol{U}} = \boldsymbol{U}_{(k+1):d}$. The value of k bounded by the rank of $\mathbf{\Omega}$. The rank of $\mathbf{\Omega}$ is bounded from above by d and d', the dimensions of the vectors of $\mathbf{X}$ and $\mathbf{Z}$.

Then, the vectors $\mathbf{x}^{(i)}$ are projected using either $\overline{\boldsymbol{U}}^\top$ or $\overline{\boldsymbol{U}\boldsymbol{U}}^\top$. The latter projection attempts to project $\mathbf{x}^{(i)}$ to the original dimensionality and space after removing the information. More specifically, $\overline{\boldsymbol{U}\boldsymbol{U}}^\top$ is a projection matrix to the range of $\mathbf{\Omega}$.

The criterion we use to choose k is based on the singular values in $\mathbf{\Sigma}$. More specifically, we choose a threshold $\alpha \geq 1$ and choose the minimal k such that $\mathbf{\Sigma}_{11}/\mathbf{\Sigma}_{k+1,k+1} > \alpha$.

5 Kernel Extension to SAL

To enrich the type of information that is detected as co-varying, it is possible to use two feature functions, $\phi\colon \mathbb{R}^d \to \mathbb{R}^m$ and $\psi\colon \mathbb{R}^{d'} \to \mathbb{R}^{m'}$, and apply the procedure in §3 on $\mathbb{E}[\phi(\mathbf{X})(\psi(\mathbf{Z}))^\top]$. In that case, we can erase the information from $\phi(\mathbf{X})$ and treat it as the input for further classification. If the classifier is already learned, it would have to take input vectors of the form $\phi(\mathbf{X})$, otherwise it can be re-trained with the erased inputs.

5.1 The Kernel Trick

The kernel trick refers to learning and prediction without explicitly representing $\phi(\mathbf{x})$ or $\psi(\mathbf{z})$. Rather than that, we assume two kernel functions, $K_\phi(\mathbf{x}, \mathbf{x}')$ and $K_\psi(\mathbf{z}, \mathbf{z}')$ that calculate similarities between two xs or between two zs.

Every kernel that satisfies the necessary properties can be shown to be a dot product in some feature space. This means that for a given kernel function $K_\phi(\mathbf{x}, \mathbf{x}')$ it holds that

$$K_\phi(\mathbf{x}, \mathbf{x}') = \langle \phi(x), \phi(x') \rangle, \qquad (3)$$

for some ϕ function and similarly for $K_\psi(\mathbf{z}, \mathbf{z}')$. Masking learning and prediction through a kernel function is often useful when the feature representations ϕ and ψ are hard to explicitly compute, for example, because $m = \infty$ or $m' = \infty$ (such as the case with the Radial Basis Function, RBF, kernel).

We show next that the kernel trick can be used to generalize SAL to nonlinear information removal.

5.2 Removal with the Kernel Trick

Rather than assuming a set of examples in the form mentioned in §2, we assume we are given as input

---

[3] This can be formalized using the min-max theorem of linear algebra, also referred to as the Courant–Fischer–Weyl min-max principle.

two kernel matrices of dimension $n \times n$:

$$[\boldsymbol{K}_\phi]_{ij} = K_\phi(\mathbf{x}^{(i)}, \mathbf{x}^{(j)}),$$
$$[\boldsymbol{K}_\psi]_{ij} = K_\psi(\mathbf{z}^{(i)}, \mathbf{z}^{(j)}).$$

In addition, for the justification of our algorithm, we define the following two feature matrices based on the kernel feature functions:

$$\forall i \in [m], j \in [n] \qquad [\boldsymbol{\Phi}]_{ij} = \phi(\mathbf{x}^{(j)})_i,$$
$$\forall i \in [m'], j \in [n] \qquad [\boldsymbol{\Psi}]_{ij} = \psi(\mathbf{x}^{(j)})_i.$$

Note that these two matrices are never calculated explicitly. Given the definition of the kernel as a dot product in the feature space (Eq. 3), it can be shown that $\boldsymbol{K}_\phi = \boldsymbol{\Phi}^\top \boldsymbol{\Phi}$ and $\boldsymbol{K}_\psi = \boldsymbol{\Psi}^\top \boldsymbol{\Psi}$. In addition, we slightly change the empirical cross-covariance matrix $\boldsymbol{\Omega}$ definition in Eq. 2 to: $\boldsymbol{\Omega} = \boldsymbol{\Phi}\boldsymbol{\Psi}^\top$. (This means we ignore the constant $1/n$ in the above definition of $\boldsymbol{\Omega}$ that normalizes the matrix with respect to the number of examples. This does not change the nature of the following discussion, but makes it simpler.) At this point, the question is how to perform SVD on $\boldsymbol{\Omega}$ without ever accessing directly the feature functions. This is where spectral theory of matrices comes in handy.

More specifically, it is known that the left singular vectors of $\boldsymbol{\Omega}$ ($\boldsymbol{U}$) are the eigenvectors of $\boldsymbol{\Omega}\boldsymbol{\Omega}^\top$. In addition, the singular values of $\boldsymbol{\Omega}$ correspond to the square-root values of the eigenvalues of $\boldsymbol{\Omega}\boldsymbol{\Omega}^\top$.

In addition, we show in Appendix A why an eigenvector $\mathbf{w}$ of $\boldsymbol{\Gamma} = \boldsymbol{K}_\phi \boldsymbol{K}_\psi$ can be transformed to an eigenvector of $\boldsymbol{\Omega}\boldsymbol{\Omega}^\top$ by multiplying $\mathbf{w}$ on the left by $\boldsymbol{\Phi}$ and calculating $\boldsymbol{\Phi}\mathbf{w}$.

With this fact in mind, we are now ready to find the left singular vectors of $\boldsymbol{\Omega}$ by finding the eigenvalues of $\boldsymbol{\Gamma}$, a matrix which is solely based on the kernel functions of $\mathbf{x}$ and $\mathbf{z}$.

Let $\mathbf{w}_1, \ldots, \mathbf{w}_k$ be eigenvectors of $\boldsymbol{\Gamma}$ and let $\mathbf{w}'_1, \ldots, \mathbf{w}'_k$ be the orthonormalization of $\mathbf{w}_i$, $i \in [k]$ based on the inner product $\langle \mathbf{w}_i, \mathbf{w}_j \rangle = \mathbf{w}_i \boldsymbol{K}_\phi \mathbf{w_j}^\top$. If we denote by $\boldsymbol{W}$ the matrix such that $\boldsymbol{W}_j = \mathbf{w}'_j$ for $j \in [k]$, then $\Phi \boldsymbol{W} = \boldsymbol{U}$ where $\boldsymbol{U}$ is the left singular vector matrix of $\boldsymbol{\Omega}$. Then,

$$\boldsymbol{U}^\top \phi(\mathbf{x}) = (\boldsymbol{W}^\top \boldsymbol{\Phi}^\top)\phi(\mathbf{x}) = \boldsymbol{W}^\top \kappa(\mathbf{x}), \quad (4)$$

where $\kappa(\mathbf{x})$ is a function that returns a vector of length n such that $[\kappa(\mathbf{x})]_j = K(\mathbf{x}^{(j)}, \mathbf{x})$. Eq. 4 shows we can calculate the projection of $\phi(\mathbf{x})$ while removing the information in $\psi(\mathbf{z})$ by using the smallest eigenvalue eigenvectors of $\boldsymbol{\Gamma}$ and kernel calculations of each training example with $\mathbf{x}$.

5.3 Practical Kernel Removal

Using the kernel algorithm as above may lead to issues with tractability, as it possibly requires calculating the full eigenvector matrix of a large matrix (the product of two kernel matrices). We propose an alternative algorithm (kSAL) for the kernel case which is more tractable.

For a fixed $0 \leq k \leq n$ (which does not need to be larger than the rank of either kernel matrices), we compute only the top k eigenvectors of $\boldsymbol{\Gamma}$. We then compute an orthonormal basis for the null space of the matrix $(\boldsymbol{K}_{\phi,1/2}\boldsymbol{W}_{1:k})^\top$ where $\boldsymbol{K}_{\phi,1/2} = \boldsymbol{U}_\phi \boldsymbol{\Sigma}_\phi^{1/2} \boldsymbol{V}_\phi^\top$, with $(\boldsymbol{U}_\phi, \boldsymbol{\Sigma}_\phi, \boldsymbol{V}_\phi)$ being the SVD of $\boldsymbol{K}_\phi$. Practically, this means we find a matrix $\boldsymbol{L}_\phi \in \mathbb{R}^{n\times(n-d)}$ such that $\boldsymbol{L}_\phi^\top \boldsymbol{L}_\phi = I$ and that $||(\boldsymbol{K}_{\phi,1/2}\boldsymbol{\Gamma})^\top \boldsymbol{L}_\phi||_2 \approx 0$. The final data points $\hat{\mathbf{x}}^{(j)}$ we use further down the pipeline correspond to the rows of $\boldsymbol{K}_{\phi,1/2}\boldsymbol{L}_\phi \in \mathbb{R}^{n\times(n-k)}$. If we are interested in using directly the reduced kernel matrix for the input vectors, we can use

$$\hat{\boldsymbol{K}}_\phi = \boldsymbol{K}_{\phi,1/2} \boldsymbol{L}_\phi \boldsymbol{L}_\phi^\top \boldsymbol{K}_{\phi,1/2}^\top. \quad (5)$$

Time Complexity Absorbing the kernel function computation as a constant, computing the kernel matrices is $\mathcal{O}(n^2)$ and their product $\boldsymbol{\Gamma}$ in $O(n^\omega)$ for $\omega < 2.808$ using Strassen's algorithm, but can be done much more efficiently when $\boldsymbol{K}_\psi$ is sparse, as normally expected. Calculating the top k eigenvectors of $\boldsymbol{\Gamma}$, has a cost of $\mathcal{O}(nk^2 + k^3)$ using, for example, the Arnoldi method.[4] In §6.4, we report clock running time for the kernel method.

Below, we experiment with RBF kernels (where $K_\phi(\mathbf{x}, \mathbf{x}') = \exp(-\gamma||\mathbf{x} - \mathbf{x}'||_2^2)$; we use $\gamma = 0.1$) and polynomial kernel of degree 2 (where $K_\phi(\mathbf{x}, \mathbf{x}') = (1 + \mathbf{x}^\top \mathbf{x}')^2$). The kernel of $\mathbf{z}$ remains linear (dot product).

6 Experiments

In our experiments, our main comparison algorithm is the iterative null space projection (INLP) algorithm of Ravfogel et al. (2020), which aims at solving an equivalent problem to ours. For the word embedding debiasing and fair classification (both

---

[4] For example, Matlab implements a variant of the Arnoldi method for its function `eigs`.

	SL	WS-S	WS-R	Mturk
Before	0.37	0.69	0.6	0.68
After	↑0.02 0.39	↑0.01 0.7	0.6	↑0.01 0.69

Table 1: The semantic evaluation of word embeddings before and after removing gender bias.

setups), we follow the experimental settings of Ravfogel et al. (2020).[5] SAL provides linear guarding, similarly to INLP, while kSAL also captures nonlinear regularities with respect to $\mathbf{Z}$ (one-hot vector). We can provide such guarding for representations of state-of-the-art encoders (such as BERT), provided the representations are eventually fed into a classifier for prediction. The protected attributes we experiment with are *gender* and *race*. Appendix D provides details about the datasets' splits and SAL run-time performance.

Datasets For debiasing word embeddings (§6.1), we use 7,500 male and female associated words, 15K words overall. The dataset train/validation/test split sizes are (49%/21%/30%). All the splits are balanced, i.e., containing an equal amount of male and female associated words. For the fair sentiment classification task (§6.2), we use 10K training examples across all authors' ethnicity ratios (0.5, 0.6, 0.7, and 0.8). All training sets have an equal amount of positive and negative sentiment examples. The test set is balanced for both sentiment and authors' ethnicity labels. For the profession classification task (§6.2.2) the data train/validation/test split sizes are (65%/10%/25%) and all the splits combined contain 115K samples.

6.1 Word Embedding Debiasing

Word embeddings are often prone to encoding biases in various ways (see §7). We evaluate our methods on gender bias removal from GloVe word embeddings. We use the 150,000 most common words and discard the rest. We sort the embeddings by their projection on the $\overrightarrow{\text{he}}$-$\overrightarrow{\text{she}}$ direction. Then we consider the top 7,500 word embeddings as male-associated words ($z = 1$) and the bottom 7,500 as female-associated words ($z = -1$).

Results with SAL A linear classifier can perfectly predict the guarded gender attribute when trained on out-of-the-box GloVe embeddings. Removing the first direction ($k = 1$) does not affect accuracy demonstrated in Figure 2. For $k = 2$, the performance drops to 50.2%, almost a random guess.

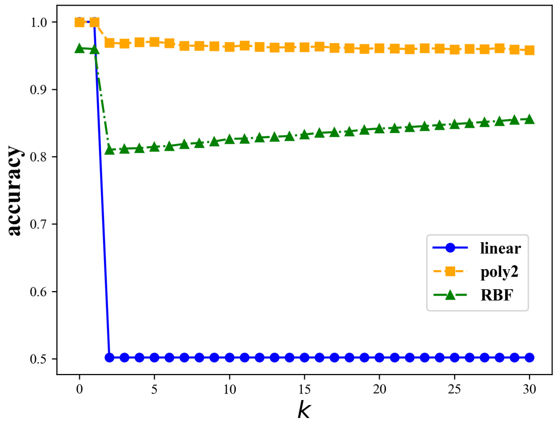

Figure 2: A classifier accuracy for gender prediction as a function of the number of principal directions that are linearly removed. For the linear classifier, we use a linear SVM. For the nonlinear classifiers, we use SVM with the polynomial kernel and with the RBF kernel.

We further perform intrinsic semantic tests to ensure the debiased embeddings remain useful. We use SimLex-999, WordSim353, and Mturk771 (similarity and relatedness datasets) to calculate the correlation between cosine similarities of the word embeddings to the human-annotated similarity score (Hill et al., 2015; Finkelstein et al., 2001; Halawi et al., 2012). We observed minor improvements for all tests when using debiased embeddings (Table 1), suggesting that our method keeps the embeddings intact. We also report the three most similar words (nearest neighbors) for ten random words before and after SAL (see Appendix C). We observe almost no change between the two sets of embedding results.

SAL debiasing does not provide a nonlinear information removal. In Figure 2 we plot the performance of nonlinear classifiers in the prediction of the **linearly-guarded** attribute (gender) as a function of the number of removed directions. We also provide linear classifier results for reference. We see that even after removing up to 30 principal directions, (linear) SAL is not sufficient for nonlinear classifiers – the gender can still be predicted. This finding is also noted by Ravfogel et al. (2020), who did not offer a direct solution. This finding partially motivates our development of kSAL.

Kernel Debiasing All three kernels achieve high gender prediction accuracy when no information is removed ($k = 0$), with accuracy of 100%, 99.9%

---

[5] We use the authors' implementation for both the INLP method and the experimental settings: `https://github.com/shauli-ravfogel/nullspace_projection`.

and 95.7% for the linear, polynomial, and RBF kernel, respectively. While the performance of the linear and polynomial kernels is not affected by removing one principal direction ($k = 1$), the RBF kernel accuracy drops to 86.3%. With $k = 2$, performance drops to 50.2%, 44.5% and 50.2% for the linear, polynomial, and RBF kernel, respectively, under **nonlinear kernel** removal. Compared to Figure 2 with SAL, we see kSAL effectively removes nonlinear information.

Deviations of Reduced Kernel from Original Kernel To quantitatively test whether the embeddings retain their geometric form when removing gender information, we compare the standard deviation (ρ) of the values in $\boldsymbol{K}_\phi$ to the average deviation (γ) of values of $\boldsymbol{K}_\phi$ from the corresponding values in $\hat{\boldsymbol{K}}_\phi$ (Eq. 5). When removing two principal directions, the largest approximation difference is seen in the linear kernel, with $\gamma/\rho = 0.64$. For the polynomial kernel, we observe $\gamma/\rho = 0.52$. For RBF, we have $\gamma/\rho = 0.16$.

6.2 Fair Classification

To further evaluate our method on downstream tasks, we follow fair classification tests of social media text.

6.2.1 Fair Sentiment Analysis

Task and Data The first task is sentiment analysis for social network users' posts. We use the TwitterAAE dataset (Blodgett et al., 2016), which contains users' tweets ($\mathbf{x}$), coupled with the users' ethnic affiliations ($\mathbf{z}$), and a binary label for the sentiment the tweet conveys ($\mathbf{y}$). The dataset splits the users into two groups, African American English (AAE) speakers and Standard American English (SAE) speakers. As users' privacy makes it hard to obtain ground truth labels for ethnic affiliation, the dataset uses the demographics of the neighborhoods the users live in as a proxy. Following NIO2020, we use the encoder of Felbo et al. (2017), DeepMoji, to obtain the tweets representation. DeepMoji is suitable for our goal, as it has been shown to encode demographic information, and therefore, might lead to unfair classification (Elazar and Goldberg, 2018).

We experiment with four different setups. The dataset consists of an equal amount of positive and negative sentiment examples for all of them. The datasets differ with respect to the guarded attribute ratio. For example, a ratio of 0.8 means that 0.8 of the positive and negative sentiment class examples are composed of AAE speakers, and 0.2 is composed of SAE speakers. We experiment with ratios of 0.5, 0.6, 0.7 and 0.8. The larger the ratio, the higher the classifier's tendency to make use of protected attributes to make its prediction.

Evaluation Measures We report the accuracy of the methods on the sentiment analysis task. To measure fairness, we use the difference in true positive rate (TPR-gap) between individuals belonging to different guarded attributes groups (Hardt et al., 2016; Ravfogel et al., 2020). The rationale behind TPR-gap is that for an equal opportunity, a positive outcome must be independent of the guarded attribute ($\mathbf{z}$), conditional on ($\mathbf{y}$) being an actual positive. See Hardt et al. (2016) for more details.

Results Table 2 presents our results for the fair sentiment classification. For the first three ratios, 0.5, 0.6, and 0.7, we can see that both SAL ($k = 1, 2$) and INLP maintain most of the main-task performance. In debiasing (TPR-Gap), SAL with $k = 2$ significantly outperforms INLP. As expected, removing two directions results in better debiasing than removing one, but it does not lead to a performance drop on the main task. While for the last ratio, 0.8, INLP achieves the highest TPR-gap result, it comes at the cost of a sharp performance drop on the main task, resulting in a nearly random classifier. SAL ($k = 1, 2$) maintains most of the main-task performance, and for $k = 2$, the TPR-gap is halved.

6.2.2 Fair Profession Classification

Task and Data The second task is profession classification. De-Arteaga et al. (2019) attempt to quantify the bias in automatic hiring systems and show that even for a simple task, predicting candidate profession based on a self-provided short biography, significant gaps result from the writer's gender. This might influence the open positions an automatic system will recommend to a candidate, thus favoring candidates from one gender over the other. We hence follow the setup of De-Arteaga et al. (2019), who experiment with professions classification ($\mathbf{y}$), from short biographies ($\mathbf{x}$), and gender as a guarded attribute ($\mathbf{z}$). We use a multiclass classifier to predict the profession, as there are 28 profession classes. We experiment with two types of text representations, FastText (Joulin et al., 2016), based on bag of word embeddings (BWE) and BERT (Devlin et al., 2018) encodings.

	Sentiment				TPR-Gap			
Rt	Orig.	INLP	SAL, $k = 1$	SAL, $k = 2$	Orig.	INLP	SAL, $k = 1$	SAL, $k = 2$
0.5	0.76	0.76	0.76	0.76	0.14	↓0.02 0.12	0.14	↓0.03 0.11
0.6	0.75	0.75	0.75	0.75	0.22	↓0.03 0.19	0.22	↓0.13 0.09
0.7	0.74	0.74	0.74	0.74	0.31	↓0.05 0.26	0.31	↓0.15 0.11
0.8	0.72	↓0.2 0.52	0.72	0.72	0.40	↓0.39 0.01	↓0.04 0.36	↓0.22 0.18

Table 2: The sentiment analysis scores (we use accuracy, as the dataset is balanced) and TPR differences (lower is better) as a function of the ratio of tweets (Rt) written by black individuals and conveying positive sentiment. Arrows with numbers indicate absolute increase/decrease from the baseline, and their background color indicates a difference with positive implications (green) or negative ones (red).

	Accuracy (profession)				TPR-Gap (RMS)			
Encoder	Orig.	INLP	SAL, $k = 1$	SAL, $k = 2$	Orig.	INLP	SAL, $k = 1$	SAL, $k = 2$
FastText	0.75	↓0.05 0.71	↑0.01 0.76	↑0.01 0.76	0.20	↓0.11 0.09	↓0.02 0.18	↓0.08 0.12
BERT	0.8	↓0.11 0.69	↓0.02 0.78	↓0.02 0.78	0.21	↓0.15 0.06	↓0.04 0.17	↓0.12 0.09

Table 3: The profession classification on the biographies dataset results. We report accuracy and TPR-RMS. The number of classes is 28.

Evaluation Measures We report accuracy for the profession classification. For bias level measurement, we use a generalization of TPR-gap for multi-class, suggested by De-Arteaga et al. (2019), calculating the root mean square (RMS) of the TPR with respect to all classes.

De-Arteaga et al. (2019) also provided evidence for a strong correlation between TPR-gap and existing gender imbalances in occupations, which may lead to unfair classification.

Results Table 3 presents the profession classification results. Similar to the sentiment analysis task, SAL ($k = 1, 2$) maintains most of the main-task performance, and for $k = 2$, the two-direction removal, the TPR-gap is lower. When comparing SAL ($k = 2$) to INLP, we observe a clear trade-off between maintaining the main task performance (SAL, $k = 2$) and low TPR-gap scores (INLP).

6.3 Scarce Protected Attribute Labels

For many real-world applications, obtaining large amounts of labeled data for protected attributes can be costly, labor-intensive, and in some cases, infeasible due to an ever-increasing number of privacy regulations. In this analysis, we stress-test our algorithm by simulating a scenario in which only a limited amount of samples from the main task are coupled with the desired protected attribute labels. For this purpose, we replicate the fair sentiment classification experiments, but this time, feeding only a fraction of the annotated data to our debiasing method. In terms of the main task, the experiment is identical, i.e., we use 100K samples for training the sentiment classifier. We experiment with different fractions of the debiasing data, i.e., 5%, of the sentiment training data contains labels about the protected attribute. We hence feed 5,000 samples for debiasing. The subsets for debiasing are chosen randomly. We repeat each experiment 10 times with different subsets. Table 4 presents our results. Using a small fraction of the data for debiasing did not significantly affect SAL's ($k = 1, 2$) main-task performance. INLP, on the other hand, suffers from a sharp performance decrease, resulting in a near-random sentiment classifier. SAL's ($k = 1, 2$) ability to debias the data is slightly worse than in the complete dataset setting but the resulting representations are still significantly less biased than the original ones. INLP achieves low TPR gaps, but it is hard to determine if this is due to an accurate bias removal or a result of corrupting the representations.

6.4 Kernel Experiments

Despite their flexibility in modeling rich feature functions, kernels have been documented to be computationally intensive. Lack of computational resources prevented us from using the full sentiment and bios datasets for our kernel experiments, and instead, we use $15,000$ training examples and $7,998$ test set examples (the full test set) for the sentiment dataset and $15,000$ training examples and $5,000$ examples for the profession dataset. For training on the acquired $15,000$ training examples, we used one Intel Xeon E5-2407 CPU, running at 2.2 GHz, for approximately five hours (for a time complexity analysis, see §5.3).

Table 5 shows that using only a small subset of the data, kSAL-poly2 reduces the TPR gaps

	Sentiment				TPR-Gap			
Ratio	Orig.	INLP	SAL, $k = 1$	SAL, $k = 2$	Orig.	INLP	SAL, $k = 1$	SAL, $k = 2$
0.5	0.76	↓0.19 0.57	0.76	0.76	0.14	↓0.12 0.02	↑0.27 0.41	↓0.03 0.11
0.6	0.75	↓0.16 0.59	0.75	0.75	0.22	↓0.19 0.03	↑0.01 0.23	↓0.13 0.09
0.7	0.74	↓0.17 0.57	↓0.01 0.73	↓0.01 0.73	0.31	↓0.26 0.05	0.31	↓0.19 0.12
0.8	0.72	↓0.15 0.57	↓0.01 0.71	↓0.01 0.71	0.40	↓0.32 0.08	↓0.08 0.34	↓0.27 0.17

Table 4: The sentiment analysis experiments, 100K samples are use to train the sentiment classifier, but only 5K examples are used for learning to remove bias. The test set is identical to the one used in §6

Sentiment Analysis (DeepMoji)				
	Main		TPR-Gap	
k	poly2	rbf	poly2	rbf
0	0.75	0.76	0.14	0.15
1	0.75	0.76	0.14	0.15
2	0.75	0.76	↓0.01 0.13	↓0.03 0.12
Profession Classification (BERT)				
	Main		TPR-Gap (RMS)	
k	poly2	rbf	poly2	rbf
0	0.77	0.61	0.33	0.23
1	0.77	↑0.07 0.68	↓0.05 0.28	↑0.11 0.34
2	0.77	↑0.07 0.68	↓0.08 0.25	↑0.08 0.31

Table 5: Kernel results with kSAL for sentiment (for a ratio of 0.5) and profession classification.

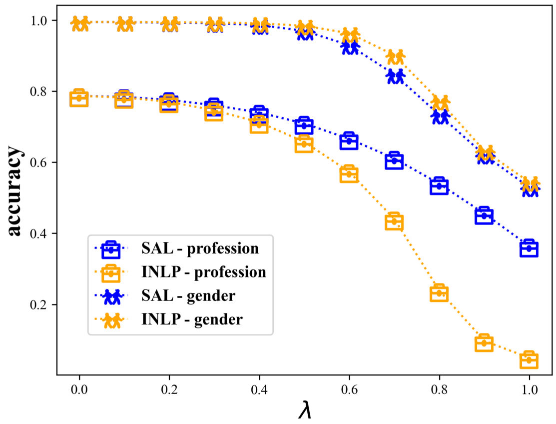

Figure 3: Gender and profession classifications as a function of the interpolation coefficient λ.

while maintaining almost identical performance to the original model on both the sentiment analysis and profession classification tasks. For the sentiment analysis task, kSAL-RBF slightly improves the main task results while reducing the TPR-gap (RMS). For the RBF profession classification task, the results are unexpected, with main task performance increasing as we remove principal directions. This could be due to the pruning of the rich, infinite feature space RBF kernel represents (we also observe significant overfitting with RBF).[6]

6.5 Perturbed Inputs

While the transformation through $\overline{\boldsymbol{U}\boldsymbol{U}}^\top$ maps $\mathbf{x}$ back into the original vector space (as a projection), it often turns out that it removes information in such a way that the *original* classifier (trained on data without removal) can no longer be used with the inputs after removal. This issue exists not only with our algorithm, but also with INLP, and indeed, like us, Ravfogel et al. (2020) re-trained their classifier after they created the cleaned projected inputs.

Ideally, we would want to remove information without necessarily having to retrain a classifier for the main task, as this is costly and perhaps unattainable. To test the effect of such an approach, we interpolated $\overline{\boldsymbol{U}\boldsymbol{U}}^\top$ with the identity matrix, to eventually project $\mathbf{x}$ using $\lambda\overline{\boldsymbol{U}\boldsymbol{U}}^\top + (1-\lambda)\boldsymbol{I}$ for $\lambda \in \{0, 0.1, \ldots, 1.0\}$. This approach weakens the impact of the removal projection and retains some of the information in $\mathbf{x}$. While an adversary can attack this approach,[7] it can mitigate the effects of privacy violations in cases where the service or software used with the modified representations cannot be retrained, especially if the service providers have no malicious intent.

Figure 3 describes an ablation experiment, ranging λ as above on the bios dataset. We see that as we increase the intensity of the use of the SAL projection (increasing λ), the accuracy of both gender prediction and profession prediction decrease when training the original classifier on the non-projected inputs. While the behavior is similar for the gender accuracy for both INLP and our method, the decrease for the profession prediction is much sharper for $\lambda > 0.4$ with INLP.

---

[6] With INLP, RBF-kernel SVM also obtains low-accuracy results.

[7] Consider that the matrix $\lambda\overline{\boldsymbol{U}\boldsymbol{U}}^\top + (1-\lambda)\boldsymbol{I}$ could be invertible for $\lambda < 1$.

Task	WED	FSC	FPCF	FPCB
SAL	0.03 sec	0.37 sec	0.16 sec	0.35 sec
INLP	50 sec	100 min	7 min	35 min

Table 6: A run-time comparison between SAL and INLP. We used 2.20GHz Intel Xeon E5-2407 CPU for all of the experiments. WED, FSC, FSCF, and FPCB stand for word embedding debiasing, fair sentiment classification, and fair profession classification (with both FastText and BERT based representations).

6.6 Runtime of SAL

We measure the time it takes both methods to learn a projection matrix for a given training set. Once we have a projection matrix, debiasing the data is done by multiplying the data representation matrix by the learned projection matrix. Since matrix multiplication is a common practice for many research disciplines, and both methods use it, we do not benchmark it as well. Table 6 presents the run-time differences between SAL and INLP. For all of the experiments, SAL runtime is smaller by at least three orders of magnitude than INLP runtime.

7 Related Work

In their influential work, Bolukbasi et al. (2016) revealed that word embeddings for many gender-neutral terms show a gender bias. Zhao et al. (2018) presented a customized training scheme for word embeddings, which minimizes the negative distances between words in the two groups, e.g., male and female related words, for gender debiasing. Gonen and Goldberg (2019) demonstrated that bias is remains deeply intertwined in word embeddings even after using the above methods. For example, they showed several methods that can accurately predict the gender associated with gender-neutral words, even after applying the methods mentioned above. Similar to Ethayarajh et al. (2019), they concluded that removing a small number of intuitively selected gender directions cannot guarantee the elimination of bias. Motivated by this conclusion, Ravfogel et al. (2020) presented iterative null space projection (INLP). This debasing algorithm iteratively projects features into a space where a linear classifier cannot predict the guarded attribute. The debiased representations are *linearly guarded*, i.e., they cannot guarantee bias removal beyond the linear level. Indeed, they show a simple nonlinear classifier can achieve high accuracy when predicting the guarded attribute. Their approach is also related to that of Xu et al. (2017). Previous work uses adversarial methods (Ganin et al., 2016) for information removal (Edwards and Storkey, 2015; Li et al., 2018; Coavoux et al., 2018; Elazar and Goldberg, 2018; Barrett et al., 2019; Han et al., 2021) with the one by Ravfogel et al. (2022) being related to ours through the use of the mini-max theorem with squared-error loss on the reconstruction of a matrix similar to our covariance matrix. In addition, methods based on similarity measures between neural representations (Colombo et al., 2022) were developed. To support the increasing interest in fair classification, Han et al. (2022) presented an open-source framework for standardizing the evaluation of debiasing methods. Finally, most relevant to this paper is an extension of SAL to the unaligned case, where protected attributes are not paired with input examples (Shao et al., 2023).

8 Conclusions

We presented a method for removing information from learned representations. We extended our method by using kernels, showing we can provide an effective nonlinear guarding. We also experimented with real-world low-resource situations, in which only a small guarded attribute dataset is provided for information removal.

Limitations

There are two main technical limitations to our work: (a) while the kernel removal is nonlinear, it still depends on a feature representation that captures a specific type of nonlinearities; (b) like other kernel methods, the kernel removal method is significantly slower than direct SVD removal in cases where the feature representations can be written out without the need of an implicit kernel. Future work may apply random projections to the kernel matrices to decompose them more efficiently.

A general limitation of current methods of information removal is that they are only able to remove information with respect to a specific class of classifiers. It could always be the case that complex correlations between the inputs and the guarded attributes exist, and that an adversary can try to exploit them to predict the guarded attribute if this class of classifiers is not too complex. Our use of kernels alleviates some of this issue, though not completely.

Finally, experimentally, we focus on text only in English. It is not clear to what extent our method generalizes to other languages in a useful manner, especially when morphology is rich, and the neural representations encode important information for the task at hand, but that information would be removed by our method.

Ethical Considerations

Public trust plays a significant role in the broad applicability of NLP in real-world scenarios, especially in critical situations that may directly impact people's lives. NLP research of the kind presented in this paper helps this issue take the spotlight it deserves. However, we discourage NLP practitioners from using our method (and similar methods) as an out-of-the-shelf solution in deployed systems. We recommend investing a significant amount of time and effort in understanding the applicability and universality of our method to the debiasing of representations. Issues such as expected type of adversariality or tolerance level for drop in system performance need to be considered.

Acknowledgments

We thank the anonymous reviewers for their helpful comments. We especially appreciate the comment provided by one of the reviewers regarding our title. Particularly that it could be misinterpreted as an indication of frustration at rejections of our paper ("gold") in previous conferences. Rather, the "gold" in our case is the principal vectors with low intensity, which are pruned in most use cases of SVD. We also thank Shauli Ravfogel for providing support with the code for INLP, Ryan Cotterell for discussions and Matt Grenander for feedback on earlier drafts. The experiments in this paper were supported by compute grants from the Edinburgh Parallel Computing Center (Cirrus) and from the Baskerville Tier 2 HPC service (University of Birmingham).

A Eigenvectors of Λ

We turn to the following Lemma used in §5.2.

Lemma 1. *Let* $\mathbf{w}$ *be an eigenvector associated with eigenvalue* $\lambda \in \mathbb{R}$ *for* $\mathbf{\Gamma} = \boldsymbol{K}_\phi \boldsymbol{K}_\psi$*. Then* $\mathbf{\Phi w}$ *is an eigenvector of* $\mathbf{\Omega\Omega}^\top$.

Proof. Since $\mathbf{w}$ is an eigenvector of $\mathbf{\Gamma}$, it holds that $\Gamma\mathbf{w} = \lambda\mathbf{w}$. Therefore:

$$\mathbf{\Psi}^\top\mathbf{\Psi}\mathbf{\Phi}^\top\mathbf{\Phi}\mathbf{w} = \lambda\mathbf{w},$$

$$\left(\mathbf{\Phi}\mathbf{\Psi}^\top\mathbf{\Psi}\mathbf{\Phi}^\top\right)\mathbf{\Phi}\mathbf{w} = \lambda\mathbf{\Phi}\mathbf{w},$$

and therefore $\mathbf{\Phi w}$ is an eigenvalue of

$$\mathbf{\Omega\Omega}^\top = \mathbf{\Phi}\mathbf{\Psi}^\top\mathbf{\Psi}\mathbf{\Phi}^\top.$$

B Nearest Neighbors Test for Word Embedding Debiasing

We give in Table 7 the ten nearest neighbor words for ten random words from the data, before and after using SAL. The neighboring words are determined through cosine similarity of the corresponding embeddings with respect to the pivot word embedding. We observe little to no difference in these two lists (before and after the removal).

Words	Nearest neighbors (before)	Nearest neighbors (after)
lobbying	lobbyists, lobbyist, campaigning	lobbyists, lobbyist, campaigning

CTC Alignments Improve Autoregressive Translation

Abstract

Connectionist Temporal Classification (CTC) is a widely used approach for automatic speech recognition (ASR) that performs conditionally independent monotonic alignment. However for translation, CTC exhibits clear limitations due to the contextual and non-monotonic nature of the task and thus lags behind attentional decoder approaches in terms of translation quality. In this work, we argue that CTC *does* in fact make sense for translation if applied in a joint CTC/attention framework wherein CTC's core properties can counteract several key weaknesses of pure-attention models during training and decoding. To validate this conjecture, we modify the Hybrid CTC/Attention model originally proposed for ASR to support text-to-text translation (MT) and speech-to-text translation (ST). Our proposed joint CTC/attention models outperform pure-attention baselines across six benchmark translation tasks.

1 Introduction

Automatic speech recognition (ASR), machine translation (MT), and speech translation (ST) have conspicuous differences but are all closely related sequence-to-sequence problems. Researchers from these respective fields have long recognized the opportunity for cross-pollinating ideas (He and Deng, 2011), starting from the coupling of statistical ASR (Huang et al., 2014) and MT (Al-Onaizan et al., 1999) which gave rise to early approaches for ST (Waibel, 1996; Ney, 1999). Notably in the end-to-end era, attentional encoder-decoder approaches emerged in both MT (Bahdanau et al., 2015) and ASR (Chorowski et al., 2015; Chan et al., 2016), rising to great prominence in both fields.

During this same period, there has been another prominent end-to-end approach in ASR: Connectionist Temporal Classification (CTC) (Graves et al., 2006). Unlike the highly flexible attention mechanism which can handle ASR, MT, and ST alike, CTC models sequence transduction as a monotonic alignment of inputs to outputs and thus fits more naturally with ASR than it does with translation. Still, many interested in non-autoregressive translation have applied CTC to MT (Libovický and Helcl, 2018) and ST (Inaguma et al., 2021b) and promising techniques have emerged, shrinking the gap between autoregressive approaches (Saharia et al., 2020; Gu and Kong, 2021; Chuang et al., 2021; Huang et al., 2022). These recent developments suggest that the latent alignment ability of CTC is a promising direction for translation – this leads us to question: *can CTC alignments improve autoregressive translation?* In particular, we are interested in frameworks that leverage the strength of CTC while minimizing its several harmful incompatibilities (see §3) with translation tasks.

Inspired by the success of Hybrid CTC/Attention in ASR (Watanabe et al., 2017), we investigate jointly modeling CTC with an autoregressive attentional encoder-decoder for translation. Our conjecture is that the monotonic alignment and conditional independence of CTC, which weaken purely CTC-based translation, counteract particular weaknesses of attentional models in joint CTC/attention frameworks. In this work, we seek to investigate *how* each CTC property interacts with corresponding properties of the attentional counterpart during joint training and decoding. We design a joint CTC/attention architecture for translation (§4) and then examine the positive interactions which ultimately result in improved translation quality compared to pure-attention baselines, as demonstrated on the IWSLT (Cettolo et al., 2012), MuST-C (Di Gangi et al., 2019), and MTedX (Salesky et al., 2021) MT/ST corpora (§6).[1]

2 Background: Joint CTC/Attn for ASR

Hard Alignment Criterion only allows monotonic alignments of inputs to outputs	**Soft Alignment** Flexible attention-based input-to-output mappings may overfit to irregular patterns	**During Training:** Hard alignment objective produces stable encoder representations allowing the decoder to more rapidly learn soft alignment patterns	✓	**L1** See §3
Conditional Independence Assumes that there are no dependencies between each output unit given the input	**Conditional Dependence** Locally normalized models with output dependency exhibit label/exposure biases	**During Decoding:** Use of conditionally independent likelihoods in joint scoring eases the exposure/label biases from conditionally dependent likelihoods	✓	**L2** See §3
Input-Synchronous Emission Each input representation emits exactly one blank or non-blank output token	**Autoregressive Generation** Need to detect end-points and compare hypotheses of different length in beam search	**During Decoding:** Input-synchronous emission determines output length based on input length counteracting the autoregressive end-detection problem	✓	**L3** See §3

Table 1: Description of three reasons why joint CTC/attention modeling is powerful in ASR. In order to understand whether these positive interactions between properties of the CTC and attention frameworks are applicable to MT/ST, we must address three corresponding concerns, L1-3, about the applicability of CTC to translation (§2).

works seek to model the Bayesian decision seeking the output, $\hat{Y}$, from all possible sequences, $\mathcal{V}^{\text{tgt}}*$, by selecting the sequence which maximizes the posterior likelihood $P(Y|X)$, where $X = \{\mathbf{x}_t \in \mathcal{S}^{\text{src}} | t = 1, ..., T\}$ and $Y = \{y_l \in \mathcal{V}^{\text{tgt}} | l = 1, ..., L\}$. The source set $\mathcal{S}^{\text{src}}$ is a discrete vocabulary in the MT case and a continuous real space in the ST case while the target set $\mathcal{V}^{\text{tgt}}$ is always a discrete vocabulary. Note that the T-length of the input is assumed to be longer than the L-length output for speech tasks (Graves et al., 2006), but this is not necessarily true for MT.

What are the critical differences between the CTC and attention frameworks? As shown in the first two columns of Table 1, CTC and attention offer different formulations of the posterior likelihood, $P_{\text{CTC}}(\cdot)$ and $P_{\text{Attn}}(\cdot)$ respectively. First of all, the attention mechanism is a flexible input-to-output mapping function which allows a decoder to perform **soft alignment** of an output unit y_l to multiple input units $\mathbf{x}_{[...]}$ without restriction. One downside of this flexibility is a risk of destabilized optimization (Kim et al., 2017). CTC on the other hand marginalizes the likelihoods of all possible input to alignment sequence, $Z = \{z_t \in \mathcal{V}^{\text{tgt}} \cup \{\varnothing\} | t = 1 \dots T\}$, mappings via **hard alignment** where each output unit z_t maps to a single input unit $\mathbf{x}_t$ in a strictly monotonic pattern. $\varnothing$ is a "blank" and Z maps deterministically to Y by removing blanks and repeated emissions.

Secondly, the attentional decoder models each output unit y_1 with **conditional dependence** on not only the input X, but also the previous output units $y_{1:l-1}$. In contrast, CTC makes a **conditional independence** assumption that each z_t does not depend on $z_{1:t-1}$ if already conditioned on X (as denoted by the strike-through in Table 1) – this is a strong assumption which allows for efficient computation of marginalized likelihoods over all $Z \in \mathcal{Z}(Y, T)$ via dynamic programming. On the plus, since CTC does not model causality between output units it is not plagued by the same label and exposure biases that exist in attentional decoders due to local normalization of causal likelihoods (Bottou, 1991; Ranzato et al., 2016; Hannun, 2019).

Finally, the attentional decoder is an **autoregressive generator** that decodes the output until a stop token, <eos>. Comparing likelihoods for sequences of different lengths requires a heuristic brevity penalty. Furthermore label bias with respect to the stop token manifests as a length problem where likelihoods degenerate for unexpectedly long outputs (Murray and Chiang, 2018). In comparison, CTC is an **input-synchronous emitter** that consumes an input unit in order to produce an output unit. Therefore, CTC cannot produce an output longer than the input representation which feeds the final posterior output layer – but this also means that CTC does not require end detection.

As previously shown by (Kim et al., 2017; Watanabe et al., 2017), jointly modeling CTC and an attentional decoder is highly effective in ASR. The foundation of this architecture is a shared encoder, ENC, which feeds into both CTC, $P_{\text{CTC}}(\cdot)$, and attentional decoder, $P_{\text{Attn}}(\cdot)$, posteriors:

$$\mathbf{h} = \text{Enc}(X) \tag{1}$$

$$P_{\text{CTC}}(z_t|X) = \text{CTC}(\mathbf{h}_t) \tag{2}$$

$$P_{\text{Attn}}(y_l|X, y_{1:l-1}) = \text{Dec}(\mathbf{h}, y_{1:l-1}) \tag{3}$$

where $\text{CTC}(\cdot)$ denotes a linear projection to the CTC output vocabulary, $\mathcal{V}^{\text{tgt}} \cup \{\varnothing\}$, followed by softmax. $\text{DEC}(\cdot)$ denotes autoregressive decoder layers followed by a linear projection to the decoder output vocabulary, $\mathcal{V}^{\text{tgt}} \cup \{\text{<eos>}\}$, and softmax. The joint network is optimized via a multi-tasked objective, $\mathcal{L}^{\text{ASR}} = \mathcal{L}^{\text{ASR}}_{\text{CTC}} + \lambda \mathcal{L}^{\text{ASR}}_{\text{Attn}}$, where λ interpolates the CTC and decoder cross-entropy losses.

Joint decoding is typically performed with a one-pass beam search where CTC plays a secondary role as a joint scorer while attention leads the major hypothesis expansion and end detection functions in the algorithm (Watanabe et al., 2017; Tsunoo et al., 2021). However, CTC is capable of taking over the lead role if called upon (e.g. for streaming applications) (Moritz et al., 2019).

3 Potential CTC Limitations in MT/ST

Why exactly does this joint CTC/attention framework perform so well in ASR? As summarized in column 3 of Table 1, we are particularly interested in three reasons which arise from the combination of the hard vs. soft alignment, conditional independence vs. dependence, and input-synchronous emission vs. autoregressive generation properties of CTC and attention respectively. These dynamics have become well understood in ASR, owing to the popularity of the joint framework (Watanabe et al., 2018) amongst ASR practitioners.

So can CTC and attention also complement each other when applied jointly to translation?[2] ASR, MT, and ST can all be generalized as sequence transduction tasks following the Bayesian formulation. Attentional decoders have been a predominant technical solution to each of these tasks. However, the CTC framework appears to have several limitations specific to MT/ST that are not present in ASR; this seemingly diminishes the promise of the joint CTC/attention framework for translation. In this work, we seek to address the following three concerns about MT/ST CTC which appear to inhibit the CTC/attention framework (please refer back to Table 1 as needed).

L1 *Can CTC encoders perform sophisticated input-to-output mappings required for translation?*

Unlike ASR, translation entails non-monotonic mappings due to variable word-ordering across languages. Additionally, inputs may be shorter than outputs as mappings are not necessarily one-to-one. Furthermore, the mapping task for ST is compositional where logically a speech signal first maps to a source language transcription before being mapped to the ultimate translation. All of these complications appear to directly contradict the **hard alignment** of CTC. If CTC cannot produce stable encoder representations for MT/ST, then during joint training attention does not receive the optimization benefit as in ASR (per row 2 of Table 1). Fortunately, prior works suggest that these challenges are not insurmountable. Chuang et al. (2021) showed that self-attentional encoders can perform latent model variable word orders for ST, Libovický and Helcl (2018); Dalmia et al. (2022) proposed upsampling encoders that produce expanded input representations for MT, and Sanabria and Metze (2018); Higuchi et al. (2022) proposed hierarchical CTC encoders that can compose multiple output resolutions for ASR. In §4.1, we incorporate these techniques into a unified hierarchical CTC encoding method for MT/ST which is capable of sophisticated input-to-output mappings.

L2 *Does CTC-based translation quality lag too far behind attention-based to be useful?*

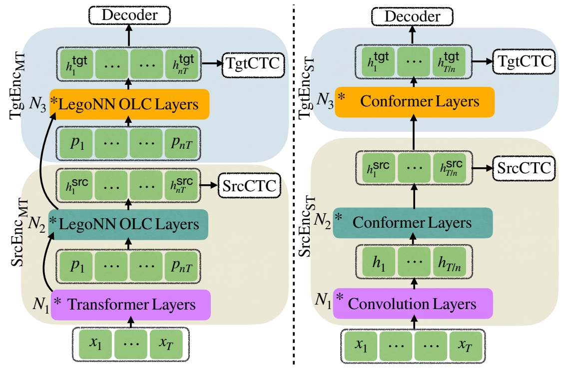
CTC-based ASR has recently shown competitive performance due in large part to improved neural architectures (Gulati et al., 2020) and self-supervised learning (Baevski et al., 2020; Hsu et al., 2021), but the gap between CTC and attention for translation appears to be greater (Gu and Kong, 2021). Perhaps the **conditional independence** of CTC inhibits the quality to such a degree in MT/ST where these likelihoods cannot ease the label/exposure biases of the attentional decoder as they do in ASR (per row 3 of Table 1). The relative weakness of non-autoregressive translation approaches has been well-studied. Knowledge distillation (Kim and Rush, 2016; Zhou et al., 2019) and iterative methods (Qian et al., 2021; Chan et al., 2020; Huang et al., 2022) all attempt to bridge the gap between non-autoregressive models and their autoregressive counterparts. In §6, we address this concern empirically; we find that even CTC models with 28% relative BLEU reduction compared to attention yield improvements when CTC and attention are jointly decoded.

L3 *Is the alignment information produced by CTC-based translation models reasonable?*

In ASR, CTC alignments are reliable enough to segment audio data by force aligning inputs to target transcription outputs (Kürzinger et al., 2020) and exhibit minimal drift compared to hidden Markov models (Sak et al., 2015). However,

---

[2] This particular question has not been addressed in literature. For an account of related works, please see §8.



(a) Hierarchical MT Encoder

(b) Hierarchical ST Encoder

Figure 1: Hierarchical MT/ST encoders where representations are first up/down-sampled by $\textsc{SrcEnc}_{\text{MT/ST}}$ and then re-ordered by $\textsc{TgtEnc}_{\text{MT/ST}}$.

CTC alignments are not as well studied in translation. It is an open question of whether or not the **input-synchronous emission** of CTC for translation has sufficient alignment quality to support the end detection responsibility during joint decoding as it does in ASR (per row 4 of Table 1). Ideally, the CTC alignments are strong enough such that CTC can lead joint decoding by proposing candidates for hypothesis expansion in each beam step until all input units are consumed (at which point the end is detected), as in an input-synchronous beam search. More conservatively, the CTC alignments may be too unreliable to take the lead but could still guide the attentional decoder's end detection by penalizing incorrect lengths via joint scoring, as in an output-synchronous beam search. In §4.2, we lay out comparable forms for input and output-synchronous beam search which allows us to examine the impact on translation quality depending on whether CTC is explicitly responsible for or only implicitly contributing to end detection.

4 Joint CTC/Attention for Translation

4.1 Hierarchical CTC Encoding

Per L1 described in §3, we seek to build a CTC encoder for translation which handles sophisticated input-to-output mappings. Unlike ASR where outputs are assumed to be 1) always shorter than inputs and 2) monotonic with respect to inputs, translation needs to account for variability of lengths and and word orderings. We therefore propose to use a hierarchical CTC encoding scheme which 1) aligns inputs to length-adjusted *source*-oriented encodings before 2) aligning to re-ordered *target*-oriented encodings, as shown in Figure 1. Our encoding process thus consists of two compartmentalized functions: length-adjustment and re-ordering.

Length-adjustment For MT, we up-sample the lengths of the source-oriented encodings in order to output sequences longer than the input. For ST, we down-sample the lengths of the source-oriented encodings to coerce a discrete textual representation of the real-valued speech input. We enforce source orientations using CTC criteria that seek to align the length adjusted intermediate layer encoder representations towards source text sequences (for MT this is the same as the input and for ST this is the ASR target). By compartmentalizing length-adjustment within this initial stage, we allow subsequent encoder layers to focus solely on re-ordering.

Re-ordering We then obtain target-oriented encodings with subsequent encoder layers, where re-ordering is enforced using CTC criteria that seek to align final layer encoder representations towards target text sequences. Critically, the underlying neural network architecture must be able to model latent re-ordering as the CTC criterion itself will only consider monotonic alignments of the final encoder representation to the target.

Our proposed MT/ST hierarchical encoders consist of the following components:

$$\mathbf{h}^{\text{SRC}} = \textsc{SrcEnc}_{\text{MT/ST}}(X) \tag{4}$$

$$P_{\text{CTC}}(z_t^{\text{SRC}}|X) = \textsc{SrcCTC}_{\text{MT/ST}}(\mathbf{h}_t^{\text{SRC}}) \tag{5}$$

$$\mathbf{h}^{\text{TGT}} = \textsc{TgtEnc}_{\text{MT/ST}}(\mathbf{h}^{\text{SRC}}) \tag{6}$$

$$P_{\text{CTC}}(z_t^{\text{TGT}}|X) = \textsc{TgtCTC}_{\text{MT/ST}}(\mathbf{h}_t^{\text{TGT}}) \tag{7}$$

The hierarchical encoders are jointly optimized with an attentional decoder using a multi-tasked objective, $\mathcal{L} = \mathcal{L}_{\textsc{SrcCTC}} + \lambda_1 \mathcal{L}_{\textsc{TgtCTC}} + \lambda_2 \mathcal{L}_{\textsc{Attn}}$, where λ's interpolate source-oriented CTC, target-oriented CTC, and decoder cross-entropy losses.

As shown in Figure 1.a, $\textsc{SrcEnc}_{\text{MT}}(\cdot)$ consists of N_1 Transformer (Vaswani et al., 2017) layers followed by N_2 up-sampling Output Length Controller (OLC) layers used in LegoNN (Dalmia et al., 2022) – the layer-wise positional embeddings of the OLC architecture enable latent length-adjustment of textual inputs. $\textsc{TgtEnc}_{\text{MT}}(\cdot)$ consists of N_3 non-up-sampling OLC layers – the layer-wise attention of the OLC architecture enables latent re-ordering. Our ST encoder is similar, but uses Conformers (Gulati et al., 2020) to capture the local and global dependencies in speech, as shown in Figure 1.b. $\textsc{SrcEnc}_{\text{ST}}(\cdot)$ consists of N_1 convolutional blocks (Dong et al., 2018) for down-sampling fol-

            else
                newPrtHs[$\tilde{y}$] = $P_{\text{Beam}}(\cdot)$
            end if
        end for
    end for
    return newPrtHs, endHs
end procedure
```

lowed by N_2 Conformer layers – this stage is analogous to the ASR sub-task of ST where a long speech signal is length-adjusted to a shorter latent textual representation. TGTENC$_{\text{ST}}(\cdot)$ consists of N_3 Conformer layers – this stage is analogous to the MT sub-task of ST where latent re-ordering is enabled by self-attention. LegoNN and Conformer are further described in §A.4.

4.2 Input/Output-Synchronous Decoding

Per L2 and L3 described in §3, we seek to design a joint decoding algorithm with input and output-synchronous variants of one-pass beam search which differ only in whether CTC or attention takes the leading role. As shown in Algorithms 1 and 2, we propose to align the input and output beam-step functions along three common functions: hypothesis expansion, joint scoring, and end detection. Using these mirrored forms, let us now interpret the respective roles of CTC and attention.

Output-Synchrony Consider first that attention is in the leading role, which means that we are working with an output-synchronous beam search. Note that this is the algorithm originally proposed by Hori et al. (2017). OUTPUTSTEP performs *hypothesis expansion* by computing the attentional decoder's output posterior at label step l, $P_{\text{Attn}}(y_l|X, y_{1:l-1})$ for each partial hypothesis, $y_{1:l-1}$. A pre-beam size, p, is then used to select the top candidate output units (Seki et al., 2019), attnCnds, which are used to expand the partial hypotheses via concatenation, denoted by $\oplus$. In the *joint scoring* block, the attentional decoder likelihood, $\text{AttnScore}(\cdot)$, and length penalty/reward, $\text{LengthPen}(\cdot)$ yield the estimated joint likelihood P_{Beam}. Finally in *end detection*, OUTPUTSTEP must check for the stop token, <eos>, which may be proposed by attnCnds.

Input-Synchrony Now let us consider the differences when CTC is in the leading role. Note that this algorithm extends Hannun et al. (2014)'s CTC beam search algorithm to include joint scoring with attentional likelihoods. INPUTSTEP performs *hypothesis expansion* by computing CTC's alignment posterior at time step t, $P_{\text{CTC}}(z_t|X)$. Unlike in output-synchrony, here each hypothesis expansion also consumes one step of the input. The same pre-beam size, p, is used to select top candidate alignment units, CTCCnds, but partial hypotheses are only expanded for non-blank and non-repeat candidates. The *joint scoring* block is identical to output-synchrony except for one difference: CTC likelihood, $\text{CTCScore}(\cdot)$, is applied over the full input, $X_{1:T}$, in OUTPUTSTEP and over the partial input, $X_{1:t}$, in INPUTSTEP. This difference engenders a speed vs. accuracy trade-off, which we discuss in D2 of §7. Finally, *end detection* simply occurs when all input units have been consumed ($t = T$). Therefore, INPUTSTEP does not require checking for the stop token as all hypotheses at time T are ended.

We propose this particular form of input-

		MODEL TYPE			MT			ST

Table 2: Test set performances, as measured by BLEU (↑), of our proposed joint CTC/Attention models compared to pure-attention baselines. Joint CTC/Attention models are always jointly trained, but can be either jointly decoded using input/output synchrony or decoded using only their CTC or attention branches. For IWSLT14, we mention (*tokenized BLEU*) for comparison with prior works: †Raunak et al. (2020) and ‡Inaguma et al. (2020). $^\diamond$Prior MTedX works show only All-All or pair-wise settings.

synchronous beam search in order to exactly mirror the functions of its output-synchronous counterpart; without this mirrored formulation, we cannot attribute differences in decodings to the swapped roles of CTC and attention. For instance, now we can answer questions such as *can CTC perform hypothesis expansion on par with attention*, allowing us to address concerns about applying weaker joint CTC models during decoding per L2 and L3 in §3. To the best of our knowledge, we are the first to examine the theoretical and empirical differences of input and output synchrony through a unified formulation, as discussed further in §7. Other forms of input-synchronous beam search in prior works cannot directly be used for this purpose. Triggered Attention (Moritz et al., 2019) is one such example which is purpose-fit for streaming to a degree where several core components (e.g. look-ahead and re-triggering) cannot trivially be re-factored into an output-synchronous variant.

5 Experimental Setup

Data We examine the efficacy of our proposed approaches on two language pairs for each of the MT and ST tasks. For MT, we use German-to-English (De-En) and Spanish-to-English (Es-En) from IWSLT14 (Cettolo et al., 2012). For ST, we use English-to-German (En-De) and English-to-Japanese (En-Ja) from MuST-C-v2, reporting tst-COMMON results (Di Gangi et al., 2019). We also examine the multilingual setting of 6 European languages to English (All-En) from MTedX (Salesky et al., 2021) for both tasks. Full dataset descriptions for reproducibility are in §B.

Modeling We compare our joint CTC/Attention models to purely attentional encoder-decoder baselines. All proposed and baseline models were tuned separately, using validation sets only, within the same hyperparameter search spaces for training and decoding to ensure fair comparison. All experiments were conducted using ESPnet-ST (Inaguma et al., 2020). Full descriptions of model sizes, hyperparameters, and pre-processing are in §B.[3]

Evaluation: Unless otherwise indicated, we measure performance with detokenized case-sensitive BLEU (Post, 2018) on punctuated 1-references.[4]

6 Results and Analyses

In this section, we first present our main results on 6 benchmark MT and ST tasks. We then present evidence that hierarchical encoding (§4.1) produces stable encoder representations that simplify the decoder's source attention (addressing L1 in §3). Next we present evidence that joint decoding is beneficial despite the fact that CTC-only performance lags behind that of attention-only (addressing L2 in §3). Finally, we present evidence that CTC's alignment information alleviates attention's end-detection problem in both input and output synchronous joint decoding (§4.2) (addressing L3 in §3).

6.1 Joint CTC/Attention Models Outperform CTC-only and Attention-only Baselines

As shown in Table 2, joint CTC/Attention with output-synchronous decoding outperforms pure-

---

[3] We compare our baselines for MuST-C-v2 to the default recipes in ESPnet in Table 2. For back-compatibility with additional prior works using MuST-C-v1 En-De, see §A.2.

[4] Evaluation with additional metrics is provided in §A.1.

attention across *all* MT and ST tasks (line 2 vs. 6). Joint training while only decoding with the attention branch still outperforms pure-attention models without any joint training (line 2 vs. 4). Note that *CTC is consistently the weaker* of the two branches in jointly trained models (line 3 vs. 4). Joint input/output-synchronous decodings yield further improvements overall, confirming that *both joint training and decoding are beneficial* (line 4 vs. 5/6). However, we find that input-synchrony lags behind output-synchrony (line 5 vs. 6); this phenomenon is discussed further in §7.

6.2 Hierarchical Encoding Reduces Attention's Alignment Burden

We examine the regularization effect that CTC joint training has on the attentional decoder, per L1 in §3, by first quantifying the monotonicity, m of a (L, T) shaped source attention pattern, A:

$$m = \Big(\sum_{2<l\leq L} [\operatorname*{argmax}_{t\in T} A_l \geq \operatorname*{argmax}_{t\in T} A_{l-1}] \Big) / L$$

where $[\cdot]$ denotes the Iverson bracket. In other words, we define monotonicity m as the rate at which the decoder at step l attends most sharply on an input index, $\operatorname{argmax}_{t\in T} A_l$, which is greater than or equal to that of the previous step $l-1$, $\operatorname{argmax}_{t\in T} A_{l-1}$. We compute m over all examples in our validation sets for De-En MT and En-De ST and show the layer-wise averages over all examples and attention heads in Figure 2. It can be seen that *the decoder source attention patterns are more monotonic* when using jointly trained hierarchical encoders. Per line 2 of Table 1, we argue that this greater monotonicity allows the decoder to more rapidly learn soft alignment patterns – ultimately this advantage is reflected in the overall performance gains observed from joint training without joint decoding (line 2 vs. 4 in Table 2).

For a qualitative example illustrating the increased monotonicity of decoder source attention patterns, please see §A.7. We also found that *increased monotonicity leads improves multilingual parameter sharing* in our All-En MT and ST models, suggesting that the target-orientation of our encoder reduced the decoder's burden of soft-aligning target English outputs to source languages with varying word-orders (discussed further in §A.5).

What are the respective contributions of SrcCTC *and* TgtCTC*?* TgtCTC holds elevated importance as joint decoding is not possible without it.

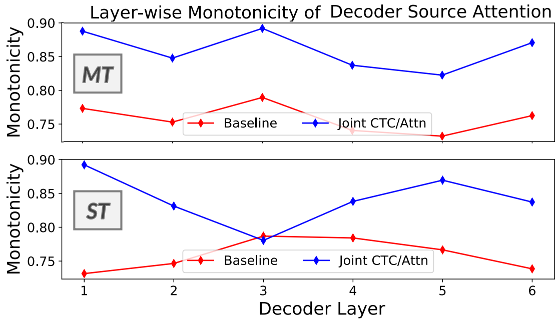

Figure 2: Layer-wise monotonicity (↑) of the source-attention patterns produced by MT/ST decoders.

		MT (De-En)	ST (En-De)
SrcCTC	TgtCTC	IWSLT14	MuST-C-v2
✗	✗	32.1	27.7
✓	✗	34.1	27.8
✗	✓	33.3	28.1
✓	✓	**34.8**	**28.3**

Table 3: Ablation on the impacts of SrcCTC and TgtCTC CTC components of hieraractical encoding, as measured by performance on validation sets. Only attention is used in decoding to enable fair comparisons.

However, we'd like to understand how each component contributes to the benefits observed from joint training without joint decoding in §6.1. In Table 3, we ablate SrcCTC and TgtCTC in order to confirm that both contribute to performance gains. Note that SrcCTC on its own appears to contribute more to MT than it does to ST, suggesting that the length adjustment stage is more critical in MT.

6.3 Even Weak CTC Models Strengthen Joint CTC/Attention Models

We examine the generalization effect that augmenting autoregressive likelihoods with conditionally independent likelihoods has during inference, per L2 in §3, by evaluating De-En MT and En-De ST models on out-of-domain EuroParl test sets (Iranzo-Sánchez et al., 2020). As shown in Table 4, joint CTC/Attention models outperform pure-attention baselines across in-domain (In-D) and out-of-domain (Out-D) settings. When decoding only the CTC branch of joint models (denoted as CTC I-Sync in the table) performance is significantly degraded compared to the attention branch of the same models (denoted as Attn O-Sync in the table). This gap appears slightly lessened in the out-of-domain setting where CTC's conditional independence may offer some robustness. Nonetheless

Model	Decoding Method	MT (De-En) In-D	MT (De-En) Out-D	ST (En-De) In-D	ST (En-De) Out-D
Pure-Attn	Attn Only	32.8	15.8	27.8	20.5
Joint C/A	Attn Only	33.6	17.1	28.3	21.0
	+CTC Rescore	33.6	17.1	28.3	21.0

Table 4: In/out domain test performances of joint CTC/attention models with various decoding methods.

these weak CTC models still boost their stronger attention counterparts during joint decoding (both via input and output-synchrony), suggesting that *ensembling of conditionally independent and dependent likelihoods is a powerful technique*.

Further, synchronous joint decoding methods outperform their two-pass re-scoring counterparts (discussed in D2 of §7), suggesting that *joint selection of the hypothesis set is necessary* for easing the respective weaknesses of autoregressive and conditionally independent likelihood estimation.

6.4 CTC's Alignment Information Resolves Attention's End-Detection Problem

Finally, we examine the effect that CTC's alignment information has on end detection during decoding, per L3 in §3. In Figure 3, we observe the change in translation quality (as measured by BLEU) and output length (as measured by hypothesis-to-reference length ratio) when the length penalty (denoted as $\mathrm{LengthPen}(\cdot)$ in Algorithms 1 and 2) is gradually increased, forcing decodings to produce longer outputs. Pure-attention baselines rapidly degenerate when forced to produce hypotheses that are longer than references as they struggle to detect the ends of hypotheses (Murray and Chiang, 2018). On the other hand, joint decoding produces gradually longer outputs regardless of whether CTC is in a primary role (input-synchrony) or a secondary role (output-synchrony), demonstrating that *CTC alignments ease the decoder's end-detection problem* by explicitly or implicitly ruling out hypotheses of incorrect lengths.

7 Discussion: More on Joint Decoding

D1 *Why do input vs. output-synchronous joint decodings yield slightly different results?*

By comparing the CTC likelihood estimation in INPUTSTEP vs. OUTPUTSTEP, it can be seen that there is a trade-off between speed vs. accuracy. First, note that in OUTPUTSTEP, $\mathrm{CTCScore}(y_{1:l}, X_{1:T})$, is a marginalization over the likelihoods of all possible alignments of the partial hypothesis $y_{1:l}$ to the full input $X_{1:T}$ (Seki et al., 2019). On the other hand, $\mathrm{CTCScore}(\tilde{y}, X_{1:t})$ in INPUTSTEP is an estimation of the marginalized likelihoods of the partial hypothesis $y_{1:l}$ to the *partial* input $X_{1:t}$ (Graves, 2012; Hannun et al., 2014). Even at step T, these two $\mathrm{CTCScore}(\cdot)$'s are not equivalent. Since CTCCnds may include the blank token, INPUTSTEP may prune partial hypotheses at a previous beam step which would have merged with $y_{1:l}$. Therefore, $\mathrm{CTCScore}(\cdot)$ in *input-synchrony is less accurate*. However, *input-synchrony requires fewer computations*. Using dynamic programming, output-synchrony computes $\mathrm{CTCScore}(\cdot)$ for all partial hypothesis within a single beam step with $\mathcal{O}(bpT)$ log-additions (Watanabe et al., 2017) while input-synchrony uses only $\mathcal{O}(bp)$ log-additions (Hannun et al., 2014).

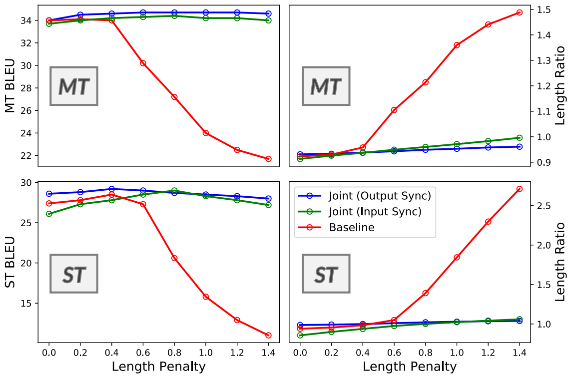

Figure 3: Elasticity of BLEU and length ratios ($|\mathrm{hyp}|/|\mathrm{ref}|$) w.r.t length penalty in validation sets.

Decoding Type		Accuracy		Speed
Method	Beam Size	BLEU	Search Error	RTF
Joint O-Sync	5	29.1	0.73%	0.9
Joint O-Sync	10	29.2	0.44%	1.7
Joint O-Sync	50	29.0	0.36%	9.0
Joint I-Sync	5	28.1	1.02%	0.4
Joint I-Sync	10	28.6	1.09%	0.9
Joint I-Sync	50	29.0	0.87%	6.4

Table 5: Speed vs. accuracy for joint input/output-sync decoding of En-De ST val. set as a fxn. of beam size.

In Table 5, we perform an experimental validation of our theoretical understanding of the speed vs. accuracy trade-off between the two synchronous joint decoding variants. To quantify speed, we compute the real-time factor (RTF) as the ratio of decoding time over the duration of input speech. To quantify accuracy beyond the BLEU metric, we compute the search error rate (Meister et al., 2020) by counting the sequences for which the hypothesis has higher exact likelihood than the reference. *For the same beam size, output is slower but more accurate than input-synchronous.* We conclude that input-synchrony may in fact be preferable in applications with latency constraints.

D2 *Why did synchronous joint decodings outperform re-scoring decodings in Table 4?*

There is a family of two-pass decoding algorithms (Watanabe et al., 2017; Sainath et al., 2019), which also achieve joint decoding by first estimating the likelihoods of a subset of sequences $\mathcal{V}'$ with one module and then re-scoring the estimates with the other module. In these approaches, the subset $\mathcal{V}'$ is determined asynchronously, meaning the joint likelihood is not considered until the re-scoring step; this delayed consideration of the joint likelihood is the main drawback compared to the synchronous approaches. If the attentional decoder is used to determine $\mathcal{V}'$, then $\mathcal{V}'$ would suffer from exposure/label bias and the length problem (§2). On the other hand, if CTC is used to determine $\mathcal{V}'$, the lack of causal modeling in CTC leads to poor estimates of $\mathcal{V}'$ – particularly for translation.

8 Related Works

The idea of using latent alignments to improve autoregressive translation has been explored previously by Haviv et al. (2021) who concluded that CTC alignments are not compatible with teacher forcing. The key difference is that we train CTC and autoregressive models jointly while Haviv et al. (2021) sought to apply CTC to train autoregressive models, replacing cross-entropy entirely. More recently in a concurrent work, Zhang et al. (2022) have also shown the effectiveness of jointly training CTC and attention in the context of ST for unwritten languages where no ASR transcriptions are available. We believe that our contribution showing the effectiveness of also jointly decoding CTC and attention demonstrates an additional technique which can further improve their direction. Our work also differs in that we seek to incorporate the ASR objective into ST via hierarchical encoding.

Other concurrent works integrated CTC and attention within blockwise streaming (Deng et al., 2022) and compositional multi-decoder (Yan et al., 2022) architectures for ST in particular. Our work supports their findings by addressing *why* CTC is helping, and we provide a unified approach that generalizes to both MT and ST. Prior works have also used the non-autoregressive property of CTC as means for speeding up autoregressive models during inference (Inaguma et al., 2021a; Gaido et al., 2021), but these works focus on latency and do not apply CTC to improve translation quality.

DECODING TYPE		SPEED	
Method	Beam Size	RTF	%Δ
Pure-Attn O-Sync	5	0.9	-
Pure-Attn O-Sync	10	1.2	-
Pure-Attn O-Sync	50	3.5	-
Joint CTC/Attn O-Sync	5	0.9	+0%
Joint CTC/Attn O-Sync	10	1.7	+42%
Joint CTC/Attn O-Sync	50	9.0	+157%
Joint CTC/Attn I-Sync	5	0.4	-56%
Joint CTC/Attn I-Sync	10	0.9	-25%
Joint CTC/Attn I-Sync	50	6.4	+85%

Table 6: **Limitations Table:** comparison of joint decoding and pure-attention RTFs across different beam sizes. %Δ between the joint RTF and pure-attention RTF for the same beam size is shown, where positive %'s indicate slow-downs and negative %'s indicate speed-ups.

9 Conclusion

We propose to jointly train and decode CTC/attention models for MT and ST using 1) hierarchical encoding to resolve incompatibilities between CTC and the non-monotonic mappings in translation and 2) synchronous decoding to ease the exposure/label biases of autoregressive decoders with CTC's conditionally independent alignment information. Our analyses reveal several reasons why even weak CTC models benefit autoregressive translation via joint modeling, suggesting that future explorations into jointly modeling attentional decoders with other latent alignment models (Graves, 2012; Ghazvininejad et al., 2020; Saharia et al., 2020) may uncover similar benefits.

Limitations

There are several potential limitations pertaining to the increased computational overhead and latency of the joint modeling approach. One concern is that joint decoding is much slower, but we found that input-synchronous joint decoding is actually faster than pure-attention decoding for smaller beam sizes, as shown in Table 6.

The other limitation is that our MT models upsample input representations in the early layers of the encoder, thereby increasing the computations in subsequent encoder layers and the decoder's cross-attention. We can use LegoNN-based encoders (Dalmia et al., 2022) to adjust the up-sampling rate to a fractional value, minimizing the computations given dataset statistics. Alternatively, we may avoid the need for up-sampling by applying a larger byte-pair encoding size (Kudo and Richardson, 2018) to the target language compared to the source language. CTC's use in guiding efficient down-sampling of representations in ST (Gaido et al., 2021) suggest that it may also be applied for efficient up-sampling for MT – we leave this study on efficiency to future work.

Finally, note that the corpora used for the MT experiments in this work are considered medium resourced. Prior work (Murray and Chiang, 2018) has shown that the autoregressive end-detection problem exists across low to high resourced scenarios; suggesting that the CTC/attention approach would be generally beneficial. We leave the study of joint CTC/attention modeling on higher resourced MT corpora to future work.

A Supplementary Information

A.1 Additional Translation Metrics

To supplement our BLEU evaluation in Table 2, we also measure the translation quality of our models using Translation Error Rate (TER) (Snover et al., 2006) and METEOR (Banerjee and Lavie, 2005). As shown in Table 7, our findings are consistent across all three metrics for both MT and ST models.

A.2 MuST-C-v1 Back-Compatibility

See Table 9 for results compared to prior works.

A.3 Valid Set performances

Table 8 presents the validation performances for our ST and MT models.

A.4 Description of Encoder Architectures

LegoNN Encoder (Dalmia et al., 2022) is a stacked multi-block architecture that was introduced to encode and re-sample the input sequence into a sequence of representations of a desired length, which is typically a factor of the input sequence. It first encodes the input using transformer encoder blocks (Vaswani et al., 2017) and then re-encodes them into a sequence of latent representations using cross-attention. Starting from a sequence of learnable positional embeddings (Gehring et al., 2017), these latent representations are learned using another stack of transformer encoder layers with an added cross-attention component over the input representations in each block.

The Conformer encoder (Gulati et al., 2020) is a stacked multi-block architecture and has shown consistent improvement over a wide range of E2E speech processing applications (Guo et al., 2021). It includes a multi-head self-attention module, a convolution module, and a pair of position-wise feed-forward modules in the Macaron-Net style. While the self-attention module learns the long-range global context, the convolution module aims to model the local feature patterns synchronously.

A.5 Increased Cross-Attentional Monotonicity Leads to Increased Multilingual Parameter Sharing

We further examine the source attention parameters in our All-En models to understand the impact that the increased monotonicity of decoder attention (§6.2) has on multilingual parameter sharing. To do so, we extract sparse subnets for each language pair following the Lottery Ticket Sparse Fine-Tuning proposed by Ansell et al. (2022) and compute the pair-wise sharing across the 6 source languages, as measured by the count of overlapping parameters between subnets. In Figure 4, we show the relative change ($\Delta\%$) in multilingual sharing when using hierarchical encoding compared to the baseline. The broad increases suggest that the target-orientation of our encoder *reduced the decoder's burden of soft-aligning* target English outputs to source languages with varying word-orders, allowing for more efficient allocation of capacity.

A.6 `compare_mt.py` Length Analysis

As shown in Figure 5, both joint synchronous decodings are more robust than pure-attention for long output lengths across both MT and ST. Input-synchrony appears particularly more robust in generation of very long outputs for ST.

A.7 View of Regularized Attention

See Figure 6 for a qualitative example of monotonic source attention patterns (supplementary to the quantitative monotonicity in Figure 2).

B Reproducibility

B.1 Dataset Descriptions

See Table 10 for dataset descriptions. Data preparation was done using ESPnet recipes.

B.2 Model Architectures

See Table 11 for model architectures.

B.3 Training/Decoding Hyperparameters

See Tables 12-15 for hyperparameter descriptions.

B.4 Metrics

Sacrebleu signature for all non-Japanese:
`BLEU+case.mixed+numrefs.1`
`+smooth.exp+tok.13a+version.1.5.1`

Sacrebleu signature for Japanese:
`BLEU+case.mixed+lang.en-ja+numrefs.1`

Abstract

Past studies on the ICD coding problem focus on predicting clinical codes primarily based on the discharge summary. This covers only a small fraction of the notes generated during each hospital stay and leaves potential for improving performance by analysing all the available clinical notes. We propose a hierarchical transformer architecture that uses text across the entire sequence of clinical notes in each hospital stay for ICD coding, and incorporates embeddings for text metadata such as their position, time, and type of note. While using all clinical notes increases the quantity of data substantially, superconvergence can be used to reduce training costs. We evaluate the model on the MIMIC-III dataset. Our model exceeds the prior state-of-the-art when using only discharge summaries as input, and achieves further performance improvements when all clinical notes are used as input.

1 Introduction

ICD (International Classification of Diseases (World Health Organization, 1978)) coding refers to the task where medical professionals classify clinical diagnoses and medical procedures associated with each patient using standardised taxonomies, which in turn supports billing, service planning and research. The process is manual and laborious in nature (O'Malley et al., 2005), however there is potential to automate it by identifying relevant information from clinical notes, which are already captured in EHR systems. With this in mind, researchers have started to explore whether machine learning models can succeed at this task (Mullenbach et al., 2018).

The current research on the ICD coding task focuses on the extraction of codes from the discharge summary. This document is commonly written at the end of a hospital stay and provides a textual description of the important diagnoses and procedures for a given patient, making it particularly helpful for the task. However, many other clinical notes are also created during the hospital stay, which can provide important details or useful additional context that may be missing from the discharge summary itself. Analysing the full sequence of notes would allow models to make more accurate decisions and make the problem more similar to a real-life setting, where clinicians have to consider all information about a patient for ICD coding, rather than information only in a single document.

In this work we study how the inclusion of clinical notes across the entire hospital stay can affect performance on the ICD coding task. We propose the **H**ierarchical **T**ransformers for **D**ocument **S**equences (**HTDS**) model, which is an adaptation of the hierarchical transformer model (Zhang et al., 2019) for temporal modelling of document sequences. The model takes text and metadata (such as the time and type of note) from a sequence of multiple documents as input and achieves improved performance when additional clinical notes are used for modelling. We compare different prioritisation criteria for selecting which notes to use as input and how to best represent the sequence information. Methods related to superconvergence are applied to speed up the model training process in order to handle the increased size of the data that needs to be processed.

Our experiments show that the inclusion of additional clinical notes indeed improves model accuracy and leads to better predictions. We evaluate our models against the MIMIC-III-50 (Johnson et al., 2016) test set. When considering only the discharge summaries of each hospital stay as input, our model exceeds the current state-of-the-art performance in terms of Micro-F1. When considering all clinical notes as input, further performance improvements across all metrics of interest are observed, exceeding the state-of-the-art performance in Micro-F1, Micro-AUC, Macro-AUC, and Precision@5 scores.

2 Related Work

Publicly available electronic health record (EHR) datasets, such as the Medical Information Mart for Intensive Care III (MIMIC-III) dataset (Johnson et al., 2016), provide a shared context for researchers to work on ICD coding. Recent work on ICD coding concentrates on the benchmark tasks presented by Mullenbach et al. (2018), which extracts ICD codes from the free-text discharge summary generated at the end of each hospital stay. Mullenbach et al. (2018) also publicly release their data preprocessing codes and train/dev/test data splits, and these were followed by later works for comparability of result.

In recent years, state-of-the-art work on the ICD coding problem commonly used methods based on convolutional neural networks (CNNs) or recurrent neural networks (RNNs) for text encoding. CAML (Mullenbach et al., 2018) uses a single convolutional layer along with "per-label attention" to extract representations for each label from the convolution output. MSAttKG (Xie et al., 2019) improves the performance further by using a densely connected convolutional network with variable n-gram features, and incorporating knowledge graphs to capture relationships between medical codes. EffectiveCAN (Liu et al., 2021) uses a deep convolutional approach, with a "squeeze-and-excitation" module that repeatedly compresses and then decompresses the convolutional features. LAAT (Vu et al., 2021) uses a bidirectional LSTM to encode the texts, with a per-label attention step on the output to get the final classification. MSMN (Yuan et al., 2022) uses the same architecture as LAAT, with an additional step of extending code descriptions from the Unified Medical Language System (UMLS) with synonyms, and using an attention layer with a separate head for each code synonym.

Researchers using transformer-based models for text encoding experienced difficulties in matching state-of-the-art performance. Ji et al. (2021) apply a range of different transformer-based models but found that none of them outperformed their reimplementation of a simple CNN-based model. Pascual et al. (2021) similarly found it difficult to achieve competitive performance and concluded that better methods of handling long input sequences are required to improve the models further. Gao et al. (2021) also find that a simple self-attention network with far less parameters outperformed BERT-based models on many tasks. Dai et al. (2022) show that incorporating task-adaptive pre-training, overlapping chunks, and using a large pretrained language model make it possible to achieve performance that is close to, but still slightly below the state-of-the-art. In general, language models that were pretrained on texts in the biomedicine domain, such as ClinicalBERT (Alsentzer et al., 2019), BioBERT (Lee et al., 2020), BlueBERT (Peng et al., 2019), and PubMedBERT (Gu et al., 2021) tend to achieve higher performance (Dai et al., 2022; Ji et al., 2021) as compared to language models such as BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) which are trained on general domain corpora, as the models have been adapted to the specialised language used in clinical notes. Among the range of pretrained language models available for the biomedicine domain, better performance was achieved when a specialised token vocabulary is used (Gu et al., 2021; Lewis et al., 2020) and when the pre-training corpora is closer in nature to those used for the downstream task (Gururangan et al., 2020). Very recently, Huang et al. (2022) identified the restricted capacity of the [CLS] token as a potential limiting factor, and showed how using all tokens in the label attention step leads to state-of-the-art performance on the MIMIC-III-Full problem. However, they do not report results on the MIMIC-III-50 problem.

While transformer-based language models have been very successful on short sequences of text (BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) use a maximum sequence length of 512 tokens), challenges arise when attempting to apply it to longer text sequences due to the quadratic computational complexity of the self-attention mechanism. Experiments conducted by Gao et al. (2021) show that transformer models require 3x more processing time compared to CNNs, making it more tedious to explore different hyperparameters and modelling strategies. Various modifications have been proposed to the transformer architecture to reduce computation costs, in models such as TransformerXL (Dai et al., 2019), LongFormer (Beltagy et al., 2020), and BigBird (Zaheer et al., 2020), however domain-pretrained models for these architectures are relatively scarce. Most transformer-based models for the ICD coding problem adapt the hierarchical transformer (Zhang et al., 2019), which splits the text into chunks that are encoded separately with the pre-trained language model, and then feeds the output of the [CLS] token into a second transformer to allow interaction of information across chunks.

To the best of our knowledge, there has been no prior work that attempts to extend the ICD coding task with other clinical documents.

3 Approach

Our **H**ierarchical **T**ransformers for **D**ocument **S**equences (**HTDS**) model is based on the hierarchical transformer architecture (Zhang et al., 2019), with additional adaptations specifically to handle document sequences. Figure 1 provides an illustrated diagram of the full HTDS model architecture. We process documents using the following steps:

Step 1 - Preprocess and Chunk: The text in each document is sequentially tokenized and split into chunks, each containing up to T_c tokens. Every new document or clinical note always starts a new chunk.

From these tokenized chunks we select up to N_c chunks for processing. If more than N_c chunks are available, various prioritisation strategies can be considered to select which chunks to use as model input. In our main model we use a strategy that prioritized diversity in the categories of notes used. To do this, we select the last note by timestamp of each category, and then the second last note of each category, and so on until N_c chunks of text are selected.

Step 2 - Encode with Language Model: The chunks are encoded using the pre-trained language model, producing an output of dimension N_c x T_c x H_e, where H_e is the dimension of the hidden state in the pre-trained LM.

Step 3 - Add Chunk Meta-Information: Meta-information of each chunk is added. These are learnable embeddings, retrieved via index lookup, with size H_e. Positional Embeddings (PE) capture the positional index of the chunk, and are numbered from 0 for the first chunk until N-1 for the last chunk. Temporal Sequence Embeddings (TE) capture the temporal order in which the documents were captured, and are indexed in running order from 0 for chunks belonging to the first document and incremented with each subsequent document. We noted that this indexing approach would often assign varying indices to the last chunk or document, as the number of chunks and documents for each case would vary. This might limit the ability of the model to identify the last chunk or document of the text. Hence, we also include Reversed Positional Embeddings (Rev-PE) and Reversed Temporal Sequence Embeddings (Rev-TE), which start from 0 for the last chunk (or document) and are then incremented with each preceding chunk (or document). Category Embeddings (CE) capture the category of the note, with a unique index for each CATEGORY code. All learnable embeddings use values initialised from a $N(0, 0.1)$ distribution. We hypothesise that these embeddings can help the model to factor in chunk meta-information which may be relevant for classification.

Step 4 - Second Transformer: The embeddings are added together (token embeddings + meta-information embeddings), then concatenated across all the chunks and given as input to a second transformer with N_e encoder layers. This allows for information from each chunk to interact with all the other chunks and the use of only a small number of layers in this second transformer will keep the computational requirements feasible. The output is an updated embedding of each token, with dimensions (N_c x T_c) x H_e.

Step 5 - Label Attention: A label attention layer is applied. We train learnable embeddings α_l for each label ($\alpha = [\alpha_1 ... \alpha_{N_l}]$ has dimensions N_l x H_e, where N_l is the number of labels) which are applied against the chunk embeddings ($H = [h_1 ... h_{N_c}]$) in an attention step as follows:

$$A = softmax(H\alpha^T)$$

$$V = H^T A$$

$$Dim(A) = (N_c \times T_c) \times N_l$$

$$Dim(V) = H_e \times N_l$$

The i-th column in V would be an independent representation, of dimension H_e, for the i-th label for classification.

Step 6 - Generate Final Classification: A classification layer is applied. We take $\sigma(W_l v_l)$ to get the probability of label l, where W_l is a learnable weight matrix of dimension H_e for label l, v_l is the l-th item of matrix V, and σ is the sigmoid activation function. To obtain the final classification we apply a threshold t for positive classification that is optimised for micro-F1 on the validation set.

4 Experiment Setup

Dataset: For our experiments, we use the MIMIC-III (Medical Information Mart for Intensive Care)

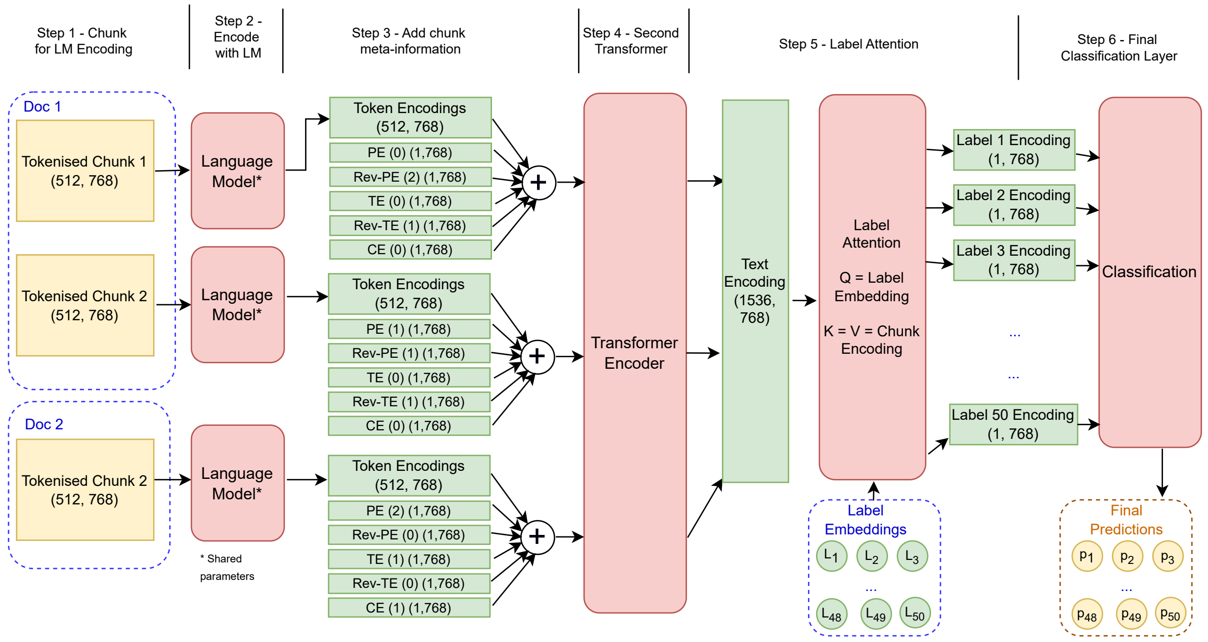

Figure 1: HTDS Model Architecture. The document sequence is first split into chunks (Step 1) and encoded with a pre-trained language model (Step 2). Meta-information of each chunk is then added to the token encodings (Step 3) before a second transformer is applied to allow attention of information across chunks (Step 4). Finally a label attention layer is applied (Step 5) and the outputs are used for classification (Step 6).

	Mean	**SD**
Discharge Summaries		
Total Documents	1.1	0.4
Total Words	1896	929
Total Tokens	3594	1760
All Notes		
Total Documents	33	59
Total Words	10442	21334
Total Tokens	21916	46461

Table 1: Summary statistics: Amount of text contained in clinical documents per hospital stay, measured in terms of total number of documents, words, tokens (using the RoBERTa-PM-M3-Voc tokenizer).

dataset (Johnson et al., 2016), which contains multimodal information on patients admitted to critical care between 2001 and 2012 at the Beth Israel Deaconess Medical Center in Boston, Massachusetts. To limit computational costs, we focus on the MIMIC-III-50 problem, which limits the problem to the top 50 ICD codes by frequency.

To construct the task dataset, we follow Mullenbach et al. (2018) preprocessing steps, with a few exceptions: (1) we keep the text and metadata (specifically the datetime and the category of note) of all notes rather than just the discharge summaries, (2) we do not remove punctuation as we found that performance drops when punctuation is excluded. Each record represents one hospital stay (uniquely identified by the HADM_ID value) and contains the texts and ICD codes linked to that hospital stay. There are 8066, 1573 and 1729 records in the train, dev and test sets respectively, giving us a total of 11368 records.

During the data cleaning process, we noticed that the train set contains clinical notes tagged under the category "Nursing/Other", but no clinical notes were tagged in this category in the dev and test sets. For our experiments we grouped "Nursing/Other" and "Nursing" into a single category.

Table 1 shows summary statistics of the dataset. In general, discharge summaries are far longer than other documents, with an average of 1724 words per document as compared to the overall average of 316 words per document. However, the text in discharge summaries only accounts for less than 20% of the words generated in each hospital stay, suggesting the possibility that the other notes might carry additional information that can improve ICD coding accuracy. We also provide the number of tokens produced when the text is tokenized with the RoBERTa-PM-M3-Voc (Lewis et al., 2020) tokenizer, and we see from the numbers that most hospital stays involve text data that is beyond the 512-token maximum of a single transformer language model.

We also note that the amount of text in each hospital stay can vary widely and has a right-skewed distribution. There is a notable proportion of longer hospital stays which generate substantially more documents and text as compared to the rest. The 90th percentile for Total Words and Total Document Count across all notes is 20556 and 72 respectively. For these hospital stays, the effects of the note prioritisation strategy on model performance would be more prominent.

Task Definition: We investigate two variations of the ICD classification task on this dataset. For Task 1, the notes that are available for modelling are restricted to discharge summaries only. Some hospital stays (11% of stays) have multiple discharge summaries, typically because of addenda, and in these cases we keep all of them. This would be equivalent to the MIMIC-III-50 task attempted by past works. For Task 2, all notes in each hospital stay are available for use in modelling. This vastly increases the number of documents (from an average of 1.1 to 33 per hospital stay) and the number of words (from an average of 1896 to 10442) to be considered. Task 2 uses the same data splits and labels as Task 1, allowing us to compare the results to assess whether information from the additional notes is able to improve performance.

For both tasks, we use the same evaluation metrics as defined by Mullenbach et al (Mullenbach et al., 2018) and then subsequently followed by other researchers: micro-F1, macro-F1, micro-AUC, macro-AUC, and Precision at k=5.

Implementation and Model Hyperparameters: Pytorch was used for the implementation of our models, and NVIDIA Tesla A100 80GB GPUs were used for finetuning. Hyperparameters were tuned manually; Table 2 details the search space and final hyperparameter values used for the HTDS model. The pretrained language model was initialised to the RoBERTa-base-PM-M3-Voc (Lewis et al., 2020) model checkpoint, which was pretrained on texts in PubMed, PubMed Central, and MIMIC-III physician notes. The second transformer uses 1 encoder layer with 8 attention heads.

Texts are tokenized into chunks of T_c=512 tokens and a maximum of N_c=32 chunks were used as model input. With these values for T_c and N_c, the note selection strategy to maximise diversity of document categories (detailed earlier in Section 3) was applied for 45% of samples which have more than 32 chunks of text. The model has 136M parameters in total.

Attention Heads	**8**, 12

Table 2: Hyperparameter search space. Bolded text indicates hyperparameters used in the HTDS model.

These hyperparameters were selected to maximise Micro-F1 on the dev set, with a few exceptions to manage training and computation costs: (1) while using the larger RoBERTa-large-PM-M3-Voc model was found to achieve better performance, we kept to the smaller RoBERTa-base-PM-M3-Voc model; (2) while increasing the maximum number of chunks N_c in general leads to better performance, we limit our model to a maximum of 32 chunks.

Training models that take text across all clinical documents as inputs, compared to using only the discharge summary, requires substantially more computational resources. With A100 GPUs, 15.5 samples are processed per second when training on discharge summaries only[1], and 4.9 samples are processed per second when training with all clinical documents. To speed up the model optimisation process, we apply the 3-phase *1cycle*

---

[1] TrLDC (Dai et al., 2022), which we consider to be a comparable model in terms of architecture, processed 7.4 samples per second when training on discharge summaries on NVIDIA V100 GPUs.

Table 3: Performance of models on the MIMIC-III-50 test set. Models are sorted by Micro-F1 within each category. Metrics are averaged across 5 replications. Subscripts indicate the standard deviation across runs. Bolded values indicate the best score achieved for each metric.

learning rate scheduler for superconvergence as described in (Smith and Topin, 2019). The learning rate (LR) progresses via cosine annealing from 1/25 of the peak LR to the peak LR (5e-5) in the first phase (30% of iterations) and then goes back to 1/25 of the peak LR in the second phase (30% of iterations). Finally in the third phase (40% of iterations), LR is annealed to 1/1000 of the peak LR. The AdamW optimizer is used, with an effective batch size of 16 achieved through gradient accumulation. The model is trained for up to 20 epochs with an early stopping patience threshold of 5. With this setup, training is stopped at around the 14th epoch on average. We note that this is at least 50% less (in terms of number of epochs) compared to past works on the MIMIC-III-50 problem where transformer-based models would be trained for 30 epochs or more (Dai et al., 2022; Ji et al., 2021; Pascual et al., 2021).

5 Results

5.1 Main Results

Table 3 shows the results when our models are evaluated against the MIMIC-III-50 test set, as well as comparisons against published works. We report the averaged metrics across 5 training replications.

As we can see from the table, prior works with transformer-based models faced challenges in achieving competitive performance on this problem. Dai et al. (2022) managed substantial improvements with the TrLDC model over the work of Ji et al. (2021), however even with a large-sized model their performance still fell slightly behind the best-performing CNN-based and RNN-based models. When using only discharge summaries, HTDS achieves state-of-the-art performance in terms of Micro-F1, the primary metric used for comparison. It also exceeds past CNN-based and Transformer-based models on all metrics of interest.

When including all clinical documents, as compared to including only discharge summaries, the performance of HTDS improves on all metrics of interest (all differences are statistically significant at p<0.05), including an additional 0.7% increase in Micro-F1. Comparing against all other models, we see that the model achieves state-of-the-art performance in terms of all metrics except for Macro-F1. We hypothesize that the modelling of code synonyms in MSMN (Yuan et al., 2022) helped to increase its performance on rarer ICD codes and hence achieve a higher Macro-F1 score, but also note that steps used to improve performance by incorporating synonyms based on UMLS concepts could also be adapted into our model to achieve similar improvements.

Put together, our results demonstrate the value of including clinical documents beyond the discharge summary in modelling.

5.2 Ablation Experiments

To analyse the effect of various components and hyperparameter choices on model performance, we start with our main model and then ablate or vary individual components one at a time, keeping all other components constant, and evaluate their performance on the development set. We share our results in this section.

For all ablation experiments, we report the impact on Micro-F1, the primary metric of interest, averaged across 5 replications.

Quantity of Text Input: Table 4 shows how performance varies as the quantity of text is varied. The quantity of text used as input has a substantial impact on the compute requirements of the entire model architecture. When N_c is reduced 16, 7.5 samples are processed per second when training on A100 GPUs, an increase of 0.5x as compared to 4.9 samples per second for HTDS which uses N_c=32. However, as we can see from the results of this ablation experiment, reducing the quantity of text input leads to a substantial drop in model performance.

	Micro F_1
HTDS (Max 32 Chunks)	74.0
Max 16 Chunks	73.0

Table 4: Performance when the quantity of text input is varied on the development set.

Metadata embeddings: Table 5 shows how the performance varies as the metadata embeddings used in the model are varied. The ablation of each of the embedding types in isolation results in small but consistent decreases in model performance. It is possible that the model compensates by learning to capture some of this information from the text itself without explicit embeddings. Indeed, past works have observed that the clinical notes in the MIMIC-III dataset have a high degree of structure and templating (Liu, 2018). Nevertheless, in our experiments the overall best results were obtained by using the combination of all the proposed metadata embeddings.

	Micro F_1
HTDS (All meta embeddings)	74.0
Ablate CE	73.9
Ablate PE+Rev-PE	73.9
Ablate TE+Rev-TE	73.8

Table 5: Performance when metadata embeddings are varied on the development set.

Chunk Representations: In a traditional hierarchical transformer, only the encoding of the [CLS] token is kept and used as an aggregate representation of the chunk. However, recent works have suggested that the [CLS] token might have insufficient capacity to capture information for the large number of labels in the ICD coding problem (Huang et al., 2022). In Table 6, we show the results when only the [CLS] token is used as an aggregate representation of each chunk, and see that there is a sizeable decrease in performance.

	Micro F_1
HTDS (All token representations)	74.0
CLS token representation only	71.7

Table 6: Performance when the embeddings used for chunk representation are varied on the development set.

Second Transformer: The second transformer in Step 4 allows tokens from each chunk to attend to tokens from other chunks. While earlier studies (Dai et al., 2022; Ji et al., 2021) include this second transformer, it also adds to the computational costs of the model due to the quadratic complexity of the attention step and (Huang et al., 2022) show that the second transformer can be dropped if the encodings of all tokens (rather than just the [CLS] token) are kept for the label attention step.

Our ablation experiments in Table 7 provide some additional insight on this. When considering only the discharge summary, the second transformer can be dropped without substantial impact on performance. However, when modelling the sequence of all clinical documents, ablating the second transformer leads to a noticeable decrease in performance, suggesting that the information in other documents can help further refine token representations before classification.

	Micro F_1
HTDS (Discharge Summaries)	73.2
Ablate 2nd Transformer	73.3
HTDS (All Notes)	74.0
Ablate 2nd Transformer	73.6

Table 7: Performance when second transformer is ablated on the development set.

Note Selection: In around 45% of admissions, tokenizing the text in all available clinical notes will produce more than 32 chunks of 512 tokens. In those cases, we would need to select which chunks are used as inputs to our model. Table 8 shows our results. We considered the following strategies to prioritise which chunks to use:

- By timestamp: We select the first or last 32 chunks by the timestamp of the clinical notes. Taking the last chunks achieved far superior performance.
- By category: We select first the discharge summary[2], then notes of a certain category (Radiology/Nursing/Physician), and then other notes until 32 chunks of text are selected. Our results indicate that the differences in performance are mostly marginal, suggesting that there could be multiple possible strategies that achieve close to optimal performance.
- Prioritise diversity: We select first the last note by timestamp of each category, and then the second last note of each category, and so on until 32 chunks of text are selected. This maximises the diversity (in terms of categories of notes) used as inputs to the model. This approach was found to have the highest score on the development set, and hence used for HTDS.

	Micro F_1
HTDS (Prioritise diversity)	74.0
Prioritise First	68.4
Prioritise Last	73.8
Prioritise Radiology	73.8
Prioritise Nursing	73.7
Prioritise Physician	73.8

Table 8: Performance when note selection is varied on the development set.

In general, we also note that the effects of note selection strategies would be more pronounced when the maximum number of chunks N_c for model input is smaller, as it would result in a greater proportion of text being excluded.

6 Conclusion

As we work towards automated ICD coding, it would be helpful to build models that can consider information that is captured across the patient's EHR record, rather than just the discharge summary (which may not always be exhaustive). Such an approach would also be more similar to a real-life setting, where clinicians consider all available information for ICD coding, rather than information in a single document.

In this paper, we demonstrated the HTDS model, which is an adaptation of the hierarchical transformer model that considers the text and metadata from the entire clinical document sequence for ICD coding. While transformer-based models have faced difficulties achieving competitive performance on the ICD coding problem in the past, with HTDS we show that these challenges can be overcome. When evaluated on the MIMIC-III-50 test set using only discharge summaries, HTDS exceeded the prior state-of-the-art performance in terms of Micro-F1 score. When all clinical documents were considered, the performance of HTDS improved further on all performance metrics of interest, and exceeded prior state-of-the-art performance in all metrics except for Macro-F1. The results demonstrate the value of including clinical documents beyond the discharge summary in the ICD coding problem.

Possibilities for improving performance even further are plenty. These include: using a large-sized language model or using overlapping text chunks to reduce fragmentation in the initial encoding step (Dai et al., 2022), considering other transformer architectures for long texts (Beltagy et al., 2020; Dai et al., 2019; Zaheer et al., 2020), smarter strategies for chunking the input text to reduce fragmentation, further improving the strategy for selecting which text to use as model input (possibly going down to text-level rather than document-level approaches), and incorporating methods to better model rare ICD codes (Vu et al., 2021; Yuan et al., 2022). Approaches for improving the computational efficiency and training time of the model can be considered to help to reduce GPU resource requirements, and enable the testing of more models and hyperparameter settings. Going even further from here, we could consider multi-modal models that use information across the entire EHR database for ICD coding.

We hope that our findings will encourage future

---

[2] Our exploratory tests find that the discharge summaries contain the most relevant information. We note also that prior work achieved good performance with just the discharge summaries, without the need for other notes.

studies that tap on the full breadth and depth of information available in modern EHR databases today in order to further push the limits of performance on the ICD coding problem in future.

Limitations

Although applying HTDS on the full clinical document sequence in each hospital stay helped to push performance on the ICD coding problem further as compared to the prior state-of-the-art, we note a few limitations to our work.

Firstly, the computational requirements to train HTDS is not trivial. When using NVIDIA A100 GPUs, one training run took 8 GPU-hours on average (for 5 replications this would require 40 GPU-hours). The increased computation cost for HTDS, as compared to other models on the ICD coding problem, could be attributed to the higher number of model parameters in transformers as compared to CNN/RNNs and the increase in input data size as a result of using all clinical documents as input. It is hoped that this issue of high compute costs can be mitigated in future by either further refinements in modelling to improve efficiency or improvements in the compute capabilities of hardware used for model training.

Secondly, we note that our work focuses only on the MIMIC-III-50 problem, where only the top 50 ICD codes by frequency are considered. This would be insufficient in a real-life setting, which would require clinicians to consider all ICD codes. Extending our work on the MIMIC-III-Full problem, which uses a dataset that is 4x in size, was not attempted due to limitations on compute resources. However, we speculate that the benefits of using all clinical documents to perform ICD coding would apply similarly to the MIMIC-III-Full problem.

Finally, while we have taken the actual ICD codes assigned by clinicians as the "ground truth" for the purpose of model evaluation, there have been errors made during the process. We would not expect clinicians to thoroughly read the entire clinical document sequence (consisting an average of over 10,000 words) for every patient when performing ICD coding, and hence there is a possibility that some codes could have been missed. A more thorough approach for model evaluation could involve extracting a sample of records where different codes were assigned by the clinicians and our models for further evaluation by experts, in order to determine the extent to which this might have affected our evaluation metrics.

Ethics Statement

No conflicts of interest are declared by the authors. Clinical data in the MIMIC-III database is de-identified through removal of identifying data elements and date-shifting in accordance with Health Insurance Portability and Accountability Act (HIPAA) standards, and protected health information was further removed from clinical notes using dictionary look-ups and pattern-matching (Johnson et al., 2016). The use of the data is in accordance with the MIMIC-III data use agreement.

Abstract

While human evaluation remains best practice for accurately judging the faithfulness of automatically-generated summaries, few solutions exist to address the increased difficulty and workload when evaluating *long-form* summaries. Through a survey of 162 papers on long-form summarization, we first shed light on current human evaluation practices surrounding long-form summaries. We find that 73% of these papers do not perform any human evaluation on model-generated summaries, while other works face new difficulties that manifest when dealing with long documents (e.g., low inter-annotator agreement). Motivated by our survey, we present LONGEVAL, a set of guidelines for human evaluation of faithfulness in long-form summaries that addresses the following challenges: (1) How can we achieve high inter-annotator agreement on faithfulness scores? (2) How can we minimize annotator workload while maintaining accurate faithfulness scores? and (3) Do humans benefit from automated alignment between summary and source snippets? We deploy LONGEVAL in annotation studies on two long-form summarization datasets in different domains (SQuALITY and PubMed), and we find that switching to a finer granularity of judgment (e.g., clause-level) reduces inter-annotator variance in faithfulness scores (e.g., std-dev from 18.5 to 6.8). We also show that scores from a *partial* annotation of fine-grained units highly correlates with scores from a full annotation workload (0.89 Kendall's τ using 50% judgments). We release our human judgments, annotation templates, and our software for future research.[1]

1 Introduction

Human judgments are considered the gold standard for evaluating model-generated summaries (Kryscinski et al., 2019; Fabbri et al., 2021) and generated text more broadly (Celikyilmaz et al., 2020). Unfortunately, human evaluation tends to be labor-intensive, expensive to scale, and difficult to design. This is problematic as a large number of judged examples is needed to draw statistically significant conclusions about system performances (Wei and Jia, 2021) or correlations between human judgments and automatic metrics (Deutsch et al., 2021). Human evaluation is especially challenging when *long* sequences of generated text need to be evaluated, due to the inherent subjectivity in the task (Karpinska et al., 2021; Clark et al., 2021; Krishna et al., 2021; Goyal et al., 2022).

To better understand the challenges of human evaluation on long-form summaries (150 words or longer), we first conduct a comprehensive survey of 162 publications and preprints on long-form summarization (Section 2). We find that 119 papers (73%) do not perform human evaluation on long-form summaries, while the remaining papers deviate significantly from suggested best practices for reproducibility (Gehrmann et al., 2022). Current human evaluation setups lack standardization in their design decisions (such as annotation granularity), some of which can significantly impact inter-annotator agreement (Section 3.1). Finally, 20 papers explicitly mention human evaluation is expensive, difficult, and time-consuming due to the long length of summaries and source documents.

To move towards a more consistent and efficient human evaluation, we present LONGEVAL, a set of guidelines for human evaluation of faithfulness in long-form summarization (Section 3). We empirically evaluate LONGEVAL using human annotation studies on two long-form summarization datasets: SQuALITY (Wang et al., 2022) and PubMed (Cohan et al., 2018). We provide an overview of our main research questions and findings in Figure 1 and enumerate them here:

Q1: Can inter annotator agreement be improved with fine-grained annotations?

Q2: Can annotator workload be reduced by annotating just a fraction of the long summary?

Q3: Is it helpful to automatically align summary units with the long source document?

Asa Graybar is a biological engineer who studies keeping Slider eggs alive and he is accused of a crime at the opening of the story . He thinks he was framed by Tom Dorr , Hazeltyne 's general manager . He was offered one year as a " changeling " on another planet or 5 years in rehabilitation on Earth . He elects to do the one year , and thinks that he will get into smuggling Slider eggs on Jordan 's planet .....

.... He recognized her as old Hazeltyne 's daughter Harriet , no doubt come to see justice done . She did n't have the hothouse - flower look Asa would have expected in a girl whose father owned the most valuable of the planetary franchises . She was not afraid to meet his eye , the eye of a judicially certified criminal . There was , perhaps , a crease of puzzlement in her brow , as if she had thought crimes were committed by shriveled , rat - faced types , and not by young biological engineers who still affected crewcuts . Tom Dorr , Hazeltyne 's general manager , was her escort . Asa felt certain , without proof , that Dorr was the man who had framed him for the charge of grand theft by secreting a fresh Slider egg in his laboratory . The older man stared at Asa coldly as he was led out of the courtroom and down the corridor back to jail . Jumpy , Asa 's cellmate , took one look at his face as he was put back behind bars . " Guilty , " Jumpy said ....Asa took four steps to the far wall of the cell , stood there briefly with his head bent and turned to face Jumpy . " Nope , " Asa said softly . " I 'm going into a conversion tank . I 'm going to be a muck man , Jumpy . I 'm going out to Jordan 's Planet and hunt Slider eggs . " " Smuggling ? It wo n't work . " Asa did n't answer . The Hazeltyne company had gone after him because he had ...

Figure 1: Overview of research questions considered in LONGEVAL. Example summary taken from SQuALITY.

RQ1: *Can inter-annotator agreement be improved while evaluating faithfulness of long-form summaries via fine-grained annotations?*

Finding: Annotating faithfulness of individual summary clauses and aggregating them leads to significantly higher inter-annotator agreement, compared to the dominant paradigm of evaluating whole summaries at once via Likert ratings (std-dev 18.5 to 6.8 on SQuALITY).

RQ2: *Can we reduce annotator workload by partially annotating a long summary while maintaining accurate faithfulness scores?*

Finding: Despite annotating a fraction of summary clauses, faithfulness scores under a reduced workload maintain high correlation with those from a full workload (0.89 Kendall's τ at 50% workload).

RQ3: *Do humans benefit from automatically aligning summary units to relevant sentences in the source document?*

Finding: Unlike suggestions in prior work on short-form summarization (Hardy et al., 2019; Kryscinski et al., 2020), aligning parts of the summary to source document is only useful when the summary is highly extractive or mostly correct.

Overall, our contributions are:
(1) a 162-paper survey of current human evaluation practices in long-form summarization;
(2) LONGEVAL, a set of three guidelines for evaluating faithfulness in long-form summarization;
(3) an empirical validation of LONGEVAL guidelines on two long-form summarization datasets in different domains (SQuALITY and PubMed);
(4) A dataset with 3-way fine-grained human faithfulness judgments for 120 SQuALITY & PubMed summaries annotated using LONGEVAL which can be used for benchmarking automatic metrics.

We open-source our human evaluation data, annotation interface, and code for future research.[1]

2 Survey of human evaluation practices

Before discussing LONGEVAL, we first attempt to understand current human evaluation practices in long-form summarization through a comprehensive survey of 162 papers. Our survey reveals several concerning trends: absence of human evaluation, non-reproducible experimental setups, lack of standardization, and complaints of long summaries being challenging and expensive to evaluate. These results show an urgent need to develop more efficient and standardized human evaluation protocols.

Selection of papers: We consider existing summarization datasets with an average summary length of at least 150 words, which includes several popular datasets like arXiv (Cohan et al., 2018), BillSum (Kornilova and Eidelman, 2019) and Multi-News (Fabbri et al., 2019); see Table 1 for a full list. For our survey, we select all papers that evaluated summarization models using at least one of these datasets.[2] All of these papers were published between June 2018 and September 2022, after the first long-form summarization datasets were released (PubMed / arXiv). Most of the 162 surveyed papers

---

[2] We exclude five papers which used long-form summarization data for pre-training only, like Wei et al. (2022).

were published in major NLP/ML venues, but we also include newer preprints from 2022.

Long-form summaries are rarely evaluated by humans. We find that 101 out of 162 papers (62%) do not perform any human evaluation. 17 papers (11%) only perform human evaluation on short summaries (datasets like XSUM, Narayan et al., 2018), for which human evaluation is much easier.

Human evaluation studies of long-form summaries are not reproducible. We further analyze the 44 papers performing human evaluation of long-form summaries to observe how often they follow reproducible practices from Gehrmann et al. (2022). Overall, we find that most studies do not follow these guidelines. Only 2 of the 44 papers release their raw human annotation data for further analysis. Only 9 papers provide details of their annotator instructions or interface, and just 12 papers perform any kind of statistical analysis, despite most papers annotating less than 50 summaries. While 33 papers report using multiple annotators per summary, only 12 report inter-annotator agreement. Finally, just 14 papers conduct human evaluation on more than one dataset (more statistics in Appendix C).

Existing human evaluation setups lack standardization. In Table 2, we catalog the wide spectrum of human evaluation setups in the surveyed papers. 37 papers collect judgments of the full-length summary at once ("COARSE-grained"), while 6 papers collect judgments at a finer granularity such as sentences or entities ("FINE-grained"). Even within a granularity, setups differ: Likert-scale (24 papers), A/B testing (13 papers), binary per-sentence labels (4 papers) are the dominant protocols. In Section 3.1, we will see that this design decision is critical since COARSE annotations have much lower inter-annotator agreement than FINE.[3]

Human evaluation of long-form summaries is challenging and expensive. Several of the surveyed papers discuss challenges in human evaluation of long-form summaries. 13 papers mention that expert annotators are necessary for human evaluation of long-form summaries, especially in technical domains like PubMed. 20 papers report that human evaluation of long-form summarization was *time-consuming*, *challenging*, and *expensive*, primarily due to the long length of the summary and source document. To tackle the issue of high annotator workload, we propose a partial annotation method in Section 3.2 and report high correlation to a full workload. Additionally, in Section 3.3 we investigate the usefulness of highlighting sentences to help annotators navigate the long source document. While this has been advocated for in short-form summary evaluation (Hardy et al., 2019; Kryscinski et al., 2020) and used in 3 surveyed long-form papers, we find that it is only helpful when summaries are mostly correct and extractive.

Dataset	|source| (words)	|summary| (words)	papers
PubMed (2018)	3092	205	59
arXiv (2018)	5906	163	55
BillSum (2019)	1284	174	19
MultiNews (2019)	2103	263	54
GovReport (2021)	7551	547	16
BookSum (2021)	5102	505	4
SummScreen (2022)	6965	227	11
SQuALITY (2022)	5194	227	1

Table 1: List of long-form summarization datasets considered in our survey along with average source document and summary lengths. Each dataset considered has at least 150 word summaries on average.

Type of human evaluation	# papers	% papers
None	101	62%
Short-form summaries only	17	11%
Likert-scale COARSE-grained	24	15%
A/B testing COARSE-grained	13	8%
Extrinsic evaluation	1	1%
Binary per sentence FINE-grained	4	2%
QA-based FINE-grained	2	1%

Table 2: Human evaluation setup in 162 summarization papers that evaluate long-form summaries. 73% of the papers do not evaluate long-form summaries with humans, while others vary significantly in their setups.

3 The LONGEVAL guidelines for faithfulness human evaluation

In Section 2, we report several concerning issues with current human evaluation practices in long-form summarization. To move towards more efficient, reproducible and standardized protocols for human evaluation, we develop the LONGEVAL guidelines (Section 3.1-3.3, see Figure 1 for an overview). We focus on human evaluation of *faithfulness*, which Wang et al. (2022) define as:

---

[3] Besides granularity, we also observe a large spectrum of annotator qualifications in our survey, ranging from MTurkers to expert graduates (Appendix C). Since non-experts are known to be unsuitable for this task (Gillick and Liu, 2010; Fabbri et al., 2021), we use experts in our work (Appendix B).

> "*Checking the factual errors in the summary, where a factual error is a statement that contradicts the source document, or is not directly stated, heavily implied, or logically entailed by the source document*"

We conduct human annotation studies to empirically motivate LONGEVAL. Our experiments are on two long-form summarization **datasets** spanning diverse domains and levels of abstractiveness:

(1) **SQuALITY** (Wang et al., 2022) is a summarization dataset in the literary domain (avg. summary length of 227 words) where summaries describe the plots of English science fiction stories. SQuALITY is highly abstractive: on average just 16% of bigrams in the summary are present in the source document. We closely follow the human evaluation setup in Wang et al. (2022), and use BART (Lewis et al., 2020) and BART-DPR (Karpukhin et al., 2020) as our summarization models along with human-written summaries.

(2) **PubMed** (Cohan et al., 2018) is a summarization dataset in the scientific domain (avg. summary length of 205 words) that pairs English biomedical articles from PubMed[4] with their abstracts as summaries. Compared to SQuALITY, PubMed is more extractive: 54% of summary bigrams are present in the source. We use BigBird-PEGASUS-large (Zaheer et al., 2020) and LongT5-large (Guo et al., 2022) as our summarization models,[5] along with human written summaries. By default, LongT5 / BigBird were highly extractive compared to human-written PubMed summaries (87% / 74% vs 54% bigram overlap with source). Hence, for half the generations we block 6-grams from being copied from the source,[6] reducing extractiveness to ∼54%. We call this setting "PubMed-ngram-block".

3.1 RQ1: Does inter-annotator agreement improve using fine-grained annotations?

In Section 2, we found that the dominant paradigm in literature (37 out of 44 papers) is to evaluate the whole summary at once ("COARSE"-grained, Figure 1 top left). 6 papers instead obtain fine-grained annotations for individual units (e.g., sentences) and average them (FINE, Figure 1 top right). Intuitively, FINE annotation has many advantages for longer summaries — it is less subjective than COARSE, since shorter spans needs to be judged rather than a long summary, and it helps localize model errors. However, the distinction between COARSE and FINE is never justified in literature, and inter-annotator agreement is rarely reported to understand the task subjectivity in each setup. To better understand the tradeoff, in this section we conduct human evaluations annotating the same set of summaries using these two different protocols.

Task formulation: Let F_{summ} denote the faithfulness score of a summary. For COARSE, k-point Likert scale ratings are obtained for the summary ($F_{\text{summ}} \in \{0, 1...k\}$), based on the faithfulness definition provided earlier. For FINE, we collect binary judgments of individual units in the summary and average them,

$$F_{\text{summ}} = \frac{1}{|\mathcal{C}_{\text{summ}}|} \sum_{c \in \mathcal{C}_{\text{summ}}} F_c, \ F_c \in \{0, 1\}$$

where $\mathcal{C}_{\text{summ}}$ is a set of units in the summary and F_c is the faithfulness judgment for the unit c. In both protocols, the faithfulness score of a system is defined as $\frac{1}{|\mathcal{S}|} \sum_{\text{summ} \in \mathcal{S}} F_{\text{summ}}$ where $\mathcal{S}$ is the set of summaries generated by the system.[7]

While sentences are a popular granularity for FINE (4 of the 6 surveyed papers), we found that summary sentences in both datasets were overloaded with information. Hence, we segment sentences on conjunctions and punctuation to obtain more atomic units as $\mathcal{C}_{\text{summ}}$. These units are often clauses,[8] similar to summary content units (SCUs) in Pyramid (Nenkova and Passonneau, 2004).

Collecting COARSE annotations: For SQuALITY, we re-use the annotations provided by Wang et al. (2022) for faithfulness assessments. In their data, three annotators give each summary a 1-100 direct assessment rating (Bojar et al., 2016). Annotators with experience in professional copyrighting and editing were hired on Upwork,[9] and these annotators were also involved in the creation of SQuALITY. Unfortunately, none of the surveyed papers that reported human evaluation results on PubMed

---

[4] `https://pubmed.ncbi.nlm.nih.gov/`

[5] LongT5 is the best publicly available PubMed summarizer. BigBird is a popular long-form summarization baseline.

[6] Reducing extractiveness / copying is also a suggestion for fair-use of copyrighted work (Harvard, 2016; UMGC, 2020).

[7] We assume all summary units get an equal weight. However, some units may be more important than others, we discuss this in the Limitations section.

[8] An even finer granularity is entities / numbers. We avoid this due to prohibitive annotation cost on long summaries.

[9] `https://www.upwork.com/`

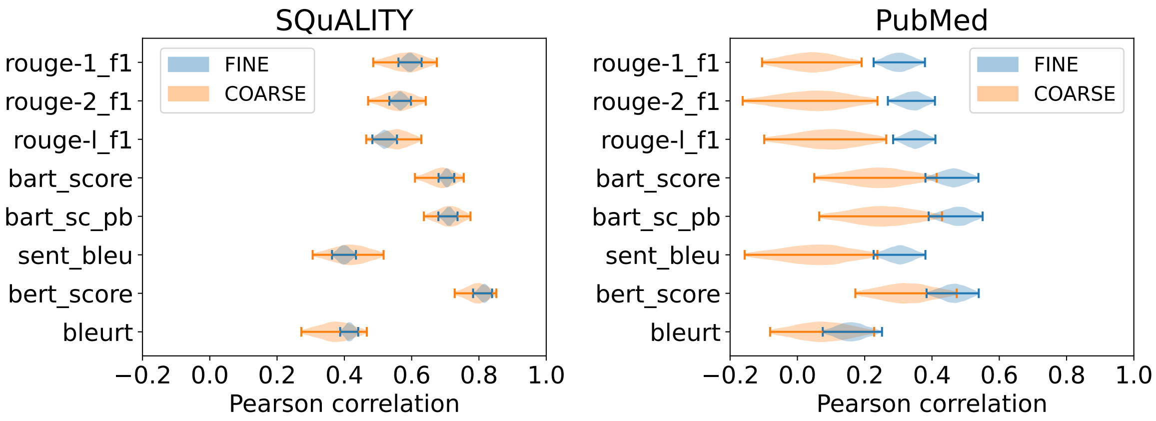

Figure 2: 95% confidence intervals of Pearson correlations between various automatic evaluation metrics and using human evaluation data collected with FINE (blue) and COARSE (orange) annotation methods. In both datasets, FINE annotations lead to much narrower CIs than COARSE annotations. See Appendix G for plot with Kendall's Tau.

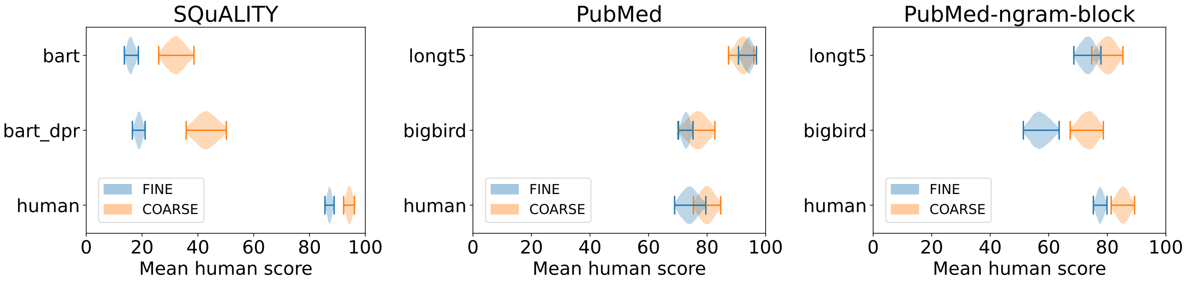

Figure 3: 95% confidence intervals of estimated model performances using FINE (blue) and COARSE (orange) annotation methods. Intervals calculated using bootstrap resampling across annotators (Appendix A). While both annotation granularities lead to similar relative ordering of systems, FINE annotations have narrower confidence intervals. The higher LongT5 score vs human in PubMed is due to highly extractive LongT5 summaries (Section 3).

released their raw human annotations.[10] Hence, we collect our own COARSE evaluations on PubMed summaries on Upwork, using freelancers with professional experience reading and writing research papers (details in Appendix B.2). We collect 3 annotations per summary and use a 5-point Likert scale, the most common choice for COARSE assessment in our survey (18 out of 38 papers). In total, 120 summaries are evaluated.

Collecting FINE annotations: For both SQuALITY and PubMed, we collect FINE annotations on Upwork (3 annotators per FINE unit) for the *same set* of 120 summaries evaluated using COARSE annotations. For SQuALITY, we hire freelancers with professional experience in English, creative writing, or education. For PubMed, we hire freelancers with prior experience analyzing biomedical articles. See Appendix B.1 for details of our annotator screening process, compensation, instructions, and screenshots of our annotation interface.

Dataset	COARSE	FINE
SQuALITY	18.5	**6.8**
PubMed	11.8	**7.3**
PubMed + ngram block	11.7	**9.3**
Average	14.0	**7.8**

Table 3: Average standard deviation of faithfulness scores across annotators on a 100-point rating scale. Lower variation means higher agreement. Overall, we find that FINE-grained annotations have higher inter-annotator agreement than COARSE-grained annotations. Note that all FINE units of a summary were annotated to obtain these results ($f = 1.0$ in Section 3.2).

FINE annotations have higher inter-annotator agreement than COARSE annotations. This leads to more confident downstream estimates. We present our results in Table 3. Overall, we observe that across all settings, FINE annotations have lower

---

[10] In our email correspondence with authors of these works, they mentioned losing access or compliance issues as reasons for not sharing human evaluations. We received some examples from Guo et al. (2021) and Ju et al. (2021) for reference.

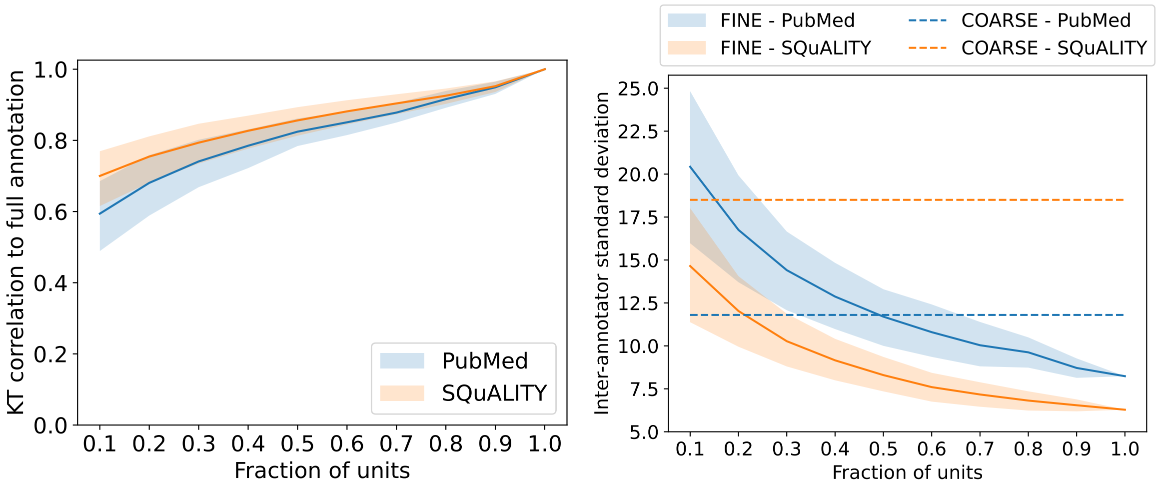

Figure 4: Accuracy and variance after annotating a fraction of units per summary (X-axis) with FINE. Despite annotating just a fraction of the summary, we observe a high segment-level Kendall tau correlation with a full annotation (left). However we observe higher inter-annotator variance as the fraction reduces (right). Confidence intervals shown are 95% and computed across 1000 random subsets (see Appendix F for left plot with Pearson).

standard deviation (and thus higher agreement) in faithfulness scores than COARSE annotations (7.8 vs 14.0 average on 100-point scaled ratings). To illustrate the importance of higher agreement, we measure its effect on two downstream statistics that human evaluation is primarily used for: (1) correlation with automatic metrics; and (2) mean system performance. We adapt the bootstrap resampling analysis[11] of Deutsch et al. (2021) to estimate confidence intervals of these two downstream statistics for COARSE and FINE.

In Figure 2, we plot the 95% confidence intervals of the Pearson correlation of various automatic evaluation metrics against FINE-grained and COARSE-grained human evaluation data. Across both datasets, FINE data leads to much narrower confidence intervals (0.15 vs 0.35 average uncertainty in Pearson correlation on PubMed) for the same number of summaries, implying higher statistical power. In Figure 3, we observe a similar trend with mean system performance. Interestingly, both annotation methods give the same relative ordering of systems (human > bart-dpr > bart for SQuALITY, human > longT5 > BigBird for PubMed-block), confirming the alignment of FINE and COARSE judgments on average.

Recommendation: Unlike the dominant trend in prior work, FINE-grained evaluations should be preferred over COARSE grained evaluation for long-form summaries. FINE annotations have lower inter-annotator variance than COARSE annotations and help localize model errors. In our setup we assume all FINE units are equally weighted while aggregating them to the final summary score. Despite this assumption, in our results we observe a consistent relative ordering of systems/metrics between COARSE and FINE annotations. Nevertheless, non-uniform weighing of units is an interesting future work direction; more in the Limitations section.

3.2 RQ2: Can we reduce annotator workload by partially annotating a long summary?

In Section 3.1, we found that FINE annotations have lower variance than COARSE annotations. However, long summaries may be composed of several units (sentences or phrases) which each require FINE annotation. This could make FINE annotation very expensive for longer summaries (as also noted in our survey). What if we instead annotate a random subset of units from the summary? While this will lower annotation cost, how accurate would these partial annotations be? We explore this tradeoff by re-using the annotations collected in Section 3.1. For every summary, we randomly sample a fraction of units $f \in \{0.1, 0.2 ... 0.9\}$ and then measure its correlation to the full set of annotations collected. Each annotator gets a different random sample of units for the same summary. In initial experiments, we found that this yielded higher accuracy than when keeping the same set of units per annotator.

---

[11] We slightly modify the algorithm in Deutsch et al. (2021) for inter-annotator variance, see Appendix A.

Partial annotation has a high correlation to full annotation, but higher variance: In Figure 4 (*left*) we plot the segment level Kendall's τ correlation (relative ordering of summary scores) between a partial annotation and full annotation for different values of f. Overall, we observe a high correlation across different values of f. Despite annotating just half the summary ($f = 0.5$), in both datasets we observe a high correlation of 0.78-0.89 Kendall's τ (95% interval) with a full annotation. Does a partial annotation preserve the variance benefits of FINE VS COARSE? In Figure 4 (*right*) we plot the inter-annotator variance for different values of f. In both datasets we find that a partial annotation has a higher variance than a full annotation. While for all values of f in SQuALITY we find that FINE annotations still have lower variance than COARSE, in PubMed COARSE has lower variance than FINE for $f <= 0.3$ with 95% confidence.

Recommendation: Having annotators judge a random subset of units in a long-form summary is a simple way to reduce FINE annotation cost, and has high correlation with a full annotation. However, it increases inter-annotator variance. Annotating 50% of the summary results in 0.78-0.89 Kendall's τ correlation, with a 30-40% increase in standard deviation compared to full FINE annotation. Partial annotation may be limited in its ability to identify issues in summaries with very few errors. However, we find that this is not the case in current systems, which are abundant in faithfulness errors.

3.3 RQ3: Is it useful to align summary units to sentences in the source document?

So far, we have focused on design decisions on the summary side of evaluation. However, evaluating faithfulness requires a comparison of facts between a summary and a *source document*. Long-form summaries tend to have long source documents (Table 1): 3.1K words for SQuALITY and 5.1K words for PubMed. In Section 2, we found several mentioned human evaluation is challenging since annotators need to read long source documents. Some prior work has suggested highlighting spans in the source document that align with the summary (Hardy et al., 2019; Kryscinski et al., 2020; Vig et al., 2021) as shown in Figure 1. However, these efforts have exclusively focused on news summarization with relatively short source documents, like CNN/DM (804 words) (Nallapati et al., 2016) or XSUM (438 words) (Narayan et al., 2018). How useful is highlighting based on alignment, or "*hints*", when the spans are chosen from much longer documents?

Algorithm	R@3	R@5	R@10
BM25 (1995)	0.38	0.46	0.56
ROUGE-1 (2004)	0.31	0.34	0.46
SIM (2019)	0.37	0.52	0.60
DPR (2020)	0.29	0.31	0.41
BERTScore-DB-XL (2020)	0.30	0.37	0.46
SummaC-NLI (2022)	0.22	0.26	0.34
MultiVers-FEVER (2022)	0.47	0.58	0.71
SuperPAL (2021)	**0.61**	**0.68**	**0.77**

Table 4: A comparison of algorithms finding the top source document sentences for summary units in SQuALITY. R@k (recall@k) denotes the fraction of times the gold sentence was in the top-k predictions.

Hints	Acc. (↑)	Agree. (↑)	Time (secs) (↓)	
	(2-way)	(Fleiss)	All	First 5
None	**93%**	**0.71**	41.4	115.6
SuperPAL	92%	0.64	48.2	84.6
Gold	92%	0.63	**40.4**	**60.4**

Table 5: Annotator performance (accuracy, agreement, median time) in detecting summary errors with different types of source document highlight hints. Overall, we see little difference across the three settings.

What is the best highlighting algorithm? We conduct a study to identify the alignment algorithm best suited for highlighting hints. We manually annotate 125 FINE units from human-written summaries of the SQuALITY validation split, marking the sentences best supporting them from the source document. We then test several candidate methods for linking summary units to the source document. These include token overlap methods like ROUGE (Lin, 2004), retrievers (Karpukhin et al., 2020), and fact verifiers (Wadden et al., 2022). In Table 4, we find that SuperPAL (Ernst et al., 2021), a weakly supervised linking algorithm, performs best (0.61 recall@3 vs the next best 0.47). To improve precision, we filter matches scoring less than 0.3 on SuperPAL, and show at most five highlights.

Do highlighted hints improve summary error detection? To answer this question, we manually perturb 50 FINE summary units in SQuALITY validation summaries, introducing entity errors or negations like Kryscinski et al. (2020). We modify the summary context of the perturbed unit to ensure summaries are self-consistent. Annotators

Question & TL;DR response	Response Snippets
Q: Did you find the highlighted hints useful while making your judgment? **TL;DR**: 4 out of 5 annotators said **Sometimes**, 1 said **Yes**. More useful for SQuALITY, summary units copied verbatim from source, correct summaries.	"**With summaries that had poor correctness, the hints were often a mess**, and even correct spans had to be carefully checked. In summaries that were more correct, I could often just read the span and remember that it was correct, and then the **hints helped me find the right source position**, or **refresh my memory** about details." "They were more useful when the summary was a **near verbatim source reproduction**." "Yes, they were useful. Often they would highlight the exact passage needed to support the summary span." "In **PubMed, they were a little more chaotic**, even for good summaries." "SQuALITY summaries consisted of sentences or parts of sentences taken straight from the story (wording was exactly as in the text). So hints often lead to the exact place." "For **SQuALITY, they were mostly accurate and helpful**. For PubMed, they were less accurate and relevant."
Q: Would the highlights have been sufficient to make judgments, or was reading the entire source document necessary? **TL;DR**: 3 out of 5 annotators said **No**, 2 said **sometimes in SQuALITY**. Reading the entire document was critical.	"**Reading the entire source document was very helpful** to understand the basic story plot" "Even when the hints were relevant, sometimes **they left out information** (like character name)..." "Initially I tried skimming ... then **concluded it's easier to read the entire document** first." "With SQuALITY there were cases where almost all of the highlights did not make any sense and nothing of that was even mentioned in the story. With **PubMed, it was even more difficult to find hints** that support the text" "**Reading the entire document was essential** to understanding the whole process, the hints in isolation were not good enough. The **hints and the summary often confused similar objects**, especially when pronouns were involved, from different parts of the source. In PubMed a similar thing happened when the source discussed what other papers had done – punctuation, acronyms, and abbreviations played a big role in providing context."
Q: Did you use Ctrl+F searches in the source document while making judgments? **TL;DR**: 4 out of 5 annotators said **Yes**, 1 said **yes only for PubMed**. Ctrl+F helped locate synonyms, entities.	"Yes, **all the time**. It was usually a **safer bet than using the hints**. The hints are given out of context of the whole SQuALITY story. There were a lot of problems with the PubMed hints involving **numbers**, which I often searched for. They were very rarely supported by the document, or contained wrong symbols (= instead of >)." "Yes, mostly in cases the highlight did not support the summary unit partially or entirely." "I used Ctrl+F when looking for very specific words, like **names**. Searching was less helpful when it came to words that had synonyms or emotions." "I did Ctrl+F on keywords taken directly from the summary unit as well as **synonyms and any specific words** that I remembered from the story that could help me get to that place in the source document quickly."

Table 6: Results and snippets from our questionnaire with FINE annotators. Overall, annotators find hints only sometimes useful, and mention reading the entire source document along with keyword searches.

are shown 50 perturbed and 50 un-perturbed summaries, and asked to annotate whether the summary units are faithful to the source in three settings:[12] (1) no highlighted hints; (2) SuperPAL highlighted hints; (3) gold hints manually annotated by us. In Table 5, we show accuracy, inter-annotator agreement, and median time[13] for each setting.

Highlighted hints have almost no effect in evaluating long-form summaries: Surprisingly, we observe that in all three metrics (accuracy, agreement, median time taken), scores are quite similar across the three settings. In fact, the "no-hint" setting scores slightly higher than the SuperPAL hint settings (93% vs 92% accuracy, 0.71 vs 0.64 Fleiss κ) and takes annotators less time (41.4 vs 48.2 seconds per unit). However, we find that hints helped annotate the first few units of a summary quicker (84.6 secs vs 115.6 secs per unit). We attribute our findings to a *learning effect* over time. FINE annotation of long-form summaries requires annotation of several units for the same document - summary pair. As annotation progresses, annotators get more familiar with the contents of the source document and summary, reducing the need for hints over time. See Appendix E for learning trajectory plots.

Questionnaire with FINE annotators confirm limited utility of hints: Our evaluation so far is limited to perturbed human summaries. How effective are hints on model-generated summaries? To answer this, we ask five of our FINE Upwork annotators (from Section 3.1) a set of three questions about their experiences using highlighted hints.[14] Detailed questionnaire results along with answer snippets are shown in Table 6. Overall, annotators find hints were useful only sometimes. Hints were *less useful* when (1) the summary unit was not supported in the source; (2) the summary unit was highly abstractive compared to the source; (3) pronouns, numbers, or abbreviations were involved; and (4) Pubmed summaries were annotated. Almost all annotators said it was necessary to read the entire source document before annotation to get an overall idea of the plot and resolve coreferences. Nearly all annotators used "Ctrl+F" searches along with hints to search for specific keywords while making judgments. This was especially true when

---

[12] To prevent any bias, each annotator receives only one of these settings for a particular summary.

[13] Calculated using the method in Akoury et al. (2020).

[14] The FINE annotations in Section 3.1 were shown hints in the source document. Since hints may not be helpful, annotators were told not to solely rely on hints for annotation.

the summary unit was incorrect, since the source document had to be thoroughly searched (beyond the hints) before confidently marking "Incorrect".

Recommendation: In contrast to recommendations in prior work, automatically highlighted hints are useful only in some specific cases of long-form summarization: mostly correct summaries, almost verbatim copied sentences. Annotators should be instructed to read the entire source document and to not rely solely on highlighted hints, since that could bias their judgments. Based on a small-scale study, we found SuperPAL (Ernst et al., 2021) to be the most accurate method for finding hints, but its performance (61% recall@3) is far from ideal.

3.4 To what extent do our findings generalize to short-form summarization?

In this work, we exclusively focus on summarization datasets with an average summary length of at least 150 words. This constraint excludes two popular benchmarks in summarization research over the last five years: CNN/DM (Nallapati et al., 2016) and XSUM (Narayan et al., 2018). How relevant are our research questions (RQs) and findings for these short-form summarization benchmarks?

On average, XSUM (24 words) and CNNDM (60 words) contain much shorter summaries than SQuALITY (237 words). XSUM outputs typically contain only 1 sentence or roughly 2-3 FINE units per summary. This blurs the distinction between FINE and COARSE units, which makes it less useful to study RQ1 in these short-form settings. The shorter length of outputs also implies that evaluation is less expensive and consumes less time, which makes our RQ2 less relevant. Finally, on average, XSUM (440 words) and CNNDM (800 words) also have much shorter source documents than datasets like SQuALITY (5200 words), reducing the need for alignment (the main premise for RQ3). The main motivation behind our study is that human evaluation of long-form summarization datasets like SQuALITY and PubMed is challenging and expensive due to the long length of the generated text. **Overall, our research questions and findings are more relevant for long-form summarization datasets than for short-form summarization datasets like XSUM and CNNDM**.

4 Related Work

A large body of recent work has focused on new *automatic* evaluation methods for summarization via NLI-based algorithms (Falke et al., 2019; Laban et al., 2022) or QA-based algorithms (Wang et al., 2020; Fabbri et al., 2022). Our work focuses on the much less studied area of *human* evaluation, the gold standard for developing automatic metrics. A notable effort in this space is the **Pyramid method** (Nenkova and Passonneau, 2004), along with work improving Pyramid efficiency (Shapira et al., 2019; Zhang and Bansal, 2021). Efficient Pyramid-like protocols have been used to collect large-scale datasets human judgments (Bhandari et al., 2020; Liu et al., 2022) in short-form news summarization tasks like CNN/DM. While these efforts focus on salience evaluation and assume access to multiple references, our work focuses on faithfulness and operates in a reference-free setting. Moreover, we focus on *long-form* summarization tasks like SQuALITY and PubMed, which are much more challenging and expensive to evaluate.

Evaluating summary faithfulness relates to **fact verification** (Vlachos and Riedel, 2014), where claim sentences are checked against a large knowledge source (Wikipedia). Prior work (Nakov et al., 2021) attempts to simplify the human fact checking process by methods like knowledge source snippets (Fan et al., 2020), similar to hint highlights (§3.3). Faithfulness in summarization differs from fact verification in three ways: (1) summaries are paragraph-long and contextual compared to single sentence stand-alone claims in fact verification; (2) summaries are grounded to a source document, compared to a large knowledge source in fact verification; (3) summaries are model-generated compared to human-written claims in fact checking datasets (Thorne et al., 2018; Wadden et al., 2020).

5 Conclusion

We present the LONGEVAL guidelines, a set of recommendations for moving towards standardized human evaluation of long-form summarization. We empirically analyze each recommendation on two datasets. Overall, we find that (1) FINE-grained annotations have lower inter-annotator variance than COARSE-grained annotations; (2) partially annotating a summary reduces annotator workload while maintaining accuracy; (3) highlighting hints in the source document has limited usefulness for evaluating long-form summaries. As future work, we plan to conduct experiments on other aspects of summarization evaluation like salience and coherence.

Limitations

Human evaluation is a noisy process with many **confounding variables**. Some of these variables were kept constant among experiments on a dataset, but modifying them could change the trends in the results. These include: (1) number of annotations per summary; (2) the specific annotation interface used; (3) granularity for FINE evaluation (sentences vs phrases); (4) Number of points in the Likert scale for COARSE evaluation; (5) set of summarization systems evaluated; and finally (6) relative (eg: A/B tests) vs absolute evaluation (eg: Likert), which has been discussed in Tang et al. (2022) for short-form news summarization datasets like CNN/DM.

Our paper is **limited to faithfulness evaluation**, but summaries are typically evaluated for salience, fluency, coherence as well (Fabbri et al., 2021). While fluency may be less of an issue due to large-scale language model pretraining (Dou et al., 2021), coherence and salience are important aspects to evaluate especially in long-form summarization (Goyal et al., 2022). Our findings may not generalize to evaluation of coherence or salience.

Our experiments in Section 3.1 **assigned an equal weight** to each FINE unit while calculating the overall score of the summary. However, the faithfulness of some FINE units may be more important than others. A non-uniform weighing of FINE units may be a good strategy if there is a notion of how critical a particular unit is for a summary's correctness. For example: (1) PICO units are critical in medical summaries (DeYoung et al., 2021); (2) the Pyramid scheme (Nenkova and Passonneau, 2004) uses a reference frequency-based unit importance, assuming access to multiple gold references. However, a consistent notion of importance is difficult to establish across different domains, and also depends on an individual consumer's preferences. Designing non-uniform weighing schemes is an interesting direction for future research.

Ethical Considerations

All experiments involving human evaluation in this paper were exempt under institutional IRB review. We fairly compensated each Upwork freelancer involved in this study, at a rate of 15-20$ per hour (respecting their suggested Upwork hourly wage). For each round of annotation, we estimated the average amount of time the task would take (by running pilots among ourselves), and provided annotators with the estimated time requirement. Most freelancers finished the task within the time window, but sometimes exceeded it by 0.5-1 hr. We compensated freelancers based on the actual time they took and their hourly wage, rather than a fixed amount per annotation.

Acknowledgments

First and foremost, we would like to thank all the nine Upwork freelancers who contributed human annotations to this project. We are very grateful to Yixiao Song, Alex Wang, John Giorgi, Dustin Wright, Yulia Otmakhova, Daniel Deutsch, Arie Cattan, Shiyue Zhang, Tanya Goyal, Greg Durrett, Marzena Karpinska, Ankita Gupta, Nader Akoury and the Semantic Scholar team for several useful discussions at various points during the project. This work was mostly done while Kalpesh Krishna (KK) was an intern at the Allen Institute for Artificial Intelligence. KK was partly supported by a Google PhD Fellowship awarded in 2021.

Author Contributions: Kalpesh Krishna led the project and performed all the technical contributions including literature review, dataset collection and processing, model implementation, annotation interface development, running experiments, and data analysis. Kalpesh also contributed to project scoping and ideation and led the writing of the paper. Erin Bransom and Bailey Kuehl helped with obtaining human judgements, including piloting the task and giving feedback, performing the annotation themselves, and hiring and managing annotators on Upwork. Pradeep Dasigi, Arman Cohan, and Kyle Lo were mentors of the project during and after Kalpesh's internship, contributing equally to project scoping, experimental design, ideation and direction throughout the course of the project and paper writing. Mohit Iyyer provided mentorship after the internship, in particular providing important feedback and direction on data analysis and contributing to paper writing.

Appendix

A Bootstrap analysis of inter-annotator variance

We utilize the bootstrap resampling (Tibshirani and Efron, 1993) technique described in Deutsch et al. (2021) to estimate confidence intervals for human evaluation data. At a high level, bootstrap resampling helps capture the uncertainty in a downstream test statistic by repeatedly sampling from the data with replacement. We consider two downstream test statistics in our work — (1) average system level performance; (2) correlation of human judgements to automatic metrics.

While Deutsch et al. (2021) were primarily interested in uncertainty due to the specific instances and systems evaluated, our goal is to capture uncertainty due to the inter-annotator variance. Hence unlike Deutsch et al. (2021), we sample with replacement from the set of *annotators* for every instance. Our precise formulation can be found in Algorithm 1, which operates on a $X \in \mathbb{R}^{N \times M}$ matrix of human annotations where N is the number of summaries, and M the number of annotators.

Algorithm 1 Bootstrap Confidence Interval

```
Input: $X \in \mathbb{R}^{N \times M}$, $k \in \mathbb{N}, \alpha \in [0, 1]$.
       $N$ is summaries, $M$ is annotators
Output: $(1 - \alpha) \times 100\%$-confidence interval
samples ← an empty list
for $k$ iterations do
    $X_s \leftarrow$ empty $N \times M$ matrix
    for $i \in \{1, \dots, N\}$ do
        $D \leftarrow$ samp. $\{1, \dots, M\}$ w/ repl. $M$ times
        for $j \in \{1, \dots M\}$ do
            $X_s[i, j] \leftarrow X[i, D[j]]$
        end for
    end for
    Calculate test statistic on $X_s$ and append to samples
end for
$\ell, u \leftarrow (\alpha/2) \times 100$ and $(1 - \alpha/2) \times 100$ percentiles of samples
return $\ell, u$
```

B Human evaluation details

B.1 FINE-grained evaluations of SQuALITY and PubMed summaries

We interviewed a total of 9 Upwork freelancers for the position, offering a compensation of $15-16.5 / hr (depending on their Upwork hourly rate). The screening procedure involved a qualification task on synthetically perturbed summaries from the SQuALITY dataset validation split. Similar to the final annotation task, annotators were shown a

	F-κ	R-κ	all agree
Random	0.00	0.00	25%
SQuALITY	0.74	0.76	82%
PubMed	0.53	0.65	74%

Table 7: Fleiss kappa (F-κ), Randolph kappa (R-κ), and agreement scores of our FINE annotation per summary unit. All κ scores are well above a random annotation baseline, indicating good agreement.

highlighted clause from the summary, and asked to mark whether or not it is supported by the source document. 50% of the clauses were synthetically perturbed (via negation or entity swapping as in Kryscinski et al., 2020) and manually checked to ensure they were not supported by the source document. A total of 6 freelancers scored 85% or better, and were recruited for the main set of experiments. All 9 freelancers were compensated for the screening round at the rate of 15$ USD / hr.

All six hired annotators are native or bilingual English speakers. All annotators have completed a degree at the undergraduate level and three also have Masters degrees, with the most common focuses of the degrees being English/creative writing and education. The annotators' common professional experiences include copywriting, editing, proofreading, writing, and teaching. Finally, for PubMed annotations we re-hired three annotators from the pool of six SQuALITY annotators who mentioned they had experience reading and analyzing biomedical articles. These three annotators were provided with an additional bonus of $30 after they completed all annotations.

Annotators are provided with a detailed annotation guideline along with examples of faithfulness (Table 10). Our guidelines are mostly consistent with a recently proposed set of guidelines for checking attribution in text generation (Rashkin et al., 2021). The final annotation interface is implemented in AMT Sandbox, as shown in Figure 8.

Inter-annotator agreement (binary): Much of the analysis in Section 3 uses standard deviation across summaries scores to measure inter-annotator agreement. However, another way to calculate inter-annotator agreement for FINE annotations is measuring agreement on individual units which received a Yes / No judgment. In Table 7 we show these inter-annotator agreement statistics. We measure Fleiss Kappa (Fleiss, 1971), Randolph Kappa (Randolph, 2005; Warrens, 2010), and the fraction of sentence pairs with total agreement.[15] In the table we can see all agreement statistics are well away from a uniform random annotation baseline, indicating good agreement.

B.2 COARSE-grained evaluation of PubMed summaries

None of the surveyed papers evaluating PubMed summaries with humans released their human evaluation data. Hence, we decided to collect our own COARSE annotations. Since FINE annotations (Section B.1) may have biased our original set of annotators, we hire three new annotators to perform overall assessments on a 5-point Likert scale. In other words, we use a "between-subject" experiment design to compare FINE against COARSE.

We hired three freelancers on Upwork, all of whom have extensive professional experience reading research papers (two of them had PhDs in biomedical fields). All annotators were compensated at a rate of 20$ USD / hr, their hourly rate on Upwork. All three annotators had been previously screened and hired by us for different projects in the past. Two of them had assisted us in an annotation task involved reading short summaries of biomedical academic papers and evaluating them for fluency, accuracy, correctness.

Annotators are provided with a detailed annotation guideline along with examples of faithfulness (Table 11). Our guidelines are mostly consistent with a recently proposed set of guidelines for checking attribution in text generation (Rashkin et al., 2021). The final annotation interface is implemented in LabelStudio, as shown in Figure 9.

B.3 Crowdworkers or expert annotators?

Several prior works have raised the issue of low inter-annotator agreement and poor accuracy with non-expert annotators (eg: MTurk crowdworkers) in human evaluation of summarization (Gillick and Liu, 2010; Fabbri et al., 2021; Falke et al., 2019) and open-ended long-form generation (Karpinska et al., 2021; Clark et al., 2021). In our survey (Table 9), we found the type of annotators used in long-form summarization is often not specified (16 / 43 papers). Among other papers, 10 papers use non-experts while 17 papers use expert annotators (often graduate students).

---

[15] The κ scores are measured using the library `https://github.com/statsmodels/statsmodels`.

Overall, we echo the concerns with non-expert annotators and recommend hiring freelancers on Upwork (or experts) who are well-versed with the domain for annotation. In initial experiments, we attempted to recruit Amazon Mechanical Turk crowdworkers filtered by the "Master's qualification" and having a 90%+ approval rating. In our qualification task of error detection in synthetically perturbed SQuALITY summaries, MTurkers scored just 62% (binary classification) with a three-annotator Fleiss κ of 0.15. On the other hand, Upwork freelancers (with professional writing experience) an accuracy 90% with a high inter-annotator agreement (Fleiss $\kappa = 0.71$).

C Additional Survey Statistics

In Table 8 and Table 9 we document some additional statistics for the 44 papers conducting human evaluation of long-form summarization.

Best practice	# papers
Raw human evaluation data released	2 / 44
Interface or instructions provided	9 / 44
Inter-annotator agreement reported	12 / 44
Statistical analysis conducted	12 / 44
Multiple datasets are human evaluated	14 / 44
Multiple annotators per summary	33 / 44
Annotator background reported	33 / 44
Specific summary aspects evaluated	42 / 44

Table 8: Fraction of surveyed papers following the best practices recommended by Gehrmann et al. (2022). We include only the 44 papers here which conducted a human evaluation of long-form summarization.

Type of annotator	# papers
No details specified	11 / 44
Native English speaker**	5 / 44
Mechnical Turk crowdworker	9 / 44
Non-expert volunteers	1 / 44
Extensive prior experience**	3 / 44
Graduate students / researchers	13 / 44
Upwork freelancers	2 / 44

Table 9: The types of annotators used across different long-form summarization papers. ** - No additional details were specified.

D Automatic summarization metrics used for evaluation

The following metrics are considered while measuring Pearson's correlation with our human evaluation data (Figure 2) — ROUGE-1 / 2 / F (Lin, 2004), BARTScore / BARTScore-Parabank (Yuan et al., 2021), Sentence-BLEU (Papineni et al., 2002), BERTScore (Zhang et al., 2020) and BLEURT (Sellam et al., 2020). A number of metrics were calculated using the SacreROUGE repository (Deutsch and Roth, 2020).

E Learning effect while annotating long-form summaries

In Section 3.3 we discussed a learning effect where annotators get more familiar with the contents of a source document as they annotate more FINE-grained units in a long-form summary. To better understand this effect, in Figure 5 we plot the average time taken by annotators as they progress in their annotation of a summary. Overall, we find that annotators get significantly faster in annotating the summary after the first 20% units. We hypothesize that annotators get pretty familiar with the general topics in the source document after the first few annotations, speeding up subsequent annotations.

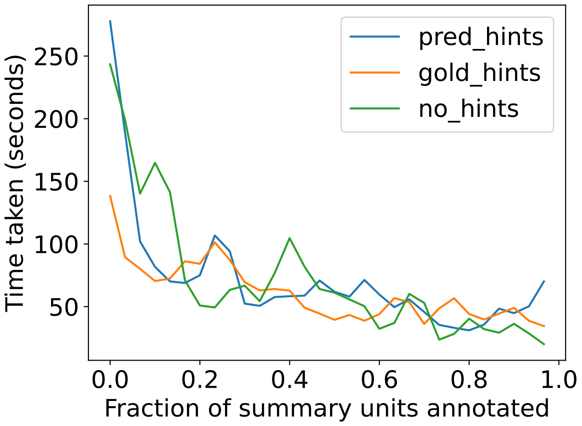

Figure 5: Learning effect over time while evaluating long-form summaries with FINE annotation. As the annotators evaluate more summary units, they learn the document better and are much faster at annotation irrespective of whether hints are shown to them.

F Partial summary annotation with pearson correlation

G Metric correlations using Kendall's Tau

See Figure 7.

In this task, you will be shown a long document ("Source Document") and its Summary. A span of text will be highlighted in the summary, and the goal is to check if this span is factually supported by the source document. You will need to choose one of two options:

1. **Yes**: if ***all*** the facts in the highlighted summary span are supported by the source document
2. **No**: if the highlighted summary span presents some information that is not supported by the source document (either a direct contradiction, or not present)

In addition to the source document, you will be provided with some highlighted text ("hints") in the source document which may help you in making a decision. Press the "Next Hint" button to scroll through the highlighted hints. Source document hints may or may not be helpful. Do not make a judgment solely based on these hints. Skim through the source document yourself / search for keywords with Ctrl + F if the hints are not helpful.
Below you can find some short representative **examples**.

Example 1
Summary (only highlighted span shown) = ... Retief is not Lemuel's cousin. ...
Source Document (snippets shown) = He eyed Retief ... "He ain't no cousin of mine," Lemuel said slowly.
Supports = Yes

Example 2
Summary (only highlighted span shown) = ... Lemeul knocks down Retief. ...
Source Document (snippets shown) = Retief's left fist shot out, smacked Lemuel's face dead center. He stumbled back, blood starting from his nose; ... He caught himself, jumped for Retief ... and met a straight right that snapped him onto his back: out cold. "Wow!" said Potter. "The stranger took Lem ... in two punches!"
Supports = No (Reason: Retief knocks down Lemeul, not the other way around.)

Example 3
Summary (only highlighted span shown) = ... Potter and his team do not trust the Embassy. ...
Source Document (snippets shown) = Lemme up. My name's Potter. Sorry 'bout that. I figured it was a Flap-jack boat; looks just like 'em . He waved a hand toward the north, where the desert lay.
Supports = No (Reason: The claim is irrelevant to the evidence.)

Summary to annotate

introductionout - of - hospital cardiac arrest has a low survival rate to hospital discharge . recent studies compared a simplified form of cpr , based on chest compression alone versus standard cpr including ventilation . we performed systematic review and meta - analysis of randomized controlled trials , focusing on survival at hospital discharge.methodswe extensively searched the published literature on out - of hospital cpr for non traumatic cardiac arrest in different databases.resultswe identified only three randomized trials on this topic , including witnessed and not - witnessed cardiac arrests . when pooling them together with a meta - analytic approach , we found that there is already clinical and statistical evidence to support the superiority of the compression - only cpr in terms of survival at hospital discharge , as 211/1842 (11.5%) patients in the chest compression alone group versus 178/1895 (9.4%) in the standard cpr group were alive at hospital discharge : odds ratio from both peto and dersimonian - laird methods = 0.80 (95% confidence interval 0.65 - 0.99) , p for effect = 0.04 , p for heterogeneity = 0.69 , inconsistency = 0%).conclusionsavailable evidence strongly support the superiority of bystander compression - only cpr . reasons for the best efficacy of chest compression - only cpr include a better willingness to start cpr by bystanders , the low quality of mouth - to - mouth ventilation and a detrimental effect of too long interruptions of chest compressions during ventilation . based on our findings , compression - only cpr should be recommended as the preferred cpr technique performed by untrained bystander .

On a scale of 0-5, how factually correct is the summary with respect to the source document?

○ 0 ○ 1 ○ 2 ○ 3 ● 4 ○ 5

Source Document

out - of - hospital cardiac arrest is still a major public health issue , claiming hundreds of thousands of lives worldwide yearly .
bystander - initiated cardiopulmonary resuscitation (cpr) is essential to increase the chance of survival and neurological recovery .
despite huge efforts to train laypeople to recognize and treat cardiac arrest , incidence of bystander reluctance to perform mouth - to - mouth ventilation is one of the major reason .
whereas cpr including ventilation is still considered the gold standard approach before advanced life support can be instituted , a growing number of studies compared a simplified form of cpr , based on chest compression alone versus standard cpr including ventilation .
animal studies showed no difference in survival or even worse outcomes when ventilation was added to chest compressions ; nevertheless , in animal models of cardiac arrest due to respiratory causes a positive effect of ventilations was demonstrated .
in humans ,
observational studies of bystander - initiated cpr comparing standard and compressions - only cpr reported similar survival rates ; however , interpretation of the results is made difficult due to the high heterogeneity of the causes of cardiac arrest and of the rescue characteristics .
chest compression - only cpr is simpler than standard cpr to teach (during courses but even by dispatchers under real conditions) , and likely a higher percentage of bystanders would accept to perform it while avoiding mouth - to - mouth contact : the demonstration that it is (at least) as effective as standard cpr can be crucial to improve survival rate in out - of - hospital cardiac arrest .
with the underlying hypothesis that out - of - hospital cardiac arrest bystander - initiated compression
- only cpr is equivalent to cpr including ventilation (standard cpr) , we performed a comprehensive systematic review and meta - analysis of randomized controlled trials , focusing on survival at hospital discharge .
pertinent studies were independently searched in biomedcentral , central , and pubmed (updated september 1 , 2010) by several trained investigator .

Comments (optional)

Figure 9: The LabelStudio annotation interface used for COARSE evaluation of PubMed summaries (Appendix B.2).

Instructions for Likert-scale evaluation. Please read all instructions before starting the annotation.

Setup

1. Start by signing up on Label Studio, you will need to provide an email ID and password. It's okay to use a non-existent throw-away email ID here. Also, do not use any personal / sensitive passwords (but make sure to remember your email / password for logging in next time!). Click on the box saying "<your name> — Summarization Evaluation"
2. In this batch a total of 30 summaries need to be evaluated. Every three consecutive rows are different summaries of the same source document. You can evaluate a summary by clicking on a row, and annotating it. Optionally, you can click on "Label All Tasks" at the top of the screen.

Annotation Task

Each summary needs to be evaluated for its "correctness". You need to provide a 0-5 judgment for the entire summary, where "correctness" can be defined as, "The absence of factual errors in the summary, where a factual error is a statement that contradicts the source document, or is not directly stated, heavily implied, or logically entailed by the source document". For example,
Source Document (snippet shown) = ….. Vitamin C was discovered in 1912, isolated in 1928, and, in 1933, was the first vitamin to be chemically produced. It is on the World Health Organization's List of Essential Medicines. Vitamin C is available as an inexpensive generic and over-the-counter medication. Partly for its discovery, Albert Szent-Györgyi and Walter Norman Haworth were awarded the 1937 Nobel Prizes in Physiology and Medicine and Chemistry, respectively. Foods containing vitamin C include citrus fruits, kiwifruit, guava, broccoli, Brussels sprouts, bell peppers, potatoes, and strawberries. Prolonged storage or cooking may reduce vitamin C content in foods. ….
Summary 1 (snippet shown) = … Chicken contains vitamin C …
Summary 2 (snippet shown) = … Albert Szent-Györgyi won the 1955 Nobel Prize for discovering Vitamin C …
Summary 3 (snippet shown) = … Vitamin C was the first chemically produced Vitamin …
Summary 4 (snippet shown) = … Apple contains vitamin C …
Errors marked in red. Here, the snippets for summary 1 are incorrect, summary 2 partially correct, and summary 3 completely correct with respect to the source document. Summary 4 is incorrect with respect to the source document (since it's never discussed), but a globally correct fact. You should treat such a summary as incorrect since it is not mentioned in the source document.
(This is an illustrative example only, the actual annotation task has much longer summaries / source documents.)
The rating scale is from 0 to 5, where 0 is the lowest possible rating (most or all of the summary is wrong / irrelevant to the source document), and 5 is the highest rating (most or all of the summary is correct).
While it is compulsory to provide a judgment from 0 to 5 for each summary, you can optionally provide additional comments in your annotation. For instance, if the judgment needs to be more nuanced than a 5-point scale, you prefer to mark something like "3.5", or you would like to add some other notes about your judgment.
Press "Submit" after you have provided your annotation.

Suggested workflow

Every three consecutive rows contain different summaries for the same source document. We suggest the following workflow while annotating documents —
1. Spend the first 15 minutes reading the source document and getting a general sense of the facts mentioned in the document.
2. Spend 5 minutes to read and annotate the summaries in each of the three consecutive rows which correspond to the same document. Add optional comments / notes if necessary.
3. In the last 5 minutes, re-calibrate your ratings across the three rows if needed (for instance, you significantly preferred the correctness of summary 1 vs summary 2, but you gave it the same rating in the initial pass). Add optional comments / notes if necessary.
Following this workflow, it should take 35 minutes to annotate each set of 3 rows. For 30 rows, this should take 6 hrs.

Table 11: Annotation guidelines provided to annotators for COARSE evaluation of PubMed summaries (Appendix B.2).

Cluster-Guided Label Generation in Extreme Multi-Label Classification

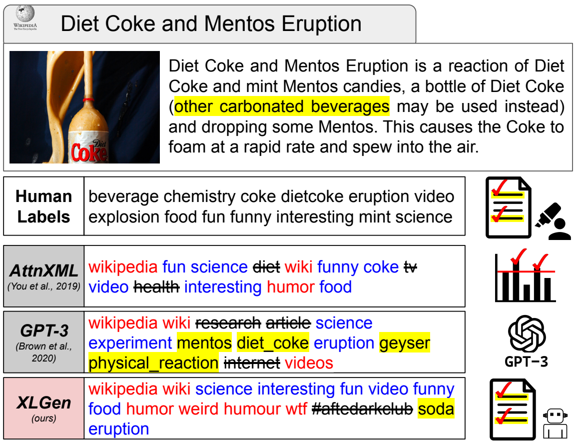
Abstract

For extreme multi-label classification (XMC), existing classification-based models poorly perform for tail labels and often ignore the semantic relations among labels, like treating "Wikipedia" and "Wiki" as independent and separate labels. In this paper, we cast XMC as a *generation* task (`XLGen`), where we benefit from pre-trained text-to-text models. However, generating labels from the extremely large label space is challenging without any constraints or guidance. We, therefore, propose to guide label generation using label cluster information to hierarchically generate lower-level labels. We also find that frequency-based label ordering and using decoding ensemble methods are critical factors for the improvements in `XLGen`. `XLGen` with cluster guidance significantly outperforms the classification and generation baselines on tail labels, and also generally improves the overall performance in four popular XMC benchmarks. In human evaluation, we also find `XLGen` generates unseen but plausible labels. Our code is now available at `https://github.com/alexa/xlgen-eacl-2023`.



Diet Coke and Mentos Eruption

Diet Coke and Mentos Eruption is a reaction of Diet Coke and mint Mentos candies, a bottle of Diet Coke (other carbonated beverages may be used instead) and dropping some Mentos. This causes the Coke to foam at a rapid rate and spew into the air.

Human Labels	beverage chemistry coke dietcoke eruption video explosion food fun funny interesting mint science
AttnXML *(You et al., 2019)*	wikipedia fun science ~~diet~~ wiki funny coke ~~tv~~ video ~~health~~ interesting humor food
GPT-3 *(Brown et al., 2020)*	wikipedia wiki ~~research~~ ~~article~~ science experiment mentos diet_coke eruption geyser physical_reaction ~~internet~~ videos
XLGen *(ours)*	wikipedia wiki science interesting fun video funny food humor weird humour wtf ~~#aftedarkclub~~ soda eruption

Figure 1: The predicted and generated labels from AttentionXML (You et al., 2019), GPT-3 (Brown et al., 2020), and `XLGen-BCL`, respectively, for Wikipedia page on diet coke and mentos eruption. We marked labels to be correct (blue), wrong (~~strikethrough~~), and positive unlabeled (red). Our `XLGen` could generate completely new labels from input text, e.g., soda, inferred from context that other carbonated beverages can replace diet coke.

1 Introduction

Extreme multi-label classification (XMC) is a task to predict multiple relevant labels for a given input where the label space is extremely large. Conventional approaches for XMC decompose the problem into a set of binary classifications, training one-vs-all classifiers for each label. However, they encounter several issues in practical use cases.

First, the labels in XMC are long-tail distributed. In other words, only a few labels have sufficient positive samples, thereby the other infrequent labels could be rarely predicted during inference as we see the heavily right-skewed distribution in the long-tail in Figure 2a. Second, multi-label classification techniques such as one-by-one and label powerset (Gibaja, 2015) assume independent and identically distributed labels, while the user-generated labels in XMC are dependent on each other. Moreover, annotated labels are only a portion of possible labels, thus, resulting in positive and unlabeled (PU) setting (Yu et al., 2014; Kanehira and Harada, 2016).

In this paper, we tackle extreme multi-label classification with a *generative approach*, called extreme multi-label generation (`XLGen`). In particular, we fine-tune a pre-trained Transformer-based encoder-decoder model (Raffel et al., 2020) with input documents and their known positive labels. This (label) generation approach is more intuitive and closely similar to how humans tag documents with text labels without a fine-grained ontology or guideline.

However, the generated labels from the extremely large label space without any constraints

(a) Frequency Histogram (b) Label-wise Recall

Figure 2: (a) Frequency histograms of top-100 occurring labels in EUR-LEX (blue) and WIKI10-31K (red) (b) Label-wise recall scores from AttentionXML and `XLGen-BCL` on Wiki10-31K. For the presentation, graphs are smoothed by least-squared polynomial regression.

and/or guidance can be noisy and not cover infrequent labels. To address this issue, we propose a method to leverage label clusters into generation: first, generate cluster IDs of semantically similar labels, and then generate text labels utilizing the cluster IDs as additional contextual inputs. Specifically, we propose two `XLGen` architectures (`XLGen-BCL`, `XLGen-MCG`) in which such clusters are jointly trained with labels in different ways. Using clusters for label generation is motivated by showing label categories to human annotators. As an example, humans often start by setting high-level topics first and then hierarchically create actual tags under each high-level topic. The clusters, however, are treated as additional guidance rather than a constraint since we do not restrict the model to only predict labels under the given clusters.

Similarly to `XLGen`, Simig et al. (2022) proposed GROOV, which fine-tunes T5 to generate labels in XMC. In particular, GROOV aims to implement a label order invariant training objective by randomly shuffling label orders and using multi-softmax function, which does not penalize if any first tokens of true labels are predicted regardless of the label orders. However, it does not outperform classification baselines consistently, and we empirically find that label order by frequency helps alleviate the issue in our ablation study.

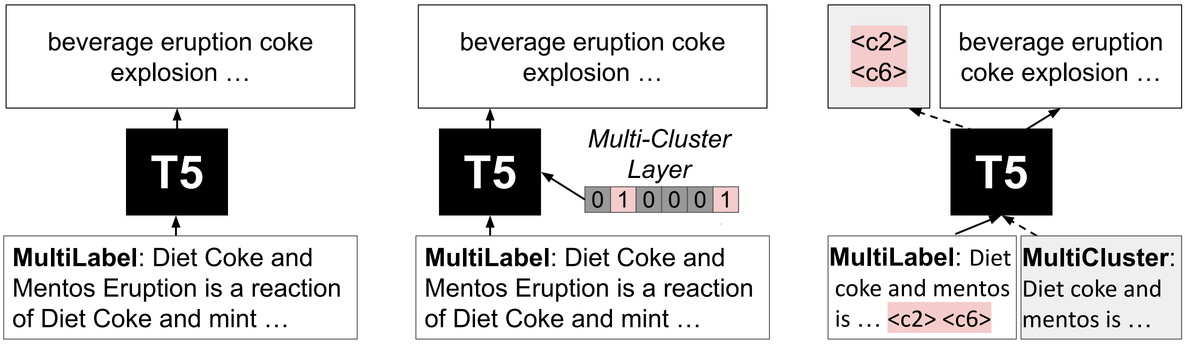
Our experiment shows that `XLGen` (and its variants) outperforms classification baselines on four XMC benchmarks. Furthermore, `XLGen` with cluster guidance (`XLGen-BCL` and `-MCG`) significantly and consistently outperforms the classification and generation baseline (`XLGen-base`) on tail labels, respectively. The effect on tail labels from `XLGen-BCL` is demonstrated in Figure 2b.

Figure 1 shows predicted or generated labels from different models. A Wikipedia page of diet coke and mentos eruption has true labels such as "beverage", "fun", and "eruption". We find `XLGen` can also generate a new positive label "soda" based on the context of "carbonated beverage" in the input text. From a human evaluation (S6.1), we find newly generated labels by `XLGen` are highly associated with the input texts, which potentially helps automatically find new labels without manual tagging. We also show the generated labels from large language models (LLMs) like GPT-3 (Brown et al., 2020): we find that the overall performance of in-context learning is significantly less than `XLGen` (See §4.4 for details), but LLMs could generate reasonable labels with a few examples as `XLGen` does.

2 Related Work

Extreme multi-label classification (XMC). Classification-based approaches on XMC suffer from dealing with enormous label spaces under the one-vs-all classification setting (Babbar and Schölkopf, 2017; Yen et al., 2017; Jain et al., 2019). To address the efficiency issue, state-of-the-art XMC models partition label space to the scalable subsets via hierarchical clustering (Prabhu et al., 2018; Wydmuch et al., 2018; You et al., 2019; Chang et al., 2020; Yu et al., 2022; Tagami, 2017), graph-based approximations (Jain et al., 2019; Zong and Sun, 2022), or random forest (Siblini et al., 2018). However, they still suffer from predicting tail or unseen labels. To efficiently deal with such long-tail issues, few-shot learning frameworks and methods (Gupta et al., 2021; Xiong et al., 2022) are proposed. Rather, we show how encoder-decoder language model can improve tail label scores by fine-tuning it with guidance from label clusters.

LMs and Generative approach in XMC. For XMC, pre-trained LMs such as XLNet (Ye et al., 2020) and Transformer (Chang et al., 2020) are used but only for encoding input texts, thus, it still relies on the classification approach for label prediction. Previously, other works address multi-label classification with generative approaches (Nam et al., 2017; Tsai and Lee, 2020; Yang et al., 2018, 2019; Zhang et al., 2021b) but in much smaller label spaces. Recently, Simig et al. (2022) also used T5 (Raffel et al., 2020) for directly generating labels in end-to-end manners for XMC, but



(a) `XLGen-base` (b) `XLGen-BCL` (c) `XLGen-MCG`

Figure 3: Three `XLGen` architectures, where the basic model can be any pre-trained text-to-text models like T5. (a, `base`): Simple fine-tuning that encodes input text with a prefix of task name and decodes text of label sequences. (b, `BCL`): A fine-tuning with a multi-cluster prediction layer as an auxiliary task. (c, `MCG`): A multi-task fine-tuning with multi-cluster generation and multi-label generation (MCG); two tasks are trained simultaneously and at decoding time the output of the cluster generation is concatenated to the input for the label generation.

its performance was not convincing compared to classification-based models.

Positive and unlabeled data. In practice, XMC is inherently with positive and unlabeled (PU) setting as the label space is extremely large and it is infeasible to manually review all the labels (Kim and Kim, 2020). Multi-label performances on PU tasks can be simulated by leaving only a few labels per train instance (e.g., leaving 8 out of 10 positive labels in one instance for label deficit rate 20%) positive (Hu et al., 2021). In this work, we show how `XLGen` works on such PU settings in §4.3.

3 Extreme Multi-label Generation (`XLGen`) with Cluster Guidance

Classifying a document with multiple labels can be regarded as tagging a document with possible topical labels, which is basically decoding the free-formed text labels in an encoder-decoder setting. Moreover, if encoder and decoder are trained on large text corpora, labels are generated with an understanding of their lexical variations and semantic similarities. Our baseline framework fine-tunes a pre-trained Transformer using the input text as an encoder input and the label sequences as a decoder output. In addition, to more effectively address a huge number of labels in a long-tail distribution, we propose two different architectures, `XLGen-BCL` (§3.2) and `XLGen-MCG` (§3.3), generating labels guided by pre-computed cluster information, inspired by class-based language models (Brown et al., 1992).

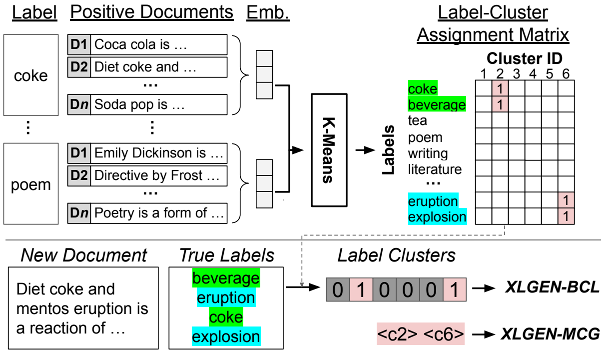


Figure 4: Architecture of pre-computed label clusters. For each label, we use the averaged embedding of positive documents including the label in train set and compute the label cluster assignment matrix (top). For training, we assign label clusters for each training document based on the true labels using the label cluster assignment matrix (bottom).

Pre-computed clustering. We compute label clusters using K-Means algorithm, as depicted in Figure 4. We first obtain label features using average embedding of positive documents in a train set, following Chang et al. (2020), and compute the label-cluster assignment matrix. Label clusters are assigned to each training document using this matrix and ground-truth labels, and used as a multi-cluster prediction layer for `XLGen-BCL` training or sequence of cluster IDs for `XLGen-MCG` training.

3.1 Baseline Fine-Tuning

Figure 3a shows our baseline `XLGen` which simply fine-tunes text-to-text Transformers, e.g., T5 (Raffel et al., 2020) or BART (Lewis et al., 2020), as our encoder-decoder framework on XMC dataset.

- *Input*: **task prefix**: input text
- *Output*: A sequence of label texts

For encoding, we add a prefix token 'MultiLabel' to the input text to inform the task type. Then, the output labels are generated as a sequence of labels in decoding. The model is fine-tuned with cross-entropy loss ($\mathcal{L}_{xent}$) given the sequence of label texts. In practice, the order of labels in decoding significantly influences the model performance. Following Yang et al. (2018), we sort the target labels in decreasing order of the frequencies. We also investigate various ordering effects and their impact on performance in §5.1.

3.2 Fine-Tuning with Cluster Prediction

Figure 3b shows the fine-tuning of text-to-text with an additional multi-cluster prediction layer (`XLGen-BCL`). By doing so, we expect the model learns label similarities and hence biases itself to generate labels relevant to the given cluster.

- *Input*: **task prefix**: input text
- *Multi-Cluster Layer*: a vector of $v_1, ...v_k$ where $v_i = 1$ if i^{th} cluster c_i is a positive cluster; otherwise $v_i = 0$ (1 1 0 ... 1...)
- *Output*: A sequence of label texts

The multi-cluster prediction layer is a vector of 0 or 1 that corresponds to the assigned clusters of instance, and is trained using the sequence of the last layer's hidden states of the encoder with a binary cross-entropy loss, $\mathcal{L}_{bce}$. The final objective is as follows:

$$\mathcal{L}_{xmc-bcl} = \mathcal{L}_{xent} + \lambda \mathcal{L}_{bce} \quad (1)$$

where $\mathcal{L}_{xent}$ is a cross-entropy loss term for the original text-to-text framework and $\mathcal{L}_{bce}$ is a binary cross entropy loss term for the cluster layer. λ is a weighting parameter for controlling $\mathcal{L}_{bce}$, to be chosen by dev-set performance.

3.3 Fine-Tuning with Cluster Decoding

`XLGen-BCL` utilizes a cluster prediction only as an auxiliary task to improve representations for a label prediction, thus, predicted clusters are not used in inference. Figure 3c shows the third variant, `XLGen` with a multi-cluster generation (`MCG`), which leverages predicted clusters as additional input tokens so that the cluster information can be used in inference.

- *Input1*: **task prefix**: input text ; a sequence of positive cluster IDs (c_1 c_2 c_{11}..)
- *Output1*: A sequence of label texts
- *Input2*: **cluster prediction prefix**: input text
- *Output2*: A sequence of positive cluster IDs (c_1 c_2 c_{11}..)

We add a sequence of cluster IDs to the input text so that cluster information can be used while training (Input1-Output1). On the other hand, we have a new task with a clustering prefix 'MultiCluster' appended to the input text and predicts the sequence of labels (Input2-Output2). In training, these two tasks are trained simultaneously. Note that in inference, the predicted cluster IDs are appended to Input1 for the final label generation.

WIKI-500K	1,779,881	769,421	498,152	917

Table 1: Data statistics of the benchmark datasets; the number of train examples ($|D_{trn}|$), number of test examples ($|D_{tst}|$), number of labels in both train and test set ($|L_{seen}|$), and number of labels only in test set ($|L_{unseen}|$), which is zero-occurred labels in Table 3.

4 Experiments

4.1 Experimental Setups

Datasets. We use four widely used XMC benchmark datasets; three large-scale datasets with 4K∼30K labels (EURLEX-4K,AMZNCAT-13K, and WIKI10-31K) and one very-large-scale datasets with 500K labels (WIKI-500K). See Table 1 for the detailed data statistics.

Baseline and `XLGen` Training. We compare `XLGen` with three state-of-the-art baselines in XMC tasks; AttentionXML (You et al., 2019), X-Transformer (Chang et al., 2020), and XR-Linear (Yu et al., 2022). Note that all baseline models partition labels using hierarchical clustering. See A.1 for the detailed setups of baselines. Note it is common to upscale scores by ensemble learning for XMC baselines. However, for a fair comparison, we do not use any ensemble models for `XLGen` and baselines.

We train `XLGen` with T5 because BART (Lewis et al., 2020) performs worse for our task as shown in Table 13. By default, we sort labels in the decreasing frequency order to provide the training target sequence and infer the labels by beam search with size 5. For `XLGen-BCL` and `XLGen-MCG`, cluster sizes are optimized by dev set performance.

Table 4: Macro-averaged F1 scores in PU setting (50% of label deficit ratio).

We get the input text embedding by averaging the last hidden states from the pre-trained T5 encoder since T5 model does not have a CLS token. See A.2 to check more details.

4.2 Evaluation Metrics

Following the prior work in XMC, we report F1 score (F@k) of top-k label probabilities as a supplementary metric in A.4. However, such ranking metrics are not applicable to label generation tasks since the generative model only output positive label texts *sequentially* and the order of generated labels does not align with the confidence of the label; in other words, the formerly generated labels do not need to be more confident than the latter ones. Thus, we use conventional multi-label classification metrics, like micro-averaged F1 score ($Mic.$) and macro-averaged F1 score ($Mac.$), as main evaluation metrics.

In principle, evaluating XMC task with the ranking format is not appropriate for most cases as it requires predicting the number of correct labels as well (Amigo and Delgado, 2022). We therefore select predicted labels only when the predicted score is greater than the threshold optimized from the validation set as in You et al. (2019).

4.3 Results

We compare performances of `XLGen` and baselines in full labels (Table 2), tail labels (Table 3), and PU data setting (Table 4). For tail label and PU setting, we do not include AmznCat-13K as it does not have zero-occurred labels. The best scores are **bold** and the second best scores are underlined. See A.4 for the full scores on tail labels and PU setting.

Full label performance. In the evaluation with full benchmark sets, all the `XLGen` models show outperforming or competitive performance compared to the classification-based baselines. For macro F1 scores, `XLGen` models hugely outperform the baselines, which empirically represents that our approach is strong at predicting infrequent but correct labels. In other words, `XLGen` models are less biased to predicting frequent labels. Compared to `XLGen-base`, both `XLGen-BCL` and `XLGen-MCG` generally show better performance, which demonstrates the effectiveness of the cluster prediction as an auxiliary loss.

Tail label performance. We measure macro F1 scores only for tail labels which never or one-time occur in the train set. We find every baseline extremely suffers from the tail labels, while `XLGen` shows significant improvements, demonstrating the power of generative models for long-tail labels. Surprisingly, `XLGen` even predicts never-seen, zero-occurred labels, only inferred from the semantic meaning of the input text. Similarly to full label performance, `XLGen-BCL` and `XLGen-MCG` perform better than `XLGen-base`, indicating

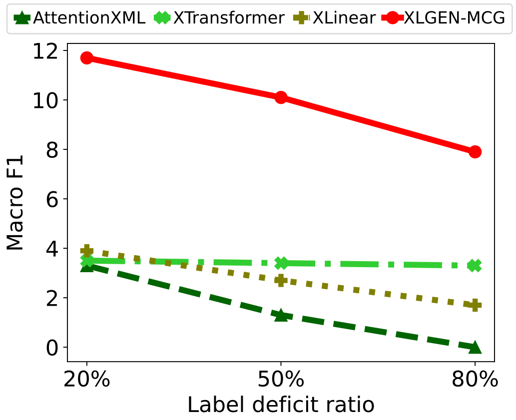

Figure 5: Macro-averaged F1 scores in PU setting on WIKI10-31K.

that guidance of label cluster improves tail label performance as well.

PU setting. In XMC, it is infeasible to annotate all relevant labels for an input text by checking every millions of labels. Therefore, many XMC datasets are indeed in PU setting. To evaluate the robustness against the positive and unlabeled properties, following Hu et al. (2021), we make PU data setting by randomly eliminating positive labels for each instance with 50% of deficit rate.

As `XLGen` is trained with fewer positive labels in PU settings, the generated output labels tend to be fewer as well, causing lower recall than expected. To increase the recall, we generate diverse label sequences using various sampling schemes in inference, which we call *ensemble generation*. We combine generated results from three decoding strategies; beam search with size 5, Top $P + K$ sampling, and sampling with 0.8 temperature.

We find `XLGen` models outperform the baselines. Specifically, `XLGen-MCG` shows significantly strong scores, which indicates having predicted clusters as an additional input helps predict infrequent but correct labels. In Figure 5, we additionally visualize macro F1 scores of PU settings on WIKI10-31K with various deficit rates. Although `XLGen-MCG` drops with an increasing deficit rate, it still shows significant gaps with baseline scores.

4.4 Feasibility of in-context learning in XMC

In-context learning (Brown et al., 2020) shows a potential of generating unseen but positive labels as depicted in Figure 1, such as “geyser” and “physical_reaction”. In order to thoroughly validate the feasibility of in-context learning in XMC problems, we select 100 samples randomly from EURLEX-4K and WIKI10-31K, and predict their labels using GPT-3 (Brown et al., 2020) in zero/one/five-shot setups. We explore a few variations of prompts by tweaking label order or selecting few-shot examples differently, and report the best scores in Table 5. The performance of in-context learning significantly improves when we use more examples in the prompt, but they are far from the performance of `XLGen`. Moreover, the performance gap between GPT-3 and `XLGen` is much larger in EURLEX-4K where labels are formally annotated than in WIKI10-31K where labels are annotated by random users without a solid guideline. Unlike other multi-label classification tasks, XMC treats an extremely large number of labels, making it difficult to predict most unseen labels based on a few examples in in-context learning. See A.3 for the details of the experimental setup for in-context learning and the performance comparison among prompt variations.

		EURLEX-4K		WIKI10-31K	
		Mic.	*Mac.*	*Mic.*	*Mac.*
`XLGen-BCL`		**60.7**	**52.4**	**37.7**	**20.0**

	1-shot	17.2	14.7	20.3	13.4
	5-shot	15.7	10.4	23.5	16.6

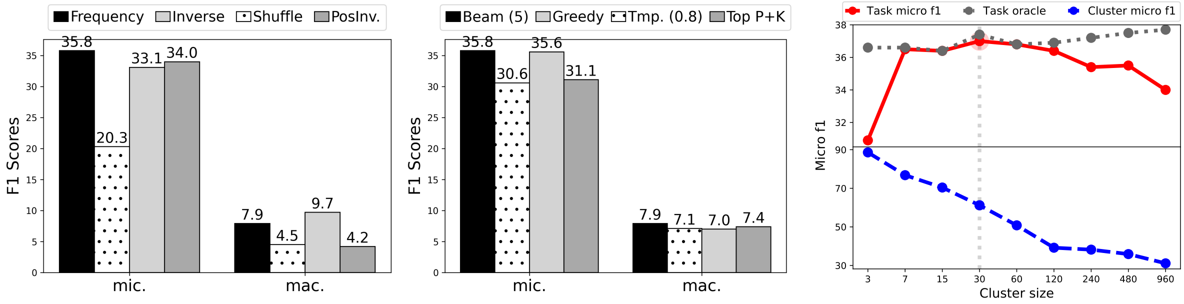
Table 5: Label performance of `XLGen-BCL` and in-context learning settings on 100 randomly selected samples.

5 Ablation Study

We explore various factors that impact the performance of `XLGen` on WIKI10-31K, such as label orders (§5.1) and sampling strategies (§5.2) In order to reduce training costs, we mainly train `XLGen-base` on the base size model with epoch 5 for ablation tests. We then investigate the model performance by clustering sizes and algorithms (§5.3).

5.1 Label Orders

Label orders in decoder are important as `XLGen` sequentially generates labels. We compare three different label orders; label frequencies from high to low (Frequency), inverse label frequencies from low to high (Inverse), and shuffling where labels are randomly ordered per training epoch. Inspired by Lee et al. (2019), we also consider ignoring label orders by resetting positional embeddings of



(a) Label Order (b) Decoding Strategy (c) Cluster Size

Figure 6: Ablation study results on WIKI10-31K. (a) Performances of `XLGen-base` trained with various label orders. (b) Performances of `XLGen-base` trained with various decoding strategies. (c) Cluster sizes vs task and clustering performance. We also report oracle scores by using ground-truth cluster information in inference time.

each label as initial values in decoder [1] which we call label positional invariant setting (PosInv.).

Figure 6a shows task performance across different label orders. We find trade-offs between macro and micro F1 scores by the label frequency order (Frequency and Inverse) because inversely frequent label orders make the model generate long-tail labels earlier with certainty, thus, the scores of long-tail labels could improve. On the other hand, shuffling (Simig et al., 2022) crucially downgrades the performance since with randomly shuffled labels, `XLGen` tends to ignore co-occurrence patterns among labels in training time. Also, we conjecture that positional invariant setting does not work well as it tweaks the original positional embeddings of pre-trained T5 model.

5.2 Decoding Strategy

We now explore task performances with various sampling strategies in label generation. We compare greedy search, beam search, sampling with restrictions such as Top-K (Fan et al., 2018) and Top-P (Holtzman et al., 2020), and sharpening vocabulary distributions with a temperature parameter. In Figure 6b, we find that beam search with size 5 achieves the best scores. Interestingly, most sampling methods heavily degrade performances since our label spaces are not entirely open-ended. We also explore ensemble methods to combine label outputs from different sampling strategies. Unlike the PU setting, however, they are not helpful in the full data setup since a sufficient number of labels are already generated by a single best generation strategy. Find the Appendix A.6 for details.

5.3 Cluster Strategy

We show the effect of clustering algorithms and their parameters. We train `XLGen-MCG` fine-tuning T5-base with epoch 5. We compare two clustering methods; K-means and Agglomerative clustering, and two text representations; TF-IDF and the recent T5 encoder. We find K-means and pre-trained T5 encoder shows the best performance over other combinations, as described in Appendix A.7.

Cluster size is another important factor for model performance. For example, a larger cluster size helps find label groups at a higher granularity, while it is much harder to be accurately predicted in inference time. Here, we choose cluster size to be a power of two on average (e.g., around 30 containing 1024 labels for WIKI10-31K on average). Figure 6c shows micro F1 scores of `XLGen-MCG` across cluster sizes in WIKI10-31K. Here we also report the upper bound of task performance (oracle) by using ground-truth cluster information. As we expect, clustering performance decreases as the cluster size increases since it is much harder to predict clusters in a larger cluster space. In terms of label prediction, we find that the model with smaller cluster sizes (e.g., ≤ 30) outperforms the larger ones, where the peak is around 30. Although a larger cluster size helps elaborately specify labels in the same category, lower cluster prediction performance harms label performances as well and leads to a bigger performance gap compared with oracle task scores.

6 Qualitative Analysis

Lastly, we evaluate the quality of generated labels via human evaluation (§6.1) and visualization of the semantic relations among labels (§6.2).

---

[1] But we keep the position embeddings for token sequences in one label to learn token positions.

		AttentionXML		`XLGen-BCL`	
		#	%	#	%
Existing labels	*Correct*	674	39.2%	596	39.2%
	Wrong	776	45.1%	457	30.0%
	PU	270	15.7%	393	25.8%
New labels	*Correct*	0	0.0%	45	3.0%
	Wrong	0	0.0%	30	2.0%
Total		1,720	100%	1,521	100%

Table 6: Human evaluation on WIKI10-31K having 1,720 true labels. The predicted labels are annotated and categorized to *correct*, *wrong*, and *PU* labels, with their precision scores. Note that *correct* labels in the newly generated labels means they are possibly correct, according to the human annotators' decision.

6.1 Human Evaluation

The benchmark datasets have different label qualities. For example, the labels from EURLEX-4K, annotated by the Publication Office of EU, are refined and structured while Wiki datasets are collaboratively labeled by general users, so the quality of labels is relatively lower than the other benchmarks. Hence, we conduct human evaluations in both quantitative and qualitative ways to accurately measure the potential existence of PU labels and newly-generated labels. In particular, we randomly select 100 instances from the test set and extract incorrectly predicted labels and/or newly predicted labels by `XLGen` and baseline models. We then ask three human annotators to annotate and decide on possibly positive labels via majority voting.

Table 6 shows human evaluation results on the annotated WIKI10-31K. Note that the number of predicted labels by `XLGen-BCL` is less than true labels because `XLGen` does not generate label with low confidence. In AttentionXML, on the other hand, we choose top-K labels as many as the number of true labels for each instance, so it has the same total labels as true labels. Compared to the best baseline, AttentionXML, `XLGen-BCL` could generate more PU labels and reduce the number of wrong labels. Also, our method generates 75 (=45+30) newly generated labels out of 1,521 where 60% (=45/75) of them are correct, showing a relatively good generation quality of new labels. Of course, we can control our model to only count the candidate labels and not any of these new labels for more accurate predictions, as measured in Table 2.

Lastly, we provide annotation examples in Table 7. As we sort the label sequence by frequency in training for `XLGen`, frequently generated labels such as “wikipedia" or “wiki" are predicted first, followed by long-tail labels specified in the input text. For AttentionXML, on the other hand, top predicted labels seem more aligned with the input context, although frequently generated labels still come in front. Interestingly, new labels generated by `XLGen` come not only from the input context, but also previously generated labels. For instance, on the Wikipedia page of diet coke and mentos eruption, a new label “soda" is generated because input text contains “carbonated beverages" which is synonym of “soda". On the Wiki page of Vimeo, on the other hand, after `XLGen` generates the PU label “socialnetworking", followed by its synonyms such as “social_network" and “social_networking".

6.2 Label Semantics in `XLGen`

To better understand the semantics behind labels generated by `XLGen`, we visualize an annotated labels of three examples from Table 7 in Figure 7. We get label embeddings from the last hidden state of the fine-tuned `XLGen-BCL` decoder and project them into two-dimensional T-SNE (van der Maaten and Hinton, 2008). If a single label is split by multiple tokens, we average the last hidden layers of all tokens. We observe that frequently co-occurred labels (e.g., “wiki"-“wikipedia" or “weird"-“funny") have similar label embeddings. Also, the newly generated labels become close to the co-occurred labels (e.g., “soda" - “funny" or “eruption" in diet coke and mentos eruptions) via `XLGen` optimization.

7 Conclusion

We apply text-to-text Transformers to extreme multi-label classification, by tweaking the classification problem as generation of label texts. As we do not control the vocabulary space of generated labels, `XLGen` can create completely unseen but still relevant labels, inferred from the input context and semantic relationship from the previously generated labels. Our experiments show that `XLGen` outperforms the classification baselines in general, and significantly improves the long-tail performance and PU setting. Also, we observe utilizing label cluster information helps improve the performance in various settings. `XLGen` is expected to more benefit from pre-trained models as they become larger and powerful (Kaplan et al., 2020).

Limitations and Future Directions

First, we conduct our main experiments and additional analyses on certain languages such as English that has tremendous text corpora. Extension to the low-resource languages might be challenging since this work requires text2text pre-trained models where those languages are applicable (e.g., multilingual T5 model), as well as the corresponding XMC datasets.

Also, compared to the efficient classification baselines, generative models are relatively expensive in terms of memory and time. For example, our experiment requires a lot of training resource as pre-trained models have >200 millions parameters to be tuned. Thus, we use three p3.16xlarge AWS instances with 8 Nvidia V100 GPUs for training. Using more efficient version of Transformers (Tay et al., 2022) or applying distributed training should be considered for a resource reduction.

While in-context learning does not show comparable performance in XMC, we do observe that as the number of examples increases from zero to one to five, in-context learning can generate reasonable unseen but positive labels. It would be interesting to explore the potential of in-context learning in XMC with more advanced prompting and example sampling in the future.

Lastly, the XMC task has a risk of being biased or overfit to small training datasets (e.g., EURLEX-4K and WIKI10-31K contain only about 15,000 training examples). As with other commonly used NLP benchmarks, there is a potential risk that our proposed method may not work properly in the new test/train sets, though we anticipate that such a risk will be quite small.

Ethics Statement

We use the four XMC benchmark datasets which are publicly available and widely used in research [2]. The datasets with social tags (e.g., WIKI10-31K and WIKI-500K) may contain inappropriate vulgarisms if they are not filtered out from the original data processing.

A Appendix

A.1 Details on Baseline Models

AttentionXML (You et al., 2019) is a label tree-based deep learning model. It uses a shallow and wide probabilistic label tree which allows to handle millions of labels and a multi-label attention mechanism by using raw text as input to capture the most relevant part of text to each label.

X-Transformer (Chang et al., 2020) is the first scalable approach to apply deep transformer models in XMC task. In particular, it uses a pre-trained transformer encoder to assign labels to corresponding cluster. For each hierarchical cluster level, OVA classifiers are trained by only using sample instances under the same cluster, called teacher forcing negative (TFN) strategy. Unlike AttentionXML which only uses negative sampling, X-Transformer also uses the negative instances positively predicted by the classifier from the previous cluster level, called matcher-aware negatives (MAN). Recently, Zhang et al. (2021a) proposed XR-Transformer to speed up X-Transformer's training time in recursive manner. Thus, we use XR-Transformer instead of X-Transformer for the comparison.

XR-Linear (Yu et al., 2022) has a very similar architecture with XR-Transformer, except that it only uses simple tf-idf text features instead of transformer encoder outputs. For OVA classification, linear matchers recursively solve XMC sub-problem for each hierarchical cluster level.

In order to fit score outputs into [0,1], we apply sigmoid post processor implemented by the authors for XR-Transformer and XR-Linear.

A.2 Details on `XLGen` Training

	`XLGen-BCL`	`XLGen-MCG`
EurLex-4K	80	20
AmznCat-13K	80	20
Wiki10-31K	60	20
Wiki-500K	80	20

Table 8: Optimal cluster sizes for the `XLGen` training.

We finetune the T5-large (EurLex-4K, Wiki10-31K) or the T5-base (AmazonCat-13K, Wiki-500K), with epoch 10 (EurLex-4K, AmazonCat-13K) or epoch 5 (Wiki10-31K, Wiki-500K) based on the data and/or label size.

We set up input length as 500 for all benchmark datasets and use different output length based on the label lengths in train set; 90 for EurLex-4K and 165 for other three benchmarks. We optimize `XLGen` using AdamW (Loshchilov and Hutter, 2019) with learning rate 2e-4.

	Most Label	Frequency	15.1	12.2	18.1	16.1
5-shot	Random	Random	**15.7**	10.4	17.9	14.2
	Random	Frequency	13.1	9.7	**23.5**	16.6
	Most Label	Random	11.0	9.6	19.8	**18.0**
	Most Label	Frequency	12.5	**11.3**	21.5	15.1

Table 9: Micro-averaged and macro-averaged F1 scores in-context learning settings on 100 randomly selected samples. We test two label ordering strategies, random and decreasing label frequency (frequency), as well as two sampling strategies, random and selecting examples with the most labels (most label). The highest scores are **bold**.

For `XLGen-BCL`, we set up an initial weight value λ as 1.0 and reduce it to $\frac{1}{k}$ for every epoch number k.

For cluster-based `XLGen` architectures, we train k-means clustering and optimize the cluster size via cross-validation from the range of {10,20,30,...,100}. In Table 8, we report optimal cluster sizes for `XLGen` training.

Note that each of T5 models have 220 million (T5-base) or 770 million (T5-large) parameters to be tuned. Also for training, we use a small batch size (1) since pre-trained T5 models are large to be fitted in a single GPU machine. Due to the model size, we use two GPU machines via model parallelism for T5-large and a single GPU machine for T5-base in training. Also, due to the training cost and time, we report the performance scores from the single running of training and inference. We basically modify the T5 code from huggingface library [3], and our code will be publicly available at `https://github.com/alexa/xlgen-eacl-2023`.

A.3 In-context learning in XMC

For in-context learning, we use OpenAI GPT-3 text-davinci-002 model with temperature 0.7 and max tokens 256. To find the optimal prompt, we use prompt variations with different label orders

Predict multiple labels on Wikipedia page.

Example: Malware, a portmanteau from the words malicious and software, is software designed to infiltrate or damage a computer system without the owner's informed consent. The expression is a general term used by computer professionals to mean a variety of forms of hostile, intrusive, or annoying software or program code.[1] The term "computer virus" is sometimes used as a catch-all phrase to include all types of malware, including true viruses. Software is considered malware based on the perceived intent of the creator rather than any particular features. Malware includes computer viruses, worms, trojan horses, most rootkits, spyware, dishonest adware, crimeware and other malicious and unwanted software. In law, malware is sometimes known as a computer contaminant, for instance in the legal codes of several U. S. states, including California and West Virginia.[2] [3] Mal

(a) Label frequency order with random sample

Predict multiple labels on Wikipedia page.

Example: Democratic Primary Results (popular vote). Purple denotes an Obama win and green a Clinton win. (Clinton also won in Michigan, but Obama was not on the ballot there.) The 2008 Democratic presidential primaries were the selection process by which voters of the Democratic Party of the United States chose their candidate for the 2008 United States presidential election. The Democratic Party candidate for president was selected through a series of primary elections and caucuses culminating in the 2008 Democratic National Convention held from Monday, August 25, through Thursday, August 28, 2008, in Denver, Colorado. In order to secure the nomination at the convention, a candidate needed to receive at least 2,117 votes from delegates—a simple majority of the 4,233 delegate votes, including half-votes from American Samoa, Guam, the United States Virgin Islands, and Democrats Abroad. Senator Barack Obama surpassed that total on June 3, 2008, becoming the apparent Democratic nominee.

(b) Label random order with random sample

Figure 8: Input prompt and generated outputs (green-shaded) for Wikipedia page of Elizabeth Dickinson with 1-shot example.

and few-shot example sampling strategy. Furthermore, we test two label ordering strategies, random and decreasing label frequency, as well as two sampling strategies, random and selecting examples with the most labels. See Figure 8 for GPT-3 prompt input and generated output. Table 9 shows the in-context learning performances across different label ordering and sampling strategies. The best macro-averaged F1 scores for WIKI10-31K are achieved with label frequency ordering with random sampling; however, there is no consistently outperforming strategy for EURLEX-4K.

A.4 Additional Task Performances on Benchmark Datasets

For the full setup, we also report ranking based scores in Table 10. In general, for supplementary metrics (F@k) `XLGen` shows comparable results with baselines except F@1, and F@3 in EurLex-4K and Wiki10-31K. Note that for `XLGen`, we just treat the order of generated labels as a rank, which might **not** be correct since such generated labels should have a equal priority in theory. For this reason, `XLGen` has lower F@k scores with smaller k. However, such score gaps between baselines and `XLGen` decrease as k increases, like EurLex-4K with `XLGen-BCL`, or even `XLGen` achieves higher performances in the larger benchmarks (e.g., F@5 and F@10 in AmznCat-13K and Wiki-500K). Also, full micro/macro F1 scores for tail labels and PU settings are in Table 11 and Table 12, respectively.

A.5 Additional Analyses on Base Model Comparison

`XLGen-base`	EurLex-4K		Wiki10-31K	
	Mic.	*Mac.*	*Mic.*	*Mac.*
T5-base	**58.0**	**23.8**	**35.8**	**7.9**
BART-base	55.6	23.4	35.0	7.7

Table 13: Task performances of `XLGen-base` trained with different pre-trained model architectures on EurLex-4K and Wiki10-31K. The highest scores are **bold**.

For `XLGen`, we can use any pre-trained text-to-text models. We compare task performance of two popular text-to-text models in Table 13; T5 (Raffel et al., 2020) and BART (Lewis et al., 2020) by finetuning `XLGen-base`. In general T5 model outperforms BART, therefore, we use pre-trained T5 architectures for our main experiments.

A.6 Additional Analyses on Decoding Strategy

Followed by Figure 6b, Table 14 shows a task performance across various decoding strategies, including different beam size for beam search and a single sampling restriction.

Additionally, instead of choosing single generation strategy, we can even consider to integrate generation outputs from different generation strategies. For ensemble generations, we choose three single generation strategies; beam search with size 5, Top $K + P$ sampling and sampling with temperature 0.8 to get diverse label sequences. We also consider two different types of joining method; inner join to union all labels and outer join to intersect labels from single generations.

	EurLex-4K		Wiki10-31K	
	Mic.	*Mac.*	*Mic.*	*Mac.*
Greedy	57.5	23.3	35.6	7.0
Beam (3)	**58.0**	23.7	35.7	7.8
Beam (5)	**58.0**	**23.8**	**35.8**	**7.9**
Beam (10)	57.9	**23.8**	35.4	7.8
Tmp. (0.8)	53.7	21.9	30.6	7.1
Top-K (50)	51.7	20.8	28.7	6.8
Top-P (0.9)	53.2	21.1	28.8	6.5
Top $P + K$	53.6	21.5	31.1	7.4

Table 14: Performances of `XLGen-base` trained with different decoding strategies.

`XLGen-base`	EurLex-4K		Wiki10-31K	
	Mic.	*Mac.*	*Mic.*	*Mac.*
Beam (5)	**58.0**	23.8	**35.8**	7.9
Ens. Outer	53.5	**24.5**	31.5	**10.0**
Ens. Inner	54.0	18.9	29.2	4.2

Table 15: Task performance of `XLGen-base` from the best single stratagy (beam search with size 5) and ensemble generations on EurLex-4K and Wiki10-31K. The highest scores are **bold**.

Table 15 shows task performance of ensemble generations. We find that outer joining ensemble generation could improve macro F1 scores as it includes more labels than single result. However, it simultaneously drops other micro F1 scores due to the high chance to contain wrongly predicted labels as well. On the other hand, inner joining ensemble generation in general harms the performance by restricting predicted labels occurring at any single generations, though this yields higher micro F1 scores than inner joining ensemble results.

A.7 Additional Analyses on Clustering and Representation

`XLGen-base`	EurLex-4K		Wiki10-31K	
	Mic.	*Mac.*	*Mic.*	*Mac.*
Kmn. + tf-idf	58.4	24.1	36.6	**8.9**
Kmn. + t5-enc.	**58.5**	23.9	36.8	8.8
Ahcl. + tf-idf	58.4	**24.4**	36.8	8.8
Ahcl. + t5-enc	58.0	24.0	**37.0**	8.6

Table 16: Task performances trained with different cluster algorithm and input features on EurLex-4K and Wiki10-31K. Here we fix cluster size as 30. The highest scores are **bold**.

We compare two clustering algorithms; K-means and Agglomerative hierarchical clustering, and two text representations for the label features; TF-IDF and the last hidden states of T5 encoder in Table 16. We find that both algorithms show comparable per-

(g) Typography of Apple (h) Jackalope (i) Anti-humor

Figure 9: Visualization of generated labels by `XLGen-BCL` for Wikipedia pages of annotated examples in Table 17.

formances. As computing cost is more expensive in Agglomerative hierarchical clustering, we mainly use K-means in our experiments. For text representation, the pre-trained T5 encoder achieves similar or slightly better performance to TF-IDF vectors. Pre-trained T5 encoder is more efficient in training as it has much lower size of dimensionality (e.g., 768 in t5-base) than tfidf (e.g., >100,000 for both EUR-Lex and Wiki10-31K). Thus, for all experiments with clustering method, we use K-means with pre-trained T5 encoder text representation.

A.8 Additional Examples of Human Annotation

In Table 17, We provide more annotation examples from Wiki10-31K, following the Table 7 to show how `XLGen` generates labels. In Figure 9, we also provide visualizations of generated labels by `XLGen` for examples in Table 17.

Empathy Identification Systems are not Accurately Accounting for Context

Andrew Lee[†] **Jonathan Kummerfeld**[†‡] **Larry An**[†] **Rada Mihalcea**[†]
[†] University of Michigan [‡] University of Sydney
`ajyl@umich.edu`

Abstract

Understanding empathy in text dialogue data is a difficult, yet critical, skill for effective human-machine interaction. In this work, we ask whether systems are making meaningful progress on this challenge. We consider a simple model that checks if an input utterance is similar to a small set of empathetic examples. Crucially, the model does not look at what the utterance is a response to, i.e., the dialogue context. This model performs comparably to prior work on standard benchmarks and even outperforms state-of-the-art models for empathetic rationale extraction by 16.7 points on T-F1 and 4.3 on IOU-F1. This indicates that current systems rely on the *surface form* of the response, rather than whether it is suitable in context. To confirm this, we create examples with dialogue contexts that change the interpretation of the response and show that current systems continue to label utterances as empathetic. We discuss the implications of our findings, including improvements for empathetic benchmarks and how our model can be an informative baseline.

1 Introduction

Empathy is a fundamental phenomenon that allows us to better communicate and relate with others. Studies show that empathy is significantly correlated with counseling treatment outcomes (Moyers and Miller, 2013; Elliott et al., 2018). Computer systems could be improved by adding the ability to understand empathy.

EPITOME (Sharma et al., 2020b) took a step towards understanding empathy in language, introducing tasks such as *empathy identification* and *empathetic rationale extraction*. Models built using EPITOME have been used to build or evaluate empathetic dialogue systems (Sharma et al., 2021; Zheng et al., 2021; Majumder et al., 2022; Kim et al., 2021) or study social effects of empathy (Chen and Xu, 2021).

In this work, we explore whether current models are effectively considering dialogue context (shortened to *context* for the rest of this paper). We show that a simple model that does not consider context can achieve strong results, and that a model from prior work does not change its predictions when we make substantial changes to the context. Together, these results indicate that models are more limited than previously thought.

We introduce an adapted version of *micromodels* (Lee et al., 2021), a simple and explainable approach that combines a set of models, with each model identifying a specific linguistic phenomenon. This approach performs much better than the EPITOME's model on five metrics, comparably on five metrics, and much worse on two. Critically, we achieve this *without any use of context*.

We inspect our model's behavior and find that it can achieve accuracy scores that are as good as or better than the EPITOME model's for empathetic rationale extraction with as few as three seed/training utterances for our model.

We also conduct an experiment to probe EPITOME's behavior. We take utterances from empathetic responses and randomly insert them as part of the response in another context. Despite these insertions mainly being nonsensical and non-empathetic, prior models nearly *always* predict these responses as empathetic, demonstrating that the models rely on the *surface form* of the response rather than contextual understanding.

The authors of EPITOME noted that empathy is *contextual*; a "reaction to an emotional stimulation" or a "deliberate process of understanding and interpreting the experiences" of others.[1] However, current systems do not effectively account for context: they may identify empathetic *style*, but they do not consider whether a response is indeed a *reaction* to feelings and experiences. Future work

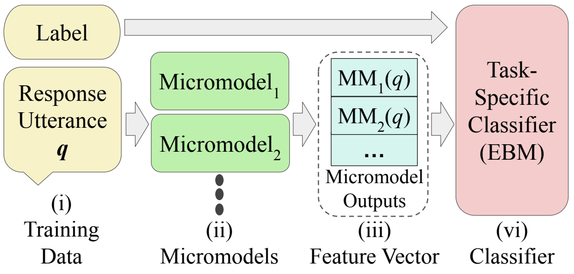

Figure 1: The micromodel framework training process. Notably, our approach does not use any *dialogue context*, yet still performs strongly on current empathy detection benchmarks, raising the question of whether current systems and benchmarks are accounting for context.

should conduct probing experiments like the one we use here, and could consider micromodels as a baseline. This will help assess the contextual understanding of empathy for future models.

2 Benchmarks and Tasks: EPITOME

EPITOME (Sharma et al., 2020b) is a framework for computationally assessing empathy in text-based dialogue. We denote their dataset as EPITOME$_{\text{Data}}$ and the model as EPITOME$_{\text{Model}}$.

EPITOME$_{\text{Data}}$ consists of pairs of dialogues from Talklife and Reddit, and two tasks: empathy prediction (**EmpPred**) and empathetic rationale extraction (**EmpRE**). Given a seeker's post $S_i = s_{i1}, ..., s_{im}$ and a response $R_i = r_{i1}, ..., r_{in}$, each response R_i is annotated with an empathy level (None, Weak, or Strong) in the context of S_i across three communication mechanisms: Emotional Reactions, Interpretations, and Explorations.[2]

Empathetic rationales are spans of text that provide evidence of empathy. They are annotated at the token-level, e.g., the response *"I feel you. Are you okay?"* is represented as $[1, 1, 1, 0, 0, 0]$, $[0, 0, 0, 1, 1, 1]$, and $[0, 0, 0, 0, 0, 0]$ for Emotional Reactions, Exploration, and Interpretations, with one digit per token.

The goal of **EmpPred** is to predict the correct level of empathy given (S_i, R_i) across each communication mechanism. The goal of **EmpRE** is to correctly extract the rationale spans.

3 Micromodels

Lee et al. (2021) introduced the micromodel framework to assess the mental health status of social media users. We give a brief overview of the framework, followed by our adaptations to tackle each task. Further details are provided in the appendix.

3.1 Micromodel Framework

Figure 1 depicts the micromodel framework. The framework consists of a set of micromodels, in which each micromodel MM is a binary classifier that is initialized with a set of *seed* utterances $Z = z_1, ..., z_n$. Given an input query q, micromodel MM gives a binary prediction if q is semantically similar to any of the seed utterances in Z:

$$MM(q) = \exists_{z \in Z} CosSim(BERT(q), BERT(z)) > \theta \tag{1}$$

The outputs of the micromodels are used as features to train a task-specific classifier. Lee et al. (2021) uses explainable boosting machines (EBM) (Caruana et al., 2015), which are generalized additive models (Lou et al., 2012) that make predictions based on adding a set of feature functions learned on each input feature, where each feature function is trained using bagging and gradient boosting.

3.2 Micromodels for EmpPred

For EPITOME's tasks, we build three micromodels, one for each communication mechanism c. For each micromodel MM_c, the seed utterances Z_c are initialized using the annotated rationales of each communication mechanism in the training split of EPITOME$_{\text{Data}}$. Once initialized, rather than using the binary outputs from each micromodel, we use the maximum similarity score between each sentence from the response post $r_{ij} \in R_i$ and each of the seed utterances $z \in Z_c$.

$$MM_c(R_i) = \max_{\substack{r_{ij} \in R_i \\ z \in Z_c}} (Sim(BERT(r_{ij}), BERT(z))) \tag{2}$$

We use the resulting similarity scores as features to train an EBM model[3] to predict the empathy level. We use S-BERT (Reimers and Gurevych, 2019) models[4] to compute similarity scores.

3.3 Micromodels for EmpRE

Figure 2 depicts how we apply micromodels to extract empathetic rationales. Given a response post R_i, we first split it into sentences $r_{i1}, ..., r_{in}$. Each micromodel MM_c runs on each sentence r_{ij}, returning 1 if sentence r_{ij} is semantically similar to any of the seed utterances Z_c and 0 otherwise. This results in a binary vector v_c of length n. Each

---

[2] The definition of each communication mechanism can be found in the appendix.

[3] https://github.com/interpretml/interpret

[4] "paraphrase-xlm-r-multilingual-v1"

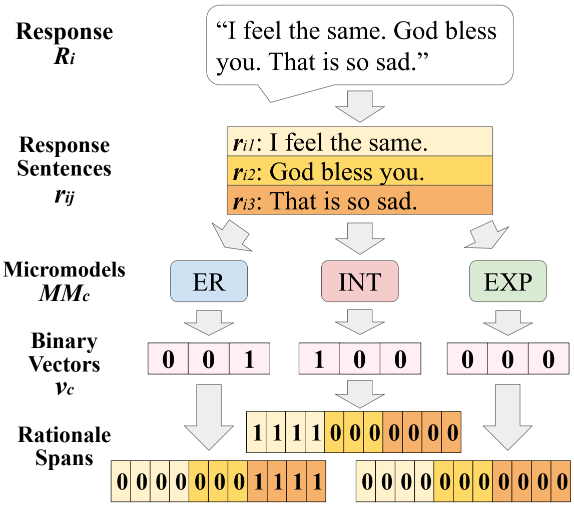

Figure 2: Extracting empathy rationales using micromodels. Each micromodel MM_c determines if each response sentence r_{ij} is empathetic. Each token w_k^{ij} of sentence r_{ij} is then assigned the binary value of r_{ij}.

sentence r_{ij} is then tokenized[5] into a set of tokens $w_1^{ij}, ..., w_l^{ij}$, where $l = len(r_{ij})$ and each token w_k^{ij} is assigned the binary value of r_{ij}. This results in a sequence of 0's and 1's where spans of 1's represent rationales.

4 Experiments and Results

4.1 Experimental Setup

For our experiments, we use random splits of 75:5:20 for our train, validation, and test sets.[6] We report average scores from 10 runs. For θ (Eq. 1), we use a threshold value of 0.7, based on experiments from the validation set. Following EPITOME's authors, we report token-level F1 (T-F1) and Intersection Over Union F1 (IOU-F1) scores.[7]

4.2 Baselines: EPITOME$_{\text{Model}}$

We compare our approach to several baselines, including EPITOME$_{\text{Model}}$. EPITOME$_{\text{Model}}$ is a multitask bi-encoder model initialized with the weights of RoBERTa. Each encoder encodes the seeker's post S_i and the response post R_i. An attention layer attends over both encodings, which is then jointly trained on the two EPITOME tasks. Further details are provided in the appendix.

4.3 Baselines: Other

We also include baseline results as reported by the authors of EPITOME. These baseline models include popular models used in similar tasks, each of which have been fine-tuned or trained on the EPITOME tasks:

- Logistic regression over tf-idf vectors
- Recurrent neural network
- Hierarchical recurrent encoder-decoder (HRED, Sordoni et al. (2015))
- BERT (Devlin et al., 2019)
- GPT-2 (Radford et al.)
- DialoGPT (GPT-2 adapted for dialogue, Zhang et al. (2020))
- RoBERTa (Liu et al., 2019)

4.4 Results

EmpPred$_{\text{EPIT}}$. The first six columns of Table 1 show the accuracy and F-1 scores of empathy prediction. While our F-1 scores are lower than EPITOME$_{\text{Model}}$, they often outperform other fine-tuned language models.

EmpRE. The last six columns of Table 1 show the T-F1 and IOU-F1 scores for empathetic rationale extraction. Other than for Interpretations, we demonstrate significant improvements of up to 16.7 points for T-F1 and 4.3 points for IOU-F1, resulting in the highest scores to our knowledge.

4.5 Follow-Up Analyses

Probing our model: As a post-analysis, we examine which seed utterances $z \in Z_c$ trigger each micromodel during testing and observe that only a small subset of seed utterances are meaningfully used. To demonstrate this, we conduct an experiment in which we iteratively reduce the number of seed utterances used by each micromodel based on how frequently they trigger a micromodel during testing. Figure 3 shows the resulting IOU-F1 scores[8] from 10 random runs, demonstrating that for some communication mechanisms, state-of-the-art results can be achieved by simply checking for semantic similarity against as few as three seed utterances, which are shown in Table 2. Note, this analysis requires modifying the training based on the test performance, so the results are not necessarily representative beyond that dataset.

Probing EPITOME$_{\text{Model}}$: We run an experiment to study whether these utterances are also driving EPITOME$_{\text{Model}}$'s behavior. We gather 1,000

---

[5] We use NLTK for tokenization

[6] This is the same ratio used in the original EPITOME paper. There were no official splits.

[7] We use the same IOU match threshold as EPITOME (0.5).

[8] T-F1 showed nearly identical patterns

Table 1: Performance on empathy prediction and empathetic rationale extraction.

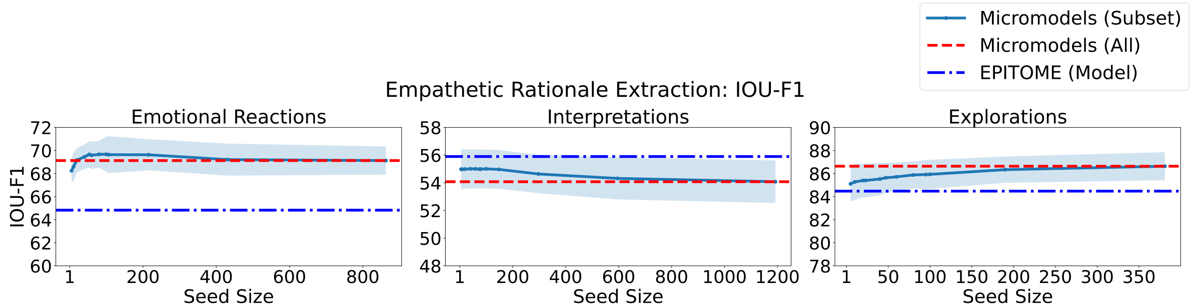

Figure 3: F1 scores with varying seed sizes per micromodel. Simply checking for semantic similarity with as few as three utterances in Table 2 demonstrates either better or competitive performance scores compared to previous state-of-the-art models. The shaded light blue regions indicate the standard deviation across our 10 runs.

Communication Mechanism	Seed Utterance
Emotional Reactions	"I know how you feel." "I'm sorry." "I feel you."
Interpretations	"I feel the same way." "I know how you feel." "I understand how you feel."
Explorations	"Why?" "What happened?" "Why do you feel like that?"

Table 2: Utterances from the smallest subset of seed data used in Figure 3. Simply checking for semantic similarity between response utterances and these seed utterances may outperforms prior state-of-the-art models in empathetic rationale extraction.

Is Empathetic?	PersonaChat		Ubuntu	
	No	Yes	No	Yes
Emotional Reactions	3	997	8	992
Interpretations	305	695	556	444
Interpretations†	10	990	11	989
Explorations	31	969	6	994

Table 3: Number of times non-empathetic dialogues are predicted as empathetic by EPITOME$_{\text{Model}}$. †indicates when we always insert "I feel the same way" (The most commonly seen seed utterance for Interpretations – see Table 2).

random conversations from PersonaChat (Zhang et al., 2018), an open-domain dialogue dataset, and Ubuntu Dialogue (Lowe et al., 2015), a dialogue dataset around technical support for Ubuntu-related problems. For each sample, we insert one of the three utterances from Table 2 as part of the response, resulting in a nonsensical and non-empathetic response. Table 3 shows the results, with EPITOME$_{\text{Model}}$ almost always predicting these artificial dialogues as empathetic. This indicates that it relies on the *surface form* of the response for its prediction, regardless of context.

5 Related Work

Limited access to treatment for mental health, along with a rise in demand for scalable yet high-quality interventions (Miner et al., 2019), has led to an abundance of conversational systems that provide mental health support (Shen et al., 2020; Welch et al., 2020; Han et al., 2013).[9][10] A critical capability for these systems is to understand and interact with empathy, as studies show that

---

[9] https://woebothealth.com/
[10] https://www.wysa.io/

empathy is significantly correlated with counseling treatment outcomes (Moyers and Miller, 2013; Elliott et al., 2018).

Broadly, recognizing empathy within dialogue has been studied under the following contexts: online platforms (Sharma et al., 2020a, 2021; Khanpour et al., 2017), formal counseling settings (Gibson et al., 2015; Zhang and Danescu-Niculescu-Mizil, 2020; Pérez-Rosas et al., 2017), or social media interactions (Hosseini and Caragea, 2021; Lahnala et al., 2021; Wang and Jurgens, 2018; Zhou and Jurgens, 2020).

For instance, Lahnala et al. (2021) examined the interactions between practitioners and non-practitioners that provide support on Reddit. Wang and Jurgens (2018) and Zhou and Jurgens (2020) analyzed the language of condolence and empathy in various social platforms. Other settings for assessing empathy include reacations to news stories (Buechel et al., 2018).

Another direction in the study of empathy within dialogue includes empathetic response generation (Rashkin et al., 2019; Liu et al., 2021; Zhong et al., 2020; Zheng et al., 2021). In order to assess the empathy level of their systems, researchers often use models such as EPITOME. (Sharma et al., 2021; Zheng et al., 2021; Majumder et al., 2022; Kim et al., 2021). Our work demonstrates the pitfalls that researchers should be aware of when taking such approach.

Other efforts include a taxonomy of empathetic responses (Welivita and Pu, 2020), fine-tuned language models for empathy (Guda et al., 2021), as well as empathy-lexicons (Sedoc et al., 2020).

6 Conclusion

In this paper, we assessed whether empathetic systems are correctly taking dialogue context into account. We demonstrated that a simple model with no contextual understanding can achieve results comparable to the EPITOME model and better than all baselines. We find that these results can be achieved by simply checking for semantic similarity to just three utterances. We also found that EPITOME$_{\text{Model}}$ nearly always classifies a response as empathetic regardless of context, as long as it contains one of these three utterances. We conclude that current empathy recognition models do not effectively take contextual information into account.

Future work on benchmarks should consider including examples that require contextual understanding to answer (S: *"I got promoted!"* R: *"That's terrible, I'm sorry."*). Work on models should consider comparing with Micromodels, a simple and practical baseline that serves as a reference point for performance without contextual understanding. These changes will better inform progress on models that meaningfully capture empathy.

The code for our experiments is publicly available at `https://github.com/MichiganNLP/micromodels`.

7 Limitations

The main focus of our paper is on the limitations of empathy recognition models, both our micromodel approach as well as the prior state-of-the-art model EPITOME$_{\text{Model}}$. Namely, our micromodel approach is based on semantic similarity matching, and lacks any representation learning and contextual knowledge. On the other hand, our experiments demonstrate that EPITOME$_{\text{Model}}$ also does not account for context. Despite given non-empathetic contexts, it continues to predict a response as empathetic as long as the *style* of empathy is present. Other limitations of our work include the scope of our study, as we only examine a single benchmark. This is due to the lack of available resources regarding the task of empathy recognition in dialogue. Datasets like EmpatheticDialogue (Rashkin et al., 2019) consists of empathetic conversations, but do not measure the empathy level of utterances. Other empathy prediction tasks (Hosseini and Caragea, 2021; Buechel et al., 2018) do not pertain to dialogue. With more benchmarks regarding empathy recognition in dialogue available, a more thorough study should be conducted.

8 Ethical Considerations

It is important to distinguish our improved accuracy scores from the ability to computationally understand empathy. Because of the lack of representational learning or contextual knowledge, our approach would undoubtedly fail in distinguishing empathetic utterances from false-positive cases, such as sarcastic or even offensive statements (R: *"What's the matter?"* versus *"What's the matter with you?"*). Given the sensitive nature of the mental health domain, mishandling these situations can exacerbate one's situation. Another risk of relying too heavily on such accuracy numbers include overlooking the degree to which a mishandling of a situation can affect an afflicted user. Measuring this additional personal and humanistic dimension in benchmarks for computational systems is undeniably a difficult problem, but likely a necessary step to bridge the gap for effective systems for mental health support. Lastly, while we are able to do a thorough analysis of our findings with the explanations provided by micromodels, there are still portions of their decision making process that remain opaque. Concretely, the computation of semantic similarity by large pre-trained language models like BERT is a key step in our procedure. Using a simpler, more transparent representation for micromodels may mitigate this problem. We believe there is an interesting trade off between accuracy and explainability in designing each micromodel.

A Empathetic Communication Mechanisms

The EPITOME (Sharma et al., 2020b) framework introduces three communication mechanisms to capture the multi-dimensionality of empathy in text-based dialogue – *Emotional Reactions*, *Interpretations*, and *Explorations*. The definitions and examples of each communication mechanism according to the original EPITOME paper can be found below.

Emotional Reactions Expressions of emotions such as warmth, compassion as a response to the seeker's post. These expressions can explicitly label an emotion (e.g., *"I feel really sad for you."*) or may allude to an emotion (e.g., *"Everything will be fine."*).

Interpretations A reactive statement of one's own understanding of feelings and experiences inferred from the seeker's post. Such statement may simply state their understanding (e.g., *"I understand how you feel."*) or specify their inferred feelings or similar experiences (e.g., *"This must be terrifying.", "I also have anxiety attacks at times which makes me really terrified."*).

Explorations Seeking further information to improve one's understanding of the seeker and their feelings and experiences. These can include generic follow-ups (e.g., *"what happened?"*) or specific inquiries (e.g., *"Are you feeling alone right now?"*).

B Detailed Explanation of Micromodels

Micromodels (Lee et al., 2021) were originally inspired by recent work in microservice architectures, in which complex web applications are built by orchestrating a collection of loosely coupled *microservices*. Each of these microservices has a fine-grained focus of responsibility. In a similar manner, the micromodel framework consists of multiple *micromodels*, in which each micromodel is responsible for representing or identifying a specific linguistic phenomena. In this work we build a micromodel for each communication mechanism.

Here we describe the training procedure using micromodels.

The first step in the framework is to initialize each micromodel. The original authors scrape Reddit and use BERT to look for utterances that are representative of each micromodel. In this work, we simply use the annotated rationales that are available in the training split of EPITOME (see Figure 4). Each micromodel only needs to be initialized once.

Next, given supervised training data in the form of (x, y), each micromodel MM runs on the input query x. While any algorithm of choice can be used for micromodels, the original authors use binary classifiers based on semantic similarity. Concretely, each micromodel that is initialized with a set of seed utterances $Z = z_1, ..., z_n$ makes a binary decision, returning 1 if its input query q is semantically similar to any of the seed utterances $z \in Z$:

$$MM(x) = \exists_{z \in Z} CosSim(BERT(x), BERT(z)) > \theta \tag{3}$$

In this work we use our validation set to determine the θ value.

Once every micromodel runs on x, we are left with a binary vector $\mathbf{v}$ of size n where n is the number of micromodels that were used. The binary vector $\mathbf{v}$ serves as a feature vector for a task-specific classifier to train off of. One can think of the inference from the micromodels to be a featurization step to convert the input data (x, y) into a feature vector $(\mathbf{v}, y)$, while the task-specific classifier is an independent classification model that actually learns a task from such featurized values.

Given $(\mathbf{v}, y)$, a task-specific classifier can be trained. Similar to micromodels, the framework allows for any algorithm of choice to be used for task-specific classification, from simple regression models to complex neural networks. The original authors use explainable boosting machines (EBM) (Caruana et al., 2015) because of the explanations it provides. More specifically, the use of EBMs allows one to understand the impact that each micromodel had on the task-specific classifier's decision making process. For more details on EBMs, we point our readers to both the original paper as well as its widely used open-source repository (https://github.com/interpretml/interpret).

C Detailed Explanation of EPITOME$_{\text{Model}}$

Epitome$_{\text{Model}}$ is a multi-task bi-encoder model in which the two encoders are initialized with the weights of RoBERTa and pre-trained with in-domain data that was available to the authors of EPITOME. The two encoders then each encode the seeker's post S_i and the response post R_i.

$$e_i^{(S)} = \text{S-Encoder}(S_i); e_i^{(R)} = \text{R-Encoder}(R_i) \quad (4)$$

Borrowing terminology from transformers, the response post encoding is used as a query and the seeker post is used as keys and values.

$$a_i(e_i^{(R)}, e_i^{(S)}) = \text{softmax}(e_i^{(R)} e_i^{(S)} / \sqrt{d}) e_i^{(S)} \quad (5)$$

The encoded response $e_i^{(R)}$ is summed with the output of the attention layer $a_i(e_i^{(R)}$ to obtain a residual mapping, resulting in a seeker-context aware representation of the response post, which is used to jointly train on the two tasks.

Enhancing Multi-Document Summarization with Cross-Document Graph-based Information Extraction

Abstract

Information extraction (IE) and summarization are closely related, both tasked with presenting a subset of the information contained in a natural language text. However, while IE extracts structural representations, summarization aims to abstract the most salient information into a generated text summary – thus potentially encountering the technical limitations of current text generation methods (e.g., hallucination). To mitigate this risk, this work uses structured IE graphs to enhance the abstractive summarization task. Specifically, we focus on improving Multi-Document Summarization (MDS) performance by using cross-document IE output, incorporating two novel components: (1) the use of auxiliary entity and event recognition systems to focus the summary generation model and; (2) incorporating an alignment loss between IE nodes and their text spans to reduce inconsistencies between the IE graphs and text representations. Operationally, both the IE nodes and corresponding text spans are projected into the same embedding space and pairwise distance is minimized. Experimental results on multiple MDS benchmarks show that summaries generated by our model are more factually consistent with the source documents than baseline models while maintaining the same level of abstractiveness.[1,2]

1 Introduction

Information extraction (IE) (Lin et al., 2020; Li et al., 2021) and summarization (Xiao et al., 2022; Pasunuru et al., 2021) are inherently similar tasks, sharing the objective of identifying and presenting a targeted subset of the information present in a natural language text. However, there are also conceptual and methodological distinctions. First of all, IE aims to extract specific structured information from natural language text while abstractive text summarization targets abstracting the most salient information of a given text into a natural language summary. Secondly, IE methods frequently have access to world knowledge via external schema and knowledge resources (e.g., Wikidata) whereas summarization methods often rely on the information encoded in large-scale pretrained embeddings to produce coherent summaries. The complementary aspects of these tasks imply an opportunity to transfer knowledge from one task to another.

Hence, in this paper, our primary motivation is to take advantage of the complementary nature of IE and summarization tasks, using the structured output of entity and event extraction systems to improve abstractive text summarization by focusing text generation toward explicitly observable grounded concepts. There are a few previous research studies exploring the mutual enhancement between IE and summarization. For example, Lu et al. (2022) use text summarization to improve relation extraction and Pasunuru et al. (2021) adopt open-domain IE to provide additional structural inputs for Multi-Document Summarization (MDS). However, these approaches have two notable limitations. First, IE is performed on single documents without analyzing cross-document interactions between the extracted knowledge elements. Such cross-document interactions could be essential to identifying salient parts of the source documents, which is especially useful for MDS. Moreover, previous studies use linearized graphs without actually constructing the graph as a whole, and hence failing to capture some global interactions between the extracted knowledge elements.

Based on these motivations, in this paper, we propose a text summarization model which is enhanced by IE. We focus on multi-document summarization (MDS) and improve the MDS model with cross-document IE graphs. Specifically, given a cluster of documents related to the same topic, we

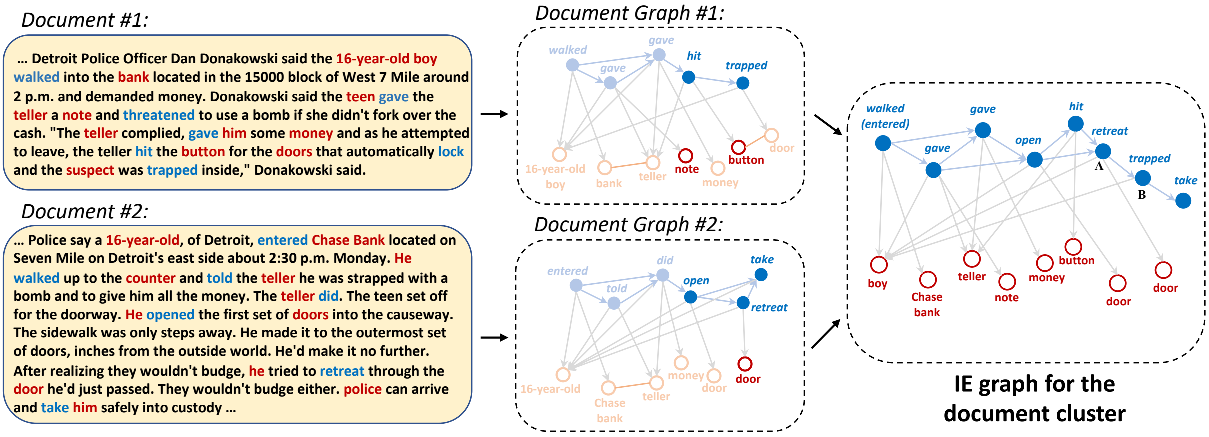
Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1696–1707
May 2-6, 2023



… Detroit Police Officer Dan Donakowski said the 16-year-old boy walked into the bank located in the 15000 block of West 7 Mile around 2 p.m. and demanded money. Donakowski said the teen gave the teller a note and threatened to use a bomb if she didn't fork over the cash. "The teller complied, gave him some money and as he attempted to leave, the teller hit the button for the doors that automatically lock and the suspect was trapped inside," Donakowski said.

… Police say a 16-year-old, of Detroit, entered Chase Bank located on Seven Mile on Detroit's east side about 2:30 p.m. Monday. He walked up to the counter and told the teller he was strapped with a bomb and to give him all the money. The teller did. The teen set off for the doorway. He opened the first set of doors into the causeway. The sidewalk was only steps away. He made it to the outermost set of doors, inches from the outside world. He'd make it no further. After realizing they wouldn't budge, he tried to retreat through the door he'd just passed. They wouldn't budge either. police can arrive and take him safely into custody …

Figure 1: An example of an extracted cross-document IE graph. There are two documents in the cluster and both of them describe a story where a boy failed to rob a bank. However, each document lists different details about the event. For example, the first document mentions that the bank teller hit the button to lock the boy inside; while the second document mentions that boy was trapped between two different doors of the bank. We highlight the unique nodes and edges in the document graph. The merged graph has a more comprehensive description of the story.

first use a cross-document fine-grained IE system to extract a cluster-level information graph, where each node could be an entity or an event trigger and each edge could be "*event-event*" temporal relations, "*event-argument*" links, or "*entity-entity*" relations. Each node in the graph is merged from separate documents according to entity and event coreference. After obtaining the cluster-level IE graph, we use an edge-conditioned graph attention network to encode the IE graph and to merge the graph information into the sequence-to-sequence summary generation pipeline. To better utilize the signals from IE, we further propose two novel training objectives. First, we propose an auxiliary task of entity and event recognition, where an additional classification module is incorporated to train a model to select the important entities and event triggers when performing summarization. The purpose of this auxiliary task is to help the model better recognize and remember the important events and entities which could be crucial for generating high-quality summaries. Second, we propose a graph and text alignment loss that minimizes the distance between IE graph nodes (e.g., nodes A and B in Figure 1) and their corresponding text segments (e.g., *retreat* and *trapped*) in a shared latent embedding space. Such an alignment loss can effectively incorporate IE graph information into the text representations and also mitigate the errors and inconsistencies caused by inevitable noise in the automatically extracted IE graphs. We conduct extensive experiments on multiple MDS benchmarks and show that our model outperforms several strong baselines both in terms of ROUGE scores as well as factual consistency metrics, all while maintaining the same level of abstractiveness. In summary, our main contributions are:

- We improve multi-document summarization (MDS) with cross-document IE graphs.
- We propose two novel training objectives to help the model better utilize the guidance from IE: (1) an entity and event recognition task loss and (2) a node-text alignment loss.
- Our proposed approach is proven effective by extensive experiments on multiple MDS benchmarks while achieving new state-of-the-art performance.

2 Problem Formulation

Our problem definition follows the typical formulation of abstractive multi-document summarization (MDS). Specifically, given a cluster of input documents $\mathcal{D} = \{D_1, D_2, \cdots, D_N\}$, we aim to build a model to generate a summary S of the document cluster. In this paper, we particularly focus on using IE to enhance summarization using the IE graph $\mathcal{G}$ merged from the individual graphs $\{G_1, G_2, \cdots, G_N\}$ extracted from N documents.

2.1 Cross-Document Information Extraction

We first perform cross-document information extraction on each document cluster using a state-of-the-art entity extraction and disambiguation system ReFinED (Ayoola et al., 2022) and event extraction and tracking system RESIN-11 (Du et al., 2022). Specifically, we first extract individual entity men-

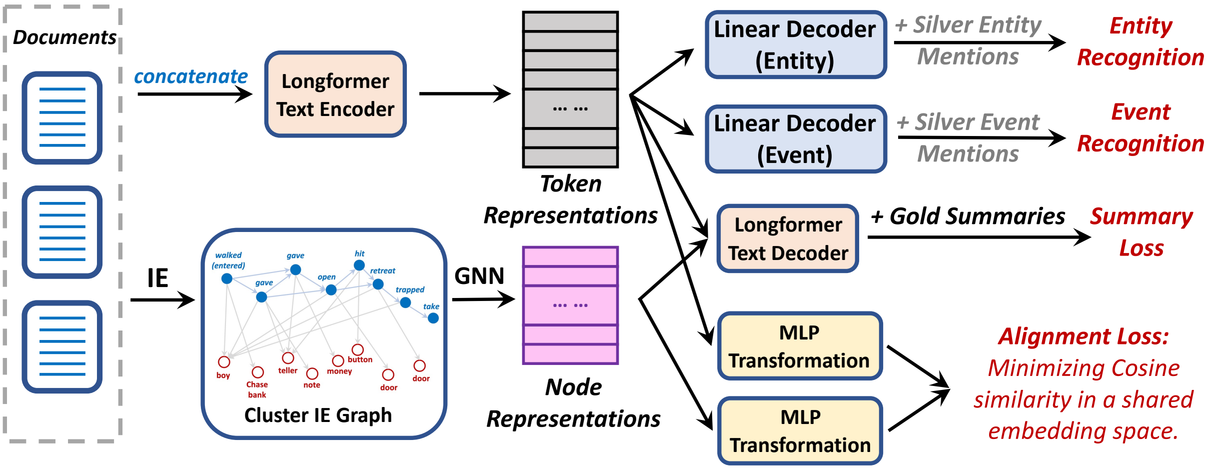


Figure 2: An overview of our IE-enhanced summarization pipeline. We first truncate and concatenate all documents in the cluster and feed them into the text encoder to obtain token representations. Meanwhile, we use a cross-document IE system to generate a cluster-level IE graph, and then use a GNN to get the node representations. During training, in addition to minimizing the distance between the generated and the reference summaries, we further use an entity and event recognition task and a node-text alignment loss to take advantage of the guidance from IE and improve MDS performance.

tions and event triggers as nodes from each document in the cluster. We then perform relation extraction, event argument role labeling, and event-event temporal relation extraction to add edges and to obtain a complete IE graph for each document. As shown in Figure 1, an example extracted event mention could be a "*Transport*" event triggered by "*walked*" with two event arguments "*boy*" and "*Chase bank*", where all such events are connected to form a unified document-level IE graph. To further connect document-level IE results into a cross-document IE graph, we then perform cross-document entity and event coreference resolution.[3] We merge all coreferenced entity and event nodes with their corresponding edges to form a cross-document IE graph. Specifically, if two nodes are labeled as the same entity or event, we merge these two nodes into a unified node and connect all related edges to it. It is worth noting that our framework does not rely on a specific IE systems and/or schema. Hence any form of structured IE outputs will work with our proposed method.

Notation Each node $v \in \mathcal{V}$ could be an entity or event trigger. We use $E = \{e_1, e_2, \cdots, e_{|E|}\}$ and $T = \{t_1, t_2, \cdots, t_{|T|}\}$ to denote the set of entities and event triggers respectively, where each e_i and t_i also act as a node in $\mathcal{V}$. Accordingly, there are three types of edges in $\mathcal{E}$ and we use p_{ij}, q_{ij}, and r_{ij} to represent the "*event-event*" temporal relations, "*event-entity*" argument roles, and "*entity-entity*" relations respectively. As shown in Figure 1, each blue node represents an event trigger (e.g., gave) while each brown node is an entity (e.g., bank), where the unique event triggers and entities are highlighted. The IE results include "*entity-entity*" relations connecting two different entities (e.g., <$button, door$>), "*event-argument*" links connecting an event trigger and an entity mention (e.g., <$gave, teller$>), and "*event-event*" temporal relations connecting two events (e.g., <$hit, retreat$>).

3 Approach

In this paper, our main goal is to improve multi-document summarization (MDS) with the extracted cross-document IE graph. As illustrated in Figure 2, we first concatenate all documents in a cluster and feed this concatenated input into a Longformer encoder (Beltagy et al., 2020) that is capable of handling long text sequences. We also use the cross-document IE system to obtain a cluster-level IE graph, as shown in the example highlighted in Figure 1, and use a graph attention network to obtain the node representations. During training, in addition to the cross-entropy summary loss between the generated and the ground-truth summaries, we propose two additional novel training objectives: (1) an *entity and event recognition* task that makes the model aware of the locations of important events and entities; and (2) an *alignment loss* between the IE graph nodes and their corresponding text spans

---

[3] The entity mentions extracted from ReFinED are merged according to the Wikidata IDs, while the event coreference resolution is done by a neural model (Lai et al., 2021).

to ensure that they are factually consistent in the latent space. We will go into details of our model design in the following sections.

3.1 Document Encoding

To handle the long input sequences, we use the encoder of the pre-trained *PRIMERA* (Xiao et al., 2022) model which is continually pre-trained from the Longformer-Encoder-Decoder (*LED*) model (Beltagy et al., 2020) to encode the documents and obtain the token representations $\{\boldsymbol{w}_1, \boldsymbol{w}_2, \cdots\}$. We truncate each document to the size of L_{max}/N (where N is the number of documents in the cluster), and concatenate all documents with a special token `[doc-sep]` to fit the maximum input length L_{max} of the *LED* model.[4]

$$\{\boldsymbol{w}_1, \boldsymbol{w}_2, \cdots\} = \text{Enc}\left(D_1, D_2, \cdots, D_N\right).$$

Similar to the work of Xiao et al. (2022), we assign the global attention on the `[doc-sep]` tokens to make sure that the model is aware of the document boundaries and that it analyzes the relationships between the documents.

In addition to directly encoding the documents, we also use the cross-document IE system described in Section 2.1 to extract a cross-document IE graph $\mathcal{G} = \{\mathcal{V}, \mathcal{E}\}$. Similar to Zhang and Ji (2021), we use an edge-conditioned graph attention network to encode the entity nodes E and event nodes T respectively. The initial node representations of entities and events are computed by the average of the representations over all tokens in the entity mention or event trigger.

$$\boldsymbol{e}_i = \frac{1}{|e_T - e_S|}\sum_{j=e_S}^{e_T-1}\boldsymbol{w}_j,\ \ \boldsymbol{t}_i = \frac{1}{|t_T - t_S|}\sum_{j=t_S}^{t_T-1}\boldsymbol{w}_j,$$

where $[e_T, e_S]$ and $[t_T, t_S]$ denote the entity and event trigger spans respectively. After initializing the node embeddings, the updated entity embeddings are computed as follows:

$$\boldsymbol{e}_i^{L+1} = \boldsymbol{e}_i^{L} + \gamma\cdot\sum_{j\in\mathcal{N}_i}\alpha_{ij}\boldsymbol{f}_n\left(\boldsymbol{v}_j^{L}\right).$$

In this equation, $\boldsymbol{f}_n(\cdot)$ is a linear transformation layer and γ is a hyper-parameter controlling the level of neighborhood aggregation, where a larger γ means more information from the neighbors is incorporated when updating the node representations. The attention weights α_{ij} are determined by the node pair and the type of the edge connecting the pair of nodes.

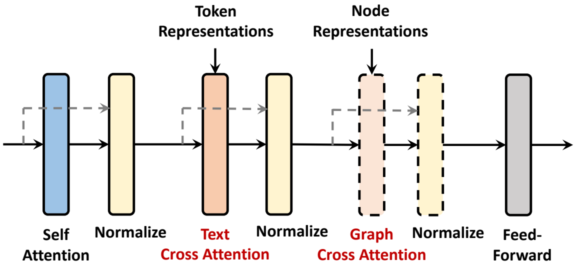

Figure 3: An example of the decoder layer components with graph cross-attention mechanism, where the dashed components are newly initialized weights while others are intialized from pre-trained weights.

$$\alpha_{ij} = \frac{\exp\left(\text{MLP}\left([\boldsymbol{v}_j, \boldsymbol{r}_{ij}, \boldsymbol{v}_i]\right)\right)}{\sum_{k=1}^{\mathcal{N}_i}\exp\left(\text{MLP}\left([\boldsymbol{v}_k, \boldsymbol{r}_{kj}, \boldsymbol{v}_i]\right)\right)},$$

where $\boldsymbol{r}_{ij}$ and $\boldsymbol{r}_{kj}$ are from a pre-initialized edge embedding matrix which could be optimized during training.[5] The event trigger embeddings are computed in the same way as the entities do. We use the node representations from the final layer as the output node representations.

3.2 Summary Generation

We use the pre-trained *LED* decoder to generate the summaries based on both token and node representations. In addition to the original pre-trained cross-attention mechanism $f_T(\cdot)$ for token representations, we include another similar cross-attention mechanism $f_G(\cdot)$ after f_T in all decoder layers for the system to model the relationships between each node in the graph and each token in the generated text. We use the pre-trained weights for text cross-attention mechanism $f_T(\cdot)$ and the graph cross-attention mechanism $f_G(\cdot)$ is randomly initialized, where both of them are continually optimized during the downstream training. An illustration of the pipeline in each decoder layer is shown in Figure 3. Therefore, each summary S_i is generated in an auto-regressive manner using the *LED* decoder $\text{Dec}(\cdot)$ with both text and graph cross-attention mechanism:

$$S_i = \text{Dec}\left([\text{BOS}], \{\boldsymbol{w}_1, \boldsymbol{w}_2, \cdots\}, \{\boldsymbol{v}_1, \boldsymbol{v}_2, \cdots\}\right),$$

where [BOS] is the *start* token in transformer decoders. Given a set of reference summaries

---

[4] The maximum length L_{max} is set as 4096 in pre-trained *PRIMERA* and *LED-large* models.

[5] We only consider three edge types here: event-event temporal relations, event-entity argument relations, and entity-entity relations.

$\hat{S}_1, \cdots, \hat{S}_N$ and a set of generated summaries $S_1, \cdots, S_N$, the summary loss is defined to minimize the cross-entropy distance $f_{CE}(\cdot)$ between each pair of summary sequences.

$$\mathcal{L}_{\text{summ}} = \frac{1}{N} \sum_{i=1}^{N} f_{CE}\left(S_i, \hat{S}_i\right). \tag{1}$$

3.3 Entity and Event Recognition

The main goal of our model is to use IE results to enhance the performance of the summarization task. We first add an auxiliary entity and event recognition task to make the model more sensitive to the locations of important events and entities. This will ensure that the model will not miss these events and entities when summarizing the document. Specifically, we use a Multi-Layer Perceptron (MLP) based classifier to classify each token into three different types: [ENTITY], [EVENT] or [NONE], and we use the spans of entity mentions and event triggers extracted by our proposed IE system to provide silver-standard training signals. Each token $\boldsymbol{w}_i$ is transformed to logits $\boldsymbol{p}_i$ by an MLP classifier:

$$\boldsymbol{p}_i = \text{softmax}\left(\text{MLP}\left(\boldsymbol{w}_i\right)\right). \tag{2}$$

Given a set of input tokens $\boldsymbol{w}_1, \boldsymbol{w}_2, \cdots, \boldsymbol{w}_M$, the entity and event recognition loss is computed as:

$$\mathcal{L}_{\text{recognition}} = -\sum_{i=1}^{M} p_{ij},$$

where j is the index of the correct label for w_i.

3.4 Node and Text Alignment

Incorporating graph information for summarization could be challenging, since the IE graphs are extracted from automatic extraction systems which may introduce noise and errors. To this end, we propose a novel alignment loss to minimize the distance between node representations and their corresponding texts to ensure coordination between the graphs and summarization text. Specifically, we first use two MLPs to map the node and text representations into the same embedding space Z:

$$\boldsymbol{z}_i^w = \text{MLP}_w\left(\boldsymbol{w}_i\right), \quad \boldsymbol{z}_i^v = \text{MLP}_v\left(\boldsymbol{v}_i\right),$$

where $\boldsymbol{z}_i^w$ and $\boldsymbol{z}_i^v$ denote the representations for token w_i and node v_i in the shared embedding space. Given each node v_i and the set of its corresponding text tokens $\mathcal{W}_i$, we minimize the cosine similarity between the node embedding $\boldsymbol{v}_i$ and the average embedding of all tokens in $\mathcal{W}_i$:

$$\mathcal{L}_{\text{align}} = \sum_{v_i \in \mathcal{V}} d_{cos}\left(\boldsymbol{z}_i^v, \frac{1}{|\mathcal{W}_i|} \sum_{w_j \in \mathcal{W}_i} \boldsymbol{z}_j^w\right). \tag{3}$$

The intuition behind $\mathcal{L}_{align}$ is to ensure that the node embedding is centered around its corresponding text. This helps ensure that the graphs and input text are factually consistent with each other, thereby reducing the errors and noise propagated from the IE system. As an example in Figure 1, the latent distance between each pair of nodes and texts (e.g., the node representation of *boy* and the text representation of its corresponding tokens *16-year-old boy*) are minimized to reduce the noise of the extracted graph.

Multi-Task Training. We conduct multi-task training where the total loss is a weighted sum from Equation (1), (2), and (3). The weighting coefficients β_1,β_2, and β_3 are tunable hyper-parameters.

$$\mathcal{L} = \beta_1 \cdot \mathcal{L}_{\text{summ}} + \beta_2 \cdot \mathcal{L}_{\text{recognition}} + \beta_3 \cdot \mathcal{L}_{\text{align}}$$

4 Experiments

4.1 Data

Our experiments are conducted on three most widely-used MDS benchmarks, where the detailed dataset statistics are shown in Table 1.

Dataset	# Train / Val / Test	Docs per Cluster	Average Summary Length
Multi-News	44972 / 5622 / 5622	2.8	217
WCEP-10	8158 / 1020 / 1022	9.1	28
DUC-2004	0 / 0 / 50	10	115

Table 1: Statistics of the MDS Datasets

Multi-News. The Multi-News benchmark (Fabbri et al., 2019) is the most widely-used dataset for multi-document summarization. The summaries are long and informative news abstracts written by human editors, and the documents are extracted from multifarious news articles.

WCEP-10. The WCEP-10 (Gholipour Ghalandari et al., 2020) dataset is extracted from Wikipedia Current Event Portal, where each document cluster also describes a news event. Compared to Multi-News, the WCEP dataset has a much larger number of documents in each cluster, and we manually reduce them to a maximum of 10 documents per cluster as previous research (Xiao et al., 2022; Parnell et al., 2022) did to obtain the WCEP-10 version of dataset. We include both Multi-News and WCEP-10 in our experiments to evaluate whether our model can stay effective in both long-summary and short-summary scenarios.

DUC-2004. There are only 50 test document clusters in DUC-2004 benchmark,[6] and we use this dataset to evaluate our model's zero-shot transfer ability. We train our model on Multi-News and directly test it on DUC-2004 since these two datasets have similar lengths of summaries.

4.2 Baselines and Implementation Details

For baselines, we mainly compare our model with state-of-the-art multi-document summarization models *PRIMERA* (Xiao et al., 2022) and *REFLECT* (Song et al., 2022). *REFLECT* only reports ROUGE scores on the Multi-News dataset and we directly use the reported scores for comparison. Besides, we also include a previous model *BART-Graph* (Pasunuru et al., 2021), which uses a linearized IE graph to improve summarization. We compare our model with it to see whether encoding the graph structurally improves the summarization performance. We also experiment with three ablation variants of our proposed model: (1) *Recognition-Only:* for the model with only the entity and event recognition loss; (2) *Alignment-Only:* for the model with only the graph encoder and the node-text alignment loss. (3) *Separate-Graphs:* for encoding the IE graphs for each document separately and using a collated matrix as the node representations. For Multi-News and WCEP-10, we train all of these models on the training set, choose the best model checkpoint based on the performance on the validation set, and test the models on the test set. For DUC-2004, we use the trained checkpoint on Multi-News dataset for evaluation, since the summary length on Multi-News is more similar to DUC-2004 compared with WCEP-10.[7]

4.3 Evaluation Metrics

Co-occurrence. Similar to previous research studies, we first include the most widely-used ***ROUGE-F1*** score which measures the overlap between the generated summaries and the reference summaries in terms of overlapping n-grams and longest common subsequence.

Factual Consistency. Intuitively, our proposed IE-enhanced summarization should improve factual consistency of the generated summary with the source documents, since the entities and events in the original documents are mined and memorized by the model through the two proposed IE enhancement loss. Therefore, we include several factuality metrics to measure the improvements in terms of factuality of the generated summaries. Specifically we use ***FactCC*** (Kryscinski et al., 2020), ***FactGraph*** (Ribeiro et al., 2022), ***EntityPrecision*** (Nan et al., 2021), **SUMMAC** (Laban et al., 2022), and **BERTSCORE** (Pagnoni et al., 2021).

Abstractiveness. To measure abstractiveness of our generated summaries, we use the MINT score (Dreyer et al., 2023), which is based on contiguous and non-contiguous extractive overlaps between summaries and their source documents. Our goal is to measure whether the novelty of the generated summary is sacrificed due to the improvements of factual consistency, e.g., by generating a more extractive summary.

4.4 Results

Table 2 shows the results of our proposed model, as well as the baselines on the three datasets. In general, the full version of our proposed model outperforms the baselines in terms of both ROUGE scores and factuality metrics while maintaining the same level of MINT scores. This shows that our model can generate high-quality summaries that are factually consistent without sacrificing any novelty. Specifically, entity and event recognition mainly improve factual consistency, while node-text alignment improves the similarity with the referenced summaries. This follows our intuition since the recognition task is mainly designed to help the model better notice the important event triggers and entity mentions, which prevents the model from hallucination and thereby improves factual consistency. On the other hand, the alignment loss can reduce the noise and errors in those extracted IE graphs, which makes the model better optimized on the ground-truth summaries.

4.5 Human Evaluation

We conduct a human evaluation on Amazon Mechanical Turk to evaluate the effect of adding our

Table 2: Evaluation results with various metrics on the three MDS datasets. We primarily compare our results with three most recent transformer-based baselines *BART-Graph*, *REFLECT*, and *PRIMERA*. We also include two variants of our own model for ablation study, where we remove the recognition loss and the alignment loss respectively and test the model on these MDS datasets.

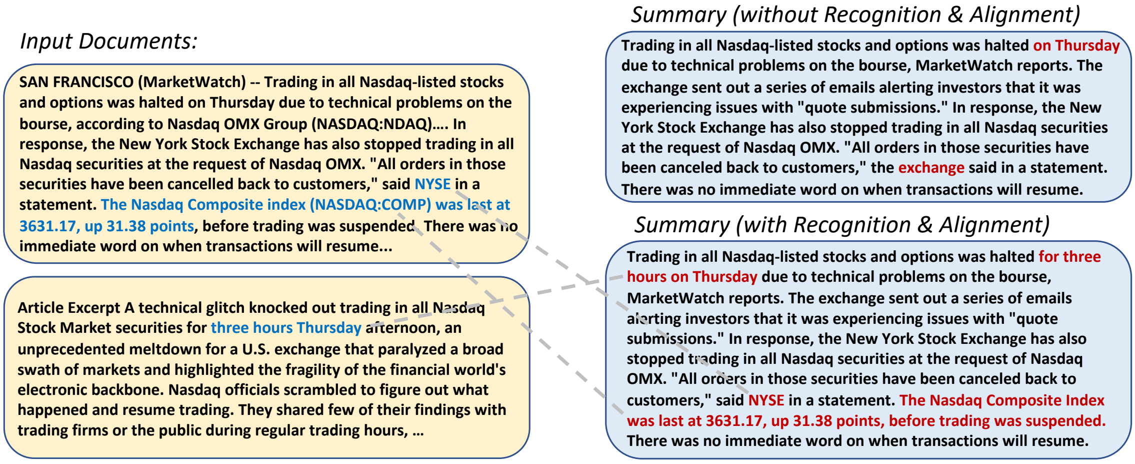
two proposed training objectives. We randomly select 300 document clusters for each of Multi-News and WCEP and use all the 50 document clusters in DUC-2004, asking three annotators per summary to score the factual consistency: 1 for major factual errors, 2 for minor factual errors, and 3 for no factual errors. Figure 5 in the Appendix shows the annotation guidelines. We aggregate the three judgements per summary using majority voting. We follow the qualification procedure for annotators described in Dreyer et al. (2023). Table 3 shows the percentages for each factuality score, where *baseline* denotes the *PRIMERA* (Xiao et al., 2022) model and *ours* denotes our proposed model. We find that our model can substantially reduce major factual errors on all three datasets, and is able to obtain higher average factuality scores on Multi-News and DUC-2004. Particularly, on DUC-2004 where the model is directly transferred from another dataset, our model can especially outperform the baseline in terms of factual consistency.

Dataset	Major (1.0)	Minor (2.0)	No (3.0)	Avg Scores
baseline	6.0%	11.3%	82.7%	2.767
Multi-News (ours)	**4.7%**	12.7%	82.7%	**2.780**
baseline	10.7%	9.0%	80.3%	**2.697**
WCEP-10 (ours)	**9.0%**	19.3%	71.7%	2.627
baseline	22.0%	22.0%	56.0%	2.340
DUC-2004 (ours)	**18.0%**	12.0%	70.0%	**2.520**

Table 3: Human evaluation results.

4.6 Qualitative Analysis

To better understand the effects made by our proposed training objectives, we look into the prediction results and show a typical example in Figure 4, explaining how our proposed method works to improve the summaries. In this example, the document cluster is mainly talking about a shut-down incident of the Nasdaq trading market. Compared to the summary from the baseline model, our model is better at memorizing the important facts and showing them in the output summary, e.g., the exact Nasdaq Index (3631.17) when the trading was suddenly suspended. Some other facts such as *"three hours"* are also memorized by our model but ignored by the baseline model. Moreover, our model is able to generate more informative mentions of those key entities (e.g., *NYSE*), where the baseline model fails to generate a named mention and only writes *"the exchange"*.



SAN FRANCISCO (MarketWatch) -- Trading in all Nasdaq-listed stocks and options was halted on Thursday due to technical problems on the bourse, according to Nasdaq OMX Group (NASDAQ:NDAQ).... In response, the New York Stock Exchange has also stopped trading in all Nasdaq securities at the request of Nasdaq OMX. "All orders in those securities have been cancelled back to customers," said NYSE in a statement. The Nasdaq Composite index (NASDAQ:COMP) was last at 3631.17, up 31.38 points, before trading was suspended. There was no immediate word on when transactions will resume...

Article Excerpt A technical glitch knocked out trading in all Nasdaq Stock Market securities for three hours Thursday afternoon, an unprecedented meltdown for a U.S. exchange that paralyzed a broad swath of markets and highlighted the fragility of the financial world's electronic backbone. Nasdaq officials scrambled to figure out what happened and resume trading. They shared few of their findings with trading firms or the public during regular trading hours, ...

Trading in all Nasdaq-listed stocks and options was halted on Thursday due to technical problems on the bourse, MarketWatch reports. The exchange sent out a series of emails alerting investors that it was experiencing issues with "quote submissions." In response, the New York Stock Exchange has also stopped trading in all Nasdaq securities at the request of Nasdaq OMX. "All orders in those securities have been canceled back to customers," the exchange said in a statement. There was no immediate word on when transactions will resume.

5 Related Work

Multi-Document Summarization. Abstractive multi-document summarization (MDS) aims to build models to generate summaries given a set of similar documents related to the same topic. With the tremendous success of sequence-to-sequence pre-trained language models such as BART (Lewis et al., 2020) and T5 (Guo et al., 2022), finetuning on pre-trained models, like DeYoung et al. (2021); Parnell et al. (2022); Zhao et al. (2022); Moro et al. (2022); Song et al. (2022); Ernst et al. (2022), has become the primary style of methods for summarization tasks. There are also research studies on how to handle cross-document information overlap and redundancy. For example, Pasunuru et al. (2021) propose to use graph structures generated by OpenIE systems to make the model more sensitive about the main message of the document cluster. More recently, Xiao et al. (2022) propose to integrate entity overlap into the pre-training scheme, where the overlapping entities are used to select out salient sentences for pre-training.

Cross-Document Information Extraction. Information Extraction (IE) aims to extract structured representations from unstructured text, which includes various subtasks from Named Entity Recognition (Reich et al., 2022; Ayoola et al., 2022; Ding et al., 2021), to Relation Extraction (Yu et al., 2022; Tian et al., 2022), and Event Extraction (Xu et al., 2021; Yu et al., 2021) on news documents. There are also a number of research studies (Yao et al., 2021; Wu et al., 2022; Du et al., 2022) focusing on corpus-level cross-document extraction models. However, all these models still rely on cross-document entity and event coreference systems, which could bottleneck the efficiency and effectiveness of corpus-level IE models.

Joint IE and Summarization. IE and summarization share inherent similarities; both of them are designed to find the main information from an input natural language text. Therefore, it is promising to design a joint learning framework so that the two tasks could provide each other with mutual enhancement. There are some preliminary explorations of previous studies to train a model to learn IE and natural language generation (NLG) tasks jointly. For example, Li et al. (2021) train a template-based generative model for event argument extraction, and Du and Cardie (2020) propose to generate natural questions to ask the model for event extraction. However, although generation-based methods are proposed, these models are still doing a single task (IE) without multi-task settings for both IE and NLG. Recently, Lu et al. (2022) use summarization to provide indirect training signal for relation extraction tasks, however, their method is only suitable for relation extraction tasks and cannot cover general-concept IE tasks.

6 Conclusions

In this paper, we focus on improving multi-document summarization (MDS) model with cross-document Information Extraction (IE). We propose two novel training objectives – an entity and event recognition loss and a node-text alignment loss – that can help the model better utilize the signals from IE. Experimental results show that our model can generate summaries that are more factual, while not losing any abstractiveness.

7 Limitations

One limitation of our proposed method is the IE graphs are pre-extracted separately, where the IE model is not optimized during the model training and the IE results are only used as side inputs for summarization. It would be more exciting if we can really build a joint IE and Summarization model which are trained simultaneously in the pipeline, although it is very difficult since passing the gradients through a cross-document system is nearly intractable. We intend to address this limitation in our future work.

A Experiment Details

We list our detailed hyper-parameter settings for training our model on each of the datasets in Table 4 and Table 5, where each hyper-parameter is determined based on grid search among 5 candidate values. We train our model on 8 NVIDIA V100 GPUs with 32GB memory, and the total training time is about 7 hours for Multi-News and 3 hours for WCEP-10.

Hyper-parameters	Values
Num of features for each node	1,024
Num of GNN layers	1
Message Passing Level γ	0.01
Weights of the losses β_1, β_2, β_3	1.0, 0.2, 0.2
Learning Rate	3e-5
Batch Size	16
Maximum Length of Generated Summaries	256
Maximum Training Steps	25,000
Warm-up Steps	2,500
Beam Size for Generation	5

Table 4: Detailed hyper-parameter settings for model training on Multi-News.

Hyper-parameters	Values
Num of features for each node	1,024
Num of GNN layers	1
Message Passing Level γ	0.005
Weights of the losses β_1, β_2, β_3	1.0, 0.1, 0.1
Learning Rate	3e-5
Batch Size	16
Maximum Length of Generated Summaries	50
Maximum Training Steps	5,000
Warm-up Steps	500
Beam Size for Generation	5

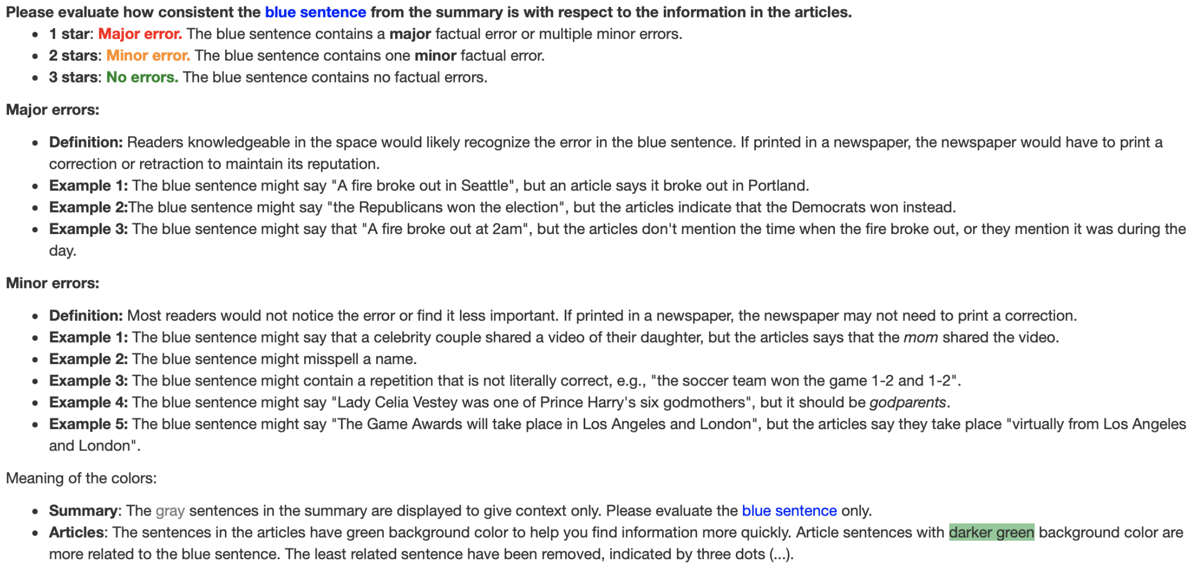
B Annotation Guidelines

We use Amazon MTurk to do human evaluation, where the detailed annotation guidelines for human evaluators are shown in Figure 5.



Please evaluate how consistent the blue sentence from the summary is with respect to the information in the articles.

- **1 star**: **Major error.** The blue sentence contains a **major** factual error or multiple minor errors.
- **2 stars**: **Minor error.** The blue sentence contains one **minor** factual error.
- **3 stars**: **No errors.** The blue sentence contains no factual errors.

Major errors:

- **Definition:** Readers knowledgeable in the space would likely recognize the error in the blue sentence. If printed in a newspaper, the newspaper would have to print a correction or retraction to maintain its reputation.
- **Example 1:** The blue sentence might say "A fire broke out in Seattle", but an article says it broke out in Portland.
- **Example 2:**The blue sentence might say "the Republicans won the election", but the articles indicate that the Democrats won instead.
- **Example 3:** The blue sentence might say that "A fire broke out at 2am", but the articles don't mention the time when the fire broke out, or they mention it was during the day.

Minor errors:

- **Definition:** Most readers would not notice the error or find it less important. If printed in a newspaper, the newspaper may not need to print a correction.
- **Example 1:** The blue sentence might say that a celebrity couple shared a video of their daughter, but the articles says that the *mom* shared the video.
- **Example 2:** The blue sentence might misspell a name.
- **Example 3:** The blue sentence might contain a repetition that is not literally correct, e.g., "the soccer team won the game 1-2 and 1-2".
- **Example 4:** The blue sentence might say "Lady Celia Vestey was one of Prince Harry's six godmothers", but it should be *godparents*.
- **Example 5:** The blue sentence might say "The Game Awards will take place in Los Angeles and London", but the articles say they take place "virtually from Los Angeles and London".

Meaning of the colors:

- **Summary**: The gray sentences in the summary are displayed to give context only. Please evaluate the blue sentence only.
- **Articles**: The sentences in the articles have green background color to help you find information more quickly. Article sentences with darker green background color are more related to the blue sentence. The least related sentence have been removed, indicated by three dots (...).

What happens *before* and *after*: Multi-Event Commonsense in Event Coreference Resolution

Abstract

Event coreference models cluster event mentions pertaining to the same real-world event. Recent models rely on contextualized representations to recognize coreference among lexically or contextually similar mentions. However, models typically fail to leverage commonsense inferences, which is particularly limiting for resolving lexically-divergent mentions. We propose a model that extends event mentions with temporal commonsense inferences. Given a complex sentence with multiple events, e.g., "The man killed his wife and got arrested", with the target event "arrested", our model generates plausible events that happen before the target event – such as "the police arrived", and after it, such as "he was sentenced". We show that incorporating such inferences into an existing event coreference model improves its performance, and we analyze the coreferences in which such temporal knowledge is required.

1 Introduction

The goal of cross-document event coreference resolution is to determine if various event mentions (e.g. *shot*, *gunshot*), across one or more documents, refer to the same event. Existing systems represent each mention within its context using a language model (Cattan et al., 2021a; Allaway et al., 2021), and train a scorer to predict if two mentions corefer, based on their lexical and contextual similarity.

While many coreferring mention pairs in event coreference datasets such as ECB+ (Cybulska and Vossen, 2014) are lexically and contextually similar, or even share the same lemma (Wolfe et al., 2015), the difficulty arises for dissimilar coreferring mentions. For example, in Figure 1, *spent* and *hospitalized* are coreferring. These mentions are not lexically similar, and are not often used in similar contexts. In this paper, we improve the ability of existing cross-document event coreference systems to resolve such challenging coreferring mentions, by providing additional context in the form of commonsense knowledge. We focus on two temporal commonsense relations — *before* and *after* — pertaining to typical events that happen before and after the target event. For instance, in Figure 1, we may infer that before Dalton was *shot*, a shooter loaded their gun. Similarly, we may infer that Dalton was hurt prior to his *hospitalization* and got discharged afterward.

Our first contribution is the development of a commonsense reasoning engine that can reason about these two temporal relations. Existing commonsense models (Gabriel et al., 2021a; Hwang et al., 2021) may generate such inferences for simple sentences with a single event, such as "Bryant Dalton was shot", but they do not support complex sentences with multiple events of interest (e.g. *shot*, *hospitalized*). Further, they may conflate the inferences for different events. We develop a multi-event commonsense model that considers the entire context and is capable of generating separate inferences for each target event in complex sentences.

As an additional contribution, we incorporate the inferences into the pairwise mention scorer of a cross-document event coreference system (Cattan et al., 2021a). We produce *before* and *after* inferences for each event mention. We then embed the inferences, either by attending each mention to its own inferences (intra-span) or to the other mention's inferences (inter-span).

The results confirm that commonsense inferences are useful for event coreference. Each of our model variants improves upon the baseline performance, with the intra-span version performing the best. We further analyze the successful predictions and interpret how the commonsense inferences help resolve difficult mention pairs. In the future, we plan to extend our multi-event inference engine to additional commonsense knowledge types and apply it to other discourse tasks, such as summa-

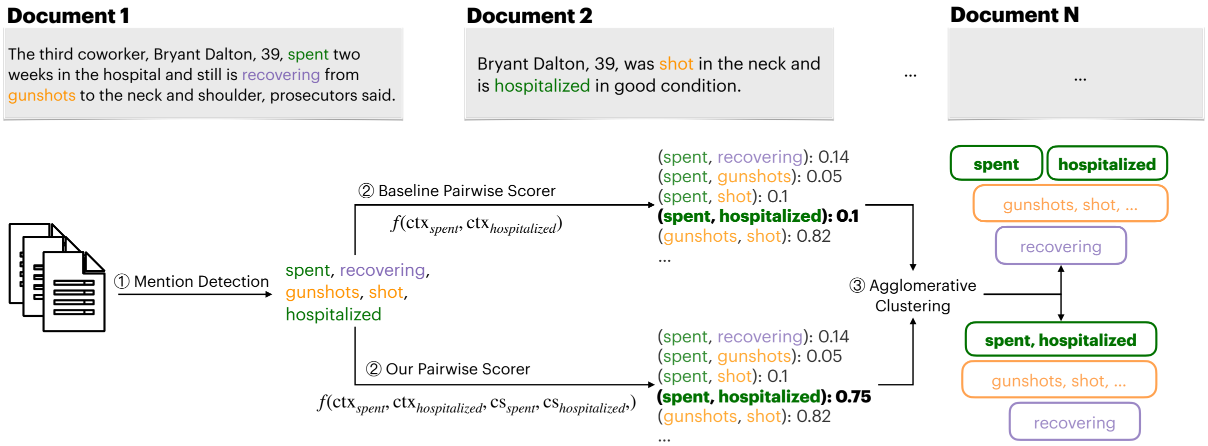

Figure 1: The architecture of our event coreference model, exemplified on a set of documents. The baseline pairwise scorer is based on contextual similarity (top), and we enhance it with temporal commonsense inference embeddings – indicated with *cs* (bottom). Such inferences help identify lexically divergent co-referring pairs, such as *spent* [time at a hospital] and *hospitalized*.

rization, dialogue, and story comprehension.[1]

2 Background

In this work, we improve the performance of a system for cross-document coreference resolution by incorporating temporal commonsense inferences pertaining to the events. We first provide background on event coreference resolution (§2.1). We then describe related work concerning event-centered commonsense (§2.2), along with approaches for using language models for data augmentation (§2.3).

2.1 Event Coreference Resolution

Event coreference resolution aims to cluster event mentions that refer to the same underlining real-world occurrence. Our work focuses on cross-document coreference resolution (CD), which aims to resolve mentions across an entire corpus of documents. In contrast, the problem of within-document coreference resolution (WD) only resolves mentions on a per-document basis. Event coreference is often performed jointly with *entity* coreference resolution, which concerns resolving mentions of people, locations, and organizations.

Datasets. In this paper, we use the ECB+ dataset proposed by Cybulska and Vossen (2014) and widely accepted as the standard benchmark for coreference resolution (CD). ECB+ contains 86 sub-topics, each of which concerns a specific news event. To introduce complexity and difficulty, each sub-topic is highly similar to – yet distinctly different from – exactly one other sub-topic. ECB+ includes both entity and event mentions; however, this work focuses solely on events. Table 1 shows event statistics from ECB+ corpus.

	Train	Dev	Test
Topics (subtopic-pairs)	25	8	10
Event mentions	3808	1245	1780
Event clusters	1527	409	805

Table 1: Statistics on the standard train/dev/test split of event coreferences in ECB+ dataset (Cybulska and Vossen, 2014)

Models. Recent approaches to CD event coreference often follow the architecture described in Figure 1. First, candidate event mentions are extracted from documents. Second, a pairwise scorer is trained to classify every pair of mentions as being coreferent or not. Finally, these scores are used to form distinct clusters of event mentions, typically using agglomerative clustering. Amongst these components, coreference models tend to mostly vary in their scoring approach (i.e., second component).
Early approaches relied on lexical and syntactic features (Yang et al., 2015; Choubey and Huang, 2017), or used semantic roles to encode the relationships between entities and events. Recently, Meged et al. (2020) improved performance by leveraging a resource of predicate paraphrases. Finally, Lai et al. (2021) incorporated entities, relations, and events extracted from a state-of-the-art information ex-

---

[1] The code is available here.

traction system. Generally, current state-of-the-art models often rely on pre-trained language models to compute a contextualized representation for each candidate mention, which serve as input to the pairwise scorer (e.g. Yu et al., 2020; Zeng et al., 2020; Cattan et al., 2021a; Allaway et al., 2021).

Our model is an enhancement of the model proposed by Cattan et al. (2021a). It targets both entity and event coreference resolution, and in an end-to-end fashion it performs mention extraction, pairwise scoring, and clustering (Figure 1). Mentions are represented by contextualized embeddings from RoBERTa (Liu et al., 2019). We chose to base our model on Cattan et al. (2021a) for two reasons. First, it is a simple model following the standard approach presented in Figure 1. Later approaches rely on hierarchical representations (Yadav et al., 2021a) or discourse coherence theory (Held et al., 2021). Second, it is based on RoBERTa and is more efficient and less memory consuming than the succeeding CDLM model (Caciularu et al., 2021) that is based on the much larger Longformer model (Beltagy et al., 2020).

More recently, Yadav et al. (2021a) built on Cattan et al. (2021a) by proposing a hierarchical approach to representing uncertainty of clustering event and entity mentions. The state-of-the-art models for cross document coreference are Caciularu et al. (2021), which models cross-text relationships by using larger context windows, and Held et al. (2021), which applies discourse coherence theory to coreference.

2.2 Event-Centric Commonsense

Commonsense reasoning helps humans bridge the gap between utterance and intended meaning. Reasoning about events has long been of interest to AI research. Schank and Abelson (1975) introduced "scripts" as a prototypical series of events, e.g. going to a restaurant is composed of ordering food, eating, and paying, and the participants: customer, waiter, and cook. Various methods have been proposed to learn such scripts from text (e.g. Chambers and Jurafsky, 2008; Pichotta and Mooney, 2014; Rudinger et al., 2015).

The ATOMIC knowledge base (Hwang et al., 2021; Sap et al., 2019) consists of 1.1M crowdsourced event-relation-event triplets pertaining to the causes, effects, and mental states of the event participants. To generate contextually-relevant ATOMIC-style inferences, Bosselut et al. (2019) developed COMET, a pre-trained language model fine-tuned on ATOMIC. COMET has shown promising results on tasks such as therapy chatbots (Kearns et al., 2020), persona-grounded dialogue (Majumder et al., 2020), figurative language interpretation and generation (Chakrabarty et al., 2020, 2022), and temporal ordering of sentences (Ghosal et al., 2021).

Several variants of COMET have been subsequently released. ParaCOMET (Gabriel et al., 2021a) adapts COMET to generate sentence-level inferences within the context of an entire paragraph. VisualCOMET (Park et al., 2020) generates ATOMIC-style inferences for images. Finally, the updated version of COMET (Hwang et al., 2021) extends the relation inventory and crowdsources more inferences. The additional inferences include the two temporal relations that are the most relevant to our work, "happens before" and "happens after".

2.3 LM-generated Data Augmentation

The success of using large pre-trained LMs in a few-shot setup for generation tasks has led to an increased interest in using such models to generate data for downstream tasks. Recent work augmented datasets by fine-tuning a pre-trained LM on real data, then generated new, silver-labelled instances (Anaby-Tavor et al., 2020; Papanikolaou and Pierleoni, 2020; Kumar et al., 2020). Similarly, the few-shot capabilities of GPT-3 (Brown et al., 2020) were leveraged to generate free-text explanations (Wiegreffe et al., 2022), semantically-related sentence pairs (Schick and Schütze, 2021), atomic event commonsense triples (West et al., 2022), and labels for various generation and understanding tasks (Wang et al., 2021). In this work, we fine-tune GPT-3 with minimal human supervision to generate additional contextual data pertaining to events.

3 Method

The architecture of our method is shown in Figure 1. We use the same clustering method as in Cattan et al. (2021a) but revise the pairwise scorer. Our goal is to improve the model's ability to resolve coreferences between mention pairs that are not lexically or contextually similar, but where one mention could be inferred from the other using commonsense knowledge and reasoning. Thus, we develop a commonsense inference engine (Sec 3.1)

Instructions: Read the context sentence and write at least **two** inferences for question 1 and **two** inferences for question 2. As shown in the examples, each inference is expected to be a short sentence between **5-10 words**.

Context: A publicist says Tara Reid has **checked herself** into rehab.
Question 1: What typically happens before the event checked herself?
Question 2: What typically happens after the event checked herself?

Figure 2: An example task on Amazon Mechanical Turk.

and use it to enhance the pairwise scorer (Sec 3.2).

3.1 Multi-Event Commonsense Inferences

We enhance the pairwise scorer with commonsense inferences regarding the events' temporal aspects. Specifically, we focus on plausible events that might have happened before or after the target event. For example, in Figure 1, after being hospitalized, the victim received treatment.

We found COMET and its variants to be ineffective for generating inferences for our task. COMET was trained on the ATOMIC knowledge base (Sap et al., 2019). As the name implies, events are atomic, i.e., comprise a single verb phrase. Conversely, the existing event coreference datasets are based on news articles, where sentences often contain multiple events. COMET predictions for document 1 (Figure 1) have no indication which verb they pertain to. Moreover, COMET predicts that what happens after document 1 is murder, which contradicts the fact that the victim survived and was taken to the hospital. ParaCOMET (Gabriel et al., 2021b) facilitates generating consistent inferences for multi-sentence paragraphs, but it was trained on the ROCStories dataset (Mostafazadeh et al., 2016), which is in the fiction domain and in which sentences are also simple.

To that end, we trained a new multi-event commonsense inference engine. Given a sentence with multiple events (such as document 1), and a target event (e.g. *hospitalized*), the goal is to generate what might have happened before and after the target event—in the context of the entire sentence.

Model. We base the inference engine on GPT-3 (Brown et al., 2020). While GPT-3 is not directly applicable to the task of event coreference (Yang et al., 2022), it has been shown to contain a wealth of factual and commonsense knowledge as a result of extensive pre-training. Our goal is to use this knowledge to generate event-centric commonsense inferences without requiring extensive training. GPT-3 is especially well-suited for this task, as it has shown remarkable performance in learning from fewer examples in a variety of tasks.

Data. As the first step in training a multi-event commonsense model, we crowdsourced annotations for 100 events – using the gold standard event mentions from the ECB+ training set. To include a wide range of topics, we selected the first four events from each of the 25 topics in the training set.

We presented workers with a sentence with one or more events, and asked them to describe what happens immediately before and after the target event. Figure 2 shows an example[2]. We obtained annotations from three workers for each sentence, and instructed workers to write at least two inferences for each relation. This yielded a total of 600 inferences ($100 \times 3 \times 2 = 600$). We carefully reviewed the data and removed a handful of inferences that were of poor quality (i.e., incomplete or irrelevant sentences, which amounted to roughly 5% of the annotations).

The annotation task was conducted on Amazon Mechanical Turk (AMT). To ensure the quality of annotations, we required workers to have previously completed 5,000 AMT tasks, and to have an acceptance rate of 98% or higher. We limited the worker location to the U.S. and Canada, and presented workers with a qualification test similar to the task. We paid 7 cents for each event.

Training. We fine-tuned GPT-3 on the collected inferences. The input and output format was as follows:

`Context:` <context>
`Event:` <event>
`Before:` <before>
`After:` <after>

Table 7 shows the format inputted into GPT-3 for training (top row) and inference (bottom row).

Inference To generate inferences, we prompt the fine-tuned GPT-3 model with the context and the event. We generate up to 150 tokens using top-p decoding (Holtzman et al., 2020) with a cumulative

Bryant Dalton, 39, was shot in the neck and is hospitalized in good condition.

The third coworker, Bryant Dalton, 39, spent two weeks in the hospital and still is recovering from gunshots to the neck and shoulder, prosecutors said.

Before hospitalized:	After hospitalized:
He was wounded.	The victim received treatment.
He was taken to hospital.	The victim was released from the hospital.
He was bleeding.	The victim recovered from his wounds.
His friends brought him to the hospital.	The victim was stitched up and released.

Before spent:	After spent:
He was injured in a shooting.	He was discharged.
He sought medical attention.	He began to recover.
His injuries were diagnosed as serious.	He needed further treatment.
He was admitted for treatment.	He went home to recuperate.

$$\mathrm{cs}_{spent} = [\ \text{Attention-weighted before vector}\ ;\ \text{Attention-weighted after vector}\ ]$$

Figure 3: An illustration of the new additions to the pairwise scorer. We input each document into a GPT-3-based multi-event temporal commonsense inference engine, which outputs plausible events that happened before and after the target event (e.g. *spent*). For each temporal relation (i.e., *before* and *after*), we embed the corresponding inferences and compute an attention-weighted vector. We concatenate the *before* and *after* vectors to the mention representations as input to the pairwise scorer.

Context	**Before**	**After**
	Human-Written	
[...] Chris Weitz will direct the sequel to Twilight, New Moon, replacing Catherine Hardwicke.	They couldn't strike a [...] deal with Hardwicke. The executive producer contacted Weitz's agent. Lindsay Lohan checks into rehab at Betty Ford Center, rehires longtime lawyer Shawn Holley	She decided to change her life from bad to good. She decided to seek help for her addiction. She is assessed by the staff at Betty Ford. She is welcomed by staff members at Betty Ford.	She is treated for her addiction. She attended daily group therapy meetings. She ends up in the hospital. She no longer has a problem.
Lindsay Lohan checks into rehab at Betty Ford Center, rehires longtime lawyer Shawn Holley	Lindsay needs advice on her case. Lindsay needs legal counsel in her case. she fired her old lawyer. she got a new director.	He gets a good pay. He looks for another case. she went through planning stages of her recovery. she started to addiction treatment.

Table 2: Human-written (top) and model-generated (bottom) examples from our multi-event temporal commonsense inference engine. Some examples are slightly abbreviated for readability.

probability of $p = 0.9$. Table 2 provides examples of the training data (top part) and generated inferences (bottom part) of our multi-event commonsense inference engine. Note, both the human-written and model-generated inferences differ for different events belonging to the same context. For example, according to our model, *after* the event "Lindsay checks into rehab," a plausible inference is that "she gets treated for her addiction." Yet, *after* the event "she rehires her longtime lawyer," our model infers that "he gets a good pay." [3]

3.2 Inference-Enhanced Pairwise Scorer

Figure 3 shows the overall architecture of our commonsense-enhanced pairwise scorer. We follow Cattan et al.'s mention span representation for mention m_i:

$$\mathrm{ctx}_i = [x_{START(i)}, x_{LAST(i)}, \hat{x}_i, l_i] \quad (1)$$

---

[3] We also experimented with prompting GPT-3 in a few-shot setup (Sec 5.3).

where x_j corresponds to the RoBERTa (Liu et al., 2019) embedding of the jth token in the span. Each mention is represented as the concatenation of: the first ($x_{START(i)}$) and last ($x_{LAST(i)}$) tokens; an attention-weighted sum of tokens $\hat{x}_i$; and a feature vector denoting the length l_i.

To incorporate the commonsense inference, we use the inference engine to generate up to $k = 5$ inferences for each of the before (b) and after (a) relations: $b_1 ... b_k$, and $a_1 ... a_k$. We describe below the representation of the relation vector using *after* as an example. The representation of the *before* relation is identical. We first compute the contextualized representation of each inference similarly to the span representations in Equation 1.

We then stack all the contextualized representations of the inferences:

$$\overrightarrow{A_i} = [\mathrm{ctx}_{a1} \ldots \mathrm{ctx}_{ak}] \quad (2)$$

and input them into a single head attention layer, which produces a single attention-weighted vector for the *after* relation.

In the context of the pairwise scorer, consider that we have two mention spans m_i and m_j and their corresponding *after* inference representations A_i and A_j. We implement two variants of the attention mechanism:

1. *Intra-span*, where the attention is between the mention span m_i and the corresponding inferences $\overrightarrow{A_i}$. This is exemplified in Figure 3, where attention is computed between the mention span of *spend* and the inferences corresponding to the same document. The query vector is the mention span ctx_i, and the key vector is the contextualized *after* vector $\overrightarrow{A_i}$. The idea behind this method is to emphasize inferences that are the most relevant to the given mention and provide additional context.

2. *Inter-span*, where the attention is between the mention span m_i and the inferences generated for the context of the other mention, $\overrightarrow{A_j}$. For example, in Fig 3, this would mean the purple and orange arrows originating in document 1 would need to be moved to the top row of inferences, corresponding to document 2. The query vector is the span ctx_i, and the key vector is the contextualized *after* vector $\overrightarrow{A_j}$. The goal of this method is to emphasize inferences that are relevant to the other mention, and to bring lexically divergent mentions closer.

In both cases, this leads to an attention-weighted commonsense vector for each of the before and after relations, which are then concatenated to create a single commonsense vector $\mathrm{cs}_i = [\overrightarrow{B_i}, \overrightarrow{A_i}]$ as shown in Figure 3. The input to the pairwise scorer for mentions m_i and m_j is therefore:

$$g_{i,j} = [\mathrm{ctx}_i, \mathrm{ctx}_j, \mathrm{cs}_i, \mathrm{cs}_j] \quad (3)$$

The scores from the pairwise scorer are then used to cluster mentions using agglomerative clustering, identically to Cattan et al. (2021a). Agglomerative clustering merges the most similar cluster pairs until their pairwise similarity score falls below a predetermined threshold.

4 Experimental Setup

4.1 Implementation Details

The implementation of our model is based on Cattan et al. (2021a). We use their official codebase[4] and modify it to support the additional components. Since we use gold event mentions to generate inferences from the multi-event commonsense inference engine (Sec 3.1), during both training and inference, we train and evaluate the coreference pipeline on gold mentions. During testing, we evaluate both GPT3 and the coreference system on new gold mentions that are not seen during training. This is in contrast to Cattan et al. (2021a) which learned to extract candidate mention spans and train the coreference system. However, using gold mentions is common practice among many coreference systems where the focus is on improving the pairwise scorer (e.g. Barhom et al., 2019; Yadav et al., 2021a). For a fair comparison, we report the baseline performance by re-running Cattan et al. (2021a) using gold mentions similar to the baseline used in Yadav et al. (2021b). We compare this baseline to two variants of our model, based on intra-span and inter-span attention (Sec 3.2). We train all model versions using 15 different random seeds, and we report the average performance.

For our GPT-3 based inference engine, we fine-tuned the *Davinci* model which we accessed via the OpenAI API.[5]. The hyperparameters for all the models are detailed in Appendix B.

4.2 Evaluation Setup and Metrics

The primary metric we use is the standard CONLL-F_1 implemented by Moosavi and Strube (2016)[6], which is the average of three metrics: B^3 (Bagga

Table 3: Topic-level performance for event coreference on the ECB+ test set (with gold mentions, no singletons) - Baseline, Inter-span (multi-event commonsense), Intra-span (multi-event commonsense)

and Baldwin, 1998), MUC (Vilain et al., 1995), and CEAF$_e$ (Luo, 2005). We follow the evaluation setup used in recent work (Cattan et al., 2021a; Yadav et al., 2021a; Held et al., 2021; Cattan et al., 2021b) and evaluate all our models at the topic level. That is, each metric is computed for each topic separately and averaged across all topics. We also remove singleton clusters (clusters with a single mention) as they have shown to artificially boost the scores when using gold mentions (Cattan et al., 2021a).

5 Evaluation

We discuss the results on the event coreference task (Sec 5.1), the validity of the commonsense inferences generated by our inference engine (Sec 5.2), and present ablation tests (Sec 5.3).

5.1 Results

Table 3 shows the performance of the baseline and the inter-span and intra-span variants of the proposed multi-event commonsense models on event coreference on the ECB+ test set. Both of our proposed variants improve upon the baseline in terms of CONLL-F_1, with our intra-span model yielding an increase of 1.37 (± 0.24) points, and our interspam model yielding an increase of 0.75 (± 0.35). Overall, the improvement in performance indicates that the temporal commonsense inferences helped in resolving a considerable number of coreferences, which we analyze in more detail in Sec 6.1. In particular, both models improve upon the baseline precision across all metrics, with the intra-span model achieving the highest precision across all metrics. Error analysis of the best model (intra-span, Sec 6.2) shows that in some cases when mentions had similar (and possibly generic) inferences, the model falsely classified non-coreferring mentions as coreferring. We hypothesize that this error is more common for the inter-span model. When one mention's inference is lexically similar to the other mention, it would get more attention, increasing the likelihood of a false positive error.

5.2 Human Evaluation of Inferences

We manually evaluate the quality of the commonsense inferences generated by our inference engine (Sec 3.1). We randomly sampled 600 inferences from the validation set. We used the same AMT qualifications as in Sec 3.1 and paid 20 cents per HIT.[7] We presented three workers with a sentence and a target event, followed by the before and after inferences generated by the model. We asked them about the inference's (i) *likelihood*, i.e. how often would the given inference actually occur before (after) the target event; (ii) *relevance* with respect to the context; and (iii) *specificity* of the inference with respect to the target event. Table 4 presents the results. As expected, the generated inferences were almost always relevant to the corresponding event contexts. The majority of inferences (78.8%) were specific to the target event, but there was a significant percent of moderately specific inferences (19.4%) that often pertained to other events in the context. Finally, the majority of inferences either always (58%) or sometimes (36.1%) happen before or after the target event. These results reconfirm the extrinsic gains in Sec 5.1, and suggest that the inference engine may be useful for other NLP tasks. The inter-annotator agreement in terms of Fleiss kappa for the three metrics are as follows: Likelihood = 0.71, Relevance - 0.65, and Specificity - 0.84 (substantial agreement).

5.3 Ablation Tests

In Sec 3.1, we argued that COMET is insufficiently accurate for complex sentences with multiple events. To collect evidence, we replace our GPT-3 based commonsense inference engine with COMET and re-train the event coreference model. We used the newest COMET version (Hwang et al., 2021), along with beam search to decode the top 5 inferences for each relation type (before/after), ranked based on the model's confidence.

In addition, to justify fine-tuning GPT-3, we also

[7] See Appendix E for the HIT template.

	Metric	% High	% Moderate	% Low
1.	Likelihood	58.0	36.1	6.1
2.	Relevance	97.3	0.0	2.7
3.	Specificity	78.8	19.4	1.8

Table 4: Human evaluation results for the inferences generated by our commonsense inference engine.

Model	**Inter-span**	**Intra-span**
Baseline (no inf.)	61.3 ± 0.31	
COMET	61.51 ± 0.21	61.39 ± 0.32
GPT-3 few-shot	61.59 ± 0.26	61.64 ± 0.35
GPT-3 FT (ours)	62.05 ± 0.35	62.67 ± 0.24

Table 5: CONLL-F_1 performance on the ECB+ test set using different event commonsense knowledge sources.

replace our multi-event commonsense inference engine with a few-shot version of the model. We randomly sampled 8 of the human-written inferences (Sec 3.1) to prompt GPT-3, and we used the same instructions to prompt it to generate before and after inferences. In all experiments, the rest of the model is as described in Sec 3.2.

Table 5 presents the ablation results. The COMET-based model shows a marginal improvement from the baseline, yet performs worse than the multi-event inference engine. The few-shot GPT-3 model performs better, but we discovered that more training data could improve the specificity and accuracy of the inferences. Finally, our fine-tuned GPT-3 inference engine outperforms all models, thanks to its explicit training on multi-event inferences.

6 Analysis

6.1 Attention Scores

Figure 4 presents an example of a mention pair (*drunken driving*, *DUI*) that was incorrectly predicted as non-coreferring by the baseline and correctly predicted as coreferring by the intra-span model. The inferences for each mention are sorted and highlighted according to their corresponding attention weights. The highest scoring *before* inference for the first mention, "Jamal is drinking and driving", and the second inference for the second mention "Wiliams drank alcohol", are similar, which likely contributed to recognizing the coreference. Figure 5 similarly shows an example that was incorrectly predicted as non-coreferring by the baseline and correctly predicted as coreferring by the inter-span model. Here, we can clearly observe the interplay between the second mention *drove off* and the inferences of the first mention *hit* related to driving and fleeing from the scene. The lexical and contextual diversity of these mentions necessitates commonsense inferences to resolve the coreference. Appendix C provides a second set of examples.

Category	**%**
① Lack of Structure	29.5
② Generic Inferences	24.6
③ Insufficient Knowledge	19.5
④ Incorporation	18.1
⑤ Attention	8.3

Table 6: Error analysis of the intra-span model.

6.2 Error analysis

We analyze the errors in the best version of our model (intra-span). 95% of the errors made by this model overlapped with the errors made by the baseline, and only 5% were newly-introduced. We sampled 100 errors from the validation set and manually categorized them into the following categories, detailed below and quantified in Table 6. See Appendix D for examples from each category.

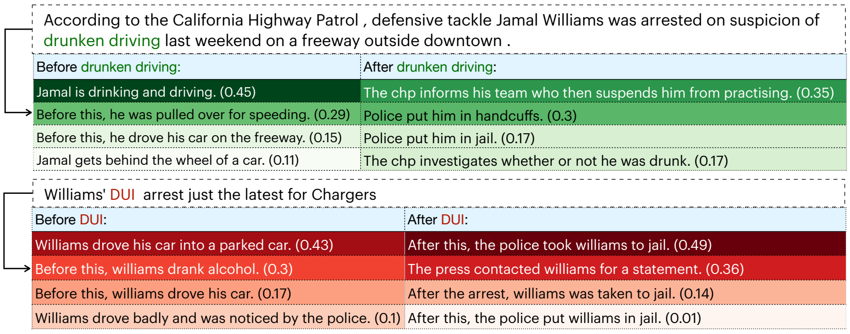
① **Lack of Structure**: Similar or identical mentions may refer to different events, as in "*Jackman* hosting the Academy awards" vs. "*Ellen* hosting the Oscars". Previous work incorporated semantic roles into the mention representation to identify such cases (Barhom et al., 2019). Our baseline model, as well as the inferences from our proposed approach, do not explicitly incorporate any linguistic structure, which results in these errors.

② **Generic Inferences**: The generated commonsense inferences are not specific enough with respect to the target event. This causes both false positive errors, when a pair of non-corefering mentions have similar generic inferences; and false negative errors, when coreferring mentions have dissimilar generic inferences.

③ **Insufficient Knowledge**: The inferences are relevant to the target event, but don't contain all the knowledge required to resolve these coreferences.

④ **Incorporation**: The inferences and attention scores were accurate, but the model did not use them effectively during incorporation.

⑤ **Attention**: The model either attended too much to unnecessary inferences (weights close to 1) or ignored crucial inferences (weights close to 0).



According to the California Highway Patrol , defensive tackle Jamal Williams was arrested on suspicion of drunken driving last weekend on a freeway outside downtown .

Before drunken driving:	After drunken driving:
Jamal is drinking and driving. (0.45)	The chp informs his team who then suspends him from practising. (0.35)
Before this, he was pulled over for speeding. (0.29)	Police put him in handcuffs. (0.3)

The police are informed that a drunken driver escaped. (0.12)	The driver drove home. (0.29)
Before , the driver realized that the victim is dead. (0.09)	After , the driver drove home. (0.25)
The driver realized that the victim is dead. (0.05)	The police investigate the accident. (0.14)

Figure 5: An example mention pair and the inter-span attention weights between the contexts and the inferences.

7 Conclusions

In this paper, we investigated the effect of injecting temporal commonsense knowledge in the task of event coreference resolution. By using event-specific inferences generated by our commonsense model, we improve the performance of a baseline model. Our analysis shows that the pairwise scorer attends to inferences that are beneficial in solving challenging coreferences. In the future, we plan to extend the multi-event commonsense model to additional relations, and to incorporate such knowledge into other discourse tasks.

8 Limitations

Data. As shown by Barhom et al. (2019), ECB+ suffers from annotation errors. In particular, the event coreference annotations are incomplete, which might lead to false positive errors for truly coreferring mention pairs. In this work, we intentionally addressed the edge cases in event coreference that haven't been addressed by prior research: lexically/contextually-divergent mentions. The number of such corefering clusters in ECB+ is small, and it has been shown that just clustering together mention pairs with the same lemma yields an F1 score of 42.3 on the dataset (Upadhyay et al., 2016). Further, our analysis of corefering pairs on the validation set revealed that only 11% of the pairs were contextually dissimilar (cosine similarity below 0.9), indicating that commonsense may impact only these cases. Unfortunately, this is the standard dataset for event coreference, but in the future, we could think of collecting a more challenging (and realistic) dataset.

Models. The accuracy of the commonsense model is primarily limited by the accuracy of inferences from GPT-3. Marcus and Davis (2020) tested GPT-3 on various types of commonsense reasoning and found mixed results for temporal commonsense. Our human evaluation in Sec 5.2 revealed that GPT-3 generates inferences that are not specific enough to the target event in 19.3% of the cases, which decreases performance as shown in Sec 6.2. We aim to address this in future work by building a more robust multi-event commonsense engine. Another error our model doesn't address concerns semantic roles, which happens when the main difference is in the person, time or location (e.g. two earthquake reports in different times and locations) (Barhom et al., 2019).

Evaluation. Since our commonsense engine was trained with gold event mentions, we used gold mentions to evaluate the coreference model as well. Using predicted mentions instead of gold mentions would provide a more realistic estimate of the performance of an event coreference system. With that said, our work focused on improving the coreference decisions; hence, we followed previous work and used the gold mentions (Barhom et al., 2019; Held et al., 2021).

10 Appendix

A Multi-Event Commonsense Inference Engine

B Hyper-Parameters

Table 8 shows the hyperparameters used by all our models. It took an average time of *120* minutes to run the entire pipeline for the inter-span and inter-span versions, and an average time of *80* minutes for the baseline version. We used a single NVIDIA GeForce GTX 1080 Ti GPU for each run. It took 5 minutes to fine-tune the GPT-3 Davinci model and costed 170 USD for training and generating all the inferences.

```
Context: Rumored to be the front runner earlier in the week , Entertainment Weekly has now confirmed
that Chris Weitz will direct the sequel to Twilight , New Moon , replacing Catherine Hardwicke.

Event: replacing

Before: They could not strike a favorable deal with Catherine Hardwicke. They decided to replace him.
Before this, the film's executive producer contacted Weitz's agent. Before this, Weitz's agent
communicated the director's message.

After: Chris Weitz received an advance from the studio. Chris signed the contract. After, his agent
put out a press release. Chris was happy. END
```

```
Context: Lindsay Lohan checks into rehab at Betty Ford Center , rehires longtime lawyer Shawn Holley

Event: rehires
```

Table 7: Examples of the input format of the multi-event commonsense inference engine. Top: a training example is fed into GPT-3 with the inputs (context and event) and the outputs (before and after inferences). Bottom: a test example is fed with only the inputs (context and event).

Parameter	Value
Batch Size	128
Learning Rate	0.0001
Dropout	0.3
Optimizer	Adam
Hidden layer	1024
Attention heads	1

Table 8: Hyperparameters used by all three model versions-Baseline, Inter-span and Intra-Span

C Attention Scores

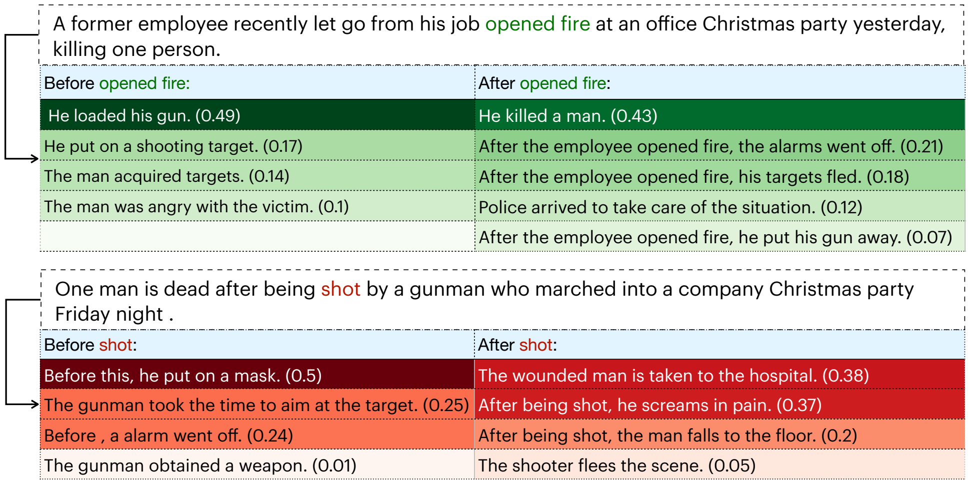
In Figures 6 and 7, we provide examples for mention pairs incorrectly predicted by the baseline and correctly predicted by the intra-span and inter-span models, repsectively, similarly to Sec 6.2.

D Error Analysis

Table 9 shows one example of each error category described in Sec 6.2.

E Crowdsourcing Templates

Figures 8 and 9 show the HIT templates used for obtaining inference annotations and evaluating generated inferences, respectively.



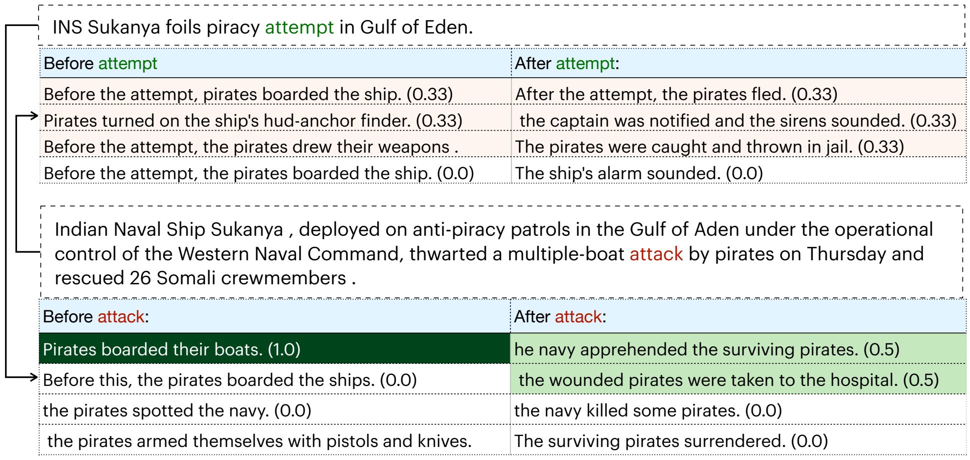
A former employee recently let go from his job opened fire at an office Christmas party yesterday, killing one person.

Before opened fire:	After opened fire:
He loaded his gun. (0.49)	He killed a man. (0.43)
He put on a shooting target. (0.17)	After the employee opened fire, the alarms went off. (0.21)
The man acquired targets. (0.14)	After the employee opened fire, his targets fled. (0.18)
The man was angry with the victim. (0.1)	Police arrived to take care of the situation. (0.12)
	After the employee opened fire, he put his gun away. (0.07)

One man is dead after being shot by a gunman who marched into a company Christmas party Friday night .

Before shot:	After shot:
Before this, he put on a mask. (0.5)	The wounded man is taken to the hospital. (0.38)
The gunman took the time to aim at the target. (0.25)	After being shot, he screams in pain. (0.37)
Before , a alarm went off. (0.24)	After being shot, the man falls to the floor. (0.2)
The gunman obtained a weapon. (0.01)	The shooter flees the scene. (0.05)

Figure 6: An example mention pair and the intra-span attention weights between the contexts and the inferences.



INS Sukanya foils piracy attempt in Gulf of Eden.

Before attempt	After attempt:
Before the attempt, pirates boarded the ship. (0.33)	After the attempt, the pirates fled. (0.33)
Pirates turned on the ship's hud-anchor finder. (0.33)	the captain was notified and the sirens sounded. (0.33)
Before the attempt, the pirates drew their weapons .	The pirates were caught and thrown in jail. (0.33)
Before the attempt, the pirates boarded the ship. (0.0)	The ship's alarm sounded. (0.0)

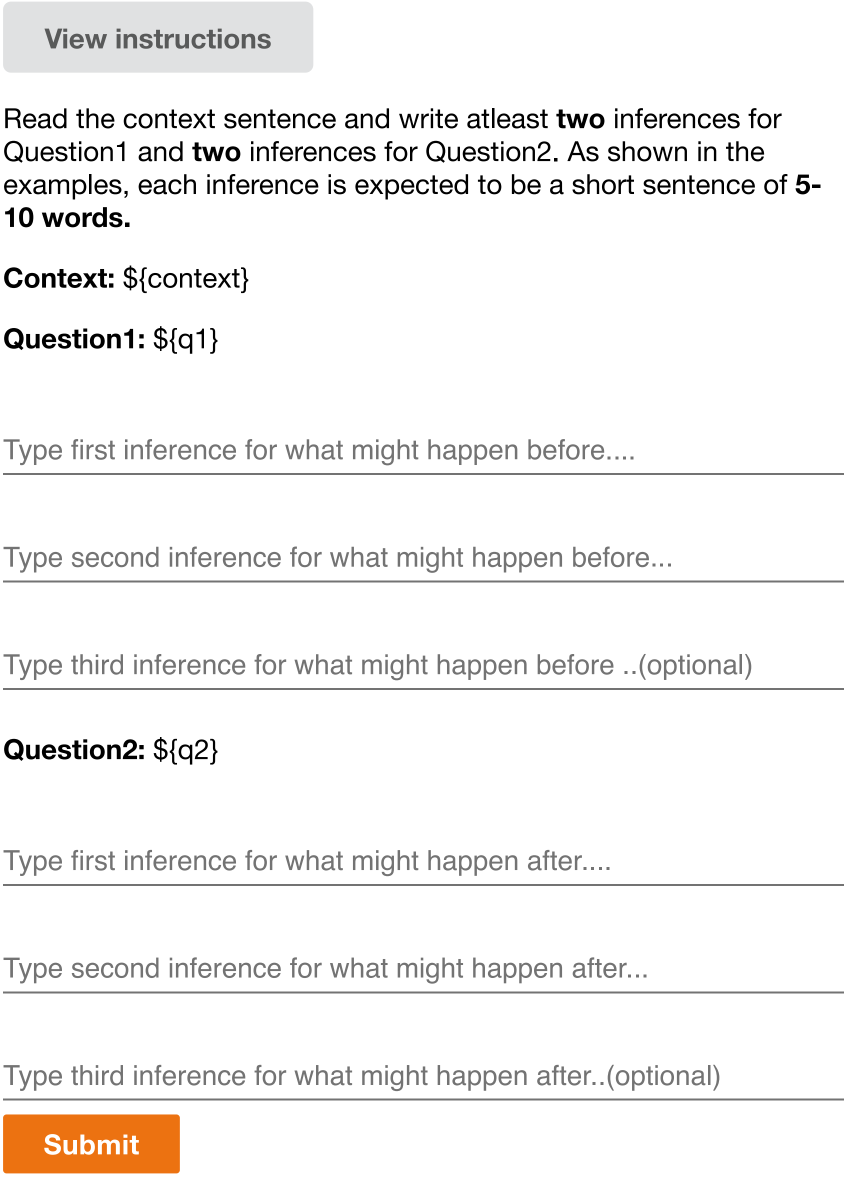
Indian Naval Ship Sukanya , deployed on anti-piracy patrols in the Gulf of Aden under the operational control of the Western Naval Command, thwarted a multiple-boat attack by pirates on Thursday and rescued 26 Somali crewmembers .

Before attack:	After attack:
Pirates boarded their boats. (1.0)	he navy apprehended the surviving pirates. (0.5)
Before this, the pirates boarded the ships. (0.0)	the wounded pirates were taken to the hospital. (0.5)
the pirates spotted the navy. (0.0)	the navy killed some pirates. (0.0)
the pirates armed themselves with pistols and knives.	The surviving pirates surrendered. (0.0)

Figure 7: An example mention pair and the inter-span attention weights between the contexts and the inferences.

Context	Before	After
① Lack of Structure: Different arguments (Robert Buckley vs Duncan Rait), similar event mentions and contexts.		
Robert Buckley the second climber to die in the Aoraki - Mount Cook national park.	He slipped and fell down. (0.68)	The bodies of the climbers are found by the other climbers. (1.0)
	He set out to climb a mountain. (0.19)	The families of the two climbers are notified. (0.0)
	He was exhausted from the trek. (0.13)	the police investigate his cause of death. (0.0)
The day before Buckley's death another climber Duncan Rait, died after slipping and falling [...].	Before this, the climber slipped and fell. (0.5)	A rescue team went to look for the climber. (0.5)
	The climber had an accident. (0.5)	A funeral is held for the dead body. (0.5)
	Before this, the climber sustained injuries. (0.0)	the climber was pronounced dead. (0.0)
② Generic error - Inferences of the first event (crash) are not specific and accurate.		
Man charged with DWI , leaving scene after S . Rich Hill mother killed in crash : NYPD	They spotted a car on fire. (0.35)	They called the fire department. (0.41)
	She swerved to avoid a cat crossing the road. (0.33)	Her family had to deal with the death. (0.34)
	The driver got into an accident. (0.22)	Police arrived on the scene. (0.18)
	The car collided with the rich hill mother. (0.05)	She was taken to the hospital. (0.07)
	The rich hill mother is driving her car. (0.05)	
Woman Killed in Queens Hit - Run , Driver Charged	He changed his mind and decided to go forward with the plan. (0.46)	The woman is killed. (0.64)
	A driver wants to kill the woman. (0.27)	They file a case against the driver. (0.11)
	A driver sees the woman. (0.15)	The driver gets worried about the consequence. (0.1)
	He gets scared and attempts to flee the scene. (0.06)	The woman is denied basic rights. (0.08)
	He flees the scene. (0.06)	The woman is denied a burial. (0.08)
③ Insufficient knowledge error- More knowledge may be beneficial (*e.g.*pre-requisites of events)		
MSNBC is reporting that the Indian Navy claims they have captured 23 pirates in the Gulf of Aden	The navy ships noticed the pirates. (0.33)	The captured pirates were taken to prison. (0.25)
	They boarded the ship. (0.33)	They will decide what to do with them. (0.25)
	The captain ordered an alert. (0.33)	the captain signaled the all-clear. (0.25)
	The navy ships surrounded the pirates. (0.0)	The navy notified the police about the capture. (0.25)
The Indian Navy on Saturday prevented pirates from attacking a merchant vessel[..] took 23 into custody.	They planned to attack the ship. (0.33)	The navy handed them over to the police. (0.33)
	The pirates hid their weapons. (0.33)	The navy interrogate them (0.33)
	The navy received a distress call from the ship. (0.33)	The navy took them to a different place (0.33)
④ Incorporation error - Inferences seem relevant, but the model fails to use them.		
5 Thoughts on Why the Academy Picked Ellen DeGeneres As Oscar Host	Ellen accepted to host the Oscars. (0.36)	Ellen feels happy(0.34)
	Ellen was practicing out ideas.(0.36)	The host gets paid. (0.26)
	Ellen DeGeneres was selected as the host. (0.19)	Ellen was given a plaque of honor. (0.22)
	They academy contacted Ellen(0.09)	
	The audience clapped for Ellen. (0.18)	
It will be her second stint in the job , after hosting the 2007 ceremony and earning an Emmy nomination for it	She practiced her speech. (0.32)	The press contacted her for interviews. (0.55)
	She contacted her suppliers about a new gown for the show. (0.48)	She was very happy. (0.23)
	She was effective in her duties. (0.1)	She informed her staff about the nomination. (0.12)
	She was nominated for hosting the 2007 ceremony. (0.05)	She bought some new clothes. (0.1)
⑤ Attention error: Increased attention on irrelevant inferences (first inference)		
Woman Killed in Queens Hit - Run , Driver Charged	The driver came into contact with the woman. (1.0)	The driver flees the scene of the collision. (1.0)
	The person driving a vehicle saw the woman and pursued, not caring about the person's safety. (0.0)	The woman is injured. (0.0)
	The driver and the woman crossed paths.(0.0)	The woman is hospitalized. (0.0)
	The driver drove his vehicle at the woman. (0.0)	The driver tried to hide his involvement in the crime. (0.0)
Cops : Queens Woman Killed In Hit - And - Run	A car flees the scene. (0.34)	They put out an alert to look for him. (0.28)
	A car crashes into a dying woman. (0.26)	They put out a press release calling for information. (0.28)
	They searched the area the car was spotted in. (0.21)	They arrested him. (0.22)
	They interviewed neighbors who might have seen them. (0.2)	The criminal went to court (0.22)

Table 9: An example of each error category described in Sec 6.2



Read the context sentence and write atleast **two** inferences for Question1 and **two** inferences for Question2. As shown in the examples, each inference is expected to be a short sentence of **5-10 words.**

Context: ${context}

Question1: ${q1}

Type first inference for what might happen before....

Type second inference for what might happen before...

Type third inference for what might happen before ..(optional)

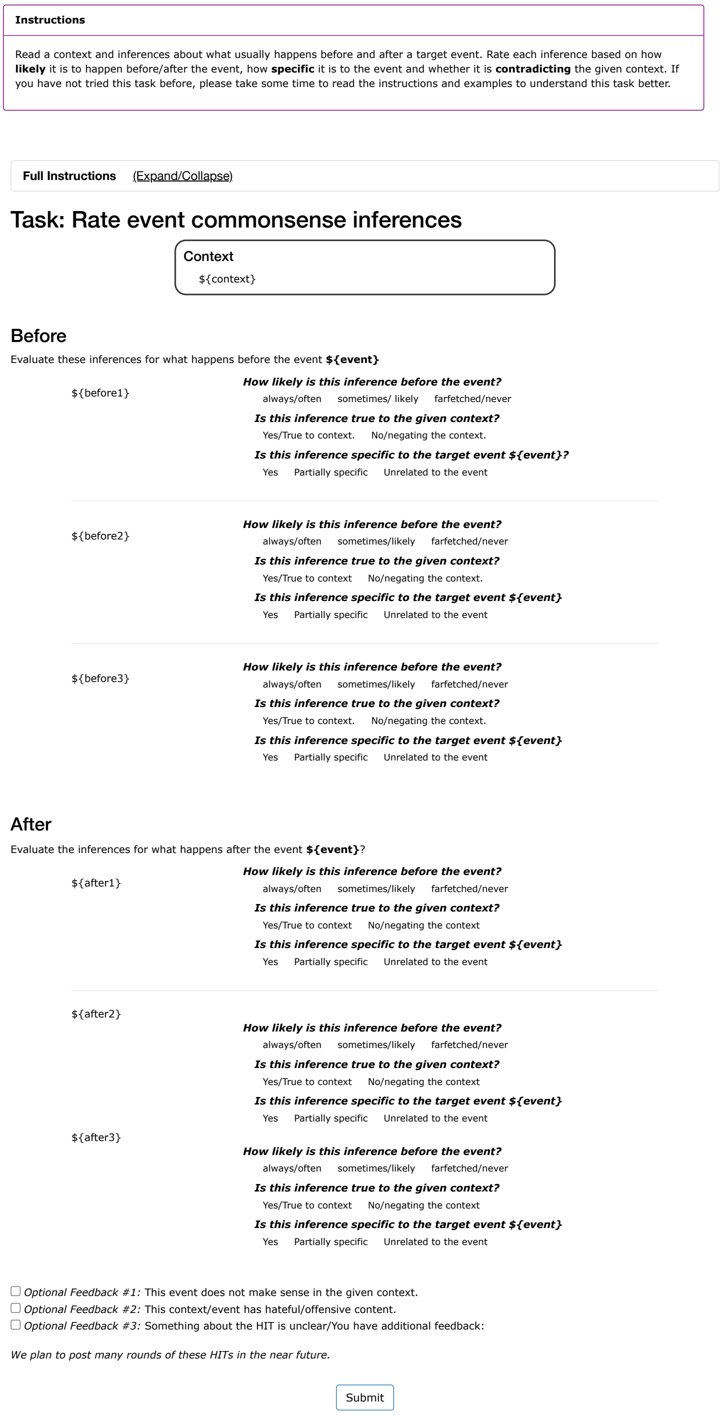
Question2: ${q2}

Type first inference for what might happen after....

Type second inference for what might happen after...

Type third inference for what might happen after..(optional)

Figure 8: Crowdsourcing template for obtaining before and after inferences.



Instructions

Read a context and inferences about what usually happens before and after a target event. Rate each inference based on how **likely** it is to happen before/after the event, how **specific** it is to the event and whether it is **contradicting** the given context. If you have not tried this task before, please take some time to read the instructions and examples to understand this task better.

Full Instructions (Expand/Collapse)

Task: Rate event commonsense inferences

Context
${context}

Before

Evaluate these inferences for what happens before the event **${event}**

${before1}

How likely is this inference before the event?
always/often sometimes/ likely farfetched/never

Is this inference true to the given context?
Yes/True to context. No/negating the context.

Is this inference specific to the target event ${event}?
Yes Partially specific Unrelated to the event

${before2}

How likely is this inference before the event?
always/often sometimes/likely farfetched/never

Is this inference true to the given context?
Yes/True to context No/negating the context.

Is this inference specific to the target event ${event}
Yes Partially specific Unrelated to the event

${before3}

How likely is this inference before the event?
always/often sometimes/likely farfetched/never

Is this inference true to the given context?
Yes/True to context. No/negating the context.

Is this inference specific to the target event ${event}
Yes Partially specific Unrelated to the event

After

Evaluate the inferences for what happens after the event **${event}**?

${after1}

How likely is this inference before the event?
always/often sometimes/likely farfetched/never

Is this inference true to the given context?
Yes/True to context No/negating the context

Is this inference specific to the target event ${event}
Yes Partially specific Unrelated to the event

${after2}

How likely is this inference before the event?
always/often sometimes/likely farfetched/never

Is this inference true to the given context?
Yes/True to context No/negating the context

Is this inference specific to the target event ${event}
Yes Partially specific Unrelated to the event

${after3}

How likely is this inference before the event?
always/often sometimes/likely farfetched/never

Is this inference true to the given context?
Yes/True to context No/negating the context

Is this inference specific to the target event ${event}
Yes Partially specific Unrelated to the event

☐ *Optional Feedback #1:* This event does not make sense in the given context.
☐ *Optional Feedback #2:* This context/event has hateful/offensive content.
☐ *Optional Feedback #3:* Something about the HIT is unclear/You have additional feedback:

We plan to post many rounds of these HITs in the near future.

Figure 9: Crowdsourcing template for rating before and after inferences.

Multi-Modal Bias: Introducing a Framework for Stereotypical Bias Assessment beyond Gender and Race in Vision–Language Models

Abstract

Recent breakthroughs in self-supervised training have led to a new class of pretrained vision–language models. While there have been investigations of bias in multimodal models, they have mostly focused on gender and racial bias, giving much less attention to other relevant groups, such as minorities with regard to religion, nationality, sexual orientation, or disabilities. This is mainly due to lack of suitable benchmarks for such groups. We seek to address this gap by providing a visual and textual bias benchmark called MMBias, consisting of around 3,800 images and phrases covering 14 population subgroups. We utilize this dataset to assess bias in several prominent self-supervised multimodal models, including CLIP, ALBEF, and ViLT. Our results show that these models demonstrate meaningful bias favoring certain groups. Finally, we introduce a debiasing method designed specifically for such large pretrained models that can be applied as a post-processing step to mitigate bias, while preserving the remaining accuracy of the model.

1 Introduction

The recent emergence of large pretrained vision–language models has revolutionized many multimodal tasks previously considered impractical to solve. Although architectures capable of jointly addressing computer vision and NLP tasks using a single unified model have been around for a while (Lu et al., 2019; Tan and Bansal, 2019; Li et al., 2019), recent advances in self-supervised training methods have amplified the significance and applicability of such models. The sheer power of these methods is highly dependent on the scale of the model and the diversity and distributional properties of the dataset on which they are trained. Due to their wide range of diverse applications (Eslami et al., 2021), it is of utmost importance to be aware of the shortcomings of vision–language pretrained (VLP) models as well as their capabilities.

One such limitation is that, like any other machine learning system, multimodal models may be prone to exhibiting human-like stereotypical biases such as gender or race-related stereotypes (Nadeem et al., 2020; Garrido-Muñoz et al., 2021). For instance, pretrained language models have been shown to associate male-gendered phrases and sentences to a greater extent with certain high-paying professions and even with individual traits such as intelligence, in comparison to female-gendered phrases (Wang et al., 2021a). Similarly, it has been found that Hispanic and African American names may be tied to words representing danger and crime more often than Caucasian names (Manzini et al., 2019). Certain biases have also been identified in computer vision models as well (Wang et al., 2019). Such biases are discriminatory towards affected population groups and can be extremely harmful to society the more these models are deployed in real-world applications.

While there has been some research aimed at identifying and addressing biases in vision–language models, most such studies have focused on gender and racial biases, while other notable groups such as religious minorities, national minorities, LGBTQ people, and people with disabilities have received much less attention, despite their legal status as protected groups in the US. This is alarming considering the fact that the potentially affected groups together constitute a considerable part of the global population. For instance, the US Census Bureau reported approximately 40 million people identifying as immigrants in the US and 244 million world-wide as of 2015.[1] Furthermore, approximately 40 million people in the US and about 1 billion people in the world suffer from some sort of disability.[2] One of the main obstacles for bias analysis of these relevant population groups has been the lack of standardized benchmark datasets

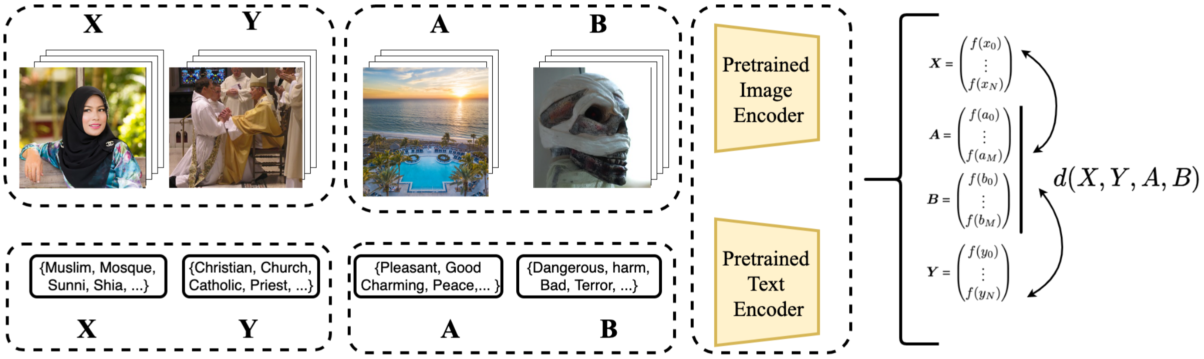

Figure 1: Experiment pipeline. We feed target and attribute data to the model. The embeddings obtained from pretrained encoders are then used to measure bias metrics between visual and textual stimuli following Eq. 1.

that specifically enable an analysis of how they may be affected. In this paper, we attempt to address this problem by gathering and releasing a visual and textual bias benchmark called MMBias, consisting of approximately 3,500 images and 350 phrases covering over 14 minority subgroups. Furthermore, we utilize the dataset to measure stereotypical bias in several prominent self-supervised multimodal VLP models that have attracted significant attention recently, namely OpenAI CLIP (Radford et al., 2021), ALBEF (Li et al., 2021), and ViLT (Kim et al., 2021). In our experiments, we quantify the bias present in these models, including both cross-modal and intra-modal bias. Our results confirm that these models harbor meaningful biases favoring certain groups. Finally, we introduce a novel debiasing method designed for such large pretrained models that can be applied as a post-processing step to mitigate bias, and we show that this step does not adversely affect the performance in a substantial way.

2 Related Work

The majority of work on language models only focuses on gender and racial bias assessment (Guo and Caliskan, 2021; Bordia and Bowman, 2019). However, there have been some studies that consider bias with regard to other categories such as profession, religion, and disability as well (Nadeem et al., 2020; Hutchinson et al., 2020). However, these forms of bias are not just exclusive to the language domain, and image classifiers as well as multimodal models have also been shown to demonstrate such biases (Srinivasan and Bisk, 2021; Ross et al., 2020).

Thus far, there has been rather limited work on multimodal bias assessment of self-supervised models such as CLIP, and prior work considers only gender and racial biases. Wang et al. (2021b) measures the gender and racial bias in CLIP's image classification module using the Fairface dataset, while Wang et al. (2021a) further show that CLIP associates male-gendered phrases to high-paying professions more than female-gendered phrases. Agarwal et al. (2021) provide insights towards potential applications of the CLIP model and further study and evaluate its gender/racial bias as well as measuring the misclassification differences between different subgroups. Bhargava and Forsyth (2019) measure and propose solutions to gender bias in several image captioning systems.

The only work that addresses other relevant groups such as religion, sexual orientation, and disability in the image space is Steed and Caliskan (2021). However, the data considered in the study is limited, consisting of only around 600 images, out of which around 500 again correspond to gender and racial biases. This leaves only around 100 for other protected groups, i.e., fewer than 20 images for each protected group study. Sirotkin et al. (2022) use this limited dataset to measure bias in several self-supervised visual models but the authors do not explore multimodal models such as CLIP. An orthogonal line of research has been pursued in Zhou et al. (2022), where several multimodal vision-language models are analyzed to measure these models' tendency to pick stereotypical statements as captions for anti-stereotypical images in pre-trained vision-language models. With MMBias, we thus hope to enable further research on diverse forms of bias in vision–language models.

Figure 2: Sample images from the MMBias dataset. Each row corresponds to one of the target classes: religion, nationality, disability, and sexual orientation. Images are compiled from the image sharing service Flickr.

3 Methodology

Bias and Fairness. In conventional social studies, one of the most well-established and widely-investigated forms of biases is what is known as implicit bias, or as social stereotypes, defined and investigated in Greenwald and Banaji (1995). This type of bias is usually measured using Implicit Associate Testing (IAT), introduced in the seminal work of (Greenwald et al., 1998), and has so far been widely used to describe and account for a wide range of implicit prejudices (Kiefer and Sekaquaptewa, 2007). IAT experiments quantify human implicit bias by measuring response times differences when human subjects are asked to pair similar concepts and different concepts. In its original form, IAT was used to to measure the degree of *pleasantness* (a.k.a. *valence* in psychology), of entities such as “flowers” and “insects” by pairing them with abstract attributes such as *pleasant* and *unpleasant* (Russell, 2003). Caliskan et al. (2017) showed that a similar IAT testing paradigm can be applied to bias measurement in deep embeddings. In this approach, instead of subject reaction time, the proximity of embeddings of a basket of words that represent a concept is measured. Furthermore, word sentiment is usually used to represent valence, due to well-established studies linking word sentiment with the psychological concept of valence (Mohammad, 2016). The experimental methodology used in our study follows similar principles.

More generally, a machine learning system may be deemed *unbiased* or *fair* when its predictions do not favor members of any relevant population group or discriminate against any other (Garrido-Muñoz et al., 2021). For instance, suppose that the class under consideration is religion and we are evaluating *pleasantness* / *unpleasantness* scores a system would assign to each considered religious subgroup. A machine learning system is assessed as fair if and only if the scores it assigns to different religious subgroups do not differ substantially.

More formally, in a bias study, the two subgroups under study, also known as target entities, may be represented as sets of instances $\boldsymbol{X} = \{x_1, x_2, ..., x_N\}$ and $\boldsymbol{Y} = \{y_1, y_2, ..., y_N\}$. For example, $\boldsymbol{X}$ may be images corresponding to Islam and $\boldsymbol{Y}$ to Christianity. Furthermore, the attributes towards which the bias is being measured may be given as sets $\boldsymbol{A} = \{a_1, a_2, ..., a_M\}$ and $\boldsymbol{B} = \{b_1, b_2, ..., b_M\}$. For example, $\boldsymbol{A}$ could be a set of words representing *pleasantness*, while $\boldsymbol{B}$ represents *unpleasantness*. Similarly, many gender-bias studies consider sets for *high paying* vs. *low paying* professions as attribute sets. A machine learning model is then said to be fair towards subgroups $\boldsymbol{X}$ and $\boldsymbol{Y}$ with respect to attributes $\boldsymbol{A}$ and $\boldsymbol{B}$ if and only if $\phi(\boldsymbol{X}, \boldsymbol{A}, \boldsymbol{B}) \approx \phi(\boldsymbol{Y}, \boldsymbol{A}, \boldsymbol{B})$, where ϕ is some scoring function that scores the similarity of the sets of attributes $\boldsymbol{A}$, $\boldsymbol{B}$ to a target entity $\boldsymbol{X}$ or $\boldsymbol{Y}$.

Scoring Functions. There can be different choices for the scoring function ϕ above. Caliskan et al. (2017) introduced the *Caliskan* test shown below in Eq. 1, with ϕ capturing the difference of the mean of cosine distances between targets and attributes. This method is ideal for the analysis of models such as CLIP, since they operate directly on entity embeddings. The effect size represented by $d(X, Y, A, B)$ is a measure of the magnitude of the bias. Larger numbers indicate a stronger bias, while the sign reflects which target entity the attributes show a stronger bias towards.

However, for vision–language fusion models that do not provide explicit access to separate image/text embeddings, an alternative scoring function can be defined as the difference in the image–text matching probabilities, as in the last row of Eq. 1. Sets $\boldsymbol{X}$ and $\boldsymbol{Y}$ as well as $\boldsymbol{A}$ and $\boldsymbol{B}$ are usually constructed to have equal number of samples.

$$d = \frac{\underset{x \in X}{\text{mean}}\, \phi(x, A, B) - \underset{y \in Y}{\text{mean}}\, \phi(y, A, B)}{\underset{w \in X \cup Y}{\text{std-dev}}\, \phi(w, A, B)} \tag{1}$$

$$\phi(w, A, B) = \underset{a \in A}{\text{mean}}\ \cos(w, a) - \underset{b \in B}{\text{mean}}\ \cos(w, b)$$

$$\phi(w, A, B) = \underset{a \in A}{\text{mean}}\ \sigma(w, a) - \underset{b \in B}{\text{mean}}\ \sigma(w, b)$$

Here, $\cos(\cdot, \cdot)$ denotes the cosine similarity of vectors, while $\sigma(\cdot, \cdot)$ denotes the probability of a text and image pair being a match.

Evaluation Pipeline Fig. 1 shows the pipeline followed in our experiments. The target and attribute stimuli are fed into the model and embeddings it emits are used to compute the bias score.

4 The MMBias Dataset

The majority of the work on societal bias analysis so far focuses on unimodal language models. Although there has been some limited work on multimodal models, these studies mainly focus on gender and racial disparities. As a result, bias with regard to other classes, including religion, nationality, sexual orientation, and disability have largely been unexplored. This has been mainly due to the lack of standardized benchmark datasets that specifically target these minority groups. To address this concern, we gather and release the first multimodal dataset of this size in this line of research that spans over a wider range of groups. We hope that this dataset can serve as a benchmark in future research.

Our dataset, referred to as **MMBias**, contains 3,500 target images and 350 English phrases corresponding to different target concepts. Each target category has 250 corresponding images obtained from the popular image uploading website Flickr. Our dataset also contains 20 textual phrases related to each target concept, used for bias experiments in the textual domain.

Target Concept $\boldsymbol{X}$	Target Values $\{x_1, ..., x_N\}$
Religion	Islam, Christianity, Judaism, Buddhism, Hinduism
Nationality	American, Arab, Chinese, Mexican
Disability	Physical disability, Mental disability, No disability
Sexual Orientation	Homosexual, Heterosexual

Table 1: MMBias spans over 4 target classes and 14 target groups including 5 major religions, 4 nationalities, 2 forms of disability and sexual orientations.

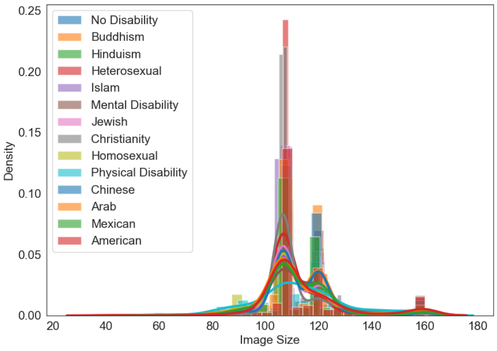

Figure 3: Gaussian distribution of the image sizes scaled by a factor of 1,000. Most images are sized around 340x340 pixels.

Data Compilation For gathering the image data, we invoke the Flickr API and retrieve 1,000 most relevant images for each target concept using 10–12 search keywords for each. The keywords are chosen to be as diverse as possible to minimize any potential bias in the data gathering process to the extent possible. Then human annotators are used to filter out noisy images. Annotators were instructed to manually eliminate irrelevant or explicit content as well as images that contained private information or names/addresses. In order to balance the dataset, 250 images were randomly chosen for each concept out of the filtered images, and we only consider images with a Creative Commons license. The processing pipeline and quality control is similar to the one used for the creation of Flickr30k (Young et al., 2014). Furthermore, the textual part of the dataset contains phrases such as "This is *X*." replacing *X* with a "Muslim person", "Christian person", etc. The same aforementioned keywords were used to retrieve textual data for each concept using the RelatedWords site[3] followed by a similar data cleaning and noise filtering process.

Table 1 shows the classes MMBias covers as well as the considered groups in each class. MMBias spans over 4 target classes, including religion, national origin, disability, and sexual orientation. In this study, we did not include gender and race, as there is already a large body of work focusing on them. For religion, our dataset includes the 5

---

[3] relatedwords.org/

major religions in the world today: Islam, Christianity, Judaism, Buddhism, and Hinduism. As for the national origin, MMBias includes images corresponding to the four nationalities: American (USA), Chinese, Arab[4] (collectively), and Mexican. Furthermore, another two additional nationalities, French and Italian, are also included in the textual phrases in addition to the former. As for disability, MMBias contains images for two common forms of disability: physical disability, mental disability as well as people with no disability. In addition to these, the textual data includes phrases corresponding to visual disability and hearing disability as well. Finally, the two most common types of sexual orientations, homosexuality and heterosexuality, are included in MMBias. The selection of subgroups as well as their pairings was a result of consulting several social studies that show present bias against people with disabilities (Dovidio et al., 2011), homosexuals (Hebl et al., 2002), certain nationalities (Park et al., 2007; Buriel and Vasquez, 1982) and religions (Abid et al., 2021; Rowatt et al., 2005; Rudman and Ashmore, 2007). However, we plan to extend our data to a larger pool of classes and respective subgroups in the future.

Finally, in order to conduct intra-visual bias studies, MMBias also contains two sets of images corresponding to visual pleasantness and unpleasantness, called the valence dataset. These sets were constructed by following a similar method to Steed and Caliskan (2021), retrieving images corresponding to pleasant concepts such wealth, peace, babies, love, butterflies, etc. and unpleasant concepts such as death, injury, prison, fear, etc.

Analysis. Fig. 2 provides some sample images taken from the dataset. Each row shows a different target class. Fig. 3 provides deeper insights into the sizes of the crawled images. The x-axis reflects the surface area of the image in pixels, scaled by a factor of 1,000. As can be seen, image sizes in most classes follow a normal distribution with a mean of around 110,000 pixels, translating to approximately 340x340 images, with the exception of images corresponding to the nationality class, which have a slightly higher mean of around 350x350. The height and width of images does not vary substantially across the dataset.

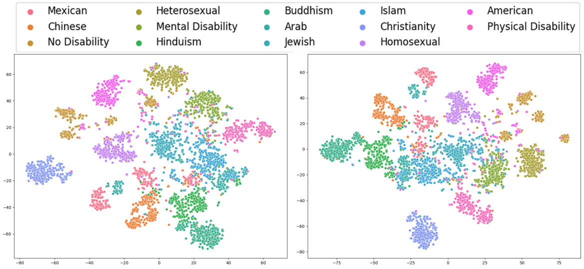

Figure 4: t-SNE representation of image embeddings. Left shows embedding clusters before bias mitigation. Right shows embedding clusters after bias mitigation. Both cases show well-separated clusters, suggesting bias mitigation has negligible effects on cluster separability.

Furthermore, we analyze the separability of our dataset with regards to image classes. The images are fed into the CLIP model and the first 100 principal components are extracted from the resulting embeddings, and then t-SNE is applied. Fig. 4 shows the t-SNE representation of the images. We observe that the dataset can be well-separated forming clearly-defined clusters. For instance, we notice that different religions form well-separated clusters. Interestingly the clusters that are more intertwined correspond to correlated subjects such as the religion Islam and the Arab nationality designation. This is not surprising given Islam is particularly prevalent in Arab countries and thus many of the images share similar features.

5 Experimental Evaluation

We have conducted three sets of experiments to assess and quantify the bias in the aforementioned models: CLIP, ALBEF, and ViLT. The following sections explain the details of each setting.

5.1 OpenAI CLIP

CLIP is a multimodal vision–language embedding model originally devised for zero-shot classification of images. It utilizes a self-supervised contrastive loss to learn a joint embedding space for both images and text. The model is jointly trained on the WebImageText dataset, a set of 400 million paired image–text pairs crawled form the web. Although primarily designed for image classification, CLIP embeddings have been used in numerous other downstream applications, making it a prime candidate for our analysis. The architecture of CLIP has independent visual and textual encoding modules providing explicit access to each modality's embedding. As a result, it is possible to not

---

[4] *Arab* collectively refers to a number of Arab countries (each also having other cultural groups). We hope that more specific nationalities and cultural groups can be added in the future.

Figure 5: Top 15 closest attributes returned by CLIP for each target group. Red colors represent negative sentiment while blue represents positive sentiment. Stereotypical patterns can be seen among different groups.

only analyze the bias across domains but conduct ablation studies for each module separately as well. We used the "ViT-B/32" model with the official CLIP code. Our experiments are as follows.

5.1.1 Cross-Modal Zero-Shot Classification

CLIP was originally introduced as a means for zero-shot image classification. In this experiment, we measure bias for this task across different modalities. Given a set of target concept images $\boldsymbol{X}^I$ and $\boldsymbol{Y}^I$, and a set of textual attribute phrases $\boldsymbol{A}^T$ and $\boldsymbol{B}^T$, we use CLIP to perform zero-shot classification of target images to attribute words. For each image group, the top 15 classified words are returned. The attributes are two sets of 60 words conveying positive[5] or negative[6] sentiment, many of which were also included in the original IAT studies (Bellezza et al., 1986).

The resulting correlation scores are provided in Fig. 5. Each row shows the top 15 words returned by the model for each of the target classes. Words with positive sentiment are blue-colored while adjectives with negative sentiment are given in red. The number inside each bar as well as the color intensity represent the degree to which the model associates that target class with that word. Fig. 5 shows stereotypical patterns emerging, e.g., the most associated attributes to Islam and Judaism are words related to poverty, terror, and extremism such as: "impoverished", "vagrant", ”terrorist“, ”oppression“, "outcast", "extremist", etc., which carry a highly negative sentiment.

However, unlike Islam and Judaism, in the case of Buddhism and Christianity, 12 of the 15 top attributes have positive sentiment. The most associated attributes are words resembling peace and happiness such as: "peace", "blessing", "compassionate", "admirable", etc., carrying a highly positive sentiment. This is aligned with societal stereotypes that certain religions are looked upon less favorably than others. Similar patterns can be observed for other classes such as nationality as well. Certain nationalities such as Americans are viewed as more favorably by the model compared to Arab, Mexican, and Chinese people. Interestingly, biases against the Arab category are very similar to biases against Islam, e.g., both obtaining high scores for "terrorism", "extremist", and "impoverished". This likely stems from the the fact that most Arab countries are predominantly Muslim and the model may have acquired latent correlations among the two. For the target class "Mexican", the highest-scoring words are "undocumented", "greed", and "illegal", followed by "impoverished", which reflects the typical right-wing media portrayal of this group in the US. Similarly, Chinese nationals are associated

---

[5] ptrckprry.com/course/ssd/data/positive-words.txt

[6] ptrckprry.com/course/ssd/data/negative-words.txt

with negative attributes relating to poverty and dictatorship. The next category that exhibits a bias is sexual orientation, where the LGBTQ community is mostly associated with words such as “offending”,“vulgar”, “hateful”, “perverse”, etc. Finally, we can see the large negative sentiment the model exhibits towards people with disabilities.

5.1.2 Cross-Modal Bias Assessment

This experiment quantifies the bias in CLIP using Caliskan cosine similarity metric in Eq. 1. Given a set of target concept images $\boldsymbol{X^I}$ and $\boldsymbol{Y^I}$ and a set of textual attribute phrases $\boldsymbol{A^T}$ and $\boldsymbol{B^T}$, the goal is to measure the effect size, $d(\boldsymbol{X^I}, \boldsymbol{Y^I}, \boldsymbol{A^T}, \boldsymbol{B^T})$, distance between image target concepts $\boldsymbol{X^I}$, $\boldsymbol{Y^I}$ and textual pleasantness attributes. The results are provided in the first column of Table 2. Positive numbers reflect a negative bias towards the first target $\boldsymbol{X}$, while negative numbers indicate a positive bias towards $\boldsymbol{X}$. The magnitude represents the intensity to which the bias is present in the model with regard to test data. The results in Table 2 are consistent with the results in the zero-shot classification experiment, confirming certain societal stereotypes. For instance, in the case of religion, we have already observed that Islam and Judaism are tied to negative words much more frequently, compared to Christianity and Buddhism. Similarly, here, we observe that bias scores for “Islam vs. Christianity” and “Judaism vs. Christianity” are fairly high as well. In the case of “Islam vs. Judaism”, Islam is viewed more unfavorably, reflecting the surge of Islamophobic tendencies in recent decades. In this regard, the most favorably assessed religions are Christianity and Buddhism. Similar trends can be seen when considering nationality as well. The model shows a negative bias towards Arab, Chinese, and Mexican people compared to Americans. This is again consistent with previous observations in the zero-shot classification experiment. Finally, we find that people with disabilities as well as the LGBTQ community are viewed more negatively.

	Target $\boldsymbol{X}$	Target $\boldsymbol{Y}$	CLIP Cross	CLIP Textual	CLIP Visual	ALBEF	ViLT

Table 2: Bias assessment for CLIP, ALBEF, and ViLT models. CLIP-Cross has numbers for cross-modal bias assessment experiment, while CLIP-Textual and CLIP-Visual show effect sizes for intra-modality ablation studies. Positive numbers favor target Y while negative numbers favor target X.

5.1.3 Ablation: Intra-Modal Encoder Bias

Since CLIP provides explicit access to textual and visual embeddings, we can run ablation studies by measuring the bias in each module independently. In order to do so, we measure the effect size using the Caliskan formula $d(\boldsymbol{X^T}, \boldsymbol{Y^T}, \boldsymbol{A^T}, \boldsymbol{B^T})$ for textual data and Image Association test $d(\boldsymbol{X^I}, \boldsymbol{Y^I}, \boldsymbol{A^I}, \boldsymbol{B^I})$ for images, where unlike the cross-modal experiment, both target concepts as well as attributes have the same modality. These experiments can provide insights as to which module is more heavily responsible for the observed bias. Columns 2 and 3 in Table 2 present the findings. For the image modality, we have images with positive and negative valence, analogous to positive and negative-sentiment words. As we can see, the model demonstrates similar bias to the cross-modal case. Similarly, we notice that “Islam” and “Judaism” attract more negative bias in comparison with “Christianity” and “Buddhism”. In some cases the effect size is slightly different, which can be explained by the fact that the number of samples in the case of textual data is smaller, entailing a greater standard deviation, which in turn alters the effect size.

5.2 Fusion-based Models

We next evaluate two fusion-based models. Although these models typically have independent textual and visual encoding modules in their lower layers, their architecture is complemented by a fusion module in higher levels to combine the information in different modalities, enabling them to learn joint embeddings of the visual and textual domains. This has been shown to be essential for more complex tasks such as VQA and NLVR that require more complex reasoning. The first such model we consider is ALBEF. Similar to CLIP, ALBEF (Li et al., 2021) first learns separate visual and textual embeddings using Transformer-based image and text encoders coupled with contrastive loss. However, unlike CLIP, ALBEF further combines these embeddings by adopting an attention-based fusion architecture to model more complex interactions between these modalities, and directly aims to address several vision–language objectives, including image–text matching and masked language modeling. This model is pretrained on conceptual captions and SBU captions (Sharma et al., 2018; Ordonez et al., 2011). Furthermore, the model is trained using momentum distillation to facilitate learning by adding an auxiliary learning network to stabilize the leaning process.

ViLT (Kim et al., 2021) is another recent VLP model that is devised as a more computationally efficient alternative to CLIP and ALBEF. Unlike large and computationally-heavy image and text encoders in CLIP and ALBEF, ViLT utilizes only shallow linear layers to process the sequence of word embeddings and image patches of the text–image input pair. Furthermore, in order to enable the model to solve complex vision–language tasks such as VQA, NLVR, and ITM, a Transformer-based architecture is employed on top to capture the complex dynamics between the modalities. This model is trained using a combination of image–text matching, word patch alignment, and masked language modelling objectives.

With regard to bias assessment, unlike CLIP, fusion-based models do not provide explicit access to separate visual and textual embeddings but rather provide a combined embedding of the pair. As a result, computing the Caliskan distance in Eq. 1 is not possible. However, interestingly one of the objectives these models optimize for is the image–text matching (ITM) objective. ITM is the problem of estimating the probability that a given image–text pair is a match. This task is directly related to our bias evaluation problem. We can argue that a model is fair if the probability of assigning pleasantness scores is similar across different concepts. In other words, the following should hold for the ITM scores:

$$P_{\text{ITM}}(\boldsymbol{A}|\boldsymbol{X}) - P_{\text{ITM}}(\boldsymbol{B}|\boldsymbol{X}) \approx P_{\text{ITM}}(\boldsymbol{A}|\boldsymbol{Y}) - P_{\text{ITM}}(\boldsymbol{B}|\boldsymbol{Y})$$

Columns 4 and 5 in Table 2 include the results for ALBEF and ViLT. The numbers provided are probabilistic differences and are not comparable to the Caliskan scores provided for CLIP. In order to reduce irrelevant noise only the top 15 most significant matches are considered. Again, we see that these models exhibit strong biases favoring Christianity vs. Islam and Judaism, matching Christian images to positive words 45% more than Muslim and 51% more than Judaism. However, in case of nationality, these models show fewer signs of bias. Furthermore, ViLT and ALBEF show less bias towards physical disabilities compared to mental disability.

Algorithm 1 Bias Mitigation Algorithm

```
Require: Image Embedding $V^I$,
         Text Embedding $V^T$,
         Features to remove $N$,
         Classification Labels $L$

$X \leftarrow \emptyset$
$\Psi \leftarrow$ Compute_Bias($V^I, V^T$)
for $d \leftarrow 1$ to $\mathrm{len}(V^I)$ do
    $\overline{V^I} \leftarrow V^I \setminus v^I_d$
    $\overline{V^T} \leftarrow V^T \setminus v^T_d$
    if MI($v^I_d, L$) $< \Theta$ then
        $\psi_d \leftarrow$ Compute_Bias($\overline{V^I}, \overline{V^T}$)
        if $\psi_d < \Psi$ then
            $X \leftarrow X \cup \{(d, \psi_d)\}$
        end if
    end if
end for
$Z \leftarrow \mathrm{sort}_{\psi_d}(X)[0 : N]$ // Dimensions to remove
$X \leftarrow X \setminus Z$
return $X$
```

6 Bias Mitigation Algorithm

Bias mitigation methods typically fall into one of three categories: data augmentation (fair resampling), model adjustment, and embedding post processing algorithms. Each of these alternatives have their own benefits and drawbacks, but a major limitation of the first two is that they require retraining the models. This can be burdensome in many cases. In particular, we often lack access to the dataset, the model's training procedure, or in the case of large pretrained models, retraining may also be computationally infeasible on typical hardware and cost budgets. Post-processing methods, on the other hand, may be invoked as a fast and efficient plug-and-play method to modify learned embeddings without the need for retraining. Since vision–language tasks are complex, VLP models usually have large architectures to be able to capture all the complex dynamics. However, this can cause them to learn redundant or highly correlated features, since they are not optimally compressed. These features are not only computationally wasteful but can also amplify model bias. Due to the high correlation among some features, we can remove some without affecting performance, while simultaneously reducing bias. In order to identify those features, we directly optimize for the objective in Eq. 1 by removing features in a greedy manner, pruning N dimensions that cause the largest decrease in bias effect size. However, we only consider the features that exhibit a small mutual information with respect to classification labels. Θ can be set empirically and this ensures only redundant dimensions are removed. Algorithm 1 details the steps of our technique.

Bias	Before	After	Reduction
Muslim vs Christian	1.72	0.57	66%
Jewish vs Christian	1.69	0.75	55%
Muslim vs Buddhist	1.62	0.11	93%
Jewish vs Buddhist	1.61	0.30	82%
Muslim vs Hindu	1.65	0.71	57%
Arab vs American	1.28	0.33	74%
Mexican vs American	1.13	0.85	26%
Chinese vs American	0.89	0.56	38%
Mental Dis. vs No Dis.	1.48	0.49	66%
LGBTQ vs Heterosexual	1.67	0.92	45%

Table 3: Bias Mitigation Results. Our algorithm is able to significantly reduce bias without substantially affecting performance.

The results of this debiasing method are presented in Table 3. We removed 54 dimensions (10% of all dimensions), which leads to up to 93% bias reduction in some cases. This however only minimally affects the model's classification accuracy. We have tested the accuracy of the model on the MMbias dataset as well as the CIFAR-100 dataset. On MMbias, the accuracy dropped by only 1.1% , and on CIFAR100 by only 1.3% from 80.1% to 78.8%. Furthermore, Fig. 4b shows that even after removing the aforementioned dimensions, the embeddings still remain well-separable, confirming the redundancy of some of the embedding features.

Regarding the choice of N (number of features removed) in the bias mitigation algorithm, a larger N will affect the performance of the model more negatively, as previously observed in other dimensionality reduction algorithm. In order to find a reasonable N we can plot the bias reduction as well as performance reduction as a function of N. Inspecting this graph allows us to consider the trade-off between greater bias removal and the loss of accuracy, allowing us to choose an N that decreases the bias in a meaningful way while not affecting performance significantly.

7 Conclusion

Most bias analysis studies focus on gender and racial biases, which is primarily due to a lack of suitable data to consider further important forms of bias. In this study, we have compiled a new multimodal bias assessment dataset called MMBias enabling the study of bias affecting population groups largely neglected in prior studies. Our dataset consists of around 3,500 images and hundreds of phrases covering over 14 minority subgroups. Furthermore, based on a formulation of the bias-fairness problem, we draw on this data to assess the level of bias in several prominent self-supervised multimodal models, including CLIP, ALBEF, and ViLT. Our results show that these models demonstrate meaningful bias towards certain groups. Finally, we introduce a novel bias mitigation technique designed specifically for large pretrained models that can be applied as a post-processing step to reduce bias, and show that it has negligible effects on classification performance as well as data separability. Our data and code is available at github.com/sepehrjng92/MMBias.

Limitations

This work seeks to make a contribution towards vision–language models that exhibit less biased behavior. To this end, we provide a large new dataset, new experimental results, and also investigate a bias mitigation method for pre-trained vision–language models. Yet, bias measurement data as well are prone to biases, most notably in the selection of classes and groups, but also with regard to the particular data instances. We envision that MMBias will grow to encompass further groups and additional data in the future, e.g., further ethnic minorities, sexual identities, and gender identities. We also hope that our dataset can serve as a starting point for research on additional natural languages.

Clearly, our bias mitigation algorithm can only mitigate certain fairly overt expressions of bias in vision–language models. Large pre-trained models have millions of parameters that affect the model behavior. As vision–language models necessarily need to rate ties between images and text, they will continue to prefer or disprefer certain associations, leading to remnant biases. Still, we hope that our work will enable the community to pay closer attention to these challenges and work towards models that behave in more equitable ways.

Ethics Statement

With our work, we wish to encourage further analysis of bias in machine learning models. To this end, we provide data that enables an assessment of a number of potential manifestations of bias. We acknowledge that the images harbor a multitude of different stereotypes that cannot be taken to be representative of the various groups. Moreover, we acknowledge that the pairings of classes of people adopted thus far in our work leaves out other groups of people, e.g., further forms of faith and belief, and also further pairings. We view our work as a step towards a more inclusive bias assessment resource that should keep growing in the future.

Abstract

Recent geometric-based approaches have been shown to efficiently model complex logical queries (including the intersection operation) over Knowledge Graphs based on the natural representation of Venn diagram. Existing geometric-based models (using points, boxes embeddings), however, cannot handle the logical negation operation. Further, those using cones embeddings are limited to representing queries by two-dimensional shapes, which reduced their effectiveness in capturing entities query relations for correct answers. To overcome this challenge, we propose unbounded cylinder embeddings (namely CylE), which is a novel geometric-based model based on three-dimensional shapes. Our approach can handle a complete set of basic first-order logic operations (conjunctions, disjunctions and negations). CylE considers queries as Cartesian products of unbounded sector-cylinders and consider a set of nearest boxes corresponds to the set of answer entities. Precisely, the conjunctions can be represented via the intersections of unbounded sector-cylinders. Transforming queries to Disjunctive Normal Form can handle queries with disjunctions. The negations can be represented by considering the closure of complement for an arbitrary unbounded sector-cylinder. Empirical results show that the performance of multi-hop reasoning task using CylE significantly increases over state-of-the-art geometric-based query embedding models for queries without negation. For queries with negation operations, though the performance is on a par with the best performing geometric-based model, CylE significantly outperforms a recent distribution-based model.

1 Introduction

Multi-hop Reasoning (MHR) on Knowledge Graphs (KGs) is a primary task in answering queries over large-scale knowledge graphs. Queries can be represented using First-Order-Logic (FOL) connectives (Brachman and Levesque, 2004), involving these operations: existential quantification ($\exists$), conjunction ($\wedge$), disjunction ($\vee$) and negation ($\neg$). MHR involves learning to answer these FOL queries, which has recently received attention from several studies (Hamilton et al., 2018; Ren et al., 2020; Ren and Leskovec, 2020). A common approach is to first transform the FOL query into a computation graph (see Figure 1), where nodes represent entity constants or variables and edges map to predicates and logical operations. Representing queries in this way enables the learning process to traverse paths of KGs via the computation graph, so as to find a set of answers for a given query. However, large-scale KGs (Bollacker et al., 2008; Vrandečić and Krötzsch, 2014; Lehmann et al., 2015; Speer et al., 2017; Fellbaum, 2010; Mitchell et al., 2018) are often incomplete and noisy, which makes explicit query mechanism, such as graph traversal incapable of returning correct answers to a query.

Motivated by the challenge above, we aim to reason about incomplete KGs using MHR (Lin et al., 2018; Zhang et al., 2021a). To achieve MHR, recent studies have proposed several query embedding (QE) methods based on geometry (Hamilton et al., 2018; Ren et al., 2020; Zhang et al., 2021b) and probability distribution representations (Ren and Leskovec, 2020; Choudhary et al., 2021a). A common approach of QE in the literature is to project the FOL queries into an embedding space, allowing a model to learn the embeddings of queries and entities. Answering these queries is equivalent to finding the similarity between the embedded queries and the embedded entities. Geometric-based models using cone embeddings ConE (Zhang et al., 2021b) are shown to be superior over the others, especially the ability of handling negations. ConE represents queries as Cartesian product of sector-cones in an embedding space. ConE projects target entities as lines and queries as areas of sector-cones. Intuitively,

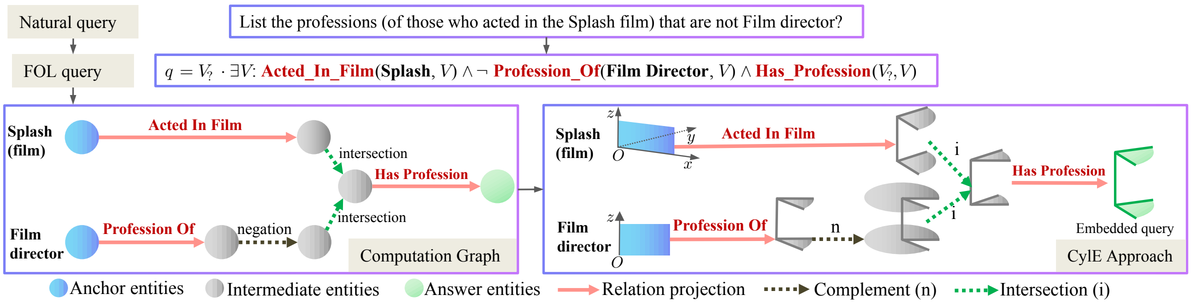

Figure 1: **(Left):** An example of a computation graph for a FOL query (rewritten from a natural query). **(Right):** The intuition of CylE is to model anchor and target entities as perpendicular boxes regarding the base of sector-cylinders. Each edge of the computation graph transforms the entity with its relation into the sector-cylinder embedding via projection, intersection or complement operations; then outputting an embedded query.

if the line is inside the area, the corresponding entity is considered as a match to the query. Nevertheless, cone embeddings are limited to the 2D space in a flat plane, to represent the query and entity embeddings. For example, one entity in a cluster of the sub-topic */movie/action* and one in another */movie/documentary* can be in the sector-cone region for those labels in the topic */movie* (see Figure 2(a)). Answering a query regarding the */movie/action* can return irrelevant entities from the */movie/documentary*. In multi-dimensional space, entities assigned to multiple labels can be achieved using multi-dimensional classification (Read et al., 2013). In the 3D space, for instance, apart from the xy-plane, semantics of entities can be additionally classified by different levels of degree in the height segment (along the z-axis).

In this paper, we propose to expand the two dimension sector-cone embeddings into the three dimension coordinate system. We represent queries by augmenting the shape of the sector-cones to be similar as unbounded sector-cylinders (shortly called *sector-cylinders*) in an embedding space, compared to closed sector-cylinders in a normal situation (see examples of unbounded sector-cylinders, their intersection or union in Figure 2 and further definitions in Section 4.1). In short, we name this approach **Cyl**inder **E**mbeddings (CylE). Answering a query is similar to finding entities that are subsets of the sector-cylinders representing queries. We investigate whether there is any improvement in answering correctly any query structures, using CylE over other approaches. Our approach can handle the conjunction as we notice that the intersection of sector-cylinders (along the z-axis) can be a sector-cylinder. Since the union of sector-cylinders is no longer a sector-cylinder, we first transform queries to Disjunctive Normal Form (DNF), which enables CylE to handle disjunction. With regard to the negation operation, we consider the closure-complement of sector-cylinders to model this operation. Our contributions are: (1) introducing the first 3D geometric-based approach to model the QE for MHR to the best of our knowledge, (2) enabling the model to handle a complete set of the basic FOL queries (existential quantification, conjunction, disjunction and negation) and (3) demonstrating that CylE significantly outperforms state-of-the-art (SOTA) geometric-based models for non-negation queries and is on par for queries with negations by empirical results.

2 Related works

Multi-hop Reasoning for logical query Studies in MHR employed approaches such as (distributions (Ren and Leskovec, 2020; Choudhary et al., 2021a; Huang et al., 2022), geometric shapes (Hamilton et al., 2018; Ren et al., 2020; Zhang et al., 2021b), fuzzy logic (Chen et al., 2022; Arakelyan et al., 2021)), others using count-min sketch (Sun et al., 2020) and neural-symbolic approach (Zhu et al., 2022), to achieve the common goal of learning representation of queries, *i.e.* query embeddings. The primary difference in these approaches is based on how queries are represented. For example, distribution-based models use Beta distributions (Ren and Leskovec, 2020) or Multivariate Gaussian distributions (Choudhary et al., 2021a). In geometric shapes, Hamilton et al. (2018) represented queries as point embeddings, Ren et al. (2020) then furthered this using box embeddings, and Bai et al. (2022) made an improvement by introducing 'particle' embeddings (a set of points using multiple vectors). Zhang et al. (2021b) have made the geometric approach more expressive using cone embeddings. Another difference is the ability to model a complete set of logical operations (Brachman and Levesque, 2004) (conjunction, disjunction and negation). Several methods (Ren and Leskovec, 2020; Zhang et al., 2021b; Bai et al., 2022; Chen et al., 2022) have achieved a coverage of all operations including the negation, compared to others (Hamilton et al., 2018; Ren et al., 2020; Choudhary et al., 2021a) without negation.

Reasoning about KGs using geometric shapes Historically, these approaches received attention since the introduction of translation-based methods (Bordes et al., 2013), rotation (Sun et al., 2019; Zhang et al., 2020) and 3D-rotation (Gao et al., 2020) for learning knowledge graph embeddings. Inspired by a Poincaré ball, other studies (Nickel and Kiela, 2017; Balažević et al., 2019) proposed hyperbolic space (non-Euclidean geometry). A common task of these studies is KGs completion. However, furthering it to MHR task poses a challenge because of the complex structures of queries (see Figure 3). Using geometric shapes for the MHR task (point Hamilton et al. (2018); Bai et al. (2022), box Ren et al. (2020), hyperbolic Choudhary et al. (2021b) and cone embeddings Zhang et al. (2021b)) have increasingly gained popularity. Cone embeddings were also mentioned in (Ganea et al., 2018), but not for the MHR task. Since existing geometric-based methods of cone embeddings rely on 2D shapes, we extend the representation learning for this geometric family to 3D shapes for the MHR task. Other studies (*e.g.* spherical text embeddings (Meng et al., 2019)) learned word embeddings for document clustering and classification tasks, but still not for the MHR task.

3 Preliminaries

3.1 Knowledge Graphs

Given a set of *vertices* (*entities*) $\mathcal{V}$ and a set of *edges* (*relations* or *predicates*) $\mathcal{E}$, we define a knowledge graph ($\mathcal{G}$) as a set of *triples*. Each triple is (v_s, e, v_o), where $(v_s, v_o \in \mathcal{V})$ and $(e \in \mathcal{E})$ is a *vertex subject*, a *vertex object* and an *edge* respectively. Assuming $(r \in \mathcal{R})$ denotes each element in a set of relation functions $(\mathcal{R})$, where (r) – associated with (e) – is a binary function $r : \mathcal{V} \times \mathcal{V} \to \{\text{True}, \text{False}\}$ that denotes an asymmetric direction of relation from (v_s) to (v_o), and vice versa. A symmetric direction of relation (non-directional relation) is $r : \mathcal{V} \times \mathcal{V} \to \{\text{True}, \text{True}\}$. Notice that there are two sets involving in edges/relations: $(\mathcal{E})$ for edge instances and $(\mathcal{R})$ for relation functions.

3.2 First-Order Logic queries

There are four basic logical operations involving in the interpretation of FOL queries[1]: conjunction ($\wedge$), disjunction ($\vee$), negation ($\neg$) and existential quantification ($\exists$). We adopt definitions and notations of BetaE (Ren and Leskovec, 2020) to assume that a FOL query consists of three folds: (1) a constant anchor entity set $(\mathcal{V}_a \subseteq \mathcal{V})$, (2) existentially quantified bound variables $(V_1, \dots, V_k)$ and (3) a target entity variable $(V_?)$ to respond a certain query. A FOL query can be written in Disjunctive Normal Form (DNF) as a combination of disjunctions of conjunctive queries (c_i) in the following:

$$q[V_?] = V_? \cdot \exists V_1, \dots, V_k : c_1 \vee c_2 \vee \dots c_n,$$

where $c_i = e_{i1} \wedge e_{i2} \cdots \wedge e_{im}$, including at least one literal $e_{ij} = r(v_a, V)$ or $\neg r(v_a, V)$ or $r(V', V)$ or $\neg r(V', V)$, and $(v_a \in \mathcal{V}_a)$ while $V \in \{V_?, V_1, \dots, V_k\}$, $V' \in \{V_1, \dots, V_k\}$ and $V' \neq V$. Finding the answer entities of a query (q) is similar to searching for an answer set $[\![q]\!] \subseteq \mathcal{V}$, where $v \in [\![q]\!]$ if and only if $q[v]$ is True.

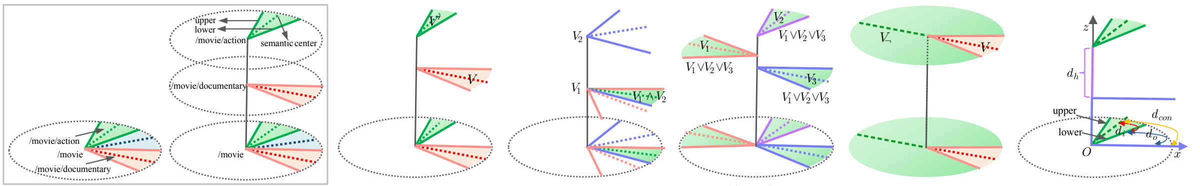
3.3 Query Decomposition

We adopt the definitions of FOL query decomposition in Zhang et al. (2021b) using a computation graph, including *vertices* and *edges* (see an example in Figure 1). Each intermediate vertex is a set of entities and each edge demonstrates relational projection or logical operations over entity sets:

- **Relation Traversal** → **Projection**: Given a set of entities $\mathcal{S} \subset \mathcal{V}$ and a relation function $r \in \mathcal{R}$, estimate adjacent entities $\cup_{v \in \mathcal{S}} \mathcal{A}(v, r)$, where $\mathcal{A}(v, r) \equiv \{v' \in \mathcal{V} : r(v, v') = \text{True}\}$.
- **Negation** → **Complement**: Given a set of entities $\mathcal{S} \subset \mathcal{V}$, estimate $\overline{\mathcal{S}}$ where $\overline{\mathcal{S}} \equiv \mathcal{V} \backslash \mathcal{S}$.
- **Conjunction** → **Intersection**: Given a number of sets of entities $\{\mathcal{S}_1, \mathcal{S}_2, \dots, \mathcal{S}_n\}$, compute the intersection $\cap_{i=1}^{n} \mathcal{S}_i$ of these sets.
- **Disjunction** → **Union**: Given a number of entity sets $\{\mathcal{S}_1, \dots, \mathcal{S}_n\}$, find the union $\cup_{i=1}^{n} \mathcal{S}_i$.

---

[1] Universal quantification ($\forall$) rarely appears in the real world (Ren and Leskovec, 2020), this operation is therefore not considered.



(a) **(Left)**: ConE and **(Right)**: CylE (b) Projection (c) Intersection (d) Union (e) Complement (f) Distance

Figure 2: An overview of cone and cylinder embeddings with projection, logical operations (intersection, union, complement) and distance. The color dot line represents the semantic center axis. **(c)** Intersection between a sector-cylinder (red semantic center) and another higher sector-sector (royal blue semantic center) is the sector-cylinder having green semantic center. **(d)** Union of three sector-cylinders (having red, purple and royal blue semantic center axis) are in green regions. **(f)** Distance is from the green sector-cylinder (of an embedded query) to a purple target box (of an embedded target entity); d_i, d_o, d_h denotes the inside, outside and height distance.

4 Cylinder embeddings

We first provide a background of parameterizing cylinder (Section 4.1) and modeling cylinder embeddings for conjunctive queries (Section 4.2). Next, we show the cylinder embeddings process with logical operators (Section 4.3), then provide an optimization method (Section 4.4).

4.1 Cylinder definitions and parameterization

We define an *unbounded sector-cylinder* (without parameterizing radius) as having only two bounds for its body: the upper bound and the lower bound with an intersection as a height (see Figure 2(a)). We call the angle between the two bounds aperture, which has a range in $[0, 2\pi]$. In short, we call an unbounded sector-cylinder a *sector-cylinder* or a *cylinder* based on their apertures. Notice that a sector-cylinder becomes a cylinder when the aperture is zero. We use three variables for parameterization (the first two for the sector-cylinder's base adapt from ConE): (1) the *semantic center axis* $\theta_{ax} \in [-\pi, \pi)$ is the angle between the positive x-axis and the symmetric axis, (2) $\theta_{ap} \in [0, 2\pi]$ is the *aperture* and (3) $\theta_{he} \in (-\pi, \pi)$ is the *height*.

Note that the base of cylinders and cones share similarity in properties (semantic axis and aperture), which can be illustrated in the same plane, such as xy-plane. Thus, the base of cylinders in our study inherit some definitions and propositions from cones. These are a *cone*, a *convex cone* (Boyd et al., 2004), a *closure-complement* of a cone and a *sector-cone*. Each of these, which is defined by ConE (Zhang et al., 2021b), is a set in 2D space. Further, sector-cylinder's base has the same proposition as the sector-cone: *"always axially symmetric"* which has been proven in ConE.

Precisely, we define $(\mathbb{K})$ as a space consisting of all $(\theta_{ax}, \theta_{ap}, \theta_{he})$. An arbitrary sector-cylinder S_0 is as: $S_0 = (\theta_{ax}, \theta_{ap}, \theta_{he}) \in \mathbb{K}$. Then, a d-ary Cartesian product of sector-cylinders, called S, is a product of each sector-cylinder $S_{i=1\to d}$ (or each element of S is a d-dimensional vector in $\mathbb{K}^d$): $S = S_1 \times S_2 \cdots \times S_d$ or be rewritten as follows:

$$\begin{aligned} S := & \Big((\theta^1_{ax}, \theta^1_{ap}, \theta^1_{he}), \ldots, (\theta^d_{ax}, \theta^d_{ap}, \theta^d_{he})\Big) \\ = & \, (\boldsymbol{\theta}_{ax}, \boldsymbol{\theta}_{ap}, \boldsymbol{\theta}_{he}) \subset \mathbb{K}^d. \end{aligned} \tag{4.1}$$

4.2 Cylinder embeddings for conjunctive queries and entities

In this section, we describe query embeddings for conjunctive queries. Note that disjunctive queries can be transformed to DNF form as a set of conjunctive queries (as mentioned in Section 3.2). We model the *embedding region* $(\mathbf{V}_q)$ for the answer set $[\![q]\!]$ of the query (q) (see Section 3.3) using a Cartesian product of sector-cylinders (as mentioned in Section 4.1) as: $\mathbf{V}_q = (\boldsymbol{\theta}_{ax}, \boldsymbol{\theta}_{ap}, \boldsymbol{\theta}_{he})$, where embedding of semantic center axis is $\boldsymbol{\theta}_{ax} \in [-\pi, \pi)^d$, embedding of aperture is $\boldsymbol{\theta}_{ap} \in [0, 2\pi]^d$ and embedding of height is $\boldsymbol{\theta}_{he} \in (-\pi, \pi)^d$; and (d) denotes the dimension of the embedding space (see Eq. (4.1)).

Next, an *arbitrary entity* $(v \in \mathcal{V})$ is represented by a Cartesian product of cylinders having zero apertures. The corresponding embedding $(\mathbf{v})$ is as: $\mathbf{v} = (\boldsymbol{\theta}_{ax}, \mathbf{0}, \boldsymbol{\theta}_{he})$. The intuition is to embed the anchor or target entity into one similar as a *perpendicular box* with regard to a base of the cylinder, Precisely, all elements of the d-dimensional vector $(\boldsymbol{\theta}_{ap})$ is equal to zero.

4.3 Cylinder embeddings with logical operators

We describe the process of modeling relational projection (*projection* module) and modeling logical operators (*intersection*, *complement*, *union* module), to embed the FOL queries in the following:

Projection module: This module aims to learn the projection operation (see Section 3.3), which outputs the adjacent entities (of an anchor entity) linking to a given relation. To this end, we maps the embedding region of an entity set $(\mathbf{V}_q)$ to another $(\mathbf{V}'_q)$ (see Figure 2(b)) via a mapping function (f):

$$f : \mathbb{K}^d \rightarrow \mathbb{K}^d, \mathbf{V}_q \rightarrow \mathbf{V}'_q.$$

We use a *shallow neural network* to approximately represent the mapping function $f(x)$. Overall, $(\mathbf{V}_q)$ is a summation of the embeddings of entity set $(\mathbf{V})$ and a relation $(\mathbf{r})$ as: $\mathbf{V}_q = \mathbf{V} + \mathbf{r}$; where the representation of each relation $(\mathbf{r})$ is sector-cylinder embeddings. Then, a composition function $f(\mathbf{V}_q)$ has a scaling of chunking function $g(x)$ and a multilayer perceptron (**MLP**) network:

$$f(\mathbf{V}_q) = g(\mathbf{MLP}([\mathbf{V}_q])),$$

where $\mathbf{MLP} : \mathbb{R}^{3d} \rightarrow \mathbb{R}^{3d}$, and the function $g(x)$ is to split a three-dimensional vector into three d-vectors for semantic center axis, aperture and height embeddings. In addition, there is a scaling operation, adapt from Zhang et al. (2021b), involving in the function $g(x)$ to scale the semantic center axis, the aperture and the height embeddings into their normal ranges (as mentioned in Section 4.2):

$$[f(\boldsymbol{x})]_i = \begin{cases} \theta'^{i}_{ax} = \pi \tanh(\lambda_1 x_i), & \text{if } i \leq d, \\ \theta'^{i-d}_{ap} = \pi \tanh(\lambda_2 x_i) + \pi, & \text{if } i > d, \\ \theta'^{i}_{he} = 2\pi(sigmoid(\lambda_3 x_i) - 0.5), & \end{cases}$$

where $[f(\boldsymbol{x})]_i$ is the i-th element of $f(\boldsymbol{x})$; $(\lambda_1, \lambda_2, \lambda_3)$ are the scaling hyper-parameters.

Intersection module: This module aims to learn the conjunction operation (see Section 3.3). Assuming a conjunction of conjunctive queries (q_i) associates with a query (q), its answer is $[\![q]\!] = \cap_{i=1}^{k} [\![q_i]\!]$. Notice that entities in the set $[\![q]\!]$ share semantic similarity with one another, as the conjunction of conjunctive queries based on sector-cylinder embeddings are conjunctive queries (see Figure 2 (c)). Supposing $\mathbf{V}_{\cap q} = (\boldsymbol{\theta}_{ax}, \boldsymbol{\theta}_{ap}, \boldsymbol{\theta}_{he})$ and $\mathbf{V}_{i,q} = (\boldsymbol{\theta}_{i,ax}, \boldsymbol{\theta}_{i,ap}, \boldsymbol{\theta}_{i,he})$ are embedding region of $[\![q]\!]$ and $[\![q_i]\!]$ respectively. To obtain the $\mathbf{V}_{\cap q}$, we then take the summation w.r.t. the number of conjunctive queries (of the Hadamard product $\odot$ between $\boldsymbol{A}_i$ and $\mathbf{V}_{i,q}$), which is shown below:

$$\mathbf{V}_{\cap q} = \textstyle\sum_i^k \boldsymbol{A}_i \odot \mathbf{V}_{i,q},$$

where $\boldsymbol{A} \in \mathbb{R}^{k \times d}$ is an attention matrix defined by:

$$\boldsymbol{A}_{i \times d} = \frac{\exp\Big(\mathbf{MLP}([\mathbf{V}_q])_i\Big)}{\sum_j^n \exp\Big(\mathbf{MLP}([\mathbf{V}_q])_j\Big)},$$

where (k) is the number of involving conjunctive queries and $[\mathbf{V}_q]_i \in \mathbb{R}^{3d}$ is a concatenation of $(\boldsymbol{\theta}_{i,ax}, \boldsymbol{\theta}_{i,ap}, \boldsymbol{\theta}_{i,he})$ for the i-th conjunctive query and $\mathbf{MLP} : \mathbb{R}^{3d} \rightarrow \mathbb{R}^d$. As mentioned in Ren et al. (2020), using attention mechanism is important in comparison to other approaches (*e.g.* averaging, deep sets Zaheer et al. (2017)). Note that our approach is to approximately model the conjunction operation. Further, this approach is different than that in cone embeddings which required an intermediate process (Zhang et al., 2021b): to convert the semantic center axis to points on the unit circle, then to map these points back to angles to recover the semantic center axis.

Complement module: This module aims to represent the negation operation (see Section 3.3), by finding the complementary set of $[\![q]\!]$ (or $\mathcal{V} \backslash [\![q]\!]$): $[\![\neg q]\!]$. Supposing $\mathbf{V}_q = (\boldsymbol{\theta}_{ax}, \boldsymbol{\theta}_{ap}, \boldsymbol{\theta}_{he})$ and $\mathbf{V}_{\neg q} = (\boldsymbol{\theta}'_{ax}, \boldsymbol{\theta}'_{ap}, \boldsymbol{\theta}'_{he})$ are sector-cylinder embeddings region of $[\![q]\!]$ and $[\![\neg q]\!]$ respectively. From a geometric aspect, the closure-complement is close to the set of sector-cylinders (see Figure 2(e)). Thus, the sum of apertures of $(\mathbf{V}_q)$ and $(\mathbf{V}_{\neg q})$ should be close to 2π. Assuming semantic center of $(\mathbf{V}_{\neg q})$ should be opposite to those in $(\mathbf{V}_q)$ while the height of $(\mathbf{V}_{\neg q})$ should be equivalent to those in $(\mathbf{V}_q)$ as follows:

$$[\boldsymbol{\theta}'_{ax}]_i = \begin{cases} [\boldsymbol{\theta}_{ax}]_i - \pi, & \text{if } [\boldsymbol{\theta}_{ax}]_i \geq 0, \\ [\boldsymbol{\theta}_{ax}]_i + \pi, & \text{if } [\boldsymbol{\theta}_{ax}]_i < 0, \end{cases}$$

$$[\boldsymbol{\theta}'_{ap}]_i = 2\pi - [\boldsymbol{\theta}_{ap}]_i,$$

$$[\boldsymbol{\theta}'_{he}]_i = [\boldsymbol{\theta}_{he}]_i.$$

Note that the height variable cannot be involved in this module, as the negation should be closed without this variable. Since the negation is not closed w.r.t. entities as long as keeping the same height for $(\mathbf{V}_{\neg q})$ and $(\mathbf{V}_q)$, this can be a bottleneck of negation queries under the three dimension space. This can be addressed by designing closed negation for both queries and entities; however, we leave this direction for future work.

Union module: This module aims to represent the disjunction operation (see Section 3.3). Assuming a disjunction of conjunctive queries (q_i) associates with a query (q), the aim of this operation is to represent its answer: $[\![q]\!] = \cup_{i=1}^{k}[\![q_i]\!]$. We face a challenge as the union of sector-cylinders having different height is no longer a sector-cylinder, or the union over sector-cylinders is not closed (see Figure 2(d)). As mentioned by Ren et al. (2020), there is an issue of non-scalability when modeling directly the disjunction. To address this issue, we adapt a technique of Ren et al. (2020) by transforming queries into a DNF (Davey and Priestley, 2002) (*e.g.* disjunction of conjunctive queries). The union operation in DNF is moved to the last step of converted computation graphs, which contain conjunctive queries (see Section 3.2). Thus, we can apply the other logical operations (as mentioned in above modules) to have a set of embeddings of these conjunctive queries. The answer entities are those nearest to any embeddings of these conjunctive queries (see further details of estimating the aggregated distance score in Eq. (4.2)).

4.4 Optimization method

Distance score: We define a distance score $d(\mathbf{v};\mathbf{V})$ between the embedded region entity $\mathbf{v} = (\boldsymbol{\theta}'_{ax}, \mathbf{0}, \boldsymbol{\theta}'_{he})$ and the embedded region query $\mathbf{V} = (\boldsymbol{\theta}_{ax}, \boldsymbol{\theta}_{ap}, \boldsymbol{\theta}_{he})$. Inspired by Ren et al. (2020) and Zhang et al. (2021b), we adapt two types of this distance: (1) d_{con} (for those conjunctive queries) and (2) d_{dis} (for those disjunctive queries). In terms of estimating (d_{con}), there are three terms: an outside distance (d_o), an inside distance (d_i) and a height distance (d_h) as follows:

$$d_{con}(\mathbf{v};\mathbf{V}) = d_o(\mathbf{v};\mathbf{V}) + \lambda d_i(\mathbf{v};\mathbf{V}) + d_h(\mathbf{v};\mathbf{V}),$$

where the hyper-parameter $\lambda \in (0, 1)$ is to encourage the expected entity $(\mathbf{v})$ to be inside the embedded region $(\mathbf{V})$. Intuitively, $(\mathbf{v})$ is close to the upper or lower bound of $(\mathbf{V})$ when (λ) is close to zero or one. The three distances contributing to the (d_{con}) for conjunctive queries are defined by:

$$d_o = \left|\left|\min\{d_l, d_u\}\right|\right|_1, \; d_i = \left|\left|\min\{d_{ax}, d_{ap}\}\right|\right|_1,$$
$$d_h = \left|\left|\boldsymbol{\theta}'_{he} - \boldsymbol{\theta}_{he}\right|\right|_1,$$

where $(d_l = |1 - \cos(\boldsymbol{\theta}'_{ax} - \boldsymbol{\theta}_l)|)$ denotes the outside distance between the semantic center axis of the entity and the *lower bound* of the query, $(d_u = |1 - \cos(\boldsymbol{\theta}'_{ax} - \boldsymbol{\theta}_u)|)$ denotes the outside distance between the semantic center axis of the entity and the *upper bound* of the query; $(d_{ax} = |1 - \cos(\boldsymbol{\theta}'_{ax} - \boldsymbol{\theta}_{ax})|)$ denotes the inside distance between the semantic center axis of the entity and that of the query, $(d_{ap} = |1 - \cos(\boldsymbol{\theta}_{ap}/2)|)$ denotes the inside distance between the semantic center axis and either of the two bounds of the query (see Figure 2(f) for an example to estimate these distances). Further, $(\boldsymbol{\theta}_l = \boldsymbol{\theta}_{ax} - \frac{\boldsymbol{\theta}_{ap}}{2})$ is the *lower bound* and $(\boldsymbol{\theta}_u = \boldsymbol{\theta}_{ax} + \frac{\boldsymbol{\theta}_{ap}}{2})$ is the *upper bound* of the embedded query, the notation $||\cdot||_1$ is the L_1 norm. The higher value of the cosine function is, the less distance is. Notice that the maximum of this function is equivalent to one, we therefore subtract one from this, to ensure the minimum distance to be close to zero. Next, we adapt the DNF technique of Ren et al. (2020) to estimate (d_{dis}) by obtaining the minimum distance between a target entity and each conjunctive query:

$$d_{dis}(\mathbf{v};\mathbf{V}) = \min\{d_{con}(\mathbf{v};\mathbf{V}_i)\}_{i:1\to n}. \quad (4.2)$$

Training objective function: To optimize the training loss, we follow the objective function $(\mathcal{L})$ from Ren and Leskovec (2020), $\mathcal{L} = -\log\sigma(\gamma - d(\mathbf{v};\mathbf{V})) - \frac{1}{n}\sum_i^n \log\sigma(d(\mathbf{v}';\mathbf{V}) - \gamma)$ is a summation of two terms: (1) a positive loss is to minimize the distance $d(\mathbf{v};\mathbf{V})$ between a positive embedded entity $(v \in [\![q]\!])$ and an embedded query and (2) a negative sampling loss is to maximize the distance $d(\mathbf{v}';\mathbf{V})$ between negative embedded entities $(v'_{i:1\to n} \notin [\![q]\!])$ and an embedded query; where (n) is the number of negative sampling entities, $\sigma(x)$ denotes the sigmoid activation function and the hyper-parameter (γ) is a pre-fixed positive margin.

5 Experiments

5.1 Experimental designs

For benchmarking, we follow experimental designs (datasets, query structures, training and evaluation protocol) of Multi-hop Reasoning (MHR) task from (Ren and Leskovec, 2020).

Datasets: We use benchmarking datasets for the MHR task: FB15k (Bollacker et al., 2008), FB15k-237 (Toutanova and Chen, 2015) and NELL995 (Xiong et al., 2017). Using the same pre-processing steps as BetaE (Ren and Leskovec, 2020), we split each dataset into the training, validation, and test set. The aim of MHR task is to obtain *non-trivial* answers, which *cannot be discovered* by directly *traversing* the *incomplete KGs*, for each arbitrary FOL query. Please see Appendix A.1 for further details of these datasets.

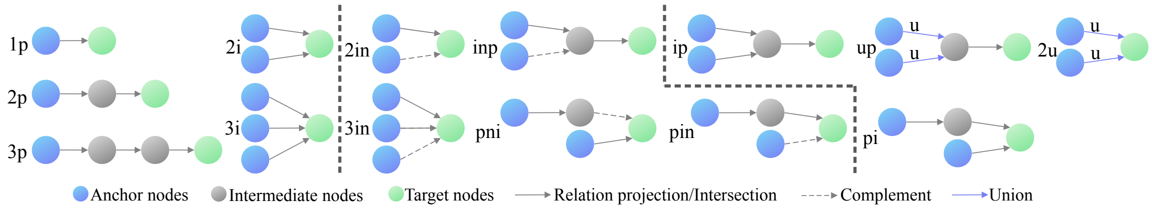


Figure 3: **(Left)** & **(Middle):** query structures are involved in the training process. **(Left)**, **(Middle)** & **(Right):** all queries are involved in the evaluation process; p is projection, i is intersection, n is negation and u is union.

Table 1: The average **MRR** (%) results in different query structures without negation ($\exists$, $\wedge$, $\vee$) using these datasets: FB15k, FB15k-237 and NELL995. The results of baselines (GQE, Q2B, BetaE, ConE) are taken from (Zhang et al., 2021b). Query structures with union operations ($2u/up$) are in DNF forms.

Queries: We adopt FOL query structures of (Ren and Leskovec, 2020) for the training, validation and test process. In terms of the training, there are five structures without negation ($1p/2p/3p/2i/3i$) and five structures with negation ($2in/3in/inp/pni/pin$). With regard to the evaluation process, we not only use the same query structures as those in the training process, we also use unseen structures ($ip/pi/2u/up$), which have not been involved in the training process, to evaluate the ability of generalization for the model.

Training and evaluation protocol: In terms the training process, we use Adam optimizer (Kingma and Ba, 2015). We follow the similar hyper-parameter settings of (Zhang et al., 2021b) to initialize the model, but search for the most effective combination of these hyper-parameters in the situation of cylinder embeddings (see more details in Appendix A.2). With regard to the evaluation process, we adopt the evaluation protocol of (Ren and Leskovec, 2020). There are three involving KGs: the training KG ($\mathcal{G}_{train}$ for training edges), the validation KG ($\mathcal{G}_{valid}$ for training and validation edges) and the test KG ($\mathcal{G}_{test}$ for training, validation and test edges) (see Appendix A.1). Specifically, given a test query (q) of incomplete KGs, our aim is to find *non-trivial* answers $[\![q]\!]_{\text{test}} \backslash [\![q]\!]_{\text{valid}}$ ($[\![q]\!]_{\text{valid}} \backslash [\![q]\!]_{\text{train}}$). We use the same metric Mean Reciprocal Rank (MRR) as described in (Ren et al., 2020; Ren and Leskovec, 2020; Zhang et al., 2021b) to evaluate the performance of Multi-hop Reasoning. Suppose ($\mathcal{Q}$) is a set of $[\![q]\!]_{\text{test}} \backslash [\![q]\!]_{\text{valid}}$, for each *non-trivial* answer ($v \in \mathcal{Q}$), we rank (v) against non-answer entities $\mathcal{V} \backslash [\![q]\!]_{\text{test}}$ (where v is associated with the rank r). We estimate the MRR as follows: $\text{MRR} = \frac{1}{|\mathcal{Q}|} \sum_{v \in \mathcal{Q}}^{|\mathcal{Q}|} \frac{1}{r}$. The higher MRR is, the better performance of the model is.

Baselines: There are four baseline models: GQE (Hamilton et al., 2018), Query2Box/Q2B (Ren et al., 2020), BetaE (Ren and Leskovec, 2020) and ConE (Zhang et al., 2021b). We obtain the recent results of these models from Zhang et al. (2021b), which are slightly higher than those reported by Ren and Leskovec (2020). We not only use the same embedding dimension $d = 800$ as ConE for fair comparisons, but we also run experiments using $d = 512$ for the sensitivity analysis[2].

5.2 Results

We report our main results of Multi-hop Reasoning using CylE regarding FOL queries with and without negation. Specifically, we compare the performance of CylE with these baselines: GQE, Q2B, BetaE and ConE using the same benchmarking datasets as mentioned above. We obtain the average results of five experiments for each dataset when the embedding dimension $d = 800$ (see Appendix B.1 for error bars of these results). For the sensitivity analysis with $d = 512$, we obtain results of an experiment for each dataset.

Modeling queries without negation: Table 1 demonstrates the average performance of Multi-hop Reasoning using CylE regarding existential positive first-order (EPFO) queries (a subset of FOL queries without negation), compared to baselines. Overall, CylE significantly outperforms all baselines. In comparison with the SOTA model ConE ($d = 800$), the average performance for all query structures (**AVG**) of CylE gains around 6.4%, 4.7% and 3.7% using the dataset FB15k, FB15k-237 and NELL995 respectively. More specifically, CylE achieves the highest improvement regarding ip queries, by nearly 14.3%, 12.1% and 9.1% using these datasets. In comparison with the previous model BETA, the **AVG** of CylE ($d = 800$) is also considerably higher, by around 27.4%, 17.2% and 14.6%, observed in the three datasets.

In terms of using the DNF technique, notice that the performance of answering those queries with unions ($2u$) only is significantly lower than those of queries with intersections ($2i$), by a large margin. We consistently observed this point in the three datasets. This can be due the limitation of representing union queries using the DNF technique, where it is challenging to expect an answer entity, for example, to be nearest to all conjunctive queries in the DNF form (see Eq. (4.2)). We also report the results for query structures regarding the union operation using De Morgan's (DM) law. Since there might be a problem of inconsistency with the real set union (as discussed in (Zhang et al., 2021b)), the results for union operation using DNF ($2u/up$) are higher than those using DM law (see Section 5.3 for further details).

Modeling queries with negation: Table 2 shows the average performance of Multi-hop Reasoning using CylE regarding query with negation, compared to baselines. Although ConE achieves the highest performance in average using the three datasets, the **AVG** of CylE ($d = 800$) is close to those in ConE. In comparison with the previous model BetaE, the **AVG** of CylE outperforms significantly. This increasing trend is similar to that in the ConE. Note that handling queries with negation are still challenging in all models (BetaE, ConE and CylE) since the **AVG** are significantly lower than those in queries without negation operations. This challenge may be due to a high uncertainty in the large number of answers for negation queries.

Dataset	**Model**	**2in**	**3in**	**inp**	**pin**	**pni**	**AVG**
FB15k	BetaE	14.3	14.7	11.5	6.5	12.4	11.8
	ConE ($d = 800$)	**17.9**	**18.7**	12.5	**9.8**	**15.1**	**14.8**
	CylE ($d = 512$)	15.6	15.9	13.3	7.5	13.6	13.2
	CylE ($d = 800$)	15.7	16.3	**13.7**	7.8	13.9	13.5
FB15k-237	BetaE	5.1	7.9	7.4	3.6	3.4	5.4
	ConE ($d = 800$)	**5.4**	**8.6**	7.8	**4.0**	**3.6**	**5.9**
	CylE ($d = 512$)	4.8	8.3	8.1	3.6	3.4	5.7
	CylE ($d = 800$)	4.9	8.3	**8.2**	3.7	3.4	5.7
NELL995	BetaE	5.1	7.8	10.0	3.1	3.5	5.9
	ConE ($d = 800$)	**5.7**	**8.1**	10.8	**3.5**	**3.9**	**6.4**
	CylE ($d = 512$)	5.6	7.5	11.2	3.4	3.7	6.3
	CylE ($d = 800$)	5.4	7.6	**11.3**	3.4	3.7	6.3

Table 2: The average **MRR** (%) in different query structures with negation using these datasets: FB15k, FB15k-237 and NELL995. The baseline results (BetaE and ConE) are taken from (Zhang et al., 2021b).

Effects of the embedding dimension: In terms of queries without negation, there is a slight difference in MRR results of CylE between the embedding dimension $d = 800$ and $d = 512$ (see Table 1). MRR results in these query structures with $d = 800$ are higher than those with $d = 512$ using these datasets FB15k and FB15k-237. In the NELL995 dataset, however, MRR results with $d = 800$ are lower than those with $d = 512$. There is a different trend in these datasets as there may be

---

[2] Source code is available at https://github.com/nlp-tlp/cyle

an over-fitting problem when implementing CylE using the NELL995 dataset, but not for the FB15k and FB15k-237 dataset. Notice that large number of entities increase the complexity of the model using the NELL995 dataset. Precisely, the number of entities in this dataset (63,361) is considerably larger than those in the FB15k (14,951) and FB15k-237 dataset (14,505) (see Appendix A.1). Similarly, the number of relations also contribute to the complexity of the model. Although the number of relations in the NELL995 dataset (200) is less than those in the FB15k (1,345) and FB15k-237 dataset (237), this difference is slight, compared to that in the number of entities across the three datasets. With regard to negation queries, MRR results of CylE with $d = 512$ are close to those with $d = 800$ (see Table 2). Hence, there is little effect of the embedding dimension on the performance of CylE in these query structures.

5.3 Comparisons results of disjunctive queries using DNF and De Morgan's law

Table 3 shows the comparisons of MRR results (in percentage) of query structures regarding union operations using DNF and DM transformation. We compare results of CylE with those in ConE and BETA, since these models can handle the negation operations requiring for the transformation in DM queries. Overall, the MRR in DNF query structures of the approaches using ConE and CylE are higher than those in DM query structures. There is a similar trend in ConE and CylE, since these approaches share similarity in the aperture (the boundary of shapes in sector-cone and sector-cylinder respectively). Note that we use complement operations to transform union queries into DM forms, the queries in this situation are represented in geometry (sector-cone and sector-cylinder respectively). However, not all queries are represented well in geometry as discussed in (Zhang et al., 2021b). Further, we also observe a higher margin in MRR results of CylE than those in ConE, regarding most of DNF and DM query structures, using the three datasets (FB15k, FB15k-237 and NELL995).

Dataset	Model	2u-DNF	2u-DM	up-DNF	up-DM
FB15k	BetaE	40.1	25.0	25.2	25.4
	ConE	55.7	37.7	31.4	29.8
	CylE	**59.4**	**42.4**	**33.5**	**32.0**
FB15k-237	BetaE	12.4	11.1	9.7	9.9
	ConE	14.5	13.4	10.8	9.9
	CylE	**15.3**	**13.4**	**11.2**	**10.6**
NELL995	BetaE	12.2	11.0	8.5	8.6
	ConE	15.3	**14.8**	11.3	10.8
	CylE	**15.4**	13.3	**12.2**	**11.5**

Table 3: **MRR** (%) for answering FOL disjunctive query structures using DNF and DM on these datasets: FB15k, FB15k-237 and NELL995. The results of BetaE and ConE are taken from (Zhang et al., 2021b).

6 Conclusion

We have presented a novel query embeddings (QE) model using cylinder embeddings (CylE), which can handle a complete set of arbitrary FOL queries, to perform the Multi-hop Reasoning (MHR) task. To the best of our knowledge, CylE is the first 3D geometric-based QE model for MHR. Experiments show significant performance gain over previous approaches for non-negation queries. For queries with negation operations, we face a similar challenge to previous models *i.e.* low MHR performance. This is a future direction to improve CylE on these queries. This work paves the way for opening the geometric-based QE method using three dimensional shapes.

Limitations

Although CylE can learn to achieve the Multi-hop Reasoning task or answering complex queries, several limitations in this work are taken into account. First, the modeling process of logical operators (conjunction, disjunction and negation) using geometric-based perspective is an approximate method in a learning manner which may not satisfy some logic laws. This can be addressed by using fuzzy logic under fuzzy sets representation for these logical operators Chen et al. (2022). Fuzzy logic is a learning-free manner for logical operators in FOL queries. Combining this approach with the neural models to learn these operators can be a potential approach, but we leave this extension as a direction for future work.

Another limitation is that modeling union operators in EPFO queries using the DNF technique may not find all expected answer entities. Note that modeling this operator is similar to finding nearest entities to all conjunctive queries (in the DNF form), which may not an optimal solution when the geometric embeddings of these queries locate far from one to another, as mentioned in Section 5.2, queries structure $2u$ and $2i$ in particular.

A Further experimental details

We provide additional details for Section 5.1 in this section, divided into parts: Datasets & query structures A.1 and training & evaluation protocol A.2.

A.1 Datasets and query structures

We train and evaluate models using the same datasets (FB15k (Bollacker et al., 2008), FB15k-237 (Toutanova and Chen, 2015) and NELL995 (Xiong et al., 2017)) as those in (Ren and Leskovec, 2020) for the task of Multi-hop Reasoning (see Table 4 for a number of entities, a number of relations, a number of edges for each dataset). These datasets has been pre-processed by (Ren and Leskovec, 2020) to generate query structures for the training/validation/test set (see Table 5 for a description of these query structures and Table 6 for a description of average number of answer entities for test queries). These datasets are available at this link [3].

Dataset	Entities	Relations	Edges			
			Training	Validation	Test	Total
FB15k	14,951	1,345	483,142	50,000	59,071	592,213
FB15k-237	14,505	237	272,115	17,526	20,438	310,079
NELL995	63,361	200	114,213	14,324	14,267	142,804

Table 4: A statistical description of number of entities, relations, training/validation/test edges, reported from (Ren and Leskovec, 2020), in three datasets: FB15k, FB15k-237 and NELL995.

A.2 Training and evaluation protocol

We compare our results with these baselines (GQE, Query2Box, BetaE and ConE), taken from (Zhang et al., 2021b). We conduct all experiments using the Pytorch framework. Our implementation is done based on the original work of BetaE (Ren and Leskovec, 2020). [4] We adopt hyper-parameters, found by (Zhang et al., 2021b): the dimension of embedding $d = 800$, $\lambda_1 = 1.0$, $\lambda_2 = 2.0$, $\lambda = 0.02$, the batch size $b = 512$ and the negative sampling size $n = 128$. We also search for these hyper-parameters for best performance in MRR: the γ in the loss function [20, 30], the learning rate $\{1e^{-4}, 5e^{-5}\}$ and the scaling weight for the height variable λ_3 $\{1.0, 2.0\}$. We use a three-layer **MLP** (for a projection module) while two-layer **MLP** (for an intersection module), using 1600 dimension for hidden layers and Swiss activation function (Ramachandran et al., 2017). We run each experiment on a single NVIDIA Tesla V100 GPU. More details of hyper-parameters are shown in Table 7. Note that we also search for hyper-parameters in terms of experiments using ReLU activation function (in MLP) for ablation study. In this situation, we follow the same found hyper-parameters in Table 7 as those in the situation using Swiss activation function (the dimension of embedding d, the batch size b, the number of negative sampling size n, the maximum number of training steps m, the scaling hyper-parameters $\lambda_{i=\{1,2,3\}}$, the controlling distance λ, the learning rate l and the γ in the loss function), except for the found $\gamma = 30$ in the loss function using the FB15k-237 dataset, during the training process.

B Additional experimental results

B.1 Error bars

Table 8 and Table 9 show the error bars of MRR for the task of Multi-hop Reasoning using our approach with CylE, for queries without and with negation respectively using the three dataset FB15k, FB15k-237 and NELL995. More specifically, we run five experiments using different seed values in $\{0, 10, 100, 1000, 10000\}$ during the initialization process (for each dataset). We estimate the average MRR for different query structures of five experiments and obtain the standard deviation (for each dataset).

In terms of queries without negation, the standard deviation of the average MRR is small, at around 0.101, 0.039 and 0.113 using the dataset FB15k, FB15k-237 and NELL995 respectively. A similar trend is observed in queries with negation operation, since the standard deviation of the average MRR is also small using the three datasets. These error bars show a level of degree in stability of MRR (for each dataset) using different values of random seed during the initialization process.

B.2 Modeling the cardinality of answer sets using correlation coefficients

It is argued that the aperture embeddings may have a correlation with the number of the answer set $[\![q]\!]$. This correlation though is not guaranteed under different circumstances (*e.g.* entities having identical relations to one another), the learnt embeddings can have a positive relationship with the number of elements (cardinality) of $[\![q]\!]$. We follow a technique

of ConE (Zhang et al., 2021b) to compute this correlation. We use two types of correlation as (Ren and Leskovec, 2020; Zhang et al., 2021b): (1) Spearman's rank-order correlation coefficient (SRCC) (to measure the monotonicity relationship or the statistical dependence between the rankings of the two variables) and (2) Pearson correlation coefficient (PCC) (to measure the linear relationship between the two variables). We do not compute SRCC and PCC regarding disjunctive queries, which is the same as (Ren and Leskovec, 2020; Zhang et al., 2021b), since we model queries with disjunctions using the DNF technique. Table 10 shows SRCC of Q2B, BetaE, ConE and CylE using the FB15k dataset. No SRCC results are available in G2B for queries with negation since this model cannot handle this operation (Ren et al., 2020). Overall, the SRCC results of CylE are significantly higher

Table 12: **Pearson** correlation coefficient between embeddings of learnt embeddings and a numer of answers for queries using the dataset FB15k, FB15k-237 and NELL995. Correlation results of Q2B, BetaE and ConE are taken from (Zhang et al., 2021b).

than those in ConE in most of query structures, by a large margin. These results demonstrate the expressiveness of modeling cardinality of answer sets using CylE. Note that SRCC results using CylE also significantly exceed the other previous models.

We show additional results of Spearman's Rank Correlation Coefficient (SRCC) in Table 11 using the dataset FB15k-237 and NELL995. In terms of the dataset FB15k-237, although the SRCC results in several query structures (*e.g.* $3p, 2in, 3in, inp, pni$) using the approach in CylE are lower than those in ConE, the SRCC in the rest of query structures using CylE outperform those in ConE. A slight decrease in SRCC results, from CylE to ConE, can be mostly observed in queries that are involved in negation operations. These observations are due to the fact that the height variable might not play a role in embedded queries with complement operations. Similar to the dataset FB15k-237, in the dataset NELL995, the SRCC results in some query structures (*e.g.* $2i, 3i, 2in, 3in, pni$), particularly in queries with negation operations, are also lower than those in ConE. However, most of SRCC results in queries without negation operations surpass SRCC results

Table 13: Average **MRR** (%) results of CylE in different FOL query structures without negation (∃, ∧, ∨) using ReLU and Swiss activation for the MLP in these datasets: FB15k, FB15k-237 and NELL995.

in ConE. In comparisons with BetaE and Q2B, SRCC results in all query structures (with and without negation) using CylE are significantly higher than SRCC results in these models.

The similar trend of results are also observed in the Pearson Correlation Coefficient (PCC) between the aperture embeddings and the cardinality of answers set using the three dataset FB15k, FB15k-237 and NELL995 (see Table 12).

B.3 Further ablation study

We compare the performance of CylE using the different activation function (ReLU and Swiss) for the MLP networks (in the projection and intersection module), during the training process in this ablations study (see Table 13 and 14). Overall, the average MRR results in most of query structures for the approach using Swiss activation are slightly higher than those in the approach using ReLU activation in the three datasets FB15k, FB15k-237 and NELL995. Since the Swiss activation was shown to be an efficient activation function (Ramachandran et al., 2017) for the MLP networks.

C Computational complexity

The computational complexity of CylE is similar to ConE since these models share similarity in geometric shapes. Note that the computational complexity of ConE and G2B is also similar to one another (Zhang et al., 2021b). It is arguably that CylE, ConE and G2B have similar computational complexity. Assuming a Disjunctive Normal Form (DNF) query q: that consists of conjunctive queries $q_{i:1\rightarrow n}$, where $q = q_1 \vee \cdots \vee q_n$. The computational complexity of CylE for answering q is equivalent to the computational complexity for answering the number n of conjunctive queries q_i. This answering process is involved in the estimation of a sequence of geometric sector-cylinder operations in which a constant time can be taken for each operation, then performing a range search which can be achieved using techniques according to Locality Sensitive Hashing (Indyk and Motwani, 1998).

Models	GQE	Q2B	BetaE	ConE	CylE	CylE
Emb. dimension d	800	800	800	800	800	500
Running time (s)	75.87	81.43	168.91	119.90	154.79	121.65

Table 15: Average running time (seconds) for the first 500 training steps in different approaches using the FB15k-237 dataset.

We record the average running time (seconds) for the first 500 training steps using the same dimensional embedding for all models (GQE, G2B, BetaE, ConE and CylE) and another one with lower embedding dimension for CylE, on the same single NVIDIA Tesla V100 GPU, for fair comparisons. The lower this value is, the faster training process is. Overall, the fastest model is GQE while the slowest model is BETA. The running time of CylE is slightly slower than ConE, but CylE with lower dimension ($d = 500$) is on par with ConE. Further, the running time of CylE is also faster than BetaE.

D The range values for the height

The range of values for the height variable $\boldsymbol{\theta}_{he}$ for an arbitrary embedded query $\mathbf{V}_q = (\boldsymbol{\theta}_{ax}, \boldsymbol{\theta}_{ap}, \boldsymbol{\theta}_{he})$ can be varied without any constraints. For example, this range of values can be infinite. However, there is a numerical problem in a way that values of $\boldsymbol{\theta}_{he}$

might dominate those in the semantic center $\boldsymbol{\theta}_{ax}$ and the aperture $\boldsymbol{\theta}_{ap}$. This problem can lead to a reduction in the performance of MHR in this situation. Since $\boldsymbol{\theta}_{ax} \in [-\pi, \pi)^d$ and $\boldsymbol{\theta}_{ap} \in [0, 2\pi]^d$ are in a small range of values, compared to infinite range of $\boldsymbol{\theta}_{he}$. Thus, we set a small range of values for the height variable and scale the range to $(-\pi, \pi)$, to avoid the numerical issues, making this variable have a consistent systematic range of values (based on the multiples of π) as those in the semantic center $\boldsymbol{\theta}_{ax}$ and the aperture $\boldsymbol{\theta}_{ap}$.

Fiction-Writing Mode: An Effective Control for Human-Machine Collaborative Writing

Abstract

We explore the idea of incorporating concepts from writing skills curricula into human-machine collaborative writing scenarios, focusing on adding *writing modes* as a control for text generation models. Using crowd-sourced workers, we annotate a corpus of narrative text paragraphs with writing mode labels. Classifiers trained on this data achieve an average accuracy of $\sim 87\%$ on held-out data. We fine-tune a set of large language models to condition on writing mode labels, and show that the generated text is recognized as belonging to the specified mode with high accuracy.

To study the ability of writing modes to provide fine-grained control over generated text, we devise a novel turn-based text reconstruction game to evaluate the difference between the generated text and the author's intention. We show that authors prefer text suggestions made by writing mode-controlled models on average 61.1% of the time, with satisfaction scores 0.5 higher on a 5-point ordinal scale. When evaluated by humans, stories generated via collaboration with writing mode-controlled models achieve high similarity with the professionally written target story. We conclude by identifying the most common mistakes found in the generated stories. The datasets and codes are available at the Github[1].

1 Introduction

Large-scale pre-trained language models (PLMs) have demonstrated a remarkable aptitude for generating text with an exceptional degree of fluency and structure (Guan et al., 2021; Tan et al., 2021), sparking renewed efforts to utilize them for the purpose of generating narrative fiction. Recent work has explored various ways of controlling PLMs, using sentiment (Luo et al., 2019), style (Kong et al., 2021a), and even character information (Liu et al., 2020a), in an attempt to cater the generated text to an author's intentions.

Summary: A boy was walking along a path in the forest, when he came across a heap of leaves.

Mode	Story
Dialogue	"Here are some leaves," he **whispered**. "They were wet when we came, and are wet now. I'll lie them down and wait." "What is it?" I **exclaimed**. "If you will stand still," **said** my boy, "I will show you … "
Action	He **stood** for a moment **looking** at me, then quietly he **picked up** the leaves, and **carrying** them in his hand, **climbed** to the top of the heap, and **examined** them …
Description	This heap consisted of **dead leaves**, many of them **rotten**, and still **wet**, with one or two **lying flat** on the ground, others **lying up against** the branches. The first to fall was the one I had thought **dead**. It had been crushed by the wind. …

Figure 1: Example of expanding the **Summary** into stories using different writing **Mode**s. The bold words imply the particular manner of expression in that mode. **Dialogue** focuses on the utterances spoken by characters, **Action** on the motion of characters, and **Description** on the depiction of characters or places.

However, the aforementioned controls deal primarily with *static* text attributes; an attribute like style is more synonymous with an entire author or book than with a single passage of text. Less attention has been paid to designing effective control factors for the real demands of human authors in collaborative writing settings, where authors typically exercise more *dynamic* control over their writing, varying attributes of the text at the sentence or paragraph level. Here we find inspiration from the creative writing literature, where the notion of a *fiction writing mode* is often presented as an important concept to consider when crafting narrative fiction (Klaassen, 2015).

A fiction-writing mode (also referred to as a rhetorical mode) is a particular manner of writ-

Table 1: The number of instances for dialogue (**Dia.**), action (**Act.**), description (**Des.**), and uncertain (**Unc.**) modes in the dataset. **Kappa** is the inter-annotator agreement and **Len.(std)** is the average token number in each instance and its standard deviation.

ing, encapsulating the focus, style, and pacing of the text (among other things). Figure 1 illustrates how the same event can be described in different ways depending on the writing mode, using the three most common types, *Dialogue*, *Action*, and *Description*. Skilled authors proficiently use writing modes as a stylistic choice to engage readers and progress the narrative (see Section 2 for more detail) (Klaassen, 2015). Thus, we hypothesize that conditioning text generation models on writing modes can provide important controls to authors in a human-machine collaborative writing scenario.

To verify this hypothesis, we are faced with two challenges. First, to the best of our knowledge, there is no available dataset annotated with writing modes to train generation models. We create a Fiction wRIting moDE dataset (**FRIDE** dataset) containing 1,736 fiction paragraphs annotated by crowd-source workers with the three writing mode labels. Subsequently, we train a classifier on the **FRIDE** dataset and use it to annotate paragraphs of a large fiction corpus in order to create a larger-scale dataset. Using the established paradigm of training conditional text generation models by summarizing and reconstructing text (Sun et al., 2020), the dataset is used to train models which can be conditioned on a writing mode label.

Second, to measure whether writing modes allow for more effective control of text generation models, we need to compare the generated texts to the author's intention, which is unobservable. We design a new evaluation framework for human-machine collaborative writing where the author is given a paragraph of text, and is asked to recreate it solely through interaction with generative models. By using the paragraph as a proxy for the author's intention, we are able to assess the similarities between the intention and the generated text, and analyze the differences as indications of where current controls fail.

Through both automatic and human evaluation we show: (1) the use of writing mode labels with conditional text generation models contributes to average 1.4 and 2.0 points improvements on ROUGE-L and BERTScore; (2) the writing modes of generated text are effectively controlled, and are classified as belonging to the target mode in 87.6% of cases; (3) authors are 22.2% more likely to choose the suggestions from writing mode-controlled models, and assign them an average 0.5 higher satisfaction score (on an ordinal 1-5 scale) compared to the uncontrolled models; (4) applying writing mode control to collaborative writing enhances the similarities between the generated text and the authors' intention.

2 Fiction-Writing Mode Dataset

Fiction-writing modes have long been proposed as a useful abstraction in the study of literature and creative writing (Morrell, 2006; Klaassen, 2015), dating as far back as Aristotle (Halliwell and Aristotle, 1998). While there is no consensus on the categorization of writing modes, most sources prefer to introduce at least three modes: (1) *Dialogue*, direct quotation of characters speaking, (2) *Action*, an account of a series of events, one after another, chronologically, and (3) *Description*, a more detailed inspection of people, places, or things and their properties. These are the three major writing modes which are the focus of study in this paper.

Just as there is no agreement on how best to categorize writing modes, there is also no consensus on what text exhibits a particular mode. Even a single sentence can exhibit multiple writing modes, in varying degrees. However, for the purpose of this work, we assume that each paragraph can be categorized as exhibiting a single writing mode.

FRIDE Dataset In order to train models which generate text in a specified writing mode, we must first create a dataset, which we refer to as Fiction-wRIting moDE dataset (**FRIDE** dataset), which pairs paragraphs of narrative text with their corresponding writing mode labels. However, directly annotating writing modes on a large-scale narrative dataset is expensive and time-consuming. We first collect a modestly sized dataset from crowd-sourced workers, and utilize it to train a writing mode classifier. The classifier can then be used to provide high confidence labels to a much larger dataset of narrative text paragraphs, on a scale suitable for training large text generation models.

Paragraphs for annotation are collected from fic-

	Precision	Recall	F1
BERT-base	85.7	85.0	85.0
XLNet-base	84.7	84.4	84.3
RoBERTa-base	**86.3**	**85.2**	**85.2**

Table 2: The performance of writing mode classifiers on the **FRIDE** dataset.

tion books sourced from Project Gutenberg[2] (128 books) and, for more contemporary writing, Smashwords[3] (150 books). Each book is divided into paragraphs using Chapterize[4], and paragraphs longer than 200 words are removed. In situations where a continuous dialogue takes place over paragraph boundaries, we group them into a single paragraph. Each paragraph was annotated with one of the three aforementioned writing modes using Amazon Mechanical Turk (AMT). In addition, we add a fourth category, *Uncertain*, to encompass cases where the writing mode is unclear or does not fit well into the three main modes. All annotators were native English speakers, and three annotators were assigned to each paragraph. Paragraphs were assigned the majority label, or marked as *uncertain* in cases where each annotator provided a different label. We continued the annotation process until we had approximately 1,000 instances labeled and balanced across the three main modes (Table 1).

Writing Mode Classifier While it is possible to use the collected data to train a model, the relatively small pool of examples may cause the model to be sensitive to other text characteristics unrelated to the writing mode. To help alleviate this problem, we train a writing mode classifier and employ it to predict writing modes on a larger collection of texts. We experiment with training three separate classifiers, each trained by fine-tuning a different PLM (BERT (Devlin et al., 2019), XLNet (Yang et al., 2019), or RoBERTa (Liu et al., 2019)) on the **FRIDE** dataset. We randomly sample 300 instances from each type of writing mode and divide them using a 1000/100/100 train/dev/test split, with an equal number of each label in each split. An evaluation of these models (Table 2) shows that all models perform similarly. The RoBERTa-based model was used as the final writing mode classifier throughout the remainder of this paper.

FRIDE-XL Dataset In order to construct a larger dataset of writing modes suitable for training mode-conditional text generation models, we utilize the classifier trained in the preceding section on a larger set of texts, extending the previous text to 5,946 fiction books from Project Gutenberg. We leverage the writing mode classifier to assign a writing mode label to each paragraph of books and randomly select 362,880 paragraphs. We refer to this dataset as **FRIDE-XL**. Additional statistics of the dataset are provided in Table 7 of Appendix.

To test the accuracy of the classifier on the **FRIDE-XL** dataset, we ask three additional annotators to label 150 instances taken from the **FRIDE-XL** dataset. The results show the inter-rater agreement between annotators is 0.73. The predictions of the trained classifier agree with the majority label provided by the annotators in 85.1% instances. In terms of accuracy, classifier F1 on **FRIDE-XL** is 83.9, compared to 85.2 on the **FRIDE** dataset. It is important to reiterate that text often reflects multiple writing modes to varying degrees, and so some disagreement is inherent in the task. We find that the writing mode predicted by the classifier fails to match any label provided by human annotators in only 4.8% of cases. In Section 4.2 we show that this is indeed sufficient accuracy for producing the data and models necessary for generating mode-specific text.

3 Models

We evaluate writing mode as a control factor on three different PLM architectures: BART, (Fan et al., 2018), T5 (Raffel et al., 2020), and GPT2 (Radford et al., 2018). All models have been used previously for text generation but differ in ways that may impact their ability to adhere to the conditioning information and the quality of the generated text. For instance, the comparatively larger size and contextual window of GPT2 has made it a common choice for story generation with long text (Wang et al., 2021; Clark and Smith, 2021; Akoury et al., 2020), but smaller models like T5 show great controllability (Clive et al., 2021). We assess each of these three models, fine-tuning them to reconstruct paragraphs from the **FRIDE-XL** dataset.

For training conditional text generation models, we follow an established paradigm of summarization, conditioning, and reconstruction, as used by Sun et al. (2020). First, each paragraph is summarized using an existing summarization model.

Table 3: Automatic evaluation on quality and controllability as model inputs (summaries (**S**), length (**L**), and writing modes (**M**)) vary. Quality is evaluated by perplexity (**PPL**), BLEU-4 **(B4)**, ROUGE-L (**RL**), BERTScore (**BS**), and controllability is measured by the accuracy of the generated stories matching the specified writing modes when the writing modes (**M**) are specified as **Dialogue**, **Action**, and **Description**. The inputs such as summaries (**S**), length (**L**), and writing modes (**M**) for the evaluation of quality and controllability are respectively inferred from the leading context and the target stories.

Here we use the narrative text summarization proposed in Kryscinski et al. (2021), and decode using beam search with a beam size of 5 as in that work. We then fine-tune a PLM to reconstruct the original paragraph, conditioning on the summary. In this way, the summary acts as a semantic control: the trained model accepts user summaries and attempts to expand upon them to generate a longer paragraph, embellishing missing and less important details in a reasonable way.

Other forms of information can also be added to the summaries to function as additional controls. The conditioning factors provided to models are:

- Summary, generated from the paragraph by a pre-trained model as shown in Appendix.
- Context, the preceding paragraph.
- Length, the number of tokens in the paragraph divided into ten equally-sized bins.
- Writing Mode, the mode assigned to the paragraph by the classifier as described in Sec. 2.

For T5 and BART, the training methodology is straightforward: we concatenate the controlling information and use it as input to the encoder, training the decoder to generate the original paragraph. For GPT2, which has only a decoder, we concatenate the conditioning information as prompts.

4 Automatic Evaluation

In this section, we study the influence of model inputs (e.g., summaries, length, and writing modes) on the quality of text, and assess to what extent the writing modes of text can be controlled, as measured by automatic evaluation metrics.

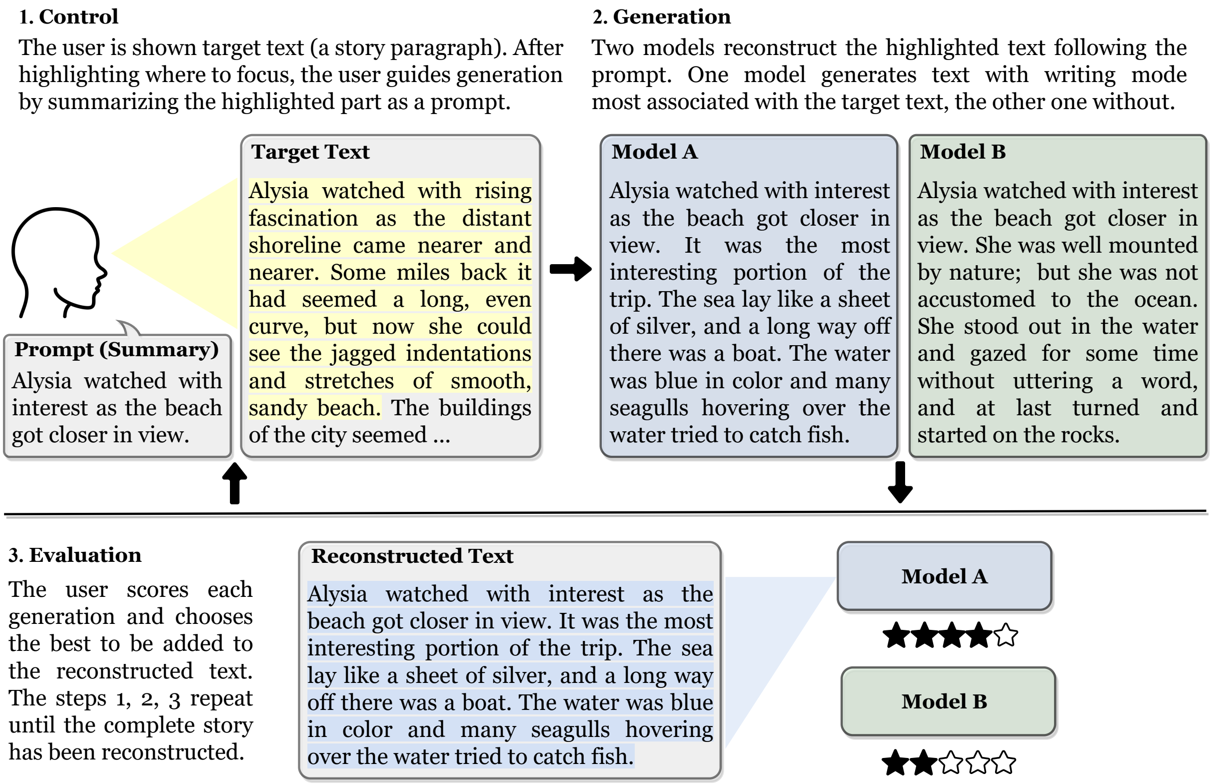
4.1 Baseline Models

In addition to ablations of our proposed models, we compare against three baseline systems:

GPT2 We finetune GPT2 (Radford et al., 2018) identically to our proposed system, but using only the preceding paragraph and without other inputs.

PPLM Dathathri et al. (2020) employ an attribute classifier to guide the pretrained language model to generate text with specified attributes. To adapt the PPLM to our task, we train a writing mode classifier as the attribute classifier on the **FRIDE** dataset. As the writing modes of preceding paragraphs would interfere with the classifier, the PPLM does not take the preceding paragraphs as context.

FIST Fang et al. (2021) propose a system which utilizes keywords instead of summaries to sketch the semantic content of the desired stories. As there is no prompt in our dataset, following their idea, we infer the keywords from the leading context (the



1. Control The user is shown target text (a story paragraph). After highlighting where to focus, the user guides generation by summarizing the highlighted part as a prompt.

Target Text Alysia watched with rising fascination as the distant shoreline came nearer and nearer. Some miles back it had seemed a long, even curve, but now she could see the jagged indentations and stretches of smooth, sandy beach. The buildings of the city seemed ...

Prompt (Summary) Alysia watched with interest as the beach got closer in view.

2. Generation Two models reconstruct the highlighted text following the prompt. One model generates text with writing mode most associated with the target text, the other one without.

Model A Alysia watched with interest as the beach got closer in view. It was the most interesting portion of the trip. The sea lay like a sheet of silver, and a long way off there was a boat. The water was blue in color and many seagulls hovering over the water tried to catch fish.

Model B Alysia watched with interest as the beach got closer in view. She was well mounted by nature; but she was not accustomed to the ocean. She stood out in the water and gazed for some time without uttering a word, and at last turned and started on the rocks.

3. Evaluation The user scores each generation and chooses the best to be added to the reconstructed text. The steps 1, 2, 3 repeat until the complete story has been reconstructed.

Reconstructed Text Alysia watched with interest as the beach got closer in view. It was the most interesting portion of the trip. The sea lay like a sheet of silver, and a long way off there was a boat. The water was blue in color and many seagulls hovering over the water tried to catch fish.

Figure 2: A turn-based text reconstruction game. Users aim to reconstruct the target text solely through interaction with story generation models, providing prompts (summaries) to guide generation, and choose between a number of options to continue the text. Each option is generated by a different model. Users report satisfaction at each turn, and the reconstructed text is used in further evaluation.

preceding paragraphs) and then generate stories conditioning on the context and keywords.

4.2 Results

We evaluate the models along three axes: fluency, similarity, and controllability, using the test set of the **FRIDE-XL** dataset. The results of our automatic evaluation are shown in Table 3.

Fluency We evaluate fluency using perplexity computed by the pre-trained GPT2 model. We find that there is an average 0.8 decrease in perplexity when summaries are added and 1.2 increase when writing modes are added.

Similarity Our task is very similar to summarization, so we adopt the same evaluation metrics including BLEU-4 (Papineni et al., 2002), ROUGE-L (Lin, 2004), and BERTScore (Zhang et al., 2020). It is also quite common to include these automatic measures in narrative text generation work, despite their known flaws. We observe a consistent improvement across all models as the amount of conditioning context increases, and the models using writing mode factors outperform those without.

Controllability Lastly, we evaluate the controllability of mode-controlled models. For each paragraph, a target writing mode is chosen using the writing mode classifier, and used as conditioning for a text generation model. The classifier is then used to predict the writing mode of the generated text, and we measure the accuracy of generating stories with the specified writing modes.

On average, including writing mode as condition improves the accuracy of generating text which is classified as that mode, but the effect varies drastically by the specific mode. For Action and Description modes, the inclusion of writing mode conditioning improves accuracy on average by 45.4% and 45.6%, respectively, compared to their non-mode counterparts. For dialogue, the improvement is 21.5%, relatively lower.

It is interesting to note that the inclusion of summaries to the length-only model results in significant improvements to the controllability of the text. This implies that the pre-trained models are able to naturally infer the intended writing mode from the summaries to some degree, with modest accuracy ($\sim 44\%$) on average for Action and De-

Model	Writing Mode Control	Selection Percentage			Satisfaction Score		
		Dialogue	Action	Description	Dialogue	Action	Description
GPT2	✗	31	44	32	2.27	2.84	2.67
	✓	**69**	**56**	**68**	**2.96**	**3.27**	**3.59**
BART	✗	36	39	43	2.82	2.64	3.10
	✓	**64**	**61**	**57**	**3.28**	**3.11**	**3.34**
T5	✗	47	36	44	3.19	2.91	3.22
	✓	**53**	**64**	**56**	**3.24**	**3.36**	**3.55**

scription modes, and up to 86% on Dialogue with BART. Summaries may contain some cues about the intended modes, especially, the summaries for Dialogue have strong cues (*said*, *replied*, *argued*, ...) in most cases. However, the consistent large margins of accuracy scores when conditioning on writing modes illustrates the effectiveness of modes as a control factor.

5 Human Evaluation

In the preceding section, we used automatic measures to show consistent improvements in similarity and controllability when conditioning text generation models on writing modes. In this section, we assess whether these improvements translate into higher author satisfaction and story quality as judged by human participants.

Text Reconstruction Game To evaluate writing mode-controlled models within human-machine collaborative writing, we devise a story generation game (Figure 2). Using a web interface, participants are presented with a target story, drawn from **FRIDE-XL**, and asked to reconstruct it through interaction with the trained models. Each session utilizes two models, each using the same PLM, one trained to condition on writing modes, and one that does not.

At each round, (1) the author highlights a selection of text from the target story, and provides a text summary which serves as a rough sketch of the story described therein. Constraints on the summary length and a time limit on each session force the author to extract essential elements of the text and prevent them from simply specifying the entire text as the summary. (2) The models then each return a sample of generated text, and (3) the author is asked to score each in terms of overall satisfaction (ordinal, 5-point scale), and choose one to continue the story. The source of the suggestions (model name) is not given to the participant, and they are presented in random order. The above process repeats until the author has attempted to recreate the entire target text. The author is then asked to provide feedback on overall satisfaction with the story and interface, the efficiency of using the interface over generating the text from scratch, and what errors were present in the generated text.

Our approach takes inspiration from previous human-in-the-loop evaluations (Akoury et al., 2020; Clark and Smith, 2021) where authors are asked to construct stories by collaborating with story generation models, but do so freely, without being provided any specific direction for how the story should unfold. Therefore we cannot observe the author's intention, and it is difficult to ascertain how closely the generated stories match the author's original intention, or the extent to which bias may be affecting the model scores when satisfaction with the models is self-reported.

Our solution to these issues is to present the author with a target text they must attempt to reconstruct. The target text serves as a substitute for the author's intention, allowing us to more objectively measure the differences between the generated story and the target. While this design shifts the nature of interaction away from a more creative use case, we argue that increased awareness of the models' limitations provides a worthwhile trade-off when used strictly as a means of evaluation.

Using the unique properties of our proposed evaluation design, we evaluate: (1) the effectiveness of writing mode control when generating text as an author, (2) their effectiveness from the perspective of a reader, comparing generated stories with target stories in a blind study, and (3) the types of errors made where authors were unable to exert desired

control over the models.

5.1 Evaluation by Authors

We randomly sample 36 target stories (each annotated with a writing mode) from **FRIDE-XL**, such that there is an equal number of stories from each mode and each genre. For the writing mode-controlled model, we use the mode annotated in the dataset as the true mode (users are not asked to specify a mode explicitly). The authors are recruited via crowdsourcing on AMT, and each target story is reconstructed using the proposed interface, with each story given to three annotators.

Do authors prefer the suggestions from writing mode-controlled models? We measure authors' preferences for models by the win/loss rate for which model was selected to continue the story at each step, and the average satisfaction score of each model's suggestions. The results are presented in Table 4. Suggestions of writing mode models are preferred consistently, irrespective of model type, and are chosen on average 22.2% more than suggestions from uncontrolled models. In terms of satisfaction score, using writing mode as a conditioning factor improves satisfaction by 0.5 / 5.0 points on average, an improvement consistent across all writing modes. We conclude that the strong and consistent improvements when using writing mode-conditional models demonstrate they are an effective control for story generation.

5.2 Evaluation by Readers

Evaluation by authors using the story reconstruction game interface provides compelling evidence for the effectiveness of writing modes as a control, but how close to the author's intention are the stories generated using the writing interface? By providing authors with a target story, new evaluation methods are possible, such as having the stories scored by a separate group of participants, in order to avoid any bias from self-reporting.

Here we evaluate the generated texts via similarity with the target texts, in two different scenarios. We enlist 197 human participants from AMT, none of which participated in the story generation task, to serve as readers. We present each reader with three stories: the target story, the generated story, and a baseline story. Readers are asked to score the similarity between the target text and the other stories on an ordinal 5-point scale, in terms of plot and style.

How similar to the target text are the generated stories? The generated stories are written interactively via the writing interface, where authors have access to suggestions from mode and non-mode models. The baseline stories are generated in a purely automated manner using the model to predict the entire paragraph from a summary (generated by the same summarization model we use in the fine-tuning process), together with the writing modes provided from the dataset annotations.

The left side of Table 5 shows the results. We observe higher similarity scores between the target text and the stories generated via collaborative writing in almost all cases, an average increase of 0.31 on plot, and 0.25 on style. On one hand, this is an expected conclusion given that the collaborative process allows authors to select the best of two automatic suggestions at each point, and one may expect the quality of collaborative writing stories to be strictly better than automatic ones. However, we do note trends based on model type; BART in particular scores high (3.80) in terms of similarity on style.

How effective is writing mode control for automatic generation While our focus is primarily on the use of additional controls in collaborative story writing, we also measure the effectiveness of writing modes as a useful control in a purely automatic sense. Using the story generation models, as above, we generate full stories without writing mode conditioning and contrast them with the previously generated stories generated automatically using writing modes. We report the similarity of

Error Type	GPT2	BART	T5
Missing Information	61	65	32
Irrelevant Information	45	40	22
Wrong Information	8	8	2
Incoherence	22	22	22
Inconsistency	22	13	20
Disfluency	15	27	18
Repetition	0	0	0

Table 6: The counts of each error occurring in the reconstructed text across different models.

each to the target text in the right side of Table 5.

We again find that writing mode-controlled models significantly improve the control of the generated text, producing stories closer to the target text in both style and content. The addition of a writing mode control improves average similarity to target text by 0.28 on plot and 0.38 in style. Although writing modes are more inherently tied to the style of the text, it is interesting to observe improvements in plot similarity as well. This may indicate that the mode has a positive effect in pressuring the model to focus on summary plot points, via explicitly disentangling these factors. However, we leave further analysis of this phenomenon to future work.

5.3 Error Analysis

To understand what errors are likely to occur in the generated stories we ask annotators to identify aspects of the generated text which differed from the target, from a set of pre-determined categories (Table 6). The most frequent errors are the *missing information* and *irrelevant information*, suggesting that the models extrapolated from the summaries in undesirable ways.

Note that the counts of most errors made by T5 are appreciably lower than those made by GPT-2 or BART, yet BART has higher similarity scores in both plot and style. We infer that some errors made by T5 must play a more important role in overall similarity, and that missing or irrelevant information must not play a crucial role in similarity metrics.

6 Related Work

Our work is based on prior research in computational modeling for story generation. Early approaches to automatic story generation relied on graph-based planning and hand-crafted rules to structure narratives (Meehan, 1977; Callaway and Lester, 2002; Riedl and Young, 2004; Li et al., 2013). More recent works generate stories by finetuning on large-scale PLMs (See et al., 2019) to improve its fluency and incorporating structured knowledge such as planned events (Chen et al., 2021; Fang et al., 2021; Li et al., 2022), summaries (Yao et al., 2019; Tan et al., 2021; Sun et al., 2020), and external knowledge (Guan et al., 2019; Xu et al., 2020b; Guan et al., 2020) to enhance its coherence and consistency. Our story generation models are also finetuned on the large-scale PLMs to generate text following the given summaries.

Our work bears similarity to work on controllable story generation, which aims to control different attributes of stories such as the sentiments (Luo et al., 2019; Kong et al., 2021b), genres (Cho et al., 2022), intention (Sun et al., 2021), and characters (Lee and Jung, 2020; Xu et al., 2020a; Liu et al., 2020b) of stories. However, these attributes are largely unchanging throughout the story, while we focus on writing mode, a more dynamic attribute of text. Thus our work is also more inherently related to interactive story generation where the author works closely with the model to craft text on a comparatively finer level of granularity (sentences or paragraphs).

Finally, our evaluation method is inspired by work on human-in-the-loop storytelling (Roemmele and Gordon, 2015; Samuel et al., 2016; Clark et al., 2018; Goldfarb-Tarrant et al., 2019; Brahman et al., 2020), where the authors are asked to work in concert with story generation models, curating their suggestions to craft the final story. Human-in-the-loop evaluations overcome many of the shortcomings of automatic evaluations, which capture rough statistics, but may be unaware of important errors in plot development and story continuity (Sagarkar et al., 2018). By asking users to select between models' suggestions, we can instead gain a more accurate picture of which system improvements yield real benefits to a potential human-machine writing collaboration (Akoury et al., 2020; Clark and Smith, 2021; Khashabi et al., 2021). Our approach is similar to this, but the addition of a target text allows us to examine the difference between the generated and intended text, which we argue is a more important comparison when dealing specifically with understanding *control*.

7 Conclusion

In this work, we introduced writing modes as a control for human-machine collaborative writing scenarios and showed that training models to condition on writing modes resulted in stories that were closer to targets. Both the automatic and human evaluation shows that the writing modes of text are effectively controlled, authors prefer text suggestions made by writing mode-controlled models, and readers score stories to be more similar to targets in terms of both plot and style. To verify the hypothesis, we collected **FRIDE** and **FRIDE-XL**, datasets of narrative text annotated with writing modes, which we released to help facilitate further research in writing modes and fine-grained control for storytelling. In future work, we wish to apply reconstruction-based evaluation for other factors of human-machine storywriting, and incorporate a dynamic use of writing modes into fully automatic hierarchical story generation models.

Limitations

This work is subject to known biases in the dataset used throughout this work. Due to existing copyrights on most contemporary examples of professional narrative fiction, researchers often turn to works in the public domain, as we do here. While many public domain novels are literary classics, the lack of comparable contemporary work results in models which are biased towards reproducing older works, both in terms of style and content. More contemporary approaches to writing style are not represented in our work, and plot points may be biased by the worldview of the authors at the time.

8 Appendix

8.1 Writing Mode Classifier

To study how many samples are enough to train the classifiers, we test the classifiers trained on the subsets of the FRIDE dataset. The subset size increases from 0 to 1000. The results in Figure 3 show the classifiers reach the best performance when the subset size is around 200.

When training the classifiers, we use the optuna [5] to do a hyper-parameter search. We run hyper parameter search 20 times and try to search the optimal value for learning rate (in range 1e-5∼5e-5), batch size (in range 2∼8), and training epochs (in range 2∼10). The optimal value for learning rate is 1e-5, for epoch is 10, and for batch size is 5. The reported test results are the average of 10 trails with different random seeds.

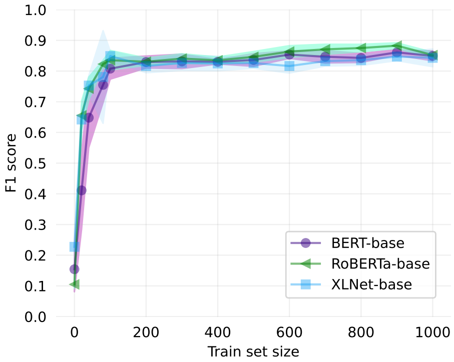

Figure 3: The F1 score of 3 classifiers trained on subtrain sets with different size.

8.2 Writing Mode Distribution

The writing mode is a kind of style to tell stories, and thus, it could be related to the genre of fictions. To verify that the writing modes are a style independent of the genres, we select 9 frequent genres and analyze the distribution of the writing modes within each genre. The results in Figure 4 show that the writing modes have similar distribution across different genres, demonstrating that the distribution of writing modes is irrelevant to the category of genre. Thus, the writing mode is a style independent of the genre.

8.3 Training Settings

The story generation models are finetuned from three types of pretrained language models such as BART, GPT2, and T5. We utilize the large version of the pretrained models such as “bart-large",“gpt2-large", and “t5-large", for better performance, and these models are downloaded through huggingface [6] model library. The story generation models are trained on 8 Tesla A100 with a learning rate 4e-5 and a batch size 32 for 5 epochs about 24 hours. The warm up steps for all models are the first 10% steps of the total steps. During inference phase, we adopt nuclear sampling method with top_p being 0.9 recommended by Holtzman et al. (2020).

8.4 Summarization Model

Most prior works focus on the summarization of news articles, which is a domain different from the narrative text in books. Recently, Kryscinski et al. 2021 collect a summarization dataset for the narrative text in books. Each book in the dataset is summarized in different levels including paragraph-level, chapter-level, and book-level. We run their

---

[5] https://optuna.readthedocs.io/en/stable/

[6] https://huggingface.co

codes[7] and train a paragraph-level summarization model. The quality of summaries is evaluated by ROUGE scores as shown in the Table 8. The Table shows that we basically reproduce their results in the paper. However, better summarizers for narrative text could greatly improve the output of our story generation models. In particular, while the summaries are often correct, the focus of what aspects of the narrative text is summarized is not always the most appropriate, and improving this is a clear direction for future work. As for the summary size, the trained model summaries the original paragraph (∼116 tokens) into sentences (∼26 tokens). The average compression rate is 18.2%.

Abstract

Recent work has focused on compressing pre-trained language models (PLMs) like BERT where the major focus has been to improve the in-distribution performance for downstream tasks. However, very few of these studies have analyzed the impact of compression on the generalizability and robustness of compressed models for out-of-distribution (OOD) data. Towards this end, we study two popular model compression techniques including knowledge distillation and pruning and show that the compressed models are significantly less robust than their PLM counterparts on OOD test sets although they obtain similar performance on in-distribution development sets for a task. Further analysis indicates that the compressed models overfit on the shortcut samples and generalize poorly on the hard ones. We further leverage this observation to develop a regularization strategy for robust model compression based on sample uncertainty. Experimental results on several natural language understanding tasks demonstrate that our bias mitigation framework improves the OOD generalization of the compressed models, while not sacrificing the in-distribution task performance.

1 Introduction

Large pretrained language models (PLMs) (e.g., BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), GPT-3 (Brown et al., 2020)) have obtained state-of-the-art performance in several Natural Language Understanding (NLU) tasks. However, recent studies (Niven and Kao, 2019; Du et al., 2021; Mudrakarta et al., 2018) indicate that PLMs heavily rely on shortcut learning/spurious correlations, rather than acquiring higher level language understanding and semantic reasoning in several NLU tasks. Specifically, these models often exploit dataset biases and artifacts, e.g., lexical bias and overlap bias, as shortcuts for prediction. Due to the independent and identically distributed (IID) split of training, development, and test sets, these models that learn spurious decision rules from training data can perform well on in-distribution data (Du et al., 2022). Nevertheless, the shortcut learning behavior will result in models that have poor generalization performance on out-of-distribution (OOD) data, raising concerns about their robustness.

On the other hand, it is difficult to use these large PLMs models in real-world applications with latency and capacity constraints, e.g., on edge devices and mobile phones. Thus, model compression emerges as one of the techniques to reduce model size, speed up inference, and save energy without significant performance drop for downstream tasks. State-of-the-art model compression techniques such as knowledge distillation (Sanh et al., 2019; Sun et al., 2019) and pruning (Sanh et al., 2020) primarily focus on evaluating compressed model performance in in-distribution test data. However, in-distribution testing is insufficient to capture the generalizability of PLMs (D'Amour et al., 2020). In contrast to existing work that is geared towards general-purpose PLMs (Niven and Kao, 2019; Du et al., 2021; Mudrakarta et al., 2018), this work aims to study the impact of compression on the shortcut learning and OOD generalization ability of compressed models.

Towards this end, we conduct comprehensive experiments to evaluate the OOD robustness of compressed models, with BERT as the base encoder. **We focus primarily on two popular model compression techniques in the form of pruning and knowledge distillation** (Sanh et al., 2019; Wang et al., 2020). For pruning, we consider two popular techniques including iterative magnitude pruning (Sanh et al., 2020) and structured pruning (Prasanna et al., 2020; Liang et al., 2021). Specifically, we explore the following research questions: *Are distilled and pruned models as ro-*

bust as their PLM counterparts for downstream NLU tasks? What is the impact of varying the level of compression on OOD generalization and bias of compressed models? We evaluate the performance of several compressed models obtained using the above techniques on both standard in-distribution development sets and OOD test sets for downstream NLU tasks. Experimental analysis indicates that distilled and pruned models are consistently less robust than their PLM counterparts. Further analysis of the poor generalization performance of compressed models reveals some interesting observations. For instance, we observe that the compressed models overfit on the easy / shortcut samples and generalize poorly on the hard ones. This motivates our second research question: *How to regularize model compression techniques to generalize across samples with varying difficulty?* This brings some interesting challenges since we do not know which samples are easy or hard apriori.

Based on the above observations, we propose a bias mitigation framework to improve the OOD robustness of compressed models, termed as RMC (Robust Model Compression). First, we leverage the uncertainty of the deep neural network to quantify the difficulty of a training sample. This is given by the variance in the prediction of a sample from multiple sub-networks of the original large network obtained by model pruning. Second, we leverage this sample-specific measure for smoothing and regularizing different families of compression techniques. The major contributions of this work can be summarized as follows:

- We perform a comprehensive analysis to evaluate the OOD generalization ability and robustness of compressed models for NLU tasks.
- We further analyze plausible reasons for the low generalizability of compressed models and demonstrate connections to shortcut learning.
- We propose a mitigation framework for regularizing model compression, termed as RMC, which smoothes the knowledge distillation training based on the estimated sample difficulties.
- We perform experiments to demonstrate that our RMC framework improves OOD generalization while not sacrificing the standard in-distribution task performance on multiple NLU tasks.

2 Related Work

Shortcut Learning and Mitigation. Recent studies indicate that PLMs tend to exploit biases and artifacts in the dataset as shortcuts for prediction, rather than acquiring higher level semantic understanding and reasoning for NLU tasks (Niven and Kao, 2019; Du et al., 2021; McCoy et al., 2019a). There are some preliminary work to mitigate the bias of general PLMs, including product-of-experts (Clark et al., 2019; He et al., 2019; Sanh et al., 2021), re-weighting (Schuster et al., 2019; Yaghoobzadeh et al., 2019; Utama et al., 2020), adversarial training (Stacey et al., 2020), posterior regularization (Cheng et al., 2021), etc.

Robustness in Model Compression. Current practice for evaluating model compression performance focuses mainly on standard benchmark performance (Zhu et al., 2020; Wang et al., 2021). In the computer vision domain, previous work shows that compressed models perform poorly in Compression Identified Exemplars (CIE) (Hooker et al., 2019), and compression amplifies algorithmic bias towards certain demographics (Hooker et al., 2020). The most similar work to ours are two concurrent work (Xu et al., 2021a; Li et al., 2021) that investigate the performance of compressed models beyond standard benchmarks for natural language understanding tasks. However, both work mainly focus on evaluating the robustness of compressed models with respect to the scenario of adversarial attacks, i.e., TextFooler (Jin et al., 2020), and the unified adversarial framework (Li et al., 2021). In contrast, we comprehensively characterize the robustness of BERT compression in OOD test sets to probe the OOD generalizability of the compression techniques. Besides, we use insights from this robustness analysis to design a generalizable and robust model compression framework.

3 Are Compressed Models Robust?

We perform a comprehensive analysis to evaluate the robustness of compressed language models.

3.1 Compression Techniques

We consider two popular families of compression, namely, knowledge distillation and model pruning.

Knowledge Distillation: The objective here is to train a small-size model by mimicking the behavior of the larger teacher model using knowledge distillation (Hinton et al., 2015). In this work, we focus on task-agnostic distillation. In particular, we consider DistilBERT (Sanh et al., 2019) and MiniLM (Wang et al., 2020) distilled from BERT-base. For a fair comparison, we select compressed models with similar capacities ($66M$ parameters in this work). In order to evaluate the impact of compression techniques on model robustness, we also consider similar capacity smaller models without using knowledge distillation. These are obtained via simple truncation where we retain the first 6 layers of the large model, and via pre-training a smaller 6-layer model from scratch.

Iterative Magnitude Pruning: This is a task-specific unstructured pruning method (Sanh et al., 2020). During the fine-tuning process for each downstream task, the weights with the lowest magnitude are removed until the pruned model reaches the target sparsity. Note that we utilize the standard pruning technique, rather than the LTH-based pruning (lottery ticket hypothesis) that uses rewinding (Chen et al., 2020). We also consider different pruning ratios to obtain pruned models with different levels of sparsity.

Structured Pruning: This method family is based on the hypothesis that there is redundancy in the attention heads (Prasanna et al., 2020; Voita et al., 2019; Bian et al., 2021; Chen et al., 2021). We also consider task-specific pruning. During the fine-tuning process for each task, it prunes the whole attention heads based on their importance to the model predictions. Please refer to Sec. A in Appendix for more details. We prune around 20% attention heads in total (i.e., 28 attention heads). Further pruning increases the sparsity with significant degradation of the model's performance on in-distribution development sets.

3.2 Evaluation Datasets

To evaluate the robustness of the compressed models introduced in the last section, we use three NLU tasks, including MNLI, FEVER, and QQP[1]. Please refer to Sec. B in Appendix for more details.

- **MNLI** (Williams et al., 2018): This is a natural language inference task. In this work, we report the accuracy metric on the matched subset. We use HANS (McCoy et al., 2019b) as the adversarial test set, which contains $30,000$ synthetic samples. Models that exploit shortcut features have been shown to perform poorly on the HANS test set.
- **FEVER** (Thorne et al., 2018): This is a fact verification dataset. Recent studies indicate that there are strong shortcuts in the claims (Utama et al., 2020). To facilitate the robustness and generalization evaluation of fact verification models, two symmetric test sets (i.e., Sym v1 and Sym v2) were created, where bias exists in the symmetric pairs (Schuster et al., 2019). Both OOD test sets have 712 samples.
- **QQP**: The task is to predict whether a pair of questions is semantically equivalent. We consider the OOD test set PAWS-qqp, which contains 677 test samples generated from QQP corpus (Zhang et al., 2019; Yang et al., 2019). Besides, we also consider the PAWS-wiki OOD test set, which consists of $8,000$ test samples generated from Wikipedia pages.

For all three tasks, we employ accuracy as the evaluation metric and evaluate the performance of the compressed models on both the in-distribution development set and the OOD test set.

3.3 Evaluation Setup

In this work, we use the uncased BERT-base as the teacher network, and study the robustness of its compressed variants. The final model consists of the BERT-base encoder (or its compressed variants) with a classification head (a linear layer on top of the pooled output). Recent studies indicate that factors such as learning rate and training epochs could have a substantial influence on robustness (Tu et al., 2020). In particular, increasing training epochs can help improve the generalization of the OOD test set. In this work, we focus on the relative robustness of compressed models compared to the uncompressed teacher, rather than their *absolute accuracies*. For a fair comparison, we unify the experimental setup for all models. We use Adam optimizer with weight decay (Loshchilov and Hutter, 2017), where the learning rate is fixed as $2e$-5, and we train all models for 5 epochs on all datasets. We perform the experiments using PyTorch and use the pre-trained models from the Huggingface model pool (Wolf et al., 2019). We report the average results over three runs for all experiments.

3.4 Relative Robustness Metric

As we later demonstrate, with increase in compression ratio or model sparsity, the performance of the smaller models degrades for both in-domain and OOD test sets. To compare the gap between

---

[1] MNLI, FEVER, and QQP are the three most widely used datasets to evaluate the shortcut learning/bias behavior and OOD generalization of PLMs in the literature (Tu et al., 2020; He et al., 2019; Clark et al., 2019; Schuster et al., 2019)

Table 3: Accuracy comparison (in percent) and relative bias $\mathcal{F}_{bias}$ (the smaller the better) of compressed models with structured pruning. *Pruned models have relatively higher degradation in OOD test set compared to the development set.* All compressed models have been pruned 28 attention heads.

in-distribution task performance and OOD generalizability, we define a new metric that measures this performance gap of the compressed models with respect to the uncompressed BERT-base (teacher). First, we calculate the accuracy gap between in-distribution development set and OOD test set as $\frac{F_{\text{dev}}-F_{\text{OOD}}}{F_{\text{dev}}}$ for BERT-base (denoted by $\Delta_{\text{BERT-base}}$); and its compressed variant (denoted by $\Delta_{\text{compressed}}$). Second, we compute the relative bias as the ratio between the accuracy gap of the compressed model with respect to BERT-base: $\mathcal{F}_{bias} = \frac{\Delta_{\text{compressed}}}{\Delta_{\text{BERT-base}}}$. Here $\mathcal{F}_{bias} > 1$ indicates that the compressed model is more biased than BERT-base with the degree of bias captured in a larger value of $\mathcal{F}_{bias}$. Since FEVER has two OOD test sets, we use the overall accuracy of sym1 and sym2 to calculate $\mathcal{F}_{bias}$. Similarly, the OOD accuracy for QQP is the overall accuracy on PAWS-wiki and PAWS-qqp.

3.5 Experimental Observations

We report the performance of accuracy and the relative bias measure $\mathcal{F}_{bias}$ for iterative magnitude pruning in Table 1, knowledge distillation in Table 2 and structured pruning in Table 3. We have the following key observations.

Iterative Magnitude Pruning: First, for slight and mid-level sparsity, the pruned models have comparable and sometimes even better performance on the in-distribution development set. Consider FEVER as an example, where the compressed model preserves the accuracy on the in-distribution set even at 60% sparsity[2]. However, the generalization accuracy on the OOD test set has a substantial drop. This indicates that the development set fails to capture the generalizability of the pruned models. Second, as the sparsity increases, the generalization accuracy on the OOD test set substantially decreases while dropping to random guess for tasks such as MNLI. Third, at high levels of sparsity (e.g. 70%), both development and OOD test set performances are significantly affected. In general, we observe $\mathcal{F}_{bias} > 1$ for all levels of sparsity in Table 1. Note that we limit the maximum sparsity at 70% after which the training is unstable with a significant performance drop even on the development set (Liang et al., 2021). As in the previous cases, there is substantial accuracy drop on the OOD test

---

[2] Here, 60% sparsity indicates that 40% parameters are remaining after pruning.

set compared to the development set (e.g., 7.6% vs 1.9% degradation respectively for the MNLI task).

Knowledge Distillation: Similar to pruning, we observe a higher accuracy drop in the OOD test set compared to the in-distribution development set for distilled models. Consider DistilBERT performance on MNLI as an example with 1.9% accuracy drop in development set compared to 8.6% drop in the OOD test set. This can also be validated in Table 2, where all $\mathcal{F}_{bias}$ values are larger than 1, depicting that all the distilled models are less robust than BERT-base. Another interesting observation is that distilled models, i.e., DistilBERT and MiniLM, have higher bias $\mathcal{F}_{bias}$ compared to the pre-trained models, i.e., Pretrained-l6 and Truncated-l6, as we compare their average $\mathcal{F}_{bias}$ values in Table 2. This indicates that the compression process plays a significant role in the low generalizability and robustness of the distilled models.

Structured Pruning: Recent studies have reported the super ticket phenomenon (Liang et al., 2021). The authors observe that, when the BERT-base model is slightly pruned, the accuracy of the pruned models improves on in-distribution development set. However, we observe that this finding does not hold for OOD test sets. From Table 3, we observe that all pruned models are less robust than BERT-base, with $\mathcal{F}_{bias}$ much larger than 1.

4 Attribution of Low Robustness

In this section, we explore the factors that lead to low robustness of compressed models. Previous work has demonstrated that the performance of different models on the GLUE benchmark (Wang et al., 2018) tends to correlate with the performance on MNLI, making it a good representative of natural language understanding tasks in general (Phang et al., 2018; Liu et al., 2020). For this reason, we choose the MNLI task for a study.

For the MNLI task, we consider the dataset splits from (Gururangan et al., 2018). The authors partition the development set into easy/shortcut [3] and hard subsets. In this experiment, we use pruned models with varying sparsity to investigate the reason for the low robustness of the compressed models. We have the following key observations.

Observation 1: The compressed models tend to overfit the easy/shortcut samples and generalize poorly on the hard ones. The performance of pruned models at five sparsity levels (ranging between $[0.2 - 0.85]$) on the easy and hard samples for the MNLI task is illustrated in Figure 1. It demonstrates that the accuracy on the hard samples is much lower compared to the accuracy on the easy ones. As the sparsity increases, we observe a larger accuracy drop on the hard samples compared to the easy ones. In particular, the accuracy gap between the two subsets is 22.7% at the sparsity of 0.85, much higher than the 16.1% accuracy gap at the sparsity of 0.4. These findings demonstrate that the compressed models overfit on the easy samples, while generalizing poorly on the hard ones. Furthermore, this phenomenon is amplified at higher levels of sparsity for the pruned models.

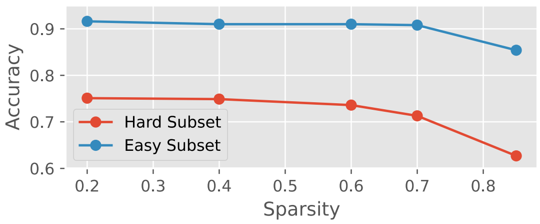

Figure 1: Pruned model performance on hard vs easy / shortcut samples with varying sparsity, where x-axis denotes the sparsity level.

Observation 2: Compressed models tend to assign overconfident predictions to easy samples. One of the potential reasons is that compressed models are more prone to capture spurious correlations between shortcut features in training samples with certain class labels for their predictions (Geirhos et al., 2020; Du et al., 2021).

4.1 Variance-based Difficulty Estimation

Based on the above observations, we propose a variance-based metric to quantify the difficulty degree of each sample. For each sample in the development set, we calculate its loss at five different levels of pruning sparsity as shown in Figure 1. We further calculate the variance of the above losses for each sample and rank them based on the variance. Finally, we assign the samples with low variance to the “easy" subset and rest to the “hard" one. Comparing our variance-based proxy annotation with the ground truth annotation in (Gururangan et al., 2018) gives an accuracy of 82.8%. This indicates that the variance-based estimation leveraging pruning sparsity is a good indicator of sample difficulty. This motivates our design of the mitigation technique introduced in the next section.

---

[3] We use ‘easy’ and ‘shortcut’ interchangeably in this work.

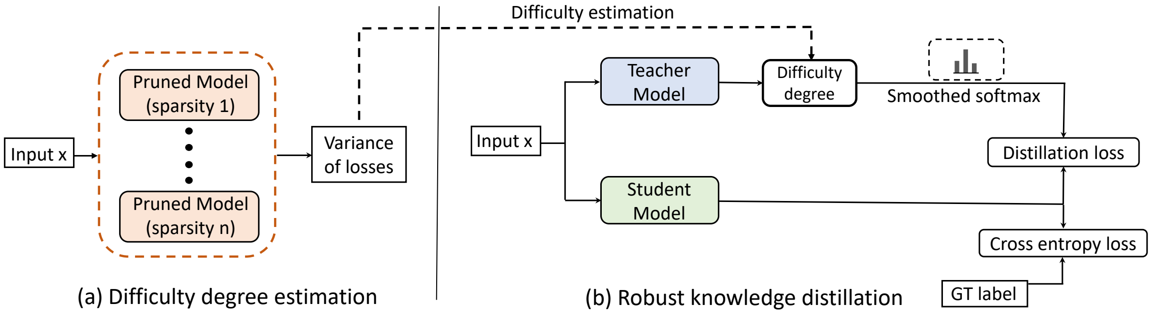

Figure 2: RMC framework for bias mitigation with two-stage training. In the first stage, we feed the training samples to pruned models at different levels of sparsity (ranging from $[0.2 - 0.85]$) as introduced in Section 4.1); compute corresponding losses and their variance to estimate the difficulty degree of each training sample. In the second stage, we use the difficulty degree to regularize the teacher network for robust model compression.

5 Mitigation Framework

In this section, we propose a general bias mitigation framework (see Figure 2), termed as RMC (Robust Model Compression), to improve the robustness of compressed models on downstream tasks. Our RMC framework follows the philosophy of task-specific knowledge distillation (Sanh et al., 2020; Jiao et al., 2020), but with explicit regularization of the teacher network leveraging sample uncertainty. This prevents the compressed model from overfitting in the easy samples that contain shortcut features and helps improve its robustness. This regularized training is implemented in two stages.

5.1 Quantifying Sample Difficulty

In the first stage, our objective is to quantify the difficulty degree of each training sample.

Variance Computation: Following the observations obtained in Section 4.1, we first use iterative magnitude pruning to obtain a series of pruned models from BERT-base with different levels of sparsity and then we use the losses of the pruned models at different levels of sparsity to compute their variance v_i for each training sample x_i: $v_i = \frac{\sum_{t=1}^{n}(l_{i,t}-\bar{l_i})^2}{n}$. We choose five sparsity levels, i.e., $n = 5$, that are diverse enough to reflect the difficulty degree of each training sample. Here, samples with high variance correspond to hard ones.

Difficulty Degree Estimation: Based on the variance v_i for each training sample x_i, we can estimate its difficulty degree as:

$$d_i = \alpha + \frac{1-\alpha}{V_{\max} - V_{\min}} \cdot (v_i - V_{\min}) \,, \qquad (1)$$

where $V_{\min}$ and $V_{\max}$ denote the minimum and maximum values of the variances, respectively. Equation 1 is used to normalize the variance of the training samples in the range of [α, 1], where $d_i = 1$ denotes the most difficult training sample, according to our criteria of loss variance. Samples with d_i closer to α are treated as shortcut/biased samples. Prior work (Niven and Kao, 2019) show that the bias behavior of the downstream training set can be attributed to data collection and annotation biases. Since the bias level is different for each dataset, we assign a different α in Equation 1 to each training set to reflect its bias level.

5.2 Robust Knowledge Distillation

In the second stage, we fine-tune BERT-base on the downstream tasks to obtain the softmax probability for each training sample. We then use the difficulty degree of the training samples (discussed in the previous section) to smooth the teacher predictions. The instance-level smoothed softmax probability is used to guide the training of compressed models through regularized knowledge distillation.

Smoothing Teacher Predictions: We smooth the softmax probability $\hat{y}_i^T$ from the teacher network, according to the difficulty degree d_i of each training sample x_i. The smoothed probability is given as:

$$s_{i,j} = \frac{(\hat{y}_i^T)_j^{d_i}}{\sum_{k=1}^{K}(\hat{y}_i^T)_k^{d_i}}, \qquad (2)$$

where K denotes the total number of class labels. We perform instance-level smoothing for each training sample x_i. If the difficulty degree of a training sample $d_i = 1$, then the softmax probability s_i for the corresponding sample from the teacher is unchanged. In contrast, at the other extreme as $d_i \to \alpha$, we increase the regularization to encourage the compressed model to assign less overconfident predictions to the sample. The difficulty degree range is $[\alpha, 1]$ rather than $[0, 1]$ to avoid over-smoothing of the teacher predictions.

Table 4: Generalization accuracy comparison (in percent) and the corresponding $\mathcal{F}_{bias}$ values for iterative magnitude pruning at 40% sparsity with different *mitigation methods*. The last column indicates average $\mathcal{F}_{bias}$ over three tasks.

Smoothness-Induced Model Compression: We employ the smoothed softmax probability s_i from BERT-base to supervise the training of the compressed models, where the overall loss function is:

$$\mathcal{L}(x) = (1-\lambda) * \mathcal{L}_1\left(y_i, \hat{y}_i^S\right) + \lambda * \mathcal{L}_2\left(s_i, \hat{y}_i^S\right), \quad (3)$$

where y_i is the ground truth and $\hat{y}_i^S$ is the probability of the compressed model. $\mathcal{L}_1$ denotes the cross-entropy loss, and $\mathcal{L}_2$ represents the knowledge distillation loss with KL divergence. Hyperparameter λ manages the trade-off between learning from hard label y_i and softened softmax probability s_i. Among the different families of compression techniques introduced in Section 3.1, we directly fine-tune the distilled models using Equation 3. For iterative magnitude pruning, we use Equation 3 to guide the pruning during the fine-tuning process.

6 Mitigation Performance Evaluation

In this section, we conduct experiments to evaluate the robustness of our RMC mitigation framework.

6.1 Experimental Setup

For all experiments, we follow the same setting as in Section 3.3, and the same evaluation datasets as in Section 3.2. We use the OOD test set exclusively for evaluation. We compute the variance of samples (outlined in Section 4.1) in the in-distribution development set to split it into a shortcut and hard subset. The relative robustness between the hard and easy subset is used to tune the hyperparameter α in Equation 1, where we set α as 0.5, 0.3, 0.2 for MNLI, FEVER, and QQP, respectively. The weight λ in Equation 3 is fixed as 0.9 for all experiments.

6.2 Baseline Methods

We consider the following five baselines. Please refer to Sec. C in Appendix for more details.

- **Vanilla**: This only fine-tunes the base encoder without any regularization.
- **Distil** (Task-Specific Knowledge Distillation) (Sanh et al., 2020): This first fine-tunes BERT-base on the downstream NLU tasks. The softmax probability from the fine-tuned BERT-base is used as the supervision signal for distillation.
- **Smooth** (Global Smoothing) (Müller et al., 2019): This performs global smoothing for *all* training samples with task-specific knowledge distillation, where we use the same level of regularization as in RMC ($d_i = 0.9$ in Equation 2). In contrast, RMC uses instance-level smoothing.
- **Focal** (Focal Loss) (Lin et al., 2017): Compared to cross-entropy loss, focal loss has an additional regularizer to reduce the weight for easy samples and assign a higher weight to hard samples bearing less-confident predictions.
- **JTT** (Just Train Twice) (Liu et al., 2021): This is a re-weighting method, which first trains the BERT-base model using standard cross-entropy loss for several epochs, and then trains the compressed model while up-weighting the training examples that are misclassified by the first model, i.e., hard samples.

6.3 Mitigation Performance Analysis

We compare our RMC framework with the above baselines and have the following key observations.

Iterative Magnitude Pruning: Table 4 shows the mitigation results of accuracy and relative bias $\mathcal{F}_{bias}$. All mitigation methods are performed with pruned models at 40% sparsity. We observe that task-specific knowledge distillation only slightly improves accuracy on the OOD test set compared to Vanilla tuning, since the teacher model itself is not robust for downstream tasks (Niven and Kao, 2019). Global smoothing further improves generalization accuracy compared to prior methods. Our

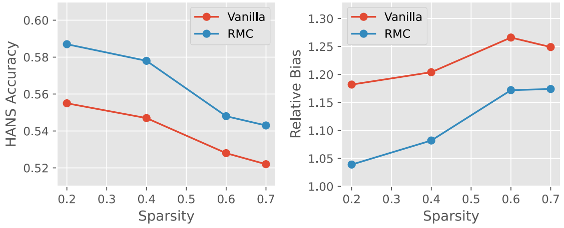
Table 5: Generalization accuracy and the $\mathcal{F}_{bias}$ values comparison of different training strategies with and without mitigation on in-distribution development set and OOD test set using MiniLM as the compressed encoder.



(a) Accuracy on OOD test set (b) Relative bias F_{bias}

Figure 3: RMC mitigation performance for iterative magnitude pruning at different levels of pruning sparsity for MNLI task.

RMC framework obtains the best accuracy on OOD test set across all the tasks on aggregate. RMC further reduces the average relative bias $\mathcal{F}_{bias}$ by 10% over Vanilla tuning, as shown in Table 4, indicating the benefits of uncertainty-based sample-wise smoothing in terms of improving model robustness. For the MNLI task, we also illustrate the mitigation performance of our RMC framework for different levels of sparsity in Figure 3. We observe that RMC consistently improves accuracy on OOD HANS while reducing the relative bias $\mathcal{F}_{bias}$ for all levels of sparsity over the Vanilla method.

Knowledge Distillation: Table 5 shows the mitigation results of accuracy and relative bias $\mathcal{F}_{bias}$. We observe that RMC significantly improves over MiniLM for OOD generalization leveraging smoothed predictions from BERT-base teacher. With instance-level smoothing in RMC, the generalization accuracy for the compressed model on the OOD test set is significantly closer to BERT-base teacher compared to the other methods. We also decrease the relative bias $\mathcal{F}_{bias}$ in Table 5 by 10.4% over Vanilla tuning. On the QQP task, RMC simultaneously improves the performance of compressed model on both the in-distribution development set and the two OOD test sets.

Models	DEV	HANS	Hard (H)	Easy (E)	Gap (E-H)
MiniLM–Vanilla	83.1	51.4	73.2	90.9	17.7
MiniLM–RMC	83.7	57.8	74.9	90.6	15.7
40%–Vanilla	84.0	54.7	74.9	91.0	16.1
40%–RMC	84.2	58.6	75.9	90.3	14.4

Table 6: Our RMC framework improves accuracy of the compressed models on the hard samples and reduces overfitting on the shortcut/easy samples, leading to reduced performance gap between the two subsets.

6.4 Further Analysis on Robust Mitigation

In this section, we further investigate the reasons for the improved generalization performance with RMC with an analysis on the MNLI task. Table 6 shows the accuracy performance of RMC for model pruning and distillation on the shortcut/easy and hard samples. We observe RMC to improve the model performance on the under-represented hard samples, where it reduces the generalization gap between the hard and shortcut/easy subset by 10.6% at 0.4 level of sparsity and by 11.3% for knowledge distillation. This analysis demonstrates that RMC reduces the overfitting of the compressed models on the easy samples and encourages them to learn more from the hard ones, thus improving the generalization on the OOD test sets.

7 Conclusions

In this work, we conduct a comprehensive study of the robustness challenges in compressing large PLMs when fine-tuning in downstream NLU datasets. Furthermore, we propose a general mitigation framework with instance-level smoothing for robust model compression. Experimental analysis demonstrates our framework to improve the generalization and OOD robustness of compressed models for different compression techniques, while not sacrificing the in-distribution performance.

Limitations

First, we study the shortcut learning/bias problem and OOD generalization of model compression techniques, exclusively focusing on the two most widely used families of compression techniques, including knowledge distillation and pruning. Our empirical analysis indicates that these two families of compression techniques suffer from the low generalization issue. However, other types of compression technique, such as matrix decomposition and quantization, are not discussed in this work. Studying the whole compression techniques is a challenging topic and will be investigated in our future research. Second, our RMC framework needs to calculate the variance of losses for each training sample, thus requiring additional training time. Training efficiency can be further improved by implementing parallel training or more efficient ways of calculating sample difficulty, which will also be studied in our future research.

A More Details of Pruning Methods

In this section, we introduce more details about the compression techniques studied.

knowledge Distillation: For a fair comparison, we do not compare with TinyBERT (Jiao et al., 2020) and MobileBERT (Sun et al., 2020), since TinyBERT is fine-tuned with data augmentation on NLU tasks, and MobileBERT is distilled from BERT-large rather than BERT-base.

Magnitude Pruning: It is based on the overparameterization assumption of pre-trained language models (Xu et al., 2021b; Huang et al., 2021). For iterative magnitude pruning, we freeze all the embedding modules and only prune the parameters in the encoder (i.e., 12 layers of Transformer blocks). After pruning, the pruned weight values are set to 0 to reduce the amount of information to store. Unlike the LTH version, we consider standard magnitude pruning without using rewinding.

Structured Pruning: To calculate the importance, we follow (Michel et al., 2019; Prasanna et al., 2020) and calculate the expected sensitivity of the attention heads to the mask variable $\xi^{(h,l)}$: $I_h^{(h,l)} = E_{x \sim X} \left| \frac{\partial \mathcal{L}(x)}{\partial \xi^{(h,l)}} \right|$, where $I_h^{(h,l)}$ denotes the contribution score of the attention head h in layer l, $\mathcal{L}(x)$ represents the loss value for the sample x, and $\xi^{(h,l)}$ is the mask of the attention head h in layer l. After obtaining the contribution scores, the attention heads with lowest score $I_h^{(h,l)}$ are pruned.

B More on Evaluation Datasets

In this section, we introduce more details about the three benchmark datasets.

MNLI: This task aims to predict whether the relationship between the premise and the hypothesis is contradiction, entailment, or neutral. It is divided into a training set and development set with $392,702$ and $9,815$ samples, respectively.

FEVER: The task is to predict whether the claims support, refute, or not-have-enough-information about the evidence. Recent studies indicate that there are strong shortcuts in claims (Utama et al., 2020). It is divided into a training set and a development set with $242,911$ and $16,664$ samples, respectively.

QQP: It is divided into a training set and a development set with $363,846$ and $40,430$ samples, respectively.

C More on Comparing Baselines

In this section, we introduce more details on comparing baselines.

Distil and Smooth: For both baseline methods, we use a loss function similar to that of Equation 3. We fix the weight λ to 0.9 for all experiments, to encourage the compressed model to learn more from the probability output of the teacher network. A major difference between the two baselines is that Smooth has an additional smoothing process involved during the fine-tuning process.

Focal Loss: The original focal loss function is: $\mathrm{FL}(p_\mathrm{i}) = -(1-p_\mathrm{i})^\gamma \log(p_\mathrm{i})$. Our implementation is as follows:

$$\mathrm{FL}(p_\mathrm{i}) = -\frac{(1-p_\mathrm{i})^\gamma}{\frac{1}{N}\sum_{k=1}^{N}(1-p_\mathrm{k})^\gamma} \log(p_\mathrm{i}).$$

The hyperparameter γ controls the weight difference between hard and easy samples, and is fixed at 2.0 for all tasks. We use the denominator to normalize the weights within a batch, where N is the batch size. This is used to guarantee that the average weight for a batch of training samples is 1.0. As such, the weight for the easy samples would be down-weighted to lower than 1.0, and the weight for hard samples would be up-weighted to values larger than 1.0.

JTT: This is also a reweighting baseline that encourages the model to learn more from hard samples. The hyperparameter λ_{up} in (Liu et al., 2021) is set to 2.0. We also normalize the weights so that the average weight for each training sample is 1.0.

D Running Environment

For a fair evaluation of the robustness of compressed models, we run all experiments using a server with 4 NVIDIA GeForce 3090 GPUs. All experiments are implemented with the Pytorch version of the Hugging Face Transformer library.

E The Capacity Issue

One natural speculation about the low robustness of compressed models is due to their low capacity (i.e., smaller size). To disentangle the two important factors that influence model performance, i.e., low capacity and compression, we compare distilled models with Uncased-l6, which is trained only using pretraining. The results are given in Table 2. The results indicate that Uncased-l6 has better generalization ability over the MNLI and

FEVER two tasks. Take structured pruning as an example; although the three pruned models in Table3 have the same model size, their generalization accuracy is different. These results indicate that the low robustness of compressed models is not entirely due to their low capacity, and compression plays a significant role.

F MNLI Easy and Hard Subsets

The authors train a hypothesis-only model and use it to generate predictions for the whole development set (Gururangan et al., 2018). Samples that are given correct predictions by the hypothesis-only model are regarded as easy samples, and vice versa. The easy subset contains 5488 samples, and the hard subset contains 4302 samples.

Don't Blame the Annotator:
Bias Already Starts in the Annotation Instructions

Abstract

In recent years, progress in NLU has been driven by benchmarks. These benchmarks are typically collected by crowdsourcing, where annotators write examples based on annotation instructions crafted by dataset creators. In this work, we hypothesize that annotators pick up on patterns in the crowdsourcing instructions, which bias them to write many similar examples that are then over-represented in the collected data. We study this form of bias, termed *instruction bias*, in 14 recent NLU benchmarks, showing that instruction examples often exhibit concrete patterns, which are propagated by crowdworkers to the collected data. This extends previous work (Geva et al., 2019) and raises a new concern of whether we are modeling the *dataset creator's instructions*, rather than the task. Through a series of experiments, we show that, indeed, instruction bias can lead to overestimation of model performance, and that models struggle to generalize beyond biases originating in the crowdsourcing instructions. We further analyze the influence of instruction bias in terms of pattern frequency and model size, and derive concrete recommendations for creating future NLU benchmarks.[1]

1 Introduction

Benchmarks have been proven pivotal for driving progress in Natural Language Understanding (NLU) in recent years (Rogers et al., 2021; Bach et al., 2022; Wang et al., 2022). Nowadays, NLU benchmarks are mostly created through crowdsourcing, where crowdworkers write examples following annotation instructions crafted by dataset creators (Callison-Burch and Dredze, 2010; Zheng et al., 2018; Suhr et al., 2021). The instructions typically include a short description of the task, along with several examples (Dasigi et al., 2019; Zhou et al., 2019; Sakaguchi et al., 2020).

Despite the vast success of this method, past studies have shown that data collected through crowdsourcing often exhibit various biases that lead to overestimation of model performance (Schwartz et al., 2017; Gururangan et al., 2018; Poliak et al., 2018; Tsuchiya, 2018; Le Bras et al., 2020; Mishra et al., 2020a; Mishra and Arunkumar, 2021; Hettiachchi et al., 2021). Such biases are often attributed to annotator-related biases, such as writing style and background knowledge (Gururangan et al., 2018; Geva et al., 2019) (see more discussion on related work in §A).

In this work, we propose that biases in crowdsourced NLU benchmarks often originate at an early stage in the data collection process of designing the annotation task. In particular, we hypothesize that task instructions provided by dataset creators, which serve as the guiding principles for annotators to complete the task, often influence crowdworkers to follow specific patterns, which are then propagated to the dataset and subsequently over-represented in the collected data. For instance, $\sim 36\%$ of the instruction examples for the QUOREF dataset (Dasigi et al., 2019) start with *"What is the name"*, and this same pattern can be observed in $\sim 59\%$ of the collected instances.

To test our hypothesis, we conduct a broad study of this form of bias, termed *instruction bias*, in 14 recent NLU benchmarks. We find that instruction bias is evident in most of these datasets, showing that $\sim 73\%$ of instruction examples on average share a few clear patterns. Moreover, we find that these patterns are propagated by annotators to the collected data, covering $\sim 61\%$ of the instances on average. This suggests that instruction examples play a critical role in the data collection process and the resulting example distribution.

It is difficult to represent a task with a few examples, and bias in instruction examples makes

it even more difficult since a task and its associated reasoning have a larger scope than instruction patterns. For example co-reference resolution, temporal commonsense reasoning, and numerical reasoning are much broader tasks than the prevalent patterns in QUOREF (*"what is the name..."*), MC-TACO (*"how long..."*) and DROP (*"how many field goals..."*) datasets.

We investigate the effect of instruction bias on model performance, showing that performance is overestimated by instruction bias and that models often fail to generalize beyond instruction patterns. Moreover, we observe that a higher frequency of instruction patterns in the training set often increases the model performance gap on pattern and non-pattern examples and that large models are generally less sensitive to instruction bias.

In conclusion, our work shows that instruction bias widely exists in NLU benchmarks, often leading to an overestimation of model performance. Based on our study, we derive concrete recommendations for monitoring and alleviating this bias in future data collection efforts. From a broader perspective, our findings also have implications on the recent learning-by-instructions paradigm (Efrat and Levy, 2020; Mishra et al., 2021), where crowdsourcing instructions are used in model training.

2 Instruction Bias in NLU Benchmarks

Instructions are the primary resource for educating crowdworkers on how to perform their task (Nangia et al., 2021). Bias in the instructions, dubbed *instruction bias*, could lead crowdworkers to propagate specific patterns to the collected data.

Here, we study instruction bias in NLU benchmarks[2], focusing on two research questions: (a) Do crowdsourcing instructions exhibit patterns that annotators can pick up on? and (b) Are such patterns propagated by crowdworkers to the collected data? In our study, we use the instructions of 14 recent NLU benchmarks:[3] (1) CLARIQ (Aliannejadi et al., 2020), (2) COSMOSQA (Huang et al., 2019), (3) DROP (Dua et al., 2019), (4) DUORC (Saha et al., 2018), and (5) HOTPOTQA (Yang et al., 2018) (6) HYBRIDQA (Chen et al., 2020), (7) MC-TACO (Zhou et al., 2019), (8) MULTIRC (Khashabi et al., 2018), (9) PIQA (Bisk et al., 2020), (10) QASC (Khot et al., 2020), (11) QUOREF (Dasigi et al., 2019), (12) ROPES (Lin et al., 2019), (13) SCIQA (Welbl et al., 2017), (14) WINOGRANDE (Sakaguchi et al., 2020). These benchmarks were created through different crowdsourcing protocols to evaluate diverse tasks (Mishra et al., 2021) (see dataset statistics in §B).

Dataset	**Pattern**	**% Ins.**	**% $\mathcal{S}_{\text{train}}$**	**% $\mathcal{S}_{\text{test}}$**
CLARIQ	`[Are|Would|Do] you`	72.2	85.1	89
COSMOSQA	`What AUX`	87.5	45.1	38.4
DROP	`How many [field goals | years | yards | points | touchdowns]`	70	62.5	62.5

Average		8.4

Table 2: Tasks of each dataset and number of examples in crowdsourcing instruction of each dataset. RC: Reading Comprehension, QA: Question Answering.

involves a wide range of different tasks. Also, we believe that the lower number of examples in crowdsourcing instructions might be limiting the imagination of annotators while creating samples, resulting in instruction bias.

2.1 Patterns in Crowdsourcing Instructions

Our goal is to quantify biases in instruction examples that propagate to collected data instances. In this study, we focus on an intuitive form of bias of recurring word patterns, which crowdworkers can easily pick up on. To find such patterns, we manually analyze the instruction examples of each dataset to find a *dominant pattern*, using the following procedure: (a) identifying repeating patterns of $n \geq 2$ words, (b) merging patterns that are semantically similar or have a substantial word overlap, and (c) selecting the most frequent pattern as the dominant pattern (an example is provided in §C).

Tab. 1 shows the dominant pattern in the instruction examples of each dataset. On average, 72.7% of the instruction examples used to create a dataset exhibit the same dominant pattern, and for 10 out of 14 datasets, the dominant pattern covers more than half of the instruction examples. This suggests that crowdsourcing instructions demonstrate a small set of repeating "shallow" patterns. Moreover, the short length of the patterns (2-4 words) and the typical low number of instruction examples (Tab. 2) make the patterns easily visible to crowdworkers, who can end up following them.

Notably, our results are an underestimation of the actual instruction bias, since (a) we only consider the dominant pattern for each dataset (b) our manual analysis over instruction examples has a preference for short patterns (c) we do not consider paraphrased patterns (beyond the shallow paraphrases which are visible in annotation instructions), and (d) datasets may include implicit patterns (e.g. writing style and biases from the annotator's background knowledge) that also contribute to instruction bias. Accounting for such patterns is expected to increase the bias percentage in Tab. 1 further.

2.2 Instruction Bias Propagation to Datasets

We now turn to investigate whether patterns in instruction examples are further propagated by crowdworkers to the collected data. We analyze the train and test sets of each benchmark[4] to find the same patterns, using simple string matching. To account for syntactic modifications in identified patterns based on some examples from dataset, we also consider synonym words where appropriate and match the paraphrased version of each pattern.

Tab. 1 shows the results. Across all datasets, instruction patterns are ubiquitous in the collected data, occurring in 60.5% of the instances on average, with similar presence in training (59%) and test (62%) examples. While the dominant pattern's frequency in the data is typically not higher than in the instructions, for CLARIQ, DUORC, MULTIRC, QUOREF and ROPES, the pattern frequency was amplified by the crowdworkers. Interestingly, these datasets used a relatively large number of instruction examples (Tab. 2), suggesting that more examples do not necessarily alleviate the propagation of instruction bias. Example data instances with instruction patterns are provided in §D.

A natural question that arises is whether patterns in collected data reflect the true task distribution rather than a bias in the instructions. We argue that this is highly unlikely. First, while the space of possible patterns for a NLU task is arguably large, the dataset patterns are imbalanced proportionately

to the patterns in the instructions for collecting it. For example, questions for assessing temporal commonsense reasoning could have various forms, such as *"What is the duration of..."*, *"For how much time..."*, and *"How long..."*. However, MC-TACO (event duration) is heavily dominated (87.6%) by questions with the pattern *"how long"*, which appears in 100% of the instruction examples (Tab. 1). In addition, datasets of similar tasks have different dominant patterns, while each dataset's dominant pattern correlates with the pattern in the corresponding instructions; the pattern 'What is' appears in 48% of the questions in QASC and in 57% of the instruction examples, but it is entirely different from the dominant pattern of HOTPOTQA, which is another QA dataset for multi-hop reasoning.

We further validate the propagation of bias in instruction examples by comparing the pattern distributions of collected instances when the instructions include and do not include examples. We conduct this experiment for MC-TACO and QUOREF and find that, without any examples provided, the dominant pattern is substantially less frequent, showing that instruction bias is propagated during data collection. Full details are provided in §E.

Propagation of instruction bias to the test set raises concerns regarding its reliability for evaluation, which we address next.

3 Effect on Model Learning

Let $\mathcal{S}_{\text{train}}$ ($\mathcal{S}_{\text{test}}$) be the set of training (test) examples, and denote by $\mathcal{S}^{p}_{\text{train}}$ ($\mathcal{S}^{p}_{\text{test}}$) and $\mathcal{S}^{-p}_{\text{train}}$ ($\mathcal{S}^{-p}_{\text{test}}$) its disjoint subsets of examples with and without instruction patterns, respectively. We conduct two experiments where we fine-tune models on (a) $\mathcal{S}^{p}_{\text{train}}$ and (b) $\mathcal{S}^{p}_{\text{train}} \cup \mathcal{S}^{-p}_{\text{train}}$, and evaluate them on $\mathcal{S}^{-p}_{\text{test}}$ and $\mathcal{S}^{p}_{\text{test}}$. This is to assess to what extent models generalize from instruction patterns to the downstream task (a), and to compare model performance on instances with and without instruction patterns (b).

3.1 Experimental Setting

Datasets Since model training is computationally expensive, we select a subset of seven datasets from those analyzed in §2: (1) CLARIQ, (2) DROP, (3) MULTIRC, (4) PIQA, (5) QUOREF, (6) ROPES, and (7) SCIQA. These datasets cover a variety of tasks, different types and levels of instruction bias (Tab. 1), and are different in size (§B).

Models For all datasets except DROP, we evaluate T5-base and T5-large (Raffel et al., 2020), and BART-base and BART-large (Lewis et al., 2020). For DROP, we use Numnet+ (Ran et al., 2019), a RoBERTa model (Liu et al., 2019) with specialized output heads for numerical reasoning. Numnet+ has 355M parameters, which is closer to T5-base (220M) than to T5-large (770M) in size.

Evaluation We evaluate model performance using the standard F_1 evaluation score, and report the average score over three random seeds.

3.2 Results

We observe similar results for T5 and BART, and thus, present only the results for T5 in this section. Results for BART are provided in §F.

Models often fail to generalize beyond instruction patterns. Tab. 3 shows the performance on $\mathcal{S}^{p}_{\text{test}}$ and $\mathcal{S}^{-p}_{\text{test}}$ when training only on examples with instruction patterns. Across all experiments, there are large performance gaps, reaching to 58% in DROP and $> 10\%$ in both base and large models for CLARIQ, MULTIRC, PIQA, and QUOREF. This indicates that models trained only on examples with instruction patterns fail to generalize to other task examples, and stresses that instruction bias should be monitored and avoided during data collection. Notably, the gap is lower for large models than for base ones, showing that large models are less sensitive to instruction bias. This might be attributed to their larger capacity to capture knowledge and skills during pre-training.

Model performance is overestimated by instruction bias. We compare the performance on $\mathcal{S}_{\text{test}}^{p}$ and $\mathcal{S}_{\text{test}}^{-p}$ of models trained on the full training set (Tab. 4). The average performance across all datasets is higher on examples that exhibit instruction patterns by $\sim 7\%$ and $\sim 3\%$ for the base and large models, respectively. Specifically, base models perform worse on $\mathcal{S}_{\text{test}}^{-p}$ than on $\mathcal{S}_{\text{test}}^{p}$ for all datasets except DROP, in some cases by a dramatic gap of $> 15\%$ (e.g. 18.7% in ROPES and 15.7% in QUOREF). In contrast, results for the large models vary across datasets, while the performance gap is generally smaller in magnitude. This shows that model performance is often overestimated by instructions bias, and reiterates that large models are generally less sensitive to instruction patterns.

4 Conclusions and Discussion

We identify a prominent source of bias in crowdsourced NLU datasets, called *instruction bias*, which originates in annotation instructions written by dataset creators. We study this bias in 14 NLU benchmarks, showing that instruction examples used to create NLU benchmarks often exhibit clear patterns that are propagated by annotators to the collected data. In addition, we investigate the effect of instruction bias on model performance, showing that instruction patterns can lead to overestimated performance as well as limit the ability of models to generalize to other task examples.

Based on our findings, we derive three recommendations for future crowdsourced NLU benchmarks: (1) Crowdsourcing instructions should be diverse; this could be achieved, for example, by having a large number of instructive examples, rephrasing examples using neural models, or periodically sampling examples from a *diverse* set of previously collected examples. The latter could be done, for example, by maintaining a pool of diverse examples during the collection process and then presenting every annotator with a different random sample from this growing pool. (2) Word patterns in collected instances should be analyzed during data collection, as well as possible correspondence to instruction examples. Such analysis will help researchers monitor the collection process and the quality of the resulting data. (3) Correlation between model performance and input patterns should be checked during evaluation.

Limitations

This work covers 14 NLU datasets, for which annotation instructions are publicly available. However, most of these datasets are QA datasets. Our analysis can be extended to other NLU task categories, such as Natural Language Inference (NLI) and Relation Extraction (RE).

Our study reveals a concrete bias that skews the collected data distribution toward specific patterns. While the effect of instruction examples on collected data is prominent, it is hard to quantify how different the distribution of crowdsourced examples is from the natural distribution of the task. Concretely, to conduct a study that compares the distributions of crowdsourced versus natural complex reasoning questions, datasets of complex natural questions are needed. However, to the best of our knowledge, as of today, no such datasets exist.

In our analysis, we focused on shallow patterns based on word matching, however, it is known that there are other types of biases that are implicit in the text. Exploring these kinds of biases can be an interesting future direction. In addition, our analysis of model performance is based on splitting dataset instances based on the dominant pattern. However, it might be possible that there are more patterns, and the non-pattern subset might include other less frequent patterns. Hence, exploring the effect of different less frequent patterns on model learning can be a future work.

Last, our work studied the effect of instruction bias on widely used generative models (i.e., T5 and BART); it would be valuable to investigate whether our findings hold in encoder-only models, such as BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019).

Acknowledgement

We thank Daniel Khashabi, Sewon Min, and Avia Efrat for helpful feedback, and the anonymous reviewers for constructive suggestions. We acknowledge the Research Computing (RC) at Arizona State University (ASU) for providing computing resources for experiments.

A Biases in NLU Benchmarks

Crowdsourcing has been a widely adapted approach to create large scale datasets such as SQuAD 1.1(Rajpurkar et al., 2016, 2018), DROP(Dua et al., 2019), QUOREF(Dasigi et al., 2019) and many more (Najafabadi et al., 2015; Callison-Burch and Dredze, 2010; Lasecki et al., 2014; Zheng et al., 2018; Chang et al., 2017). Many past works investigate different types of bias in crowdsourcing datasets such as cognitive bias (Eickhoff, 2018), annotator bias (Gururangan et al., 2018; Geva et al., 2019), sampling bias (Hu et al., 2020), demographic bias (Rahmani and Yang, 2021) and others (Hettiachchi et al., 2021). Many works on bias in NLU benchmarks focus on biases resulting from the crowdsourcing annotations, and how annotator-specific patterns create biases in data (Geva et al., 2019).

To mitigate the bias, prior works have focused on priming crowdsourcing annotators with minimal information to increase their imagination (Geva et al., 2021; Clark et al., 2020) to avoid recurring patterns. Arunkumar et al. (2020) develops a real time feedback and metric-in-the loop (Mishra et al., 2020b) workflow to educate crowdworkers in controlling dataset biases. Nangia et al. (2021) provides an iterative protocol with expert assessments for crowdsourcing data collection to increase difficulty of instances. (Swayamdipta et al., 2020) introduces dataset map as a model-based tool to characterize and diagnose datasets. Also, Karimi Mahabadi et al. (2020); Mahabadi et al. (2021) propose learning strategies to train neural models, which are more robust to such biases and transfer better to out-of-domain datasets.

In this work, we show that biases exhibited by annotators start from the crowdsourcing instructions designed by dataset creators.

B Dataset Statistics

Tab. 5 describes the statistics of train and evaluation sets of datasets used in our experiments. Here, we can observe that each selected dataset differs in terms of number of training samples, % of instruction patterns, and tasks.

C Pattern Extraction Method

Here, we describe an example to show how we extract the dominant pattern from the crowdsourcing instructions and subsequently identify the same pattern in the dataset. We try to find recurring word patterns such as *“Are you...”*, *“how many points...”*, *“Was... still...”*, *“since... the...”*.

For example, MC-TACO (event duration) has 3 examples in crowdsourcing instructions: (1) how long did Jack play basketball?, (2) how long did he do his homework?, and (3) how long did it take for him to get the Visa? In step (a), we analyze examples manually and find *dominant pattern*. Here, we can see that all examples contain tri-gram pattern, i.e., *“how long did"*. In step (b), we try to generate more possible patterns that are semantically similar to the *dominant pattern* or have a significant word overlap. Here, *“how long did"* can be *“how long was"*, *“how long does"*, etc. (i.e, `How long AUX`). In step (c), we look for all these possible patterns in datasets using simple word-matching techniques.

D Pattern Examples

Tab. 8 provides dataset, instruction patterns and corresponding examples of data instances that exhibit the instruction patterns.

E The Effect of Instruction Examples on Pattern Frequency in Collected Data

To study the effect of bias in instruction examples on collected data, we asked NLP graduate students to write five questions for each of (1) temporal reasoning (event duration) and (2) coreference resolution, based on the crowdsourcing instructions of MC-TACO and QUOREF, respectively. For each task, we conduct two surveys, where the instructions include and do not include any examples.

We collected responses from 10 participants. The dominant patterns of MC-TACO (‘how long’) and QUOREF (‘What is the name’) only contribute to 38% and 8% of our collected data where examples are not given, in contrast to 68% (↑79%) and 32% (↑300%) in collected data where examples are given. This indicates that crowdsourcing examples bias crowdworkers to follow certain patterns, whereas showing no examples increases the creativity of crowdworkers.

In addition, our collected responses where examples are not given contain 10 and 9 unique patterns for MC-TACO (event duration) and QUOREF respectively, in contrast to only 4 and 5 unique patterns in collected data where examples are given. Our finding shows that there is substantial linguistic diversity associated with the NLP tasks, unlike

The task instructions and collected annotations are available at `https://github.com/Mihir3009/instruction-bias/blob/main/SURVEY.md`.

F Additional Results

Tab. 6 and Tab. 7 show the performance of BART on $\mathcal{S}^{p}_{\text{test}}$ and $\mathcal{S}^{-p}_{\text{test}}$ when training only on examples with instruction patterns and the full training set, respectively. From Tab. 6, there are large performance gaps reaching 45.9% in MULTIRC and $>$ 20% in both base and large models for QUOREF, and PIQA. Overall, the average performance across all datasets is 27.9% and 22.2% higher on $\mathcal{S}^{p}_{\text{test}}$ for the base and large models, respectively. This indicates that both base and large models often fail to generalize beyond instruction patterns.

From Tab. 7, we see that the average performance across all datasets is higher on examples that exhibit instruction patterns by $\sim$ 10.5% for both base and large models. From the results, we can conclude that the model's performance is overestimated by instruction bias.

Dataset	Pattern	Examples
CLARIQ	[Are|Would|Do] you	Are you looking for a specific web site?
		What kind of train are you looking for?
		Do you want to watch news videos or read the news?
		Would you like the location of the ritz carlton lake las vegas?
COSMOSQA	What AUX	What may happen after the young man makes his call?
		What might happen if you have him for the whole day?
		What's a possible reason the writer doesn't look disabled on the outside?
DROP	How many [field goals | years | yards | points | touchdowns]	How many touchdowns did Jones have?
		How many field goals did Kris Brown kick
		How many yards was the longest touchdown of the game?
		After Akers 32-yard field goal, how many points behind was Washington?
HOTPOTQA	[in|of|from|_] [Which|What] AUX	Which franchise was founded in 1978, Chuck E. Cheese's or Jet's Pizza?
		Busan, in the area surrounding the mountain of Geumjeongsan, is the second most populated city in which country?
		What is the name of the third album from singer Selena Quintanilla-Pérez?
MC-TACO	How long AUX	How long was his mother ill?
	What AUX	What did the government decide after the 9/11 attack?
	How often AUX	How often would one family be able to do something like this?
	AUX... [still|always]	Will electronic espionage always be happening in the U.S.?
		Is she still gone?
	When did / What time	What time did the planes crash into the World Trade Center?
		When did Durer die?
MULTIRC	What AUX	What was Poe's first published work?
		What is the full name of the person described?
		What kind of career does Christie Brinkley have?
PIQA	How [do|can]	How do I make orange icing if I have store-bought white frosting?
		How can I make popsicles for dogs?
		Are you nervous about giving a speech or doing something? How can you calm yourself?
QUOREF	What AUX the [full | real | first |last] name	What is the first name of the person who purchases a revolver?
		What is the full name of the person who is calmly asked to leave?
		What was the name of the house where Appleton Water Tower was built?
		What is the last name of the person who convinces the girls to help him look for the treasure?
ROPES	Which AUX	Which area would be less likely to experience a drought and have better chance at a new growth?
		Which hair spray brand should Greg buy to be environmentally friendly?
		Which markalong was produced asexually?
SCIQA	What AUX	What are by far the most common type of invertebrate?
		What do waves deposit to form sandbars and barrier islands?
		What is the term for the total kinetic energy of moving particles of matter?

Abstract

Performance prediction for Natural Language Processing (NLP) seeks to reduce the experimental burden resulting from the myriad of different evaluation scenarios, e.g., the combination of languages used in multilingual transfer. In this work, we explore the framework of Bayesian matrix factorisation for performance prediction, as many experimental settings in NLP can be naturally represented in matrix format. Our approach outperforms the state-of-the-art in several NLP benchmarks, including machine translation and cross-lingual entity linking. Furthermore, it also avoids hyperparameter tuning and is able to provide uncertainty estimates over predictions.

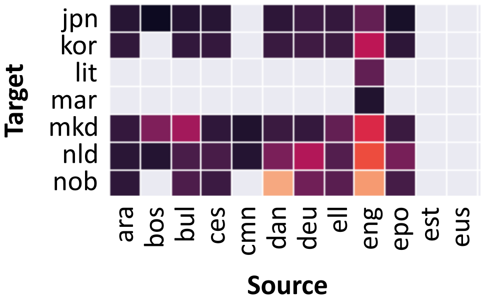

Figure 1: Matrix representation showing a subset of the performance scores for Wiki MT (Schwenk et al., 2021). Black: Lowest performance scores. Light orange: Highest performance scores. Grey: No performance score available. The goal is to predict the performance of language pairs depicted by grey cells.

1 Introduction

Natural language processing (NLP) is an empirical discipline, with progress driven by a myriad of tasks, domains, computational models and datasets (Xia et al., 2020). Models are often developed to be applicable to a large number of languages. Given that there are more than 7000 languages spoken in the world (Haddow et al., 2022), evaluating the model performance of each possible NLP scenario leads to a combinatorial explosion and would require excessive time for training and testing, as well as the significant costs of evaluation resource creation. This is very time consuming and computationally expensive, especially for large models and massively multilingual applications (Xia et al., 2020; Sharir et al., 2020).

To illustrate, for neural machine translation (MT) models, retraining and testing for each new language pair is required (Fan et al., 2021), which quickly increases the number of experiments (as shown in Figure 1). In those scenarios, whether the model is appropriate for the considered test languages is not clear upfront. Similarly, for cross-lingual transfer (TSF) tasks like parsing (Das and Sarkar, 2020) or part-of-speech (POS) tagging (de Vries et al., 2022), the performance on all languages of interest is only known after training and testing has been performed. This is particularly interesting for the development of NLP technologies for low-resource languages (de Vries et al., 2022).

In this paper we propose a method for performance prediction which can solve the above problems through automatically estimating performance scores of machine learning models, thus avoiding the need for excessive training and test cycles, and data creation costs. The goal is to predict the performance of a model solely based on past experimental records – a task of great interest for decision making in aforementioned high-cost applications. We propose to use Bayesian probabilistic matrix factorization methods and incorporate context features describing the language pairs of interest. This is realisable because many performance prediction problems in NLP can be modelled as a matrix, as illustrated in Figure 1. The result will inevitable be an incomplete matrix because some data are missing, as they were either to costly to obtain or no datasets were available (Xia et al., 2020; Schwenk et al., 2021).

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1790–1801
May 2-6, 2023 ©2023 Association for Computational Linguistics

Our key contribution is a Bayesian approach for performance prediction, contrasting with prior work which is exclusively frequentist. This confers the following advantages: 1) it enables us to quantify the uncertainty of our predictions by providing credible intervals (CIs); and 2) predictions of performance scores can be provided in a more principled way via a posterior distribution after integrating over the model's parameters and hyperparameters. We provide an extensive experimental study of matrix factorization methods, including our proposed Bayesian technique, applied to several important benchmarks, and show several improvements over the state-of-the-art.

2 Problem Formulation and Methods

As demonstrated in Figure 1, the performance scores for a suitable NLP task can be arranged in a matrix with the rows displaying the source languages and the columns showing the target languages[1]. The matrix is the score matrix $\mathbf{R} \in \mathbb{R}^{N_s \times N_t}$ and each cell (s, t) contains either the performance score for a source-to-target language relationship or is empty. The number of considered source and target languages is denoted by N_s and N_t, respectively.

The performance of a model, measured by an evaluation metric (e.g. BLEU, Papineni et al. (2002)), depends on properties like the model architecture $\mathcal{M}$, training dataset $\mathcal{D}$, languages $\mathcal{L}$, the training procedure $\mathcal{P}$ and the test dataset $\mathcal{D}'$. The score matrix $\mathbf{R}$ is then given by

$$\hat{\mathbf{R}}_{\mathcal{L},\mathcal{D}} = f_\theta([\Phi_{\mathcal{L}}; \Phi_{\mathcal{D}}]),$$

with $f_\theta(\cdot)$ being a function which denotes a linear or non-linear relationship of its arguments and $\Phi_{\mathcal{X}}$ represents the feature set of each characteristic $\mathcal{X}$. The dependency on test set features is omitted. We assume that the distributions of training and test datasets are the same, ignoring a possible domain shift (following Xia et al. (2020)).

As the completion of an arbitrary matrix is ill-posed, we reformulate $f_\theta(\cdot)$ as a low-rank matrix approximation problem. In its simplest, noiseless form, the matrix $\mathbf{R}$ can be reconstructed as (Koren et al., 2009)

$$\mathbf{R} \approx \mathbf{W}^T \mathbf{H}, \tag{1}$$

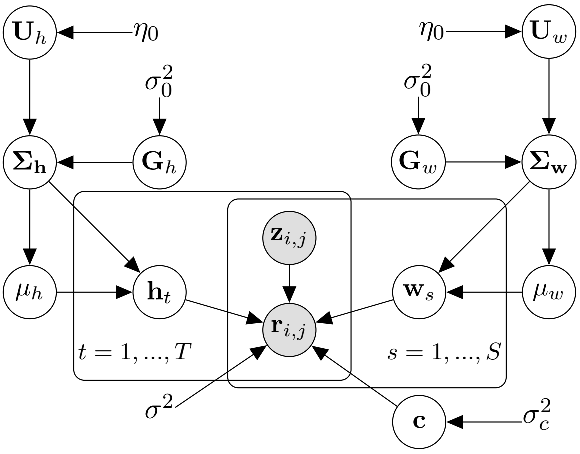

Figure 2: The graphical model for our approach based on Bayesian Probabilistic Matrix Factorisation with context information.

using two lower rank matrices $\mathbf{W} \in \mathbb{R}^{D \times N_s}$ and $\mathbf{H} \in \mathbb{R}^{D \times N_t}$, with $\mathbf{W}$ and $\mathbf{H}$ being the latent matrices for the source and target languages, respectively. Due to the low-rank assumption, for the latent dimensions it holds that $D \ll N_s, N_t$. Hence, each individual score $r_{s,t}$ of a source-target pair can be calculated by $r_{s,t} \approx \mathbf{w}_s^T \mathbf{h}_t$, where each latent source and target language vector is given by a low-dimensional vector, $\mathbf{w}_s^T \in \mathbb{R}^D$, $\mathbf{h}_t \in \mathbb{R}^D$, respectively (Cabral et al., 2013; Chen et al., 2018b).

The matrix factorisation (MF) approach described above is inspired by research on recommender systems, which use latent factor models for preference predictions (Koren et al., 2009). In those models, the low rank behavior is a widely used assumption. We assume in our model that the performance of a bilingual task is determined by a small number of unobserved factors. Using a linear factor model the performance for translating from a source language is modeled by linearly combining target language factor vectors using source language specific coefficients.

2.1 Bayesian Probabilistic Matrix Factorisation

Our approach is represented by the graphical model shown in Figure 2. It illustrates a linear probabilistic model, where the conditional distribution over the observed ratings, assuming Gaussian observation noise, is given as

$$p(\mathbf{R}|\mathbf{W}, \mathbf{H}, \mathbf{c}, \mathbf{z}, \sigma^2) = \prod_{s=1}^{S} \prod_{t=1}^{T} [\mathcal{N}(r_{s,t}|\mathbf{w}_s^T \mathbf{h}_t + \sum_{i=1}^{N} c_i z_{s,t}^i, \sigma^2)]^{I_{s,t}}, \tag{2}$$

---

[1] This is an assumption, appropriate for our considered tasks. Without any loss of generality, this scenario can be expanded to other NLP settings which can be reformulated as a matrix, e.g. hyperparameter search for language models.

with $I_{s,t}$ being the indicator function that is 1 if a source language s has a performance score for a target language j and 0 otherwise. $\mathcal{N}(\mu, \sigma^2)$ denotes a Gaussian distribution with mean μ and variance σ^2. The mean of this likelihood function consists of a latent factor model $\mathbf{w}_s^T \mathbf{h}_t$ and is also additionally regressed on the available context information given by $z_{s,t}^i$ for $i \in 1, ..., N$ available context features (Chen et al., 2018b). The prior for the regression coefficients c_i of each context feature z_i is given by $p(c_i|\sigma_c^2) = \mathcal{N}(c_i|0, \sigma_c^2)$. Furthermore, spherical Gaussian priors are placed for source and target language latent feature vectors given by

$$p(\mathbf{W}|\sigma_w^2) = \prod_{s=1}^{S} \mathcal{N}(w_s|\mu_w, \mathbf{\Sigma}_w) \tag{3}$$

$$p(\mathbf{H}|\sigma_h^2) = \prod_{t=1}^{T} \mathcal{N}(h_t|\mu_h, \mathbf{\Sigma}_h), \tag{4}$$

with hyperparameters $\Theta_w = \{\mu_w, \mathbf{\Sigma}_w\}$ and $\Theta_h = \{\mu_h, \mathbf{\Sigma}_h\}$, where $\mathbf{\Sigma}$ is the covariance matrix. In contrast to the original work (Salakhutdinov and Mnih, 2008) on which we base our approach, we choose to incorporate the Lewandowski-Kurowicka-Joe (LKJ) prior (Lewandowski et al., 2009) into the computation of samples for the covariance matrices. This method is better suited for modern Bayesian computations, due to sampling difficulties the inverse-Wishart prior causes and its restrictive form (Team, 2018; Barnard et al., 2000). A correlation matrix $\mathbf{U}$, with elements $u_{ij} = \frac{\sigma_{ij}}{\sigma_i \sigma_j}$ and σ being the standard deviation, can be reformulated into a covariance matrix $\mathbf{\Sigma}$ using the separation strategy (Barnard et al., 2000) as

$$\mathbf{\Sigma} = \mathbf{GUG}, \tag{5}$$

with $\mathbf{G} = \sqrt{\text{diag}(\mathbf{\Sigma})}$. The matrix $\mathbf{U}$ is sampled from the LKJ prior given by

$$p(\mathbf{U}|\eta_0) = c \cdot \det(\mathbf{U})^{\eta_0 - 1},$$

indicating a uniform distribution on correlation matrices for $\eta_0 = 1$, a normalization constant c and $\det(\cdot)$ denoting the determinant. As a prior for $\mathbf{G}$ we choose the halfnormal distribution (Seyboldt, 2019), as it holds that $\sigma > 0$, which is given for each element $g \in \mathbf{G}$ by

$$p(g|\sigma_0^2) = \frac{\sqrt{2}}{\sigma_0 \sqrt{\pi}} \exp\left(-\frac{g^2}{2\sigma_0^2}\right), \; g \geq 0,$$

with unit variance σ_0^2. This is equivalent to placing an inverse-Gamma distribution on the precision. The covariance matrix $\mathbf{\Sigma}$ obtained according to Equation (5) is used to parameterise the priors given in Equations (3) and (4) and the Gaussian prior of their means. More information can be found in Salakhutdinov and Mnih (2008).

The predictive distribution is obtained by marginalizing over the model's parameters and hyperparameters. Since exact evaluation of this predictive distribution is analytically intractable, we use approximate inference via Markov chain Monte Carlo (MCMC) sampling, leading to an approximation of the predictive posterior as (Salakhutdinov and Mnih, 2008):

$$p(\mathbf{R}^*|\mathbf{R}, \Theta_0) \approx \frac{1}{K} \sum_{k=1}^{K} p(\mathbf{R}^*|\mathbf{W}^k, \mathbf{H}^k), \tag{6}$$

for $\Theta_0 = \{\eta_0, \sigma_0^2\}$ and $\mathbf{R}^*$ denoting the matrix of predictions on the test set. The K samples are generated by running a Markov chain. Its stationary distribution will be the posterior distribution over the model parameters and hyperparameters $\{\mathbf{W}, \mathbf{H}, \Theta_w, \Theta_h\}$.

2.2 Credible Intervals

One measure of uncertainty in Bayesian inference is the credible interval (CI) or more generally a credible set (Casella and Berger, 2021). A $100(1-\beta)\,\%$ equal tail CI for a random variable X is an interval $[a, b]$ such that the probability that X lies in the interval is $1 - \beta$, given as

$$P(X \in [a, b]) = 1 - \beta.$$

In Bayesian inference, analyses are made considering the posterior distribution of the parameter of interest. Hence, a CI provides us with upper and lower bounds which define an interval with the probability of interest around the mean of the posterior distribution (Hespanhol et al., 2019; Rice and Ye, 2022). It quantifies how precise the obtained posterior, i.e. the posterior belief, is, with a narrower interval around the point estimate indicating more certainty in the predictions. Hence, using the samples from Equation (6), an approximation of the posterior predictive distributions for each language pair can be obtained and used to construct CIs in addition to the point estimates. This is useful for performance prediction in NLP settings, as the widths and bounds of the obtained CIs can guide further decision-making regarding whether a model is theoretically worth deploying.

2.3 Non-Bayesian Matrix Factorisation Methods

Probabilistic MF (PMF) has been shown to perform well on sparse and imbalanced datasets (Mnih and Salakhutdinov, 2007). The conditional distribution over the observed ratings, assuming Gaussian observation noise given by Equation (2), without considering additional context information. As in Bayesian PMF (BPMF) spherical Gaussian priors are placed on $\mathbf{W}$ and $\mathbf{H}$ following Equations (3) and (4), assuming $\mu_w = \mu_h = 0$; $\mathbf{\Sigma}_w = \sigma_w^2 \mathbf{I}$ and $\mathbf{\Sigma}_h = \sigma_h^2 \mathbf{I}$. Learning the latent source and target matrices is done via maximizing the log-posterior, where all hyperparameters, being the observation noise and prior variances, are fixed. This is equal to the following optimization problem, where latent factor representations are learned by finding the matrices $\mathbf{W}$ and $\mathbf{H}$ which minimize the regularized squared error, given by (Chen et al., 2018b)

$$\mathbf{W}^*, \mathbf{H}^* = \underset{\mathbf{W},\mathbf{H}}{\arg\min} \frac{1}{2} \sum_{(s,t)\in\delta(\mathbf{R})} (\mathbf{r}_{s,t} - \mathbf{w}_s^T \mathbf{h}_t)^2$$
$$+\beta_w \sum_{s=1}^{N_s} ||\mathbf{w}_s||_2^2 + \beta_h \sum_{t=1}^{N_t} ||\mathbf{h}_t||_2^2, \quad (7)$$

where $||\cdot||_2^2$ is the squared l_2 norm[2]. Additionally, separate regularization parameters for $\mathbf{W}$ and $\mathbf{H}$ are assumed, being β_w and β_h, respectively. In the case of missing values, the optimization problem is on the set of known ratings $\delta(\mathbf{R})$.

Additionally, the framework of MF offers the option of biased MF, which provides a means of incorporating context. It incorporates model characteristics of each source language, b_s, and target language b_t and considers a global tendency μ which is independent of source-target language interactions. The biases account for the fact that certain performance values might contain universal shifts or exhibit systematic tendencies with respect to certain source and target languages. Furthermore, it is common that all performance predictions are non-negative and in a certain range, i.e., the global bias μ accounts for global effects. The predictions are given by (Chen et al., 2018b)

$$\hat{r}_{s,t}^{\text{CTX}} = \mathbf{w}_s^{\text{T}} \mathbf{h}_t + \sum_{i=1}^{N} c_i z_{s,t}^i + \mu + b_s + b_t. \quad (8)$$

During learning, the optimization problem in Equation (7) has to be adapted to $\hat{r}_{s,t}^{\text{CTX}}$ accordingly, also adding additional regularization terms for b_s and b_t.

The non-probabilistic approaches, but also PMF need manual control of their hyperparameters, which makes those approaches computationally expensive to develop compared to BPMF.

3 Experiments and Analysis

Following the evaluation setting of *NLPerf* (Xia et al., 2020), we consider a set of tasks described in the following, all of which allow a reformulation into a matrix representation. The performance scores are predicted for bilingual lexicon induction (BLI); machine translation on aligned Wikipedia data (Wiki^{MT}), and with cross-lingual transfer for translation into English (MT^{TSF}); cross lingual dependency parsing ($\text{Parsing}^{\text{TSF}}$); cross-lingual POS tagging (POS^{TSF}) and cross-lingual entity linking (EL^{TSF}). Despite also considering cross-lingual transfer tasks, for reasons of simplicity and without any loss of generality, we refer to each cell in the matrix as a *source-target* language pair unless otherwise stated. All tasks and their matrix properties are stated in Table 1. More information about the models underlying each task can be found in Appendix A.

To allow a fair comparison to the closest related work *NLPerf* (Xia et al., 2020), we consider an identical set of features for our predictions: Dataset size, word/subword vocabulary size, average sentence length, word/subword overlap, type-token ratio, type-token ratio distance, single tag type, fused tag type, average tag length per word, dependency arcs matching WALS features and six distance features from the URIEL Typological Database (Littell

---

[2] Solving this optimization problem to obtain a point estimate is referred to as MF in our experiments. We use a Bayesian approach for PMF and therefore apply MCMC sampling, which is another alternative and can be easily extended via hyperpriors to BPMF.

Table 2: RMSE ± standard deviation for various all tasks considered. D: Latent factor dimension. CTX: Approaches incorporating context features.

et al., 2017). Further information regarding each feature can be found in Xia et al. (2020).

All features were normalized using their corresponding z-score. For each task, (except BLI), we predict scores for a single model. This means that there is exactly one underlying statistical or neural model considered for each task. For BLI however, our dataset consists of two metrics *Vecmap* and *Muse*. The performance is obtained as in the equivalent multi-model scenario in Xia et al. (2020), by averaging over both metrics.

The *NLPerf* framework is based on gradient boosting trees (Friedman, 2001) and implemented with XGBoost (Chen and Guestrin, 2016). The parameterisation of this predictor was kept as in (Xia et al., 2020), assuming a squared error as the objective function for the regression, a fixed learning rate of 0.1, a maximum tree depth of 10 and the number of trees being 100. The default setting was used for the regularization terms. We evaluate the performance of our methods by using the root mean squared error (RMSE).

Predictions for MF are obtained according to Equation (8) but through omitting the context information, whereas MF CTX makes use of the latter. The conditional distribution over observed ratings as given in Equation (2) is used to obtain predictions for BPMF, and adapted accordingly for PMF. All non-Bayesian models are trained using nested 5-fold cross validation and stochastic gradient descent (SGD) over 2000 training iterations. Referring to Figure 1, note that during training of the latent vectors $\mathbf{w}_s$ and $\mathbf{h}_t$, all available scores in the corresponding column s and row t are used. The regularization parameters are chosen using a validation set. All non-probabilistic experiments are averaged over 10 runs. Training of the probabilistic models was performed using MCMC sampling and the results are averaged over 2 runs, due to MCMC time complexity.[3] More information about the execution times of each experiment is given in Appendix B.

3.1 Random Train-Test Splits

We start by investigating the behaviour of all methods on a randomly chosen training and test split containing a subset of language pairs. Note that we create one split per task and keep it constant across all methods to allow fair comparison of the obtained results. An example for such a train-test split is depicted in Figure 3 on the left for BLI.

The RMSE and standard deviations of our predicted performances for all tasks are provided in Table 2. For all single model tasks, the MF approaches consistently outperform the state-of-the-art *NLPerf* (Xia et al., 2020). While general MF already outperforms *NLPerf* in all but one setting, using context information (MF CTX) leads to further improvements in terms of RMSE – outperforming the SOTA with reductions in RMSE of up to 64% (Parsing$^{\text{TSF}}$). While the improvement is significant for tasks like EL$^{\text{TSF}}$, POS$^{\text{TSF}}$ and the aforementioned Parsing$^{\text{TSF}}$, we observe a smaller but still noticeable reduction in RMSE for Wiki$^{\text{MT}}$ and MT$^{\text{TSF}}$ of around 13% and 16%, respectively. Note however, that the RMSE scores cannot be directly compared across tasks as the scales of all

evaluation metrics differ.

While the Bayesian version BPMF CTX also outperforms the *NLPerf* baseline in all but one single model task, we observe particularly good results for the task EL$^{\text{TSF}}$, where BPMF CTX outperforms all other methods and achieves new state-of-the-art results with a relative reduction in RMSE of 35%. As introduced in Section 2, the non-Bayesian PMF requires hyperparameter optimization and as shown in Table 2 for all tasks but MT$^{\text{TSF}}$, BPMF outperforms PMF – potentially due to non-optimal hyperparameter choices for PMF. This might also be the cause for the PMF results in the EL$^{\text{TSF}}$ experiments, while they converge to a solution, the obtained model does not represent the underlying data well. The outliers for POS$^{\text{TSF}}$ are caused by divergences, which can be avoided by using a higher number of latent dimensions. Further research is required in those cases to understand how the models in those cases can be better adapted to the data and is part of future work.

Observing all single model results obtained, we conclude that if a dataset is given for which a matrix can be constructed with a limited number of missing cells, MF approaches provide a strong alternative to gradient boosting trees. Results for all tasks show that linear MF approaches with rather small latent dimension sizes of 10 or 20 show often significant performance improvements over *NLPerf*.

In contrast to the single model tasks, the BPMF approaches achieve competitive performance in the BLI two model scenario, but none of the MF approaches are able to outperform the SOTA. We suspect this might be due to the matrix size and available data, which is significantly smaller than in all other tasks (Table 1). Furthermore, only 6 distance features are available for this setting, indicating that additional features like *dataset size* and *vocabulary size* (among others) that are available for the other tasks might play a important role in facilitating accurate performance prediction.

3.2 Uncertainty of the Predicted Scores

The Bayesian approaches offer the advantage of providing a measure of uncertainty in terms of CIs. An example showing the 95 % CIs for all language-pairs available in the test set is depicted in Figure 3. Predicted performance scores for cells where only limited training data in the corresponding rows and columns is available show wide approximations of the predictive posterior distribution in terms of CIs, e.g. the language pairs "fr_uk" or "fr_hi". In contrast, those with more training data lead to narrower CIs like for "be_es" or "en_be".

Apart from having a direct measure of uncertainty, one can use upper confidence bounds (UCB) and lower confidence bounds (LCB) of the obtained CIs to guide further decision-making (Auer, 2002). Maximum UCBs can help to determine language-pairs for which the underlying model could be especially high-performing, justifying the cost to

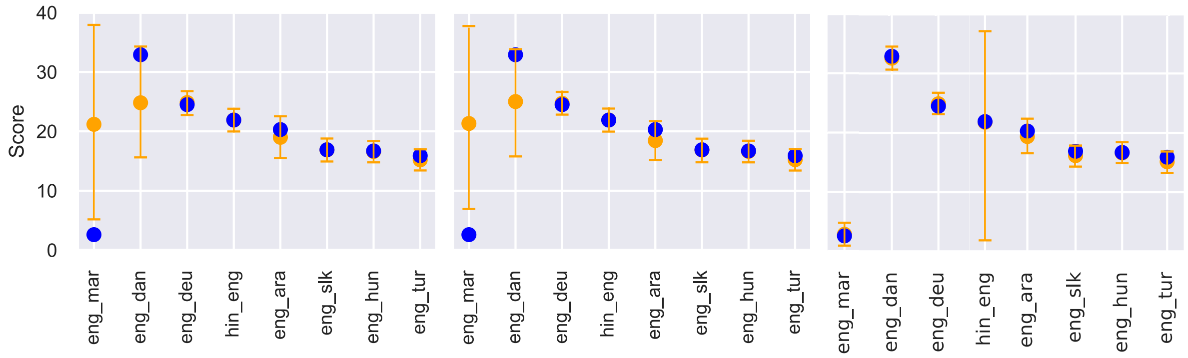

Figure 4: Credible intervals for the task: $\mathrm{MT}^{\mathrm{Wiki}}$. Orange: Predicted Score. Blue: Actual scores. **Left:** BPMF, latent factor dimensionality: 10. **Middle:** BPMF, latent factor dimensionality: 20. **Right:** BPMF CTX, latent factor dimensionality: 20. An increase in latent factor dimensionality and adding additional features leads to narrower CIs. However, adding features to the language pair “hin_eng” causes a wider CI, indicating that the used features might be unsuitable for this language-pair.

train and acquire the necessary datasets for such language-pairs. The example given in Figure 3 on the right shows CIs for the BLI task. Using the UCBs, the language-pairs “fr_ru”, “fr_uk” and “en_sv” could potentially provide us with the highest achievable scores (between 65 and 75). In contrast, using the minimum UCBs, we can conclude that only very low possible maximum scores for the language pairs “ru_ko”, “be_es” and “be_gl” can be achieved. Those will be between 15 and 20, therefore it is discouraged to train and test the underlying models on those. Moreover, the decision whether a model is suited for a language-pair can also be based on the maximum LCBs, indicating the potential that a performance score will be higher or equal then the obtained bounds. For the considered task, this is true for the language pairs “fr_en”, “en_gl” and “en_sv”.

Furthermore, CIs provide important additional insights that help to interpret design choices. Figure 4 shows the impact and importance that an increase in latent factor dimensionality as well as the addition of additional features has on the performance of the task $\mathrm{MT}^{\mathrm{Wiki}}$. The left figure shows predictions and corresponding CIs using BPMF for a latent vector dimension of 10. After increasing the dimensionality to 20, the resulting CIs get slightly narrower as shown in the middle figure. Finally on the right, it can be observed that after adding CTX for language pairs like “eng_dan” and “eng_hun”, the CIs get significantly narrower and indicate increased certainty of the predictions. However, the CI for “hin_eng” interestingly becomes wider, indicating that the additionally chosen features for this language pair might be less beneficial and even hurt performance prediction. Further investigation of the feature set shows that “hin_eng” exhibits the highest value of the feature *average sentence length of the source language*, leading to the conclusion that extreme feature values lead to more uncertainty in the predictions, which is to be expected as the Bayesian model has not encountered this feature value during training.

It is clear from Figures 3 and 4 that the credible intervals are imperfect, not always including the test results. This is to be expected 5% of the time by chance, following the definition of the credible interval. However, deviations can arise through modelling biases. Consider the language pairs “fr-en” and “sk-cs” in Figure 3. The scores for these instances are not seen during training, and thus generalisation errors may occur. For the former, there is lack of training data for a translation from French to other languages. For the latter, although both languages are closely related, there is not enough training data support confident predictions. Further-

	LOLO transfer	LOLO target
NLPerf	**8.08**	10.62
MF	13.29 ± 0.01	11.86 ± 0.02
MF CTX	11.16 ± 0.02	**6.78 ± 0.02**
Bayes	13.09 ± 0.00	10.85 ± 0.00
Bayes CTX	13.04 ± 0.00	10.68 ± 0.00

Table 3: RMSE ± standard deviation for $\mathrm{Parsing}^{\mathrm{TSF}}$. Experiments leaving-one-language-out (LOLO). Dimensionality of latent factors: 20.

more, BPMF does not use any additional features. As visible from Figure 4 for the language pair "eng-mar", adding context features provides additional information and greatly improves the accuracy of the Bayesian credible interval.

NLPerf	8.78
LR	17.26
BPMF CTX $D = 20$	9.20 ± 0.07

Table 4: Contrasting the performance of predictors, being NLPerf, linear regression (LR) and BPMF CTX.

3.3 Leave-one-Language-out Scenarios

We further investigate the importance of additional features for performance prediction in cold start scenarios. In such settings, a new language occurs in the test set which has not been encountered during training. This is referred as leave-one-language-out (LOLO). We conducted the experiment for Parsing$^{\text{TSF}}$ as this includes a complete matrix with the same target and transfer languages as rows and columns. This provides us with the opportunity to contrast the performance of the predictors regarding having the same target and transfer languages.

The vectors of the latent factor models of MF and MF CTX are initialized to small random values during training. Thereby, the latent vector corresponding to the missing language will not be further changed as there is no training data available. Note that MF leverages additionally the information of additional bias as shown in Equation (8). In the Bayesian setting, the latent vectors are sampled according to the probabilistic model from the specified priors. Further training details are kept the same as in Section 3.1.

The results are shown in Table 3. Our experiments demonstrate that when leaving one target language out, the predicted performance of MF CTX significantly outperforms all other approaches. However, when leaving one transfer language out, although the performance scores predicted by MF CTX are better then other MF approaches, they do not outperform *NLPerf*. These results indicate that the performance of a predictor based on the MF framework seems to heavily depend on the missing LOLO direction, being target or transfer – rendering MF CTX well suited for cold start predictions when performance scores for unseen target languages are of interest.

3.4 On the Effects of Non-Linearity

In Table 4 the performance in terms of RMSE of XGBoost, linear regression (LR) and BPMF CTX for BLI is shown. The proposed MF methods were not able to outperform the SOTA in this scenario. However, while *NLPerf* is a non-linear method, our approaches are all bilinear. Comparing to the performance of LR, BPMF CTX clearly outperforms, having the additional advantage of being able to provide measures of uncertainty. This suggests that further investigations are necessary in whether a non-linear model would be better suited for the prediction of performance scores for BLI.

4 Related Work

Matrix completion (MC) is an important technique used to recover a matrix from a subset of its entries, widely applied and studied in many areas of research like machine learning, data science, signal processing and communications (Du and Swamy, 2013; Yuchi et al., 2022). In NLP, it is found in keyword searches or recommender systems, among others (Chen et al., 2018b,a). MC in the context of recommender systems can be interpreted as e.g. the task of predicting a product to recommend to costumers. In the famous *Netflix price competition*, targeting recommender systems for movies, it has been shown that an approach based on matrix factorization (MF) via low-rank latent factor models is the basis for the best algorithm to predict user ratings (Koren et al., 2009; Chen et al., 2018b).

There are two main directions of performance prediction in machine learning. The performance can either be predicted as a function of certain training dataset properties or as a function of its training time or number of iterations (Kolachina et al., 2012). Following the former, current state of the art approaches like *NLPerf* (Xia et al., 2020) or *LITMUS* (Srinivasan et al., 2022) leverage the advantages of regression models like gradient boosting trees. We use *NLPerf* as a competitive baseline in this work. Note that *NLPerf* was shown to outperform several simple mean-value baselines, namely the average over the performances of all available test instances; the average over shared source languages; and the average over models if multiple models are used. This approach can easily incorporate additional features of the experiments, but they do not provide a direct measure of uncertainty.

In Ye et al. (2021) methods used for performance prediction are based on tensor-regression-based approaches being robust PCA and CP decomposition. Those are developed to provide a more fine-grained performance measure. While confidence intervals in the frequentist sense are provided, no Bayesian analysis was conducted. In Srinivasan et al. (2021) collective MF was used for performance prediction of massive multilingual language models, where it underperformed XGBoost. However, no experiments were shown for bilingual tasks. We differ in our work because we explore the framework of MF extensively and are able to provide a range of experiments contrasting probabilistic and non-probabilistic approaches. Additionally our approach can give CIs as a measure of uncertainty of our predictions. Closer to our approach is the work of Elsahar and Gallé (2019), where instead of evaluating domain similarity or diversity, a linear classifier is used to predict the performance drop under domain shift using metrics based on $\mathcal{H}-$divergence, reverse classification accuracy and confidence measures. In contrast to this body of literature, our methods provide the additional benefit of Bayesian uncertainty quantification.

An area of application for performance prediction, to be additionally highlighted here, is data selection, during which the method can be used to identify a suitable training dataset under domain shift, which will lead to the best model performance. Earlier work in this field in e.g. Blitzer et al. (2007) uses the unsupervised $\mathcal{A}-$distance measure of divergence between domains, while existing literature on phrase based machine translation in Axelrod et al. (2011) and Moore and Lewis (2010) show that perplexity- or cross-entropy based scoring methods are beneficial to select suitable sentences for training, increasing the overall model performance. Connected to this stream of literature is also the work of Ruder and Plank (2017). They present a Bayesian optimisation approach, which is model-independent and is used to learn data selection measures for transfer learning. Additionally, incorporating not only information about the data set, but also about the model, Atwell et al. (2022) shows that the $h-$discrepancy, which is a generalisation of the source guided discrepancy (Kuroki et al., 2019), can be used to identify the best generalization performance of discourse models.

5 Conclusion

In this work, we presented an extensive study of various MF methods applied to the problem of performance prediction. Using a Bayesian approach we can give a measure of uncertainty in terms of CIs in addition to point estimates. Additionally, we show that leveraging the obtained bounds of the CIs can guide decision-making regarding whether it is lucrative to deploy a model for certain language-pairs and whether the corresponding datasets for the language-pairs should be acquired.

Our results confirm that bilinear MF methods can be used to predict the performance scores of various NLP tasks, which is computationally less expensive than using a non-linear model like XGboost in *NLPerf*. Furthermore, we show that the MF framework is suited to predict performance scores in cold-start scenarios.

The MF framework was not able to outperform the SOTA for the two-model scenario BLI, which might be due to the small matrix size and unsuitable features. However, BPMF CTX clearly outperformed LR. This suggests that further studies are required regarding non-linear MF methods.

While we chose to present a specific set of tasks within this work, the proposed MF methods can be used for other NLP scenarios where the considered problem can be modelled as a matrix.

Limitations

While a variety of NLP problems can be modelled as a matrix as our investigations in this paper show, this does not apply to all existing NLP tasks and excludes our methods in its current form from being used on datasets, provided for tasks like e.g. universal dependency parsing or morphological analysis as done in Xia et al. (2020). The reason is, that a suitable matrix representation is not possible.

While we were able to show that context features significantly improve the estimation results, we found that language features did not improve the predictions. Therefore, further studies are necessary to understand how language information can be additionally incorporated into the MF framework for performance prediction.

Our Bayesian approach uses MCMC sampling to perform approximate inference, a process that can be rather time consuming and could be replaced by more efficient sampling methods in the future. Furthermore, our methods are currently limited to linear approaches, for a fair comparison with the non-linear model *NLPerf*, non-linear methods needs to be investigated.

A Models Considered in the Experiments

The MT model behind the $\mathrm{MT}^{\mathrm{Wiki}}$ data is trained on aligned Wikipedia data (Schwenk et al., 2021). The training data for translation are WikiMatrix bitexts (Schwenk et al., 2021) containing a mixture of high and low resource languages, mined using an approach based on multilingual sentence embeddings, and tested using NMT (fairseq[4], Transformer) on the TED test set (Qi et al., 2018a) using BLEU performance. The BLI performance dataset is obtained based on the following procedure. Multilingual semi-supervised word embeddings (Conneau et al., 2017), and fully unsupervised cross-lingual word embeddings (Artetxe et al., 2018) for high and low resource languages, which are learnt under a bilingual setting, are tested on BLI using accuracy as the performance measure (Anastasopoulos and Neubig, 2019). For all TSF tasks, the performance scores are obtained using LangRank (Lin et al., 2019), which gives a rank to each transfer language. Therefore, additionally a feature showing the *rank* of each transfer language can be leveraged. In the following a short description about the underlying models is given, a more comprehensive explanation can be found in (Lin et al., 2019). For $\mathrm{MT}^{\mathrm{TSF}}$ the underlying trained model is an attention-based sequence-to-sequence model (Bahdanau et al., 2015). Training is performed on the multilingual TED talk corpus (Qi et al., 2018b). For the $\mathrm{EL}^{\mathrm{TSF}}$ performance scores two character-level LSTM encoders are trained (Rijhwani et al., 2019). The $\mathrm{POS}^{\mathrm{TSF}}$ dataset is obtained through the training of a bi-directional LSTM-CNNs-CRF model (Ma and Hovy, 2016), while the dependency parsers uses a deep biaffine attentional graph-based model (Dozat and Manning, 2016). The diversity of the underlying models, namely being statistical-, neural network- or dictionary based, gives us a better impression about the usability of our predictor.

B On Computational Complexity

Non-Bayesian MF models have linear time complexity in the number of latent factors $O(D)$ per SGD iteration or $O(D|\delta(\mathbf{R})|)$ for one pass of all observed source-language pairs. The Bayesian MF models have cubic complexity on the size of the latent factors and linear on the number of source/target languages. Due to very small sizes of our datasets, computations were possible on a single cpu. The execution times per model per one run of training and inference are given in Table 5. Compared to the Bayesian approaches, the Non-Bayesian MF methods have a short execution time. It increases with the size of the score matrix, e.g. the model for $\mathrm{MT}^{\mathrm{TSF}}$ with a score matrix size of 54×54 has the highest number of cells compared to all other models and takes also the longest time to perform one training and inference run. The times shown can be taken as a reference point. Furthermore, implementing the experiments on GPU would speed up the process further, in our case we report the execution times on CPU for a better comparison. The CPU used for our experiments is Intel(R) Xeon(R) Silver 4216 CPU @ 2.10GHz. Implementing MCMC sampling using GPU will lead to a further execution time improvement.

Abstract

Two types of topic modeling predominate: generative methods that employ probabilistic latent models and clustering methods that identify semantically coherent groups. This paper newly presents UTopic (Unified neural Topic model via contrastive learning and term weighting) that combines the advantages of these two types. UTopic uses contrastive learning and term weighting to learn knowledge from a pretrained language model and discover influential terms from semantically coherent clusters. Experiments show that the generated topics have a high-quality topic-word distribution in terms of topic coherence, outperforming existing baselines across multiple topic coherence measures. We demonstrate how our model can be used as an add-on to existing topic models and improve their performance.

1 Introduction

One of the most common tasks in natural language processing (NLP) is to find cohesive topics in a text corpus. Topic modeling is widely used in various applications, including trend extraction from real-time streams such as social media (Lau et al., 2012; Park et al., 2021) and identification of notable events upon risk (Shin et al., 2020). Two representative lines of work exist: *generative methods* and *clustering-based methods*.

Generative methods follow the assumption of probabilistic latent semantic analysis (hereafter p-LSA) such that every word token in a document is sampled from a mixture of latent topics (Hoffman, 1999). Such methods estimate both the latent topic distribution per document and word distribution per topic from Bag-of-Words (BoW) representation (Blei et al., 2003; Fisher et al., 2020; Miao et al., 2017; Yan et al., 2013). Latent Dirichlet Allocation (LDA), for example, uses a Bayesian model to estimate the latent topic distribution (Blei et al., 2003). Variational Autoencoder (VAE) retrieves latent topics from the topic distribution while also recovering the original input (Srivastava and Sutton, 2017). Recent techniques have employed pretrained language models on top of VAE-based models to improve topic quality (Bianchi et al., 2021a,b). Generative probabilistic models work on the assumption that each topic is a mix of words from a larger set. However, they share a common weakness: the BoW representation only contains word-level co-occurrences and fails to capture each word token's importance in the document's context information. Consequently, the quality of the estimated topic is reliant on the choice of the word set.

Clustering methods, on the other hand, regard topics as semantic clusters discovered over the document or word embedding space (Angelov, 2020; Grootendorst, 2022; Sia et al., 2020). They utilize the knowledge of the pretrained language model (e.g., BERT (Devlin et al., 2019)) to generate high-level summaries of given documents (or words). Then, document (or word) clusters are identified according to the embedding distance via clustering methods, such as DBSCAN or k-means. They do not require word selection and effectively leverage context information for discovering topics. Nevertheless, their core is clustering; hence, they cannot assign a mixture of topics to each document.

This research takes a step further by combining the benefits of the previous methods by including novel considerations: contrastive learning and term weighting. We start with a generative method and add a term weighting scheme that mimics the clustering method. We use a contrastive learning framework to help the language model instill pretrained knowledge and enable the model to focus on influential words. Our model, **UTopic** (Unified neural Topic model via contrastive learning and term weighting), has three stages: (1) identifying semantic clusters, (2) calculating term weights, and (3) estimating the latent topic distribution. In

May 2-6, 2023

Stage 1, input documents with similar meanings are grouped into a single cluster. This procedure uses a pretrained language model, which extracts meaningful embeddings from the input document. Stage 2 computes the term weights for each word to represent the importance of each term, where high weights are given to frequent terms in one semantically coherent cluster (but not in other clusters). The model selects words with top-k term weights as the final word set for BoW representations. In Stage 3, the model estimates the latent topic distribution by reconstructing BoW representations from inputs. Term weights can represent each term's importance, allowing the model to learn a coherent topic. Contrastive learning manages the entire process of instilling pre-trained knowledge from the language model and generating a more distinct topic distribution with a predefined prior.

Experiments show that UTopic outperforms conventional methods in a wide range of scenarios, including human-annotated datasets (Table 1). When compared to SOTA models like CTM (Bianchi et al., 2021a), ClusterTM (Sia et al., 2020), and BERTopic (Grootendorst, 2022), our model consistently achieves the overall highest topic coherence score, while others excel in only one or two metrics (Table 2). In the 20-Newsgroups dataset, for example, the NPMI score increased by 3.65%. Our word set selection scheme (Stages 1&2 in Fig. 1) can be used as a standalone module to improve other models (Table 8). Major contributions are as follows:

- We present a unified method for combining the benefits of two topic modeling approaches (i.e., generative and clustering) into a single framework via term weighting.
- We modify the contrastive objective to discover semantically coherent clusters, which gives distinct and interpretable word sets for each cluster.
- Our model consistently outperforms existing baselines across multiple topic coherence measures and produces topics that align well with human labels.

Codes and implementation details of the model are available at a GitHub repository.[1]

2 Related Works

Topic modeling algorithms can be divided into two major streams: generative and clustering-based.

2.1 Generative approach

Most generative approaches follow the p-LSA assumption such that a set of tokens in each document are independently sampled from a mixture of topics (Hoffman, 1999). LDA (Blei et al., 2003) is a representative example that establishes the prior distribution following the p-LSA assumption. Many variants have been proposed, including Prod-LDA, Neural-LDA, and Hierarchical-LDA (Srivastava and Sutton, 2017; Blei et al., 2010). Some algorithms like NVDM, VTMRL, Wasserstein-LDA, and TAN-NTM use VAE for estimating the latent topic distribution (Miao et al., 2016; Gui et al., 2019; Nan et al., 2019; Panwar et al., 2021), while other algorithms, including DocNADE, use auto-regressive architecture (Larochelle and Lauly, 2012).

Adding a pretrained language model (or word embeddings) to traditional topic models has yielded promising results (Grootendorst, 2022; Liu et al., 2015; Qiang et al., 2017; Sia et al., 2020). Contextualized topic model (CTM), for example, obtains the embedding vector for each sentence using a model like BERT (Devlin et al., 2019) and bundles the embedding and the BoW (bag-of-words) (Bianchi et al., 2021a). The bundled vector based on VAE is then used to reconstruct BoW and uncover latent topics. However, these approaches have common limitations; word-level co-occurrences cannot fully convey words that represent themes. Naturally, the topic quality depends on the vocabulary set used for calculating word co-occurrences (Gui et al., 2019).

2.2 Clustering based approach

Keeping up with the recent achievement on deep representation learning in NLP domain (Devlin et al., 2019; Mikolov et al., 2013a), several works showed that discovering clusters over the sentence/word representation space can be one viable way to represent topics (Angelov, 2020; Grootendorst, 2022; Sia et al., 2020). Unlike generative approaches, they first extract high-level abstract features from the input document. Then, centroid-based clustering approaches are applied to identify dense clusters, which are finally regarded as topics. For example, Top2Vec (Angelov, 2020) utilizes Doc2Vec embedding (Le and Mikolov, 2014) to

---

[1] `https://github.com/mingi-sid/utopic`

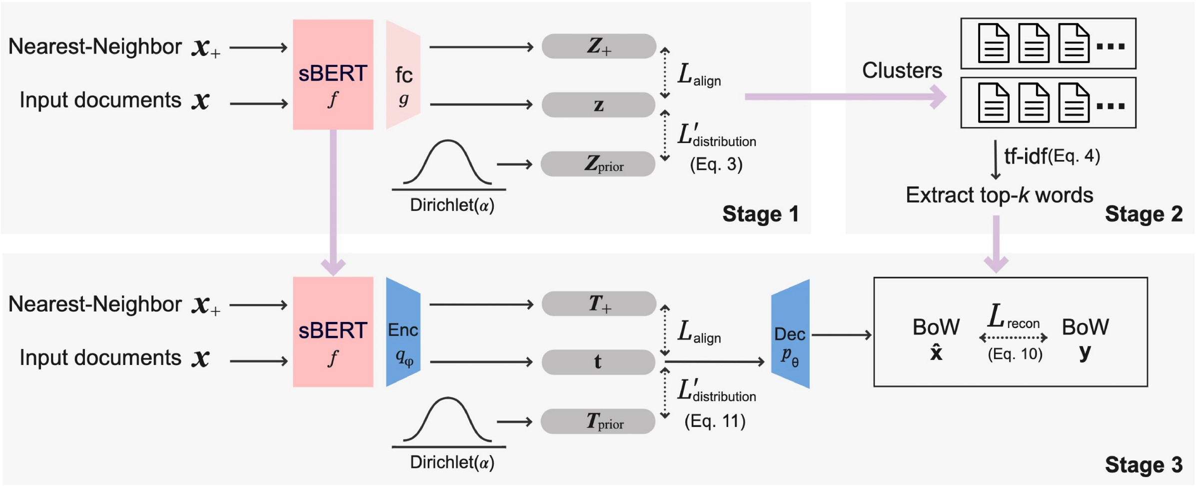

Figure 1: The illustration of the proposed neural topic model, UTopic . It divides documents into clusters based on their context (Stage 1). Then, term weights are computed according to every term's importance. As a topic word set, influential words with the highest term weight are retrieved (Stage 2). UTopic is fine-tuned by estimating the latent topic distribution with the help of term weights and contrastive learning (Stage 3).

jointly embed word and sentence representations, while BERTopic (Grootendorst, 2022) introduces BERT's sentence embedding to identify topic clusters. Another work demonstrates that word-level clusters can represent latent themes from the corpus (Sia et al., 2020). Nevertheless, these methods are clustering-based, so they cannot easily assign multiple topics to each document.

3 Methods

Problem definition: Let $\mathbf{x}$ be an input document and $\mathcal{X}$ be a collection of documents in the corpus (i.e., $\mathbf{x} \in \mathcal{X}$). A primary goal of our topic model is to estimate the topic distribution $\mathbf{p}$ from $\mathcal{X}$. Given a finite number of topics K, we extract top-k relevant words (hereafter referred to as *topic words*) $\mathcal{W}_i$ for each topic i to interpret the underlying theme and evaluate the topic quality. The topic word comes from the word set $\mathcal{W}_{dict}$, which has a size N (i.e., $\mathcal{W}_i \subset \mathcal{W}_{dict}$ for all i).

We propose to compute the *weight importance* of each term on semantically coherent clusters and then estimate the latent topic distribution by reconstructing the BoW representations based on term weights. Our idea is depicted in Figure 1, where a clustering model groups documents with similar contexts in the corpus (Section 3.1). Term weights are computed by treating each document cluster as a single unified document. If certain terms are significant in one group but not in others, we consider them *influential*. Top-k influential subject terms are selected as the word set $\mathcal{W}_{dict}$ for constructing BoW representation (Section 3.2). The model estimates topic distribution using the discovered word set and its term weight to recover the BoW representation of documents (Section 3.3). *Contrastive learning* (hereafter CL) improves representation quality at every phase, and the Dirichlet prior controls the entropy of the topic distribution. These steps are outlined in the following sections.

3.1 Stage 1: Document grouping via CL

Let f be a language model (e.g., BERT) that has been pre-trained, and g be an unsupervised classifier attached on top of f's sentence embedding (e.g., BERT's [CLS] token embedding). First, the models f and g are trained to classify incoming documents into K topic categories. CL facilitates this task with the InfoNCE loss (Oord et al., 2018), which learns an embedding space to maximize agreement between comparable examples while minimizing agreement between different instances. Assume that $\mathbf{z}$ is an input sample's embedding in the form of cluster assignment probability (i.e., $\mathbf{z} = \text{softmax}(g \circ f(\mathbf{x}))$), and that $\mathcal{Z}_+$ and $\mathcal{Z}_-$ are a collection of positive and negative samples' embeddings, respectively. The InfoNCE loss for each sample is defined as follows:

$$L_{\text{CL}}(\mathbf{z}) = -\log \frac{\sum_{\mathbf{z}' \in \mathcal{Z}_+} e^{\text{sim}(z,z')/\tau}}{\sum_{\mathbf{z}' \in (\mathcal{Z}_+ \cup \mathcal{Z}_-)} e^{\text{sim}(z,z')/\tau}} \quad (1)$$

$$= -\log \sum_{\mathbf{z}' \in \mathcal{Z}_+} e^{\text{sim}(z,z')/\tau} + \log \sum_{\mathbf{z}' \in (\mathcal{Z}_+ \cup \mathcal{Z}_-)} e^{\text{sim}(z,z')/\tau}$$

$$= -L_{\text{align}}(\mathbf{z}) + L_{\text{distribution}}(\mathbf{z}), \quad (2)$$

where sim(·) represents the similarity metric between two embeddings, and τ is a temperature value to control the entropy (Hinton et al., 2015). The InfoNCE loss can be broken down into two parts: *alignment loss* and *distribution loss*. The first term, alignment loss (L_{align}), directs the model to place positive pair embeddings closer together. The second term, distribution loss ($L_{\text{distribution}}$), pushes the embeddings of each sample as far apart as possible. This policy requires the model to match each instance's embedding into the predefined prior distribution with high entropy (Chen and Li, 2020; Wang and Isola, 2020).

The contrastive loss is used as follows in document clustering. For a given anchor $\mathbf{x}$, we establish a set of positive samples $\mathcal{Z}_+$ and negative samples $\mathcal{Z}_-$. Given that our model is unsupervised, there is no ground-truth label to determine which samples should be placed closer together in the embedding space. Instead, we mine the pretrained language model's top-1 nearest neighbor in the embedding space and consider it a positive sample (i.e., $\mathbf{x}_+$ in Fig. 1). The remaining instances in the same batch are considered negative samples.

Next, we guide the instance's embedding distribution to follow the prior with low entropy by modifying $L_{\text{distribution}}$ and adopting the optimal transport theory (Peyré et al., 2019; Rabin et al., 2011), a mathematical framework for transporting two sets of points while minimizing the transportation cost. The Sliced Wasserstein Distance (SWD) (Kolouri et al., 2019), a distance measure based on optimum transport that projects embeddings to random orthogonal subspaces and sums the 1-dimension Wasserstein Distance for each subspace, is one of its techniques. We replace $L_{\text{distribution}}$ with the SWD between embedding distribution and predefined low-entropy prior $\mathcal{Z}_{prior}$ (Eq. 3).

The model does not directly minimize entropy because documents can contain numerous topics; instead, it assigns the prior $\mathcal{Z}_{prior}$ to Dirichlet distribution with $\alpha < 1$ to assure low entropy of the embedding space. The alignment loss with adjusting factor λ is used to optimize the modified distribution loss at the same time.

$$\begin{aligned} L_{\text{stage1}}(\mathbf{z}) &= -L_{\text{align}}(\mathbf{z}) + \lambda \cdot L'_{\text{distribution}}(\mathbf{z}), \\ \text{where } L'_{\text{distribution}}(\mathbf{z}) &= \text{SWD}(\mathbf{z}, \mathcal{Z}_{prior}) \end{aligned} \quad (3)$$

We use the cluster assignment probability $\mathbf{z}$ to discover K clusters after training (i.e., $\arg\max_j \mathbf{z}_j$ where j indexes the vector dimension).

3.2 Stage 2: Computing term weights

Given the newly identified cluster set $\mathcal{C}$ (i.e., $c \in \mathcal{C}$), the next stage calculates the term importance weight for each word from $\mathcal{C}$ and constructs the word set $\mathcal{W}_{dict}$. If words frequently appear in one cluster but not in others, they are deemed influential. This concept is consistent with TF-IDF (Ramos et al., 2003), which measures the importance of each word in a document by multiplying two terms: term frequency (TF) and inverse document frequency (IDF)[2]. Similar to (Grootendorst, 2022), we treat each document cluster as a single unified document and calculate the TF-IDF of each word for term weights. The TF-IDF measure for each cluster is as follows:

$$\text{tf-idf}(w, c, \mathcal{C}) = \text{tf}(w, c) \cdot \text{idf}(w, \mathcal{C}) \quad (4)$$

$$\text{tf}(w, c) = \frac{\text{freq}(w, c)}{\sum_{w' \in c} \text{freq}(w', c)} \quad (5)$$

$$\text{idf}(w, \mathcal{C}) = \log \frac{|\mathcal{C}|}{|\{c \in \mathcal{C} : w \in c\}|}, \quad (6)$$

where $\text{freq}(w, c)$ denotes the number of times a given word w is found in cluster c.

To build the word set $\mathcal{W}_{dict}$ for building BoWs in the next stage, we select the top-k influential topic words for each cluster with the highest term weight (Eq. 7). The value of k is adaptively chosen based on the dictionary size $N = |\mathcal{W}_{dict}|$.

$$\mathcal{W}_{dict} = \bigcup_{c \in \mathcal{C}} \{w | \text{ tf-idf}(w, c, \mathcal{C}) \text{ is top-}k \text{ in } c\} \quad (7)$$

3.3 Stage 3: Estimating topics via BoW reconstruction with term weights

The model is then trained to estimate the latent topic distribution in the final stage. We construct an encoder-decoder network on top of the pretrained language model f for training, following the literature (Bianchi et al., 2021a; Srivastava and Sutton, 2017). The encoder and decoder networks are referred to as q_ϕ and p_θ, respectively. The input document $\mathbf{x}$ is decomposed into the BoW representation $\mathbf{y}$ given the word set $\mathcal{W}_{dict}$. To create the context-aware representation, $\mathbf{x}$ is fed into the fixed backbone language model f. The encoder network q_ϕ and softmax function (Eq.8) are used to generate the latent topic distribution $\mathbf{t}$ over $\mathbf{x}$. The decoder

---

[2] A word's relative importance within a document is represented by TF, which divides the word count in a document by the total word count in the corpus. IDF represents the target word's uncommonness across the corpus as the logarithm of the total document count divided by the document count containing the target word.

network, followed by the softmax function, reconstructs the input document's BoW representation as $\hat{\mathbf{x}}$ (Eq. 9) with this topic distribution $\mathbf{t}$.

$$\mathbf{t} = \text{softmax}((q_\phi \circ f)(\mathbf{x})) \tag{8}$$

$$\hat{\mathbf{x}} = \text{softmax}(p_\theta(\mathbf{t})) \tag{9}$$

Our topic model with the backbone network f is trained by reconstructing the original document's BoW representation $\mathbf{y}$ from the latent topic distribution $\mathbf{t}$ (depicted as a box in Figure 1). To focus more on influential words when learning topics, term weights $w_\mathbf{y}$ from the previous stage are multiplied by the loss objective (Eq. 10). This leads the model to filter out unnecessary terms and discover more coherent and human-interpretable topics.

$$L_{\text{recon}}(\mathbf{x}, \mathbf{y}) = -\mathbb{E}_{q_\phi(\mathbf{t}|f(\mathbf{x}))}[w_\mathbf{y} \cdot \log(p_\theta(\mathbf{y}|\mathbf{t}))]. \tag{10}$$

The next step is to improve the representation quality by matching the encoder's posterior distribution to the predefined prior. This approach is modulated by contrastive loss, which assumes that documents with semantically identical content have similar topic distributions. As a positive sample, we use the top-1 nearest neighbor $\mathbf{x}_+$ from the embedding space of the pretrained language model. All other instances in a batch are considered negative samples. The model then uses the alignment loss L_{align} (Eq. 11) to induce the topic distribution of positive pairs ($\mathcal{T}_+$) to be similar. Distribution loss is used to match the posterior topic distribution to the prior distribution $\mathcal{T}_{prior}$ and maintain a low entropy. We set the prior $\mathcal{T}_{prior}$ to Dirichlet distribution with α<1 to discover distinctive topics from the corpus.

$$\begin{aligned} L_{\text{CL}}(\mathbf{t}) &= -L_{\text{align}}(\mathbf{t}) + \lambda \cdot L'_{\text{distribution}}(\mathbf{t}), \\ &\text{where } L'_{\text{distribution}}(\mathbf{t}) = \text{SWD}(\mathbf{t}, \mathcal{T}_{prior}) \end{aligned} \tag{11}$$

The complete loss function is described in (Eq. 12). There are no adjusting weight parameters for objectives to reduce the tuning cost needed for hyper-parameters.

$$\begin{aligned} L_{\text{stage3}}(\mathbf{x}, \mathbf{y}) &= L_{\text{recon}}(\mathbf{x}, \mathbf{y}) + L_{\text{CL}}(\mathbf{t}), \\ &\text{where } \mathbf{t} \text{ is calculated by Eq. 8.} \end{aligned} \tag{12}$$

4 Experiments

4.1 Performance evaluation

Datasets: For evaluation, we employ a variety of datasets with varying topics. 20-Newsgroups[3], Reuters-21578[4], Wikipedia, and BBC[5]. 20-Newsgroups is a collection of 11,314 posts shared in the newsgroups with a balanced set of topic labels. Reuters-21578 is a news post collection with 10,778 training data. We also use the Wikipedia dataset, containing randomly collected 20,000 paragraphs from 2021-09-22. Finally, BBC is a dataset of 2,225 documents excerpted from the BBC news website. All datasets are in English.

Evaluation: NPMI, C_p, and word2vec similarity are used as evaluation criteria. The first two statistics measure the degree of topic coherence between each topic's top-M term (M is set to 10 in our experiments) using a reference corpus. The last one, word2vec similarity, measures the semantic similarity between the top-M terms. The details of each metric are as follows.

- *NPMI*, the Normalized Point-wise Mutual Information, is a metric that scores high if the joint probability of pairs in the top-M words is greater than their marginal probability (Aletras and Stevenson, 2013). The co-occurrence probabilities can be measured from external corpora, such as Wikipedia (*NPMI-Wiki*) or the source data itself (*NPMI-In*).
- C_p is another coherence metric computed by an aggregation of Fitelson's confirmation measure based on the sliding window over the reference corpus. It is known to be one of the most well-correlated coherence scores with human ratings. (Röder et al., 2015).
- *word2vec similarity* evaluates topic coherence using an external embedding model to ensure fair comparisons with the baselines (Ding et al., 2018). The average cosine similarity value is reported across all pairs of top-M words' word2vec embeddings.

We used *Palmetto*, a publicly available tool for measuring topic quality[6] (Röder et al., 2015), and its version of Wikipedia dump to calculate *NPMI-Wiki* and C_p. For word2vec similarity, we used the pre-trained model from Mikolov et al. (2013b).

Implementation details: As the pre-trained language model, we used Sentence-BERT, *all-MiniLM-L6-v2* (Reimers and Gurevych, 2019). The

topic count K was set to 10, 20, and 50, while the corresponding Dirichlet prior α was set to 0.1, 0.05, and 0.02 (i.e., 1/# of topics), respectively[7]. λ was set to 1, and the vocabulary size to 2,000 following the literature (Bianchi et al., 2021a).

In stage 1, a single layer perceptron, g, is added to the Sentence-BERT model and trained for 100 epochs using the RangerLars (RAdam + LARS + Lookahead) optimizer with an initial learning rate of 0.001 and a decay factor of 0.99. Input text that exceeds the maximum sequence length is truncated. In stage 3, an encoder, q_ϕ, and a decoder, p_θ, are trained for 50 epochs using the Adam optimizer with a learning rate of 2E-2. The encoder is a three-layer MLP with dropout and batch normalization, and the decoder is a one-layer linear model without bias. The backbone network, f, is fixed during this stage.

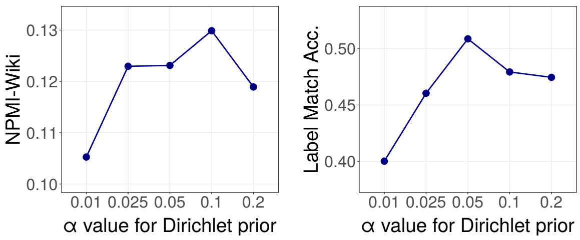
Table 6: Ablation study results on the model architecture (AE vs. VAE): 20-Newsgroups dataset is used.

Inference for Topic Models (AVITM), (*3*) ETM (Embedded Topic Model) (Dieng et al., 2020), where the likelihood of a word is produced by the dot product between the word and topic embeddings, and (*4*) CTM (Contextualized Topic Model), where a vector representation of the document from SentenceBERT is additionally encoded on top of ProdLDA (Bianchi et al., 2021a). The remaining three are clustering methods: (*5*) Top2Vec (Angelov, 2020), where Doc2Vec is used for jointly embedding sentences and words to discover topic clusters, (*6*) ClusterTM (Sia et al., 2020), a word-level clustering-based approach, and (*7*) BERTopic (Grootendorst, 2022), which applies BERT's sentence embeddings to identify topics.

We applied common preprocessing procedures, such as removing English stop-words based on *NLTK* (Bird et al., 2009), non-alphabetic words, and words with less than three characters, and lemmatizing all tokens using the WordNet lemmatizer. All baselines used the same standard parameter values, such as topic count and vocabulary size, to ensure a fair comparison.

Results: Tables 1 and 2 show the performance comparisons and their summaries. UTopic provides the best or comparable topic coherence scores against other baselines over all datasets. Our technique consistently achieves satisfactory results in all other measures, while generative methods perform poorly on Word2vec similarity and clustering methods often fail on NPMI measures.



(a) Effect on NPMI-Wiki (b) Effect on Label Acc.

Figure 2: The effect of the hyper-parameter α for Dirichlet prior on two evaluation metrics on 20-Newsgroups. Consistent performance is achieved by keeping α within a suitable range (0.025 $\sim$ 0.2).

Our model also shows the best scores based on the average rank of each evaluation metric.

Topic assignment quality analysis: It is important to check whether the discovered topics from each model are well aligned with the actual ground-truth labels. Two additional evaluation metrics were observed: *Label Matching Accuracy (Match Acc.)* and *Normalized Mutual Information (NMI)*. Given the estimated topic from each document, the Hungarian method (Kuhn, 1955) was applied to obtain the best bijection permutation mapping between the estimated topics and labels. Then, the label matching accuracy is computed with top-1 classification accuracy. The NMI measure is the mutual information between the mapping and labels with normalization to 0$\sim$1 range.

Table 3 reports the comparison results among baselines over the 20-Newsgroups and BBC-News dataset because only these datasets contain human-annotated labels. Our model outperformed all baselines in accuracy by a large margin, even when compared with recent approaches, implying that it can generate more human-interpretable topics.

Evaluation for assigning multiple topics: We next conducted an experiment to assess UTopic 's ability to assign multiple topics. We created a synthetic dataset with multiple topic labels by merging two random documents from 20-Newsgroups. Then, each topic model trained only using the original 20-Newsgroups dataset was evaluated using the newly created synthetic test set. The evaluation compares the accuracy of counting whether the top-2 estimated topics match the ground truth. Here, random selection will have an accuracy of 0.1 (=2/20). Table 4 shows that our model again outperformed baselines on this new test. Clustering-based approaches were excluded from the comparison because they are limited in assigning multiple topics.

4.2 Component analysis

Ablation studies iteratively remove one module or component to assess its unique contribution to the overall model. We now present results from the ablation study and hyper-parameters' effect over the 20-Newsgroup dataset.

Ablation study: The proposed model has three stages: document clustering, computing term weights, and estimating latent topic distribution. Our first ablation is a model with only stage 3 by directly estimating the latent topic distribution on top of the pretrained language model (*V1* in Table 5). The model without stage 3 utilizes the discovered clusters from the first stage as a topic embedding (*V2*). In this ablation, topic words extracted from the second stage are used for evaluating topic coherence. The next set of ablations remove each module in stage 3 to assess its effect (*V3*–*V7*). Table 5 reports the results for each ablation with five evaluation metrics: four topic coherence measures and label matching accuracy with human-annotated ground truths. The model with all components achieves the best topic coherence with label accuracy, indicating that each component plays an important role.

In contrast to previous works based on VAE (Bianchi et al., 2021a; Srivastava and Sutton, 2017), we used Autoencoder to enforce that the final topic distribution follows the predefined prior. To validate our design choice, we consider another ablation that uses the VAE architecture (*V8*). Experiments on 20 newsgroups show that using VAE can have a negative impact on overall performance (Table 6).

Hyper-parameter analysis: We study the effect of adjusting hyper-parameter α and λ in terms of various evaluation metrics. The α controls the density of Dirichlet prior to the match with the model's latent topic distribution. The smaller the α<1, the less the topic distribution overlaps. The results are summarized in Figure 2. Our model delivers favorable results for both measures when α is within a suitable range of 0.025$\sim$0.2. However, setting α to a value that is too low can result in poor score. This is because decreasing entropy to an excessive degree can cause the model to learn incoherent topics and have a heterogeneous word distribution. We set α to $1/K$ (i.e., 0.05 for K=20), which is a common value in LDA (Rehurek and Sojka, 2011).

λ	NPMI-Wiki	NPMI-In	C_p	Word2vec
0.1	0.055	0.105	0.364	0.210

10	0.060	0.109	0.362	0.202

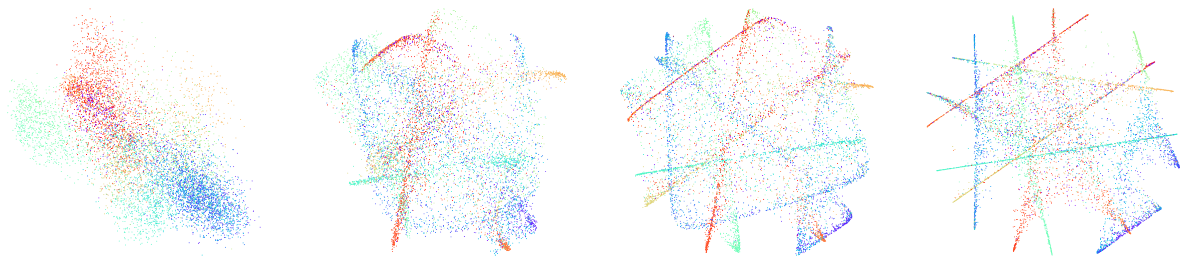
Table 7: Hyper-parameter analysis on the loss adjusting factor λ. Results are based on 20-Newsgroups.

Table 7 reports additional results on the effect of λ, the ratio between the alignment loss and the distribution loss (Eq. 11). Our model performs stable within a reasonable lambda range for most metrics. One exception is NPMI-Wiki, where the model appears influenced by extreme lambda values (λ=0.1 or 10).

4.3 Qualitative analysis

Cluster visualization: To understand the method's inner workings, we visualize the cluster assignment snapshots on the 20-Newsgroups dataset after stage 1 over four different training epochs in Figure 3. Ground-truth labels for 20 themes are displayed in different colors. More visually separable class-coherent clusters emerge as training advances. Evaluating the clustering performance via the Hungarian approach (Kuhn, 1955), epoch 30 in stage 1 already reaches a prediction accuracy of 48% without using any labels.

Application: The suggested topic word selection approach is a stand-alone module that can be used in various topic models. For example, we created the vocabulary set W_{dict} by extracting 2,000 topic words from our stage-2 model. Then we used W_{dict} to train three existing topic models: LDA, NeuralLDA, and CTM, and compared them with a traditional technique of employing the most



(a) Epoch=0, p=0.30 (b) Epoch=2, p=0.41 (c) Epoch=5, p=0.45 (d) Epoch=30, p=0.48

Figure 3: The 20-Newsgroups dataset was used to visualize intermediate clustering results at Stage 1 of UTopic . Colors represent the ground-truth class names (i.e., one of the 20 news topics), whereas dots reflect document cluster assignment. The p-value indicates that the model has already achieved a clustering accuracy of 48% after 30 epochs.

frequent 2,000 words after ignoring stop-words. For all models, we limited the number of topics to 20. The findings are provided in Table 8 for the 20-Newsgroups dataset, which shows that using our context-aware topic word selection technique improves NPMI-Wiki by about 0.7∼1.7 percent point for all evaluated models.

5 Conclusion

This work proposed a new way to leverage the benefits of combining generative and clustering methods of topic modeling into a single framework. Diverse topic coherence measures have been used to assess the quality of topics. Compared to baselines that excel in only one or two coherence measures, UTopic showed consistent improvement across multiple coherence measures and discovered topics that align well with human annotations. Our method has a wide range of applicability because it can be added as a module to other existing approaches.

Limitations

This work comes with several limitations. First, because the nearest neighbor in the embedding space of the pretrained language model is considered a positive sample, the pretrained knowledge can impact overall performance. We plan to develop advanced text data augmentation and positive sample selection approaches for topic modeling to overcome this limitation. Second, since our clustering step needs a large batch (more than 128), the proposed method may be unattainable in some real-world scenarios due to memory constraints. To reduce this memory cost, we introduce a dynamic queue to save many samples' embeddings for every iteration (see Appendix for further details). However, training is only required once per dataset and is, therefore, acceptable.

Ethical Consideration

We acknowledge that presenting a data summary using topic modeling may not adequately represent the voice of minorities and that pre-trained knowledge from an online corpus may exacerbate such bias. When applying topic modeling in high-risk real-world scenarios, human annotators can help understand the predominant view of each topic to ensure that minor viewpoints are included. This is part of the larger challenge of AI ethics, and we plan to consider this challenge in the future.

A Appendix

A.1 Release

Codes and implementation details of the model are available at `https://github.com/mingi-sid/utopic`.

A.2 Dataset details

For evaluation, we employ a variety of datasets with varying topics: (1) 20-Newsgroups[8] contains 11,314 posts from the newsgroups from 20 number of balanced topic labels, (2) Reuters-21578[9] includes 10,778 news posts from Reuters newswire in 1987, (3) Wikipedia, comprising 20,000 abstracts that have more than 200 characters, was randomly sampled from the Wikipedia dump from 2021-09-22, and (4) NeurIPS[10] has 7,241 titles of articles from the NeurIPS conference. Since the topic modeling algorithm is an unsupervised approach, we use the whole dataset for evaluation without splitting.

A.3 Implementation details

For the pretrained language model f, we use Sentence-BERT, *all-MiniLM-L6-v2* specifically (Reimers and Gurevych, 2019). In stage 1, a fully connected layer g with a single layer perceptron is appended on top of the [CLS] representation from the Sentence-BERT. The total number of parameters is about 22.8M, including the parameters from the backbone language model. The original text is used as input, and any input tokens that exceed the maximum input sequence length are truncated. We train both f and g for 100 epochs. RangerLars (RAdam + LARS + Lookahead) optimizer with exponential learning rate decay is utilized. The initial learning rate and decay factor are set to 0.001 and 0.99, respectively.

In stage 3, we use three-layer MLP, including dropout and batch normalization as an encoder q_ϕ, and use one linear layer without bias as a decoder p_θ. For all phases, λ is set to 1, and the vocabulary size is set to 2,000. The backbone network f is fixed, and the encoder-decoder network is trained for 20 epochs. The Adam optimizer is used, with a learning rate of 2e-2. The number of topics K is set to 20, the batch size is set to 128, and the Dirichlet prior hyper-parameter α is set to 0.05 (i.e., 1/# of topics) for all phases.

Computing the Sliced Wasserstein Distance (SWD) between the embedding distribution and the prior requires a large batch for concise estimation. However, expanding the batch size is unattainable in many real-world scenarios due to memory constraints. We use a simple approach involving a dynamic queue, which does not require computing many samples' embeddings in a single iteration because embeddings from earlier iterations are saved. Embeddings computed from the current batch are concatenated with saved embeddings from the queue during training. Then, the stacked embeddings are finally used to calculate the distribution loss (Eq. 3, 11).

We should point out that the model's computing cost is not excessive. It took less than an hour for all datasets to perform all training phases with four A100 GPU processors.

A.4 Full evaluation results

In Table 9-20, we present the full performance evaluation results over four datasets with three different numbers of topics: 10, 20, and 50. For each experiment, results are averaged over five trials; the mean and standard deviation are reported. Also, to determine if a model successfully distinguish latent topics, we report results of topic diversity analysis for 20-Newsgroup, which shows that our method continues to outperform the baselines (Table 21). Top2Vec and ClusterTM are excluded in comparison, since they directly apply clustering algorithm (e.g.., DBSCAN) over the word set and inevitably make a complete split (i.e., topic diversity = 1), which is unfair to compare with.

A.5 Qualitative analyses

Table 22 reports the top 10 words for each topic extracted from our model. As discussed, we can find that the proposed model produces sufficiently representative words to interpret topics. For example, we can easily infer that topic #0 refers to the "computer" theme and topic #1 represents the "sports" theme. Our topic word selection strategy and contrastive learning framework successfully estimate the latent topics with improved interpretability.

Don't Mess with Mister-in-Between: Improved Negative Search for Knowledge Graph Completion

Fan Jiang and **Tom Drummond** and **Trevor Cohn**
School of Computing and Information Systems
The University of Melbourne, Victoria, Australia
`fan.jiang1@student.unimelb.edu.au`
`{tom.drummond, t.cohn}@unimelb.edu.au`

Abstract

The best methods for knowledge graph completion use a 'dual-encoding' framework, a form of neural model with a bottleneck that facilitates fast approximate search over a vast collection of candidates. These approaches are trained using contrastive learning to differentiate between known positive examples and sampled negative instances. The mechanism for sampling negatives to date has been very simple, driven by pragmatic engineering considerations (e.g., using mismatched instances from the same batch). We propose several novel means of finding more informative negatives, based on searching for candidates with high lexical overlaps, from the dual-encoder model and according to knowledge graph structures. Experimental results on four benchmarks show that our best single model improves consistently over previous methods and obtains new state-of-the-art performance, including the challenging large-scale Wikidata5M dataset. Combing different strategies through model ensembling results in a further performance boost.

1 Introduction

A Knowledge Graph (KG) is a structured form of human knowledge consisting of entities, facts, relationships between any pair of entities, and semantic descriptions of entities. As important structures that store millions of data records that represent a part of human knowledge, KGs have been proven to bring substantial benefits to a wide range of applications, including commonsense question answering (Yasunaga et al., 2021) and reasoning (Ren and Leskovec, 2020). Knowledge Graph Completion (KGC) supports the automatic construction or completion of a KG by finding the missing entity or link in incomplete triples.

Graph embedding and textual embedding methods are two mainstream techniques for KGC problems. The former typically map entities and relations into fixed dense vectors and maximises the probability of valid triples using specially-designed scoring functions (Bordes et al., 2013; Sun et al., 2019); while the latter additionally uses available textual descriptions associated with entities to gather more information (Wang et al., 2021b). Surprisingly, textual embedding methods lag behind graph embedding methods, perhaps due to their extra computational overheads in encoding textual inputs and, thus, inefficiency in incorporating a sufficient number of negatives (i.e., incorrect KG triples) to learn discriminative KG embeddings.

Recently, Wang et al. (2022) found that the key to making textual embedding methods outperform their graph embedding counterparts is to adopt a dual-encoder structure and train using contrastive learning to differentiate between positive training instances and randomly sampled negative instances (Karpukhin et al., 2020). Although their technique outperformed various graph embedding methods, achieving a new state-of-the-art, their means of negative sampling is not optimal: this in-batch negative method has been shown to be inefficient in training dual encoders (Lu et al., 2021). Instead, as they are highly similar to positives in terms of topics and lexicons, the use of so-called 'hard' negatives have been shown to result in better models in information retrieval (Xiong et al., 2021) through providing a more informative training signal and faster convergence. However, their effectiveness has not yet been established for KGC.

Therefore, to fill this gap, in this work, we aim to systematically investigate the effects of various hard negative sampling strategies for dual-encoder-based KGC. Specifically, we construct negative samples using three different ways. Our approach first evaluates the utility of negatives that share high lexical similarity with the head entity or the correct tail entity in terms of entity names and text descriptions. Based on the knowledge graph structures, we alternatively search negatives from the head or tail entity's local neighbourhood, hypothesising

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1818–1832
May 2-6, 2023

that the neighbourhoods of a certain entity that are not directly connected to it are highly related, but not so related to be false negatives (i.e., positives). Lastly, we investigate sampling so-called 'hard negatives' from top-k predictions generated by a baseline dual-encoder KGC model, as negatives that receive high scores are believed to be important and difficult to distinguish. In addition, in order to reduce possible false negatives, we also experimented with two variant neural negative sampling strategies according to heuristics. In summary, our contributions are:[1]

1. To the best of our knowledge, we are the first to systematically investigate the impacts of different types of negative sampling strategies for dual-encoder-based KGC.
2. We explore how best to combine the benefits of different negative sampling strategies to obtain further performance gains.
3. We compare our proposed negative searching methods on four benchmark datasets of different scales. Experimental results demonstrate that our best model significantly outperforms baselines, establishing a new state-of-the-art on all datasets, while ensembling leads to further performance gains.

2 Background

2.1 Task Formulation

In this paper, we deal with the task of predicting missing entities in knowledge graph completion. Formally, given a knowledge graph $\mathcal{G}$ which has a set of entities $\mathcal{E}$ and predefined relations $\mathcal{R}$, the tail entity retrieval task $(h, r, ?)$ requires retrieving a list of entities $\{t_1, t_2, \ldots, t_k\}$ from the entity set $\mathcal{E}$, ranked by their relevance to this head-relation pair (h, r).

2.2 Dual Encoder for KGC

Following the current state-of-the-art approach to KGC (Wang et al., 2022), we use a dual encoder framework.

Figure 1 shows the architecture. In this approach, a pair of encoders E_{hr} and E_t, which are usually initialised by pretrained language models (e.g., BERT (Devlin et al., 2019)), are used to map the head entity and relation (h, r) and tail entity t into dense vectors, respectively. More specifically, to encode the tuple (h, r), we first concatenate the text description of head entity h and relation r as: [CLS] *h: entity description* [SEP] *r* [SEP] and feed the sequence into a BERT encoder E_{hr}. Similarly, we use another encoder E_t to encode the tail entity t and its description, using an analogous input method. Mean pooling is used to obtain fix-sized embeddings, which are then l_2-normalised. The relevance score between (h, r) and t is calculated as the inner dot product of the two l_2-normalised vectors:

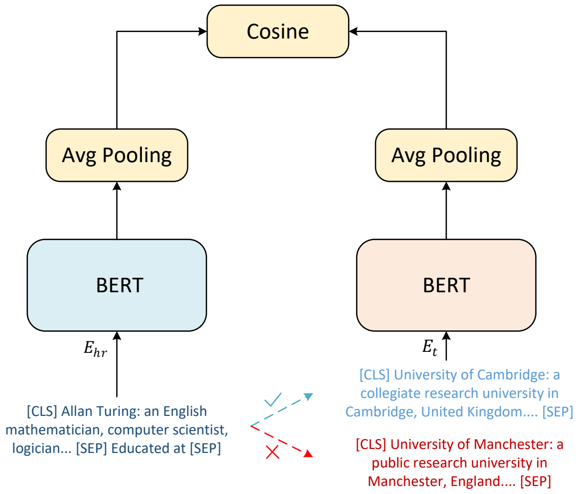

Figure 1: The Dual-Encoder Model for Knowledge Graph Completion, which learns to discriminate positive tail entities from negative ones.

$$s(h, r, t) = \frac{E_{hr}(h; r) \cdot E_t(t)}{||E_{hr}(h; r)|| \cdot ||E_t(t)||} \tag{1}$$

The dual encoders are normally trained to maximise the similarity scores of all positive triples (h, r, t). Here, we use the InfoNCE loss, following Wang et al. (2022):

$$\mathcal{L}_{hr \to t} = -\log \frac{s(h, r, t)}{\sum_{t' \in \mathcal{E}} s(h, r, t')} \tag{2}$$

where the denominator sums over all $N = |\mathcal{E}|$ entities in the KG.

Since N is usually very large, the common practice is to use specific negative sampling strategies to select a subset of negative samples to replace the full normalisation term in Equation 2. In practice, the selection of negative samples is crucial to the performance of a trained model (Zhang and Stratos, 2021). So the critical question becomes how to sample informative negatives which could generate meaningful signals for training an effective model.

---

3 Negative Sampling Strategies

3.1 In-Batch Negatives

This strategy treats as negatives the tail entities of other samples in the same mini-batch, which is a cheap way to obtain a large number of negatives (Karpukhin et al., 2020). However, the downside of this approach is that the number of negatives is limited to batch size, and it usually requires a large batch size to work well, which is not always feasible with limited computing resources.

3.2 Hard Negatives

'Hard' negatives are informative negatives, which are difficult to distinguish as they share similar characteristics with true positives (e.g., high lexical overlap or semantic similarity). They normally receive larger similarity scores from the model, which in turn results in larger loss gradients and thus larger parameter updates in training. Selecting negatives from them can effectively mitigate the diminishing gradient norms when using uninformative negative instances (i.e., in-batch negatives), thus providing more optimal training signals and leading to faster convergence speed (Xiong et al., 2021). In this paper, we systematically investigate the effectiveness of different hard negative sampling strategies for knowledge graph completion. An illustrative example of the different types of hard negatives is shown in Table 1.

Sparse Negatives Hard negatives were first shown to be useful for improving the performance of dense passage retrievers in question answering (Karpukhin et al., 2020). Their approach, which we call **Sparse Negatives** henceforth, samples hard negatives from the top-k ranked list returned by a sparse retrieval system such as BM25 (Robertson and Zaragoza, 2009). We test the generality of this method to our task of knowledge graph completion. More specifically, given a KG triplet (h, r, t), we either use the concatenation of the head entity h and relation type r or the correct tail entity t[2] to query a sparse BM25 retriever to find top entities which share similar entity names or similar tokens in their entity descriptions.[3]

Structure-Aware Negative Entities in the local neighbourhood of an entity in the KG are typically semantically related, and can serve as good candidates (Ahrabian et al., 2020). For a triplet (h, r, t), we sample hard negatives from the n-hop neighbours of either the head entity h or the tail entity t, following random edges.[4]

Neural Negative samples hard negatives from the top-k predictions of a neural model (Xiong et al., 2021; Glass et al., 2021), which has been shown to boost the performance of neural retrievers. In this paper, we use a simple method of sampling static hard negatives from a fixed learned KGC model, which we denote as **Head-Relation Negative**:

Step 1: In-batch negatives are used to train a dual-encoder KGC model.

Step 2: FAISS (Johnson et al., 2021) is used to index all entities in the KG, using their dense vector encoding, E_t.

Step 3: Employ approximate search to find the top-k retrieved entities using head-relation pair (h, r) as the query, with encoding E_{hr}. Then any positive tail entity to this query are removed based on the training dataset and all other entities will be kept as hard negatives.

Although sampled negatives are both difficult and informative, the Neural Negative method may end up including many false negatives. This is because for a good KGC model, if the same head-relation pair (h, r) appears in both training and test graphs, the top-k predictions will likely include correct answers in the test set. [5] Therefore, we propose another two variant negative sampling strategies to limit false negatives while maintaining informativeness. In particular, **Entity Similar Negative** uses either the head entity h or the tail entity t of a given KG triplet (h, r, t) as the query to find the top-k nearest entities in the embedding space of a fixed learned KGC model. **Replaced Head-Relation Negative** replaces the head h in (h, r, t) with another entity h' that is nearest to h in the embedding space and uses (h', r) as query to sample negatives from the top-k predictions.

3.3 Other Negatives

Pre-batch negatives extend in-batch negatives by using stale entity embeddings from previous n batches, which can be considered a cheaper way

---

[2] The concatenation of an entity's name and text description will be used.

[3] Whether the head h or the tail t is used to retrieve negatives is based on the development set performance.

[4] We use $n = 2$, which we found to work well.

[5] This is more true to neural negatives than previous two methods, as neural models are superior in capturing relation semantics. See Table 1 for more intuitive examples.

Head Entity **Relation** **Tail Entity**	`land_reform_NN_1`: a redistribution of agricultural land (especially by government action) hypernym `reform_NN_1`: a change for the better as a result of correcting abuses; justice was for sale before the reform of the law courts
Sparse	1. `landing_NN_3`: the act of coming down to the earth (or other surface); "the plane made a smooth landing"; "his landing on his feet was catlike" 2. `amphibious_landing_NN_1`: a military action of coordinated land, sea, and air forces organized for an invasion; "MacArthur staged a massive amphibious landing behind enemy lines" 3. `enderby_land_NN_1`: a region of Antarctica between Queen Maud Land and Wilkes Land; claimed by Australia
Structure	1. `event_planner_NN_1`: someone who plans social events as a profession (usually for government or corporate officials) 2. `price-fixing_NN_1`: control (by agreement among producers or by government) of the price of a commodity in interstate commerce 3. `lawlessness_NN_1`: a state of lawlessness and disorder (usually resulting from a failure of government)
Neural	1. `reform_NN_3`: self-improvement in behavior or morals by abandoning some vice; "the family rejoiced in the drunkard's reform" 2. `improvement_NN_1`: a change for the better; progress in development 3. `reform_NN_2`: a campaign aimed to correct abuses or malpractices

Table 1: Examples of hard negatives using different types of sampling strategies, using the head entity and relation as query for sparse and neural negatives but only the head entity for structure negatives (see top block). Sparse negatives typically overlap with the head entity in surface form but ignore the relation, while structure negatives can find entities with similar types. Neural retrievers can successfully find entities that are informative as hard negatives, but the risk of including false negatives also increases. For instance, both *improvement_NN_1* and *reform_NN_2* are feasible answers to the above query.

to expand negatives compared to memory bank approaches (He et al., 2020). Self-negatives regard the head entity h in $(h, r, ?)$ as the hard negative to reduce the model's reliance on spurious text matches. We include these two kinds of negatives, following Wang et al. (2022).

3.4 Negatives for Training

During training, we use one of the hard negative sampling strategies proposed in §3.2 together with a combination of in-batch negatives, pre-batch negatives, and self-negatives. Since extra hard negatives are used, the total number of instances used for loss calculation in Eq. 2 will be increased. For fair comparison, we reduce the batch size to ensure the total number of negatives used in training remains identical to our baseline *SimKGC* method (Wang et al., 2022). More details can be found in Appendix B.

4 Model Ensembling

Since we propose multiple hard negative sampling strategies in §3.2, we train several models, each with different types of hard negatives. It is natural to combine these models to achieve further performance improvements through model ensembling. Inspired by Lu et al. (2021), we explore two methods to ensemble results from multiple models.

Rank Fusion Reciprocal Rank Fusion (RRF) (Cormack et al., 2009) is a simple yet effective algorithm for merging ranking results from multiple retrievers, and is a prevailing technique in information retrieval. Its utility in knowledge graph completion has not yet been evaluated. The technique works by merging the ranking positions from the various models. Suppose we have a query (h, r) and each model $p \in P$ returns a ranking list $\{\text{Rank}_e^p | e \in \mathcal{E}\}$, the final ranking score is:

$$RRF(e) = \sum_{p \in P} \frac{w_p}{\text{Rank}_e^p}$$

Rank_e^p is the ranking position of an entity e returned by a model p, ranging from $[1, |\mathcal{E}|]$. w_p is the weight of a model p, which is tuned based on the performance on the development set.

Embedding Fusion An alternative aggregation method is to compute the weighted sum of ranking scores from different models, i.e., $\sum_{p=1}^{P} w_p E_{hr}^p E_t^p$. This can be implemented cheaply using the models' embeddings, which has the benefit of allowing for efficient vector indexing and search. Specifically, for each query (h, r), we obtain vectors from each models' encoder, which are then scaled by a model specific weight (tuned manually) and concatenated. Each entity $e \in \mathcal{E}$, is also embedded by each model and the vectors concatenated. This allows the aggregation method to be implemented as a simple dot product:[6]

$$s(h,r,t) = [w_P E_{hr}^P, \ldots, w_1 E_{hr}^1]^T [E_t^P, \ldots, E_t^1]$$

5 Experiments

5.1 Datasets

Our method is evaluated on WN18RR (Dettmers et al., 2018), FB15k-237 (Toutanova and Chen, 2015), DBPedia500k (Shi and Weninger, 2017) and Wikidata5M (*Transductive Setting*) (Wang et al., 2021b) datasets, where the number of entities ranges from 15K to 4.6M. More details about dataset statistics are shown in Table 7.

Following previous work (Wang et al., 2022), we focus on retrieving the missing entity of triples $(h, r, ?)$ and $(?, r, t)$, effectively doubling dataset sizes.[7] The adopted evaluation metrics are Mean Reciprocal Rank (MRR) and Hits@k($k \in \{1, 3, 10\}$). More specifically, MRR is calculated as $\mathrm{MRR} = \frac{1}{N}\sum_{i=1}^{N}\frac{1}{\mathrm{Rank}_i}$, where Rank_i is the rank of the correct tail entity in the predicted outputs and N is the total number of triples in the test set. Similarly, Hits@k is the proportion of correct tails that appear in the top-k ranked candidates.

We follow Bordes et al. (2013) and Wang et al. (2022) by conducting evaluations under *filter* settings, where for a given incomplete triple $(h, r, ?)$, the prediction scores of all its correct answers[8] except for the target to be predicted are removed. Both tail entity prediction $(h, r, ?)$ and head entity prediction $(?, r, t)$ are conducted, with their averages on all metrics reported.

5.2 Experimental Settings

We replicated the state-of-the-art SimKGC model (Wang et al., 2022) using PyTorch (Paszke et al., 2019) and Transformers (Wolf et al., 2020), and treat it as the baseline in our experiments. The uncased BERT base model is used for model initialisation.[9]

Most hyperparameters are adopted from Wang et al. (2022), and newly introduced hyperparameters are determined through grid search. We choose the best model according to Hits@1 on the dev set, which is then evaluated on the test set for all experiments. More details are in Appendix A.

5.3 Overall Results

Tables 2 and 3 show the results of our models compared with a range of high-performing graph embedding and text embedding models over four KGC datasets. We observe that the performance of our replicated baseline is competitive with that of Wang et al. (2022), achieving slightly better results on FB15k-237 and Wikidata5M but slightly worse on WN18RR. Moreover, our best single model either matches or outperforms the state-of-the-art results on all datasets for most metrics.

By looking into the models trained using different hard negative sampling strategies, the behaviours are quite different in each dataset. More specifically, simply taking the n-hop neighbours as structure-aware negatives results in significant improvement on WN18RR but marginal increases or even negative impacts on the other three datasets. Similar effects are also observed for sparse negatives. Our model achieves the best results on FB15k237, DBPedia500k, and Wikidata5M when using replaced head-relation negatives, which shows our heuristics are useful and can indeed lead to better performance. Gains over the baseline when using entity similar negatives are also significant, but it lags behind the other two types of neural negatives most of the time. Overall, we can conclude that there is no single negative sampling strategy that outperforms on all datasets. We believe this is due in part to the distinct characteristics of each dataset, which we explore in §6.1.

Furthermore, by ensembling models trained using different types of negatives at inference time, we can observe performance gains up to 1.3% MRR and 1.8% H@1 over the best single model. For model ensembling methods, we find that embedding fusion is more beneficial when improving the precision (MRR and H@1), while rank fusion is helpful to boost the recall (H@3 and H@10), especially on DBPedia500k. Besides, both methods do not help much on FB15k237 with only marginal gains. However, both ensembling methods come at the cost of increased inference latency with a factor of N, the number of ensembled models, which

---

[6] For both fusion methods, the weights were tuned through grid search. Empirically, we found that single model whose performance is better was generally given a higher weight than worse performing methods. See Table 8 and Appendix C.3 for more details.

[7] For reversed triples, a special r^{-1} relation type is used. For instance, we convert a triple (?, educated at, Cambridge University) to (Cambridge University, reverse educated at, ?). We did not conflate the reversed relations with existing relations, although this may be beneficial (e.g., hyponym $\equiv$ reverse hypernym.)

6 Analysis

6.1 Why the Effects Vary by Dataset

Next, we analyse why the benefits of different hard negative sampling strategies vary from dataset to dataset. We employ two measurements, namely *Difficulty* and *False Negative Rate*, to draw the connections to the performance on specific datasets. *Difficulty* is measured by the average model score between hard negatives and their corresponding head-relation pairs. More specifically, for a given KG triplet (h_i, r_i, t_i) and its associated hard negative pool $\mathcal{N}_i = \{t_j | 1 \leq j \leq k\}$, the difficulty is computed as follows:

$$D_i = \frac{1}{|\mathcal{N}_i|} \sum_{t_j \in \mathcal{N}_i} s(h_i, r_i, t_j)$$

where $s(h_i, r_i, t_j)$ is the score predicted by the *SimKGC replicated* model.[10] The overall difficulty is the average over training, $\frac{1}{|\mathcal{D}|} \sum_i^{|\mathcal{D}|} D_i$.

On the other hand, *False Negative Rate* is the proportion of hard negatives which are correct answers that appear in development and test graphs:[11]

$$FNR = \frac{1}{|D|} \sum_i^{|\mathcal{D}|} \frac{1}{|\mathcal{N}_i|} \sum_{t_j \in \mathcal{N}_i} \mathbb{I}(< h_i, r_i, t_j > \in \mathcal{T})$$

where $\mathcal{T}$ is the development and test sets. $\mathbb{I}(*) = 1$ if the corresponding triple appears in the development or test set; otherwise it is 0.

---

[10] The model is fixed to allow comparison of different negative sampling strategies.

[11] The real false negative rate will be higher than what we measure due to the incomplete nature of knowledge graphs.

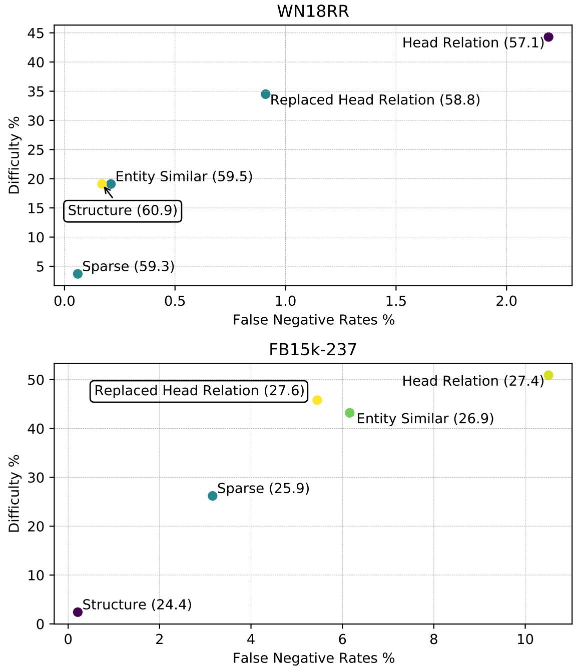

Figure 2: The difficulty and false negative rates of hard negatives extracted using different sampling strategies on WN18RR and FB15k237 datasets. Colours of points and numbers represent the Hit@1 score. The best results are circled with round boxes.

A model that is trained using hard negatives with high difficulty and low false negative rate is expected to achieve better performance. Figure 2 compares the difficulty and false negative rates for hard negative sampling strategies over two datasets. The most effective strategies are different on the two datasets: for Wordnet (WN18RR) the accuracy (Hit@1) is most sensitive to the false negative rate (horizontal axis), while for Freebase (FB15k237) it is most sensitive to difficulty (vertical) – despite the false negative rates being considerably higher on this dataset. We ascribe the difference to the underlying dataset. Wordnet is a sparsely-connected graph, and has relation types that connect entities with hierarchical structures. For instance, the *hypernym* and *derivationally related form* relations which satisfy the transitivity property account for 74% of triples in the graph. Including negatives with high difficulty for such relations (i.e., false negatives on the hierarchy that are not directly connected to a specific head entity) will inevitably encourage the model to learn embeddings that destroy such structures. However, the best-performing structure-aware negative sampling methods only sample negatives from local neighbourhoods, which we believe can effectively reduce such side-effects. In contrast, Freebase is a much more denser graph compared to Wordnet (8× in terms of node degrees), with significantly fewer entities but more diverse relations. Moreover, over 70% triples include relations that have high arity (e.g., *has part*) and many-to-many mappings. Thus, the chance of having false negatives within globally sampled hard negatives will be much higher than that on Wordnet in nature. However, since FB15k237 is a much more difficult task compared to WN18RR, highly difficult negatives should be used to encourage the model to learn embeddings that can discriminate correct tails from very similar ones, and the importance of false negatives are comparatively less important. We leave the systematic analysis of different negative sampling methods with respect to KG structures as future work.

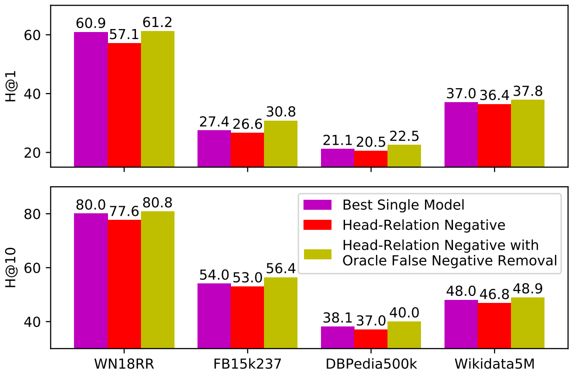

Figure 3: The comparison between the best single model and the model trained using **Head-Relation** negatives with and without oracle false negative removal.

6.2 Oracle Upper Bound

One natural following question is how much improvement we may achieve if we remove all false negatives when using the most difficult head-relation hard negatives to train a model. As shown in Figure 3, the performance increases substantially in terms of H@1 and H@10 across four datasets when simply removing false negatives. This shows that there is much room for improvement and designing effective false negative elimination methods could potentially fill the performance gap and result in better-performing models. Besides, our best single model can obtain results that are close to the upper bound on WN18RR and Wikidata5M, but still lags behind on the other two datasets.

Rel Category		**1-TO-1**	**1-TO-M.**	**M.-TO-1**	**M.-TO-M.**
Size %		0.94	6.32	20.45	72.29

	Avg.	60.9	20.8	**43.4**	20.1
Our model	Forward	**60.9**	4.3	**75.8**	**28.9**
	Backward	**67.7**	**40.8**	10.5	**17.4**
	Avg.	**64.3**	**22.6**	43.1	**23.2**

Table 4: Detailed results (H@1) on the FB15k-237 test dataset, broken down by category of relationships and prediction directions. Our model refers to the best single model trained with replaced head-relation negatives.

6.3 Relation Category

To further understand the behaviour of our model, we follow Bordes et al. (2013) by classifying triples into different groups based on the category of relationships. Relationships are broken down into four categories according to the cardinalities of their head and tail arguments: one-to-one (1-TO-1), one-to-many (1-TO-M.), many-to-one (M.-TO-1) and many-to-many (M.-TO-M.). For a given relation r, if the average number of heads h appearing in the dataset for a tuple (r, t) is lower than 1.5, the head argument will be labeled as 1 and M. otherwise. The same is applied to the tail argument.

Table 4 shows the detailed results of four categories on the FB15k-237 dataset, together with the forward and backward prediction results. Firstly, we can find that both models perform the best on triples with 1 on the tail side, while predicting the M side is significantly more difficult. Secondly, our method can beat the baseline on most relation categories. Thirdly, the substantial improvement on 1-TO-1 relations (+3.4%) shows that our model is making more precise decisions. Besides, by looking into specific prediction directions, we find that the performance mainly comes from predicting triples with 1 on the target side. When the target side contains multiple answers, adding hard negatives even hurts the performance, especially in the backward direction of M.-TO-1. Further analysis finds that its false negative rate is almost three times the overall rate (15.9% vs 5.5%), and we believe it is the high false negative rate that misleads the model and results in negative impacts on this specific relation category.

WN18RR	**Model**	**MRR**	**H@1**	**H@3**	**H@10**

Table 5: Results on test examples when only containing seen and unseen entities, respectively. Our model refers to the best single model in each dataset.

6.4 Generalise to Unseen Entities

Textual embedding methods are known to generalise better to unseen entities than graph embedding ones (Wang et al., 2021a). We conduct experiments to testify whether their generalisation ability can be further improved by using harder negatives. We split test data based on whether the head or target entity is unseen in training. 210 out of 3134 and 159 out of 5163 test triples include unseen entities on WN18RR and Wikidata5M, respectively. Furthermore, we use another *Inductive* setting on Wikidata5M, which has different data splits compared to the *Transductive* setting. We extract 336 test triples from the whole graph of *Induction* setting which include entities unseen to the *Transductive* setting's training graph. The detailed results are shown in Table 5. We observe our best model achieves considerable improvements on three unseen entity settings across all metrics. Moreover, the absolute improvements are significantly higher than those on the seen entity setting, especially on recall metrics (e.g., H@3 and H@10). This demonstrates learning from hard negatives leads entity embeddings that generalise better.

7 Related Work

Knowledge Graph Completion KGC has been extensively studied for many years as a popular research topic. Conventional KGC methods adopt graph embedding methods to map entity and relation into low-dimensional dense vectors and design various scoring functions to measure the plausibility of KG triples, including TransE (Bordes et al., 2013), DistMult (Yang et al., 2014), ComplEx (Trouillon et al., 2016) and RotatE (Sun et al., 2019). Recent text embedding methods choose to include additional text descriptions related to entities by making use of large pretrained language models, including KG-BERT (Yao et al., 2019), MTL-KGC (Kim et al., 2020) and StAR (Wang et al., 2021a). In this work, we follow Wang et al. (2022) by adopting the simple yet effective text embedding-based method using powerful pretrained language models. The above graph-based methods, which also rely on negatives to learn entity and relation embeddings, are orthogonal to the sampling strategies proposed in this work. We believe our techniques could lead to improvements when applied to graphs, but we leave this for future work.

Dual Encoder for Contrastive Learning A Dual Encoder, or Bi-Encoder, which adopts two encoders without weight sharing for feature encoding, has been widely used in many tasks, including image learning (He et al., 2020) and information retrieval (Karpukhin et al., 2020). Typically, an image with two different augmented views or query-document pairs is encoded into vectors separately by a dual encoder. The model learns to minimise the distance between positive pairs and push negative pairs further apart in the embedding space. Inspired by previous work, we decouple the encoding of (h, r) and t by dual encoder and use the contrastive learning framework to learn effective knowledge embeddings.

Hard Negatives for Contrastive Learning Hard negatives have been identified to be extremely helpful in learning better representations, including image learning (Robinson et al., 2021) and information retrieval (Karpukhin et al., 2020). For example, the DPR model (Karpukhin et al., 2020) mines hard negatives using a sparse retriever BM25. Xiong et al. (2021) proposed to sample hard negatives from the model itself by theoretically and empirically verifying such negatives can result in larger gradient norms and thus faster convergence speed. Zhang and Stratos (2021) also found doing negative sampling from the model being optimised leads to better performance, as they argued that contrastive learning is a biased estimator and sampling negatives from the model itself can reduce such bias. We follow this direction and propose various hard negative search methods in this paper and show that they can substantially improve KGC.

Negative Sampling Strategies for KGC Most KGC works employ a simple negative sampling strategy by corrupting the head entity h or tail entity t of a correct KG triplet (h, r, t) with uniformly sampled random entities from the whole knowledge graph (Yao et al., 2019). However, such easy negatives are identified to provide limited training signal, since most of them produce small scores and nearly zero gradients late in training (Sun et al., 2019). Therefore, various improved negative sampling strategies have been proposed. Self-adversarial negative sampling (Sun et al., 2019) uses the distribution generated by the model being optimised to weight sampled negatives. GAN-based methods (Wang et al., 2018) are also effective in extracting informative negatives but suffer from inefficiency and high training costs. NSCaching (Zhang et al., 2019) regards negative triplets with large scores as important and maintains a cache of such triples from which negatives are sampled. Ahrabian et al. (2020) takes the head or tail entity's n-hop neighbours as negatives and evaluates their utility on graph embedding methods. Our work also aims to explore the effects of improved negative sampling strategies for KGC but with different model architectures (dual-encoder vs graph embeddings). Many of the above negative sampling strategies are orthogonal to our work and we believe they have the potential to be employed within our method for further empirical gains.

8 Conclusion

In this paper, we successfully improve a powerful dual-encoder-based KGC model by introducing various improved negative search methods and investigating their combinatorial effects. Empirical results on four benchmarks with different scales confirm the superiority of our proposed methods, significantly beating a wide range of competitive methods and achieving state-of-the-art performance. For future work, we are interested in eliminating false negatives contained in sampled hard negatives. An exciting future direction is to use a model to filter out false negatives and potentially even identify pseudo positives, for more accurate models.

Limitations

Although our method is efficient and introduces no extra cost during inference time, it does incur the additional training cost of retrieving different types of hard negatives, which roughly doubles the time for completing the whole training pipeline. The model ensembling methods, especially the embedding fusion one, need to build indexes for entity embeddings and require extra cost for storage. Despite these drawbacks, the training of our methods has a fairly modest footprint by modern standards, taking about 36 hours of a server with 4×A100 GPUs and 200G CPU RAM for the largest datasets, Wikidata5M.

As an empirical study, we provide observations under different design choices for sampling hard negatives. We hope our findings can shed lights on future work. A theoretical analysis about each proposed negative sampling strategy with connection to KG properties (e.g., sparsity) would certainly strengthen our claims, but is out of scope of this paper. In addition, the state-of-the-art dual-encoder-based KGC model is used to verify the sampling methods proposed in this work. One would expect to test their generalisation to other underlying KGC methods, e.g., graph embedding methods, which we leave as future work.

Moreover, adapting the dual-encoder-based KGC model and our proposed negative sampling methods to multilingual KGs, e.g., for a KG with concepts in different languages, or multi-modal settings, for a KG with concepts in the form of images, videos, or audios would further test the generalisation ability, which can be a promising research direction for future work.

A Hyperparameters

The learning rates are set to 5×10^{-5} on WN18RR, 3×10^{-5} on Wikidata5M and 1×10^{-5} on the remaining datasets. All models are trained using Adam optimizer (Kingma and Ba, 2015) with a warmup learning rate scheduler. The model is trained for 50, 10, 5, and 1 epochs on WN18RR, FB15k-237, DBPedia500k, and Wikidata5M. For each hard negative sampling strategy, we generate 30 negatives for each training example.[12] During each training step, we uniformly sample a subset of hard negatives from the pool for each training example, and the best number is chosen from $[1, 5]$. For both rank fusion and embedding fusion methods, their weights are shared and are tuned based on the performance on development sets. A summary of training details and hyperparameters is shown in Table 8.

B Number of Negatives for Training

For each training example in a mini-batch, we uniformly sample N negatives from its associated hard negative pool. We also treat the hard negatives and self-negatives of other examples in the same mini-batch as in-batch negatives. Suppose the batch size is B and pre-batches are M, the total number of instances used for loss calculation in Eq. 2 will be $(N + M + 2) \times B$ for each training example. By contrast, the number of negatives used by SimKGC is $(M + 2) \times B$. If we keep the same batch size, the number of negatives used in our experiment will increase by $N \times B$, which would potentially weak our claims as more negatives are used for contrastive learning. To ensure fair comparison, we reduced the batch size so that the number of negatives used in our experiment is the same as Wang et al. (2022). For example, if we take $B = 768, N = 1, M = 1$ on WN18RR, the number of negatives equals to 3072; while we take $B = 1024$ for SimKGC, the number will also be 3072. Thus, our methods will not be affected by including more negatives. Similar settings apply to other datasets.

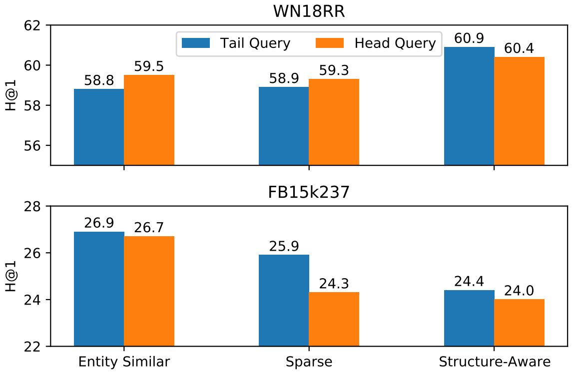

Figure 4: Results comparison when taking head or tail entity as query.

C Ablation Study

C.1 Negative Combination

Another possible way to benefit from all kinds of hard negatives is to train a model on their combinations. We experiment with training a model by uniformly sampling negatives from the union of all types of hard negatives generated from §3.2. As shown in Table 6, the model does not obtain improved results and this can even hurt the performance. We reason that although the combined negatives can provide more diverse supervisions, their false negative rates and difficulty also changes. More specifically, the false negative rate and difficulty on WN18RR change to 0.93% and 29.66%. Although more difficult negatives are included, the more important false negative rate is worse than the best structure-aware one. By contrast, the false negative rate in FB15k237 after combination reduces from Replaced Head Relation's 5.45% to 4.24%, but the more important difficulty also decreases from 45.8% to 33.7%, thus leading to inferior results.

C.2 Head Entity vs Tail Entity as Query

We analyse the performance difference between using head entity and tail entity as the query in the *sparse*, *structure-aware* and *entity similar* negative sampling strategies. Figure 4 shows that for similar and sparse negatives, using tail entity as query generally leads to worse performance on WN18RR; while in other cases, using the tail entity is more beneficial. One reason behind this is that taking the head entity as query would inevitably reduce

Table 9: Results comparison on WN18RR when using uniform and manually-tuned weights for model ensembling.

the difficulty but can avoid false negatives, a factor that is more significant for WN18RR. By contrast, the situation on FB15k237 is the other way around where the difficulty is more crucial. Again, we can confirm that there is no single design choice for each sampling strategy that works the best across datasets.

C.3 Uniform Weights for Ensembling

We show results when using uniform weights for model ensembling in Table 9. We find that simply using uniform weights has already boosted the performance. By carefully tuning the weights of each model through grid search, we can achieve further gains on all metrics, although the benefits are minimal. Making fusion weights learnable (Wang et al., 2021a) may lead to further improvements, which we leave as future work.

D Qualitative Analysis

Table 10 shows some examples of predictions from the SimKGC baseline and our best method. For the first example, both methods' predictions are wrong. However, our method ranks the correct tail entity much higher than the SimKGC baseline. Moreover, the top-1 prediction from our method *prosody_NN_1* is more reasonable as an answer compared to *articulation_NN_1*. For the second example, both methods fail according to the test set annotations. Our method returns correct tail entities based on our judgment. The same applies to SimKGC for its top-2 predictions. This also shows current automatic evaluation metrics cannot reflect the performance of KGC models precisely. For the third example, our method finds the correct answer out of other very semantically similar entities.

I. *Both SimKGC and our model fail, but our predictions are more related*	
Head Entity Relation Tail Entity	accentuation_NN_1: the use or application of an accent; the relative prominence of syllables in a phrase hypernym stress_NN_1: the relative prominence of a syllable or musical note (especially with regard to stress or pitch)
SimKGC (Rank 180)	1. articulation_NN_1: the aspect of pronunciation that involves bringing articulatory organs together so as to shape the sounds of speech 2. prosody_NN_1: the patterns of stress and intonation in a language 3. non-standard_speech_NN_1: speech that differs from the usual accepted, easily recognizable speech of native adult members of a speech community
Ours (Rank 108)	1. prosody_NN_1: *as above* 2. articulation_NN_1: *as above* 3. speech_pattern_NN_1: distinctive manner of oral expression; "he couldn't suppress his contemptuous accent".
II. *Both SimKGC and our model fail, but both models' predictions are correct based on human judgement*	
Head Entity Relation Tail Entity	pea_family_NN_1: a large family of trees, shrubs, vines, and herbs bearing bean pods... member meronym wild_pea_NN_1: any of various plants of the family Leguminosae that usually grow like vines.
SimKGC (Rank 7)	1. genus_sesbania_NN_1: small genus of tropical and subtropical leguminous herbs or shrubs or trees 2. genus_centrosema_NN_1: a genus of chiefly tropical American vines of the family Leguminosae... 3. torchwood_family_NN_1: resinous or aromatic chiefly tropical shrubs or trees
Ours (Rank 4)	1. genus_acacia_NN_1: large genus of shrubs and trees and some woody vines... 2. genus_sesbania_NN_1: *as above* 3. genus_dalbergia_NN_1: large genus of tropical trees having pinnate leaves and paniculate flowers...
III. *Our model succeeds but SimKGC fails*	
Head Entity Relation Tail Entity	wive_VB_1: take (someone) as a wife hypernym wed_VB_1: take in marriage
SimKGC (Rank 4)	1. wifely_JJ_1: befitting or characteristic of a wife 2. shack_up_VB_1: share living quarters; people who are not married and live together as a couple 3. wive_VB_2: marry a woman, take a wife
Ours (Rank 1)	1. **wed_VB_1: *as above*** 2. wifely_JJ_1: *as above* 3. shack_up_VB_1: *as above*

Table 10: Predictions of tail entities by the SimKGC baseline and our best model. The top-3 ranked outputs are reported, and the ranks of the correct results are also included. Correct predictions are in **bold**, and underline means predictions that do not exist in original KGs but are correct based on human judgment.

Semantic Frame Induction with Deep Metric Learning

Abstract

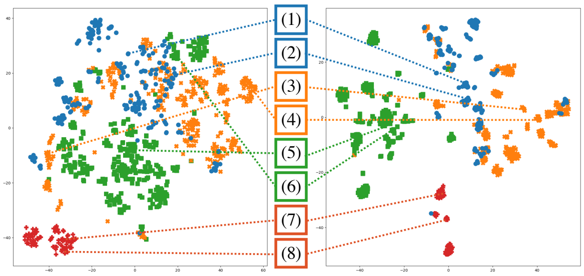
Recent studies have demonstrated the usefulness of contextualized word embeddings in unsupervised semantic frame induction. However, they have also revealed that generic contextualized embeddings are not always consistent with human intuitions about semantic frames, which causes unsatisfactory performance for frame induction based on contextualized embeddings. In this paper, we address *supervised* semantic frame induction, which assumes the existence of frame-annotated data for a subset of predicates in a corpus and aims to build a frame induction model that leverages the annotated data. We propose a model that uses deep metric learning to fine-tune a contextualized embedding model, and we apply the fine-tuned contextualized embeddings to perform semantic frame induction. Our experiments on FrameNet show that fine-tuning with deep metric learning considerably improves the clustering evaluation scores, namely, the B-CUBED F-SCORE and PURITY F-SCORE, by about 8 points or more. We also demonstrate that our approach is effective even when the number of training instances is small.

1 Introduction

Semantic frames are knowledge resources that reflect human intuitions about various concepts such as situations and events. One of the most representative semantic frame resources is FrameNet (Baker et al., 1998; Ruppenhofer et al., 2016), which consists of semantic frames, lexical units (LUs) that evoke these frames, and collections of frame-annotated sentences. Semantic frame induction is the task of grouping predicates, typically verbs, according to the semantic frames they evoke.[1] For example, given the verbs in the example sentences listed in Table 1, semantic frame induction aims to group them into four clusters according to the frames that they evoke.

Frame	Example sentence
FILLING	(1) She covered her mouth with her hand. (2) I filled a notebook with my name.
PLACING	(3) You can embed graphs in your worksheet. (4) He parked the car at the hotel.
REMOVING	(5) Volunteers removed grass from the marsh. (6) They'd drained the drop from the teapot.
TOPIC	(7) Each database will cover a specific topic. (8) Chapter 8 treats the educational advantages.

Table 1: Example sentences and the frames that their verbs evoke in FrameNet.



(a) Vanilla BERT (b) Fine-tuned BERT w/ AdaCos

Figure 1: 2D t-SNE projections of the contextualized embeddings of verbs annotated with either the FILLING (●), PLACING (×), REMOVING (■), or TOPIC (+) frames in FrameNet, by using (a) vanilla BERT or (b) fine-tuned BERT with AdaCos. The numbers in parentheses correspond to the examples listed in Table 1.

Recent studies (Arefyev et al., 2019; Anwar et al., 2019; Ribeiro et al., 2019) have demonstrated the usefulness of contextualized word embeddings such as ELMo (Peters et al., 2018) and BERT (Devlin et al., 2019) in unsupervised semantic frame induction. Figure 1(a) shows a 2D t-SNE (Maaten and Hinton, 2008) projection of the vanilla BERT[2] embeddings of verbs extracted from frame-annotated sentences in FrameNet. We can confirm that the instances of the verb "cover" in Exam-

---

[1] Strictly speaking, this task can be divided into two subtasks: verb clustering, which groups verbs according to the frames that they evoke, and argument clustering, which groups arguments of verbs according to their roles. In this study, we focus the former, the verb clustering task.

[2] We refer to BERT without fine-tuning as "vanilla BERT."

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1833–1845
May 2-6, 2023 ©2023 Association for Computational Linguistics

ples (1) and (7) are far apart in the space, which reflects the distance between their meanings. In contrast, "cover" in (7) and "treat" in (8), which are annotated with the same TOPIC frame, are close together. However, instances are not always properly placed in the semantic space according to the frames they evoke. For example, "remove" in (5) and "drain" in (6) are annotated with the same REMOVING frame but are not close together. This suggests that contextualized word embeddings are not always consistent with human intuition about semantic frames.

Hence, in this study, we tackle *supervised* semantic frame induction, which assumes the existence of annotated data for certain predicates, to induce semantic frames that adequately reflect human intuition about the frames. We propose methods that use deep metric learning to fine-tune the contextual word embedding model so that instances of verbs that evoke the same frame are placed close together and other instances are placed farther apart in the semantic space. Figure 1(b) shows the 2D t-SNE projection of BERT embeddings after fine-tuning with AdaCos (Zhang et al., 2019), which is a representative deep metric learning method. We can confirm that predicates that evoke the same frame are close together, such as those in (3) and (4) and those in (5) and (6). This suggests that deep metric learning enables fine-tuning of BERT to obtain embedding spaces that better reflect human intuition about semantic frames.

2 Related Work

For automatic construction of semantic frame resources, studies on grouping predicates according to the semantic frames they evoke can be divided into two groups: those that work on **semantic frame identification**, in which predicates are classified into predefined frames; and those that work on **semantic frame induction**, in which predicates are grouped according to the frames that they evoke, which are typically not given in advance.

Semantic frame identification is often treated as a subtask of frame semantic parsing (Das et al., 2014; Swayamdipta et al., 2017), and the methods using contextualized embedding have become mainstream. For example, Jiang and Riloff (2021) used a BERT-based model to generate representations for frames and LUs by using their formal definitions. Su et al. (2021) used a BERT-based model with a context encoder, to encode the context surrounding the frame-evoking word, and a frame encoder, to encode the frames' definitions and semantic roles. Yong and Torrent (2020) treated semantic frame identification as a clustering task.[3] They first excluded predicates that evoke frames that are not included in FrameNet by applying an anomaly detection model; then, they grouped the remaining predicates according to their meanings by using contextualized embeddings of predicates and sentence embeddings of the frame definitions.

Semantic frame induction is the task of grouping predicates in texts according to the frames they evoke. Instead of frames being given in advance, each grouping of given predicates is considered a frame. As with semantic frame identification, methods using contextualized embedding have become mainstream. Arefyev et al. (2019) first performed agglomerative clustering by using the BERT embedding of a frame-evoking verb and then split each cluster into two on the basis of the verb's substitutes. Anwar et al. (2019) used the embedding of the frame-evoking verb and the average word embedding of all the words in a sentence, as obtained by skip-gram (Mikolov et al., 2013) or ELMo and then performed agglomerative clustering. Ribeiro et al. (2019) applied graph clustering by using the ELMo embedding of the frame-evoking verb. Yamada et al. (2021a) leveraged the embedding of the masked frame-evoking verb and performed two-step clustering, which comprised intra-verb and cross-verb clustering. Yamada et al. (2021b) investigated how well contextualized word representations can recognize the difference of frames that the same verb evokes, and explored which types of representation are suitable for semantic frame induction. All of these studies focused on *unsupervised* semantic frame induction, with no training data. In contrast, in this study, we assume the existence of frame-annotated data for a subset of predicates appearing in a corpus, and work on *supervised* semantic frame induction.

3 Supervised Semantic Frame Induction

3.1 Task Description

The task of supervised semantic frame induction assumes the existence of frame-annotated data for a subset of a corpus's predicates, and it aims to

---

[3] Although they called their task semantic frame induction, we refer to the task as frame identification mainly due to the fact that their experiments excluded predicates that evoke unknown frames.

build a frame induction model that leverages the annotated data. Clustering-based methods are generally used for semantic frame induction, and this is also true for supervised semantic frame induction, where the annotated data is used to learn the distance metric for clustering. In this study, the predicates that are used for training the metric and for testing do not overlap. Note that, because different predicates may evoke the same frame, instances in the test data include predicates that evoke frames that are present in the training data.

3.2 Baseline Methods

For the simplest baseline, we use a one-step clustering-based method with contextualized embedding. The clustering method is group-average clustering based on the Euclidean distance. We also leverage the masked word embeddings and two-step clustering proposed by Yamada et al. (2021a). Regarding the former, we use a weighted average embedding (v_{w+m}) of the standard contextualized embedding of the frame-evoking word (v_{word}) and the masked word embedding (v_{mask}), which is a contextualized embedding of the frame-evoking word replaced by a special token "[MASK]." The embedding v_{w+m} is defined using a weight parameter α as follows:

$$v_{w+m} = (1-\alpha) \cdot v_{word} + \alpha \cdot v_{mask}. \quad (1)$$

Two-step clustering performs clustering for each frame-evoking word with the same lemma,[4] and it performs clustering over different frame-evoking words in the second step. We use X-means (Pelleg and Moore, 2000) for the first step and group-average clustering based on the Euclidean distance for the second step. All other settings here are the same as in Yamada et al. (2021a).

3.3 Fine-tuning by Deep Metric Learning

For supervised semantic frame induction, we fine-tune contextualized word embedding models by applying deep metric learning (Kaya and Bilge, 2019; Musgrave et al., 2020) so that the instances of predicates that evoke the same frame are closer together and those of predicates that evoke different frames are further apart. We apply two representative deep metric learning approaches: a distance-based approach and a classification-based approach.

Distance-based Approach This is a classical deep metric learning approach, and the models typically use multiple encoders to train the distance between a pair of instances. In this approach, we use two losses, a contrastive loss and a triplet loss, to build frame induction models.

The contrastive loss (Hadsell et al., 2006) is used to train the distance between a pair of instances by using a network of two encoders with shared parameters. Specifically, the model is trained to keep instances of the same class close together and instances of different classes separated by a certain margin. The loss is defined as follows:

$$L_{\text{cont}} = \begin{cases} D\left(\boldsymbol{x}_i, \boldsymbol{x}_j\right) & i = j \\ \max\left(m - D\left(\boldsymbol{x}_i, \boldsymbol{x}_j\right), 0\right) & i \neq j \end{cases}, \quad (2)$$

where $\boldsymbol{x}_i$ denotes an embedding of an instance belonging to the i-th class, m denotes a margin, and D denotes a distance function, which is generally the squared Euclidean distance.

The triplet loss (Weinberger and Saul, 2009) is used for training such that, for a triplet of instances, the distance between the anchor and negative instances, which are from different classes, is more than a certain margin greater than the distance between the anchor and positive instances, which are from the same class. The loss is defined as follows:

$$L_{\text{tri}} = \max\left(D\left(\boldsymbol{x}_a, \boldsymbol{x}_p\right) - D\left(\boldsymbol{x}_a, \boldsymbol{x}_n\right) + m, 0\right), \quad (3)$$

where $\boldsymbol{x}_a$, $\boldsymbol{x}_p$, and $\boldsymbol{x}_n$ denote embeddings of the anchor, positive, and negative instances, respectively, and m and D are the same as in Equation (2).

We create pairs for each instance in the training set by randomly selecting instances of predicates that evoke the same frame as positives and instances of predicates that evoke different frames as negatives. The margin to keep the negatives away is determined by the development set.

Classification-based Approach This is an approach that has recently become the standard for face recognition. It basically uses a network that has an encoder to obtain instance embeddings and a linear layer for multiclass classification. This is superior to the distance-based approach in that it does not require a sampling algorithm and saves memory because it uses only a single encoder. The loss function is based on the softmax loss:

$$L_{\text{soft}} = -\log \frac{e^{\boldsymbol{w}_i^\top \boldsymbol{x}_i + b_i}}{\sum_{j=1}^{n} e^{\boldsymbol{w}_j^\top \boldsymbol{x}_i + b_j}}, \quad (4)$$

---

[4] Following Yamada et al. (2021a), we refer to each cluster generated by clustering in the first step as a pseudo-LU (pLU).

where $\boldsymbol{x}_i$, $\boldsymbol{w}_i$, and b_i denote an embedding of the instance, the linear layer's weight, and a bias term, respectively, for the i-th class, and n denotes the number of classes.

Many losses used in face recognition have been adjusted by introducing different margins for the softmax loss (Liu et al., 2017; Wang et al., 2018; Deng et al., 2019). These losses typically remove the bias term b_i of the softmax loss and transform the logit as $\boldsymbol{w}_i^\top \boldsymbol{x}_i = ||\boldsymbol{w}_i|| \cdot ||\boldsymbol{x}_i|| \cdot \cos\theta_i$, where θ_i is the angle between $\boldsymbol{w}_i$ and $\boldsymbol{x}_i$. ArcFace (Deng et al., 2019) has become a popular choice because of its superior geometric interpretation. It applies l_2 regularization to $\boldsymbol{w}_i$ and $\boldsymbol{x}_i$ and introduces an angular margin m and a feature scale s as hyperparameters to simultaneously enhance the intra-class compactness and inter-class discrepancy. The ArcFace loss is defined as follows:

$$L_{\text{arc}} = -\log \frac{e^{s \cdot \cos(\theta_i + m)}}{e^{s \cdot \cos(\theta_i + m)} + \sum_{j=1, j \neq i}^{n} e^{s \cdot \cos \theta_j}}. \quad (5)$$

Zhang et al. (2019) pointed out that the performance of these losses depends on the hyperparameters and they observed the behaviors of the angular margin and the feature scale. As a result, they proposed the hyperparameter-free AdaCos loss, which removes the margin and applies the scale dynamically. The AdaCos loss is defined as follows:

$$L_{\text{ada}} = -\log \frac{e^{\tilde{s} \cdot \cos \theta_i}}{\sum_{j=1}^{n} e^{\tilde{s} \cdot \cos \theta_j}}, \quad (6)$$

where $\tilde{s}$ denotes the automatically tuned scale.

While the softmax and AdaCos losses do not require a hyperparameter search, ArcFace requires hyperparameters for the margin and feature scale. Here, we explore only the margin because Zhang et al. (2019) showed that the behavior of the margin and the scale are similar and the distance-based approach explores the margin.

4 Experiment

To evaluate the usefulness of fine-tuning with deep metric learning, we experimented with supervised semantic frame induction by comparing previous non-fine-tuned models to various fine-tuned models ranging from typical to evolved ones. By varying the number of training instances, we also verified that our models were effective even for training a small number of instances.

	#Verbs	#LUs	#Frames	#Instances
Set 1	831	1,277	429	28,314
Set 2	831	1,261	415	26,179
Set 3	830	1,280	459	28,117
All	2,492	3,818	642	82,610

Table 2: Statistics of the FrameNet-based dataset used in three-fold cross-validation.

4.1 Settings

Dataset The dataset in our experiments was created by extracting example sentences in which the frame-evoking word was a verb from the FrameNet 1.7 dataset.[5] These example sentences were split into three sets such that sentences with the same verb were in the same set. The proportions of polysemous verbs were equal. We performed three-fold cross-validation with the three sets as the training, development, and test sets. Table 2 lists the dataset statistics. Note that the verbs, LUs, and instances did not overlap among the sets, but the frames did overlap. The training set was used to fine-tune the contextualized word embeddings. The development set was used to determine the criterion for the number of clusters and the weight α of the embedding $v_{\text{W+M}}$, as well as the margin for the contrastive, triplet, and ArcFace losses. The range of α was from 0 to 1 in increments of 0.1, and the candidates of the margin were 0.1, 0.2, 0.5, and 1.0 for the contrastive and triplet losses and 0.01, 0.02, 0.05, and 0.1 for the ArcFace loss.

Comparison Methods We used BERT[6] from Hugging Face (Wolf et al., 2020) to obtain contextualized word embeddings. We compared 12 methods, which comprised the vanilla model (**Vanilla**) and five fine-tuned models (**Contrastive**, **Triplet**, **Softmax**, **ArcFace**, **AdaCos**) with one-step clustering and two-step clustering. All embeddings were processed with l_2 normalization. Regarding hyperparameters, the batch size was 32, the learning rate was 1e-5, and the number of epochs for fine-tuning was five. Also, the feature scale for ArcFace was 64. The optimization algorithm was AdamW (Loshchilov and Hutter, 2017).

We compared our methods with the three unsupervised methods used in Subtask-A of SemEval-2019 Task 2 (QasemiZadeh et al., 2019) in addition to the method of Yamada et al. (2021a) that cor-

Table 3: Experimental results on semantic frame induction with vanilla and fine-tuned models over three-fold cross-validation. Each value in the table is the average from three trials. #pLU denote the number of pLUs, and #C denotes the final number of clusters.

responds to our method with the Vanilla model.[7] Regarding those three methods, first, Arefyev et al. (2019) performed group-average clustering by using the BERT embedding of a frame-evoking verb and then split each cluster into two by using TF-IDF features based on the verb's substitutes, which were generated using Hearst-like patterns (Hearst, 1992) with BERT. Second, Anwar et al. (2019) performed group-average clustering through concatenation of the embedding of the frame-evoking verb and the average embedding of all words in the sentence as obtained by skip-gram. Third, Ribeiro et al. (2019) applied graph clustering by Chinese whispers (Biemann, 2006) with the ELMo embedding of the frame-evoking verb.

Evaluation Metrics For evaluation metrics, we used the Purity (Pu), the inverse Purity (iPu), and their harmonic mean, the F-score (PiF) (Zhao and Karypis, 2001); and the B-cubed Precision (BcP), the B-cubed Recall (BcR), and their harmonic mean, the F-score (BcF) (Bagga and Baldwin, 1998). Pu is a metric of the degree to which a cluster is occupied by a single label, while iPu is a metric of the degree to which a single label is concentrated in a single cluster. BcP and BcR evaluate the precision and recall for each sample, respectively, without associating clusters and labels. The shared task at SemEval-2019 Task 2 ranked systems according to BcF.

Method	PiF	BcF
Arefyev et al. (2019)	65.5	57.4
Anwar et al. (2019)	62.2	52.2
Ribeiro et al. (2019)	58.2	46.8
Yamada et al. (2021a)	66.9	56.5
Ours (one-step & Triplet)	73.9	63.9
Ours (one-step & AdaCos)	73.5	62.9
Ours (two-step & Triplet)	74.8	66.0
Ours (two-step & AdaCos)	**75.6**	**66.2**

Table 4: Results of comparison with previous methods.

4.2 Results

Table 3 summarizes the experimental results with the 12 methods. The fine-tuned models, especially the Triplet, ArcFace, and AdaCos models, obtained higher PiF and BcF scores than the Vanilla model except for the two-step clustering method with the Contrastive model. The reason why the Contrastive model performed worse than the other fine-tuned models could be that the space that represents the frame does not match the cluster size due to train the distance according to a fixed margin. Table 4 also lists the comparison results with previous methods. Our fine-tuning methods achieved higher PiF and BcF scores than the previous methods. These results indicate that fine-tuning with deep metric learning helps to improve the performance of semantic frame induction.

From Table 3, we can see that the two-step clustering methods tended to obtain higher overall scores than the one-step clustering methods. How-

---

[7] The SemEval-2019 Task 2 dataset is no longer available, as described on its official web page; thus, we excluded this dataset from the experiments.

Clustering	Model	PIF	BCF

	AdaCos	67.3 / 69.4 / 73.4 / **74.3 / 75.6**	57.6 / 59.7 / 64.5 / **65.3 / 66.2**

Table 5: Experimental results on semantic frame induction using the vanilla and fine-tuned models over three-fold cross-validation when varying the maximum number of training instances. Each numeric column lists the number of instances per LU included in the training set. Each value in the table is the average from three trials.

ever, the difference in BCF scores between the one-step and two-step clustering methods with the Vanilla model was 13.9, whereas the difference in the maximum BCF scores for both clustering methods with the fine-tuned models was only 2.3. Thus, for fine-tuning models, one-step clustering is still a good option in addition to two-step clustering. Note that one-step clustering is more straightforward to implement than two-step clustering, but it requires more computation time[8] and CPU memory to cluster many instances at once. Regarding the weight α, two-step clustering tended to incorporate v_{mask} more than one-step clustering did in not only the Vanilla model but also the fine-tuned models. These results suggest that two-step clustering remains effective in masking a verb's surface information even after fine-tuning.

The balance between BCP and BCR in the clustering evaluation metric depends on the final number of frame clusters, #C in Table 3. In the extreme case, BCR is 1 if #C is 1, and BCP is 1 if #C is equal to the number of instances. Hence, among models with roughly the same BCF, those with a fewer number of clusters tend to have higher BCR. For example, as shown in Table 3, #C of Triplet in two-step clustering is 454, while that of AdaCos is 656, and we can confirm that Triplet, which has fewer clusters, obtains higher BCR than AdaCos.

4.3 Effect of Number of Training Instances

We found that fine-tuned methods outperformed previous unsupervised methods when the number of training instances was around 30,000. However, the annotation cost of building a resource like FrameNet is high, so the fewer instances used for training, the easier it is to build other language resources and apply them to other tasks. Thus, we experimented with varying the number of training instances. Specifically, for each LU in the training set, the maximum number of instances was varied among 1, 2, 5, 10, and all instances. The resulting average numbers of training instances for the three sets were 1,273, 2,445, 5,680, 10,053, and 27,536, respectively. The numbers of verbs, LUs, and frames were the same in each setting.

Table 5 lists the PIF and BCF scores for each method. Because the Vanilla model was not fine-tuned, its scores are the same in each setting. The Triplet model achieved high scores even with a small number of training instances. In the two-step clustering method with the Triplet model, the score difference between the cases of "1" and "all" is only 3.1 for PIF and 3.6 for BCF, even though the number of training instances is quite different, i.e., 1,273 vs. 27,536. These results show that even when a small number of examples is annotated for each meaning of a verb, this method can be expected to perform considerably better than unsupervised methods. In contrast, the Softmax, ArcFace, and AdaCos models obtained scores closer to the Triplet model in the cases of "5" or "10" but per-

---

[8] In our experiments with 16-core Intel Xeon Gold 6134 CPU at 3.20 GHz, the computation times were about 10 minutes for one-step clustering and about 5 minutes for two-step clustering.

formed considerably worse with an even smaller number of training instances. We conclude that the relatively poor performance of these models with a small number of training instances was due to insufficient training of the linear layer's weights.

5 Analysis of Fine-tuned Embedding

It is not easy to analyze the properties of an embedding in clustering evaluation because the performance depends on the clustering method and the number of clusters. To better understand the fine-tuned embeddings, we performed a similarity ranking evaluation and visualized the embeddings.

5.1 Similarity Ranking Evaluation

We evaluated the models by ranking instances according to their embedding similarity. Specifically, we took one verb instance as a query instance; then, we computed the cosine similarity of the embeddings between the query instance and the remaining verb instances and evaluated the similarity rankings of the instances in descending order. We used v_{w+m} with the same weight α that was used for the one-step clustering in Section 4. We chose recall as the metric to evaluate the instance distribution. This metric computes the average matching rate between true instances, which are instances of the same frame as the query instance, and predicted instances, which are obtained by extracting the same number of top-ranked instances as the number of true instances. For example, Set 1 of Table 2 had 153 instances of the FILLING frame out of 28,314 total instances. When one of these instances was the query instance, the number of true instances would be 152. Thus, from the total instances, we would extract the top 152 instances that were similar to the query, and if 114 instances were true instances, the score would be $114/152 = 0.75$.

We performed the similarity ranking evaluation in three settings with respect to the search space of the ranked instances: ALL, which included all instances, SAME, which included only instances of the same verb as the query, and DIFF, which included only instances of different verbs as the query. Table 6 lists the results. The results for ALL show that all of the fine-tuned models were improved over the Vanilla model; in particular, the four fine-tuned models besides the Contrastive model performed very well, improving by more than 20. We thus confirmed that instances of the same frame were trained to be close to each other and instances of different frames are trained to be distant from each other. Score improvements were observed for both SAME and DIFF, and as expected, SAME scored higher than DIFF both before and after fine-tuning. However, the improvement was much larger for DIFF than for SAME, suggesting that the improvement in clustering performance by fine-tuning was mainly due to the fact that different verbs evoking the same frame were trained to be close to each other.

Model	ALL	SAME	DIFF
Vanilla	35.9	68.5	17.4
Contrastive	46.6	67.7	28.4
Triplet	60.6	74.2	40.7
Softmax	60.5	73.1	41.4
ArcFace	58.8	**75.6**	37.4
AdaCos	**62.1**	74.7	**42.8**

Table 6: Experimental results of recall for the similarity ranking evaluation over three-fold cross-validation. ALL, SAME, and DIFF indicate a search space of all instances, instances of the same verb, and instances of different verbs, respectively, for the query instance.

Model	OVERLAP	NON-OVERLAP
Vanilla	33.9	47.3
Contrastive	45.5	52.2
Triplet	59.0	**69.0**
Softmax	59.7	65.0
ArcFace	57.1	68.4
AdaCos	**61.2**	67.0

Table 7: Separately aggregated scores for ALL in Table 6 in the OVERLAP and NON-OVERLAP cases.

It is important to further examine whether the improved performance might have resulted only from the frames included in the training set. That is, we need to verify that the embedding of an instance of an untrained frame could be associated with a correct frame. To investigate this, we aggregated the scores separately for cases in which the frames of the query instance were included in the training set (OVERLAP) and for cases in which they were not (NON-OVERLAP). Table 7 lists the separately aggregated results for ALL in Table 6. All of the fine-tuned models obtained higher scores than the Vanilla model for not only frames that were in the training set but also frames that were not. Note that the scores for NON-OVERLAP were higher overall than those for OVERLAP. This result may be counterintuitive, but the reason is that the frames

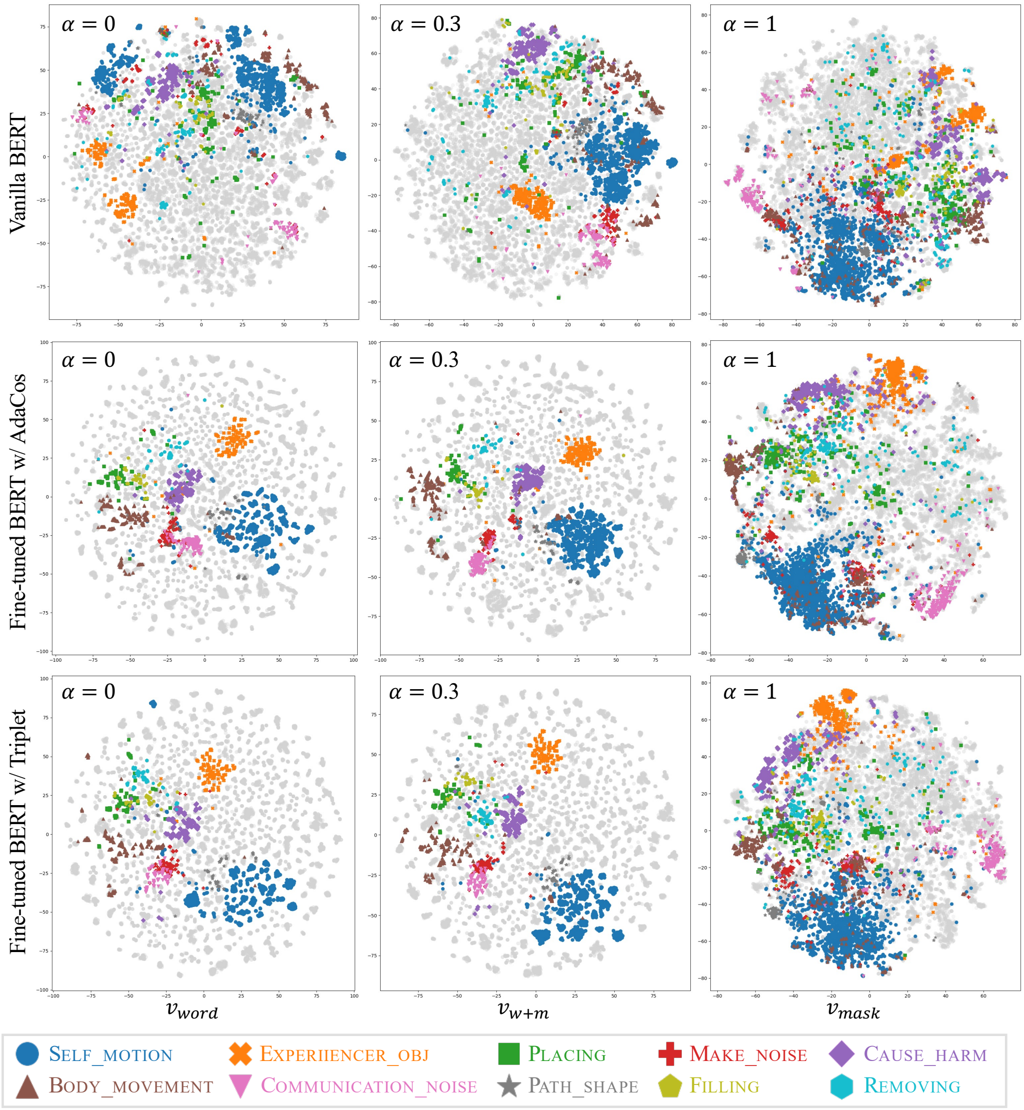

Figure 2: 2D t-SNE projections of v_{word}, v_{w+m}, and v_{mask} for the Vanilla, AdaCos, and Triplet models, respectively, for all instances with Set 1 in Table 2 as the test set. The top 10 semantic frames with the highest numbers of instances in this set are highlighted.

in the NON-OVERLAP case were only evoked by a few verbs, making it relatively easy to obtain higher ranking of instances of the same frame as the query.

5.2 Embedding Visualization

To intuitively understand the embeddings given by the Vanilla model and two fine-tuned models, we visualized them by t-SNE. Figure 2 shows the two-dimensional t-SNE projection of the contextualized embeddings of the frame-evoking verbs for all instances when Set 1 in Table 2 is the test set. We used v_{word}, v_{w+m}, and v_{mask} for the Vanilla, AdaCos, and Triplet models, respectively. The weight α for v_{w+m} was 0.3, which was the best value for one-step clustering methods with the Triplet and AdaCos models in Section 4.[9] We highlight the top ten semantic frames with the highest numbers of instances in this set.

In the Vanilla model, the instances for v_{word} tended to be grouped by frame but were not sufficiently grouped into clusters. For example, the instances of the SELF_MOTION frame were divided into two large groups, while those of the REMOVING frame were scattered. The instances for v_{mask} were somewhat more scattered than those for v_{word}. In addition, v_{w+m} tended to group instances of the same frame.

In the AdaCos and Triplet models, the instances for v_{word} were grouped much better for each frame

---

[9] For the Vanilla model, α was 0, which was the same as for v_{w+m} and v_{word}; thus, the results here are for α of 0.3.

than those for non-fine-tuned v_{word}. The results also confirmed that instances of frames with similar meanings, such as the PLACING and FILLING frames, were both identifiable and close. However, fine-tuned v_{word} formed many lumps of instances. This suggests that deep metric learning incorporates too much of a verb's surface information. On the other hand, fine-tuned v_{mask} was somewhat better than non-fine-tuned v_{mask}, but not as good as fine-tuned v_{word}. As deep metric learning may require the surface information about a verb to be induced, so fine-tuned v_{mask} may not work well. The instances in fine-tuned v_{w+m} were better grouped than those for fine-tuned v_{word}, because instances of the same frame were more grouped.

6 Conclusion

We worked on the supervised semantic frame induction, and we proposed a model that uses deep metric learning to fine-tune a contextualized embedding model and applied the fine-tuned contextualized embeddings to perform semantic frame induction. In our experiments, we showed that fine-tuned BERT models with the triplet, ArcFace, and AdaCos losses are quite promising for semantic frame induction, as the human intuition in developing semantic frames such as those in FrameNet can be well captured by deep metric learning. In particular, the fine-tuned BERT model with the triplet loss performed considerably better than vanilla BERT even when the number of training instances was small; accordingly, the fine-tuned model is expected to have a wide range of applications. We also found that the one-step clustering can be a good choice in addition to two-step clustering when performing fine-tuning.

The ultimate goal of this study is to automatically construct semantic frame knowledge from large text corpora. This goal requires not only grouping the verbs according to the frames that they evoke but also grouping their arguments according to the frame element roles that they fill. Our proposed fine-tuned contextualized word embedding with deep metric learning could be effective for clustering arguments as it is for clustering verbs. We would like to explore how to achieve this goal.

Limitations

In this study, we only conducted experiments with English FrameNet, so it is unclear how useful this method will be for other corpora and multilingual resources. However, since our method does not depend on the properties of the specific corpus and language, it is quite possible that fine-tuning would improve the scores in other datasets. In addition, as our method requires supervised data from a semantic frame knowledge resource, some annotation will be necessary when applying the method to other languages that lack such a resource.

A Clustering Results with and without Linear Completion

Tables 8 and 9 list our experimental results for semantic frame induction when using v_{word}, v_{w+m}, and v_{mask} in one-step and two-step clustering, respectively. The results show that v_{w+m} tended to perform better than v_{word} and v_{mask}, thus demonstrating the usefulness of linear completion. This tendency was noticeable for two-step clustering but more limited for one-step clustering.

Regarding the results for v_{word} and v_{mask}, the fine-tuning was effective for v_{word}, as the scores improved considerably, but the effectiveness was limited for v_{mask}. This was probably because the embedding of the special token “[MASK],” which was the source of the contextualized word embedding, was shared by all instances.

B Results for Semantic Frame Induction on Development Set

Table 10 lists our experimental results for semantic frame induction on the development set. As with the test set, the fine-tuned models obtained higher PIF and BCF scores than the Vanilla model except for two-step clustering with the Contrastive model. In particular, the Triplet, ArcFace, and AdaCos models obtained high scores for both one-step and two-step clusterings.

C Embedding Visualization of Remaining Models

In Figure 2, we showed a two-dimensional t-SNE projection of v_{word}, v_{w+m}, and v_{mask} for the Vanilla, AdaCos, and Triplet models, respectively. Figure 3 shows a two-dimensional t-SNE projection of v_{word}, v_{w+m}, and v_{mask} for the remaining models not included in Figure 2, namely, the Contrastive, Softmax, and ArcFace models, with the same setting. Figure 3 confirms that the three fine-tuned models, as well as the two fine-tuned models shown in Figure 2, are more coherent semantically than the Vanilla model, and the tendency of v_{word}, v_{w+m}, and v_{mask} is similar. In addition, for the Contrastive model, whose performance was relatively poor among the fine-tuning models in Table 3, it was confirmed that the instances were somewhat scattered compared to the Softmax and ArcFace models. For example, the instances of the BODY_MOVEMENT frame were scattered. This result confirmed the consistency of scores and visualization. The results show consistency between scores and visualization.

Abstract

In task-oriented dialog (ToD) new intents emerge on regular basis, with a handful of available utterances at best. This renders effective Few-Shot Intent Classification (FSIC) a central challenge for modular ToD systems. Recent FSIC methods appear to be similar: they use pretrained language models (PLMs) to encode utterances and predominantly resort to nearest-neighbor-based inference. However, they also differ in major components: they start from different PLMs, use different encoding architectures and utterance similarity functions, and adopt different training regimes. Coupling of these vital components together with the lack of informative ablations prevents the identification of factors that drive the (reported) FSIC performance. We propose a unified framework to evaluate these components along the following key dimensions: (1) *Encoding architectures*: Cross-Encoder vs Bi-Encoders; (2) *Similarity function*: Parameterized (i.e., trainable) vs non-parameterized; (3) *Training regimes*: Episodic meta-learning vs conventional (i.e., non-episodic) training. Our experimental results on seven FSIC benchmarks reveal three new important findings. First, the unexplored combination of cross-encoder architecture and episodic meta-learning consistently yields the best FSIC performance. Second, episodic training substantially outperforms its non-episodic counterpart. Finally, we show that splitting episodes into support and query sets has a limited and inconsistent effect on performance. Our findings show the importance of ablations and fair comparisons in FSIC. We publicly release our code and data[1].

1 Introduction

Intent classification deals with assigning one label from a predefined set of classes or *intents* to user utterances. This task is vital for task-oriented dialog (ToD) systems since the predicted intent of an utterance is an essential input to other modules (i.e., dialog management) in these systems (Ma et al., 2022; Louvan and Magnini, 2020; Razumovskaia et al., 2021). Although intent classification has been widely studied, it still represents a challenge in settings where dialogue systems, including their intent classifiers, need to have the ability to be quickly adjusted to new domains and intent classes. The main challenges in training intent classifiers in such settings lies in the costly labeling of utterances (Zhang et al., 2022a; Wen et al., 2017; Budzianowski et al., 2018; Rastogi et al., 2020; Hung et al., 2022; Mueller et al., 2022). Few-shot intent classification (FSIC), which deals with adjusting intent classifiers to new intents given only a handful of labeled instances, is thus of paramount importance for ToD systems.

Various methods (§2) for FSIC have been proposed (Larson et al., 2019a; Casanueva et al., 2020a; Zhang et al., 2020; Mehri et al., 2020; Krone et al., 2020; Casanueva et al., 2020b; Nguyen et al., 2020; Zhang et al., 2021; Dopierre et al., 2021; Vulić et al., 2021; Zhang et al., 2022b). These methods are generally similar in that they utilize pretrained language models (PLMs) to encode utterances and resort to k nearest neighbors (kNN) inference: the label of a new instance is determined based on the labels of instances with which it has the highest representational similarity, as encoded by the PLM. Despite these general similarities, FSIC methods differ in design choices across several crucial dimensions, including encoding architectures, utterance similarity scoring, and training regimes. These methods tie together what are, in principle, independent design decisions across these dimensions, hindering ablations and insights into what drives the (reported) FSIC performance.

In this work, we (1) induce a framework (PLM-based utterance encoding, utterance similarity scor-

---

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1846–1857
May 2-6, 2023

ing, and nearest-neighbor-based inference) that unifies most of existing FSIC approaches (§3); and (2) focus on three key design decisions within this framework: **(1)** *model architecture for encoding utterances (or utterance pairs)*, where we contrast the less frequently adopted Cross-Encoder architecture (e.g., (Vulić et al., 2021)) against the more common Bi-Encoder architecture[2] (Zhang et al., 2020; Krone et al., 2020; Zhang et al., 2021); **(2)** *similarity function* for scoring utterance pairs based on their joint or separate representations, contrasting the parameterized (i.e., trainable) neural scoring components against cosine similarity as the simple non-parameterized scoring function; and **(3)** *training regimes*, comparing the standard non-episodic training (adopted, e.g., by Zhang et al. (2021) or Vulić et al. (2021)) against the episodic meta-learning training (implemented, e.g., by Nguyen et al. (2020) or Krone et al. (2020)). Our framework lets us evaluate impacts of these three dimensions for different text encoders (e.g., BERT (Devlin et al., 2019) as a vanilla PLM and SimCSE (Gao et al., 2021) as the state-of-the-art sentence encoder) under the same evaluation setup (datasets, intent splits, evaluation protocols and measures) while controlling for confounding factors that impede direct comparison between the FSIC methods.

Our extensive experimental results on seven intent classification datasets reveal three new important findings. First, a Cross-Encoder coupled with episodic training, a previously unexplored FSIC combination, consistently yields best performance across all the datasets. Second, episodic meta-learning yields robust FSIC classifiers across the board: our results demonstrate that it is much more effective for FSIC than the conventional non-episodic training. Finally, although episodic meta-learning entails splitting utterances of an episode into a support and query set during training, we show, for the first time, that this does not generally have a positive effect on the FSIC performance.

In sum, our comparative evaluation over various design choices for key components of modern FSIC approaches raise the awareness about the importance of ablations and apple-to-apple comparison between complex FSIC systems that conflate several key design decisions. We hope that our findings pave the way for more deliberation in research (and in particular evaluation) for this crucial ToD task.

2 Related Work

We focus on few-shot intent classification (FSIC) methods, which perform class inference for utterances based on the labels of nearest neighbor (kNN), either directly in the representation space of the PLM or according to a trained scorer of utterance pairs. We first describe the existing FSIC inference paradigms and explain why we focus on kNN-based methods. We then categorize the literature on FSIC approaches based on kNN-inference along the three key design dimensions.

Inference algorithms for FSIC. Classical methods (Xu and Sarikaya, 2013; Meng and Huang, 2018; Wang et al., 2019; Gupta et al., 2019) for FSIC use the maximum likelihood inference, where a vector representation of an utterance is projected by the classifier into a probability distribution over the intent classes. Training such probability distribution functions, in particular when they are modeled by neural networks, mostly requires a large number of utterances annotated with intent labels, which are infamously expensive to collect in scenarios where new intents emerge on regular basis. By relying on pretrained language models, more recent FSIC methods leverage the language competences they posses (i.e., encode) to alleviate the need for learning to produce probability distributions for a large number intent classes, commonly with a few instances. These recent FSIC methods (Krone et al., 2020; Casanueva et al., 2020b; Nguyen et al., 2020; Zhang et al., 2021; Dopierre et al., 2021; Vulić et al., 2021; Zhang et al., 2022b) instead exploit the similarities between utterance embeddings in the representation space of the (fine-tuned) PLM and infer the intents for new utterances from the labels of nearest neighbors (kNN-based). Since kNN-based methods in general report state-of-the-art performance for FSIC, our comparative empirical evaluation focuses on the design choices for models that adopt this inference algorithm.

Model architectures for encoding utterance pairs. A central design decision within the kNN-based FSIC framework is the choice of the model architecture for encoding utterances. The majority of the approaches (Zhang et al., 2020; Krone et al., 2020; Zhang et al., 2021; Xia et al., 2021) leverage the Bi-Encoder architecture (Bromley et al., 1993; Reimers and Gurevych, 2019a; Zhang et al., 2022a). The core idea of Bi-Encoders is that, given a collection of utterances, each utterance is inde-

---

[2] Also known as Dual Encoder or Siamese Network.

pendently encoded by the PLM and mapped into a dense representation space. In such a space, similarities between pairs of utterances can be computed, with a parameterized (i.e., trainable) scoring function or a non-parameterized function such as dot product or cosine similarity. In contrast, some FSIC methods (Vulić et al., 2021; Zhang et al., 2020; Wang et al., 2021; Zhang et al., 2021) use the Cross-Encoder architecture, in which the two utterances are concatenated and encoded jointly by a pretrained text encoder, e.g., BERT (Devlin et al., 2019). The idea is to represent a pair of utterances together using a PLM, where each utterance becomes a context for the other. A Cross-Encoder thus does not produce an embedding for a single utterance but for a pair of utterances. In general, Bi-Encoders are more computationally efficient than Cross-Encoders because of the Bi-Encoder's ability to cache the representations of the candidates. In return, Cross-Encoders, by allowing tokens of one utterance to attend over the tokens of the other (and vice versa), capture better the semantic associations between utterances.

Similarity scoring function. A crucial component in nearest neighbor-based methods for FSIC is the function that produces a similarity score for a pair of utterances. Concerning this dimension of analysis, we categorize FSIC methods into two groups: (1) FSIC approaches that use parameterized (i.e., trainable) neural layers to estimate the similarity score between utterances (Zhou et al., 2022; Zhang et al., 2020; Xia et al., 2021); and (2) methods that rely on non-parameterized similarity metrics such as dot product, cosine similarity, and Euclidean distance (Sauer et al., 2022; Zhang et al., 2022a; Krone et al., 2020; Vulić et al., 2021; Zhang et al., 2022b; Xu et al., 2021; Zhang et al., 2021). Note that the Bi-Encoder architecture can be coupled with both, whereas the Cross-Encoder requires a parametrized scoring module.

Training strategy. To simulate FSIC, the best practice is to split an intent classification corpus into two disjoint sets of intent classes. In this way, one set includes high-resource intents for training of an FSIC classifier, and the other set includes low-resource intents for evaluating the classifier. Concerning the training strategy on the high-resource intents, FSIC methods can be divided into two clusters. One cluster of methods adopts meta-learning or episodic training (Zhang et al., 2022a; Nguyen et al., 2020; Krone et al., 2020). Under this training regime, the goal is to train a meta-learner that could be used to quickly adapt to any few-shot intent classification task with very few labeled examples. To do so, the set of high-resource intents are split to construct many episodes, where each episode is a few-shot intent classification task for a small number of intents. The other cluster includes methods (Zhang et al., 2021; Vulić et al., 2021; Xu et al., 2021; Xia et al., 2021; Zhang et al., 2020, 2021) that use conventional supervised (i.e., non-episodic) training. The non-episodic training simply fine-tunes the FSIC model using all samples from the high-resource intents of the training set.

3 Framework

We first unify formulations of the components we need for our framework. We then present their alternative configurations along our three central dimensions of comparison: (i) model architecture for encoding utterance pairs, (ii) functions for similarity scoring, and (iii) training regimes.

3.1 Nearest Neighbors Inference

Following previous work on FSIC (Zhang et al., 2020; Vulić et al., 2021), we cast the FSIC task as a sentence similarity task in which each intent is an implicit semantic class, captured by the representations of all the utterances associated with that intent. The task is then to find the most similar labeled utterances for the given query. During inference, the FSIC approach should deal with an N-way k-shot intent classification, where N is the number of intents and k is the number of labeled utterances given for each intent label.

Let q be a query utterance and $C = \{c_1, ..., c_n\}$ be a set of its labeled neighbors. The nearest neighbor inference relies on a similarity function, non-parameterized or trainable (which is learned on high-resource intents), to estimate the similarity score s_i between q and any c_i. The query's label $\hat{y}_q$ is inferred as the ground-truth label of the neighbor with the maximum similarity score (i.e., $k = 1$ in k-NN inference): $\hat{y} = y_k$, $k = \text{argmax}(\{s_1, ..., s_n\})$.

3.2 Model Architectures for Encoding Utterance Pairs

An encoder in an FSIC model represents a pair of a query and a neighbor (i.e., a labeled utterance) into vector $\mathbf{h}_{(q,c_i)} \in \mathbb{R}^d$. We formulate recently used encoders: Bi-Encoder and Cross-Encoder.

Bi-Encoder (BE). BE encodes a pair of utterances independently, deriving independent representations of the query and the neighbor utterance. In particular, for each utterance x in a pair, we pass, "`[CLS]` x", to a BERT-like PLM and use the representation of "`[CLS]`" to represent x. Worth noting that the parameters of the PLM are shared in BE.

Cross-Encoder (CE). Different from BE, CE encodes a pair of query q and neighbor c_i *jointly*. We concatenate q with each of its neighbors to form a set of query–neighbor pairs $P = \{(q, c_1), ..., (q, c_n)\}$. We then pass each pair from P as a sequence of tokens to a language model, which is pre-trained to represent the semantic relation between utterances. More formally, we feed a pair of utterances, "`[CLS]` q `[SEP]` c_i", to a BERT-like PLM and then use the representation of the "`[CLS]`" token as the representation of the pair.

3.3 Similarity Scoring Function

Given the pair representation, we compute the similarity between a query and a neighbor utterance by a *parameterized* or *non-parameterized* function.

PArameterized (PA). A neural-based parametric scoring function consists of a fully connected feed-forward network (FF) that transforms a pair representation into a score, $s_i = \sigma\left(\mathbf{W}^{1\times d}\mathbf{h}_{(q,c_i)} + b\right)$, where the weight $\mathbf{W}$ and bias b are trainable parameters, d is the size of the vector $\mathbf{h}_{(q,c_i)}$, and $\sigma(.)$ denotes the `sigmoid` activation function.

Non-Parameterized (NP). In contrast to PA, NP often uses vector-based similarity metrics as scoring functions, e.g., cosine similarity or Euclidean distance. Following Vulić et al. (2021), in this work we adopt the cosine similarity between h_q and h_{c_i}.

3.4 Model Configurations

Given the aforementioned components, we illustrate (Figure 1) three possible model configurations: (i) CE+PA; (ii) BE+PA, and (iii) BE+NP.

CE +PA. In this configuration, we feed the joint encoding of the utterance pair to a parameterized similarity scoring function. We note again, due to a single representation vector for both utterances, CE cannot be coupled with a non-parameterized scoring (NP).

BE +PA. In this configuration, we represent the pair by concatenating the representations of each utterance with the vectors of difference and element-wise product between those representations:

$$h_{(q,c_i)} = (h_q \oplus h_{c_i} \oplus |h_q - h_{c_i}| \oplus h_q \odot h_{c_i}), \quad (1)$$

where $\oplus$ is the concatenation operation and $\odot$ is the dot product. We motivate Equation 1 by the findings reported in Reimers and Gurevych (2019b). Similar to CE +PA, we use the sigmoid activation function on top of the feed-forward layer. The size of $\mathbf{W}$ is then $1 \times 4d$.

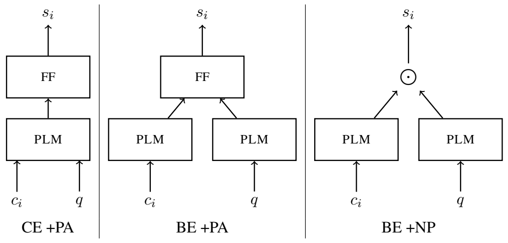

Figure 1: A demonstration of possible model configurations of encoder architectures and similarity functions to estimate the similarity score s_i between a query q and neighbor c_i. CE and BE show Cross-Encoder and Bi-Encoder architectures using a BERT-like PLM, respectively. PA and NP show parametric and non-parametric similarity functions, respectively. PA is modeled by feedforward (FF) layers and NP by the dot product $\odot$.

BE +NP. We use cosine similarity to estimate the similarity between input utterances during prediction. During training, we compute the dot product between the query and each neighbor representation vector to directly estimate their similarity scores $s_i = \sigma(h_q \odot h_{c_i})$, where $\odot$ indicates the dot product, and σ is the `sigmoid` function. We apply σ to scale s_i to a value between 0 and 1.

3.5 Training Regimes

To train the aforementioned model configurations, we formulate three training techniques as follows (Figure 2): *Non-Episodic Training (NE)*, *Episodic Training (EP)* and *Episodic Training with Support and Query splits (EPSQ)*. The training strategies rely on an identical loss function for each query.

Loss per query sample. We use the loss function defined by Zhang et al. (2020) for FSIC. In particular, we define a ground-truth binary vector y_q for a query q given a set of neighbors $C = \{c_1, ..., c_n\}$. If the query and its i-th neighbor belong to the same intent class, the corresponding label for the pair is $y_{q,i} = 1$, otherwise $y_{q,i} = 0$. Given such ground-truth label vector in consideration of the n

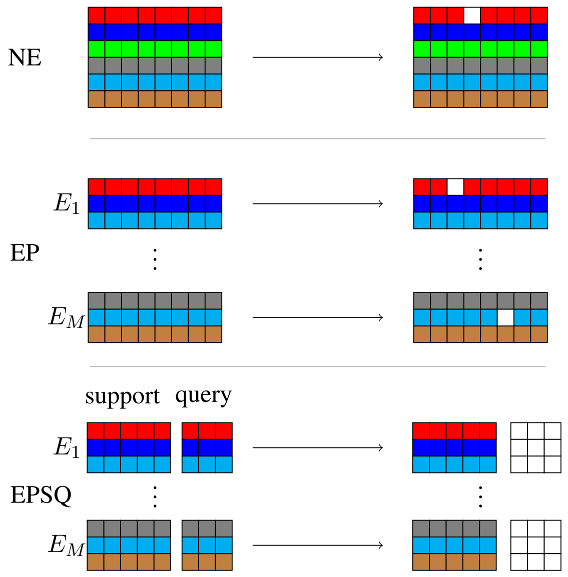

Figure 2: A illustration of training techniques, i.e., Non-episodic (NE), episodic (EP) and episodic with a support and query split (EPSQ). Each cell shows an utterance in a dataset. Each color depicts an intent class. Each row shows labeled utterances with an identical intent. In NE, the training instances are used all together and the loss is the average loss for each sample (white cell) when the other samples are neighbors. In EP, the training instances are divided into M episodes (E) and the loss is computed similar to NE for each episode. In EPSQ, each episode is split into fixed sets of of support and query instances, and the loss is computed for only the samples in the query set.

neighbors, $\mathbf{y}_q = [y_{q,t} | t = 1, ..., n]$ and similarity scores estimated by a model configuration for all pairs $\mathbf{s}_q = [s_{q,t} | t = 1, ..., n]$, we compute the binary cross-entropy loss for the query q as follows:

$$l_q(\mathbf{y}_q, s_q | C) = \\ -\frac{1}{n} \sum_{t=1}^{n} [y_{q,t} \log(s_{q,t}) + (1 - y_{q,t}) \log(1 - s_{q,t})] \, . \tag{2}$$

NE. For the NE training, the classifier learns the semantic relation between all high-resource intent classes altogether. Let D represent a batch of utterances for high-resource intent classes. Therefore, we take each utterance in D as a query q and predict its label concerning the rest of the utterances as neighbors. More formally, we estimate the loss for the NE training as follows:

$$\mathcal{L} = \frac{1}{|D|} \sum_{q \in D} l_{q|D-q}(\mathbf{y}_q, \mathbf{s}_q) \, , \tag{3}$$

where l_q is the loss defined in Equation 2 between ground truth label vector $\mathbf{y}_q$ and a vector of scores $\mathbf{s}_q$ estimated by a model configuration.

EP. An episode is a set of utterances for several intent classes. An episode formulates an N-way intent classification task, where N is the number of intent classes in the episode. The core idea behind meta-learning is to learn from a large set of high-resource intent classes by chunking the set into many episodes (Lee et al., 2022). These episodes are known as training episodes (a.k.a meta-training episodes). If set $\mathcal{I}$ denotes the intent labels of a benchmark corpus, any N randomly selected intents from $\mathcal{I}$ can be used to construct a training episode. Let's refer to these selected intents for episode E by $\mathcal{I}_E$. Then, episode E contains utterances whose intent labels are in I_E. It is worth noting that intent classes in training episodes may overlap to let a classifier learn the semantic relations between all intent labels of the benchmark. In EP, we construct M episodes from the set of utterances for high-resource intent classes D. We define the following loss function:

$$\mathcal{L} = \frac{1}{M} \sum_{i=1}^{M} \frac{1}{|E_i|} \sum_{q \in E_i} l_{q|E_i}(\mathbf{y}_q, \mathbf{s}_q) \, , \tag{4}$$

where E_i is the ith episode, $\mathbf{y}_q$ is the ground-truth labels for the query given neighbors in the episode E_i, and $\mathbf{s}_q$ is the similarity scores between the query and any neighbor in the episode.

EPSQ. The common practice in meta-learning is to imitate the few-shot setup, an episode is split into two disjoint sets: a support and a query set (Lee et al., 2022). An episode's support set includes only a few utterances from each intent class in I_E. An episode's query set includes the rest of the utterances in the episode. A classifier should classify utterances in the query set using the utterances and intent labels in the support set. Given the kNN terminology, the support set is the set of neighbors and the query set is a set of query utterances. Therefore, the main difference between EPSQ and EP is that the number of neighbors in EPSQ is limited to only a few examples of each intent in the support set. The loss function in EPSQ is defined as follows:

$$\mathcal{L} = \frac{1}{M} \sum_{i=1}^{M} \frac{1}{|Q_i|} \sum_{q \in Q_i} l_{q|S_i}(\mathbf{y}_q, \mathbf{s}_q) \, , \tag{5}$$

where Q_i is the query set and S_i is the support set of the ith episode.

TOP (18)	7	5	6	10,095	1,286	292

Table 1: The examined datasets and their main statistics. The numbers in parenthesis show the total number of intent classes for each dataset. For HWU64, each split's number of classes varies at each run to ensure there is no cross-split domain, hence the decimal number.

4 Experiments

We conduct our experiments in two different setups: (i) balabced N-way k-shot and (ii) imbalanced classes in the support sets. The former refers to the typical few-shot learning setup, where the numbers of classes and examples per class are balanced. In contrast, the imbalanced setup randomly defines the numbers of classes and examples, imitating the imbalance nature of some benchmarks for intent classification. While arguably some utterances can be annotated to transform imbalanced episodes into balanced ones, imbalanced few-shot learning is still a huge practical challenge for various expensive domains, e.g., those that require experts for annotation (Krone et al., 2020).

Datasets, splits, and episodes. Table 1 summarizes the main statistics (e.g., the number of classes per data split for each datasets) of the datasets and their splits as we use in our experiments. For the balanced N-way k-shot setup, we use Clinc (Larson et al., 2019b), Banking (Casanueva et al., 2020b), and Hwu (Liu et al., 2021) from DialoGLUE (Mehri et al., 2020) as well as Liu (Liu et al., 2021). For the sake of fair comparisons, we use the exact splits and episodes as used by Dopierre et al. (2021) for FSIC. For 5 folds, we randomly split intents of each dataset into three sets to construct training, valid and test episodes. We then generate 5-way k-shot episodes for each split in each fold, where $k \in \{1, 5\}$. For the imbalanced setup, we use ATIS (Hemphill et al., 1990), SNIPS (Coucke et al., 2018), and TOP (Gupta et al., 2018). We follow Krone et al. (2020) to construct episodes for these datasets.

Settings. We use BERT-based-uncased and SimCSE as PLMs. We fine-tune them using the AdamW optimizer (Loshchilov and Hutter, 2019) with a learning rate of $2e-5$. Both batch size and maximum sequence length are set to 64. See the Appendix for the full list of hyperparameters. For experiments on each fold of balanced datasets, we train a FSIC classifier for a maximum of 10,000 5-way K-shots episodes. We evaluate the classifier on the validation set after every 100 updates, and stop the training if validation performance does not improve over 5 consecutive evaluation steps. To alleviate the impact of random selection of few-shot samples, we report the average performance of a classifier for 600 test episodes, compatible with Dopierre et al. (2021). For the experiments on the imbalanced datasets, similar to Krone et al. (2020), we conduct the experiments over 1 fold due to the limited number of intents. The average number of shots per intent used in episodes of ATIS, SNIPS, and TOP is about 4, 5, and 4, respectively (see Appendix for details). For both N-way k-shot and imbalanced setups, the number of examples in query sets is identical for all intents in the query sets. So, for all experiments we report the accuracy metric averaged over all runs and folds.

Models in comparison. Alongside the results of the model configurations (§3), we report the results of the following FSIC methods to put our results in context. **Random** assigns a random intent class from the support set to each query utterance. **BE (fixed)+NP** represents a generic configuration employed by the majority of PLM-based FSIC baselines, e.g., ConvBERT (Mehri and Eric, 2021), TOD-BERT (Wu et al., 2020), and DNNC-BERT (Zhang et al., 2020), inter alia. These methods use pretrained BERT and further fine-tune on other NLP tasks (e.g., NLI) or other dialogue datasets. **ProtoNet** (Dopierre et al., 2021) is inspired by prototypical network method (Snell et al., 2017), which has been shown to achieve the state-of-the-art accuracy among meta-learning methods for few-shot learning tasks including FSIC (Krone et al., 2020). This method is not based on instance-level similarity. It encodes an intent class by a prototype vector, which is the mean of vector representations of a few utterances given for the intent. In any given episode, the prototype vector is computed for each intent. The probabilities of intents are then estimated based on the distances between a query vector and respective prototypes.

5 Results and Discussion

We compare the the configurations described in (§3) and baselines (§4) for balanced and imbalanced FSIC setups using BERT, as the most widely used pretrained language model, and SimCSE, the state-of-the-art model for encoding the meaning of sentences. Our main experimental findings are as follows

- The Cross-Encoder architecture with parameterized similarity function and episodic training consistently yields the best FSIC accuracy.
- Episodic training yields more robust FSIC classifiers than non-episodic training for most of the examined setups and datasets.
- Splitting episode utterances into support and query (sub)sets, a commonly adopted practice in episodic training, does not give consistent performance gains.

5.1 Balanced FSIC

Table 2 shows accuracy of the examined FSIC approaches under comparison – based on BERT as PLM – in 1-shot and 5-shots settings. All model configurations consistently outperform the "BE (fixed)+NP" baseline. This demonstrates that fine-tuning BERT's parameters for intent classification using high-resource intent classes is paramount for generalization to unseen intents.

For both 1-shot and 5-shots, CE +PA trained with either of the two episodic training regimes (EP and EPSQ, without and with support-query splitting, respectively), achieves a higher accuracy (29% on average) than when trained in non-episodic fashion (NE), reaching, on average, the performance of ProtoNet as the state-of-art FSIC method. Both episodic training regimes are more effective than the non-episodic training across the board, not just in combination with the CE architecture. BE +PA trained via EP achieves about 2% higher accuracy for 1-shot and 3% for 5-shots than when trained with NE. For BE +NP, episodic learning (EP) results in 3.8% higher accuracy than NE for 1-shot. The only exception to this trend is BE +NP with 5-shot where EP trails NE by 1%.

EPSQ tends to exhibit a similar average accuracy as EP (less than 1% difference for average across all CE +PA, BE +PA, and BE +NP setups). This leads a conclusion that splitting utterances of an episode into a support and a query set – a common practices in episodic (FSIC) learning (Dopierre et al., 2021; Krone et al., 2020) – does not really have a pronounced (positive) effect on performance. So, it does not seem to increase the capability to generalize to unseen intent classes, as has been commonly believed but until now, to the best of our knowledge, empirically untested.

As expected, more shots (5-shots vs 1-shot) lead to consistently better FSIC accuracy: BE +NP trained with NE performs 16% better (and the other FSIC about 10% better on average). This makes intuitive sense: more shots help classifiers better refine the boundaries between the new intents.

Given that utterances in task-oriented dialogue systems are short texts, we next investigate how intermediate training for sentence representations (Phang et al., 2018; Reimers and Gurevych, 2019a; Gao et al., 2021) changes the performance of FSIC

Table 4: Results for the imbalanced setup using BERT.

models. To this end, we substitute BERT with SimCSE. Table 3 shows the results. Our three main findings hold for SimCSE-based FSIC models too. Importantly, unlike with BERT, now only CE +NP trained episodically outperforms the "BE (fixed)+NP" baseline (where PLM is not fine-tuned for intent detection). This confirms the effectiveness of coupling CE and episodic training for FSIC. It also indicates that intent detection fine-tuning is well-aligned with learning sentence representations, which is why it generally brings lower gains (or no gains) over "BE (fixed) + NP", when we start from SimCSE, pretrained exactly for encoding the meaning of sentences.

5.2 Imbalanced FSIC

Table 4 shows the results on the three imbalanced datasets. CE +PA with EP again substantially outperforms all its counterparts, confirming this never-investigated FSIC configuration as a very effective approach for the FSIC task. On average, episodic training (EP) again outperforms non-episodic (NE) training. The CE + PA and BE + NP configurations generally yield higher performance when trained without splitting the support utterances from query utterances (EP vs EPSQ). This questions the common belief in episodic meta-learning that splitting episodes into support and query sets is (always) beneficial. Overall, the findings from the imbalanced datasets align well with the main findings from central experiments on balanced datasets, as reported in Table 2 and Table 3.

6 Conclusions

We shed light on factors that contribute to performance of models for few-shot intent classification (FSIC), a crucial task in modular dialogue systems. We categorize FSIC approaches across three essential dimensions: (1) the Cross-Encoder vs. Bi-Encoder encoder architectures; (2) the parameterized (i.e., trainable) vs non-parameterized utterance similarity scoring; and (3) episodic vs non-episodic training. Our extensive evaluation, encompassing seven standard FSIC datasets, reveals that the previously unexplored combination of Cross-Encoder architecture (with parameterized utterance similarity scoring) and episodic training consistently yields the best FSIC performance. We additionally find that (i) episodic meta-learning generally outperforms the non-episodic training and (ii) that the widely adopted hypothesis in meta-learning that splitting episodes into support and query sets helps generalization and boost performance may not hold for FSIC. We hope that our findings lead to more deliberation on FSIC evaluation protocols and more insightful "apple-to-apple" comparisons between competing models and model variants.

Limitations and Ethical Concerns.

In this paper, we shed light to few-shot intent classification tasks in modular (task-oriented) dialogue systems. Dialog systems, given their direct interaction with human users, must be devoid of any negative stereotypes and must not exhibit any behaviour that could be potentially harmful to humans. That said, our work does not address the generation component of dialog systems, but merely the intent classification. As such, we do not believe it raises any ethical concerns.

The main limitation of the work – conditioned primarily by the available computational resources – is the scope of our empirical comparison: we focus on FSIC methods that subscribe to pairwise similarity scoring of utterances and nearest neighbours inference. While this subsumes much of the best performing approaches in the literature, there is a fair body of recent work that does not fall in this group. Another limitation of the work is the monolingual focus on English only. We intend to extend our work to cross-lingual transfer to other languages, for which fewer labeled intent classification datasets exist.

Acknowledgements

This work has been funded by the German Research Foundation (DFG) as part of the UKP-SQuARE project (grant GU 798/29-1), by the Collaboration Lab with Nexplore “AI in Construction” (AICO) and by the European Union under the Horizon Europe grant No 101070351 (SERMAS). Abstract

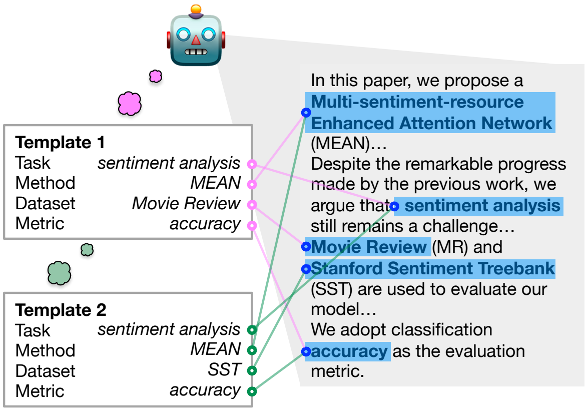
We present a novel iterative extraction model, ITERX, for extracting complex relations, or *templates*, i.e., N-tuples representing a mapping from named slots to spans of text within a document. Documents may feature zero or more instances of a template of any given type, and the task of *template extraction* entails *identifying* the templates in a document and *extracting* each template's slot values. Our imitation learning approach casts the problem as a Markov decision process (MDP), and relieves the need to use *predefined template orders* to train an extractor. It leads to state-of-the-art results on two established benchmarks – 4-ary relation extraction on SCIREX and template extraction on MUC-4 – as well as a strong baseline on the new BETTER Granular task.[1]

1 Introduction

A variety of tasks in information extraction (IE) require synthesizing information across multiple sentences, up to the length of an entire document. The centrality of document-level reasoning to IE has been underscored by an intense research focus in recent years on problems such as argument linking (Ebner et al., 2020; Li et al., 2021, *i.a.*), N-ary relation extraction (Quirk and Poon, 2017; Yao et al., 2019; Jain et al., 2020, *i.a.*), and — our primary focus — template extraction (Du et al., 2021b; Huang et al., 2021, *i.a.*).

Construed broadly, template extraction is general enough to subsume certain other document-level extraction tasks, including N-ary relation extraction. Motivated by this consideration, we propose to treat these problems under a unified framework of *generalized template extraction* (§2).[2] Figure 1 shows 4-ary relations from the SCIREX dataset (Jain et al., 2020), presented as simple templates.



Template 1
Task sentiment analysis
Method MEAN
Dataset Movie Review
Metric accuracy

Template 2
Task sentiment analysis
Method MEAN
Dataset SST
Metric accuracy

In this paper, we propose a **Multi-sentiment-resource Enhanced Attention Network** (MEAN)… Despite the remarkable progress made by the previous work, we argue that **sentiment analysis** still remains a challenge… **Movie Review** (MR) and **Stanford Sentiment Treebank** (SST) are used to evaluate our model… We adopt classification **accuracy** as the evaluation metric.

Figure 1: An example of multi-template extraction on a document (an NLP paper; Lei et al. (2018)) from the SCIREX dataset. An agent reads the entire paper and *iteratively* generates templates, each consisting of slots for `Task`, `Method`, `Dataset`, and `Metric`.

Since documents typically describe multiple complex events and relations, template extraction systems must be capable of predicting multiple templates per document. Existing approaches such as Du et al. (2021b) and Huang et al. (2021) rely on a linearization strategy to force models to learn to predict templates in a pre-defined order. In general, however, such orderings are arbitrary. Others have instead focused on the simplified problem of role-filler entity extraction (REE), which entails extracting all slot-filling entities but does not involve mapping them to individual templates (Patwardhan and Riloff, 2009; Du et al., 2021a, *i.a.*).

We present a new model for generalized template extraction, ITERX, that iteratively extracts multiple templates from a document *without* requiring a pre-defined linearization scheme. We formulate the problem as a Markov decision process (MDP, §2), where an action corresponds to the generation of a single template (§3.2), and states are sets of predicted templates (§3.3). Our system is trained via *imitation learning*, where the agent imitates a dynamic oracle drawn from an expert policy (§3.4). Our contributions can be summarized as follows:

---

[1] Code available at `github.com/wanmok/iterx`.

[2] We encourage the reader to consult Appendix A for a discussion of some important differences between generalized template extraction and traditional event extraction.

Col. Isaacs said that the guerrillas attacked the “La Eminencia” farm located near the “Santo Tomas” farm, where they burned the facilities and stole food…

He also reported that the guerrillas killed a peasant in the city of Flores, in the northern El Petén department, and burned a tank truck.

In early September, illegal border crossings by two people infected with COVID-19, triggered a week-long lockdown of another Yunnan border city, Ruili, and prompted at least eight prefectures and 25 counties to enter “wartime status.” Following the incident, Yunnan vowed to strengthen border patrols.

Twenty people have been sentenced to prison in Southwest China's Yunnan Province for crimes relating to illegal immigration from Myanmar to China during the COVID-19 pandemic, Yunnan's high people's court reported on September 28.

Figure 2: Template examples from MUC-4 (left) and BETTER Granular (right) datasets. Event triggers (e.g. *burned* above) are *not* annotated in MUC-4 and are highlighted here only for clarity.

- We show that generalized template extraction can be treated as a Markov decision process, and that imitation learning can be effectively used to train a model to learn this process without making explicit assumptions about template orderings.
- We demonstrate state-of-the-art results with ITERX on two established benchmarks for complex relation extraction: 4-ary relation extraction on SCIREX and template extraction on MUC-4.
- We introduce strong baselines for the recently introduced English BETTER Granular template extraction task.

2 Problem Formulation

We propose to treat both classic template extraction and N-ary relation extraction under a unified framework of *generalized template extraction*. Given a document $D = (w_1, \cdots, w_N)$ where each w_i is a token, we assume that some system (or model component) generates a set of candidate *mention spans* $\mathcal{X} = \{x_1, \cdots, x_M\}$, where each $x_i = D[l_i : r_i] \in \mathcal{X}$ is contiguous with left and right span boundary indices l_i and r_i.

We define a *template ontology* as a set of template types $\mathcal{T}$, where each type $t \in \mathcal{T}$ is associated with a set of slot types S_t. A *template instance* is defined as a pair $(t, \{(s_k : X_k), \cdots\})$ where $t \in \mathcal{T}$ is a template type, $s_k \in S_t$ is a *slot type* associated with t, and $X_k \subseteq \mathcal{X}$ is a subset of all mention spans extracted from the document that fills slot type s_k ($X_k = \varnothing$ indicates that slot s_k has no filler).[3] Taking Figure 2 (left) as an example, Template 1 has type $t =$ `Arson` and slots {`PerpretratorIndiv` : {“guerrillas”}, `PhysicalTarget` : {“facilities”}}.

We reduce the problem of extracting a *single* template to the problem of assigning a slot type to each extracted span $x_i \in \mathcal{X}$, where some spans may be assigned a special *null* type (ε), indicating that they fill no slot in the current template. Given this formulation, we can equivalently specify a template instance as (t, a) where a is an *assignment* of spans to slot types: $\{x_i : s_i\}_{s_i \in S_t}$. We denote the union of all slot types across all template types, along with the empty slot type ε, as $\mathcal{S} = \{\varepsilon\} \cup \bigcup_{t \in \mathcal{T}} S_t$.

With these definitions in hand, the problem of *generalized template extraction* can be stated succinctly: Given a template ontology $\mathcal{T}$, a document D, and a set of candidate mentions $\mathcal{X}$ extracted from D, generate a set of template instances $\{(t_1, a_1), \cdots, (t_K, a_K)\}$, where $t_i \in \mathcal{T}$.

As an MDP We treat generalized template extraction as a Markov decision process (MDP), where each step of the process generates one whole template instance. For simplicity, we consider the problem of extracting templates of a specific type $t \in \mathcal{T}$; extracting *all* templates then simply requires iterating over $\mathcal{T}$, where $|\mathcal{T}|$ is typically very small. This MDP $(2^{\mathcal{A}}, \mathcal{A}, E, R)$ comprises the following:[4]

- $2^{\mathcal{A}}$: the set of states. In our case, this is the set of all template generation histories. Each state $A \subseteq \mathcal{A}$ is a set of generated templates;
- $\mathcal{A}$: the set of *actions* or *assignments*: an action is the generation of a single template (an assignment of slot types to spans);
- E: the environment that dictates state transitions. Here, each transition simply adds a generated template to the set of all templates generated for the document: $E(A, a) = A \cup \{a\}$;
- $R(A, a)$: the reward from action a under the current state A.

These components are detailed in the following section. Figure 3 shows ITERX in action: the MDP

---

[3] In this work, we use *template* as an abbreviation for *template instance*, relying on the *type* vs. *instance* usage only when necessary for clarity.

[4] Our notation is consistent with prior NLP work that uses MDPs, e.g., Levenshtein Transformers (Gu et al., 2019).

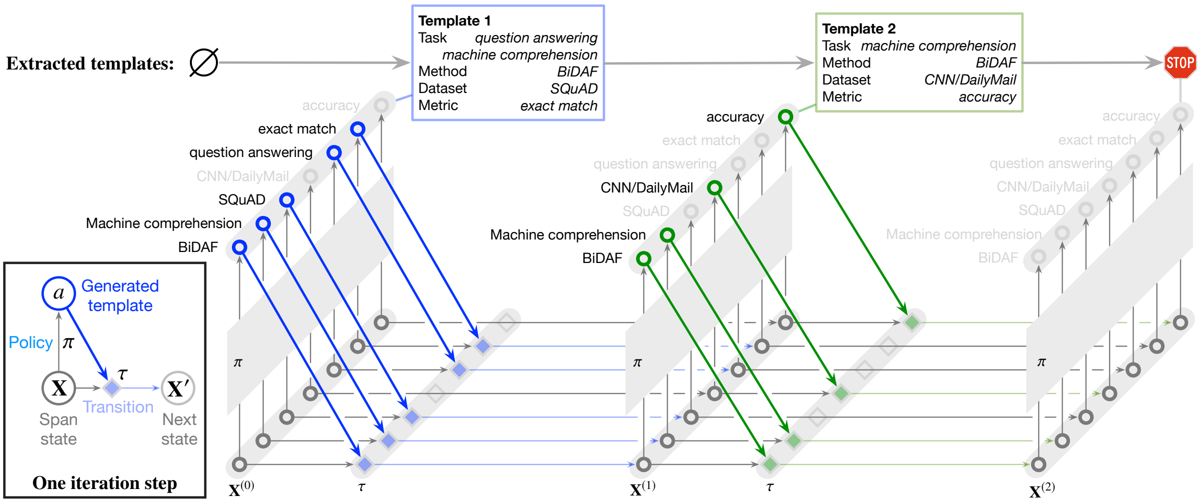

Figure 3: The basic iteration step of ITERX (left box), and an **unrolled** version on SCIREX 4-ary relation extraction (extraction of templates in the form {`Task`, `Method`, `Dataset`, `Metric`}) executed on the NLP paper *Bidirectional Attention Flow for Machine Comprehension* (Seo et al., 2017). Span embeddings ($\mathbf{X}^{(0)}$) are passed as input to the first step, where the model extracts the template {`Task`: *Machine comprehension, Question answering*; `Method`: *BiDAF*; `Dataset`: *SQuAD*; `Metric`: *Exact match*}. This information is propagated via our *memory mechanism* to the second step, and informs prediction of the next template: {`Task`: *Machine comprehension*; `Method`: *BiDAF*; `Dataset`: *CNN/DailyMail*; `Metric`: *Accuracy*}. The third step assigns the null slot type ε to all spans, indicating that the model is unable to find any further templates, thus stopping the generation process.

produces two templates sequentially, terminating on a null assignment to all input spans in $\mathcal{X}$.

3 Model

Our ITERX model is a parameterized agent that makes decisions under the MDP above: conditioned on an input document D, spans $\mathcal{X}$ extracted from D, and a specific template type t, ITERX generates a single template of type t at each step. The model consists of two parameterized components:

- **Policy π**: A policy $\pi(a \mid t, \mathbf{X})$ that generates a distribution over potential assignments of spans to slots in the current template of type t;
- **State transition model τ**: An autoregressive state encoder that maps a state (i.e., a set of predicted templates) A to a continuous representation $\mathbf{X}$ via a state transition model τ, where $\mathbf{X}^{(k+1)} = \tau(\mathbf{X}^{(k)}, a_k)$. Here the state representation $\mathbf{X} = (\mathbf{x}_1, \cdots, \mathbf{x}_M)$ comprises of a vector $\mathbf{x}_i \in \mathbb{R}^d$ for each span x_i.

ITERX generates a sequence of templates: It starts with initial state $\mathbf{X}^{(0)}$ (see Figure 3 for a running example) comprising only span representations derived from the encoder (as no templates have been predicted) and ends when no new template is generated (§3.5). ITERX is trained via imitation learning, aiming to imitate an expert policy π^* derived from reference templates.

3.1 Span Extraction and Representation

ITERX takes *spans* as input and thus relies on a span proposal component to obtain candidate spans.[5] For all experiments, we use the neural CRF-based span finder employed for FrameNet parsing in Xia et al. (2021) and for the BETTER Abstract task in Yarmohammadi et al. (2021).[6] CRF-based span finders have been empirically shown to excel at IE tasks (Gu et al., 2022).

The input document is first embedded using a pretrained Transformer encoder (Devlin et al., 2019; Raffel et al., 2020) that is fine-tuned during model training.[7] Each span $x = D[l : r]$ extracted by the span extractor is encoded as a vector $\mathbf{x}_{\text{enc}}$, which is obtained by first concatenating three vectors of dimension d: the embeddings of the first and the last tokens in the span, and a weighted sum

---

[5] Although many systems since Lee et al. (2017) that require spans as input have trained span proposal modules end-to-end, we found this to be unnecessary to obtain strong results and leave this extension for future work.

[6] The code of the span finder can be found at `github.com/hiaoxui/span-finder`. We refer the reader to these papers for further details.

[7] Different encoders are used in §4 for fair comparison with prior work. For documents exceeding maximum length $N_{\max} = 1024$, tokens are encoded in chunks of size $N_{\max}$.

of the embeddings of all tokens within the span, using a learned global query (Lee et al., 2017). This $3d$-dimensional vector is then compressed to size d using a two-layer feedforward network. Lastly, to incorporate positional information, we add sinusoidal positional embeddings based on the token-level offset of l within the document to yield $\mathbf{x}_{\text{enc}}$.

3.2 Policy: Generating a Single Template

A policy π generates a single template given span states $\mathbf{X} = (\mathbf{x}_1, \cdots, \mathbf{x}_n)$ and template type $t \in \mathcal{T}$, conditioned on the document and all of its candidate mention spans.

Since an action a represents a set of *slot type assignments* for all candidate mentions, the policy $\pi(a \mid t, \mathbf{X})$ can be factorized as

$$\pi(a \mid t, \mathbf{X}) = \prod_{(x:s)\in a} P(s|t, \mathbf{x}) \ . \qquad (1)$$

Thus we only need to model the slot type distribution for each candidate span. Here, we employ two models described below.

Independent Modeling We train a classifier that outputs a slot type (or ε) given both the template type embedding $\mathbf{t}$ and the slot type embedding $\mathbf{s}$, inspired by a standard practice in binary relation extraction (Ebner et al., 2020; Lin et al., 2020, *i.a.*). It computes the probability with a two-layer feedforward network (FFN), with slots not associated with the template type (i.e., $s \notin S_t \cup \{\varepsilon\}$) assigned 0 probability:

$$P_{\text{ind}}(s|t, \mathbf{x}) \propto \mathbf{1}_{s\in S_t\cup\{\varepsilon\}} \cdot \exp(\mathbf{s}^{\mathrm{T}} \cdot \mathrm{FFN}([\mathbf{t}; \mathbf{x}])) \quad (2)$$

where $[\cdot \ ; \ \cdot]$ denotes vector concatenation.

Joint Modeling Following Chen et al. (2020), we create a model that *jointly* considers all candidate spans given the template type. We begin by prepending $\mathbf{t}$ to the sequence of span states $\mathbf{X}$ to yield the sequence $(\mathbf{t}, \mathbf{x}_1, \cdots, \mathbf{x}_n)$. This sequence is fed to a different Transformer encoder, which naturally models interactions both between spans and between a span and the template type via self-attention (Vaswani et al., 2017):

$$(\hat{\mathbf{t}}, \hat{\mathbf{x}}_1, \cdots, \hat{\mathbf{x}}_M) = \mathrm{Transformer}(\mathbf{t}, \mathbf{x}_1, \cdots, \mathbf{x}_M) \quad (3)$$

We emphasize that the inputs to the Transformer are embeddings of *spans* (see §3.1) and not tokens, following Chen et al. (2019, 2020).[8] For each $\mathbf{x}_i$, we pass the representation $\hat{\mathbf{x}}_i$ output by the Transformer to a linear layer with output size $|\mathcal{S}|$, the total number of slot types. A softmax activation is then applied over all slot types s that are valid for t (i.e., $s \in S_t \cup \{\varepsilon\}$), with invalid types masked out, yielding the following distribution:

$$P_{\text{joint}}(s|t, \mathbf{x}) \propto \mathbf{1}_{s\in S_t\cup\{\varepsilon\}} \cdot \exp(\mathbf{s}^{\mathrm{T}} \hat{\mathbf{x}}) \qquad (4)$$

3.3 State Transition Model

A *state transition model* models the environment $E(A, a)$. Recall that a state transition just consists in the generation of a single template, where the current state A is the set of all templates that have been generated up to the current step.

Here, we propose a neural model that produces a representation of A. Specifically, we model A as a sequence of vectors $\mathbf{X}_{\text{mem}}(A) \in \mathbb{R}^{M\times d}$ — one d-dimensional state vector for each of the M candidate spans $x \in \mathcal{X}$. Each state vector $\mathbf{x}_{\text{mem}} \in \mathbb{R}^d$ acts as a *span memory*, tracking the *use* of that span across generated templates. We model state transitions using a single gated recurrent unit (GRU; Cho et al., 2014). Given the current template assignment $(x : s) \in a$ of a slot type s to a span x, the state transition for $A' = A \cup \{a\}$ is given as follows:

$$\mathbf{x}'_{\text{mem}} = \begin{cases} \mathrm{GRU}(\mathbf{x}_{\text{mem}}, [\mathbf{s} \ ; \ \hat{\mathbf{t}}]) & \text{if } s \neq \varepsilon; \\ \mathbf{x}_{\text{mem}} & \text{if } s = \varepsilon. \end{cases} \qquad (5)$$

where $\hat{\mathbf{t}}$ is a template embedding given by $\hat{\mathbf{t}} = \mathbf{t}$ when using the independent policy model given in Equation 2 and given by Equation 3 when using the joint model. Intuitively, $\hat{\mathbf{t}}$ is a summarized vector of the current template, akin to the role of the [CLS] token employed in BERT (Devlin et al., 2019). Here, we use a concatenation of the slot type embedding $\mathbf{s}$ and the template vector $\hat{\mathbf{t}}$ as the input to the state transition GRU to track the use of the span.

The input representation of a span x at each step is simply $\mathbf{x} = \mathbf{x}_{\text{enc}} + \mathbf{x}_{\text{mem}}$ — the sum of the original span embeddings $\mathbf{x}_{\text{enc}}$ described in §3.1 and the current memory vector $\mathbf{x}_{\text{mem}}$.

3.4 Policy Learning

We use *direct policy learning* (DPL), a type of imitation learning, to train our model. DPL entails training an agent to imitate the behavior of an *interactive demonstrator* as given by optimal actions a^* drawn from some expert policy π^*, a proposal

---

[8] Positional embeddings are not needed in this Transformer since sinusoidal embeddings are already added to the span representations.

distribution over actions. This expert policy is computed dynamically based on the current state of the agent, as we describe below. For this reason, the interactive demonstrator is sometimes referred to as a *dynamic oracle* (Goldberg and Nivre, 2012).

The log-likelihood of the oracle action under the ITERX *policy model is the reward.* This ensures that the learning problem can be optimized directly using gradient descent, where the objective is given by the expected reward:

$$\mathbb{E}_{\substack{a^* \sim \pi^* \\ A \sim d_{\tilde{\pi}}}} \left[\sum_{k=0}^{\infty} \gamma^k \log \pi(a^* | t, \mathbf{X}(A)) \right] \qquad (6)$$

Here, γ is a discount factor, $\tilde{\pi}$ is the *mixed* policy, and states are repeatedly sampled from their induced state distribution $d_{\tilde{\pi}}$. The mixed policy $\tilde{\pi}$ is a mixture of the expert policy and the agent's policy (Ross et al., 2011). Sampling from $\tilde{\pi}$ can thus be described as first sampling some $u \in \{0, 1\}$, then sampling from the agent's parameterized policy π if $u = 1$, or sampling an action from the dynamic oracle π^* if $u = 0$:

$$\begin{aligned} u &\sim \text{Bernoulli}(\alpha); \\ \hat{a} &\sim u\pi + (1 - u)\pi^*. \end{aligned} \qquad (7)$$

Here α, the *agent roll-out rate*, or the *agent policy mixing rate*, is a hyperparameter that controls the probability of the agent following its own policy vs. the dynamic oracle.

This process resembles *scheduled sampling* (Bengio et al., 2015), a technique commonly employed in training models for sequence generation tasks like machine translation: when updating decoder hidden states, either the gold token y^* or the predicted token $\hat{y}$ may be used, and the decision is made via a random draw. Here, the difference is that we are generating templates at each step instead of tokens.

Expert Policy We construct an expert policy based on the agent's policy. At training time, given the set of gold templates A^* and the current state A (all templates predicted thus far), the set $\bar{A} = A^* \setminus A$ contains *all gold templates not yet predicted*. Our expert policy is formulated as

$$\pi^*(a \mid t, \mathbf{X}) \propto \begin{cases} e^{\log \pi(a|t,\mathbf{X})/\beta} & \text{if } a \in \bar{A} \\ 0 & \text{if } a \notin \bar{A} \end{cases} \qquad (8)$$

where β is a temperature parameter. Intuitively, our expert policy seeks to "please" the agent: a (viable) action's probability under the expert policy is proportional to the probability under the agent's policy. Temperature β controls concentration: $\beta \to 0^+$ reduces it to a point distribution over a single action and $\beta \to \infty$ results in equal probability assigned to all remaining gold templates.

3.5 Inference

Although many search algorithms for sequence prediction can be employed (e.g. beam search, A*), we find greedy decoding to be effective, and leave further exploration for future work. Setting the initial state $A^{(0)} = \emptyset$, we take actions (i.e., generate templates) by greedy decoding $\hat{a} = \arg\max_a \pi(a \mid t, \mathbf{X})$ for every step. Decoding stops when all spans are assigned the null slot type ε in $\hat{a}$.

4 Experiments

We evaluate ITERX on three datasets: SCIREX (Jain et al., 2020), MUC-4 (Grishman and Sundheim, 1996), and BETTER Phase II English Granular.[9] SCIREX is a challenge dataset for 4-ary relation extraction[10] on full academic articles related to machine learning. MUC-4 and Granular are both traditional template extraction tasks, though they differ in important respects, which we discuss in Appendix C. For summary statistics, see Table 1.

	SCIREX			**MUC-4**			**Granular**		
	Train	Dev	Test	Train	Dev	Test	Train	Dev	Test
# documents	306	66	66	1,300	200	200	302	34	32
# templates	1,627	251	271	1,114	191	209	610	57	47
# temp. types	1			6			6		
# slot types	4			5			$92 + 4^\dagger$		

Table 1: Summary statistics of the datasets. † indicates slot types that take non-span values as fillers.

4.1 Baselines

GTT (Du et al., 2021b) To our knowledge, this is the only prior work to have attempted full template extraction in recent years, and it is thus our primary baseline for comparison on MUC-4.[11] GTT first prepends the document text with the valid template types, then passes the result to a BERT

---

[9] `https://ir.nist.gov/better`.

[10] SCIREX also contains a binary relation extraction task, but the binary relation is a subrelation of the 4-ary relation, and thus is subsumed by the more difficult task.

[11] We were unfortunately unable to obtain reasonable performance with GTT on SCIREX, and so do not compare ITERX and GTT on this task.

encoder. A Transformer decoder (whose parameters are shared with the encoder) then generates a linearized sequence of template instances.

TempGen (Huang et al., 2021) This is the current state-of-the-art system for REE (the simplified slot-filling entity extraction task) on MUC-4. On SciREX, TempGen may output multiple relation instances, but only one canonical mention as the filler for each role in the relation. On MUC-4, TempGen outputs a single aggregate template per document, but allows multiple spans to fill a template slot. We make minimal modifications to the TempGen source code to support multi-filler, multi-template prediction on both datasets, allowing for direct comparison to IterX and GTT on full template extraction.

4.2 Metrics

The standard metric for template extraction and REE on MUC-4 is CEAF-REE, proposed in Du et al. (2021a) and then used in Du et al. (2021b) and Huang et al. (2021).[12] CEAF-REE is based on the CEAF metric (Luo, 2005) for coreference resolution, that computes an alignment between gold and predicted entities that maximizes a measure of similarity ϕ between aligned entities (e.g. CEAF$_{\phi_4}$ in coreference resolution). This alignment is subject to the constraint that each reference entity is aligned to at most one predicted entity.

The CEAF-REE *implementation* (henceforth, CEAF-REE$_{\text{impl}}$) employed in Du et al. (2021a,b) and Huang et al. (2021) unfortunately departs from the stated metric *definition* (CEAF-REE$_{\text{def}}$) in two ways: (1) it eliminates the constraint on entity alignments and (2) it treats the template *type* as an additional slot when reporting cross-slot averages. For maximally transparent comparisons to prior work, we report scores under both CEAF-REE$_{\text{def}}$ and CEAF-REE$_{\text{impl}}$, obtaining state-of-the-art results on MUC-4 with each.

However, we argue that neither CEAF-REE$_{\text{def}}$ nor CEAF-REE$_{\text{impl}}$ is consistent with historical evaluation of template extraction systems. CEAF-REE$_{\text{def}}$ errs in enforcing the entity alignment constraint: doing so effectively requires systems to perform coreference resolution, which is too strict and runs contrary to the original MUC-4 evaluation. By contrast, CEAF-REE$_{\text{impl}}$ also errs in treating the template type as just another slot: this elides the important distinction between the *kind* of event being described and the participants in that event (§6).

In the interest of clarity, we define a modified version of the CEAF-REE metric that avoids both pitfalls: it relaxes the entity alignment constraint and it does not include template type in cross-slot averages. We call this version CEAF-R**M**E, where "M" stands for *mention* and emphasizes the focus on mention-level rather than entity-level ("E") scoring. Intuitively, relaxing this constraint amounts to placing the burden of coreference resolution on the metric: if the scorer aligns two predicted mentions to the same reference entity, the mentions are implicitly deemed coreferent. See Figure 4 for a comparison among these variants.[13]

For SciREX, we report CEAF-REE$_{\text{def}}$ and CEAF-RME. For BETTER Granular, we use its official metrics, described in Appendix D.

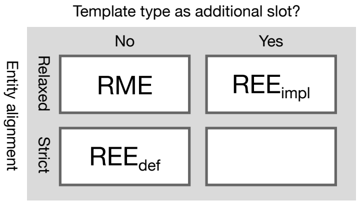

Figure 4: A comparison of the metrics discussed.

4.3 Results

SciREX For TempGen, we report models trained with BART$_{\text{base}}$ and BART$_{\text{large}}$, where only BART$_{\text{base}}$ was used in Huang et al. (2021). While BART is an encoder-decoder architecture, IterX uses only the encoder part, and thus requires about half the pretrained parameters that TempGen does.[14] Even with far fewer parameters, IterX outperforms the BART$_{\text{large}}$ baseline by a wide margin. Moreover, our best performing model under T5$^{\text{enc}}_{\text{large}}$ (Raffel et al., 2020) achieves roughly 2× the performance of TempGen[15] (see Table 2).

MUC-4 Under the most comparable setting, IterX outperforms GTT under all metrics by 1–2%, both using BERT$_{\text{base}}$ (Table 2). With T5$^{\text{enc}}_{\text{large}}$, IterX obtains even better performance, with most

---

[12] The standard metrics for template extraction may be unfamiliar to IE researchers more accustomed to sentence-level *event extraction*. Accordingly, we thoroughly motivate and describe all template extraction metrics we use in this work in Appendix D. What follows is a more abridged discussion.

[13] See `github.com/wanmok/iterx` for implementations.

[14] We add the superscript "enc" to pretrained models to denote the use of the encoder only (decoder discarded): T5$^{\text{enc}}_{\text{large}}$.

[15] Replacing BART with T5 in TempGen would have mandated destructive modifications to the pretrained architecture, and we therefore do not report results under this setting.

Model (Encoder)	SciREX						MUC-4								
	CEAF-REE$_{\text{def}}$			CEAF-RME			CEAF-REE$_{\text{def}}$			CEAF-REE$_{\text{impl}}$			CEAF-RME		
	P	R	F$_1$	P	R	F$_1$	P	R	F$_1$	P	R	F$_1$	P	R	F$_1$
TempGen (BART$_{\text{base}}$)	8.7	5.0	6.4	8.6	8.2	8.4	54.2	15.8	24.5	55.7	40.0	46.4	58.3	31.0	40.5
TempGen (BART$_{\text{large}}$)	19.9	5.0	8.0	8.9	22.3	12.7	**55.8**	18.9	28.3	**63.7**	37.4	47.2	**61.3**	32.9	42.8
GTT (BERT$_{\text{base}}$)	-	-	-	-	-	-	54.7	23.0	32.3	61.7	42.4	50.2	55.0	36.8	44.1
IterX (BERT$_{\text{base}}$)	16.2	7.6	10.4	16.2	17.4	16.8	41.3	**27.9**	33.3	52.3	**51.1**	51.7	47.2	**45.0**	46.1
IterX (BART$^{\text{enc}}_{\text{base}}$)	15.0	**15.0**	15.0	14.3	35.4	20.3	39.2	24.8	30.4	49.8	45.7	47.6	44.8	40.1	42.3
IterX (T5$^{\text{enc}}_{\text{large}}$)	**26.4**	12.4	**16.9**	**25.0**	**40.6**	**31.0**	53.5	26.2	**35.2**	60.9	46.9	**53.0**	55.8	42.4	**48.2**

Table 2: Results on SciREX and MUC-4.

gains coming from increased precision.[16] Furthermore, we note a consistent gap of > 5% F$_1$ between CEAF-RME and CEAF-REE$_{\text{impl}}$, which we suspect is due to CEAF-REE$_{\text{impl}}$'s inclusion of scores for template type into the aggregated slot F$_1$: as template type scores are higher across models than slot type scores, they are liable to inflate the aggregate score.

BETTER Granular We report scores on the English-only Phase II BETTER Granular task using the official BETTER scoring metric in Table 3. Given the complexity of the Granular task, the accompanying difficulty of developing models to perform it, and the lack of existing work on Granular, we report scores only for IterX under T5$^{\text{enc}}_{\text{large}}$. We intend these to serve as a solid baseline against which future work may be measured.

Template			Slot			Combined
P	R	F$_1$	P	R	F$_1$	
89.7	74.5	81.4	41.0	33.5	36.9	30.0

Table 3: Results on the BETTER Granular dataset. Combined score is Template F1 × Slot F1.

5 Analysis

We next conduct ablations to examine how specific aspects of IterX's design affect learning. Here, we focus on SciREX as a case study, as it has the highest average templates per document of the three datasets, allowing us to best investigate the behavior of IterX over long action sequences.

Recall that the dynamic oracle specifies an expert policy π^* (Equation 8) from which expert actions a^* are drawn. One design decision concerns the *agent roll-out rate*, α, which controls how often we draw from the expert policy vs. the agent policy when making updates. Another decision concerns how *entropic* this policy distribution should be, controlled by the temperature β. Both decisions reflect a trade-off between exploration and exploitation in the space of action sequences.

Agent Roll-out Rate α We show how model performance changes as we increase the agent roll-out rate $\alpha \in [0, 1]$ in Figure 5, where $\alpha = 0$ to always following the expert policy, and $\alpha = 1$ corresponds to always updating based on the agent's own policy. The model performs poorly under low α, but improves quickly as α increases, reaching a plateau past $\alpha \geq 0.5$. The results are intuitive, as relying more on the expert (lower α) for learning would result in a fixed and deterministic set of states that may hinder the agent from visiting new states, which are often encountered at test time. With higher α, the agent's behavior is more consistent between train and test time.

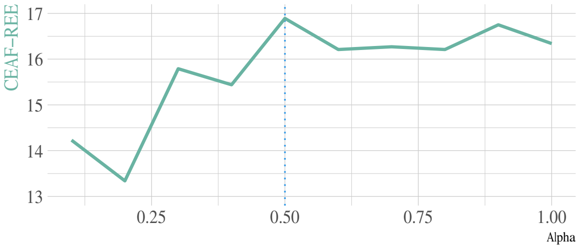

Figure 5: Performance changes on CEAF-REE$_{\text{def}}$ with respect to α, for which higher means higher probability of rolling out agent's policy for state update.

Temperature β We compare the following four settings for sampling from π^*, keeping $\alpha = 0$ to control for effects of policy mixing:

- Fixed: Select the next template in the document based on the order as is given in the dataset. In this case, β does not come into play. This setting corresponds to the standard practice of using

---

[16] For GTT, we directly use the output files included in the codebase of Du et al. (2021b). However, we were unsuccessful in adapting their codebase ourselves to make use of T5.

fixed template linearizations (Du et al., 2021b; Huang et al., 2021).

- $\beta \to 0^+$ (ARGMAX): Select the template that maximizes the likelihood with the system-predicted distributions over slots.
- $\beta = 1$ (XENT): Sample a template according to the distribution defined by the cross entropy between references and predictions.
- $\beta \to \infty$ (UNIFORM): Sample a template uniformly from the correct template set.

Test set performance for each setting is shown in Table 4. The results for CEAF-RME show a trade-off in precision and recall corresponding to the exploitation-exploration trade-off induced by β, with the higher β (more exploration) of XENT and UNIFORM, yielding higher recall. The trend for CEAF-REE is similar, though less pronounced.

Approach	**CEAF-REE$_{\text{def}}$**			**CEAF-RME**		
	P	R	F_1	P	R	F_1
FIXED	28.7	7.3	11.7	29.9	29.9	29.9
ARGMAX	26.4	6.9	11.0	29.4	30.2	29.8
XENT	28.7	10.7	15.6	27.8	32.3	29.9
UNIFORM	29.1	11.3	16.3	27.6	32.0	29.7

Table 4: Results with different choices of temperature.

Interestingly, while CEAF-RME F_1 scores are consistent across settings, CEAF-REE F_1 scores are higher under higher temperature settings. To the extent that the more entropic settings conduce to higher template and mention recall, we would expect these settings to yield more partial-credit template alignments than non-random settings, which tend to focus on correct prediction of fewer templates — thus potentially missing templates entirely and receiving no partial credit.

6 Related Work

Template Extraction The term *template extraction* was originally proposed in the Message Understanding Conferences (MUC; Sundheim, 1991, *i.a.*) to describe the task of extracting templates from articles. Researchers later focused more heavily on sentence-level IE, especially after the release of the ACE 2005 dataset (Walker et al., 2006). But following renewed interest in document-level IE, researchers (Du et al., 2021b; Huang et al., 2021; Gantt et al., 2022, *i.a.*) have begun to revisit MUC and to develop new template extraction datasets (notably, BETTER Granular).

Traditionally, template extraction comprises two sub-tasks: *template identification*, in which a system identifies and types all templates in a document, and *slot filling* or *role-filler entity extraction* (REE), in which the slots associated with each template are filled with extracted entities. Much recent work in this domain has turned away from the full task, focusing only on REE, which is tantamount to assuming that there is just a single *aggregate* template per document (Patwardhan and Riloff, 2009; Huang and Riloff, 2011, 2012; Du et al., 2021a; Huang et al., 2021).

Document-Level Relation Extraction Alongside template extraction, there has been considerable recent interest within IE in various challenging document-level relation extraction objectives, beyond the longstanding and dominant focus on coreference resolution. *Argument linking* — a generalization of semantic role labeling (SRL; Gildea and Jurafsky, 2002) in which a predicate's extra-sentential arguments must also be labeled — is one notable example, and has attracted recent attention through the RAMS (Ebner et al., 2020) and WikiEvents (Li et al., 2021) benchmarks.[17] Prior benchmarks on this task include SemEval 2010 Task 10 (Ruppenhofer et al., 2010), Beyond Nombank (Gerber and Chai, 2010), ONV5 (Moor et al., 2013), and Multi-sentence AMR (O'Gorman et al., 2018). A separate line of work has concentrated on general *N-ary relation extraction* challenge tasks, in which entities participating in the same relation may be scattered widely throughout a document. Beyond SCIREX, PubMed (Quirk and Poon, 2017; Peng et al., 2017) and DocRED (Yao et al., 2019) are two other prominent benchmarks in this area.

Imitation Learning Our approach casts the problem of generalized template extraction as a Markov decision process. SEARN (Daumé III et al., 2009) and other related work (Ross et al., 2011; Venkatraman et al., 2015; Chang et al., 2015, i.a.) have considered structured prediction under a reinforcement learning setting. Notably, in dependency parsing, Goldberg and Nivre (2012) proposed the use of a *dynamic oracle* to guide an agent toward the correct parse (see §3.4).

---

[17] Argument linking also goes by the names *event argument extraction* and *implicit semantic role labeling*, though these terms are not precisely equivalent.

We also employ direct policy learning for optimization of the template extraction MDP, thus reducing the problem to one of supervised sequence learning that is amenable to gradient descent. Such treatment is reminiscent of other similar techniques in NLP. Scheduled sampling (Bengio et al., 2015), for instance, trains a sequence generator with an expert policy consisting of a mixture of the predicted token and the gold token. Relatedly, Levenshtein Transformers (Gu et al., 2019) learn to edit a sequence by imitating an expert policy based on the Levenshtein edit distance.

7 Conclusion

We have presented ITERX, a new model for generalized template extraction that iteratively generates templates via a Markov decision process. ITERX demonstrates state-of-the-art performance on two benchmarks in this domain — 4-ary relation extraction on SCIREX and template extraction on MUC-4 — and establishes a strong baseline on a third benchmark, BETTER Granular. In our experiments, we have also shown that imitation learning is a viable paradigm for these problems. We hope that our findings encourage future work to confront the challenge of dealing with documents that describe *multiple* complex events and relations head-on, rather than veiling this difficulty behind simplified task formulations.

8 Limitations

Although we believe our iterative extraction paradigm to be promising, we acknowledge that this work is not without limitations. First, ITERX features a significant number of hyperparameters. We found that these generally required some effort to tune for specific datasets, and that there was no single configuration that was uniformly the best across domains. We showed the impact of manipulating some of these hyperparameters in §5. Second, our ITERX implementation iterates over all template types in the template ontology during training and inference, which means that runtime grows linearly in the number of template types. While our framework could in principle support template *type* prediction as well (which would reduce this to $O(1)$), it does not do so in practice, and hence runtime may be long for large ontologies. However, we again stress that actual template ontologies tend to be small.

A Terminology

Information Extraction is rife with vague and competing terms for similar concepts, and we recognize some hazard in introducing *generalized template extraction* (GTE) into this landscape. To head off possible confusion, we highlight two important differences between this problem and the well established problem of *event extraction* (EE).

First, EE requires identifying *lexical* event triggers, whereas GTE does not, as template instances do not necessarily have one specific lexical anchor. A document describing a terrorist attack may only *explicitly* describe a series of bombings, and a document describing an epidemic may only *explicitly* state that thousands of people have contracted a particular disease. This property holds of all three datasets we focus on, and can be seen in both Figure 1 and Figure 2. Template anchors are not annotated either for MUC-4 or for SciREX. And while they are annotated for BETTER Granular, they do not factor into scoring. This contrasts with major EE datasets, such as ACE or PropBank, for which typed lexical triggers *must* be extracted.

Second, we take GTE to be a fundamentally document-level task: templates concern events described over an entire document. In practice, EE has historically referred to extraction of predicate-argument structures within a single sentence. One could conceivably argue that this usage has begun to change with the recent interest in argument linking datasets like RAMS (Ebner et al., 2020) and WikiEvents (Li et al., 2021), in which arguments may appear in different sentences from the one containing their predicate. Even so, these cross-sentence arguments are still arguments *of a particular predicate*, *in a particular sentence*. Moreover, the overwhelming majority of arguments in these datasets are sentence-local (Ebner et al., 2020). As emphasized above, templates are not necessarily anchored to particular lexical items. For this reason, they also do not necessarily exhibit the level of locality one finds in EE.

These differences are what motivate the use of CEAF-REE as an evaluation metric, in contrast to the precision, recall, and F1 scores for events and arguments that are typically reported for EE. In brief, it simply is not possible to compute these for GTE in the same way as they are computed for EE. We elaborate on this point in Appendix D.

B Model Training and Hyperparameters

We implemented our models in PyTorch (Paszke et al., 2019) and AllenNLP (Gardner et al., 2018). We trained all our models with a single NVIDIA RTX6000 GPU. For all experiments that reproduce prior works, we trained models until full convergence under the patience settings provided in the publicly released code. For all IterX models, we trained and tuned hyperparameters under our grid's limit of 24 hours per run, with which we were able to obtain solid performance on all datasets. We performed hyperparameter search manually and report the best performing hyperparameters and the bounds we searched in Table 5, Table 6, and Table 7.

C Dataset Details

C.1 MUC-4

The MUC-4 dataset features a total of 1,700 English documents (1,300 for train and 200 each for dev and test) concerning geopolitical conflict and terorrism in South America. Documents are annotated with templates of one of six kinds — `Attack`, `Arson`, `Bombing`, `Murder`, `Robbery`, and `ForcedWorkStoppage` — and may have multiple templates (often of the same type) or no templates at all. All templates contain the same

slots. While the original data contains numerous slots, it has become standard practice to evaluate systems on just five of these (apart from the slot for the template's type), all of which take entity-valued fillers: `Perpetrator(Individual)`, `Perpetrator(Organization)`, `Victim`, `Weapon`, and `Target`.

C.2 BETTER Granular

The BETTER Granular dataset contains documents spanning a number of domains, and, like MUC-4, focuses on six types of complex event, though covering different topics: protests, epidemics, natural disasters, acts of terrorism, incidents of corruption, and (human) migrations. However, Granular is substantially more difficult than MUC-4 in several ways. First, each template type is associated with a *distinct* set of slots. Second, only some of the slots take entities as fillers, whereas others take events, boolean values, or one of a fixed number of strings. Finally, the formal evaluation setting for Granular — which we do not adopt in this paper — is zero-shot and cross-lingual: systems trained only on English documents are evaluated exclusively on documents in a different target language.[18] The data used in our experiments is English-only and comprises the “train,” “analysis,” and “devtest” splits from Phase II of the BETTER program, for which the target language is Farsi.

C.3 SCIREX

The 4-ary SCIREX relation extraction task seeks to idenfity entity 4-tuples that describe a `metric` used to evaluate a `method` applied to an ML `task` as realized by a specific `dataset` — e.g. (*span F1*, *BERT*, *SRL*, *ACE 2005*). The challenge of SCIREX lies not only in these pieces of information tending to be widely dispersed throughout an article, but also in the fact that only tuples describing *novel* work presented in the paper (and not merely *cited* work) are labeled as gold examples. Following Huang et al. (2021), we frame this as a template extraction task, treating each 4-tuple as a template with four slots.

D Model Evaluation Details

A key consideration that arises in evaluating generalized template extraction is the need to align predicted and reference templates: a given predicted template may be reasonably similar to multiple different reference templates, and one must decide on a *single* template to use as the reference for each predicted one. Generalized template extraction is similar in this respect to coreference resolution, in

---

[18] Systems are permitted to use machine-translated versions of this documents, but gold data in the target language is prohibited.

which predicted *entities* may (partially) match multiple reference entities, and one must determine a ground truth alignment. Importantly, this consideration also renders metrics that are traditionally reported for *event extraction* — namely, event and argument precision, recall, and F1 — inappropriate. This is because event extraction is fundamentally a span labeling problem, and the identity of the appropriate reference span is always clear for a given predicted span: either a reference span with the same boundary and type exists or it does not. By contrast, the mapping from prediction to reference for templates is only this transparent in cases of perfectly accurate predictions.

All the evaluation metrics presented in this appendix are, at base, minimal extensions of precision, recall, and F1 to cases where event alignments are both necessary and non-trivial. For CEAF-REE in particular, the various versions of the metric that we discuss (CEAF-REE, CEAF-RME, and Du-CEAF-RME) merely reflect differences in how this alignment should be performed and whether the template type should be treated in the same way as slot types for reporting purposes.

D.1 MUC-4

MUC-4 evaluation presents a special challenge, owing to its long and complicated history, and to terminological confusion.[19] Here, we discuss CEAF-REE (Du et al., 2021a), the current standard metric for MUC-4 evaluation. We begin with definitions, following with a discussion of some of its problems, and conclude with an extended presentation of our CEAF-RME variant, introduced in §4.

D.1.1 CEAF and CEAF-REE: Definitions

The CEAF-REE metric, introduced by Du et al. (2021a), has since been adopted as the standard evaluation metric for MUC-4 (Du et al., 2021b; Huang et al., 2021). To our knowledge, no official scoring script has ever been released for MUC-4, although the metrics used as part of the original evaluation are described in detail in Chinchor (1992). CEAF-REE does not attempt to implement these original metrics, but is rather a lightly adapted version of the widely used CEAF metric for coreference resolution, proposed in Luo (2005).[20] CEAF computes an alignment between reference ($\mathcal{R}$) and system-predicted ($\mathcal{S}$) entities, with each entity represented by a set of coreferent mentions, and with the constraint that each predicted entity is aligned to *at most* one reference entity. This is treated as a maximum bipartite matching problem, in which one seeks the alignment that maximizes the sum of an entity-level similarity function $\phi(R, S)$ over all aligned entities $R \in \mathcal{R}$ and $S \in \mathcal{S}$ within a document. In principle, CEAF is agnostic to the choice of ϕ, though it is generally desirable that $\phi(R, S) = 0$ when $\nexists x \in S$ such that $x \in R$ and that $\phi(R, S) = 1$ when $R = S$, for reasons described in Luo (2005). In practice, the ϕ_4 similarity function is most commonly used, defined as the Dice coefficient (or F1 score) between R and S:

$$\phi_4 := \frac{2|R \cap S|}{|R| + |S|} \tag{9}$$

The version of CEAF that uses ϕ_4 is sensibly denoted CEAF$_{\phi_4}$, or sometimes CEAF$_e$ (*e* for *entity*). CEAF-REE differs from CEAF$_{\phi_4}$ in the following two ways:

- All entities are aligned *within role, conditioned on matching template type*. E.g. only predicted entities for the `Victim` slot in `Bombing` templates would be considered valid candidates for alignment with entities filling the `Victim` slot in the reference templates of the same type.

- A binary similarity function ϕ_{REE} is used, defined as follows:

$$\phi_{\text{REE}}(R, S) := \begin{cases} 1, & \text{if } S \subseteq R \\ 0, & \text{otherwise} \end{cases} \tag{10}$$

D.1.2 CEAF-REE: Problems and Solutions

Our principal concerns with CEAF-REE lie with how it has so far been reported and implemented, and with challenges in extending it to the full template extraction task, in which multiple templates of the same type may be present in a document. We elaborate on two issues discussed briefly in §4 and also introduce a third.

First, previous work that reports CEAF-REE treats the template type merely as another slot, with template type labels treated as special "entities" that may fill this slot. This is not necessarily problematic in itself: template type-level metrics are valuable for evaluating system performance. However, it is problematic when reporting (micro

---

[19] Early writing on MUC-4 used the term *entity* to refer to what the IE community would now call a *mention*. We suspect this is the source of a great deal of confusion.

[20] Luo's motivations for proposing CEAF actually derive in large part from observed shortcomings with the original MUC-4 F1 score. See Luo (2005) for details.

or macro) average CEAF-REE figures *across* slots, as these works do. This is because incorporating the scores for template type into the average elides the distinction between roles (slots) and the kind of event being described (the template type). Moreover, the alignment between slot-filling entities is also *already* conditioned on a match between the template types. There are thus two distinct ways in which information about a system's predictive ability with respect to template type end up in a slot-level average CEAF-REE score. This results in reported values that are very difficult to interpret, and potentially misleading to the extent that these features of CEAF-REE implementations are not made apparent in writing.

Second, the constraint that at most one predicted entity be aligned to each reference entity — stipulated in the metric definition (CEAF-REE$_{\text{def}}$) — is not enforced in the implementation (CEAF-REE$_{\text{impl}}$). Practically, this means that the alignment shown in Figure 6 would receive full credit, whereas it ought to receive a precision score of only 0.75, as Du et al. (2021a) describe. As we argue in §4, we believe this constraint to be overly strict. But this point aside, the discrepancy between definition and implementation is clearly troubling in itself.

Third, full template extraction introduces a *second* maximum bipartite matching problem, which requires aligning predicted and reference *templates* of the same type, and which CEAF-REE (either CEAF-REE$_{\text{def}}$ or CEAF-REE$_{\text{impl}}$) is not natively equipped to handle, given that it operates at the level of slots. Du et al. (2021b) reports CEAF-REE for GTT under an optimal template alignment, but this is obtained via brute-force, enumerating and evaluating every possible alignment, including those between templates of different types. The similarity function, (call it $\phi_{\text{TEMPLATE}}(T_R, T_S)$) that they use for the template alignment problem is *itself* the cross-slot average CEAF-REE$_{\text{impl}}$ score for predicted template T_S and reference template T_R. This brute-force template alignment, in conjunction with the hierarchical maximum bipartite matching problem, results in prohibitively long scorer execution times in cases where there is only a modest number of predicted or reference templates of the same type.[21]

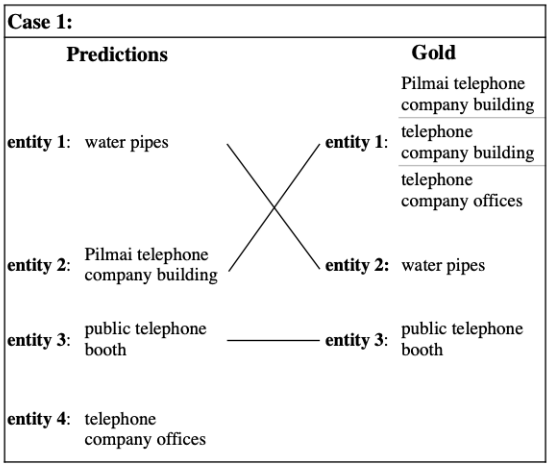

Figure 6: An example alignment between predicted and reference entities from Du et al. (2021a). In past implementations of CEAF-REE, this alignment would receive full credit, rather than being penalized for precision ($P = 0.75$).

In addition to our implementation of CEAF-RME (see below), we also present the first *correct* implementation of CEAF-REE$_{\text{def}}$ that fully addresses the first two points above: template types are no longer treated as additional slots and the entity-level alignment constraint is enforced. On the third point, our implementation efficiently computes optimal template alignments using the Kuhn-Munkres algorithm (Kuhn, 1955; Munkres, 1957). However, even with this efficient implementation, solving such hierarchical maximum bipartite matching problems is computationally intensive.

D.1.3 Coreference and CEAF-RME

As CEAF was designed for coreference, it is perhaps unsurprising that coreference considerations introduce a further wrinkle for CEAF-REE. None of the three models described in this work (including ITERX) performs entity coreference. This clearly presents a problem because CEAF-REE$_{\text{def}}$ is an entity-level metric. One way to score these models is simply to treat each extracted mention as a singleton entity and use CEAF-REE$_{\text{def}}$ exactly as defined, and we report these scores in the main text. However, reporting *only* CEAF-REE$_{\text{def}}$ would be undesirable for several reasons:

- It would render our results incomparable to past work, which reports only CEAF-REE$_{\text{impl}}$.
- It would put our work at odds with the overwhelming majority of the template extraction literature, where evaluation criteria focus on string

---

[21] Only CEAF-REE$_{\text{def}}$ requires solving a two-level maximum-bipartite matching problem. Since CEAF-REE$_{\text{impl}}$ does not enforce the entity alignment constraint, these alignments will not necessarily be bipartite.

matching between predicted and reference *mentions*. (The original MUC-4 evaluation only required systems to extract a single representative mention for each entity — not to identify all such mentions.)

- The constraint that at most one predicted entity be aligned to a given reference entity would yield punishingly low scores for systems that are highly effective at extracting relevant spans, but that simply do not perform the additional step of coreference. It is also not especially relevant for certain benchmarks, like SCIREX, where coreference is less central to the task.

For these reasons, we disfavor a template extraction metric that *requires* template extraction systems to do coreference. These considerations motivate our introduction of CEAF-RME (*role-filler mention extraction*) — that makes a minimal modification to CEAF-REE$_{\mathrm{def}}$ to address (1) and (2) above. CEAF-RME treats system-predicted mentions as singleton entities, but *deliberately* relaxes the alignment constraint, potentially allowing multiple predicted singletons to map to the same reference entity, effectively pushing the burden of coreference into the metric. We believe CEAF-RME is consistent with what template extraction research has *in fact* historically cared about (identifying *mentions* that fill some slot) while correcting implementation problems with CEAF-REE that produce misleading results.

The micro-average CEAF-RME results that we report on MUC-4 in the main body of the paper are micro-average CEAF-RME scores *under an optimal template alignment* (using CEAF-RME as the template similarity function), which is efficiently obtained using the Kuhn-Munkres algorithm.

D.2 SCIREX

We use the same CEAF-RME implementation for scoring SCIREX as we use for MUC-4. We simply treat the SCIREX 4-tuples as 4-slot templates, following (Huang et al., 2021). Since SCIREX 4-ary relations are untyped, all SCIREX "templates" are similarly untyped for scoring purposes.

D.3 BETTER Granular

Evaluation for the BETTER Granular task bears some core similarity to CEAF-REE$_{\mathrm{def}}$ in that relies on obtaining the alignment between system and reference templates that maximizes some similarity function that decomposes over slot fillers. And just as with (our corrected implementation of) CEAF-REE$_{\mathrm{def}}$, this is achieved via the Kuhn-Munkres algorithm. However, Granular scoring differs from CEAF-REE$_{\mathrm{def}}$ in four key respects. First, the overall system score — referred to as the *combined score* — incorporates both a slot-level F1 score *and* a template-level F1 score:

$$\text{CombinedScore} := \text{TypeF1} \times \text{SlotF1}$$

Only exact matches between system and reference templates types are awarded credit. It is worth noting that because this score does not decompose over template pairs, it cannot be optimized directly using Kuhn-Munkres. In practice, what is optimized is *response gain* — the number of correct slot fillers minus the number of incorrect ones — which provably yields alignments that optimize the combined score within a probabilistic error bound.

The remaining three key differences relate to the calculation of the slot-level F1. For one, Granular slots are not exclusively entity-valued, but may also be event-, (mixed) event-and-entity-, boolean-, and (categorical) string-valued, and different similarity functions must be employed in these different cases. For another, where CEAF-REE defines mentions by their string representation, the Granular score defines mentions based on document offsets. Finally, Granular also requires extraction of temporal and irrealis information for slots, and this in turn impacts the SlotF1 score.

Borrowing terminology from the discussion of MUC-4 above, we describe below how $\phi(R, S)$ is calculated for some generic reference slot filler R and system-predicted slot filler S for slots of different types.

Boolean and Categorical Values For boolean- and categorical-string valued slots (i.e., slots taking on one of a predefined set of values). $\phi(R, S) = 1$ if there is an exact match between the system and reference fillers and is 0 otherwise.

Entities Unique among the three tasks discussed in this paper, Granular features an explicit preference for *informative* arguments in its scoring structure. In particular, (proper) *name* mentions of an entity are worth more than *nominal* mentions, which in turn are worth more than *pronominal* ones.[22] Thus, if Barack Obama were represented by the reference entity $\{Obama, the\ former\ President, he\}$,

---

[22] This is precisely the hierarchy described for the *informative argument extraction* task in Li et al. (2021).

full credit would be awarded for returning only the mention *Obama*, less credit for *the former President*, and still less for *he*. Exact point values depend on the mentions present in the reference entity:

- Correct name mentions always receive full credit ($\phi(R, S) = 1$)
- Correct nominal mentions receive half-credit ($\phi(R, S) = 0.5$) if the reference entity additionally contains a name mention, and receive full credit otherwise.
- Correct pronominal mentions receive quarter-credit ($\phi(R, S) = 0.25$) if the reference entity additionally contains *both* a name and a nominal mention, and half-credit if only a nominal mention is featured. (Note that entities will never feature only pronominal mentions.)

Events Some Granular slots require *events* as fillers. Like entities, events are represented as sets of mentions (event *anchors* or *triggers*). Unlike entities, there is no informativity hierarchy for events. Furthermore, while event coreference is not a part of the Granular task, annotations for event coreference are nonetheless provided for scoring purposes: $\phi(R, S) = 1.0$ iff S contains only mentions belonging to events in the set of gold coreferent events R, and is 0 otherwise, akin to ϕ_{REE}.

Mixed Entities and Events Some slots may take a mix of events and entities as fillers. Since systems must indicate whether predicted mention clusters are entity- or event-denoting, the same similarity criteria for events and entities as described above are used to compute ϕ for events and entities that fill these slots.

Temporal and Irrealis Information One of the features of Granular that makes it decidedly more difficult than either MUC-4 or SciREX is the requirement to extract information relating to the time and irrealis status of an event when such information is available in the document. This information is encapsulated in special `time-attachments` and `irrealis` fields associated with each slot-filling entity or event. The former is given as a set of temporal expressions that describe the time at or during which the filler satisfied the role denoted by the slot (e.g. when individuals filling the `tested-count` slot in the Epidemic template were tested for the disease). The latter is given as one of a set of strings that describe whether or how the filler satisfied the role denoted by the slot: `counterfactual`, `hypothetical`, `future`, `unconfirmed`, `unspecified`, and `non-occurrence`. `time-attachments` and `irrealis` are each worth 0.25 points, where exact matches are required for full credit on either and where zero points are awarded otherwise. For slots for which `time-attachments` and `irrealis` are required, the value of ϕ appropriate to its filler type is scaled by 0.5 such that the maximum overall score $\phi(R, S)$ for a given filler — factoring in `time-attachments`, `irrealis`, *and* event or entity similarity — is 1.

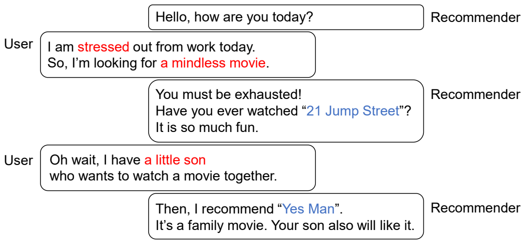
Abstract

Conversational recommender systems (CRSs) capture a user preference through a conversation. However, the existing CRSs lack capturing comprehensive user preferences. This is because the items mentioned in a conversation are mainly regarded as a user preference. Thus, they have limitations in identifying a user preference from a dialogue context expressed without preferred items. Inspired by the characteristic of an online recommendation community where participants identify a context of a recommendation request and then comment with appropriate items, we exploit the Reddit data. Specifically, we propose a **C**ontrastive **L**earning approach for **I**njecting **C**ontextual **K**nowledge (**CLICK**) from the Reddit data to the CRS task, which facilitates the capture of a context-level user preference from a dialogue context, regardless of the existence of preferred item-entities. Moreover, we devise a relevance-enhanced contrastive learning loss to consider the fine-grained reflection of multiple recommendable items. We further develop a response generation module to generate a persuasive rationale for a recommendation. Extensive experiments on the benchmark CRS dataset show the effectiveness of CLICK, achieving significant improvements over state-of-the-art methods.

1 Introduction

Recommender systems help users find potential items of interest in the rapidly expanding pool of candidates. To do so, the recommender systems aim to accurately identify user preferences. Thus, traditional recommender systems (Guo et al., 2020) utilize click or purchase data to obtain user preferences. However, such traditional approaches lack dynamically modeling user preferences since the data has a temporal validity and does not offer a diverse clue to user information. Conversational recommender system (CRS) is a research area that overcomes the limitation of the traditional recommender systems by capturing users' interests through natural conversation. The conventional CRSs (Chen et al., 2019; Ma et al., 2021; Zhou et al., 2020a) mainly derive a user preference from item-entities, which appear in a conversation and exist in a knowledge graph (KG). However, users often express their preferences without preferred items. For example, in Figure 1, the user depicts his/her requirement (*a mindless movie*), feeling (*stressed*), and situation (*with a little son*). In order for an accurate recommendation of a movie (*Yes Man*) to be derived, the recommender must capture that the user wants those characteristics of a movie, "*a movie to watch when stressed*", "*a mindless movie*" and "*a movie to watch with a little son*". Therefore, merely depending on item-entities for user preference identification is insufficient. We argue that a dialogue context also provides a user preference, regardless of the existence of item-entities.



Hello, how are you today?

I am stressed out from work today.
So, I'm looking for a mindless movie.

You must be exhausted!
Have you ever watched "21 Jump Street"?
It is so much fun.

Oh wait, I have a little son
who wants to watch a movie together.

Then, I recommend "Yes Man".
It's a family movie. Your son also will like it.

Figure 1: An example of a user-recommender conversation for movie recommendations. The important information for a recommendation is written in red, and the recommended items are written in blue.

Motivated by the characteristic of an online recommendation community where participants identify a context of a recommendation request and then comment with appropriate items, our method exploits the Reddit data to extract the contextual knowledge that enables inferring a preferred item in a KG from a recommendation request. Thus, we propose a Contrastive Learning approach for Injecting Contextual Knowledge (**CLICK**), which

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1875–1885
May 2-6, 2023 ©2023 Association for Computational Linguistics

captures not only the entity-level preference derived from mentioned entities but also identifies the context-level preference from a dialogue context by utilizing both a KG and Reddit data.

However, the different modality between recommendable item-entities in a KG and request texts in the Reddit data hinders CLICK from learning contextual knowledge. Thus, we alleviate the different modalities via contrastive learning to align the pairs of a recommended item-entity and a request text. Moreover, different from the conventional contrastive learning that classifies the pairs into only positive or negative, our distinction is to consider the relative relevance among positive pairs. For example, if a seeker asks a recommendation community for a movie to watch when feeling down, several movies can be recommended. While some movies are related to many participants, others may be referenced by a few people. Thus, to reflect differing relativity of multiple recommendable items from a request, we design a relevance-enhanced contrastive learning loss function. Consequently, leveraging the learned contextual knowledge, CLICK makes accurate recommendations based on the user preferences extracted from both entity- and context-level perspectives. In the response generation task, we develop a response generator that produces a suitable explanation with a recommended item based on a captured requirement from a dialogue context.

Our contributions are summarized as follows: (1) We propose the knowledge injection method that facilitates the inference of a recommendable item based on a dialogue context in order to identify a comprehensive user preference. (2) We design the relevance-enhanced contrastive learning loss that promotes the fine-grained reflection of positive pairs according to the relevance. (3) We further develop a contextual knowledge-enhanced recommender module and a response generation module, which captures a comprehensive user preference and produces an explanation based on a user's needs, respectively. (4) The proposed model outperforms baselines, especially regardless of the existence of item-entities in a user utterance.

2 Related Work

2.1 Conversational Recommender Systems

CRS (Gao et al., 2021) allows obtaining user preferences through dynamic interaction, overcoming the limitations of traditional recommender systems (Guo et al., 2020) that are heavily dependent on static interaction history. The research area can be broadly categorized into two groups: template-based and natural language-based CRSs. Template-based methods (Deng et al., 2021; Lei et al., 2020; Zhou et al., 2020d) interact with a user, following a slot-filling approach. Although many template-based CRSs have been proposed, they suffer from producing inflexible response due to the inherent template scheme.

On the other hand, natural language-based CRS (Chen et al., 2021; Zhou et al., 2020c) allows users to depict their needs in a free text. Such approaches focus on how to extract knowledge from external data (e.g., historical data, KGs, and review data) and how to utilize the knowledge to capture a user preference and generate a persuasive response since the CRS benchmark dataset contains repetitive and limited utterances. Following the stream of CRS research, Zhou et al. (2020b) utilize historical interaction data to enhance a sequence of preferred items. Chen et al. (2019) and Zhou et al. (2020a) exploit KGs to capture user preferences with mentioned entities. Ma et al. (2021), Moon et al. (2019), and Zhou et al. (2021) leverage explicit reasoning on a KG based on the mentioned entities. Lu et al. (2021) and Zhou et al. (2022) utilize review data to enrich insufficient item information over a KG. However, despite the diverse use of external data, the current methods still lack capturing a user's needs depicted in a free text since they identify preferences mainly with mentioned item-entities that exist in a KG. To resolve the limitation, we propose a contrastive learning approach for injecting knowledge into the CRS task by utilizing textual recommendation data (Reddit) and a KG. Thus, our approach captures user preferences from both mentioned entities and a dialogue context, taking full advantage of CRS in which users can express their preferences freely in natural language.

2.2 Contrastive Learning

Another line that motivates our work is contrastive learning, which is a dominant approach in self-supervised learning. Especially in multi-modal scenarios, contrastive learning (Oord et al., 2018) plays a vital role in refining feature representation. It aims at forcing representations to have a smaller distance between positive pairs and a greater distance between negative pairs than the positive ones. Due to the efficacy of contrastive learning strategy,

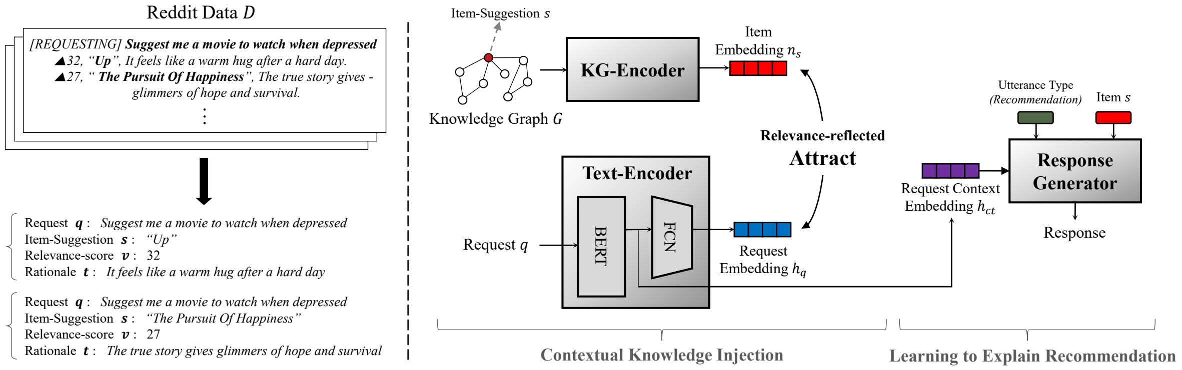


Figure 2: The pre-training stage of CLICK which consists of two encoders and a response generator.

it has been widely used in various research fields such as multilingual text-to-video search (Huang et al., 2021), visual pre-training (Yuan et al., 2021), and other domains (Xia et al., 2021; Zolfaghari et al., 2021). Especially, in recent research on CRS, Zhou et al. (2022) adopt contrastive learning to fuse multi-type external data. Likewise, we refine our multi-type external data representations by contrastive learning. However, different from the existing contrastive learning loss, we further devise relevance-enhanced contrastive learning loss to consider multiple recommendable items, of which each has a different relative relevance.

3 Pre-training for Contextual Knowledge Injection

We introduce the training scheme of CLICK that follows a two-stage mechanism: 1) a pre-training stage for the contextual knowledge injection and 2) a fine-tuning stage for the conversational recommendation task.

In the two stages, we utilize DBpedia (Bizer et al., 2009) as a KG, following the existing CRSs (Chen et al., 2019; Zhou et al., 2020a; Ma et al., 2021; Zhou et al., 2022) that take advantage of KGs to capture user preferences based on factual information such as objects, concepts, and relationships among them. The KG is defined as $G = \{(e1, r, e2) | e1, e2 \in E, r \in R\}$, where a fact $(e1, r, e2)$ consists of relation r from entity $e1$ to entity $e2$ from entity set E and relation set R.

The Reddit data (Penha and Hauff, 2020) is leveraged to learn the contextual knowledge that facilitates the inference of a preferred item from a user utterance. The Reddit data is denoted as $D = \{(q, s, v, t)\}$, where q is a seeker's request text to receive a recommendation, s is an item-suggestion by a recommender, v is a relevance score of the item-suggestion, and t is an optional rationale for the item-suggestion. We describe the details of the Reddit dataset in Section 5.1.

In the pre-training stage, our approach infuses the contextual knowledge from Reddit data into a KG-encoder and a text-encoder by training them via a devised contrastive learning loss. Then, a response generator is pre-trained to equip the ability to generate an explanation for a recommendation based on the recognized needs. The pre-training stage of CLICK is described in Figure 2.

3.1 Contextual Knowledge Injection

Following previous studies (Zhou et al., 2020a; Ma et al., 2021), we encode the KG to obtain the representations of entities via R-GCN (Schlichtkrull et al., 2018) that considers neighborhoods under the specific relation type and direction. The representation of item-entity s from the KG-encoder is denoted as n_s. Then, we employ BERT (Devlin et al., 2019) and a fully-connected layer FCN to encode a request text q that contains the seeker's needs (more details in Appendix A.1). The request embedding h_q is obtained as:

$$h_q = FCN(BERT(q)). \qquad (1)$$

Next, the above two encoders are pre-trained via a contrastive learning loss, which promotes alignment of the multi-modality originating from the KG and text. That way, the text encoder is encouraged to effectively infer a preferred item from a request. Moreover, different from a conventional contrastive learning loss that classifies the pairs into only positive or negative, we build the relevance-enhanced contrastive learning to reflect multiple recommendable items with a relative relevance as follows:

$$L_{rel} = -log \sum_{s \in S} \frac{ex^{(sim_{q,s} - v_{q,s})}}{ex^{(sim_{q,s} - v_{q,s})} + \sum_{S'} ex^{(sim_{q,s'})}}, \quad (2)$$

where $v_{q,s}$ indicates the relevance score corresponding to the number of "Upvote" about the item suggestion s from the request q in positive set S, S' is a negative set, sim means cosine similarity between the item representation vector n_s and the request representation vector h_q that the above two encoders produce respectively, and $ex^{(x)}$ is exponential of x. The proposed loss function is able to attract positive pairs in proportion to the relevance score $v_{q,s}$ while repelling the negative pairs. Then the pre-trained encoders are utilized to capture a comprehensive user preference from a user utterance depicted regardless of the presence of entities.

3.2 Learning to Explain Recommendation

At this stage, the response generator is pre-trained to generate a recommendation response of the three utterance types (*question, recommendation, chit-chat*). The recommendation response should contain a recommended item and a rationale for the recommendation based on a captured user need. Thus, we adopt GPT-2 (Radford et al., 2019) as a response generator and feed a suggested item s and the utterance type (*recommendation*) to a token embedding layer of GPT-2. The first layer of the decoder A^1 then conducts self-attention with the token embeddings. Next, having obtained the request context embedding h_{ct} from the text-encoder (only $BERT$), cross-attention is conducted in the next decoder block to generate the explanation for the item-suggestion based on the needs extracted from the request of a seeker. The cross-attention layer of the decoder can be summarized as:

$$A^2 = FFN(MultiHead(O_{A^1}, h_{ct}, h_{ct})), \quad (3)$$

where the multi-head attention layer $MultiHead(Q, K, V)$ takes query Q, key K and value matrix V as input, and O_{A^1} is the output of the first decoder layer A^1. The response generator is pre-trained to generate the rationale t for the item-suggestion s conditioned on the request q and the utterance type ut via maximum likelihood estimator (MLE) generation loss:

$$L_{exr} = -\sum_{j=0}^{J} \log p(t_j | t_{<j}, q, s, ut). \quad (4)$$

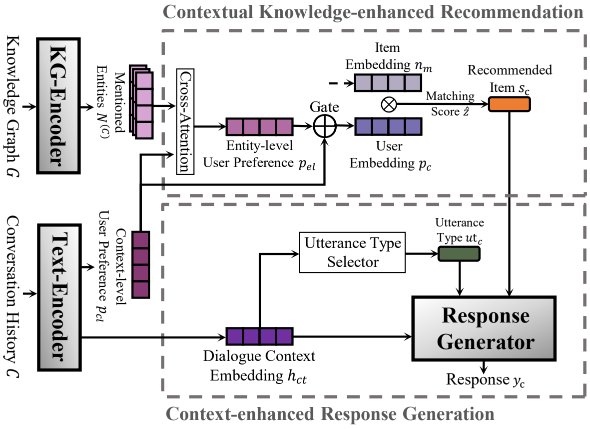

Figure 3: The fine-tuning stage of CLICK utilizing the pre-trained encoders and response generator for the conversational recommendation task.

4 Fine-tuning for Conversational Recommendation Task

In this section, the fine-tuning strategy of CLICK for the CRS task is introduced. Figure 3 illustrates the working flow of CLICK, leveraging the two pre-trained encoders and response generator from the pre-training stage. CLICK consists of two key components: (1) contextual knowledge-enhanced recommender module, which even understands user's needs from a dialogue context, and (2) context-enhanced response generation module, which generates a persuasive response based on a captured user preference. Prior to introducing the details of the fine-tuning scheme, we formulate a conversation history $C = \{x_1, y_1, ..., x_c\}$, where x_i is a user utterance, and y_i is a system utterance at turn-i. The goal of CLICK is to recommend a proper item s_c and generate the system response y_c, understanding the conversation history C.

4.1 Contextual Knowledge-enhanced Recommendation

The pre-trained text-encoder is leveraged to identify context-level user preference (e.g., *a movie to watch when feeling down*) that could not be captured with mentioned entities. In detail, the conversation history C is fed to the text-encoder, and we obtain the context-level user preference as $p_{cl} = FCN(BERT(C))$.

Next, we utilize mentioned entities to identify entity-level user preference (e.g., *a movie like Yes-Man*). In our implementation, we conduct cross-attention with a context-level user preference and entities, being different from the previous approaches that ignore the relative importance among mentioned entities based on a dialogue context. Thus, the cross-attention score is denoted as:

$$\alpha = softmax(q \cdot k^{\mathsf{T}} / \sqrt{d_k}), \\ q = p_{cl} \cdot W_q,\ k = n_e \cdot W_k, \tag{5}$$

where W_q,W_k are weight metrices, n_e is an entity embedding from the mentioned entities $N^{(C)}$, and the context-level user preference p_{cl} is from the text-encoder. Then, we obtain the entity-level user preference p_{el} as follows:

$$p_{el} = \alpha \cdot N^{(C)}, \tag{6}$$

Then, we adopt a gate mechanism to obtain the final user preference p_c at c-th turn by combining the entity-level and context-level user preferences as follows:

$$p_c = \beta \cdot p_{el} + (1 - \beta) \cdot p_{cl}, \\ \beta = \sigma(W_{gate} \cdot [p_{el}; p_{cl}]), \tag{7}$$

where W_{gate} is a weight matrix, and $[;]$ indicates the concatenation operator. Consequently, we conduct the inner product of user preference p_c and the representation n_m of item m to predict the matching score:

$$\hat{z}(c, m) = p_c \cdot n_m^{\top}. \tag{8}$$

The recommender module is fine-tuned with a cross-entropy loss as:

$$L_{rec} = -\sum_{c=1}^{C} \sum_{m=1}^{M} [z_{cm} \cdot \log \hat{z}(c, m) \\ - (1 - z_{cm}) \cdot \log (1 - \hat{z}(c, m))], \tag{9}$$

where z_{cm} is the true label.

4.2 Context-enhanced Response Generation

Prior to generating a response, at each turn, CLICK determines the type of an utterance (*question, recommendation, chit-chat*) given a dialogue context. Following Ma et al. (2021), we regard the determination of utterance's type as a 3-way classification problem:

$$Pr(y_c^{ut}|C) = softmax(W_{ut}^2 \cdot ReLU(W_{ut}^1 \cdot h_{ct})), \tag{10}$$

where h_{ct} is a dialogue context embedding from the BERT. We thus formulate the determination loss as:

$$L_{ut} = -\log Pr(y_c^{ut}|x_1, y_1, ..., x_c), \tag{11}$$

where y_c^{ut} is the true label of utterance type.

After obtaining the dialogue context embedding, the utterance type, and the recommended item, we utilize such to generate a persuasive response that contains a recommended item under the controlled type of an utterance. Compared to an implicit way of response generation in CRSs (Chen et al., 2019; Zhou et al., 2021), which lacks the ability to include a recommended item in the generated response, the explicit way of response generation by Ma et al. (2021) feeds the recommended item and the utterance type as input into the response generator, which guarantees the inclusion of the item under the controlled response type. However, the explicit approach hinders generating a response based on a dialogue context. Thus, different from Ma et al. (2021), we further infuse the dialogue context implicitly into the response generator with the cross-attention mechanism to generate a response containing an identified dialogue context.

In the same manner as the pre-training process of the response generator, an utterance type and a recommended item is fed to the token embedding layer. The first layer of the decoder conducts self-attention with the token embeddings. Then, we enforce the module to generate a response based on the user's needs via the cross-attention mechanism with the dialogue context embedding h_{ct}, which is identical to the one in Equation 3. We formulate the response generation loss as:

$$L_{gen} = -\sum_{u=0}^{U} \log p(y_{u,c}|y_{<u,c}, C, s_c, ut_c), \tag{12}$$

where U is the length of a target response, $y_{u,c}$ is a generated u-th token of system response, C is a conversation history, and s_c is the recommended item at c-th turn. ut_c indicates the type of utterance. Additionally, the implementation details are in Appendix A.2.

5 Experimental Setup

5.1 Dataset

REDIAL is a benchmark CRS dataset released by Li et al. (2018). It was constructed through Amazon Mechanical Turk (AMT). The AMT workers play the role of a seeker/recommender. In daily talk, a seeker explains his/her tastes about movie and asks for movie suggestions. A recommender tries to understand the tastes and recommends movies. Accordingly, it consists of 10,006 conversations

Model	Standard Setting			No Mentioned Item Setting			Diversity
	R@1	R@10	R@50	R@1	R@10	R@50	
REDIAL	2.3	13.2	29.7	–	–	–	5.8

Table 1: Overall performance comparison on the recommendation task.

containing 182,150 utterances and 51,699 movies. We set the training, validation, and test sets as a ratio of 8:1:1. **Reddit** is utilized as the textual recommendation data collected by Penha and Hauff (2020). Following the domain of a benchmark CRS dataset (REDIAL), we use the MovieSuggestions subreddit, which is a movie recommendation community. In the community, a seeker asks for a recommendation, and recommenders give suggestions with a rationale. Participants in the community consent to the suggested items with the "Upvote" button which is regarded as a relevance score. **Knowledge Graph** consists of 30,471 entities, 12 relations, and 392,682 triples extracted from DBpedia (Bizer et al., 2009) and MovieLens, following Ma et al. (2021). Additionally, the entities in utterances are linked to DBpedia nodes.

5.2 Baselines

We compared CLICK to the following five CRS baselines: (1) **REDIAL** (Li et al., 2018) is proposed with the CRS benchmark dataset. The model consists of an auto-encoder recommender and an RNN-based response generator. (2) **KBRD** (Chen et al., 2019) utilizes a KG to identify user preferences from mentioned entities. The transformer-based response generator uses a user representation as vocabulary bias. (3) **KGSF** (Zhou et al., 2020a) incorporates word-oriented and entity-oriented KGs to capture user preference. (4) **CR-Walker** (Ma et al., 2021) proposes tree-structured reasoning on a KG, which effectively utilizes background knowledge. It adopts GPT-2 to generate a response by feeding dialogue acts. (5) **C2CRS** (Zhou et al., 2022) leverages a KG and a review data for enriching the context information. It conducts data semantic fusion via contrastive learning. The response generator fuses the information from a KG and a review data.

Additionally, three pre-trained language models (PLMs) were tested for a fair comparison on the same data. In table 1 and 2, (+*Reddit*) indicates a PLM pre-trained on the Reddit data. The three models are as follows: GPT-2(Radford et al., 2019), BERT(Devlin et al., 2019), and BART(Lewis et al., 2020). The training details of PLMs are in Appendix A.3.

6 Experimental Results

6.1 Evaluation on Recommendation

We adopted Recall@k to measure how many predicted items were included in the set of preferred items (Standard Setting). Moreover, we compared the performance under the setting where there were no mentioned item-entities in a dialogue context (No Mentioned Item Setting). This setting aims to evaluate how well the models identify a user preference from a dialogue context without mentioned item-entities. We also evaluated recommendation diversity (Diversity), defined as the proportion of distinct recommendations.

6.1.1 Performance Comparison

Table 1 shows the experimental results on recommendation task. **Standard Setting**: KBRD, KGSF, and CR-Walker performed better compared to REDIAL by capturing user preference based on entities in KGs. Compared to the baselines, C2CRS

Model	Automatic Evlauation				Human Evaluation		
	BLEU	Dist-2	Dist-3	Dist-4	Flu.	Rel.	Info.
REDIAL	0.229	0.215	0.247	0.234	2.03	1.97	1.67
KBRD	0.231	0.281	0.376	0.438	2.18	2.19	1.98
KGSF	0.239	0.320	0.432	0.519	2.31	2.21	2.12
CR-Walker	0.271	0.361	0.493	0.573	2.54	2.37	2.31
C2CRS	0.251	0.339	0.455	0.538	2.42	2.29	2.19
GPT-2	0.247	0.352	0.474	0.521	2.35	2.01	2.04
GPT-2 (+*Reddit*)	0.261	0.359	0.481	0.536	2.39	2.09	2.02
BART	0.249	0.354	0.486	0.528	2.37	2.07	2.12
BART (+*Reddit*)	0.262	0.357	0.492	0.539	2.38	2.17	2.11
CLICK (ours)	**0.308**	**0.380**	**0.521**	**0.598**	**2.60**	**2.63**	**2.58**
w/o gen. cross-att	0.296	0.371	0.510	0.589	2.58	2.51	2.47
w/o gen. pre-training	0.289	0.364	0.503	0.583	2.53	2.45	2.44
w/o pre-training	0.281	0.359	0.497	0.579	2.48	2.39	2.40

Table 2: Overall performance comparison on the response generation task

recommended appropriate items by incorporating a KG and a review data. In contrast, CLICK achieved the best results by effectively modeling comprehensive user preference from entity-level and context-level. Another observation is from the comparison with PLMs. Although the PLMs showed impressive performances, the improvement by utilizing the Reddit data was lower than ours. Thus, it proved that CLICK efficiently extracted contextual knowledge from Reddit data and exploited it for recommendation. **No Mentioned Item Setting**: To further demonstrate the CLICK's ability of capturing a context-level user preference, we compared the baselines on this setting. KGSF and CR-Walker performed relatively better than other baselines due to the utilized word-oriented KG allowing the recognition of diverse words in a conversation. We noted that CLICK showed best performances even when there were no mentioned item-entities. This is because the contextual knowledge extracted from the Reddit data provided a significant clue to a user's needs. More details are covered in Appendix A.4. **Diversity**: CLICK recommended diverse items compared to all the baselines. The improvement was derived from our strategy of modeling user preference in a fine-grained means, considering both mentioned entities and a dialogue context.

6.1.2 Ablation Study

Pre-training with the relevance-enhanced contrastive learning loss is an essential design in our method to infer a preferable item from a user utterance. Thus, we assessed the effects of CLICK with two variants, (1) **w/o relevance**: standard contrastive learning loss (Oord et al., 2018) was used, (2) **w/o pre-training**: CLICK was only trained on REDIAL dataset without being pre-trained with the Reddit data. As shown in Table 1, the performance of CLICK *w/o relevance* was lower since it did not consider the relative relevance that helped the model to learn a fine-grained representation. CLICK *w/o pre-training* provided the evidence for the pre-training stage of learning the contextual knowledge. Besides, it showed a decline in diversity since it did not capture a fine-grained user preference with the contextual knowledge that promotes various recommendations.

6.2 Evaluation on Response Generation

BLEU (Papineni et al., 2002) and Dist-N (Li et al., 2016) were adopted to measure the word-level correspondence and diversity of responses. We further conducted a human evaluation. Five human annotators evaluated 100 generated responses on fluency, relevancy, and informativeness ranging from 0 to 3. The average score of each metric is reported.

6.2.1 Performance Comparison

Table 2 shows the experimental results on response generation task. **Automatic Evaluation**: The result proved that our method generated a better quality response with diverse words. Such improvements are derived from the explicit feeding of a recommended item and an utterance type into a response generator and the implicit injection of a context via a cross-attention mechanism. **Human Evaluation**: The responses generated from C2CRS, KGSF, and KBRD are inclined to contain safe responses that are broadly adequate for any situation, such as *"I have not seen that one"*.

This issue was reflected as the lower score on relevancy and informativeness compared to CR-Walker. While CR-Walker generated a meaningful response with an explanation for a recommendation, CLICK achieved the best performance on all human evaluations. Especially, the better relevancy and informativeness demonstrated the efficacy of our response generator incorporating a dialogue context via the cross-attention.

6.2.2 Ablation Study

The ablation study wass conducted with the following three variants of CLICK, (1) **w/o gen. cross-att**: we removed the cross-attention mechanism incorporating a dialogue context. (2) **w/o gen. pre-training**: we only pre-trained the recommender module except for the response module, (3) **w/o pre-training**: we trained the CLICK on REDIAL dataset without pre-training. As shown in Table 2, we observed a significant decrease when the proposed strategies were removed. It proved that these strategies contributed to improving the performance of response generation. We noted that the cross-attention mechanism and the pre-training scheme of the response generator affected generating a relevant and informative response. Moreover, the *w/o pre-training* case brought a further decline in all metrics, indicating the usefulness of the pre-training strategy or generating informative responses using diverse words.

6.3 Case Study

A qualitative analysis of three cases is shown in Table 3. **Case 1**, there are no mentioned item-entities. Given the user utterance, KGSF recommended "*Black Panther*" that is suggested frequently in the CRS dataset regardless of a specific situation. Thus, it did not seem to capture the user's needs (*comforting movie*) precisely. Likewise, CR-Walker asked a question since it did not identify the needs exactly. In contrast, our model recommended a proper item with a rationale based on the captured needs. **Case 2** is a common case in the CRS dataset, which explicitly expresses the user's taste. Therefore, all baselines and CLICK generated a proper recommendation. Especially, CLICK provided a suitable explanation, understanding that the user wants comedy. **Case 3** includes multiple entities and a specific situation where the recommended movie should be enjoyable for little girls. We observed that all baselines suggested action movies, concentrating on the genre prevailing in the dialogue context. Here, the recommender should understand that the user is looking for a kids' movie, such as "*The Princess and The Frog*" besides action movies. In constrast, our model grasped the relatively important entity among mentioned entities based on the dialogue context. Consequently, our model's recommendation and rationale are well-grounded on users' needs.

[Case 1] **Recommender:** hello how are you today? **User:** I'm feeling pretty down tonight so I'd like to watch a comforting movie.
KGSF: Have you ever seen "Balck Panther"? **CR-Walker**: What type of movie do you like? **Ours**: What about "Mamma Mia!"? It's a comforting movie. **Human**: I recommend "The Secret Life of Walter Mitty", It's so satisfying.
[Case2] **Recommender:** hello what kind of movie do you like? **User:** I'm in the mood for a good comedy like "Get Smart"
KGSF: Have you ever seen "Jumanji"? **CR-Walker**: "Happy Gilmore" is a really good comedy. It's my favorite adam sandler movie. **Ours**: Have you ever seen "Men in Black"? It has funny story. **Human**: You should watch "Spy". I liked the humor of the actress.
[Case3] **Recommender:** Hello! Could you let me know any movies you liked? **User:** I like action movies like "John Wick " or "Die Hard 4.0", but today I'm looking for something similar to "The Princess and the Frog". I have little girls who want to watch a movie.
KGSF: Have you seen "Black Panther"? **CR-Walker**: I recommend "Taken". It's a really good movie with lots of action! **Ours**: What about "Tangled". It's a fairytale movie. Little girls will love it. **Human**: Then, I recommend "Frozen". Becasue littile girls like it.

Table 3: A qualitative analysis of three cases. The baselines, CLICK(ours), and human generate a response based on the given dialogue context. The important information for a recommendation is written in red, and the mentioned item-entities in a KG are written in blue.

7 Conclusions and Future Work

In this paper, we proposed the contextual knowledge injection via contrastive learning to capture a comprehensive user preference from a dialogue context. Utilizing the extracted contextual knowledge, CLICK not only precisely captures the preference on mentioned entities but also identifies the user's needs in a dialogue context. Moreover, the relevance-enhanced contrastive learning loss enables the contextual knowledge to reflect the acceptance degree of recommendations. We further developed the context-enhanced response generator to provide a persuasive explanation. Lastly, experimental results on the benchmark dataset confirmed the effectiveness of CLICK on providing appropriate recommendations, as well as generating high-quality responses.

In future work, we will explore a CRS with a recommendation dialogue strategy of actively asking questions to elicit a user taste instead of passively communicating with a user.

Limitations

In this section, we summarized the limitations of our study as follows:

- The training and test experiments are conducted on the setting where the mentioned entities are aligned to a knowledge graph in the same manner as other CRSs. In a practical use, Named Entity Recognition (NER) task is needed, and entity linking is also required to align the entities to a KG.
- This work only conducts experiments on the movie domain and does not generalize to other domains since the benchmark CRS dataset is limited to the movie domain. Benchmark CRS datasets on various domains need to be published, and experiments on multiple domains are required to support a complete and objective study.

Ethics Statement

All authors of this paper acknowledged ACL Ethics Policy. We utilized public datasets, REDIAL dataset and Reddit dataset. REDIAL dataset was constructed by crowdsourcing with Amazon Mechanical Turk, which is conducted anonymously. And Reddit dataset was crawled from Reddit community site without personal information. Although we have not observed an inappropriate content in the generated response, we inform that pretrained GPT-2 is leveraged, which may produce an inappropriate response.

A Appendix

A.1 The Pipeline between BERT and FCN in Text-Encdoer

The output of BERT is an embedding vector of a CLS token containing the meaning of the entire sentence. And the embedding vector is input into FCN.

A.2 Implementation Details

We implemented CLICK with Pytorch[1] and trained it on an NVIDIA RTX 3090. We set the embedding size of the KG-encoder (R-GCN)[2] to 128, and the depth of aggregating neighbors as 1. We used pre-trained BERT[3] and GPT-2[4] to intialize the models' parameters. The hidden size of BERT in the text-encoder is set to 768, and the hidden size of the response generation module (GPT-2) is identically set to 768. When obtaining the embedding of a context-level user preference from the text-encoder, we utilized a 128×768 fully-connected layer. We normalized the relevance scores from 0.25 to 0.5 for a stable convergence. We used Adam optimizer (Kingma and Ba, 2015) with a learning rate of 1e-4 and a weight decay of 1e-3. The batch size of pre-training and fine-tuning is set to 32. The computational cost is 3 hours and 1 hour per 1 epoch for pre-training and fine-tuning, respectively.

A.3 PLMs Details

The PLMs with (+*Reddit*) are pre-trained on Reddit dataset and fine-tuned on REDIAL dataset. And the representation of the last token that a PLM generates is used for recommendation.

A.4 No Mentioned Item Setting

We utilized a special entity (*None entity*) in the same manner as other CRSs (KGSF, CR-Walker, and C2CRS) that utilize KGs. Thus, CLICK and other CRSs can be executed under any case. For example, at the first turn of the conversation in Figure 1, there is no mentioned entity. Thus, *None entity* is assigned as mentioned entities $N^{(C)}$ in Equation 6. Meanwhile, the text-encoder of CLICK is pre-trained with Reddit data to infer recommendable items (*e.g., 21JumpStreet, MadMax:FuryRoad, etc.*) from the request context where a user gets stressed or requires mindless movies. The gate mechanism in Equation 7 then emphasizes a context-level user preference p_{cl} obtained from the pre-trained text-encoder than an entity-level user preference p_{el} in the case of no mentioned entities. Thus, the user embedding concentrated on the context-level user preference p_{cl} enables CLICK to recommend *21JumpStreet* from the user's first utterance in Figure 1.

LEALLA: Learning Lightweight Language-agnostic Sentence Embeddings with Knowledge Distillation

Zhuoyuan Mao[*] and **Tetsuji Nakagawa**
Google Research
`kevinmzy@gmail.com, tnaka@google.com`

Abstract

Large-scale language-agnostic sentence embedding models such as LaBSE (Feng et al., 2022) obtain state-of-the-art performance for parallel sentence alignment. However, these large-scale models can suffer from inference speed and computation overhead. This study systematically explores learning language-agnostic sentence embeddings with lightweight models. We demonstrate that a thin-deep encoder can construct robust low-dimensional sentence embeddings for 109 languages. With our proposed distillation methods, we achieve further improvements by incorporating knowledge from a teacher model. Empirical results on Tatoeba, United Nations, and BUCC show the effectiveness of our lightweight models. We release our lightweight language-agnostic sentence embedding models LEALLA on TensorFlow Hub.[1]

1 Introduction

Language-agnostic sentence embedding models (Artetxe and Schwenk, 2019b; Yang et al., 2020; Reimers and Gurevych, 2020; Feng et al., 2022; Mao et al., 2022) align multiple languages in a shared embedding space, facilitating parallel sentence alignment that extracts parallel sentences for training translation systems (Schwenk et al., 2021). Among them, LaBSE (Feng et al., 2022) achieves the state-of-the-art parallel sentence alignment accuracy over 109 languages. However, 471M parameters of LaBSE lead to the computationally-heavy inference. The 768-dimensional sentence embeddings of LaBSE (LaBSE embeddings) make it suffer from computation overhead of downstream tasks (e.g., kNN search). This limits its application on resource-constrained devices. Therefore, we explore training a lightweight model to generate low-dimensional sentence embeddings while retaining the performance of LaBSE.

We first investigate the performance of dimension-reduced LaBSE embeddings and show that it performs comparably with LaBSE. Subsequently, we experiment with various architectures to see whether such effective low-dimensional embeddings can be obtained from a lightweight encoder. We observe that the thin-deep (Romero et al., 2015) architecture is empirically superior for learning language-agnostic sentence embeddings. Diverging from previous work, we show that low-dimensional embeddings based on a lightweight model are effective for parallel sentence alignment of 109 languages.

LaBSE benefits from multilingual language model pre-training, but no multilingual pre-trained models are available for the lightweight architectures. Thus, we propose two knowledge distillation methods to further enhance the lightweight models by forcing the model to extract helpful information from LaBSE. We present three lightweight models improved with distillation: **LEALLA-small**, **LEALLA-base**, and **LEALLA-large**, with 69M, 107M, and 147M parameters, respectively. Fewer model parameters and their 128-d, 192-d, and 256-d sentence embeddings are expected to accelerate downstream tasks, while the performance drop of merely up to 3.0, 1.3, and 0.3 P@1 (or F1) points is observed on three benchmarks of parallel sentence alignment. In addition, we show the effectiveness of each loss function through an ablation study.

2 Background: LaBSE

LaBSE (Feng et al., 2022) fine-tunes dual encoder models (Guo et al., 2018; Yang et al., 2019) to learn language-agnostic embeddings from a large-scale pre-trained language model (Conneau et al., 2020). LaBSE is trained with parallel sentences, and each sentence pair is encoded separately by

---

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1886–1894
May 2-6, 2023

a 12-layer Transformer encoder. The 768-d encoder outputs are used to compute the training loss and serve as sentence embeddings for downstream tasks. Expressly, assume that the sentence embeddings for parallel sentences in a batch are $\{(\mathbf{x}_i, \mathbf{y}_i)\}_{i=1}^{N}$ where N denotes the number of the sentence pairs within a batch. LaBSE trains the bidirectional additive margin softmax (AMS) loss:

$$\mathcal{L}_{ams} = \frac{1}{N}\sum_{i=1}^{N}(\mathcal{L}(\mathbf{x}_i, \mathbf{y}_i) + \mathcal{L}(\mathbf{y}_i, \mathbf{x}_i)), \quad (1)$$

where the loss for a specific sentence pair in a single direction is defined as:

$$\mathcal{L}(\mathbf{x}_i, \mathbf{y}_i) = -\log \frac{e^{\phi(\mathbf{x}_i, \mathbf{y}_i)-m}}{e^{\phi(\mathbf{x}_i, \mathbf{y}_i)-m} + \sum_{n \neq i} e^{\phi(\mathbf{x}_i, \mathbf{y}_n)}}. \quad (2)$$

m is a margin for optimizing the separation between translations and non-translations. $\phi(\mathbf{x}_i, \mathbf{y}_i)$ is defined as Cosine Similarity between $\mathbf{x}_i$ and $\mathbf{y}_i$.

3 Light Language-agnostic Embeddings

To address the efficiency issue of LaBSE, we probe the lightweight model for learning language-agnostic embeddings with the following experiments: (1) We directly reduce the dimension of LaBSE embeddings to explore the optimal embedding dimension; (2) We shrink the model size with various ways to explore the optimal architecture.

3.1 Evaluation Settings

We employ Tatoeba (Artetxe and Schwenk, 2019b), United Nations (UN) (Ziemski et al., 2016), and BUCC (Pierre Zweigenbaum and Rapp, 2018) benchmarks for evaluation, which assess the model performance for parallel sentence alignment. Following Feng et al. (2022) and Artetxe and Schwenk (2019b), we report the average P@1 of bidirectional retrievals for all the languages of Tatoeba, the average P@1 for four languages of UN, and the average F1 of bidirectional retrievals for four languages of BUCC.[2] Refer to Appx. A for details.

3.2 Exploring the Optimal Dimension of Language-agnostic Sentence Embeddings

Mao et al. (2021) showed that a 256-d bilingual embedding space could achieve an accuracy of about 90% for parallel sentence alignment. However, existing multilingual sentence embedding models such as LASER (2019b), SBERT (2020), EMS (2022), and LaBSE use 768-d or 1024-d sentence embeddings, and whether a low-dimensional space can align parallel sentences over tens of languages with a solid accuracy (>80%) remains unknown. Thus, we start with the dimension reduction experiments for LaBSE to explore the optimal dimension of language-agnostic sentence embeddings.

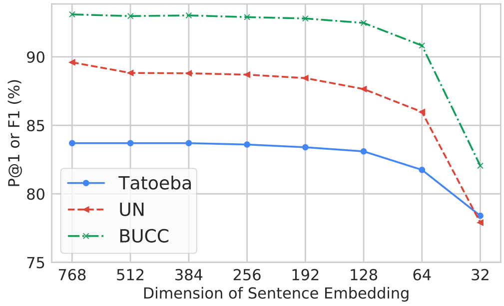

Figure 1: Dimension reduction for LaBSE.

We add an extra dense layer on top of LaBSE to transform the dimension of LaBSE embeddings from 768 to lower values. We experiment with seven lower dimensions ranging from 512 to 32. We fine-tune 5k steps for fitting the newly added dense layer, whereas other parameters of LaBSE are fixed. Refer to Appx. B for training details.

As shown in Fig. 1, the performance drops more than 5 points when the dimension is 32 on Tatoeba, UN, and BUCC. Meanwhile, given sentence embeddings with a dimension over 128, they performs slightly worse than 768-d LaBSE embeddings with a performance drop of fewer than 2 points, showing that low-dimensional sentence embeddings can align parallel sentences in multiple languages. Refer to Appx. D for detailed results.

3.3 Exploring the Optimal Architecture

Although we revealed the effectiveness of the low-dimensional embeddings above, it is generated from LaBSE with 471M parameters. Thus, we explore whether such low-dimensional sentence embeddings can be obtained from an encoder with less parameters. We first reduce the number of layers (#1 and #2 in Table 1) and the size of hidden states (#3 and #4) to observe the performance. Subsequently, inspired by the effectiveness of FitNet (Romero et al., 2015) and MobileBERT (Sun et al., 2020) and taking advantage of the low-dimensional sentence embeddings shown above, we experiment with thin-deep architectures with 24

---

[2] For BUCC, we use margin-based scoring (Artetxe and Schwenk, 2019a) for filtering translation pairs.

#	L	$\mathbf{d_h}$	H	P	$\mathbf{P_E}$	Tatoeba	UN	BUCC
LaBSE								
0	12	768	12	471M	85M	83.7	89.6	93.1

8	24	128	8	69M	5M	80.3	86.3	90.4

Table 1: Results of LaBSE variants. $\mathbf{L}$, $\mathbf{d_h}$, $\mathbf{H}$, $\mathbf{P}$, and $\mathbf{P_E}$ denote the number of layers, dimension of hidden states, number of attention heads, number of parameters, and number of encoder parameters (except for the word embedding layer). Refer to Appx. E for detailed results.

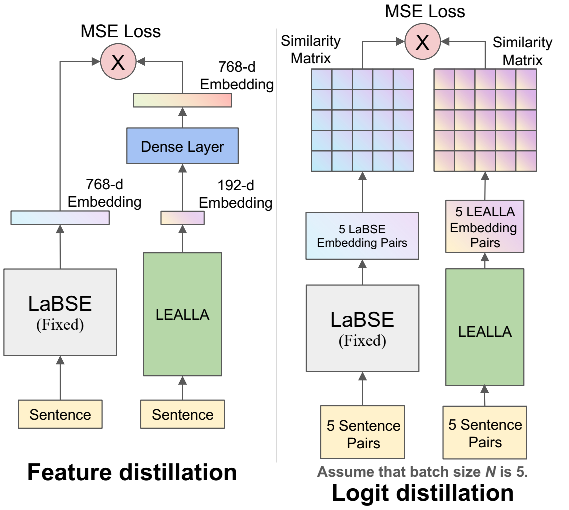

Figure 2: Feature and logit distillation from LaBSE.

layers (#5 - #8), leading to fewer encoder parameters.[3] Refer to Appx. B for training details.

We report the results in Table 1. First, architectures with fewer layers (#1 and #2) perform worse than LaBSE on all three tasks and can only decrease parameters by less than 15%. Second, increasing the number of layers (#5 and #7) improves the performance of 12-layer models (#3 and #4) with a limited parameter increase less than 10%. Referring to LaBSE (#0), low-dimensional embeddings from thin-deep architectures (#5 - #8) obtain solid results on three benchmarks with performance drops of only 3.4 points at most. Until this point, we showed that thin-deep architecture is effective for learning language-agnostic sentence embeddings.

4 Knowledge Distillation from LaBSE

Besides the large model capacity, multilingual language model pre-training benefits LaBSE for parallel sentence alignment. As no multilingual pre-trained language models are available for lightweight models we investigated in Section 3.3, we instead explore extracting helpful knowledge from LaBSE.

4.1 Methodology

Feature distillation and logit distillation have been proven to be effective paradigms for knowledge distillation (Hinton et al., 2015; Romero et al., 2015; Yim et al., 2017; Tang et al., 2019). In this section, we propose methods applying both paradigms to language-agnostic sentence embedding distillation. We use LaBSE as a teacher to train students with thin-deep architectures which were discussed in Section 3.3.

Feature Distillation We propose applying feature distillation to language-agnostic sentence embedding distillation, which enables lightweight sentence embeddings to approximate the LaBSE embeddings via an extra dense layer. We employ an extra trainable dense layer on top of the lightweight models to unify the embedding dimension of LaBSE and lightweight models to be 768-d, as illustrated in Fig. 2.[4][5] The loss function is defined as follows:

$$\mathcal{L}_{fd} = \frac{1}{N} \sum_{i=1}^{N} (\| \mathbf{x}_i^t - f(\mathbf{x}_i^s) \|_2^2 + \| \mathbf{y}_i^t - f(\mathbf{y}_i^s) \|_2^2), \tag{3}$$

where $\mathbf{x}^t$ (or $\mathbf{y}^t$) and $\mathbf{x}^s$ (or $\mathbf{y}^s$) are the embeddings by LaBSE and the lightweight model, respectively. $f(\cdot)$ is a trainable dense layer transforming the dimension from d ($d < 768$) to 768.

Logit Distillation We also propose applying logit distillation to language-agnostic sentence embedding distillation to extract knowledge from the sentence similarity matrix as shown in Fig. 2. Logit distillation forces the student to establish similar similarity relationships between the given sentence pairs as the teacher does. We propose the following

---

[3] Following MobileBERT, we attempted architectures that have an identical size for hidden state and feed-forward hidden state, but it works poorly than #5 - #8. (Refer to Appx. E)

[4] SBERT (2020) used feature distillation to make monolingual sentence embeddings multilingual, but distillation between different embedding dimensions has not been studied.

[5] We investigated another two patterns to unify the embedding dimensions in Appx. C, but they performed worse.

$\mathcal{L}_{fd}$	78.2	85.2	81.1	**88.1**	82.4	88.1
$\mathcal{L}_{ld}$	75.1	2.3	80.6	63.1	82.3	84.1

Table 3: Results of LEALLA with each loss function. "*all*" denotes LEALLA without ablation (with all the loss functions).

mean squared error (MSE) loss:

$$\mathcal{L}_{ld} = \frac{1}{N^2} \sum_{i=1}^{N} \sum_{j=1}^{N} \left(\left(\phi \left(\mathbf{x}_i^t, \mathbf{y}_j^t \right) - \phi \left(\mathbf{x}_i^s, \mathbf{y}_j^s \right) \right) / T \right)^2, \tag{4}$$

where T is a distillation temperature, and other notations follow those in Eq. 2 and 3.

Combined Loss Finally, we combine two knowledge distillation loss functions with the AMS loss (Eq. 1) to jointly train the lightweight model:

$$\mathcal{L}_{lealla} = \alpha \mathcal{L}_{ams} + \beta \mathcal{L}_{fd} + \gamma \mathcal{L}_{ld}. \tag{5}$$

Here α, β, and γ are weight hyperparameters, which are tuned with the development data.

4.2 Experiments

Training We train three models, **LEALLA-small**, **LEALLA-base**, and **LEALLA-large**, using the thin-deep architectures of #8, #7, and #6 in Table 1 and the training loss of Eq. 5. Refer to Appx. B for training and hyperparameter details.

Results The results of LEALLA on Tatoeba, UN, and BUCC benchmarks are presented in Table 2. Overall, LEALLA can yield competitive performance compared with previous work. LEALLA-large performs comparably with LaBSE, where the average performance difference on three tasks is below 0.3 points. LEALLA-base and LEALLA-small obtain strong performance for high-resource languages on UN and BUCC, with a performance decrease less than 0.9 and 2.3 points, respectively. They also achieve solid results on Tatoeba with 1.3 and 3 points downgrades compared with LaBSE. The solid performance of LEALLA on Tatoeba demonstrates that it is effective for aligning parallel sentences for more than 109 languages. Moreover, all the LEALLA models perform better or comparably with previous studies other than LaBSE.

Ablation Study We inspect the effectiveness of each loss component in an ablative manner. First, we compare settings with and without distillation loss functions. As shown in Fig. 3, by adding $\mathcal{L}_{fd}$ or $\mathcal{L}_{ld}$, LEALLA trained only with $\mathcal{L}_{ams}$ is improved on Tatoeba and UN tasks. By further combining $\mathcal{L}_{fd}$ and $\mathcal{L}_{ld}$, LEALLA consistently achieves superior performance. Second, we separately train LEALLA with each loss. Referring to the results reported in Table 3, LEALLA trained only with $\mathcal{L}_{fd}$ yields solid performance in the "small" and "base" models compared with $\mathcal{L}_{ams}$, showing that distillation loss benefits parallel sentence alignment. $\mathcal{L}_{fd}$ and $\mathcal{L}_{ld}$ perform much worse in the "small" model, which may be attributed to the discrepancy in the capacity gaps between the teacher model (LaBSE) and the student model ("small" or "base").[6] Refer to Appx. F for all detailed results in this section.

5 Conclusion

We presented LEALLA, a lightweight model for generating low-dimensional language-agnostic sentence embeddings. Experimental results showed that LEALLA could yield solid performance for 109 languages after distilling knowledge from LaBSE. Future work can focus on reducing the vocabulary size of LaBSE to shrink the model further and exploring the effectiveness of lightweight model pre-training for parallel sentence alignment.

Limitations

In this study, we used the same training data as LaBSE (refer to Fig. 7 of (Feng et al., 2022)), where more training data for high-resource languages may cause the biased model accuracy for those languages. Second, evaluation for low-resource languages in this study depended only on the Tatoeba benchmark, which contains only 1,000 positive sentence pairs for each language with English. The same limitation exists in all the related work, such as LaBSE and LASER. Further evaluation for low-resource languages will be necessary in the future once larger evaluation benchmarks, including over 100k gold parallel sentences for low-resource languages, are available. Third, all the training data used in this work are English-centric sentence pairs, which may result in the inferior model performance for aligning parallel sentences between non-English language pairs.

Acknowledgements

We would like to thank our colleagues from Translate, Descartes, and other Google teams for their valuable contributions and feedback. A special mention to Fangxiaoyu Feng, Shuying Zhang, Gustavo Hernandez Abrego, and Jianmon Ni for their support in sharing information on LaBSE, and providing training data, expertise on language-agnostic sentence embeddings, and assistance with evaluation. We would also like to thank the reviewers for their insightful comments for improving the paper.

A Evaluation Benchmarks

Tatoeba (Artetxe and Schwenk, 2019b) supports the evaluation across 112 languages and contains up to 1,000 sentence pairs for each language and English. The languages of Tatoeba that are not included in the training data of LaBSE and LEALLA serve as the evaluation for unseen languages. UN (Ziemski et al., 2016) is composed of 86,000 aligned bilingual documents for en-ar, en-es, en-fr, en-ru, and en-zh. Following Feng et al. (2022), we evaluate the model performance for es, fr, ru, and zh on the UN task. There are about 9.5M sentence pairs for each language with English after deduping. BUCC shared task (Pierre Zweigenbaum and Rapp, 2018) is a benchmark to mine parallel sentences from comparable corpora. We conduct the evaluation using BUCC2018 tasks for en-de, en-fr, en-ru, and en-zh, following the setting of Reimers and Gurevych (2020).[7] For the results of LaBSE reported in Table 2, we re-conduct the evaluation experiments using the open-sourced model of LaBSE.[8]

B Training Details

All of the models in this work are trained with the same training data and development data as LaBSE (Feng et al., 2022). Refer to Section 3.1 and

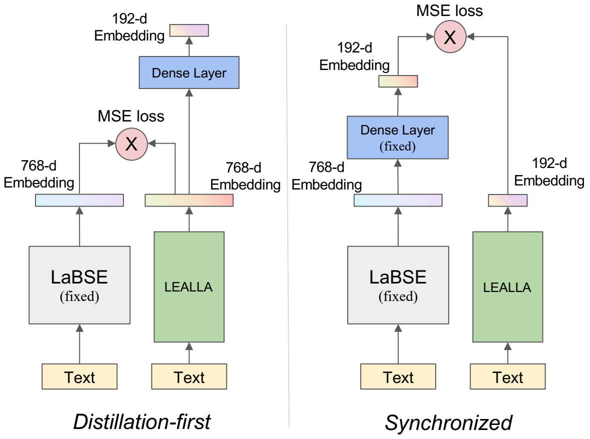

Figure 4: Another two patterns of feature distillation.

Appx. C of Feng et al. (2022) for dataset and supported language details. We train models on Cloud TPU V3 with 32-cores with a global batch size of 8,192 sentences and a maximum sequence length of 128. For a fair comparison with LaBSE for more than 109 languages, we use the 501k vocabulary of LaBSE (trained with BPE (Sennrich et al., 2016)) and do not consider modifying its size in this work. We employ AdamW (Loshchilov and Hutter, 2019) for optimizing the model using the initial learning rate of 1e-03 for models with a hidden state size larger than 384 and 5e-04 for models with a hidden state size smaller than 256. For LEALLA-small and LEALLA-base, α, β, and γ are set as 1, 1e03 and 1e-02. For LEALLA-large, they are set as 1, 1e04, and 1e-02, respectively. T in Eq. 4 is set to 100. All the models in Section 3.2 are trained for 5k steps. Models in Secton 3.3 and Section 4 with a hidden state size over 256 are trained for 200k steps, and those with a hidden state size below 192 are trained for 100k steps. It costs around 24 hours, 36 hours, and 48 hours to train LEALLA-small, LEALLA-base, and LEALLA-large, respectively. Hyperparameters are tuned using a held-out development dataset following Feng et al. (2022) with a grid search. The bounds tuned for each hyperparameter are shown in Table 5.

C Discussion about Feature Distillation

We additionally investigate another two patterns for feature distillation. As illustrated in Fig. 4, "*Distillation-first*" modifies the position for computing the MSE loss compared with $\mathcal{L}_{fd}$ of Eq. 3. The `[CLS]` pooler within the LEALLA encoder is used to generate 768-d embeddings first. A dense layer is employed to transform the 768-d embeddings to low-dimension after calculating the MSE loss. "*Synchronized*" transforms the LaBSE embeddings to low-dimension, then the MSE loss is constructed between two low-dimensional embeddings. As the MSE loss is computed simultaneously with the

Table 7: Results of thin-deep and MobileBERT-like architectures. $\mathbf{L}$, $\mathbf{d_h}$, $\mathbf{d_{ff}}$, $\mathbf{H}$, $\mathbf{P}$, and $\mathbf{P_E}$ indicate the number of layers, dimension of hidden states, dimension of feed-forward hidden states, number of attention heads, number of model parameters, and number of encoder parameters (except for the word embedding layer).

AMS loss, it is denoted as "*Synchronized*". For "*Synchronized*", it requires a fixed dense layer to conduct the dimension reduction for the LaBSE embeddings, for which we utilize the pre-trained model introduced in Section 3.2. We denote these two patterns of feature distillation as $\mathcal{L}_{df}$ and $\mathcal{L}_{syn}$.

As reported in Table 4, $\mathcal{L}_{ams} + \mathcal{L}_{fd}$ ($\mathcal{L}_{fd}$ is feature distillation introduced in the main text) consistently outperforms $\mathcal{L}_{ams} + \mathcal{L}_{df}$ and $\mathcal{L}_{ams} + \mathcal{L}_{syn}$ in all the three LEALLA models. $\mathcal{L}_{ams} + \mathcal{L}_{df}$ and $\mathcal{L}_{ams} + \mathcal{L}_{syn}$ perform comparably on Tatoeba with the models trained without distillation loss. $\mathcal{L}_{ams} + \mathcal{L}_{df}$ obtains performance gains for high-resource languages on UN and BUCC compared with $\mathcal{L}_{ams}$, but still underperforms $\mathcal{L}_{ams} + \mathcal{L}_{fd}$.

$\mathcal{L}_{df}$ forces the lightweight model to approximate the teacher embeddings first in the intermediate part of the model, on top of which the low-dimensional sentence embeddings are generated for computing the AMS loss, while $\mathcal{L}_{fd}$ (Eq. 3) is calculated after computing the AMS loss. As the AMS loss directly indicates the evaluation tasks, we suppose $\mathcal{L}_{fd}$ is a more flexible objective for feature distillation. In addition, $\mathcal{L}_{syn}$ is not beneficial because it depends on a dimension-reduced LaBSE, which is a less robust teacher compared with LaBSE.

D Results of Dimension-reduction Experiments

We report all the results of Section 3.2 in Table 6.

E Results of Thin-deep and MobileBERT-like Architectures

Table 7 presents the detailed results of each architecture we explored in Section 3.3. Besides showing the results for each language on UN and

Table 8: Results of LEALLA with different loss functions and loss combinations.

BUCC for models #0 - #8, we provide the results of a further smaller thin-deep architecture (#9) and MobileBERT-like (Sun et al., 2020) thin-deep architectures (#10 - #12). The 64-d thin-deep architecture contains only 33M parameters. However, its performance on three evaluation benchmarks downgrades by up to 7.4 points compared with #5 - #8, which demonstrates that 128-d may be a lower bound as universal sentence embeddings for aligning parallel sentences for 109 languages. Moreover, #10 - #12 show the results of MobileBERT-like architectures whose feed-forward hidden size is identical to hidden size. They have fewer parameters than #5 - #8, but they perform worse than #5 - #8, respectively (e.g., compare #10 with #6). Therefore, we did not employ MobileBERT-like architectures for LEALLA.

F Results of Ablation Study

We report all the results of the ablation study (Section 4.2) in Table 8.

Synthesizing Human Gaze Feedback for Improved NLP Performance

Abstract

Integrating human feedback in models can improve the performance of natural language processing (NLP) models. Feedback can be either explicit (*e.g.* ranking used in training language models) or implicit (*e.g.* using human cognitive signals in the form of eyetracking). Prior eye tracking and NLP research reveal that cognitive processes, such as human scanpaths, gleaned from human gaze patterns aid in the understanding and performance of NLP models. However, the collection of *real* eyetracking data for NLP tasks is challenging due to the requirement of expensive and precise equipment coupled with privacy invasion issues. To address this challenge, we propose ScanTextGAN, a novel model for *generating* human scanpaths over text. We show that ScanTextGAN-generated scanpaths can approximate meaningful cognitive signals in human gaze patterns. We include synthetically generated scanpaths in four popular NLP tasks spanning six different datasets as proof of concept and show that the models augmented with generated scanpaths improve the performance of all downstream NLP tasks.

1 Introduction

Integrating human signals with deep learning models has been beginning to catch up in the last few years. Digital traces of human cognitive processing can provide valuable signals for Natural Language Processing (Klerke et al., 2016a; Plank, 2016). Various approaches for integrating human signals have been explored. For example, human feedback for better decisioning (Christiano et al., 2017), NLP tasks (Stiennon et al., 2020; Wu et al., 2021), and most recently language modeling using reinforcement learning with human feedback (RLHF) based reward (Bai et al., 2022; Ouyang et al., 2022). RLHF involves explicit human feedback and is expensive and hard to scale. On the other hand, previous studies have also tried to use implicit human feedback in the form of eyetracking signals. It has proven to be a useful signal for inferring human cognitive processing (Sood et al., 2020; Hollenstein and Zhang, 2019; Mathias et al., 2020). NLP researchers have focused on assessing the value of gaze information extracted from large, mostly dis-jointly labeled gaze datasets in recurrent neural network models (Ren and Xiong, 2021; Strzyz et al., 2019; Barrett et al., 2018a). The proposed approaches under this paradigm include gaze as an auxiliary task in multi-task learning (Klerke et al., 2016b; Hollenstein et al., 2019), as additional signals (Mishra et al., 2016b), as word embeddings (Barrett et al., 2018b), as type dictionaries (Barrett et al., 2016a; Hollenstein and Zhang, 2019), and as attention (Barrett et al., 2018a).

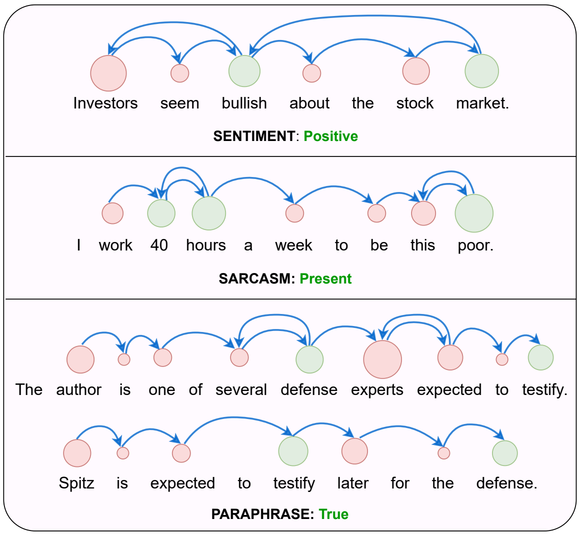

Figure 1: Generated scanpaths over text samples taken from various natural language processing (NLP) tasks. The green circles denote the important words characteristic of that task. The circles' size denotes the fixation duration, and the arrows depict the saccadic movements. As can be seen, linguistically important words often have a higher fixation duration and revisit. Regressions (word revisits) also appear in the examples.

Previous studies demonstrate that human scanpaths (temporal sequences of eye fixations, see Fig. 1) gleaned from eye tracking data improve the

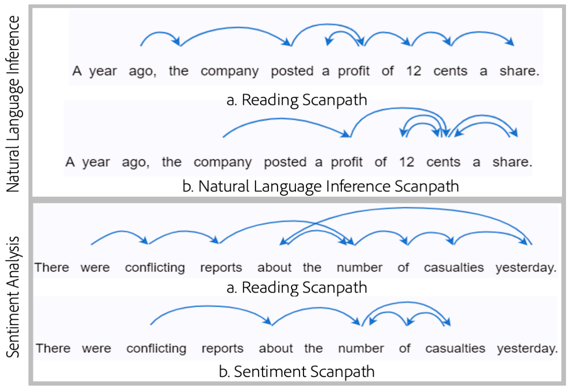

Figure 2: (Intent-aware) Scanpath samples generated by conditioning scanpath generation on different downstream natural language tasks. Note that the conditioned scanpaths are heavily biased to words important for that downstream task.

performance of NLP models. However, the real-world application of these methods remains limited primarily due to the cost of precise eye-tracking equipment, users' privacy concerns, and manual labor associated with such a setup. Therefore, generating scanpaths from existing eyetracking corpora would add great value to NLP research. To the best of our knowledge, this is the first paper to propose a model that generates scanpaths for a given read text with good accuracy. We call the model, ScanTextGAN.

We demonstrate the scanpath generation capability of ScanTextGAN over three eye-tracking datasets using multiple evaluation metrics. Further, we evaluate the utility of *generated* scanpaths for improvements in the performance of multiple NLP tasks (see Figs. 1,2) including the ones in the GLUE benchmark (Wang et al., 2018). The generated scanpaths achieve similar performance gains as the models trained with real scanpaths for classic NLP tasks like sentiment classification, paraphrase detection, entailment, and sarcasm detection.

Our contributions are threefold:

1. We propose ScanTextGAN, the first scanpath generator over text.

2. We compare ScanTextGAN with multiple baselines and conduct ablation experiments with varying models and configurations. The model performs well on the test sets and cross-domain generalization on two additional eyetracking datasets belonging to different text domains.

3. We tested the usefulness of generated scanpaths in downstream NLP tasks such as sentiment analysis, paraphrase detection, and sarcasm detection on six different datasets. The results show that the downstream NLP tasks benefited significantly from cognitive signals inherent in generated scanpaths. Further, we show how scanpaths change when finetuning with downstream natural language tasks (Figs.2,6) and that they lead to further improvements in downstream task performance (§4.3) showing how they can act as additional controls beyond the task architecture.

2 Related Work

When reading a text, humans do not focus on every word and often do not read sequentially (Just and Carpenter, 1980). A series of studies in psycholinguistics have shown that the number of fixations and the fixation duration on a word depend on several linguistic factors. The linguistic factors can also be determined given the cognitive features (Clifton Jr et al., 2007; Demberg and Keller, 2008). Though advances in ML architecture have helped bring machine comprehension closer to human performance, humans are still superior for most NLP tasks (Blohm et al., 2018; Xia et al., 2019).

It has been shown in the literature that integrating explicit (Bai et al., 2022; Ouyang et al., 2022) and implicit (cognitive processing) human feedback signals in traditional ML models is expected to improve their performance (Just and Carpenter, 1980). However, the cost of explicit feedback (e.g., using MTurk) and implicit feedback (e.g., eye tracking) at scale is excessively high. Similarly, privacy-invasive eye-tracking processes limit the scope of this idea. One way to address this problem is to use generated eye movements to unfold the full potential of eye-tracking research. Hence, the idea is to architect ScanTextGAN, a scanpath generator for text reading, and test its usefulness in downstream NLP tasks.

More precisely, this work builds upon previous works on 1) human attention modeling and 2) gaze integration in neural network architectures, which are described as follows:

Human Attention Modeling: Predicting what people visually attend to in images (saliency prediction) is a long-standing challenge in neuroscience and computer vision, the fields have seen many data-based models (Wang et al., 2021). In contrast to images, most attention models for eye movement behaviors during reading are cognitive process models, *i.e.*, models that do not involve machine learning but implement cognitive theories (Engbert et al., 2005; Xia et al., 2019). Key challenges for such models are a limited number of parameters and hand-crafted rules. Thus, it is difficult to adapt them to different tasks and domains and use them as part of end-to-end trained ML architectures (Kotseruba and Tsotsos, 2020). In contrast, learning-based attention models for text remain under-explored. Within that, all eye tracking models are saliency prediction models with non-existent work in predicting scanpaths. On the other hand, visual scanpaths generation for image-based eye tracking data has been recently explored for both traditional (Assens et al., 2019) and 360° images (Martin et al., 2022).

Matthies and Søgaard (2013) presented the first fixation prediction work for text. They built a person-independent model using a linear Conditional Random Fields (CRF) model. Hahn and Keller (2016) designed the Neural Attention Trade-off (NEAT) language model, which was trained with hard attention and assigned a cost to each fixation. Other approaches include sentence representation learning using surprisal and part of speech tags as proxies to human attention (Wang et al., 2017).

Our work differs from previous studies as we combine cognitive theory and data-driven approaches to predict scanpaths and further show its application in downstream NLP tasks (Hollenstein et al., 2021b,a).

Integrating Gaze in Network Architecture: Integration of human gaze data into neural network architectures has been explored for a range of computer vision tasks such as image captioning, visual question answering, and tagging (Karessli et al., 2017; Yu et al., 2017; He et al., 2019; Boyd et al., 2022). Hence, recent research has utilized features gleaned from readers' eye movement to improve the performance of complex NLP tasks such as sentiment analysis (Long et al., 2017; Mishra et al., 2016c), sarcasm detection (Mishra et al., 2016b), part-of-speech tagging (Barrett et al., 2016b), NER (Hollenstein and Zhang, 2019), and text difficulty (Reich et al., 2022).

While in recent years, eye tracking data has been used to improve and evaluate NLP models, the scope of related studies remains limited due to the requirement of real-time gaze data at inference time. Mathias et al. (2020) reported that there exists no automated way of generating scanpaths yet in the literature. With high-quality artificially generated scanpaths, the potential of leveraging eyetracking data for NLP can be unfolded. Additionally, generating scanpaths that mimic human reading behavior will help advance our understanding of the cognitive processes behind language understanding. Hence, we propose ScanTextGAN; researchers can use that to generate scanpaths over any text without worrying about collecting them from real users.

3 Proposed Model

In this section, we define the scanpath generation task, describe the ScanTextGAN model architecture, and provide details on loss functions and model training.

Task Definition: The task of scanpath generation is to generate a sequence $\mathcal{S}(\mathcal{T})$ representing a scanpath over the text $\mathcal{T} = \{w_1, w_2, ..., w_n\}$ composed of a sequence of words, can be defined as follows:

$$\mathcal{S}(\mathcal{T}) = \{.., (w_a^i, t^i), ..., (w_b^j, t^j), ..., (w_c^k, t^k)\} \tag{1}$$

where t^i represents the fixation duration over the word w_a occurring at the position i. Note that it is not necessary to have $a < b$ (words being read in linear order) or that $k = n$ (the number of fixations being equal to the number of words). Due to regressions, *i.e.*, backward saccades to previous words, words are also revisited. Hence, the same word could appear multiple times in the sequence.

3.1 ScanTextGAN Model Architecture

Fig. 3 illustrates the proposed conditional GAN architecture of the model. The ScanTextGAN model is composed of two competing agents. First, a conditional generator that generates scanpaths given text prompts. The second is a discriminator network, which distinguishes real human scanpaths from the generated ones. The ScanTextGAN model is trained by combining text content loss, scanpath content loss, and adversarial loss (Eq. 6). The scanpath content loss measures the difference between the predicted scanpath and the corresponding ground truth scanpath. The text content loss reconstructs the input text, and the adversarial loss depends on the real/synthetic prediction of the discriminator over the generated scanpath. We describe the losses along with the generator and discriminator architectures next.

Generator: The ScanTextGAN generator constitutes a transformer-based encoder-decoder framework. The encoder is conditioned on BERT-based text embeddings (Devlin et al., 2019), which are concatenated with noise to make the

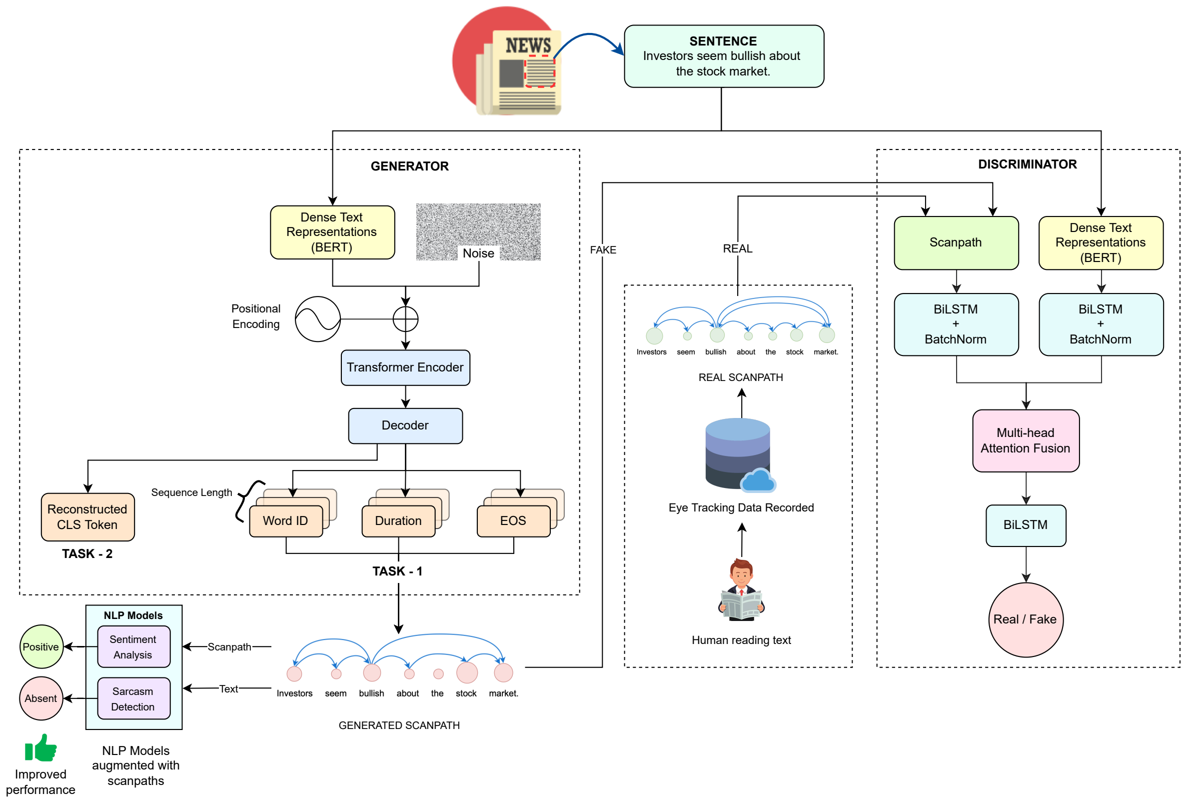

Figure 3: The architecture of the proposed **ScanTextGAN** model. The model consists of a conditional generator and a discriminator playing a zero-sum game. The generator is trained by two cognitively inspired losses: text content reconstruction and scanpath content reconstruction.

generator's output non-deterministic. The output of the transformer encoder is supplied to the decoder, which consists of task-specific feed-forward networks. One branch generates the scanpath (*Task 1*), while the other reconstructs the 768 dimensional CLS token embedding of the sentence (*Task 2*). The scanpath is output as a temporal sequence of word ID (fixation points) w_a^i, fixation duration t^i, and end-of-sequence probability EOS^i. At inference time, the length $L(G)$ of generated scanpath G is determined as follows:

$$L(G) = \begin{cases} \min_{1 \leq k \leq M}(k) & \text{if } EOS^k > \tau \\ M & \text{otherwise} \end{cases} \quad (2)$$

where M is the maximum scanpath length as described in section §3.2 and $\tau \in (0, 1)$ is a probability threshold. We use $\tau = 0.5$. The loss functions of the two branches are described below.

Scanpath Content Loss tries to minimize the deviation of generated scanpaths $\mathcal{G}(\mathcal{T},\mathcal{N})$ from the ground-truth scanpaths $\mathcal{R}(\mathcal{T},h))$ over text $\mathcal{T}$ where ground-truth scanpaths are recorded from the human h and $\mathcal{N}$ stands for Gaussian noise $\mathcal{N}(0, 1)$. The loss function $\mathbb{L}_s$ is given as:

$$\mathbb{L}_s(\mathcal{G}(\mathcal{T},\mathcal{N}),\mathcal{R}(\mathcal{T},h)) = \frac{1}{k}\Sigma_{i=0}^{k}(\alpha(id_g^i - id_r^i)^2 + \beta(t_g^i - t_r^i)^2 + \gamma(E_g^i - E_r^i)^2) \quad (3)$$

which is a weighted sum of three terms. The first term measures the error between real and predicted *fixation points* given by the mean squared difference between generated and real word-ids $(id_g^i - id_r^i)$. It penalizes permutations of word ids and trains the model to approximate the real sequence of fixation points closely.

The second term measures the difference in *fixation durations* given by the mean squared difference between generated and real duration $(t_g^i - t_r^i)$. Fixation durations simulate human attention over words in the input text. Thus, a word with a larger fixation duration is typically synonymous with greater importance than other words in the input text. This error term supplements the generator's ability to learn human attention patterns over the input text.

Finally, the third term measures the mean squared error between the prediction of end-of-sequence probability by real and generated distributions ($E_g^i - E_r^i$). These are weighted by the hyperparameters α, β, and γ. Preliminary experiments showed that optimizing the mean squared error leads to better performance over the cross-entropy loss for optimizing the EOS probability output.

Text Content Loss: Scanpaths depend heavily on the linguistic properties of the input text. Therefore, to guide the generator towards near the probable real data manifolds, we adopt reconstruction of the CLS token embedding of the input text (*Task 2*) by the generator as an auxiliary task since the CLS token embedding encodes a global representation of the input text. This text content reconstruction loss $\mathbb{L}_r$ is given as:

$$\mathbb{L}_r(\mathcal{G}(\mathcal{T},\mathcal{N}), \mathcal{R}(\mathcal{T}, h)) = (BERT(w_i^g, w_j^g, ..., w_k^g \\ - BERT(w_a^r, w_b^r, ...w_n^r))^2 \quad (4)$$

where $BERT(w_a^r, w_b^r, ...w_n^r)$ and $BERT(w_i^g, w_j^g, ...w_k^g)$ stand for the *CLS* vector representations of real and generated text respectively.

Discriminator: The goal of the discriminator is to distinguish between the real and synthetic scanpaths supplied to it. Similar to the generator, it requires text representations to distinguish between real and generated scanpaths. Specifically, the discriminator comprises two blocks of BiLSTMs that perform sequential modeling over the scanpaths and BERT embeddings. The outputs of the two branches are combined and passed to an attention fusion module with four heads, followed by another network of BiLSTMs. The hidden states of the last BiLSTM layer from both forward and backward directions are concatenated and supplied to a feed-forward network. A Sigmoid function activates the output of the feed-forward network. In this manner, the discriminator classifies the input scanpaths as either *real* or *fake*.

Adversarial Loss: The generator and discriminator networks are trained in a two-player zero-sum game fashion. The loss is given by:

$$\mathbb{L}_a = \min_G \max_D \mathbb{E}_{x \sim p_{\text{data}}(x)}[\log D(x|\mathcal{T}, h)] + \\ \mathbb{E}_{z \sim p_z(z)}[1 - \log D(G(z|\mathcal{T}, \mathcal{N}))] \quad (5)$$

Therefore, the net generator loss becomes:

$$\mathbb{L}_g = \mathbb{L}_s + \mathbb{L}_r + \mathbb{E}_{z \sim p_z(z)}[1 - \log D(G(z|\mathcal{T}, \mathcal{N}))] \quad (6)$$

3.2 Dataset

For training the ScanTextGAN model, we use the CELER dataset (Berzak et al., 2022). It contains eyetracking data of 365 participants for nearly 28.5 thousand newswire sentences, sourced from the Wall Street Journal Penn Treebank (Marcinkiewicz, 1994). Each participant in CELER reads 156 newswire sentences. Half of the sentences are shared across participants, and the rest is unique to each participant. The maximum sentence length was set to 100 characters. Participant eyetracking data were recorded using Eyelink 1000 tracker in a desktop mount configuration with a sampling rate of 1000 Hz. The ScanTextGAN model is trained to approximate the average eye movements of all the participants who read given sentences. The CELER dataset was envisioned to enable research on language processing and acquisition and to facilitate interactions between psycholinguistics and natural language processing. Furthering the goal, we use it to train our conditional GAN model through which we show human scanpath approximation capabilities (§4.2). Also, we use it to show improvements in the performance of NLP tasks (§4.3).

The data consist of tuples of participant ID, sentence ID, and word ID corresponding to fixation point and fixation duration. We compute the 99th percentile of fixation durations and treat it as the largest value. Fixations of durations longer than this are treated as outliers and hence dropped from the dataset. To apply the scanpath reconstruction loss (Eq. 3), we scale all fixation durations by the maximum value and then normalize them to [0,1]. Similarly, word IDs in each sentence are normalized to [0, 1] after scaling them by the length of that sentence. For the last fixation point in every scanpath, the binary EOS token is set to 1. The maximum scanpath length is set to 80 fixation points (99th percentile of the lengths). Thus shorter scanpaths are padded while longer scanpaths are trimmed. We use BERT to encode the sentences and obtain their 768-dimensional embeddings, keeping the max length parameter as 80, thus resulting in an 80 × 768 dimensional tensor.

3.3 Parameter Settings

Sinusoidal positional encoding is applied over the input embeddings fed to the generator. We use a 3-layer transformer encoder with four head attention and a hidden dimension size of 776 in the generator. In the discriminator, we use bidirectional LSTMs over sentence embeddings and generated scanpaths with a hidden size of 64 and a dropout ratio of 0.3, followed by batch normalization for faster convergence. An attention module with four attention heads is applied after concatenating the outputs. We employ the Adam and RMSProp optimizer to minimize generator and discriminator losses. The batch size is set to 128, the initial learning rate of the generator to 0.0001, and that of the discriminator to 0.00001. The model is trained for 300 epochs. Our implementation uses PyTorch, a popular deep-learning framework in Python. All experiments are run on an Intel Xeon CPU with Nvidia A100-SXM GPUs.

4 Performance Evaluation

We quantify the performance of ScanTextGAN in two regimes[1]; first, scanpath generation with three datasets, and second, NLP tasks with six datasets. Similar to prior computer vision studies (Sun et al., 2019; de Belen et al., 2022; Kümmerer and Bethge, 2021; Jiang et al., 2016), we evaluate the ScanTextGAN model over the scanpath generation task. For this, we use the test split of the CELER dataset, Mishra et al. (2016a), and Mishra et al. (2017). In addition, unlike the computer vision studies, we also evaluate the ScanTextGAN model for improvement in NLP tasks. The hypothesis is that the human eyes (and consequently the brain) process many language comprehension tasks unconsciously and without visible effort. The next logical step is to capture (or, in our case, generate) this mental representation of language understanding and use it to improve our machine-learning systems. For evaluation, we use four tasks from the GLUE benchmark and two from the tasks proposed by Mishra et al. (2016a). While the ScanTextGAN model is trained over news text from the CELER dataset, with the help of the other datasets, we expand our testing to other domains, including reviews, quotes, tweets, and Wikipedia text.

4.1 Evaluation Datasets

Mishra et al. (2017) comprises eye movements and reading difficulty data recorded for 32 paragraphs on 16 different topics, *viz.* history, science, literature, *etc*. For each topic, comparable paragraphs were extracted from Wikipedia[2] and simple Wikipedia[3]. The participant's eye movements are tracked using an SR-Research Eyelink-1000 Plus eye tracker. Using the ground truth scanpaths over the text corpora, we evaluate the quality of generated scanpaths.

Mishra et al. (2016a) contains eye fixation sequences of seven participants for 994 text snippets annotated for sentiment and sarcasm. These were taken from Amazon Movie Corpus , Twitter, and sarcastic quote websites. The task assigned to the participants was to read one sentence at a time and annotate it with binary sentiment polarity labels (*i.e.*, positive/negative). The same datasets were used in several studies (Joshi et al., 2015; Mishra et al., 2016b,c) to show improvements in sarcasm and sentiment analysis. We use the datasets to evaluate both the generation quality and potential improvements in NLP tasks.

Furthermore, we explore the potential of including cognitive signals contained in scanpaths in NLP models for a range of GLUE tasks which include Sentiment Analysis using Stanford Sentiment Treebank (SST), Paraphrase Detection using Microsoft Research Paraphrase Corpus (MRPC) and Quora Question Pairs (QQP), Natural Language Inference using Recognizing Textual Entailment (RTE) dataset.

Next, we cover the results of scanpath generation and its application in NLP tasks.

4.2 Evaluation of Scanpath Generation

We evaluate the scanpath generation model on two most commonly used metrics in image scanpath generation studies (Sun et al., 2019; Chen and Sun, 2018; de Belen et al., 2022; Kümmerer et al., 2022): **MultiMatch** (Jarodzka et al., 2010) and **Levenshtein Distance** (Levenshtein, 1965). Multimatch is a geometrical measure that compares scanpaths across a comprehensive set of dimensions composed of shape, lengths, position, and fixation duration. Levenshtein Distance between a pair of sequences measures the least number of edits (inserts, deletes, substitution) to transform one into the other. More details are discussed in Appendix:A.

Further, as a top-line comparison, we use **inter-subject scanpath similarity** (Sun et al., 2019). It

---

[1] All results are calculated with five random seeds and reported as the mean of those five runs

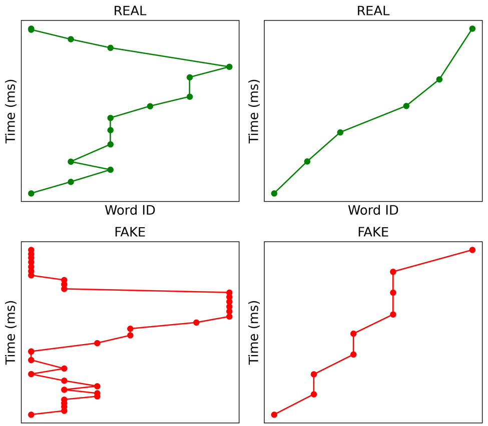
[2] `https://en.wikipedia.org/`

[3] `https://simple.wikipedia.org/`

[4] In the CELER dataset, there are only 78 shared sentences amongst all the participants. Therefore, inter-subject scanpath evaluation is done only for these sentences. In contrast, the ScanTextGAN results are reported for the entire test set (including these 78 sentences).

Generator Model	MultiMatch ↑				Levenshtein Distance ↓
	Vector↑	Length↑	Position↑	Duration↑	
Inter-subject score[4]	0.973	0.958	0.830	0.698	0.691
LSTM Encoder-Decoder trained with scanpath content loss	0.975	0.956	0.765	0.344	0.865
ScanTextGAN – Text Reconstruction – GAN Loss	0.968	0.947	0.728	0.703	0.779
ScanTextGAN	**0.983**	**0.972**	**0.787**	0.733	**0.769**
ScanTextGAN – Text Reconstruction	0.974	0.957	0.773	0.703	0.798
ScanTextGAN – GAN Loss	0.973	0.955	0.750	**0.761**	0.786
ScanTextGAN + addition of noise	0.971	0.952	0.756	0.736	0.791
ScanTextGAN – Text (CLS) Reconstruction + sentence reconstruction	0.978	0.963	0.724	0.721	0.805

Table 1: In-domain Evaluation of Scanpath Generation on the CELER dataset (Berzak et al., 2022).



Mr. Baker promises to return if the haunting continues.

Soon she was running the office.

Figure 4: Comparison of *real* and *synthesized* scanpaths corresponding to a few text samples. The proposed ScanTextGAN model generates the latter.

measures the degree of variation among real human scanpaths corresponding to each text input. To compute this, we first calculate each subject's performance by treating the scanpaths of other subjects as the ground truth. Then, the average value of all subjects is used as inter-subject performance.

Baselines: Since ScanTextGAN is the first text-based scanpath generation model, we conduct an ablation study to compare ScanTextGAN with its other variants. Specifically, we compare ScanTextGAN with the following six configurations: (1) An LSTM-based network trained with scanpath content loss. Sentence embeddings obtained through BERT are concatenated with noise in this model. The resultant is fed to an attention module with four heads, then passed to a network of LSTMs and Batch Normalization layers applied in tandem. (2) ScanTextGAN model trained with only the scanpath content loss. (3) ScanTextGAN model without the text reconstruction loss (Task-2). (4) ScanTextGAN model with BERT-based sentence embeddings reconstruction instead of CLS token reconstruction. (5) ScanTextGAN model with the addition of noise instead of concatenation. (6) ScanTextGAN model trained without GAN loss.

Results: Table 1 presents the results of our scanpath prediction model on the CELER dataset. Further, we also compare ScanTextGAN with baselines on two other contemporary datasets of movie reviews, tweets, and sarcastic quotes (Mishra et al., 2016a), Wikipedia and simple Wikipedia paragraphs (Mishra et al., 2017). Tables 2 and 3 present the results of our model on those datasets. For obtaining results on these corpora, we use the model trained on the CELER dataset, thus helping us evaluate the cross-domain performance of the model.

As can be seen in Table 1, Table 2 and Table 3, ScanTextGAN outperforms other models for scanpath prediction on most metrics. The performance of ScanTextGAN even surpasses inter-subject reference on Duration and comes very close to Vector, Length, and Position.

We observe that adopting the reconstruction of the CLS token as an auxiliary task (Task - 2) boosts the model performance. Reconstructing the full sentence embeddings rather than the CLS tokens only as an auxiliary task does not always improve the results, despite adding a larger computational overhead. The results also reveal that concatenating noise with text embeddings is more rewarding than adding it.

Further, to compare the skipping behavior of ScanTextGAN with humans, we calculate the weighted F1 score of the words skipped and attended by both model types. We find the weighted F1 to be 64.6 between them. Fig. 4 presents a visual comparison between real scanpaths from the available eyetracking data and scanpaths generated by ScanTextGAN, corresponding to some randomly chosen text samples. We can observe that the generated scanpaths resemble the real ones to a great

Generator Model	**MultiMatch ↑**				**Levenshtein Distance ↓**

Table 3: Cross-domain Evaluation of Scanpath Generation on the Dataset by Mishra et al. (2017).

extent. Thus, the quantitative and qualitative results on in-domain and cross-domain settings lead us to believe that our proposed scanpath generation model can be deemed a good approximator of the human scanpaths.

4.3 Application to NLP Tasks

We use them to augment various NLP models and measure their performance to demonstrate the usefulness of cognitive signals hidden in the *generated* scanpaths.

Sentiment Classification and Sarcasm Detection: For these tasks, we use a model consisting of a network of two branches of BiLSTMs and Batch Normalization layers that perform sequential modeling over text representations obtained through BERT and scanpaths fed as input to the model. The outputs of both branches are combined and passed to another layer of BiLSTMs, followed by a feed-forward network that predicts binary sentiment/sarcasm labels corresponding to the input after activating with the Sigmoid function. We follow a 10-fold cross-validation regime.

We compare the models with generated scanpaths, real scanpaths, and without scanpaths. Further, to investigate whether performance gains observed by adding scanpaths are due to scanpaths and not the increase in the number of parameters, we train a *Random-Random* variant in which we send Random noise as scanpaths to the model with an increased number of parameters. We also simulate the real-world case where both real and generated scanpaths are available during train time, but only generated ones are available during test time, for example, during user deployment.

Model Configuration		**F1 score**	
Train	**Test**	**Sentiment**	**Sarcasm**
w/o	w/o	0.7839	0.9438
Random	Random	0.7990	0.9397
Random	Generated	0.7773	0.9313
Real	Generated	0.8319	0.9378
Real	Real	0.8334	0.9501
Generated	Real	0.8402	0.9452
Generated	Generated	0.8332	0.9506
Real + Generated	Generated	**0.8404**	**0.9512**
Intent-Aware	Intent-Aware	**0.8477**	**0.9528**

Table 4: Sentiment analysis and sarcasm detection results on the dataset by Mishra et al. (2016a). Model configuration refers to the type of scanpath included in train and test data.

Table 4 records the results of sentiment analysis and sarcasm detection tasks (Mishra et al., 2016a). We note that generated scanpaths training and testing lead to similar gains for sentiment analysis and sarcasm detection as real scanpaths. The model with an increased number of parameters fed random noise in place of scanpaths performs similarly to the model trained without any scanpaths. Interestingly, the best results are obtained when model training uses both real and generated scanpaths. We believe this is due to ScanTextGAN bringing additional cognitive information from the news-reading CELER corpus, which is not present in the

Dataset	Model	Acc	F1 score
SST	w/o scanpaths	0.8090	0.8089
	w/ random scanpaths	0.8059	0.8061
	w/ generated scanpaths	**0.8138**	**0.8138**
	w/ intent-aware scanpaths	**0.8269**	**0.8272**
MRPC	w/o scanpaths	0.6902	0.6656
	w/ random scanpaths	0.6623	0.6680
	w/ generated scanpaths	**0.6969**	**0.6828**
	w/ intent-aware scanpaths	**0.7009**	**0.6911**

	w/ generated scanpaths	**0.8578**	**0.8596**
	w/ intent-aware scanpaths	**0.8648**	**0.8658**

Table 5: Results of training NLP models with and without scanpaths on the GLUE benchmark tasks. Including scanpaths leads to consistent improvements across all the NLP tasks.

real scanpaths in Mishra et al. (2016a). In addition to the intrinsic evaluation presented in §4.2, this downstream evaluation demonstrates the high quality of the synthesized scanpaths, showing that they contain valuable cognitive processing signals for NLP tasks.

GLUE Tasks: To validate further, we augment classification models (based on sequential modeling using LSTMs) with generated scanpaths to show performance improvement in downstream NLP tasks on four GLUE benchmark datasets – SST, MRPC, RTE, QQP as described in §4.1. Table 5 reports the accuracy and weighted-F1 scores of the models trained with and without scanpaths for these tasks. We observe that in all four tasks, the model trained with generated scanpaths outperforms the one without scanpaths.

Intent-Aware Scanpaths: Finally, we try to condition scanpaths generation on the downstream natural language task. We back-propagate gradients from the downstream NLP task to the conditional generator. In this fashion, the model learns to generate *intent-aware* scanpaths. The hypothesis is that finetuning scanpath generation based on feedback from the natural language task will bias the generator towards words more pertinent to that task and thus could help further improve performance on the downstream task. The architecture is shown in Appendix: Fig 5. The results in Tables 4 and 5 validate the hypothesis that we observe consistent improvements in all downstream tasks. Fig 2 and Appendix: Fig 6 show a few examples of scanpaths and saliency generated for three downstream natural language tasks.

Together these results corroborate the hypothesis that leveraging the cognitive signals approximated by synthetic scanpaths in NLP models leads to performance gains.

5 Conclusion

In this work, we make two novel contributions toward integrating cognitive and natural language processing. (1) We introduce the first scanpath generation model over text, integrating a cognitive reading model with a data-driven approach to address the scarcity of human gaze data on text. (2) We propose generated scanpaths that can be flexibly adapted to different NLP tasks without needing task-specific ground truth human gaze data. We show that both advances significantly improve performance across six NLP datasets over various baselines. Our findings demonstrate the feasibility and significant potential of combining cognitive and data-driven models for NLP tasks. Without the need for real-time gaze recordings, the potential research avenues for augmenting and understanding NLP models through the cognitive processing information encoded in synthesized scanpaths are multiplied.

6 Limitations

In this work, we demonstrated artificial scanpath generation over multiple eye-tracking datasets. Further, our experiments build a link between cognitive and natural language processing and show how one can inform the other. However, the proposed method has a few limitations, which we aim to address in the future. The field needs work on bigger and more diverse eye-tracking datasets, which can enable scanpath generation over longer text sequences and can model generating scanpaths conditioned on previously read context. Besides, a better understanding of the entire scanpath generation process can help model the intra and inter-sentence scanpath generation process. The understanding would enable the integration of scanpaths to generative modeling tasks, which we intend to take up in future work. Another parallel direction is to include both explicit (like using RLHF) and implicit signals (like using cognitive signals) to better NLP tasks like language modeling.

A Scanpath Evaluation Metrics

MultiMatch is a geometrical measure that models scanpaths as vectors in 2-D space, wherein the vectors represent saccadic eye movements. Starting and ending coordinates of these saccades constitute the fixation positions. It compares scanpaths across multiple dimensions, *viz.* shape, length, position, direction, and fixation duration. Shape measures the vector difference between aligned saccade pairs, which is then normalized by twice the diagonal screen size. Length measures the normalized difference between the endpoints of real and generated saccade vectors. Direction is the angular distance between the two vectors. The position is the Euclidean difference in position between aligned vectors, and duration measures the difference in fixation durations normalized against the maximum duration. Since our work deals with scanpaths over text, we use 1-D space to represent the saccade vectors where word IDs denote the fixation positions. Thus, it is easy to see that computing scanpath direction similarity is redundant here (it is subsumed within position); hence we drop it from our analysis.

Levenshtein Distance between a pair of sequences measures the least number of character edits, i.e., insertion, deletion, and substitution needed to transform one sequence into the other. Specifically, we use it to gauge the degree of dissimilarity between a pair of real R and generated G scanpaths. To account for the fixation durations of each word, R and G are temporally binned using a 50 ms bin size, similar to the computation of ScanMatch metric (Cristino et al., 2010). The resulting sequences of word IDs, R_W and G_W are transformed into character strings, $R_S = \{r_1, r_2, ..., r_n\}$ and $G_S = \{g_1, g_2, ..., g_m\}$, where R_S and G_S are strings over the ASCII alphabet and $n = |R_S|$ and $m = |G_S|$.

Levenshtein Distance (LD) between strings R_S and G_S is computed and then normalized by the length of the longer string, which yields a Normalized Levenshtein Distance (NLD) score, as given below:

$$NLD = \frac{LD(G_S, R_S)}{\max(|R_S|, |G_S|)} \tag{7}$$

Thus, a lower NLD score is indicative of greater scanpath similarity.

B Intent-Aware Scanpaths

As described in section §4.3, the generator conditioned on the downstream natural language task yields *intent-aware* scanpaths. Augmenting NLP models with these scanpaths leads to higher performance gains. Here, we provide more details on *intent-aware* scanpath generation. Please refer to figures 5 and 6 on the following page. Saliency corresponding to intent-aware scanpaths are shown in Fig. 6.

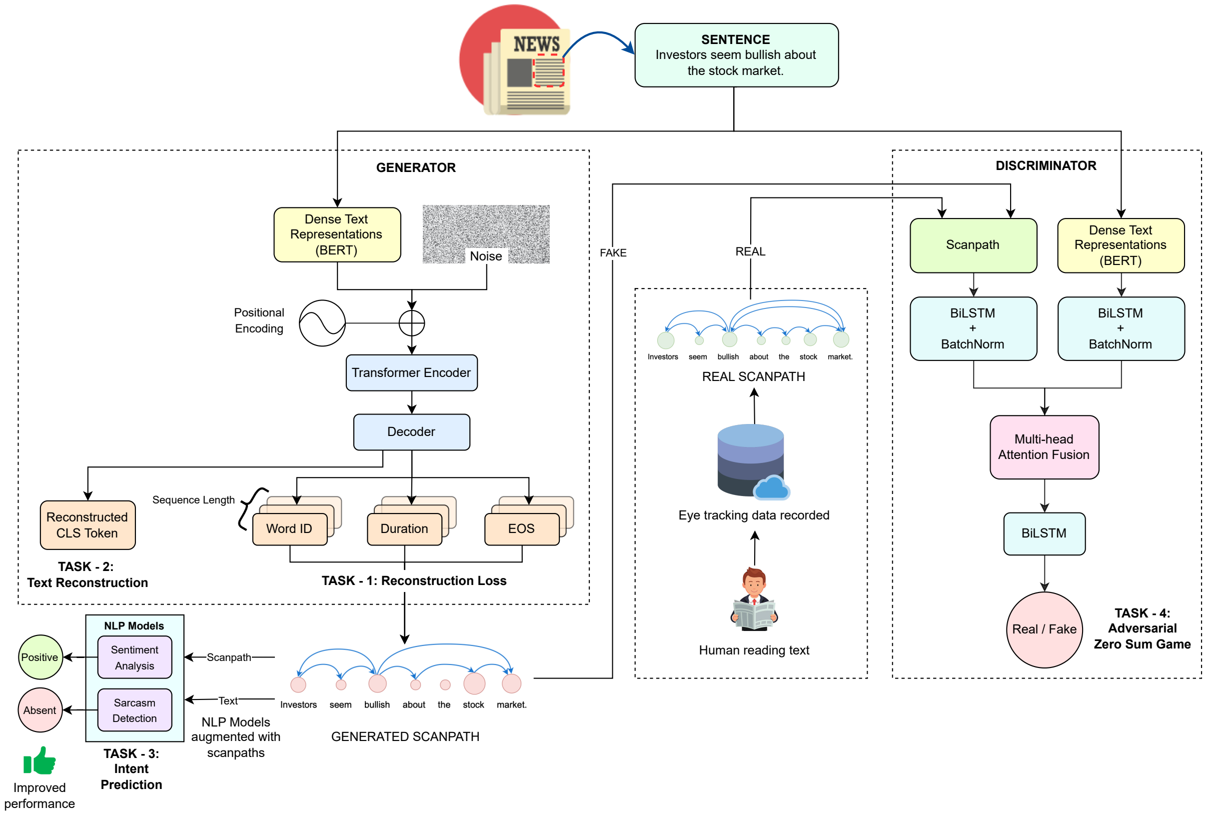

Figure 5: The architecture of the proposed Intent-Aware **ScanTextGAN** model. The model consists of a conditional generator and a discriminator playing a zero-sum game. Two cognitively inspired losses train the generator: scanpath (Task-1) and text (Task-2) reconstruction, a loss from the downstream intent of the natural language task (Task-3), and finally, the loss from the adversarial zero-sum game (Task-4). Variations of scanpaths are generated based on the downstream natural language task.

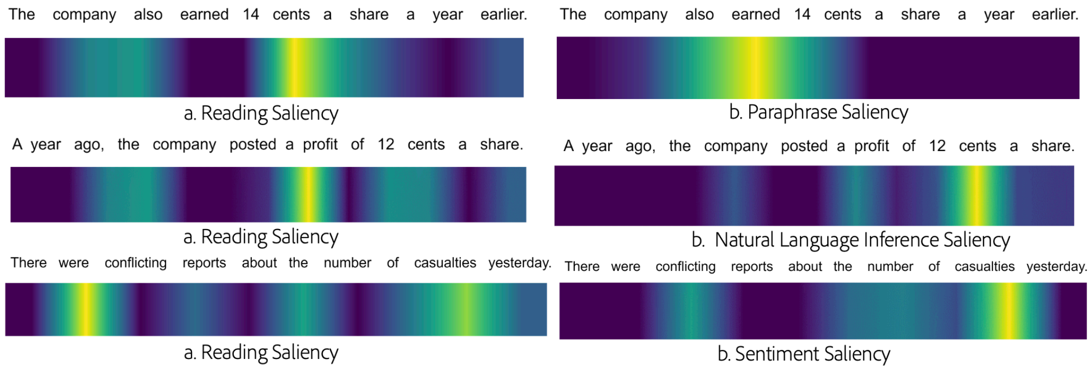

Figure 6: Saliency samples generated by conditioning scanpath generation on different downstream natural language tasks. It can be observed that the conditioned saliency pays much more attention to words important for that downstream task.

Memory-efficient Temporal Moment Localization in Long Videos

Abstract

Temporal Moment Localization is a challenging multimodal task which aims to identify the start and end timestamps of a moment of interest in an input untrimmed video, given a query in natural language. Solving this task correctly requires understanding the temporal relationships in the entire input video, but processing such long inputs and reasoning about them is memory and computationally expensive. In light of this issue, we propose Stochastic Bucket-wise Feature Sampling (SBFS), a stochastic sampling module that allows methods to process long videos at a constant memory footprint. We further combine SBFS with a new consistency loss to propose LocFormer, a Transformer-based model that can process videos as long as 18 minutes. We test our proposals on relevant benchmark datasets, showing that not only can LocFormer achieve excellent results, but also that our sampling is more effective than competing counterparts. Concretely, SBFS consistently improves the performance of prior work, by up to 3.13% in the mean temporal IoU, leading to a new state-of-the-art performance on Charades-STA and YouCookII, while also obtaining up to 12.8x speed-up at testing time and reducing memory requirements by up to 5x.

1 Introduction

Processing long untrimmed videos for understanding and reasoning is a computationally expensive task that not only demands a smart approach that can capture global and local interaction, but also requires allocating thousands of frames in memory (Wu et al., 2022). Previous work so far has mostly focused on parsing the visual content in independent snapshots of a video, which limits the approaches in terms of modeling long-term dependency between events in the input.

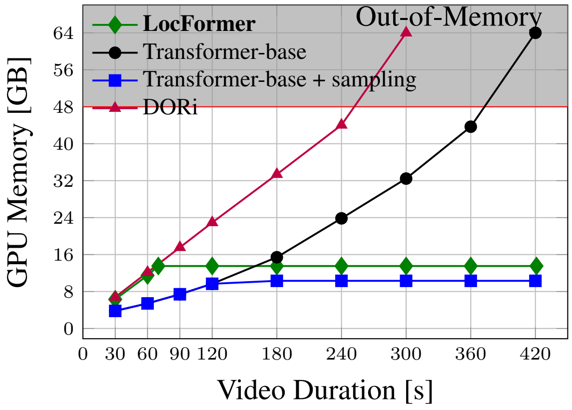

Figure 1: Empirical upper-bound memory consumption of LocFormer, Transformer-base, with and without enabling our proposed sampling technique (SBFS), and DORi (Rodriguez-Opazo et al., 2021). Memory usage (y-axis) is computed on an NVIDIA RTX-8000 GPU, using a batch size of 32 and assuming all sequences have maximum length for the given video duration.

In this paper, we particularly look at the task of temporal moment localization, which aims to identify the start and end timestamps of *a moment of interest* in an input untrimmed video given the query in natural language (Richard et al., 2018; Lin et al., 2017; Escorcia et al., 2016; Chao et al., 2018; Gao et al., 2017b; Xu et al., 2019). Recent approaches have aimed at directly predicting the starting and ending temporal locations, or regressing them from the input video, moving away from the propose-and-rank based approaches (Yuan et al., 2019c; Ghosh et al., 2019; Rodriguez-Opazo et al., 2020). Although these models are more efficient and can potentially capture the influence between different events in a video, they still require a considerable amount of computation and/or memory since they need to process the whole input video at once.

Recent improvements in both Natural Language Processing (NLP) and Computer Vision (CV) tasks can be attributed to the Transformer (Vaswani et al., 2017) model. Despite their success, one main draw-

back of these models is their computational cost, with memory usage ballooning as model sizes increase to attain better performance. This issue is exemplified by many existing developments in Transformer models for video understanding only being capable of processing short inputs at a time due to memory constraints. For example, TimeSformer-large (Bertasius et al., 2021) can only process inputs that are 24 seconds long[1], ViVIT (Arnab et al., 2021) and X-ViT (Bulat et al., 2021) can receive inputs that are up to 32 frames long, while other approaches like MERLOT (Zellers et al., 2021) and ClipBERT (Lei et al., 2021) specifically sample a single or a few frames from the whole video.

In light of this issue, we present Stochastic Bucket-wise Feature Sampling (SBFS). During training, SBFS first splits the input feature sequence into a fixed number of sections (buckets) and then selects a single feature per bucket using a stochastic approach. At testing time, our module selects the sufficient statistic of each bucket, which allows us to obtain a feature sample-set that is representative of the video content for the task at hand while keeping the memory footprint constant

To show the effectiveness of our sampling technique, we combine SBFS with a broad selection of models from previous work, and also use it to propose LOCFORMER, a Transformer-based model that operates at a constant memory footprint regardless of the input length, as shown in Figure 1. We conduct experiments on three challenging datasets, Charades-STA (Gao et al., 2017a), ActivityNet Captions (Caba Heilbron et al., 2015; Krishna et al., 2017) and YouCookII (Zhou et al., 2018b,a). We show that by applying SBFS in previous work we improve their performance in all considered datasets, leading to a new state-of-the-art on Charades-STA and YouCookII, while reducing the memory requirements by up to 5x. Furthermore, LOCFORMER is able to obtain state-of-the-art performance in the latter, and competitive results elsewhere.

We believe our results highlight the importance of sampling techniques as a valid mechanism to obtain better coverage of long input videos while keeping memory usage under budget. This ultimately provides a concrete direction for further research on tasks where it is necessary to cover long untrimmed videos, which include but are not limited to video grounding. We release our code and data[2] to encourage future research in this area.

2 Related Work

Sampling To the best of our knowledge, the earliest example of a sampling technique that is similar to ours is the work of Nakagawa and Nakanishi (1988), who proposed a stochastic version of dynamic time warping for speech recognition of the Japanese language in the late 80s. This idea was further extended by Suryanto et al. (2016) in the context of motion recognition, where a randomized version of dynamic time warping for this task was introduced. We also find several models that utilize sampling techniques for action recognition in videos, in this case to specifically select salient clips, such as SCSampler (Korbar et al., 2019) and MGSampler (Zhi et al., 2021), which were later adopted by models like MVFNet (Wu et al., 2021). Also, Adaframe (Wu et al., 2019b) recently proposed a framework that adaptively selects relevant frames on a per-input basis for fast video recognition. Fayyaz et al. (2021) introduced differentiable parameter-free Adaptive Token Sampling (ATS), which uses a scoring to adaptively sample significant tokens and can be plugged into any existing vision transformer architecture. Finally, Wu et al. (2019a), recently proposed to process short video segments at a time also augmenting the models with a long-term bank from where global features can be sampled. This ultimately enables them to process longer overall inputs without losing global information. While their motivation is similar to ours, we note that their proposed sampling technique is not stochastic and requires learning. Moreover, our results show that performance improvements are possible without access to global context, making our contributions fundamentally different in this sense.

Temporal Action and Moment Localization The goal of *Temporal Action Localization* is to solve the problem of recognizing and determining temporal boundaries of action instances in videos, with extensive previous work devoted to it (Shou et al., 2016; Gu et al., 2018; Girdhar et al., 2019). Given its limitations —restricted to a pre-defined list of labels— the task of language-driven *temporal moment localization* was introduced as a generalization (Gao et al., 2017a; Hendricks et al., 2017). In this task, the goal is to determine the start and

---

[1] TimeSformer-base/large reads 8 frames at 32/4 fps respectively.

[2] https://github.com/crodriguezo/locformer

end times of the video segment that best corresponds to a given natural language query. As this requires the model to extract useful information from the textual semantics in the query in order to identify the moment, this task is also usually regarded as video grounding. Early approaches that tackled temporal moment localization, including (Liu et al., 2018) and Ge et al. (2019), were mainly based on the generation of candidate clips which could later be ranked. Soon after, Chen et al. (2018), Chen and Jiang (2019), and Xu et al. (2019) focused mainly on reducing the number of proposals by producing query-guided or query-dependent approaches. Recently, Zhang et al. (2021a) also adopted a Transformer-based model for this setting, being the most relevant to our work.

The extensive computation of enumerating candidates in the above-mentioned proposal-based methods led to the development of methods that can directly output the temporal coordinates of the segment, namely, proposal-free approaches. In this context, Ghosh et al. (2019) first focused directly on predicting the start and end frames using regressions, and soon after Rodriguez-Opazo et al. (2020) improved results by modelling label uncertainty. While Mun Mun et al. (2020) and Zeng et al. (2020) later proposed more sophisticated modality matching strategies, some more recent approaches have focused on better contextualizing I3D (Carreira and Zisserman, 2017) video features by proposing other model variations (Li et al., 2021). More recently, Liu et al. (2021), CPNet (Li et al., 2021), VSLNet (Zhang et al., 2020a) have pushed performance further up. Finally, models like DORi (Rodriguez-Opazo et al., 2021), which also incorporates spatial features and CPN (Zhao et al., 2021) have proposed ad-hoc graph-based approaches. Compared to these models, our contributions go in a different direction which can be complementary because of their large memory consumption, as shown in Section 5.4.

3 Stochastic Bucket-wise Feature Sampling

Let G be a sequence of input video features extracted by a video encoding function $F_V(V)$. We are interested in developing a module to limit the memory budget of a given model when dealing with long video inputs. In order to do this, we limit the overall memory budget of the model by shortening the sequence of video features fed into the localization module. We do this in practice by proposing a technique that we call Stochastic Bucket-wise Feature Sampling (SBFS), which returns a sequence of length at most b derived from G, as follows.

$$\text{SBFS}(G; b) = \begin{cases} \{\boldsymbol{g}_i\}_{i=1}^{n} & \text{if } n \leq b \\ \{\boldsymbol{g}_{f(k)}\}_{k=1}^{m(n,b)} & \text{if } n > b \end{cases} \quad (1)$$

In Equation 1, $m(n, b)$ characterizes the number of buckets to be allocated to host video features, and is defined as $m(n, b) = \lfloor \frac{n}{\lceil n/b \rceil} \rfloor \leq b$, where $\lfloor\rfloor$, $\lceil\rceil$ are the floor and ceiling operators, respectively. The index $f(k)$ is sampled according to a uniform distribution over the indices of the features in the bucket, as Equation 2 shows, below.

$$f(k) \sim \mathcal{U}_{\lceil n/b \rceil \cdot (k-1)}^{\lceil n/b \rceil \cdot k} \quad (2)$$

More intuitively, we create a fixed number of buckets and allocate features to each by equally distributing them into the buckets. During training, we randomly sample a single feature for each bucket, following a uniform distribution, effectively reducing the input sequence length to at most b, the number of buckets. When doing this, we also accordingly convert the original set of labels $\tau^s, \tau^e \in [1, \dots, n]$ into $\bar{\tau}^s, \bar{\tau}^e \in [1, \dots, b]$. For simplicity, without loss of generality, for the rest of the paper we will assume the sampling module always returns total of b video features.

It is possible to prove that any sampled video feature sequence $\tilde{G}$ obtained using SBFS contains sufficient statistics of G, which allows us to train our models on very long videos with adequate guarantees. From this, it also follows that although SBFS can also be applied during inference, it is better to decouple the model from this stochastic component and instead utilize the max pooling operator over the features of the bucket at inference time. This gives models increased stability when predicting, without sacrificing performance, as we will show in Section 5.3. We refer the reader to Section A of our supplementary material for the full details on our theoretical analysis of SBFS.

4 LOCFORMER

In what follows, we assume that a given video $V \in \mathcal{V}$ can be characterized as a sequence of frames such that $V = \{v_t\}$ with $t = 1, \dots, l$. Each video in $\mathcal{V}$ is annotated with a natural language passage $S \in \mathcal{S}$ where S is a sequence of

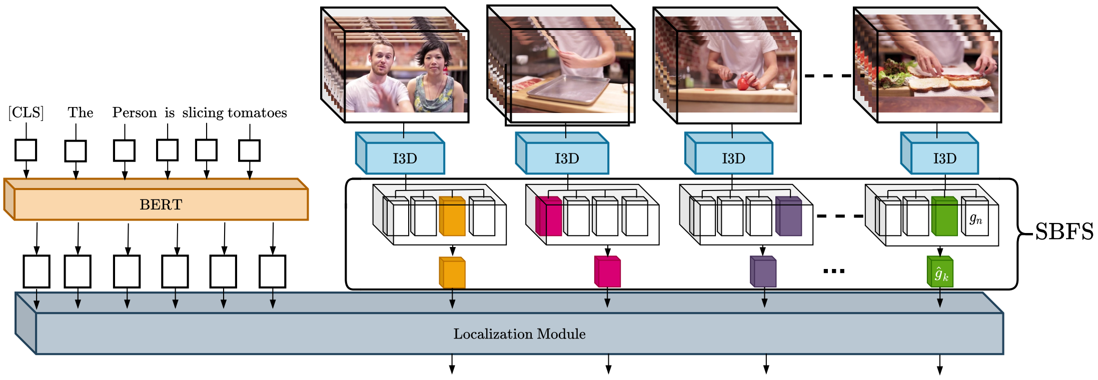

Figure 2: Our method uses a sampling technique that divides the video into a fixed number of buckets. Then, we uniformly sample a single I3D feature from each bucket, which is then fed into the localization module, a multi-modal Transformer model that receives video features and language features obtained from BERT.

tokens $S = \{s_j\}$ with $j = 1, \ldots, m$, which describes what is happening in a certain period of time. Formally, this interval is defined by t^s and t^e, the starting and ending points of the annotations in time, respectively. Although in the data a given video may be annotated with more than one single moment, and one natural language description may be associated to multiple moments, in this work we assume each derived case as an independent, separate training example.

Our model is trained to predict the most likely temporal localization of the contents of a given input query S in terms of its start and end positions $t^{s\star}$ and $t^{e\star}$ in the video. We apply the mapping $\tau = (t \cdot n \cdot \text{fps})/l$ to transform frame/feature index to time, converting t^s and t^e into τ^s and τ^e, which correspond to specific integer feature positions such that $\tau^s, \tau^e \in [1, \ldots, n]$.

LOCFORMER follows the Transformer architecture (Vaswani et al., 2017), which has been recently extended to multi-modal scenarios as in UNITER (Chen et al., 2020) in the context of vision-and-language, and Recurrent VLN-BERT (Hong et al., 2021) for vision-and-language navigation. Our model operates on sequences of tokens $\{s_j\}$ and a video $\{v_t\}$ characterized as a sequence of frames, as specified earlier. The overall architecture is composed by three main modules, as shown in Figure 2. (1) The Video Encoding Module, which is in charge of mapping video frames to vectors, and obtaining a sample that is representative of the video contents using SBFS, (2) the Text Encoding Module, a Transformer model with dimension d_m in charge of extracting useful representations from the natural language query, and (3) the Localization Module, a multi-modal Transformer, also with hidden dimension d_m, which receives both textual and video features from the previous modules and is in charge of estimating τ^s and τ^e. In the following subsections, we give details about each component and how they interact.

Video Encoding Module with SBFS Our video encoding module is in charge of mapping the l input video frames into a sequence of video features $G = \{\boldsymbol{g}_i \in \mathbb{R}^{d_v}\}, i = 1, \ldots, n$. At the core of this module lies SBFS, which we use to select a subset of the features that are representative of the contents of the video. Thus, the sampled video feature sequence $\tilde{G}$ will later be fed into the localization module.

Text encoding module Sentences are processed using the BERT tokenizer, which also prepends the special `CLS` token, and adds the `SEP` marker at the end. Each token is mapped to learned embeddings of dimension d_m and summed with learned positional encodings of the same size. These vectors are passed through $\bar{L}$ encoder transformer blocks with $\bar{M}$ attention heads, to produce final text representations $[\bar{\boldsymbol{h}}_0, \ldots, \bar{\boldsymbol{h}}_m]$.

Localization module A Transformer model that receives both textual and video features, previously obtained by the respective modules. For the former, we directly input $\bar{\boldsymbol{h}}_0, \ldots, \bar{\boldsymbol{h}}_m$, while for the latter we first project $\tilde{G} = [\tilde{\boldsymbol{g}}_1, \ldots, \tilde{\boldsymbol{g}}_b]$ into the hidden dimension using a trainable linear layer and further combine this with a set of learned positional encodings. These two encoded vector sequences are concatenated lengthwise and passed through L encoder blocks with M attention heads, to produce $[\boldsymbol{h}_0, \ldots, \boldsymbol{h}_{m+b}]$.

From these vectors, we select $[\boldsymbol{h}_{m+1}, \ldots, \boldsymbol{h}_{m+b}]$ and utilize the same localization function proposed by Rodriguez-Opazo et al. (2020) as the main training signal, namely, feature-level soft classification task on the time dimension. Concretely, two different MLP layers produce scores of each position being the start/end of the location, which are passed through a softmax activation to obtain $\hat{\boldsymbol{\tau}}^s, \hat{\boldsymbol{\tau}}^e \in \mathbb{R}^b$, which are compared to soft-labels using the Kullback-Leibler divergence ($\mathcal{L}_{KL}$).

In order to guide the model to utilize the information in the relevant section of the video, we encourage the attention heads of this module to put more weight into the target video portions during training, adapting the approach proposed by Rodriguez-Opazo et al. (2020) as shown below.

$$\mathcal{L}_{att} = -\sum_{l=1}^{L}\sum_{m=1}^{M}(\mathbf{1} - \boldsymbol{x} \otimes \boldsymbol{x}) * \log(\mathbf{1} - \boldsymbol{A}^{l,m}) \quad (3)$$

In Equation 3, $\boldsymbol{A}^{(l,m)}$ is the attention matrix of the l-th layer and m-th attention head of the localization module and $\boldsymbol{x} \in \mathbb{R}^{m+b}$ is a vector that denotes which areas of the output sequence will be subject to our guiding signal, and is defined as $\boldsymbol{x} = [\mathbf{1}_m; \boldsymbol{\delta}_{\tau^s \leq i \leq \tau^e}]$, where ; denotes concatenation, δ is the Kronecker delta returning 1 when i is inside the range of τ, and $\mathbf{1}_k$ denotes a vector of ones of size k.

Since our proposed localization loss is not sensitive to the order of the predictions of the starting and ending locations because there is no conditioning on the time in the model portions that generate them, in this paper we additionally propose to induce the model to respect the start-end order, taking a probabilistic approach. Concretely, we push the expected location of the start of the segment (S) to be before the expected location of the ending (E) location, which is equivalent to requiring $\mathbb{E}(E) - \mathbb{E}(S) > 0$. Replacing the values of the expectations, we obtain the following.

$$\mathbb{E}(E) - \mathbb{E}(S) = \sum_{i=1}^{b} \hat{\tau}_i^e i - \sum_{i=1}^{b} \hat{\tau}_i^s i = \sum_{i=1}^{b} i(\hat{\tau}_i^e - \hat{\tau}_i^s) \quad (4)$$

In Equation 4 above, $\hat{\tau}_i^s$ and $\hat{\tau}_i^e$ are integers that denote the predicted probability value of the starting and ending localizations at position i. Based on this derivation, we formally implement our loss by minimizing the negative difference of the expected values as shown in Equation 5, below.

$$\mathcal{L}_{se} = \min(0, \sum_{i=1}^{b} i(\hat{\tau}_i^s - \hat{\tau}_i^e)) \quad (5)$$

Finally, our model is trained with the direct summation of the three losses introduced earlier, such that $\mathcal{L} = \mathcal{L}_{KL} + \mathcal{L}_{att} + \mathcal{L}_{se}$.

5 Experiments

5.1 Datasets

To evaluate our proposed approach, we work with three widely-utilized and challenging datasets.

Charades-STA Built upon the Charades dataset (Sigurdsson et al., 2016), which provides time-based annotations using a pre-defined set of activity classes, and general video descriptions. We use the predefined train and test sets, containing 12,408 and 3,720 moment-query pairs respectively. Videos are 31 seconds long on average and a maximum duration of 194 seconds, with 2.4 moments on average, each being 8.2 seconds long on average.

ActivityNet Captions Introduced by Krishna et al. (2017), this dataset originally constructed for dense video captioning, consists of 20k YouTube videos with an average length of 120 seconds and a maximum duration of 755 seconds. The videos contain 3.65 temporally localized time intervals and sentence descriptions on average, where the average length of the descriptions is 13.48 words. Following the previous methods, we report the performance on the combined validation sets.

YouCookII Consists of 2,000 long untrimmed videos from 89 cooking recipes obtained from YouTube by Zhou et al. (2018b). Each step for cooking these dishes was annotated with temporal boundaries and aligned with the corresponding section of the recipe. The average video length is 316 seconds and a maximum duration of 755 seconds. In terms of relevant moment segments, each video has 7.73 moments on average, with each segment being 19.63 seconds long on average.

5.2 Implementation Details

For our experiments, we consider an off-line video encoding function $F_V(V)$, following previous work (Ghosh et al., 2019; Rodriguez-Opazo et al., 2020; Rodriguez-Opazo et al., 2021; Wang et al., 2020; Yuan et al., 2019a,b; Zhang et al., 2019). Concretely, we first pre-process the videos by extracting features of size 1024 using I3D with average pooling, taking as input the raw frames of dimension 256 × 256, at 25fps. We use the pre-trained model trained on Kinetics for ActivityNet and YouCookII released by Carreira and Zisserman (2017). For Charades-STA, we use the pre-trained model trained on Charades. For the natural language input, we use the BERT-base-uncased tokenizer and keep the parameters of the Text Encoder fixed. Models are trained using Adam (Kingma and Ba, 2014). Evaluation is based on two widely used metrics proposed by Gao et al. (2017a), namely the Recall at various thresholds of the temporal Intersection over Union (tIoU or $R@\alpha$) measuring the percentage of predictions that have tIoU with ground truth larger than certain α, and the mean averaged tIoU (mIoU). We use three α thresholds 0.3, 0.5 and 0.7.

5.3 Ablation Studies

We begin by performing an empirical study of our proposed stochastic sampling technique, comparing it to several alternatives. We specifically consider the following sampling approaches.

Random: As a naive baseline, we randomly sample features maintaining the order.

Fixed-rate video down-sampling (FRVS): We experiment with I3D features extracted at a lower frame-rate of 5fps (Ghosh et al., 2019), which can be regarded as a form of low-level down-sampling.

Fixed-rate feature down-sampling (FRFS): We experiment with two fixed-rate down-sampling techniques at the feature level, bucket-level mean-pooling and max-poling.

Dynamic Time Warping (DTW): We perform dynamic time warping between the non-structured video features and the fixed size temporal sequence created using our stochastic sampling technique and max-pooling applied inside each bucket. In this way, we assign features to each bucket that will later be randomly sampled.

Dynamic-rate feature down-sampling (DRFS): We utilize the similarity across features to dynamically create each bucket. While many variations are possible here, we decided to utilize a cosine distance-based heuristic to create the buckets. Please see Section B in the supplementary material for all the details.

SBFS Variations: We experiment with different alternatives for inference. Concretely, we always apply our stochastic sampling during training, and either use it for inference as well (SBFS-all), or replace it with bucket-wise mean pooling (SBFS-mean) or max pooling (SBFS).

Sampling	**Performance**			
	R@0.3	R@0.6	R@0.7	mIoU
Random	09.42	03.35	00.74	0 9.24
FRVS-5fps	37.54	22.68	10.62	23.90
FRFS-mean	45.99	31.01	15.46	29.98
FRFS-max	45.53	30.61	15.55	30.11
DTW	27.58	13.52	04.47	18.22
DRFS	33.48	17.84	06.56	21.57
SBFS-all	46.28	30.04	15.32	30.34
SBFS-mean	46.68	30.61	15.23	30.53
SBFS	**46.76**	**31.33**	**15.81**	**30.92**

Table 1: Performance of LOCFORMER on YoucookII replacing SBFS with alternative sampling techniques.

For the experiments, we combine each of these sampling approaches with the rest of the LOCFORMER architecture, and always use a bucket size of 200. Regarding the data, we use the YouCookII dataset, as it contains videos that can be as long as 18 minutes with queries that use rich language, which should help illustrate the importance of the sampling.

As the results in Table 1 show, the effectiveness of our sampling technique is clear, specially when compared with more naive alternatives like random sampling, or simple mean pooling. We see that low-level down-sampling techniques, that extract fewer frames from the original video, are not effective either. In contrast, the naive version of the max-pooling-based sampling stands out, performing similarly but still below SBFS. To confirm the effectiveness of our approach against FRFS-max and FRFS-mean, we further compared average results of five runs using different random seeds. We obtained baseline performances of $0.3006 \pm 1.6 \times 10^{-3}$ for FRFS-max and $0.3010 \pm 2.9 \times 10^{-3}$ for FRFS-mean. In contrast, SBFS obtained a performance of $0.3060 \pm 2.9 \times 10^{-3}$, which we find is statistically superior to both baselines at 99% confidence. These results help illustrate the importance of the stochastic approach we have taken, which enables us to limit the input to the model while still exposing it to all the training data in the long run, significantly improving its generalization capabilities. Finally, we also note that all the tested sampling alternatives except DTW and

Bucket Size	Performance			
	R@0.3	R@0.6	R@0.7	mIoU
100	35.74	27.41	11.88	29.03
200	**46.76**	**31.33**	15.81	**30.92**
300	46.36	31.07	**15.95**	30.63
400	45.25	30.30	15.58	30.23
500	44.33	28.69	14.18	29.14

Table 2: Impact on performance of LOCFORMER on the YoucookII dataset as parameter b, the bucket size, changes.

DRFS do not utilize information about the features when generating the buckets. It is interesting to see that many of these arguably simpler sampling techniques, including SBFS, outperform data-informed approaches.

We also study the impact of SBFS at different bucket sizes. For these experiments we use the YouCookII dataset, which contains the longest videos on average, and test bucket sizes ranging from 100 to 500. As we can see on Table 2, variations on parameter b have an impact consistent with its expected behavior, with diminishing results as b increases, and a clear performance sweet-spot at $b = 200$ which we adopt for the main experiments in our paper.

Finally, we ablate LOCFORMER component-by-component, to test the effects of each one of our introduced losses, and of SBFS. We also compare LOCFORMER with two highly-competitive Transformer-based model variations: (1) **Transformer-base** a randomly-initialized multi-modal Transformer-base[3], into which we directly feed the text input and the sampled video features, previously embedding them using a learned embedding matrix and a linear projection layer, respectively. Each encoder uses a separate set of positional embeddings, and we also add a type embedding to indicate the model the nature of each vector. After this, the embedded sequences are concatenated lengthwise and passed through the transformer blocks; (2) **BERT-base**, where we initialize our Transformer-base variation with the weights of BERT. In this case, the projection linear layer of the video features and the respective positional encodings are randomly initialized.

Both model variations apply our attention guiding loss $\mathcal{L}_{att}$ to all the attention heads in all the layers. This effectively means that there is no functionality separation inside these models. We note that these baselines are comparable to existing multi-modal transformer models such as VilBERT (Lu et al., 2019) and UNITER (Chen et al., 2020). Experiments are again performed in YouCookII, which contains the longest videos.

As seen in Table 3, our results first highlight the importance of SBFS, enabling all kinds of Transformer-based models we tested to process long untrimmed videos, which would otherwise lead to out-of-memory errors. Regarding the interaction of the attention loss with different model variations, we see that this additional training signal leads to consistent gains for all Transformer-based variations, but that these are larger in the case of LOCFORMER. We surmise this is due to the attention loss potentially interfering with the inductive bias that the baselines require to process the multi-modal inputs, as well as with the already acquired bias in the case of BERT, reflected in certain attention patterns for each head which have been studied and documented by Rogers et al. (2020) among others. This ultimately highlights the importance of separating functionality inside Transformer models for our task, which allows our model to perform better overall.

On top of SBFS, our results also show how each of our proposed component clearly helps increase performance. In particular, we observe that the addition of our attention loss ($\mathcal{L}_{att}$) results in the largest performance improvements, which is consistent with the findings of Rodriguez-Opazo et al. (2020). While the improvements due to $\mathcal{L}_{se}$ are comparatively less substantial, with differences across α bands, we see that combining both losses leads to the best results, showing that the losses complement each other well, as expected.

5.4 Combining SBFS with previous work

We now focus on studying the ability of our sampling technique to be combined with existing models. We do this by incorporating SBFS into three proposal-free models selected from the literature, and testing them on our datasets. We consider ExCL (Ghosh et al., 2019) and TMLGA (Rodriguez-Opazo et al., 2020), which have been extensively studied in the past years, as well as DORi. We utilized our own implementation of ExCL with our I3D features extracted at 25 fps[4],

---

[3] We follow the original notation (Vaswani et al., 2017) using 12 layers and 12 attention heads.

[4] The original implementation used a frame-rate of 5 fps.

Table 4: Results of our experiments combining SBFS with existing work. Except where indicated, experiments were performed using a batch size 32. ♣ indicates experiments performed using a batch size of 4 due to memory constraints.

Method	Training		Inference	
	TMLGA	DORi	TMLGA	DORi
Baseline	3.18	72	0.36	32
+ SBFS	0.72	10	0.08	2.5
Speed-Up	**4.41**	**7.2**	**4.5**	**12.8**

Table 5: Time in minutes for processing 10,337 and 3,492 queries from the YouCookII dataset in training and inference (test split) respectively.

and directly integrated the original implementations of the latter into our code.

As Table 4 shows, SBFS is able to consistently provide performance improvements in all cases, with gains of up to 3.13% in terms of the mean temporal IoU. These improvements lead to new state-of-the-art results on both the Charades-STA and YouCookII datasets. We note that despite not having access to the spatial information that DORi incorporates, the performance of LOCFORMER is very competitive to that of DORi+SBFS in YouCookII, which contains the longest videos.

We further study the impact on training and inference time when adding our sampling module. For this study consider TMLGA and DORi, and again use YoucookII since it contains the longest videos. As shown in Table 5, SBFS consistently leads to shorter training and inference times, with the degree of impact depending on dataset and model. Concretely, on DORi we obtain a speed-up of 7.2x in training and 12.8x for inference, which again illustrates the effectiveness of our approach, especially in the context of larger models. We also notice that the methods converge in a similar number of epochs with or without adding SBFS, meaning that we can significantly reduce the convergence time, as our sampling enables models to go through each example faster.

5.5 Comparison to state-of-the-art models

Finally, we compare the performance of our proposals on the datasets considered against several prior works. We consider models based on different approaches, specifically proposal-based models including CBP (Wang et al., 2020), MS-TAN-2D (Zhang et al., 2021b) and MNM (Wang et al., 2022), as well as TripNet (Hahn et al., 2020), based on reinforcement learning.

In addition to that, we also compare our approach to more recent methods that do not rely on proposals, including ABLR (Yuan et al., 2019c), ExCL, TMLGA and LGVTI (Mun et al., 2020), CPNet (Li et al., 2021), as well as VSLNet (Zhang et al., 2020b) and BCPN (Nawaz et al., 2022), which cast our task as visual question answering, and CPL (Zheng et al., 2022) which also incorporate Transformer-based components. Finally, we also consider CPN (Zhao et al., 2021) and DORi,

Table 6: Performance comparison of our approach with existing methods for different tIoU α levels. Underlined and bold results indicate second-best and best performance for each dataset. Values are reported on the validation split of Charades-STA and the ActivityNet Captions. † Results for ABLR are as reported by Chen and Jiang (2019). ‡ The results reported by ExCL for ActivityNet have 3,370 missing videos, and the results on YoucookII were obtained using our own implementation.

two models that contain specific graph-based approaches for the task, with DORi also incorporating spatio-temporal features.

Table 6 summarizes our best results on Charades-STA, ActivityNet Captions and YouCookII datasets, while also comparing the obtained performance to relevant prior work. We can see that overall Locformer is able to offer excellent performance, closing the gap with sophisticated graph-based models like CPN and DORi as well as Transformer-based models like CPL, with new state-of-the-art performance on the Charades-STA dataset. The results also show the effectiveness of our sampling approach when dealing with long untrimmed videos, as we observe that by combining DORi with SBFS we are able to also attain state-of-the art results on the YoucookII dataset.

6 Conclusion

In this paper we have presented Locformer, a Transformer-based model for the task of temporal moment localization which operates at a constant maximum memory footprint regardless of the input length. The success of our model fundamentally relies on our modular design, which allows us to separate functionality, and SBFS, where we split the sequence of input video features into a fixed number of buckets and select a single feature per bucket using a stochastic approach.

Experiments conducted on three challenging datasets show that Locformer obtains competitive results, and show that our sampling technique can improve the performance of prior work on all considered datasets, leading to a new state-of-the-art on YoucookII and Charades-STA. We think these results highlight the importance of sampling techniques as a valid mechanism to obtain better coverage of long input videos while keeping memory usage low.

For future work, we are interested in testing our sampling approach in other relevant tasks in the context of video-and-language, for example video retrieval. We are also interested in extending our approach to address its limitations, for example, using adaptive or iterative sampling to treat different areas of the video with different granularity.

Acknowledgements

This paper is based on results obtained from project JPNP20006, commissioned by the New Energy and Industrial Technology Development Organization (NEDO). For our experiments, computational resources of the AI Bridging Cloud Infrastructure (ABCI) provided by National Institute of Advanced Industrial Science and Technology (AIST) were used.

Limitations

We believe our results show that sampling is a valid mechanism to obtain better coverage of long input videos, while keeping memory usage under budget. However, it is important to stress that in this work we primarily focused on proposal-free models for temporal moment localization and thus have no evidence to suggest such improvements would be observed in other models.

There is also a specific scenario where our sampling could degrade the performance of a given model. This scenario occurs when the span of the query, *a.k.a.* moment, is located completely inside a given bucket, with many additional frames/features in the same bucket. In this case, the best that a model can do is to predict a moment covering the whole bucket, this losing granularity. In practice, this occurs when the ratio between the duration of a given moment and the duration of the video is vanishingly small. We believe this issue can be alleviated in future work by recursively generating and exploring buckets, an issue that we would like to tackle in the future.

Our results are also limited to the features utilized by the models we considered, and we offer no evidence that our technique will generalize to those cases as well. In terms of data, we have only experimented with queries in English. While it would be interesting to experiment with different languages, this is so far a limitation of the datasets that exist.

A Theoretical Analysis of SBFS

Let us begin by providing some key definitions that we will be requiring to perform our analysis.

A *statistic* is a function $T = r(X_1, \ldots, X_n)$ of the random sample $X_1, \ldots, X_n$, which carries information of the sampled data, such as the sample mean and sample variance. We say that a statistic satisfies the criterion of sufficiency when no other statistic which can be calculated from the same sample provides any additional information as to the value, of the parameter to be estimated. We can easily find a sufficient statistics by using the *Fisher–Neyman Factorization Theorem.*

Factorization theorem: *given a random sample* $X_1, \ldots, X_n$ *with joint density* $f(x_1, \ldots, x_n|\theta)$ *a statistic* $T = r(X_1, \ldots, X_n)$ *is sufficient if and only if the joint density can be factored as follows:*

$$f(x_1, \ldots, x_n|\theta) = u(x_1, \ldots, x_n)v(r(x_1, \ldots, x_n), \theta)$$

where u *and* v *are non-negative functions. The function* u *can depend on the full random sample* $x_1, \ldots, x_n$ *but not on the unknown parameter* θ. *The function* v *can depend on* θ, *but can depend on the random sample only through the value of* $r(x_1, \ldots, x_n)$.

In our case, let us assume that our bucket contains features X_i that are independent and uniformly distributed on $[0, \theta]$ where θ is unknown. Then, the probability dense function can be written as a product of individual densities since the observations are independent,

$$f(x_1, \ldots, x_n|\theta) = \frac{1}{\theta}\mathbf{1}_{\{0 \le x_1 \le \theta\}} \cdots \frac{1}{\theta}\mathbf{1}_{\{0 \le x_n \le \theta\}}$$

Here $\mathbf{1}(E)$ is an indicator function. It is 1 if the event E holds, and 0 if it does not. Now $x_i \le \theta$ for $i = 1, \ldots, n$ if and only if $\max\{x_1, \ldots, x_n\} \le \theta$. Therefore,

$$f(x_1, \ldots, x_n|\theta) = \frac{1}{\theta^n}\mathbf{1}_{\{0 \le \min\{x_i\}\}}\mathbf{1}_{\{\max\{x_i\} \le \theta\}}$$

Thus, the *factorization theorem* shows that $T = \max\{X_1, \ldots, X_n\}$ is a sufficient statistic since the density function takes the required form, where $u = \mathbf{1}_{\{0 \le \min\{x_i\}\}}$ and $v = \frac{1}{\theta^n}\mathbf{1}_{\{\max\{x_i\} \le \theta\}}$, which is a function that only depends on θ and $T = \max\{x_i\}$.

With this in mind, we can now move on to our analysis. We first note that nature of SBFS is that a single feature is sampled from each bucket with equal probability each time. If we assume features are i.i.d., this implies that the probability of getting a sampled video feature sequence is $P(\tilde{G}) = (b/n)^b$. As this is a very small probability, the number of potential distinct sampled video feature sets ($\tilde{G}$) is exceptionally large.

Fortunately, video features (frames) within a bucket are highly correlated as they originate from neighboring video frames which are generally very similar, and one may make a weak assumption that bucket population in bucket k may not contain sufficiently more information than any sampled feature $\boldsymbol{g}_{f(k)}$ from the bucket population.

In other words, if $\boldsymbol{g}_{f(k)}$ is sufficient statistic of the bucket k, then any sampled video feature sequence $\tilde{G}$ using SBFS contains sufficient statistics of G, and SBFS(G) is the sufficient statistic of video feature population G. Therefore, we can make the following proposition.

Proposition 1 *Any sampled video feature sequence* $\tilde{G}$ *from* SBFS *method is a sufficient statistic of video feature population* G.

The above proposition is very important as it allows us to train any complex model, such as a Transformer, on very long videos using SBFS with adequate guarantees. Next, we also present an interesting insight on how to pool features within a bucket. To do this, let us denote the j-th dimension of the feature vector $\boldsymbol{g}_i$ by g_i^j.

Proposition 2 *If the* j*-th dimension of vectors within the bucket* k *has a uniform population for all* j, *i.e.* $g_{f(k)}^j$ *is uniformly distributed on* $[1, \mu_j]$ *where* μ_j *is unknown, by the Fisher–Neyman factorization theorem (Fisher, 1922), the sufficient statistics of the population within the bucket* k *is given by the max-pooling operator over the bucket features* [5].

Although our SBFS can also be applied during inference, founded by Proposition 2, it is better to decouple the model from this stochastic component and instead utilize max pooling operator over the features of the bucket at inference time. This gives models increased stability when predicting, without sacrificing performance, as we showed in Section 5.3.

B Dynamic-Rate Feature Down-Sampling

In this section, we present details of our Dynamic-Rate Feature Down-Sampling ablation experiments. With this sampling heuristic, our intention was to

---

[5] Please check the supplementary material for details.

create buckets that satisfy the two following conditions. First, we would like each bucket to hold semantically similar features, using similarity on the embedding space as a proxy. Second, we aim to group features in a way such that the number of buckets l that hold the totality of the features in the video is smaller than the desired number of buckets b.

The bucket construction procedure works as follows. For an input feature sequence of length n, we use the cosine distance to compute the semantic similarity between each of the features in the video, and construct the pairwise distance matrix $\boldsymbol{D} \in \mathbb{R}^{n \times n}$. We then start the process with a single bucket that contains only the first feature x_1, and add features to this bucket starting from x_2. Feature x_2 will be added to the bucket if and only if the cosine-distance $D_{1,2} < th$, where th is a threshold parameter, and otherwise a new bucket is started and the process is repeated until all the features have been processed. Once this is done, we evaluate the number of buckets l that were created, and if $l > b$, then we reduce the threshold th by a small margin (0.01) and generate all the buckets again. This process is repeated until the $l \leq b$ condition is satisfied. Please see Algorithm 1 below, for additional details.

Algorithm 1 Dynamic-rate Feature down-sampling using cosine similarity Algorithm

```
$\boldsymbol{D} = 1 -$ pairwise_distances($V$)
$th = 1.0$
$flag = True$
index_sample = { }
while $flag$ do
    indx $= 0$
    $st = 0$
    $ed = 1$
    for $ed \leftarrow st$ to len($V$) do
        $s = \boldsymbol{D}_{st,ed}$
        if $s < th$ then
            samples_in_bucket = []
            for $i \leftarrow st$ to $ed$ do
                samples_in_bucket.append(i)
            end for
            index_sample[indx] = samples_in_bucket
            $st = ed$
            indx = indx + 1
        end if
        if indx <= bucket_size then:
            flag = False
        else
            $th = th - 0.01$
            index_sample = { }
        end if
    end for
end while
```

C Qualitative Results

In this section, we present qualitative results of our method for each one of datasets we use for evaluation. Ground truth (GT) and predictions in Figures 3, 4 and 5 are in seconds.

As seen on Figure 3, in the case of ActivityNet Caption, our method is able to localize the query *The man continue to rub the board using his polishing tools* with a high temporal intersection over union (IoU) of 80.41%. Though not visible in the figure, we also note that the end of this video is full of black frames and information about the creator, for example, webpage and logos. This exemplifies how ground truth annotations can be inaccurate, and how our model can adequately deal with these issues.

Figure 4 presents qualitative results for YookCookII dataset. In this case, we specifically present our predictions on one of the longest videos in the dataset, with a duration of 11 minutes and 46 seconds, and where the natural language query is *slice up the ginger finely*. As seen, our method obtains an impressive performance considering that the moment of interest lasts only 20 seconds. This figure also serves to exemplify one of the limitations of the bucketing approach we take. It is possible to see that the predictions of our model, though precise overall, add 0.96 seconds to both the start and end locations. This is a result of the maximum granularity given by the buckets and features in our system.

Finally, Figure 5 shows an example of the predictions of our model on the Charades-STA dataset. In this case, we also choose one of the longest videos in the data, with a duration of approximately 1 minute. For the query *person walks into room holding a bag*, our method obtains a good performance of 95.70% of temporal IoU.

D Experiment Details

- Total Parameters:
    - ExCL: 6.9M parameters.

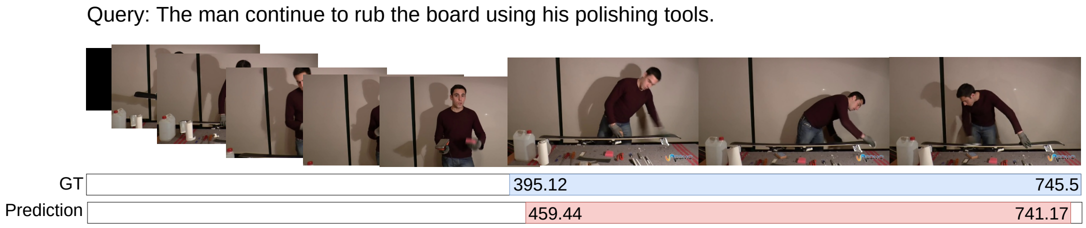

Figure 3: Results of our method on the ActivityNet dataset in a very long video of 12 minutes and 25 seconds (745.5 seconds). Our method can localize the query *The man continue to rub the board using his polishing tools* with a temporal IoU of 80.41%

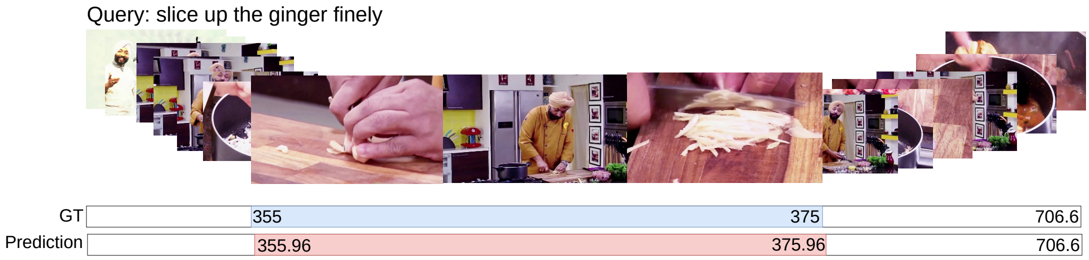

Figure 4: Qualitative result of our method on the YouCooKII dataset in one of the longest videos in the dataset (11 minutes and 46 seconds.) Our method obtains a temporal IoU of 90.83% for the query *slice up the ginger finely*.

  - TMLGA: 4.7M parameters.
  - DORi: 10.4M parameters.
  - LOCFORMER: 86.1M parameters.

- Hyper-parameters: Besides what is explained in the paper, we did not specifically run hyper-parameter exploration. On our early experiments, we tried some learning rate variations, but all of our reported results use 10^{-3} or respect the original setting of the model.

- Hardware requirements: Our experiments were performed on two kinds of GPUs, 16-GB NVIDIA V100 and 48-GB Quadro RTX 8000. The former we access by means of nodes on a large cluster, where each node has four such GPUs. Some experiments, especially on the ActivityNet dataset with DORi or LOCFORMER, were performed using data parallelism to speed up training time, but all of our proposed models can still run on single GPUs. For the experiments with the original DORi model or the baseline Transformer models without SBFS, we recommend using a GPU with at least 32GB of memory.

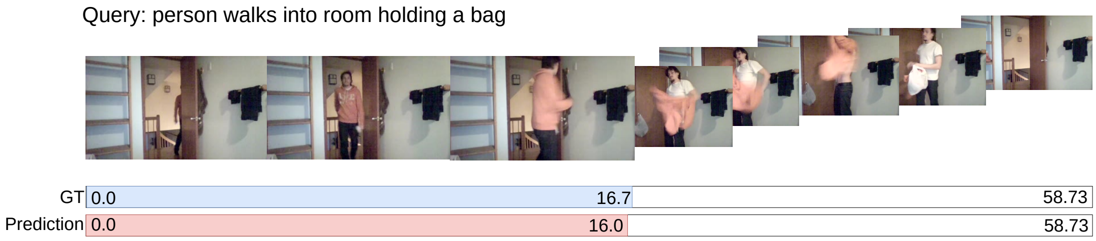

Figure 5: Charades-STA qualitative results on one of the longest videos in the dataset. For the query *person walks into room holding a bag*, our method obtains 95.70% IoU with respect to the ground truth annotations.

Extracting Victim Counts from Text

Abstract

Decision-makers in the humanitarian sector rely on timely and exact information during crisis events. Knowing how many civilians were injured during an earthquake is vital to allocate aids properly. Information about such *victim counts* is often only available within full-text event descriptions from newspapers and other reports. Extracting numbers from text is challenging: numbers have different formats and may require numeric reasoning. This renders purely string matching-based approaches insufficient. As a consequence, fine-grained counts of injured, displaced, or abused victims beyond fatalities are often not extracted and remain unseen. We cast victim count extraction as a question answering (QA) task with a regression or classification objective. We compare regex, dependency parsing, semantic role labeling-based approaches, and advanced text-to-text models. Beyond model accuracy, we analyze extraction reliability and robustness which are key for this sensitive task. In particular, we discuss model calibration and investigate few-shot and out-of-distribution performance. Ultimately, we make a comprehensive recommendation on which model to select for different desiderata and data domains. Our work is among the first to apply numeracy-focused large language models in a real-world use case with a positive impact.[1]

1 Introduction

Timely and accurate information during crisis events is crucial for rescue operations and the allocation of humanitarian aid (Lepuschitz and Stoehr, 2021). However, crisis information is often scarce, subjective, or biased, which renders reported numbers in text extremely important (Hellmeier et al., 2018; Zavarella et al., 2020; Radford, 2021). For instance, the count of injured or missing people provides quantitative information about the catastrophic impact of an earthquake. In this work, we focus on human victims in crisis events, e.g., fatalities in floods, herein referred to as *victim counts*. A reliable estimate of victim counts is helpful during crisis (Darcy and Hofmann, 2003; Kreutzer et al., 2020), and also post-crisis, benefiting research to diversify measures of crisis intensity. As of now, most intensity measures are either limited to event types (Vincent, 1979; Goldstein, 1992), fatality counts (Kalyvas, 2006; Chaudoin et al., 2017) or both (Stoehr et al., 2022). More fine-grained measures such as injured, displaced, or abused victims are not captured in most popular databases and remain unmonitored (Krause, 2013; Cruyff et al., 2017; Cullen et al., 2021).

Many victim counts are reported in full-text form within event descriptions in news media. This makes their systematic collection and analysis technically complex. Manual extraction of victim counts from text is very labor-intensive and does not scale to big data collections (Schrodt and Ulfelder, 2016; Lewis et al., 2016). Computerized approaches such as the event coding software Tabari (Schrodt, 2009) and Petrarch2 (Norris et al., 2017) focus on extracting actor and event types. They rely on lambda calculus and syntactic pattern matching, but disregard mentions of victim counts.

As we will show, parsing-based approaches perform decently well at extracting explicitly reported victim counts. They can identify the mention of the count “5” in “5 people were injured”. However, they are often inadequate when the description *implies* a correct count — for example, from the description that “one logger was shot but survived”, a human reader may infer that *one* person is injured. Since neither a count nor the injury is mentioned explicitly, a parsing-based system may fall short. Another difficulty stems from the fact that the counts can be reported in many, different formats. A reported count may be digit-based or spelled out, define an exact quantity or a range as in “dozens of people were injured”. As a conse-

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1925–1940
May 2-6, 2023

quence, formulating the task of victim count extraction is not an easy endeavor (§3). Most prior work assumes a setting where the count is explicitly mentioned in an event description (Döhling and Leser, 2011; Imran et al., 2013; Rudra et al., 2018; Camilleri et al., 2019). Such settings can be tackled by sequence labeling models that select a relevant span from the given description. However, if the victim count does not appear verbatim, as in the above "one logger" example, models with some form of abstract reasoning capacity may be needed (Roy et al., 2015). Recently, large language models have shown promising results in answering number-focused questions with and without explicit mentions of relevant numbers (Lewkowycz et al., 2022; Nye et al., 2021; Wei et al., 2022; Lefebvre and Stoehr, 2022).

This paper is concerned with studying these different approaches (§4): as baselines, we compare regular expression, dependency parsing, and semantic role labeling. We consider the NT5 (Yang et al., 2021) model as a representative numeracy-enhanced pre-trained language model. We use the representation of this model in a generation, a classification, and a regression setting. We evaluate all models along three dimensions: accuracy (§5), reliability (§6), and robustness (§7). We find that the fine-tuned language model outperforms the baseline models, especially when the victim count extraction requires reasoning. Reliability and robustness are particularly important in high-stake, human-centric tasks such as victim count extraction (Zhang et al., 2020; Kong et al., 2020; Russo et al., 2022b). Model reliability indicates to which extent model behavior can be trusted within decision-making settings (Leibig et al., 2017; Jiang et al., 2021). One dimension of reliability is model calibration which indicates if a model's confidence is aligned well with it making correct predictions (Guo et al., 2017). While calibration has been widely studied for classification, we add to the discussion of calibrated regression (Song et al., 2019) and generation settings (Widmann et al., 2021). Finally, the dimension of robustness describes how stably a model performs. For instance, when the training set is limited or when the test data is out-of-distribution, a less robust model will forfeit more of its predictive performance. To shed light on this dimension, we conduct experiments in few-shot learning and out-of-distribution settings.

We conclude with an application to showcase the extraction of fine-grained and highly specialized types of victim counts. Lastly, we discuss the benefits and drawbacks of the different approaches to assist practitioners in choosing the most suitable task formulation and model.

2 Data

We use publicly available datasets covering natural disasters and armed conflicts, namely: (1) World Atrocities Dataset (WAD) (Schrodt and Ulfelder, 2016), (2) Non-violent and Violent Campaigns and Outcomes 3.0 (NAVCO) (Lewis et al., 2016), and (3) European Media Monitor (EMM) (JRC Science Hub, 2018; Steinberger et al., 2017). For each dataset, we use the event text description and two types of victim counts: the death count and the injury count that we refer to as "WAD death" or "WAD injury". We pre-process the data by removing the samples with missing values (NaN) in the victim counts . For EMM, we only consider samples with a non-zero victim count since "0" is over-represented.

3 Task Formulation

In this section, we discuss some questions and challenges faced in formulating the task of extracting victim counts from event descriptions. We justify some of the choices we make and describe why it is not possible to have a single formulation that fits all needs:

Is the victim count always present in the text? Victim counts can be expressed in various ways in the text. When the count is expressed explicitly in the text, say "5 people were injured", a span extraction model can effectively extract the injury count 5. However, in certain cases, a single explicit number might not be mentioned, and the victim count needs to be logically or algebraically inferred from the text. Consider the description "a 4-year-old girl and her mother were found dead"; a model would need to logically deduce that the victim count of death is 2. To handle this, we not only look at span extraction models but also experiment with models that can understand the text at a deeper level and produce a victim count.

Is the victim count always a single number? Often, in the event description, the victim count is described as a range, such as "at least 330 people died", or in vague terms, like "dozens were injured". Additionally, even within a description, the victim counts for the same event can be varying, possibly because of recording the counts from different sources. This makes extracting a single exact count almost impossible. In such cases, the best a model can do is to output a close estimate of the actual victim count. Another solution would be to provide a range within which the count could lie. For a humanitarian section deciding on the quantity of aid to be deployed, a range might suffice over a single exact count. To account for this, we also look at models that are trained to output a range by classifying the victim counts into a set of binned categories.

4 Models

In §4.1, we introduce baselines models that parse an event description and heuristically extract a victim count. We then specify the model implementation for the different task formulations in §4.2.

4.1 Baseline Models

All baselines extract a victim count by locating the part of the text that could be relevant to victims and finding the nearby victim counts. The locating step requires a pre-defined list of words denoted as *locating list*. For example, to extract death counts, this list would include terms like "kill" and "die".

Regex. Regular expressions (regex) is a rule-based method to extract counts by string pattern matching. The patterns (App. A) are built based on active or passive voice to extract a count closest to phrases in the locating list.

Dependency Parsing. The dependency parsing model collects all possible numeric modifiers and their dependency relationships. Since not every numeric modifier relates to victim counts, e.g., "42-year-old", we construct dependency rules with the locating list to decide if the number is the victim count. For example, one rule is to check if the numeric modifier is for a subject phrase that would reject "42" in the example of "42-year-old". If no numeric modifier is found (e.g., "a journalist was injured"), additional rules use the locating list to return "1" if the rule is satisfied and otherwise return "0".

SRL. Semantic role labeling (SRL) recursively decomposes text input into pairs of predicates and their arguments. We define a list of predicate verbs for death and injury count as the locating list. Then, we iterate over the predicate-argument pairs, check if any predicate from the locating list occurs, and extract the count from its argument if possible. If a predicate exists, the implementation returns the first number as the count if multiple are found and returns "1" if no verbatim number is found. If no such predicate appears, the count is set to "0".

4.2 Task Modeling

We perform victim count extraction using three methods: generation, regression, and classification. As discussed above, each of these approaches caters to the different formulations of our task and can be beneficial in different scenarios. Across these methods, we use the same underlying NT5 model. For clarity, we denote NT5-Gen, NT5-Reg, and NT5-Clf for the corresponding models. The NT5 model (Yang et al., 2021) is a variant of the T5 model (Raffel et al., 2020) with further fine-tuning on numerical tasks. We query the model in a similar fashion to previous works by giving the question and event description in the form: "answer me:`[question]` context:`[passage]`". We discuss how we fine-tune this model for each of our specific methods below.

Generation. For generation, we fine-tune NT5 to decode the victim counts auto-regressively. At inference, we use beam search to generate output. Generation does not guarantee to only generate numeral tokens; therefore, we follow De Cao et al. (2021) to constrain the possible generation tokens in a prefix-conditioned way, such that only number digit tokens $0-9$ and EOS token are allowed at each decoding step.

Regression. For regression, we add two linear layers (with ReLU activation) on the encoder representation to output the numerical victim count. The model is trained to optimize the $\log$ mean-squared error between the true and predicted count.

Classification. We model the task as a classification problem by binning the victim counts into ordinal classes. Similar to regression, the model has a classification head of a linear layer and a softmax layer on top of an encoder initialized with NT5 weights. Our experiments use a 3-class classification by converting the victim counts into three categories: $[0, 3], (3, 10], (10, \infty)$.

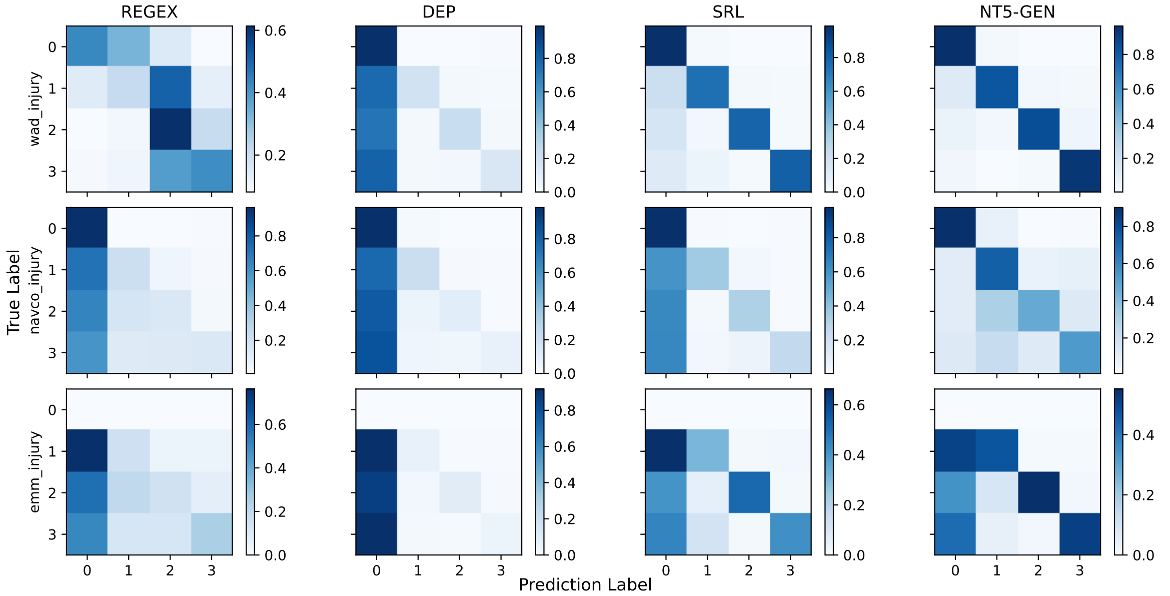

Figure 1: Confusion matrices of the baselines and the fine-tuned NT5-Gen model (columns) of extracting injury counts from different data (rows). We convert the true and prediction victim counts into 4 categories: for any count y, "0" is $y = 0$, "1" is $0 < y \leq 3$, "2" is $3 < y \leq 10$ and "3" is $y > 10$. Values are normalized over true counts. Baselines tend to have low precision on extracting injury counts (dark columns on "0"). SRL and NT5-Gen have comparable accuracy and recall; however, NT5-Gen is slightly better in precision.

5 Accuracy of Counts Extraction

We begin by evaluating the efficacy of our proposed methods for victim count extraction. We examine the model accuracy by comparing baselines and the fine-tuned model with a generation objective (§5.1). We then show the results of using classification and regression formulations (§5.2).

	Exact-Match			**F$_1$**		
	WAD	NAVCO	EMM	WAD	NAVCO	EMM
Regex	0.117	0.264	0.064	0.202	0.318	0.124
Dep	0.226	0.303	0.052	0.355	0.363	0.136
SRL	0.741	0.430	0.313	0.779	0.484	0.361
NT5-Gen	**0.813**	**0.501**	**0.443**	**0.846**	**0.544**	**0.492**

Table 1: *Exact-Match* and F_1 scores of the baseline models and the fine-tuned NT5-Gen on injury counts. The best results are **bolded**. The NT5-Gen model performs better than baselines across all datasets. `DEP` refers to the dependency parsing model and `SRL` refers to the semantic role labeling model.

5.1 Comparing Baselines with NT5-Gen

We compare the accuracy performance of the baseline models and the fine-tuned NT5-Gen model. Tab. 1 shows the results of extracting the injury counts using *Exact-Match* and F_1scores commonly used in related tasks (Yang et al., 2021; Dua et al., 2019). We measure F_1 score on digitized tokens (i.e., "34" → ["3", "4"]). The fine-tuned NT5-Gen model has an accuracy boost up by 7-13% in *Exact-Match* and by 6-13% in F_1 score than the strongest baseline model SRL. The performance of regex and dependency parsing varies heavily across different data, which implies that the regex pattern or dependency relationship may be less helpful in finding the victim counts.

Moreover, we convert the victim counts into four bins, where the bins are selected to have a balanced number of samples in each bin. As an illustration, Fig. 1 shows the confusion matrices on the transformed injury counts. For both victim types, baseline models have a low precision to falsely return "0" too often. Compared with baselines, the NT5-Gen model improves to extract victim counts whose numeric values are large (e.g., $y > 10$).

Qualitative Analysis. We qualitatively examine error samples of the SRL model that the NT5-Gen model extracts correctly. We randomly select 20 error samples for each test set to evaluate and summarize 4 types of errors with examples in Tab. 2. Out of all errors[2], 39.2% belong to diverse lin-

---

[2] There are a few samples where the ground truth might be erroneous. As the event-coding requires more domain expertise within the corresponding social science discipline, we leave the discussion out of this work.

Error Type	Context	Truth	SRL	NT5
`Diverse Expression`	*Six passengers* in a taxi also *had their throats cut*	6	0	6
`Numerical Reasoning`	Herders shot and *killed four people* [...]. Herders then shot and *killed a farmer* at Jokhana [...]	5	4	5
`Number Ambiguity`	*Unidentified gunmen* clash with army	1	0	1
`Number Spelling`	.Twenty-three people were killed [...]	23	1	23

Table 2: Error examples of SRL that the NT5-Gen model is correct on extracting death counts. `Diverse Expression` refers to the string patterns not captured by pre-defined rules. `Numerical Reasoning` shows that the correct count has to be achieved by some mathematical operation over the text. `Number Ambiguity` indicates that a verbatim number is not written but an estimate may be made (with domain expertise). `Number Spelling` refers to problems with number / text format that are typos or the tokenizer parses wrongly (e.g., “twenty-three”→ “twenty”).

guistic expressions on depicting victims, 38.3% contain number ambiguity, 8.3% need numerical reasoning, and 5.8% have spelling issues (for the tokenizer). The NT5-Gen model performs better when the count needs numerical reasoning. Even if the reasoning is not needed, SRL may fail when the linguistic expression to depict victims (e.g., “have throats cut”) is out of the pre-defined locating list (e.g., [“die”, “kill”, “slay”]). These error types are difficult for baseline models to be improved since the patterns cannot be defined beforehand.

5.2 Results on Classification and Regression

We examine the accuracy of the classification and regression formulations by comparing NT5-Clf and NT5-Reg with different initialization weights. To compare, we use T5-SMALL and BERT-BASE-UNCASED pre-trained weights for the encoder. Tab. 3 shows the classification results on NAVCO injury data. Fine-tuning T5-SMALL and NT5 reaches comparable performance; precision and recall scores are similar, but precision is slightly higher. The scatter plots (Fig. 2) show the results of regression using different pre-trained weights with the mean squared error (MSE). For a (log-transformed) victim count larger than 5, using the regression objective seems more conservative in giving small-valued predictions. The numeracy-rich NT5 weights do not particularly improve accuracy for a classification or regression objective, and employing some standard pre-trained weights might be sufficient.

6 Evaluating Reliability

Another important dimension is reliability which we evaluate through the lens of calibration (§6.1). As we approach the task with multiple formulations, calibration analysis is especially needed to understand whether a model is calibrated (§6.2), and how post-hoc calibration techniques may adjust models to be better calibrated (§6.3).

	Accuracy	$\mathbf{F}_1$	Precision	Recall
NT5	0.65	0.60	0.62	0.59
T5	0.65	0.60	0.61	0.59
BERT	0.52	0.23	0.17	0.33

Table 3: Classification results on NAVCO injury data with the NT5-Clf model initialized by different pre-trained weights: NT5, T5-SMALL, and BERT-BASE-UNCASED. F_1 , precision and recall scores are macro.

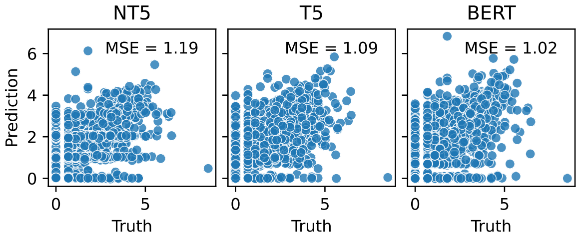

Figure 2: Scatter plots of the fine-tuned NT5-Reg model initialized with different pre-trained weights (NT5, T5-SMALL, and BERT-BASE-UNCASED). The models are trained on log-transformed victim counts.

6.1 Preliminaries: Calibration Metrics

A well-calibrated model ensures that the confidence of the output is well aligned with the chance of the output being accurate. This is a desirable property for our task — consider a model extracts “0” when the text depicts an injured person. A calibrated model would assign very low confidence to the extracted count, which may avoid error propagation to downstream decisions, e.g., medical resource dispatch. We here introduce the expected calibration error (ECE) (Pakdaman Naeini et al., 2015), a standard metric used for classification and is extended for generation decoding (Widmann et al., 2021). For regression, we apply quantile calibration error (Kuleshov et al., 2018).

Given n samples, we create M equal-width bins over the interval $[0, 1]$. ECE takes a weighted average on the differences between the classification accuracy and the mean confidence within each B_m,

$$\text{ECE} = \sum_{m=1}^{M} \frac{|B_m|}{n} \Big| \text{acc}(B_m) - \text{conf}(B_m) \Big|.$$

The quantile calibration error averages the differences between the empirical frequency $\text{freq}(B_m)$ and the upper bound of B_m (i.e., $\sup(B_m)$), where $\text{freq}(B_m)$ is the fraction of n samples whose quantiles lower or equal to $\sup(B_m)$,

$$\text{RegCE} = \frac{1}{M} \sum_{m=1}^{M} \Big| \text{freq}(B_m) - \sup(B_m) \Big|.$$

The calibration error of generation decoding takes the best b beam search answers, and applies softmax on their scores to represent the confidence. The ECE is then calculated on the best beam search answer similar to classification.

6.2 Calibration Error on Different Models

		Death		Injury	
Data	Model	Orig	Calib.	Orig	Calib.
NAVCO	Clf	0.222	0.044	0.332	0.060
	Reg	0.220	0.097	0.141	0.057
	Gen	0.054	0.040	0.092	0.092
WAD	Clf	0.192	0.055	0.228	0.088
	Reg	0.272	0.107	0.167	0.294
	Gen	0.218	0.221	0.096	0.042
EMM	Clf	0.277	0.098	0.314	0.055
	Reg	0.201	0.189	0.368	0.188
	Gen	0.087	0.092	0.328	0.122

Table 4: Calibration errors of fine-tuned NT5-Clf, NT5-Reg, and NT5-Gen models before (Orig.) and after (Calib.) applying post-hoc calibration. Post-hoc calibration effectively reduces the errors.

We show in Tab. 4 the calibration errors measured on the fine-tuned NT5-Clf, NT5-Reg, and NT5-Gen with different data. Surprisingly, the NT5-Gen model is well-calibrated on most datasets, except for EMM injury: the lowest calibration error is 0.05 on NAVCO death, and the errors on other data range between 0.08 and 0.33. Classification models tend to have large calibration errors (> 0.19). In particular, the error is larger than 0.3 on NAVCO and EMM data to classify injury counts. Regression is also prone to large calibration errors (> 0.15).

Another helpful tool is the reliability diagrams which visualize the calibration errors at different confidence bins. As an illustration, Fig. 3 shows the diagram of the NT5-Clf model fine-tuned on NAVCO injury data, and the diagonal line indicates the perfect calibration. This model is over-confident, and we can observe large gaps when the model confidence is larger than 0.8.

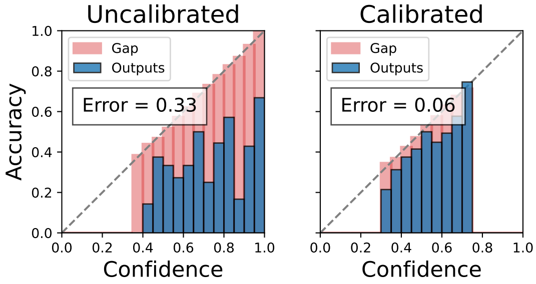

Figure 3: Reliability diagrams compare the calibration error before (left) and after (right) post-hoc calibration of the fine-tuned NT5-Clf model using the NAVCO injury data. This model is prone to large calibration errors (red gaps) in many bins. This is especially true for bins with high model confidence (> 0.8).

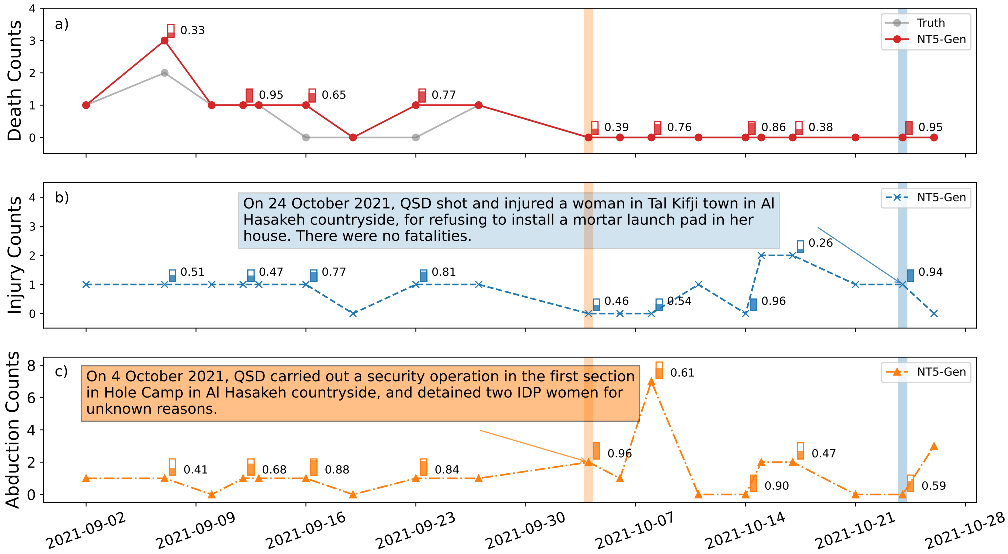
6.3 Post-hoc Calibration

Since the models can be over-confident based on the above analysis, we see the necessity to calibrate models for victim count extraction. We use temperature scaling for classification and generation decoding, and isotonic regression for regression. The post-hoc calibrators use development data to minimize negative log-likelihood and are then applied to test sets to measure calibration errors. As a comparison, Fig. 3 (right) shows the calibrated results of the fine-tuned NT5-Clf model on NAVCO injury data. The calibration error (i.e., ECE) reduces from 0.33 to 0.06. The errors of other calibrated models can be found in Tab. 4. In general, when the models have rather a large calibration error (e.g., > 0.3), post-hoc calibration is more helpful and adjusts the models to a better-calibrated level.

7 Evaluating Robustness

Typically, conflict or disaster data is noisy and limited. This is making it challenging to train models



On 24 October 2021, QSD shot and injured a woman in Tal Kifji town in Al Hasakeh countryside, for refusing to install a mortar launch pad in her house. There were no fatalities.

On 4 October 2021, QSD carried out a security operation in the first section in Hole Camp in Al Hasakeh countryside, and detained two IDP women for unknown reasons.

Figure 4: Timeline of victim counts in Syria data from Sept to Nov 2021 as given in the ACLED dataset. We use the NT5-Gen model that is fine-tuned on NAVCO data. Our model can be tested on the extraction of fatality counts which is the only victim count featured in ACLED (Fig. (a)). Beyond fatality counts, it can extract more fine-grained victim types such as (b) injury and (c) abduction counts. Confidence scores are shown for some of the predictions.

on a large-scale, high-quality training set. For this reason, we need robust models that excel in few-shot and out-of-distribution settings.

Reduced Training Size. We fine-tune the NT5-Gen, NT5-Reg, and NT5-Clf models on different-size portions of the training set. Specifically, we use 100%, 50%, 10%,5%, 0.5% and 0% of the training data and as further discussed in App. C.1. As expected, we find that the accuracy of all models drops when using a smaller training set. The NT5-Gen model reveals to be the most robust in keeping the *Exact-Match* metric above 0.6 when being fine-tuned on only 5% of the training data. The calibration error of the fine-tuned NT5-Clf model increases when the training size is reduced, while the fine-tuned NT5-Reg and NT5-Gen models do not follow this trend. In the zero-shot setting, the NT5-Reg and NT5-Gen models reach their largest calibration error. In contrast, the NT5-Clf model reaches its smallest calibration error in the zero-shot setting.

Out-of-distribution (OOD) Setting. We set up synthetic tasks in which a fine-tuned model is confronted with an out-of-distribution setting at test time. For example, we fine-tune a model on WAD death and then repurpose it to classify WAD injury. Then, we evaluate the drop in performance of this “out-of-distribution” model compared to an “in-distribution” model, that has been trained on WAD injury labels directly. We conduct this comparison on different datasets and models.

In App. C.2, we evaluate the NT5-Clf model in a classification formulation and report accuracy. As expected, we find that accuracy decreases in every setting with performance drops between 0.001% and 0.3%. In Fig. 15, we evaluate the NT5-Reg model in a regression setting measured in MSE. We find that the performance decreases in the out-of-distribution settings as evidenced by an average increase of 1.12 in MSE. Finally, in Fig. 16, we turn to an NT5-Gen model in a generative setting. As an evaluation metric, we consider *Exact-Match* and observe a decrease of 0.18 in *Exact-Match* on average.

8 Application: Overlooked Victim Types

Most event datasets feature only one column detailing victim counts. This column typically quantifies fatalities, as they are considered least ambivalent and most important (Kalyvas, 2006; Chaudoin et al., 2017). The Armed Conflict Location & Event Data Project (ACLED) (Raleigh et al., 2010; Raleigh and Kishi, 2019) recently published curated datasets containing violence against healthcare workers, media personnel, and women. Considering the ACLED dataset on Political Violence Targeting Women & Demonstrations Featuring Women, we find that more than 85% of events have *zero* fatalities. This means, many forms of violence remain non-quantified, often those against "marginalized" groups of society.

Using the methods presented in this work, we can extract much more fine-grained victim types such as "injured women" and "abducted women". To this end, we rely on the NT5-Gen model that we fine-tuned on the NAVCO data, without specifically asking for "women". In Fig. 4, we present exemplary two-month time series of events in Syria. We find that our model has a higher recall than precision on the ground truth annotations for fatality counts. This may be desirable since we would like to avoid overlooking true victim counts.

9 Discussion

This work surveys different task formulations of victim count extraction and inspects desiderata like accuracy, reliability, and robustness of different models. We now summarize our findings and conclude which approach performs best under which circumstances (Tab. 5).

Some of the parsing-based approaches have the advantage of requiring no ground truth annotations of the extracted victim counts. This means, there is no need for training, but instead, a manually curated list of patterns and rules has to be assembled. The regex approach, for instance, has minimum requirements regarding hardware, but writing regex patterns is very time-intensive and can be prone to mistakes. Overall, the baseline models shine when it comes to speed, and they perform reasonable when victim counts are explicitly mentioned. Yet they fail at complex reasoning. For instance, when asking for the count of deaths in "one child and four women lost their lives", all baselines mistakenly output "1".

This is where language model-based methods have a competitive edge. The fine-tuned NT5-Gen model has high accuracy both in *Exact-Match* metric and relative error metric. Surprisingly, it is also well-calibrated and relatively robust in the few-shot and out-of-distribution setting. This performance comes at the costs of reduced speed, the requirement of large amounts of training data, and the need for resources like GPUs to be deployed on a large scale.

Comparing classification and regression objectives, we conclude that classification is easier to handle. In most settings, it may be sufficient to extract a range rather than an exact number anyways. In comparison to generation, in classification and regression settings, models show higher calibration errors and require post-hoc calibration to adjust the model confidence.

10 Related Works

This work interfaces with related works from different disciplines to improve the measurement of crisis intensity. It draws inspiration from recent advancements in question answering models with a focus on numbers and math word problems. This includes number-enhanced language models more generally. Our work also connects with model calibration in natural language processing (NLP) more generally.

Measurement of Crisis Intensity. Extracting information about crises has been widely explored using social media data (Temnikova et al., 2015) and newspapers (Keith et al., 2017; Halterman et al., 2021). Most existing measures of crisis intensity focus on counts of event types (Goldstein, 1992; Terechshenko, 2020; Stoehr et al., 2022) or fatality counts (Kalyvas, 2006). Previous work studies friend-enemy relationships (Han et al., 2019; Russo et al., 2022a; Stoehr et al., 2021, 2023) and conflict-indicative changes in word embeddings (Kutuzov et al., 2017).

Numerical Question Answering. Numerical Question Answering pertains to the task of providing numeric answers to questions. An exemplary model is NAQANet (Dua et al., 2019), which extends QANet (Yu et al., 2018) with numerical operations. Neural Module Networks (Gupta et al., 2020) learn and execute a chain of logical learnable and differentiable modules. Some of these modules are specifically targeted at mathematical operations such `find-num` or `count`. Other approaches leverage knowledge graphs (Davidov and Rappoport, 2010; Kotnis and García-Durán, 2019) or graph neural networks (Chen et al., 2020). Thawani et al. (2021) provides a detailed overview over methods for representing and modeling numbers in NLP.

Number-enhanced Language Models. More recent work in number question answering relies on pre-trained large language models. GenBERT (Geva et al., 2020) improves numeric reasoning abilities by including a large amount of

	Accuracy Optimization			Reliability	Robustness		Hardware
	Absolute Error	Relative Error	String Match		Need Training	Stable in OOD	
REGEX	High	Medium	Medium	N/A	No	N/A	Low
DEP	Medium	High	Low-Medium	N/A	No	N/A	Low
SRL	Low-Medium	Medium	High	N/A	No	N/A	Low-Medium
CLF	N/A	N/A	N/A	Low	Medium-High	Low	Medium - High
REG	Low	Low	N/A	Low	High	Low-Medium	Medium - High
GEN	Low	Low	Medium-High	High	Low-Medium	Medium-High	High

Table 5: Overview of pros and cons of different models. We list baselines: regular expressions (`REGEX`), dependency parsing (`DEP`), and semantic role labeling (`SRL`). The `CLF`, `REG`, `GEN` refer to the fine-tuned NT5-Clf, NT5-Reg, and NT5-Gen models. `Absolute / Relative Error` pertains to the absolute/relative error between true victim counts and model predictions taking the real numerical value of the counts (e.g., mean squared error). `String Match` considers string metrics like *Exact-Match* used in question answering. The reliability column is based on experiments in model calibration. Robustness is divided into the need for training on a large annotated dataset and the stability in out-of-distribution (`OOD`). `N/A` means "Not Applicable".

synthetic data containing numbers. Codex (Chen et al., 2021) and NT5 (Yang et al., 2021) apply similar strategies and are trained on code and math word problems. Other approaches focus on step-by-step reasoning such as Minerva (Lewkowycz et al., 2022), scratchpad (Nye et al., 2021) and chain-of-thought prompting (Wei et al., 2022). Lefebvre and Stoehr (2022) propose a prompting-based method particularly for conflict event classification.

Calibration of NLP Models. The calibration of NLP models has been extensively studied in classification (Guo et al., 2017) and structured prediction tasks (Kuleshov and Liang, 2015; Nguyen and O'Connor, 2015). Calibration methods have been adapted in language modeling (Braverman et al., 2020; Kong et al., 2020), question answering (Kamath et al., 2020; Jiang et al., 2021), and machine translation (Kumar and Sarawagi, 2019; Wang et al., 2020).

11 Conclusion

We presented *victim count extraction*, a challenging and impactful task. The task can be tackled using different formulations and models. Models should be evaluated along different dimensions such as accuracy, reliability, and robustness. We survey this ambiguity of victim count extraction, identify promising directions, and discuss outlooks and applications.

Limitations

The models may be biased or reproduce biases inherent in their training data. Presenting unrelated, faulty or immoral questions to a model can cause unguided and malicious behavior. For example, we caution of asking questions such as "How many people *will be injured*...?"; and even worse "How many people *should be injured*...?". Improving model calibration will help defending against these issues and enable awareness of when to abstain from answering.

Ethics Statement

This work originated from the motivation to diversify victim count extraction towards underrepresented victim types and overlooked forms of violence. This work ultimately intends to assist researchers and analysts in the sector of humanitarian aid who are in demand of accurate victim count information.

A Regex Patterns

We convert any non-digitized numeral expressions into a digitized format (e.g. twelve → 12). Regex patterns are designed for both passive and active voices. We also distinguish plural ("are" and "were") and singular forms ("is", "was") for passive voice patterns. The algorithm checks with the following order: passive plural, passive single, and active. If multiple numbers are extracted, the first is kept. We list the regex patterns used to extract victim counts in Tab. 6, for death counts and injury counts respectively.

B Accuracy Evaluation

In this section, we complement the accuracy evaluation of the models in §5.

B.1 *Exact-Match* and F_1 score on Death Counts

The *Exact-Match* and F_1 scores on extracting the death counts are shown in Tab. 7, which compares the performance of the baseline models and the fine-tuned NT5-Gen model. Similar to the results on the injury counts Tab. 1, the fine-tuned NT5-Gen model performs better than all baselines and the SRL has the best accuracy among baselines.

B.2 Confusion Matrix on Death Counts

Similar to Fig. 1 shown in §5.1, Fig. 5 plots the confusion matrices of the binned death counts for the different datasets, which compare the accuracy of the baseline models with the fine-tuned NT5-Gen model.

B.3 Results on Classification and Regression

In §5.2, we have shown the results of the NT5-Clf model and the NT5-Reg model fine-tuned on NAVCO injury counts in Tab. 3.

Here, we use the same metrics and display the classification performance on other datasets. In specific, Tab. 8, Tab. 9, Tab. 10, Tab. 11, and Tab. 12 respectively show the classification performance of the NT5-Clf model fine-tuned on WAD death counts, WAD injury counts, NAVCO death counts, EMM death counts, and EMM injury counts.

Similarly, we provide the scatter plots of the fine-tuned NT5-Reg models initialized with different pre-trained weights in this section: WAD death counts (Fig. 6), WAD injury counts (Fig. 7), NAVCO death counts (Fig. 8), EMM death counts (Fig. 9), and EMM injury counts (Fig. 10).

C Robustness Evaluation

In this section, we provide the detailed performance of the few-shot setting (App. C.1) and the out-of-distribution setting (App. C.2) discussed in §7.

C.1 Few-shot Performance

We display the results of the few-shot settings where different proportions of the training set are used to fine-tune the models. For each formulation, the left figure is the variation of the accuracy metrics and the right figure is the variation of the calibration error. Fig. 11, Fig. 12, and Fig. 13 are performance of the few-shot settings of the fine-tuned NT5-Clf, NT5-Reg, and NT5-Gen models respectively.

With respect to accuracy metrics, the classification accuracy and the F_1 score is plotted for the fine-tuned NT5-Clf model.

For the regression, we plot the change of mean squared error on the $\log$ transformed counts. In addition, we plot the pinball losses using two targeting quantile (at 10% and at 90%).

Lastly, the *Exact-Match* and the F_1 scores are drawn for the fine-tuned NT5-Gen model.

C.2 Out-of-distribution Setting

For each task formulation, we examine the accuracy performance in the out-of-distribution setting for the fine-tuned NT5-Clf (Fig. 14), NT5-Reg (Fig. 15), and NT5-Gen (Fig. 16). For all plots, the x-axis is the accuracy metric used in each task formulation, and the y-axis indicates the test set to be made inferences on. The red bar indicates the

Abstract

A universal classification model aims to generalize to diverse classification tasks in both zero and few shot settings. A promising way toward universal classification is to cast heterogeneous data formats into a dataset-agnostic “meta-task” (e.g., textual entailment, question answering) then pretrain a model on the combined meta dataset. The existing work is either pretrained on specific subsets of classification tasks, or pretrained on both classification and generation data but the model could not fulfill its potential in universality and reliability. These also leave a massive amount of annotated data under-exploited. To fill these gaps, we propose ConEntail, a new framework for universal zero and few shot classification with supervised contrastive pretraining. Our unified meta-task for classification is based on nested entailment. It can be interpreted as “Does sentence a entails [sentence b entails label c]”. This formulation enables us to make better use of 57 annotated classification datasets for supervised contrastive pretraining and universal evaluation. In this way, ConEntail helps the model (1) absorb knowledge from different datasets, and (2) gain consistent performance gain with more pretraining data. In experiments, we compare our model with discriminative and generative models pretrained on the same dataset. The results confirm that our framework effectively exploits existing annotated data and outperforms baselines in both zero (9.4% average improvement) and few shot settings (3.5% average improvement). Our code is available at `https://github.com/psunlpgroup/ConEntail`.

1 Introduction

It has been a long-standing effort to solve various text classification tasks by training one universal model (Kumar et al., 2016). With an ideal universal classification model, we can expect extreme generalization with few or zero annotation in new domains/tasks/datasets. To this end, researchers reformulate heterogeneous task definitions into a unified format of a meta-task in natural language (Yin et al., 2020; Khashabi et al., 2020a). Solving the meta-task is equivalent to solving the isolated tasks, thus the meta-task paves the way of supplementing unsupervised pretrained Language Models (PLM) with additional supervised pretraining, to further absorb knowledge from heterogeneous labeled data.

The success of universal classification models hinges on how well a strong PLM understands natural language meta-task. The meta-task format depends on two underlying PLM types: (a) **discriminator** uses Encoder PLMs and treats all classification tasks as binary entailment classification problem (Yin et al., 2019, 2020; Xia et al., 2021; Wang et al., 2021). However, they only pretrain models on Natural Language Inference datasets, whose knowledge is not comprehensive comparing all classification tasks (Ma et al., 2021). (b) **generator** uses Encoder-Decoder PLMs and treats all tasks as text generation problem (Gao et al., 2020; Raffel et al., 2020; Sanh et al., 2021; Aribandi et al., 2021; Ye et al., 2021a; Bragg et al., 2021; Du et al., 2021; Schick and Schütze, 2021a,b). Thus they are compatible with both classification tasks and generation tasks. However, the generator nature implies that the predicted texts may not match any possible labels, thus more likely to fail on classification tasks (Sanh et al., 2021).

Based on our observations and experiments, we argue that the discriminators have more potential in universal classification, and propose a new discriminator framework, ConEntail, that can make better use of existing annotated datasets. Concretely, we reformulate the unified meta-task as a nested entailment: “Does sentence q entails [sentence p entails label h]”. Take Fig. 1 as an example, the query “We had a great breakfast at the waffle shop!” entails the same label as the premise “I bought this for myself a short time ago and I love it. An excellent

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1941–1953

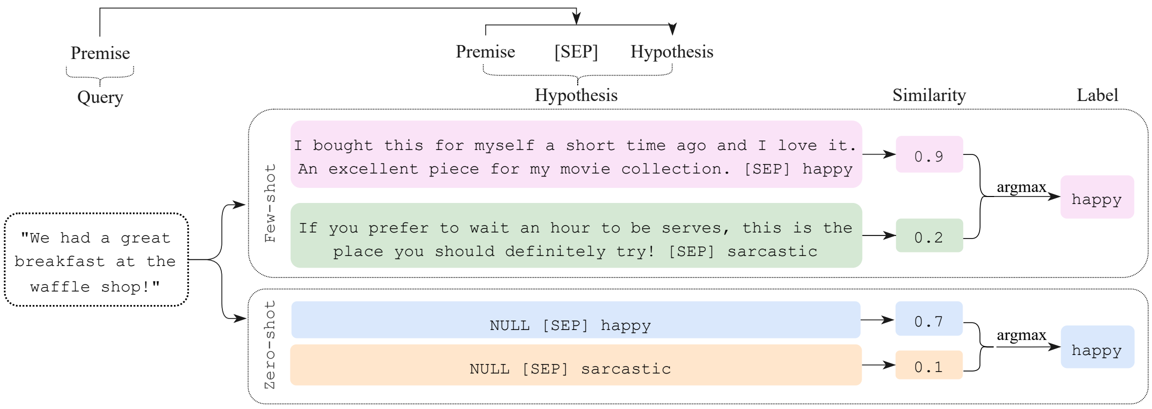

Figure 1: The overview of the ConEntail framework. By casting the classification as a nested entailment task, the model performs classification by telling if a query sentence q entails [premise example p entails hypothesis label h]. In a few-shot setting, the premise is an example sentence; in a zero-shot setting, the premise is a "NULL" placeholder.

piece for my movie collection.", so it yields a high similarity score of 0.9, in this case, it is higher than any other similarities, thus, the prediction would be "happy". For zero-shot generalization, as no annotated sentences are available, we replace the premise p with "NULL" in evaluation. We randomly nullify a small ratio of p in the supervised pretraining for training-evaluation consistency. The supervised contrastive learning framework pulls sentences embeddings with the same label together and pushes those with different labels apart, thus capturing more similarities/dissimilarities from labeled data, and benefiting few/zero-shot learning.

In experiments, we collect 56 classification datasets from Crossfit (Ye et al., 2021a), together with their templates, to formulate a large supervised pretraining dataset. We reproduce EFL (Wang et al., 2021), Unifew (Bragg et al., 2021) and Crossfit (Ye et al., 2021a) in the same setting and control influences of PLM supervised pretraining data, then conduct fair comparison with our proposed ConEntail. The experiments show that generators (Unifew and Crossfit) do not fit the classification task well and thus significantly under-perform the random guess in zero-shot evaluation; standard discriminators (EFL) under-exploit supervised pretraining datasets and thus do not gain consistent improvement as pretraining data scale up, while ConEntail makes the best use of the supervised pretraining data and keep consistent performances. Our model outperforms baselines in both zero (9.4% average improvement) and few shot settings (3.5% average improvement).

Our contributions are the following:

- We propose a novel universal classification framework based on nested entailment, ConEntail, that can be used in both zero and few shot settings. It makes better use of supervised pretraining datasets and consistently improves performances with increases of the pretraining scale.
- We design systematic experiments to compare generative and discriminative models, and more importantly, we give in-depth analysis to reveal their attributes in universal classification task.
- Our model reliably outperforms the baseline models in all kinds of pretraining size, finetuning size, and covers a wide range of tasks.

2 Related Work

Universal Meta Task Casting heterogeneous datasets into a unified meta-task allows researchers to train one model to solve all tasks. There are two types of meta-task formats, generation (Schick and Schütze, 2021a,b; Gao et al., 2020; Ye et al., 2021a; Bragg et al., 2021; Khashabi et al., 2020a) and discrimination (Yin et al., 2019, 2020; Xia et al., 2021; Wang et al., 2021). The generators formulate meta-task as a text-to-text generation problem. Although their supervised pretraining usually involves both classification and generation tasks, as the text outputs are open-ended, the model predictions may fall out of all possible labels. The discriminators formulate meta-task as an entailment classification problem, and usually use Natural Language Inference datasets for supervised pretraining. We extend discriminator pretraining to more classification datasets and propose a nested entailment meta-task to enable a more efficient supervised pretraining method.

Supervised Pretraining Supervised pretraining originates from explicit multitask learning (Caruana, 1997) which combines different task knowledge into shared representations. Phang et al. (2018) found that supplementing PLMs with supervised pretraining between unsupervised pretraining and downstream finetuning can significantly boost the performance and few-shot generalization. The discriminator models including UFO-Entail (Yin et al., 2020) and EFL (Wang et al., 2021) are trained on MNLI (Williams et al., 2018) in a supervised fashion, but they do not combine different sources of datasets. Furthermore, T0 (Sanh et al., 2021) and ExT5 (Aribandi et al., 2021) extends T5 (Raffel et al., 2020) by using 107 and 171 datasets for supervised pretraining and conduct zero-shot evaluation. FLEX (Bragg et al., 2021) and Crossfit (Ye et al., 2021a) extends the supervised pretraining evaluation to few-shot learning.

The supervised pretraining strategies from these works vary in pretraining datasets and hyperparameters, but they mostly follow their underlying language model tasks, such as Next Sentence Prediction or Text Generation. We argue that applying the unsupervised pretraining strategy to supervised pretraining is an underuse of the labeled data, and propose a supervised contrastive learning method on PLMs for better zero/few-shot generalization.

Contrastive Learning for NLP Contrastive learning aims to create embeddings such that similar examples are close while dissimilar examples are far away (Chopra et al., 2005). While most works use self-supervised contrastive learning (Shen et al., 2020; Fang et al., 2020; You et al., 2021; Ye et al., 2021b), only a few adopt supervised contrastive learning. CLIP (Radford et al., 2021) uses labeled images and captions as supervision signal. SimCSE (Gao et al., 2021) and SBERT (Reimers and Gurevych, 2019) use labeled sentence pairs from NLI to construct positive and negative examples. However, their contrastive data creations are limited to specific types of data, and thus can be hardly extended to universal classification. We reformulate all NLP classification tasks into a unified contrastive meta-task and use Supervised Contrastive Loss (Khosla et al., 2020) to train on heterogeneous labeled data during supervised pretraining.

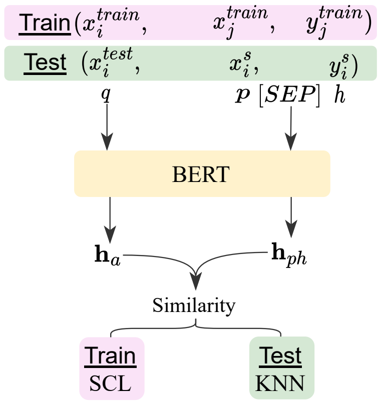

Figure 2: During supervised pertaining, the ConEntail model is optimized with pairwise contrastive learning loss SCL. Testing utilizes the K-Nearest Neighbor predictor to rank pairwise similarities between the query and premise-hypothesis pairs for retrieval of the most likely label. Zero-shot training/testing occurs when the premise example is represented by a "NULL" token."

3 Method

3.1 Universal Classification

Universal classification task aims to build a universal predictor that generalize to new domain/task/-dataset based on only a few or zero newly annotated examples. In order for models to understand a new area, any available resources should be considered for learning, including PLMs trained on large-scale unsupervised data and heterogeneous supervised classification datasets in the NLP community. To leverage heterogeneous datasets, the disparate input-output formats need to be reformulated to a unified PLM comprehensible format, i.e., “meta task”, through either human-curated or machine-generated templates. Then a universal model on the combined meta dataset is trained, which applies universal predictors to new areas. Because the meta task format is compatible with every task, we can cast target tasks into the same format, in this way solving the meta task is equivalent to solving tasks in a new area.

3.2 ConEntail: Nested Entailment

In this paper, we introduce a supervised contrastive pretraining paradigm that makes better use of supervised pretraining. The overview is shown in Fig. 2. Our ConEntail model takes 3 inputs:

$$
\begin{gathered}
f\colon \mathcal{Q}, \mathcal{P}, \mathcal{H} \rightarrow \{0, 1\} \\
q, p, h \mapsto b
\end{gathered}
$$

where $q \in \mathcal{Q}$ is the **query** sentence to be classified. $p \in \mathcal{P}$ is the exemplar sentence as a **premise**, $h \in \mathcal{H}$ is the **hypothesis** verbalized from the label of p. The task of ConEntail is to determine **if** q **entails [**p **entails** h**]**.

We follow (Khashabi et al., 2020b; Ye et al., 2021a) and translate sentence and label (x, y) to (q, p, h) in a PLM comprehensible format, e.g.,

- $x \mapsto q$, where q is the input sentence x with multiple-choice, for example, *(1) happy (2) sarcastic (3) sad, sentence: I bought this for myself ...*
- $x \mapsto p$: where p is the input sentence x with premise, for example, *sentence: I bought this for myself ...*
- $y \mapsto h$ where h is the label name, for example, h: *happy*

where we provide q with all possible labels as multiple-choice questions, and concatenate them in a linearized sentence. In supervised pretraining, q and p are two different surface forms of the same x, so that we can construct positive and negative examples for the later contrastive learning. In the test, q is the query sentence to be clarified and p and h are from the support set.

We use $\text{BERT}_{\text{base}}$ to encode sentences to vector representation $\mathbf{h}$.

$$\mathbf{h}_q = \text{BERT}_{\text{base}}(q) \tag{1}$$

p and h are then concatenated into one sequence to be fed into the encoder:

$$ph = p\,\texttt{[SEP]}\,h \tag{2}$$

$$\mathbf{h}_{ph} = \text{BERT}_{\text{base}}(ph) \tag{3}$$

In the supervised pretraining, the embeddings of each mini-batch are composed by $\left\{\mathbf{h}_q^i, \mathbf{h}_{ph}^i\right\}_{i=1,\ldots,N}$, where N is the batch size. Then we calculate their pairwise cosine similarity $\text{sim}\left(\mathbf{h}_q^i, \mathbf{h}_{ph}^j\right) = \frac{\mathbf{h}_q^i \cdot \mathbf{h}_{ph}^j}{\|\mathbf{h}_q^i\| \cdot \|\mathbf{h}_{ph}^j\|}$ for contrastive training. $s_{ij} \in \{0, 1\}$ is denoted as the groundtruth of the predicted similarity, where $s_{ij} = 1$ is a positive pair when $y_i = y_j$, and vice versa. The positive/negative examples are constructed by all combinations of instances in the batch, note that we did not mine hard examples. We follow the balanced sampling strategy from Meta Classification Learning (Hsu et al., 2019) that each label in a mini-batch has an equal number of input sentences.

In the test phase, we calculate cosine similarities between q and all possible ph and output the most similar h as the prediction result. Thus, we consider our setting as a K-way N-shot learning, where K is determined by the test set, N varies from 0 to 80 in our experiments.

Given the pairwise similarity, we use Supervised Contrastive Loss (Khosla et al., 2020) to train the model:

$$\mathcal{L} = -\sum_{i=1}^{N} \frac{1}{|P(i)|} \sum_{p=1}^{N} \mathbb{1}_{y_i=y_p} \mathbb{1}_{i \neq p} \log \frac{\exp\left(\text{sim}\left(\mathbf{h}_q^i, \mathbf{h}_{ph}^p\right)/\tau\right)}{\sum_{a=1}^{N} \mathbb{1}_{i \neq a} \exp\left(\text{sim}\left(\mathbf{h}_q^i, \mathbf{h}_{ph}^a\right)/\tau\right)} \tag{4}$$

where $|P(i)| = \sum_{p=1}^{N} \mathbb{1}_{y_p=y_i}$ is the number of all positive pairs, τ is the temperature hyperparameters. Different from self-supervised contrastive learning losses, such as SimCSE (Gao et al., 2021), the positive pairs in Supervised Contrastive Loss can be more than one.

To enable zero-shot generalization, inspired by BERT masked language model (Devlin et al., 2019), we introduce a dummy premise "NULL" in both supervised pretraining and testing. During supervised pretraining, we randomly replace 5% of the premise p with "NULL" (**if** q **entails ["NULL" entails** h**]**.). During zero-shot test, the support set is empty and the model uses only "NULL" and label names to answer the question.

4 Experiments

In this section, we describe our experiment setups including dataset selection, evaluation, and baseline models.

4.1 Dataset Selection

For universal text classification, we aim to cover the most popular text classification tasks, such as topic classification, sentiment analysis, paraphrase identification, and natural language inference. Therefore, we adopt Crossfit (Ye et al., 2021a) that provides abundant hand-craft templates covering 56 classification tasks as the source of supervised pretraining and testing. We select 47 datasets as supervised pretraining sets and 9 widely accepted datasets as test sets: CoLA (Warstadt et al., 2018), QQP (Iyer et al., 2017), SST-2 (Socher et al., 2013), MRPC (Dolan and Brockett, 2005),

Method	CoLA	QQP	Hate_speech	MRPC	SCITAIL	Amazon	AGNews	Rotten_tomatoes	SST-2	AVG

Table 1: The main results of CONENTAIL compared with baselines. † indicates the models are generative models and the others are discriminative models. In the 10-shot evaluation, to offset the high variances from fine-tuning on such a small support set, the models are fine-tuned by 3 different random sampled support sets. After conducting experiments with and without supervised pretraining, we report the mean accuracy scores and the standard deviation of the best versions of models (in **bold**). We split the test sets in two groups, *seen* and *unseen*, which indicates if the test label names have occurred in the supervised pretraining. AVG is the highest average score of the two versions of models. If a model with supervised pretraining is better than that without supervised pretraining, it is indicated with a $*$.

SCITAIL (Khot et al., 2018), Amazon Polarity (Zhang et al., 2015a), AGNews (Zhang et al., 2015b), Rotten_tomatoes (Pang and Lee, 2005), Hate_speech_offensive (Davidson et al., 2017). For the sentence-pair datasets (e.g., QQP, SST-2, MRPC), we adopt the Crossfit method by concatenating the two sentences with `[SEP]` to form one sequence for either q or p. From the 47 datasets for supervised pretraining, we randomly select 128 annotated examples per label. As the same label name may occur in different datasets, to investigate the effect of label name overlapping, we pick 5 (out of 9) selected test sets with overlapping/seen label names for the supervised pretraining. The detailed dataset list is in Appendix B.

4.2 Evaluation

Supervised Pretraining To investigate the effect of the supervised pretraining, we consider two versions of all the compared models: (1) without supervised pretraining: we apply the original PLMs directly to the reformulated input-output test set. (2) with supervised pretraining: we first perform supervised pretraining on the PLMs and then evaluate the models with the updated parameters.

Zero-shot Evaluation In zero-shot evaluation, the only available resources for the target task are the possible label names and the whole test set will be used to evaluate the model.

Few-shot Evaluation In few-shot evaluation, in addition to the label names, a small support set are available for fine-tuning the universal classification model. The support set for each dataset is composed by k random sampled annotated examples per label, from the training data. With small support sets, the evaluation score may have huge variance, thus we fine-tune and evaluate the model with 3 different support sets and report the mean and standard deviation.

4.3 Baseline Models

We aim to evaluate models in different paradigms in the same universal classification experiment setting. To this end, we compare three baselines that are most representative of the current literature on generators and discriminators.

In this paper, we only consider the differences of the baselines in the meta-task formulation and their generator/discriminator nature while keeping other factors the same, so we reproduce the baselines strictly follow this rule, and use a similar size of pretrained language models as backbones, for a fair comparison. Because our generator/discriminator taxonomy suits many other existing works, with only subtle differences either in the templates or in the backbone PLMs from the baselines mentioned

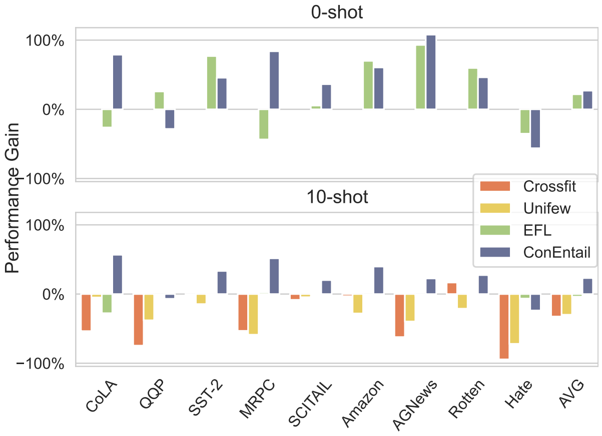

Figure 3: Relative performance gain of supervised pretraining on different datasets and models. The setting is the same with the main experiment. We do not plot zero-shot gains for the generators because most scores are 0 before and after supervised pretraining.

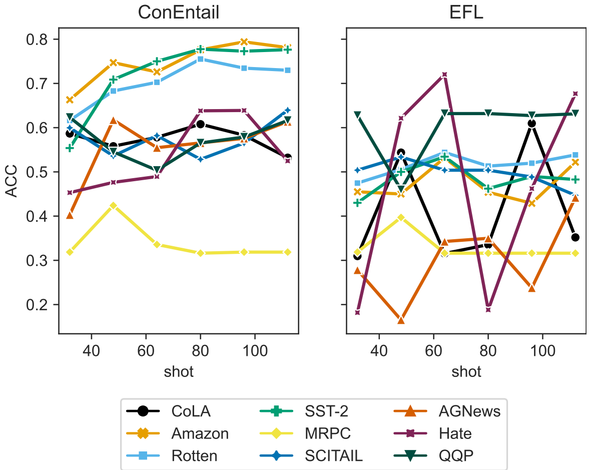

Figure 4: The effect of supervised pretraining data size. We show the zero-shot performance of CONENTAIL and EFL using different pretraining data size from 32 to 128 annotated sentences per label.

here, we do not add more baselines for comparisons.

Crossfit (Ye et al., 2021a): A generative model uses an encoder-decoder structure. The encoder takes the query sentence, and the decoder generates the label name.

Unifew (Bragg et al., 2021): A generative model concatenates all possible labels to the input sentence as multiple-choice question answering. It uses an encoder-decoder structure and generates the label names as answers.

EFL (Wang et al., 2021): A discriminative model reformulates the tasks as multiple entailment binary classifications. Both the query sentence and the label name are fed into the encoder. The embedding of `[CLS]` token is used for binary classification. The label with the highest probability is the predicted output. For supervised pretraining, we enumerate all possible labels for input and provide all the ground truths for the binary classification.

5 Results and Analysis

We design the following experiments to demonstrate and analyze the effectiveness of our method. First, we present the best scores of the compared models with or without supervised pretraining as our main result (Section 5.1). Then, we investigate the performance gain or loss of each model brought by the supervised pretraining (Section 5.2). Furthermore, we study the fine-grained impact of more labeled data in supervised pretraining or of more labeled data in support set (Section 5.3). Considering these results, we discuss the difference between discriminators and generators (Section 5.4). Finally, we show a case study of universal classification under a zero-shot scenario (Section 5.5).

5.1 Main Results

We evaluate the models in two scenarios, 0-shot learning and 10-shot learning (Table 1). The average performances of both discriminator models, EFL and CONENTAIL, significantly outperform random guess and two generation-based models. Particularly, CONENTAIL, with significantly improved average results, performs the best on 6 out of the 9 datasets in both 0-shot and 10-shot settings.

From the table, we also observe that the seen labels bring most improvements to Unifew in 0-shot setting. The 0-shot performance of Unifew in SST-2, SCITAIL and Amazon is far better than Crossfit. This is because Unifew has included the labels in the query sentences as multiple-choice questions, which provides the model additional familiarities from the supervised pretraining. In other words, although the 0-shot unseen accuracies of the generative models are mostly 0, their performances can be improved quickly with few-shot finetuning. This indicates that generative models are promising few-shot learners but not strong zero-shot learners.

5.2 Performance Gain from Supervised Pretraining

We then quantify the effect of supervised pretraining by Relative Performance Gain introduced (Ye et al., 2021a). Relative Performance Gain is the relative improvement brought by the supervised

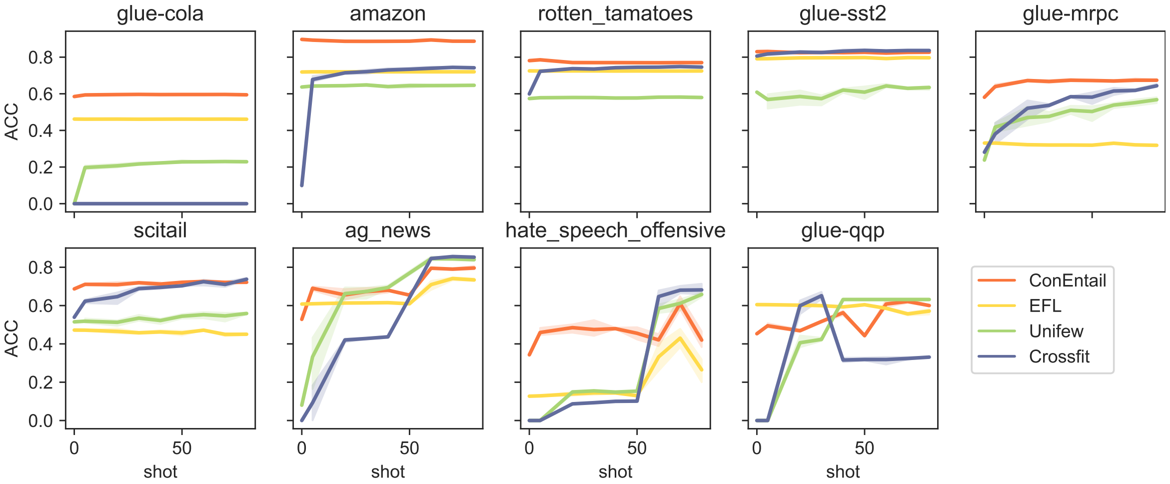

Figure 5: The effect of data size in the support set. We show the accuracy of the compared models fine-tuned with 0 to 80 examples in the support set. For each data size, we randomly sample 3 support sets for fine-tuning and evaluate on the same test set.

pretraining. It is defined as $\frac{\mathrm{Acc}_{\mathrm{w}} - \mathrm{Acc}_{\mathrm{w/o}}}{\mathrm{Acc}_{\mathrm{w/o}}}$, the performance difference between a supervised pretraining model $\mathrm{Acc}_{\mathrm{w}}$ and non-supervised pretraining model $\mathrm{Acc}_{\mathrm{w/o}}$, divided by the latter. The results are shown in Fig. 3.

We observe that supervised pretraining boosts the performance in most datasets in the 0-shot setting. But it lowers the scores in the 10-shot setting, except for CONENTAIL. CONENTAIL's performance rises in 7 out of 9 datasets in both 0-shot and 10-shot setting. This shows the general necessity of supervised pretraining for 0-shot evaluation and the effectiveness of our proposed model in both settings. The baseline models did not benefit from supervised retraining for the 10-shot setting because their conventional fine-tuning strategy is less likely to thoroughly update the parameters than our proposed contrastive learning. Noting that 10-shot evaluation means all the compared models only have 10 labeled examples for finetuning.

5.3 Impact of More Training data

More data in supervised pretraining: we investigate if more labeled data in supervised pretraining can improve zero-shot generalization. As the accuracies of generator models are close to zero in the zero-shot setting, we only consider discriminator models including CONENTAIL and EFL. These two models are supervised pretrained on different-scale datasets (32-128 sentences per label) and evaluated on the 9 test sets. As shown in Fig. 4, the performance of CONENTAIL has fewer fluctuations than the EFL, and the performance improvements of most datasets flat after 80 shots for CONENTAIL. This observation implies that the supervised pretraining has significant and reliable positive effects on CONENTAIL with merely a small amount of supervised dataset.

More data in support set: for models supervised pretrained with 128 annotated sentences per label, we plot the line chart of fine-tuning with 0 to 80 shots. As shown in Fig. 5, adding a few training sentences may not largely boost performance when the universal model is strong enough, but it improves the models significantly if the models have a slow start. Furthermore, though the generator model performances improve fast from 0 to 50 shots, the scores fluctuate largely. But after the first 50 shots, the improvements slow down, and the variances becomes much smaller. This implies that all the compared models are strong few shot learners, so that fine-tuning on large-scaled training data in the downstream tasks is unnecessary.

5.4 Discussion on the Differences Between Discriminator and Generator Models

The ineffectiveness of zero-shot Unifew and Crossfit are rooted in their generation nature. The original motivation of generation-based models is to resolve all kinds of NLP tasks, including both classification and generation. However, the universal classification task (i.e., tasks in this paper) are usually formulated as label picking from limited choices, while generation tasks aim to output human-readable sentences that match the input sentences – the target distributions for these 2 tasks are innately different. In the few-shot setting, fine-tuning with 10 more examples in the target task

I happily donate any covid vaccine dose which may be reserved for me to any person that is stupid enough to get one, or two, three, or four.									
mild	0.59	irony	0.48	happy	0.44	...	...	optimism	0.23
Guys it's OK. Delta says covid is over. IT'S OK NOW.									
mild	0.69	non-irony	0.48	irony	0.47	...	...	hate	0.10
The first patient who died of COVID in Kerala already had BP and cardiac issues, and he was 69. Bottomline : If we take precautions, we are still safe and can ensure others are safe too.									
optimism	0.51	mild	0.51	positive	0.43	...	...	hate	0.08
Could you imagine putting your faith into the narrative, getting jabs, getting sick from side effects (which is now being called the variant) and then being labeled an antivaxxer amidst this lie "only the unnvacinated are getting sick". They will use you up until there's nothing left.									
offensive	0.59	irony	0.58	mild	0.56	...	...	happy	0.25
... I don't see a monetary benefit. I don't see any professional benefit. Ask the people who believe what they are being told for an explanation because I don't see any.									
offensive	0.60	mild	0.54	irony	0.49	...	...	optimism	0.20
I can't do this anymore. I went from a house and 2 beautiful daughters and wife to homeless and left with literally nothing. ... They need to die painfully and even then they will never pay for their sins. All it takes it one moment in history for everything to change. You keep breaking men down to nothing. Those broken men will break you.									
offensive	0.80	negative	0.63	hate	0.59	...	...	optimism	0.10

Table 2: Case study of an unseen task. We use CONENTAIL in a zero-shot manner to analyze twitter and reddit sentiment during the Covid-Omicron surge. We pick 13 fine-grained sentiment labels and rank the labels by their similarity with the input sentence.

shifts the text generation distribution towards the label distribution, so the generated texts are more likely to be the labels, and this improves model performances. However, as the predictions are still in the large vocabulary space, they are likely to be altered by any disturbances. When using different support sets, the variances of the accuracy are far larger than that of the discriminator models. This also explains why Unifew performs better than Crossfit: the only difference between Unifew and Crossfit is that the input sentences of Unifew are appended with all possible label texts. By providing the generation process label hints, Unifew shifts its generation distribution towards label distribution and outperforms Crossfit. But the accuracy gap between Unifew and Crossfit drops from 15% to merely 0.7% while the number of shots increases from 0 to 10. As we stated before, Unifew performs better in the 0-shot setting because of its extra label hints. However, with an increase of shots, this advantage is diluted, resulting in a smaller performance difference between these two models.

5.5 A Case Study of Universal Classification

Consider a possible application scenario of universal classification: when dealing with new tasks and domains, especially related to newly emerged events, usually people only have the label names in hand. Based on this, we demonstrate a COVID-19 sentiment classification case study to show the universality of the proposed CONENTAIL model.

We use keywords to collect 50 sentences from Reddit and Twitter during the surge of the Omicron variant, then pick 13 fine-grained sentiment labels for this task: *positive, mild, negative, offensive, happy, anger, sad, hate, irony, non-offensive, non-irony, non-hate, optimism*. For each COVID-related query sentence, CONENTAIL model retrieves from all 13 possible labels and ranks them by similarity.

From the results Table 2 we observe that the model ranks the labels correctly most of the time. With antonyms paired with each other, such as *hate/non-hate* and *happy/sad*, our model successfully predicts the labels with only the label names, showing the polarity derived from the pairwise ranking are effective and reliable.

6 Conclusions

In this work, we study the universal classification problem, that leverages heterogeneous labeled datasets to benefit zero/few-shot learning in a new domain/task/dataset. We conduct systematic experiments on mainstream discriminators and generators models, thoroughly evaluate different models, reveal their innate properties of meta-task reformulation and supervised pretraining strategies. The results show that the generators with open-end prediction fail in zero-shot learning and the discriminators with a standard entailment meta-task hardly obtain a performance boost when more pretraining data is available. Our work provides a new angle for future researchers to explore universal NLP, and propose a new nested entailment meta-task and a supervised contrastive learning strategy, CONENTAIL, to make better use of widely available annotated datasets, and adapts to new datasets with limited resources.

Limitations

Although this paper aims to improve the universal generalization in the classification task, there are several limitations: (1) We do not compare with cloze-based models (Schick and Schütze, 2021a,b; Gao et al., 2020), because their templates are more complicated and hard to be reproduced with our current datasets. (2) We do not consider structural classification tasks, such as Named Entity Recognition and Relation Extraction. (3) We only take classification datasets into account because our implementation is restricted by huggingface datasets and human-curated templates. We plan to extend our framework to more datasets in the future. (4) Due to the constraints from the templates and datasets, the class number of each test set is below 10. We plan to extend our framework to more labels in the future work. (5) The compatibility of knowledge in similar tasks is assumed, but this assumption may not hold true due to varying annotation standards across datasets. For instance, MRPC and QQP are both paraphrase identification tasks, but MRPC uses hard example mining techniques, resulting in longer and more sophisticated sentences than QQP. (6) The current study is limited to English datasets and can be extended to multiple languages in the future by using multilingual PLMs and pretraining datasets.

Acknowledgments

We thank Qianying Liu for her valuable discussion.

A Hyperparameters and Implementation Details

Unifew and Crossfit, as generative models, use BART$_{\text{base}}$ (Lewis et al., 2020) as the backbone language model. In the supervised pretraining, we use AdamW optimizer (Loshchilov and Hutter, 2017) with learning rate 3e-5, warm-up ratio 0.6% and linear decay. In the meta-testing, we use the same hyperparameters and train 400 epochs for finetuning.

EFL and Entail2, as discriminator models, use BERT$_{\text{base}}$ (Devlin et al., 2019) as the backbone language model. In the supervised pretraining, we use AdamW optimizer (Loshchilov and Hutter, 2017) with learning rate 1e-5, warm-up ratio 6% and linear decay. In the meta-testing, we use the same hyperparameters and train 10 epochs for finetuning.

All the compared models use the same templates (map the input to the text) and the same verbalizers (map the label to the text) from the Crossfit paper (Ye et al., 2021a), as they covered more classification datasets than other frameworks. Note that the choices of template/verbalizer could cause large variance in performance (Zhao et al., 2021), and the effectiveness of Crossfit template/verbalizer had not been fully studied.

We use two NVIDIA A5000 for our experiments. The supervised pretraining takes 3 days and the evaluation takes 1 week for all the compared baselines.
